Initialization. An important detail is that training starts not from the set of all possible edges for a given set of vertices, but from a chosen subset; this subset is constructed using task-specific heuristics. The authors restrict training to a subset of edges to make it feasible for large datasets: while the number of all edges in a complete graph scales quadratically to the number of vertices, the initial subset can be constructed to scale linearly with the number of vertices.

2.1.2 GloVe

GloVe (Pennington et al., 2014) is an unsupervised method which learns word representations directly from the global corpus statistics. Each word v_i in the vocabulary V is associated with two vectors w_i and $\tilde{w}_i$; these vectors are learned by minimizing

$$\mathcal{J}=\sum_{i,j=1}^{|V|} f(X_{i,j})(w_i^T\tilde{w}_j+b_i+\tilde{b}_j-\log X_{i,j})^2. \quad (4)$$

Here $X_{i,j}$ is the co-occurrence between words v_i and v_j; b_i and $\tilde{b}_j$ are trainable word biases, and $f(X_{i,j})$ is a weight function: $f(X_{i,j}) = \min(1, [\frac{X_{i,j}}{x_{max}}]^\alpha)$ with $x_{max} = 100$ and $\alpha = 3/4$.

The original GloVe learns embeddings in the Euclidean space; Poincaré GloVe (Tifrea et al., 2019) adapts this training procedure to hyperbolic vector spaces. This is done by replacing $w_i^T\tilde{w}_j$ in formula (4) with $-h(d(w_i, \tilde{w}_j))$, where $d(w_i, \tilde{w}_j)$ is a distance in the hyperbolic space, and h is either $h(d) = d^2$ or $h(d) = \cosh^2(d)$ (see Table 1).

2.2 Our Approach: GraphGlove

We learn graph word embeddings within the general framework described in Section 2.1.1. Therefore, it is sufficient to (i) define a task-specific loss $L(G, \theta)$ in formula (3), and (ii) specify the initial subset of edges.

2.2.1 Loss function

	“$\square$” in the loss term $f(X_{i,j})(\square+b_i+\tilde{b}_j-\log X_{i,j})^2$
Euclidean	
	$w_i^T\tilde{w}_j$
Poincaré	
d^2	$-d^2(w_i, \tilde{w}_j)$
$\cosh^2 d$	$-\cosh^2(d(w_i, \tilde{w}_j))$
Graph	
d	$-d_G(v_i, v_j)$
$\langle\cdot,\cdot\rangle$	$\frac{1}{2}\left(-d_G^2(v_i, v_j)+d_G^2(v_i, 0)+d_G^2(v_j, 0)\right)$

Table 1: Original GloVe loss and several extensions. For Poincaré GloVe, d is distance in the hyperbolic space; for GraphGlove, d is the shortest path distance.

We adopt GloVe training procedure and learn edge weights and probabilities directly from the co-occurrence matrix X. We define $L(G, \theta)$ by modifying formula (4) for weighted graphs:

1. replace $w_i^T\tilde{w}_j$ with either graph distance or graph dot product as shown in Table 1 (see details below);
2. since we learn one representation for each word in contrast to two representations learned by GloVe, we set $\tilde{b}_j = b_j$.

Distance. We want negative distance between nodes in a graph to reflect similarity between the corresponding words; therefore, it is natural to replace $w_i^T\tilde{w}_j$ with the graph distance. The resulting loss $L(G, \theta)$ is:

$$\sum_{i,j=1}^{|V|} f(X_{i,j})(-d_G(v_i, v_j)+b_i+b_j-\log X_{i,j})^2. \quad (5)$$

Dot product. A more honest approach would be replacing dot product $w_i^T\tilde{w}_j$ with a “dot product” on a graph. To define dot product of nodes in a graph, we first express the dot product of vectors in terms of distances and norms. Let w_i, w_j be vectors in a Euclidean vector space, then

$$\|w_i - w_j\|^2 = \|w_i\|^2 + \|w_j\|^2 - 2w_i^T w_j, \quad (6)$$

$$w_i^T w_j = \frac{1}{2}\big(\|w_i\|^2 + \|w_j\|^2 - \|w_i - w_j\|^2\big). \quad (7)$$

Now it is straightforward to define the dot product[2] of nodes in our weighted graph:

$$\langle v_i, v_j\rangle = \frac{1}{2}\big(d^2(v_i, 0) + d^2(v_j, 0) - d^2(v_i, v_j)\big), \quad (8)$$

---

[2] Note that our “dot product” for graphs does not have properties of dot product in vector spaces; e.g., linearity by arguments.

where $d(v_i, v_j)$ is the shortest path distance.

Note that dot product (8) contains distances to a zero element; thus in addition to word nodes, we also need to add an extra "zero" node in a graph. This is not necessary for the distance loss (5), but we add this node anyway to have a unified setting; a model can learn to use this node to build paths between other nodes.

All loss functions are summarized in Table 1.

2.2.2 Initialization

We initialize the set of edges by connecting each word with its K nearest neighbors and M randomly sampled words. The nearest neighbors are computed as closest words in the Euclidean GloVe embedding space,[3] random words are sampled uniformly from the vocabulary.

We initialize biases b_i from the normal distribution $\mathcal{N}(0, 0.01)$, edge weights by the cosine similarity between the corresponding GloVe vectors, and edge probabilities with 0.9.

3 Experimental Setup

3.1 Baselines

Our baselines are Euclidean GloVe (Pennington et al., 2014) and Poincaré GloVe (Tifrea et al., 2019); for both, we use the original implementation[4] with recommended hyperparameters. We chose these models to enable a comparison of our graph-based method and two different vector-based approaches within the same training scheme.

3.2 Corpora and Preprocessing

We train all embeddings on Wikipedia 2017 corpus. To improve the reproducibility of our results, we (1) use a standard publicly available Wikipedia snapshot from `gensim-data`[5], (2) process the data with standard GenSim Wikipedia tokenizer[6]. Also, we release preprocessing scripts and the resulting corpora as a part of the supplementary code.

3.3 Setup

We compare embeddings with the same vocabulary and number of parameters per token. For vector-based embeddings, the number of parameters equals vector dimensionality. For GraphGlove, we compute number of parameters per token as proposed by Mazur et al. (2019): $(|V|+2\cdot|E|)/|V|$. To obtain the desired number of parameters in GraphGlove, we initialize it with several times more parameters and train it with L_0 regularizer until enough edges are dropped (see Section 2.2).

We consider two vocabulary sizes: 50k and 200k. For 50k vocabulary, the models are trained with either 20 or 100 parameters per token; for 200k vocabulary — with 20 parameters per token. For initialization of GraphGlove with 20 parameters per token we set $K = 64$, $M = 10$; for a model with 100 parameters per token, $K = 480$, $M = 32$.

In preliminary experiments, we discovered that increasing both K and M leads to better final representations at a cost of slower convergence; decreasing the initial graph size results in lower quality and faster training. However, starting with no random edges (i.e. $M = 0$) also slows convergence down.

3.4 Training

Similarly to vectorial embeddings, GraphGlove learns to minimize the objective (either distance or dot product) by minibatch gradient descent. However, doing so efficiently requires a special graph-aware batching strategy. Namely, a batch has to contain only a small number of rows with potentially thousands of columns per row. This strategy takes advantage of the Dijkstra algorithm: a single run of the algorithm can find the shortest paths between a single source and multiple targets. Formally, one training step is as follows:

1. we choose $b = 64$ unique "anchor" words;
2. sample up to $n = 10^4$ words that co-occur with each of b "anchors";
3. multiply the objective by importance sampling weights to compensate for non-uniform sampling strategy.[7]

This way, a single training iteration with $b \cdot n$ batch size requires only $O(b)$ runs of Dijkstra algorithm.

---

[3] In preliminary experiments, we also used as nearest neighbors the words which have the largest pointwise mutual information (PMI) with the current one. However, such models have better loss but worse quality on downstream tasks, e.g. word similarity.

[6] gensim.corpora.wikicorpus.tokenize , commit de0dcc3

[7] Let X be the co-occurrence matrix. Then for a pair of words (v_i, v_j), an importance sampling weight is $\frac{p_{i,j}}{q_{i,j}}$, where $p_{i,j} = \frac{1}{|\{(k,l):X_{k,l} \neq 0\}|}$ is the probability to choose a pair (v_i, v_j) in the original GloVe, $q_{i,j} = \frac{1}{|V|} \cdot \frac{1}{|\{k:X_{i,k} \neq 0\}|}$ is the probability to choose this pair in our sampling strategy.

Table 2: Spearman rank correlation on word similarity tasks; best is bold, second best is underlined. 50k vocabulary, 20 parameters per token. Results for other setups can be found in the supplementary material.

After computing the gradients for a mini-batch, we update GraphGlove parameters using Adam (Kingma and Ba, 2014) with learning rate α=0.01 and standard hyperparameters (β_1=0.9, β_2=0.999).

It took us less than 3.5 hours on a 32-core CPU to train GraphGlove on 50k tokens until convergence. This is approximately 3 times longer than Euclidean GloVe in the same setting.

4 Experiments

In the main text, we report results for 50k vocabulary with 20 parameters per token. Results for other settings, as well as the standard deviations, can be found in the supplementary material.

4.1 Word Similarity

To measure similarity of a pair of words, we use cosine distance for Euclidean GloVe, the hyperbolic distance for Poincaré GloVe and the shortest path distance for GraphGlove. In the main experiments, we exclude pairs with out-of-vocabulary (OOV) words. In the supplementary material, we also provide results with inferred distances for OOV words.

We evaluate word similarity on standard benchmarks: WS353, SCWS, RareWord, SimLex and SimVerb. These benchmarks evaluate Spearman rank correlation of human-annotated similarities between pairs of words and model predictions[8]. Table 2 shows that GraphGlove outperforms vector-based embeddings by a large margin.

4.2 Word Analogy

Analogy prediction is a standard method for evaluation of word embeddings. This task typically contains tuples of 4 words: (a, a^*, b, b^*) such that a is to a^* as b is to b^*. The model is tasked to predict b^* given the other three words: for example, "$a = Athens$ is to $a^* = Greece$ as $b = Berlin$ is to $b^* =$ _____$(Germany)$". Models are compared based on accuracy of their predictions across all tuples in the benchmark.

Datasets. We use two test sets: standard benchmarks (Mikolov et al., 2013b,c) and the Bigger Analogy Test Set (BATS) (Gladkova et al., 2016).

The standard benchmarks contain Google analogy (Mikolov et al., 2013a) and MSR (Mikolov et al., 2013c) test sets. MSR test set contains only morphological category; Google test set contains 9 morphological and 5 semantic categories, with 20 – 70 unique word pairs per category combined in all possible ways to yield 8,869 semantic and 10,675 syntactic questions. Unfortunately, these test sets are not balanced in terms of linguistic relations, which may lead to overestimation of analogical reasoning abilities as a whole (Gladkova et al., 2016).[9]

The Bigger Analogy Test Set (BATS) (Gladkova et al., 2016) contains 40 linguistic relations, each represented with 50 unique word pairs, making up 99,200 questions in total. In contrast to the standard benchmarks, BATS is balanced across four groups: *inflectional* and *derivational* morphology, and *lexicographic* and *encyclopedic* semantics.

Evaluation. Euclidean GloVe solves analogies by maximizing the 3CosAdd score:

$$b^* = \underset{\hat{b} \in V \setminus \{a^*, a, b\}}{\operatorname{argmax}} \left(\cos(\hat{b}, a^*) - \cos(\hat{b}, a) + \cos(\hat{b}, b) \right).$$

We adapt this for GraphGlove by substituting $\cos(x, y)$ with a graph-based similarity function. As a simple heuristic, we define the similarity between two words as the correlation of vectors consisting of distances to all words in the vocabulary:

$$\vec{d_G}(x) = (d_G(x, v_0), ..., d_G(x, v_N))$$

$$\text{sim}_G(x, y) := \text{corr}(\vec{d_G}(x), \vec{d_G}(y))$$

This function behaves similarly to the cosine similarity: its values are from -1 to 1, with unrelated

---

[8] We use standard evaluation code from `https://github.com/kudkudak/word-embeddings-benchmarks`

[9] For example, 56.7% of semantic questions in the Google dataset exploit the same *capital:country* relation, and the MSR dataset only concerns morphological relations.

words having similarity close to 0 and semantically close words having similarity close to 1. Another alluring property of $\text{sim}_G(x, y)$ is efficient computation: we can get full distance vector $\vec{d_G}(x)$ with a single pass of Dijkstra's algorithm.

We use $\text{sim}_G(x, y)$ to solve the analogy task in GraphGlove:

$$b^* = \underset{\hat{b} \in V \setminus \{a^*, a, b\}}{\text{argmax}} \left(\text{sim}(\hat{b}, a^*) - \text{sim}(\hat{b}, a) + \text{sim}(\hat{b}, b)\right).$$

For details on how Poincaré GloVe solves the analogy problem, we refer the reader to the original paper (Tifrea et al., 2019).

Results. GraphGlove shows substantial improvements over vector-based baselines (Tables 3 and 4). Note that for Poincaré GloVe, the best-performing loss functions for the two tasks are different ($\cosh^2 d$ for similarity and d^2 for analogy), and there is no setting where Poincaré GloVe outperforms Euclidean Glove on both tasks. While for GraphGlove best-performing loss functions also vary across tasks, GraphGlove with the dot product loss outperforms all vector-based embeddings on 10 out of 13 benchmarks (both analogy and similarity). This shows that when removing limitations imposed by the geometry of a vector space, embeddings can better reflect the structure of the data. We further confirm this by analyzing the properties of the learned graphs in Section 5.

5 Learned Graph Structure

In this section, we analyze the graph structure learned by our method and reveal its differences from the structure of vector-based embeddings.

We compare graph G_G learned by GraphGlove (d) with graphs G_E and G_P induced from Euclidean and Poincaré ($\cosh^2 d$) embeddings respectively.[10] For vector embeddings, we consider two methods of graph construction:

1. THR – connect two nodes if they are closer than some threshold τ,
2. KNN – connect each node to its K nearest neighbors and combine multiple edges.

The values τ and K are chosen to have similar edge density for all graphs.[11]

We find that in contrast to the graphs induced from vector embeddings:

- in GraphGlove frequent and generic words are highly interconnected;
- GraphGlove has hierarchical, similar to WordNet, structure;
- GraphGlove has non-trivial geometry containing subgraphs with different local topology.

5.1 Important words

Here we identify which words correspond to "central" (or important) nodes in different graphs; we consider several notions of node centrality frequently used in graph theory. Note that in this section, by word importance we mean graph-based properties of nodes (e.g. the number of neighbors), and not semantic importance (e.g., high importance for content words and low for function words).

---

[10] We take the same models as in Section 4.

[11] Namely, $K = 13$ and $\tau = 0.112$ for Euclidean GloVe, $K = 13$ and $\tau = 0.444$ for Poincaré Glove.

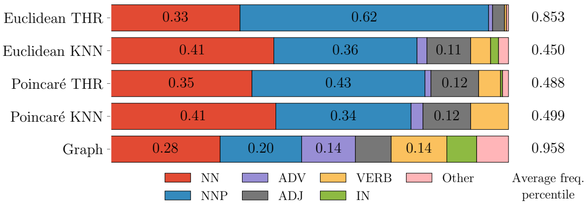

Figure 1: Top-200 words, the degree centrality. POS distribution and the average frequency percentile.

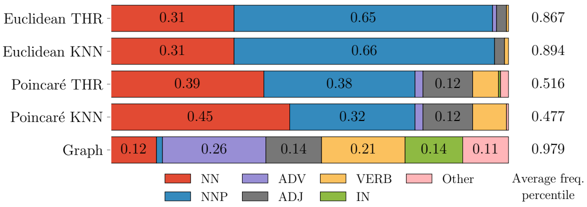

Figure 2: Top-200 words, the eigenvector centrality. POS distribution and the average frequency percentile.

Degree centrality. The simplest measure of node importance is its degree. For the top 200 nodes with the highest degree, we show the distribution of parts of speech and the average frequency percentile (higher means more frequent words). Figure 1 shows that for all vector-based graphs, the top contains a significant fraction of proper nouns and nouns. For G_G, distribution of parts of speech is more uniform and the words are more frequent. We provide the top words and all subsequent importance measures in the supplementary material.

Eigenvector centrality. A more robust measure of node importance is the eigenvector centrality (Bonacich, 1987). This centrality takes into account not only the degree of a node but also the importance of its neighbors: a high eigenvector score means that a node is connected to many nodes who themselves have high scores.

Figure 2 shows that for G_G the top changes in a principled way: the average frequency increases, proper nouns almost vanish, many adverbs, prepositions, linking and introductory words appear (e.g., 'well', 'but', 'in', 'that').[12] For G_G, the top consists of frequent generic words; this agrees with the intuitive understanding of importance. Differently from G_G, top words for G_E and G_P have lower frequencies, fewer adverbs and prepositions. This can be because it is hard to make generic words from different areas close for vector-based embeddings, while GraphGlove can learn arbitrary connections.

	size	k
Euclidean	275	198
Poincaré	235	156
Graph	197	21

Table 5: The main core size and its k value. For vector-based embeddings, the THR graphs are shown (by construction, the main core of a KNN graph is trivial).

k-core. To further support this claim, we looked at the main k-core of the graphs. Formally, *k-core* is a maximal subgraph that contains nodes of degree k or more; *the main core* is non-empty core with the largest k. Table 5 shows the sizes of the main cores and the corresponding values of k. Note that the maximum k is much smaller for G_G; a possible explanation is that the cores in G_E and G_P are formed by nodes in highly dense regions of space, while in G_G the most important nodes in different parts can be interlinked together.

5.2 The Structure is Hierarchical

In this section, we show that the structure of our graph reflects the hierarchical nature of words. We do so by comparing the structure learned by GraphGlove to the noun hierarchy from WordNet. To extract hierarchy from G_G, we (1) take all (lemmatized) nouns in our dataset which are also present in WordNet (22.5K words), (2) take the root noun 'entity' (which is the root of the WordNet tree), and (3) construct the hierarchy: the k-th level is formed by all nodes at edge distance k from the root.

We consider two ways of measuring the agreement between the hierarchies: *word correlation* and *level correlation*. Word correlation is Spearman's rank correlation between the vectors of levels for all nouns. Level correlation is Spearman's rank correlation between the vectors l and l^{avg}, where l_i is the level in WordNet tree and l_i^{avg} is the average level of l_i's words in our hierarchy.

We performed these measurements for all graphs (see Table 6).[13] We see that, according to both correlations, G_G is in better agreement with the WordNet hierarchy.

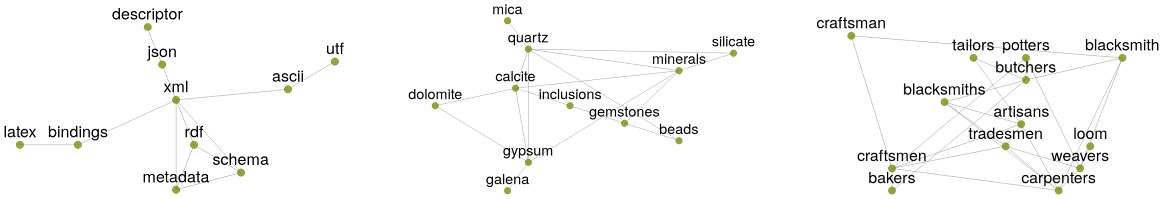
5.3 The Geometry is Non-trivial

In contrast to vector embeddings, graph-based representations are not constrained by a vector space

---

[12] See the words in the supplementary material.

[13] The low performance of threshold-based graphs can be explained by the fact that they are highly disconnected (we assume that all nodes which are not connected to the root form the last level).



(a) $\delta \approx 0$ (b) $\delta \approx 0.15$ (c) $\delta \approx 0.35$

Table 6: Correlations of hierarchies extracted from graphs and WordNet levels.

geometry and potentially can imitate arbitrarily complex spaces. Here we confirm that the geometry learned by GraphGlove is indeed non-trivial.

We cluster G_G using the Chinese Whispers algorithm for graph node clustering (Biemann, 2006) and measure Gromov δ-hyperbolicity for each cluster. Gromov hyperbolicity measures how close is a given metric to a tree metric (see, e.g., Tifrea et al. (2019) for the formal definition) and has previously been used to show the tree-like structure of the word log-co-occurrence graph (Tifrea et al., 2019). Low average δ indicates tree-like structure with δ being exactly zero for trees; δ is usually normalized by the average shortest path length to get a value invariant to metric scaling.

Figure 4 shows the distribution of average δ-hyperbolicity for clusters of size at least 10. Firstly, we see that for many clusters the normalized average δ-hyperbolicity is close to zero, which agrees with the intuition that some words form a hierarchy. Secondly, δ-hyperbolicity varies significantly over the clusters and some clusters have relatively large values; it means that these clusters are not tree-like. Figure 3 shows examples of clusters with different values of δ-hyperbolicity: both tree-like (Figure 3a) and more complicated (Figure 3b-c).

6 Related Work

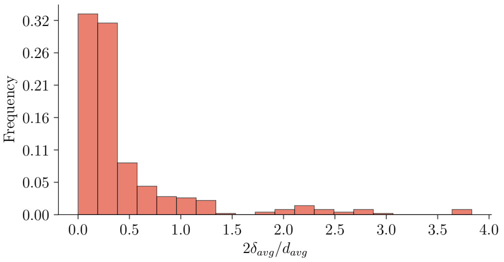

Figure 4: Distribution of cluster δ-hyperbolicities, normalized by the average shortest path length in a cluster.

Word embedding methods typically represent words as vectors in a low-dimensional space; usually, the vector space is Euclidean (Mikolov et al., 2013b; Pennington et al., 2014; Bojanowski et al., 2017), but recently other spaces, e.g. hyperbolic, have been explored (Leimeister and Wilson, 2018; Dhingra et al., 2018; Tifrea et al., 2019). However, vectorial embeddings can have undesired properties: e.g., in dot product spaces certain words cannot be assigned high probability regardless of their context (Demeter et al., 2020). A conceptually different approach is to model words as probability density functions (Vilnis and McCallum, 2015; Athiwaratkun and Wilson, 2017; Bražinskas et al., 2018; Muzellec and Cuturi, 2018; Athiwaratkun and Wilson, 2018). We propose a new setting: embedding words as nodes in a weighted graph.

Representing language data in the form of a graph has been a long-standing task (Miller, 1995; Motter et al., 2002; Cancho and Solé, 2001; Niyogi, 2006; Masucci and Rodgers, 2006). Graph lexicons were used to learn word embeddings specialized towards certain types of lexical knowledge (Nguyen et al., 2017; Vulić and Mrkšić, 2018; Liu et al., 2015; Ono et al., 2015; Mrkšić et al., 2017; Bollegala et al., 2016). It is also possible to incorporate external linguistic information from graphs, e.g. dependency parser outputs (Vashishth et al., 2018).

To learn a weighted graph, we use the method by Mazur et al. (2019). Prior approaches to learning graphs from data are eigher highly problem-specific and not scalable Escolano and Hancock (2011); Karasuyama and Mamitsuka (2017); Kang et al. (2019) or solve a less general but important case of learning *directed acyclic graphs* (Zheng et al., 2018; Yu et al., 2019). The opposite to learning a graph from data is the task of embedding nodes in a given graph to reflect graph distances and/or other properties; see Hamilton et al. (2017) for a thorough survey.

Analysis of word embeddings and the structure of the learned feature space often reveals interesting language properties and is an important research direction (Köhn, 2015; Bolukbasi et al., 2016; Mimno and Thompson, 2017; Nakashole and Flauger, 2018; Naik et al., 2019; Ethayarajh et al., 2019). We show that graph-based embeddings can be a powerful tool for language analysis.

7 Conclusions

We introduce GraphGlove — graph word embeddings, where each word is a node in a weighted graph and the distance between words is the shortest path distance between the corresponding nodes. The graph is learned end-to-end in an unsupervised manner. We show that GraphGlove substantially outperforms both Euclidean and Poincaré GloVe on word similarity and word analogy tasks. Our analysis reveals that the structure of the learned graphs is hierarchical and similar to that of WordNet; the geometry is highly non-trivial and contains subgraphs with different local topology.

Possible directions for future work include using GraphGlove for unsupervised hypernymy detection, analyzing undesirable word associations, comparing learned graph topologies for different languages, and downstream applications such as sequence classification. Also, given the recent success of models such as ELMo and BERT, it would be interesting to explore extensions of GraphGlove to the class of contextualized embeddings.

A Appendix: Additional benchmarks

A.1 Variance study

As our method relies on random initialization of a graph in PRODIGE, a natural question is whether different choice of drawn edges significantly affects the quality of representations in the end of training. Figure 5 demonstrates that after running the training procedure with distance-based loss for 5 different random seeds, the final metrics values have a standard deviation of less than 1 point in 10/13 tasks and have a standard deviation of at most 1.34 percent for the RareWord dataset. Thus, we can conclude that GraphGlove results are relatively stable with respect to selection of random edges before training.

A.2 Similarity

Below we report additional similarity benchmarks for GraphGlove and its vectorial counterparts:

- 50K tokens, 100 parameters / token - Table 7;
- 200K tokens, 20 parameters / token - Table 8.

Some word pairs in each similarity benchmark are out of vocabulary (OOV). In the main evaluation, we drop such pairs from the benchmark. However, there's also a different way to deal with such words.

A popular workaround is to calculate the distance between w_i and OOV as an average distance from w_i to other words. In the rare case when both words are OOV, we can consider them infinitely distant from each other. We report similarity benchmarks including OOV tokens in Tables 9, 10 and 11.

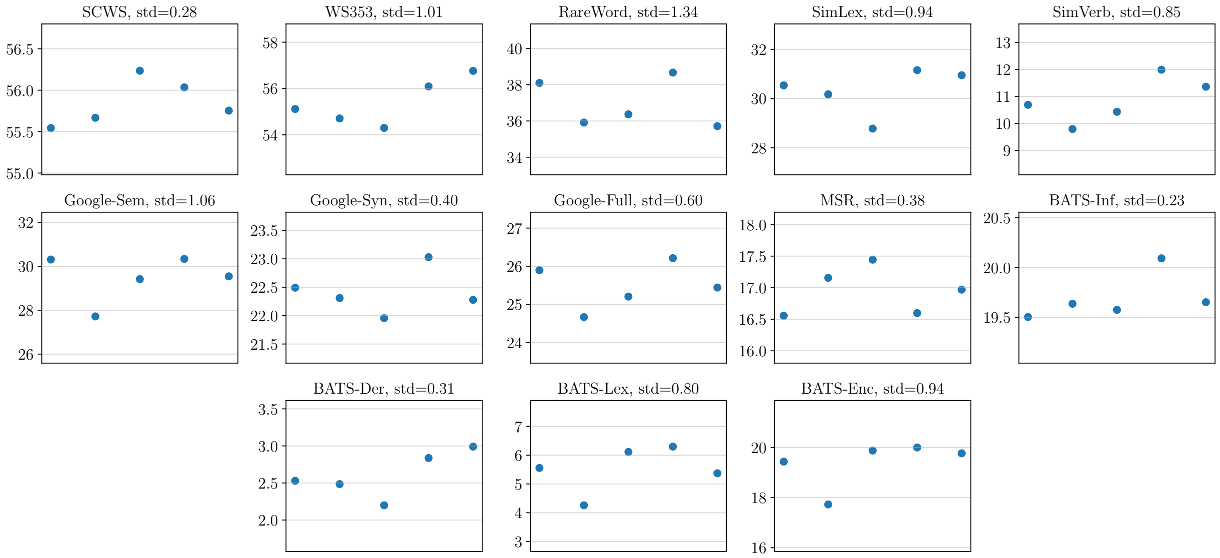

Figure 5: Results of evaluation for GraphGlove with 20 parameters per vertex on all benchmarks over 5 random initializations. Here, d is used in the loss function.

Abstract

It has been shown that knowledge graph embeddings encode potentially harmful social biases, such as the information that women are more likely to be nurses, and men more likely to be bankers. As graph embeddings begin to be used more widely in NLP pipelines, there is a need to develop training methods which remove such biases. Previous approaches to this problem both significantly increase the training time, by a factor of eight or more, and decrease the accuracy of the model substantially. We present a novel approach, in which all embeddings are trained to be neutral to sensitive attributes such as gender by default using an adversarial loss. We then add sensitive attributes back on in whitelisted cases. Training time only marginally increases over a baseline model, and the debiased embeddings perform almost as accurately in the triple prediction task as their non-debiased counterparts.

1 Introduction and Related Literature

Learning embeddings of knowledge graph entities and relations is becoming an increasingly common first step in utilizing knowledge graphs for a range of graph and NLP tasks, from missing link prediction, (Bordes et al., 2013; Trouillon et al., 2016), to more recent methods integrating learned embeddings into language models, (Zhang et al., 2019; IV et al., 2019; Peters et al., 2019).

In (Fisher et al., 2020), it is shown that knowledge graph embeddings encode similar social biases to those observed in word embeddings ((Bolukbasi et al., 2016; Caliskan et al., 2017; Garg et al., 2017)), such as the information that men are more likely to be bankers and women more likely to be nurses. This is an unsurprising finding, given that the distribution of entities in knowledge graphs is highly skewed towards historically privileged members of society; there are many more male bankers in Wikidata than female bankers.

Such biases are potentially harmful as they can propagate to downstream tasks. If graph embeddings are used for knowledge base completion, the model would be less likely to be able to predict a female bankers profession than an equivalent male banker's profession. Alternatively, if graph embeddings are used as input to a Transformer (Vaswani et al., 2017) encoder as in (Peters et al., 2019), the same effects on coreference resolution, entity linking and other downstream task as have been observed with word embeddings will re-occur.

In light of this, it is important to develop methods which enable debiasing of the embeddings with respect to user-defined sensitive attributes (e.g. gender). A potential method for debiasing was presented in (Bose and Hamilton, 2019), in which the authors train a set of filter neural networks to remove sensitive information from embeddings. Although the method proves effective on the MovieLens1M dataset, it results in a significant drop in performance as measured on the triple prediction task for the FB15K dataset, and proves ineffective in removing more than one source of bias concurrently. In addition, our benchmarks indicate the extra computation needed to train the neural network filters increase overall training time by a factor of 8 or more, making the approach unsuitable for large knowledge graphs.

We present an alternative approach, which trains all embeddings to be neutral with respect to sensitive attributes such as gender by default using an adversarial loss. We then allow the user to add sensitive information back in for whitelisted cases. For example, we may allow the model to use nationality information when predicting the languages someone speaks. We evaluate the model on FB15K, FB3M and Wikidata, and show that it is significantly faster than previous approaches, less disrup-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7332–7345,
November 16–20, 2020.

tive to the model accuracy on the original triple prediction task, and effective at producing embeddings which are neutral with respect to user-defined sensitive attributes (we present two measures to evaluate the level of sensitive information which remains in the trained embeddings).

2 Knowledge Graph Embeddings

A knowledge graph is a set of facts in triple form, where a triple consists of two entities and a relation, e.g. (France, has_capital, Paris). The aim of graph embedding methods is to use these triples to learn a continuous vector representation of dimension d of all entities and relations. The standard approach defines a score function, $g(.)$, which transforms a triple in vector form to a scalar score denoting how likely this triple is to be correct. For example the function

$$s = g(E_1, R_1, E_2)$$

gives the score, s, that the triple composed of entities 1/2 and relation 1 is correct, where $E_{1/2}$ and R_1 are all embeddings of dimension d. The score function is generally composed of a transformation, which takes as input one entity embedding and the relation embedding and outputs a vector of the same dimension, and a similarity function, which calculates the similarity or distance between the output of the transformation function and the remaining entity embedding.

Transformation functions proposed in the literature include TransE (Bordes et al., 2013), ComplEx (Trouillon et al., 2016) and RotatE (Sun et al., 2019). In this paper we use the TransE function and the dot product similarity, though the debiasing methods are applicable to any choice:

$$S = < E_1 + R_1, E_2 > \tag{1}$$

2.1 Optimization of knowledge graph embeddings

Knowledge graph embeddings (in their basic form, with no debiasing) are trained by optimizing the entity and relation embeddings to produce a high score for positive (true) triples, and a low score for randomly generated false triples. This is illustrated in Figure 1, with a batch of three triples shown in Box 1. We calculate the scores of the positive triples using Equation 1 (shown in Box 2a), and then for each positive triple calculate the scores of N negative triples, with negatives created by randomly permuting the entities on either side; we permute the right hand side (rhs) of T_1 with $N = 2$ in Box 3 of the example figure. For the standard model (i.e. no debiasing), we pass the scores of the single positive triple and the N negative triples through the softmax function (denoted "sft" in the figure) and calculate the cross-entropy[1], denoted L_{CE}, between the resulting distribution and that with all the weight on the positive triple (Box 4). The steps can be summarized using Figure 1 as Boxes 1 → 2a → 3 → 4 → 5a. This is the standard approach for training graph embeddings, which we denote "Basic" in the results tables, and on top of which we add our debiasing techniques.

3 Debiasing Motivation

To motivate our work, we begin by introducing how biases may be encoded into the embeddings of human entities. First, we define a set of "sensitive attributes"; human characteristics which may be associated with unwanted stereotypes. In this paper we define gender, ethnicity, religion and nationality as "sensitive attributes", though any choice is possible and we do not claim this list to be exhaustive/correct. For each knowledge graph, there will be a set of relations which provide these attributes (e.g. for Freebase the relation "/people/person/gender" provides a person's gender), which we term "sensitive relations".

When embeddings are trained with positive triples such as (person1, gender, male), the embedding of person1 will be updated with information related to the rhs entity "male" in order to score this triple higher than negative triples, including (person1, gender, female). This in itself is uncontroversial - we do not mind if the model is able to predict a person's gender. However, as gender information is now encoded in the embedding of person1, the model is also able to use this information when scoring other triples, such as (person1, profession, banker). (Fisher et al., 2020) shows that as knowledge graphs such as Wikidata and Freebase include, for example, many more male bankers than female bankers, the model learns to use the encoded gender information when predicting the likelihood a person is a banker, alongside other harmful stereotypes.

As knowledge graphs are based in reality, it is not easy to mitigate this effect by manually balanc-

---

[1] Common alternatives are a ranking or logistic loss which also incentivize a high score for positive triples and a low score on negatives.

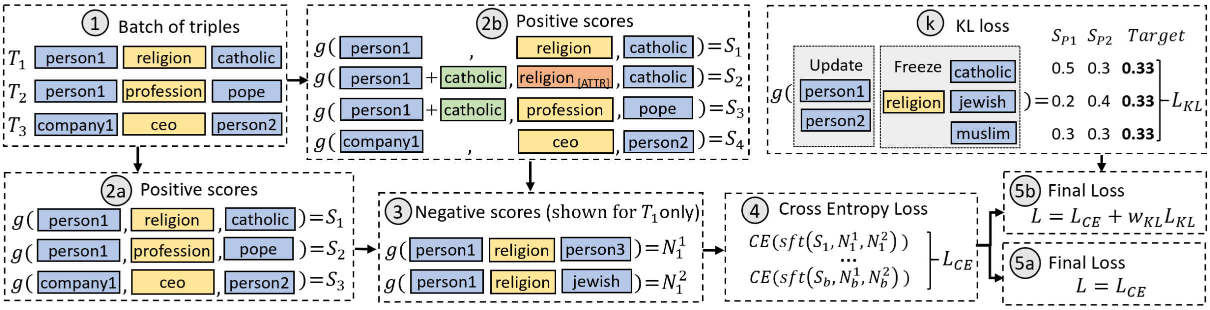

Figure 1: Training of a single batch with KL loss and attribute vectors

ing the graph[2]. Instead we aim to train all human's embeddings to be neutral with respect to sensitive attributes. That is, we wish to make it impossible to predict, for example, a person's gender, from their embedding. As a result, predictions made using these embeddings (such as about profession) will also be independent of these attributes. Note this imposes the constraint that we can no longer predict any unknown gender, religion, ethnicity or nationality of a human.[3]

4 Debiasing Architecture

4.1 Adversarial loss

A potential approach to avoiding information related to sensitive attributes being encoded in human's embeddings is to remove all triples containing sensitive relations from the training data. In Appendix A.3 , we show this is insufficient; a person's gender can often be predicted regardless, due to correlated relations. An alternative approach, introduced by (Bose and Hamilton, 2019), is to train a set of neural network "filters" to remove sensitive information from embeddings. We show (Tables 5 and 6) this approach to be ineffective at removing information about multiple sensitive attributes concurrently, as the output of each filter network is independent of one attribute only, leading to leaking of information when their outputs are averaged (see Appendix A.1 for details).

Instead, we leave the sensitive relations in the training data, and optimize their embeddings as normal.[4] We then add a Kullback-Leibler Divergence (KL-Divergence) based loss function to the model, which aims to make it impossible to make accurate predictions about these relations (e.g. about someone's gender). This addition to the "Basic" model is illustrated in Box k of Figure 1. During training, for each batch we extract the embeddings of all human entities in the batch; in Figure 1 these are denoted "person1" and "person2". We then calculate the score, S of these entities with each sensitive relation for each of the top M most frequent right hand side entities.

$$S_{p,j,m} = g(E_p, R_j, E_m)$$

where E_p denotes the embedding of Person p, R_j the embedding of sensitive relation j, and E_m the embedding of the rhs entity m. In the example Figure, we set $M = 3$, and use "religion" as the sensitive relation. In practice, we set M to 30 in all experiments, and define "top" as being the entities with the largest counts in the dataset. In the case of gender, for which there are only two rhs entities in the knowledge graph with significant counts, we simply try to balance the scores of the top two genders.

For each person i in the batch, we pass the scores for the top M right hand side entities through the softmax function. The KL-divergence is then calculated between this distribution and a target distribution, $\mathcal{G}$. In this paper, we use a balanced target distribution of weight $\frac{1}{M}$ (e.g. if $M = 3$ the distribution $\mathcal{G} = [0.33, 0.33, 0.33]$) and is denoted L_{KL}.

$$L_{KL} = \frac{1}{P}\frac{1}{J}\sum_{p=1}^{P}\sum_{j=1}^{J} KL(\mathcal{G}_j, sft(S_{P_{i,j,m}}))$$

In other words the KL loss is incentivizing the model, for the case of religion, to give an equal probability to a person having each of the top M religions (hence making it impossible for the model to predict their true religion). Note that the target distribution G does not need to be balanced, and

---

[2] There are no female U.S. Presidents in history, so we cannot balance this profession without inventing fake people or deleting male Presidents, which would distort/decimate the training data respectively.

[3] Given such relations are often in knowledge graphs, and that when they aren't predicting them is likely to be controversial, this is a small cost.

[4] That is, we update the embeddings of the relations for gender, religion etc. to attempt to enable the model to accurately predict someone's gender or religion.

can be defined by the user to put more/less weight on particular attributes.[5]

When minimizing L_{KL} we freeze the embeddings of the relations and the rhs entities, both of which have been trained using L_{CE} (i.e. to be effective at predicting an entity's sensitive attributes correctly), and update only the human entity embeddings. The KL loss and the original graph embedding loss are consequently trained adversarially to each other for the sensitive relations only.

The final loss (Box 5b) is a weighted average of the original cross-entropy loss, L_{CE} and L_{KL};

$$L = L_{CE} + w_{KL} L_{KL}$$

The weight w_{KL} controls how much emphasis we put on debiasing vs. the original triple prediction task. A discussion of the procedure for choosing w_{KL} follows in Section 4.3. We denote models trained with the KL loss included as "KL" in the results tables, and they can be summarized in Figure 1 as Boxes 1 → 2a → 3 → 4, k → 5b.

4.2 Attribute vectors

One limitation of this approach is that it prevents the model from using sensitive information (e.g. gender) for all triples. In some uncontroversial cases (e.g. predicting somebody's singing voice) we may wish to allow the use of such information. The second component of our architecture, a set of attribute vectors, facilitates this.

To illustrate, we label a set of whitelisted triples, for which we allow information from the sensitive relations to be used. We define such cases in two groups. Firstly, a set of relations for which we allow a particular sensitive attribute to be used for **all** entities. For example, when scoring the likelihood of the triple (person1, speaks_languages, french), we allow the model to use a person's nationality. We labelled a separate set of such relations for gender, religion, ethnicity and nationality, giving a total of 60 relations for Freebase and 88 for Wikidata, with examples in Appendix A.2 .

Secondly, for some relations we may only wish to allow sensitive attributes to be used for particular right hand side entities. For example, we may allow the religious attribute to be used when making a prediction of the likelihood of the triple (person1, profession, nun), but not allow it to be used when predicting the triple (person1, profession, banker). We labelled data for only one such relation (denoting someone's profession), with a total of 128 professions whitelisted for Freebase and 1411 for Wikidata. Details on labelling these professions can be found in Appendix A.2 alongside examples.[6]

4.2.1 Attribute vector training

To allow the model to use sensitive information in the whitelisted cases, for each right hand side entity of a sensitive relation (i.e. for each of the entities male, female, Catholic, Jewish etc.) we train a vector of the same dimension as the graph embeddings, termed an "attribute vector". For whitelisted triples, we can add this vector onto the human's embedding, allowing the model to utilize sensitive information.

This addition to the model is illustrated by replacing box 2a with 2b in Figure 1. We add the attribute vectors, shown as green rectangles, in two distinct cases. Firstly, for the whitelisted (for religion) triple T_2, predicting whether person1 is the pope. This allows the model to use the information that person1 is a Catholic when scoring this triple. Secondly, to aid in training useful attribute vectors only[7] we add a new triple for each triple in the batch which contains a sensitive relation (in this case T_1), replacing the relation with a twin denoted "religion$_{\text{[ATTR]}}$", shown in orange in Figure 1. In doing so, we incentivize the attribute vector to encode information about the correct sensitive attribute (in this case Catholicism), which in turn helps with predictions of whitelisted triples. Duplicating the sensitive relations is necessary, as the original sensitive relations are trained adversarially against the KL loss in Box 3, with no attribute vector added to the left hand side. The model with attribute vectors included is denoted "KL + Attr." in the results tables, and can be summarized using Figure 1 as Boxes 1 → 2b → 3 → 4, k → 5b.[8]

---

[5] E.g. for religion, one may wish to place particular emphasis on not being able to predict a believer vs. non-believer, grouping religions and defining a distribution accordingly.

[6] As with which attributes are denoted "sensitive", the decision about which relations and professions should be whitelisted with respect to these attributes is non-trivial and application dependent, and can be set by the user.

[7] i.e. we discard these relations after training as it is nonsensical predicting someone's religion when we know it.

[8] Note it is possible to freeze the embedding of person1 in the triples in rows 2 and 3 of Box 2, to avoid them updating with religious information. In practice, we found doing so was not useful, as unfrozen versions of these entities which showed up in negative samples resulted in skewed embeddings. Instead, we rely on the KL loss to enforce debiasing.

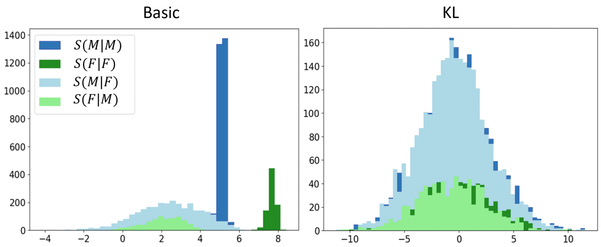
4.3 Methods for tuning W_{KL}

The model now includes two loss functions, as shown in Box 5b. The scalar weight w_{KL} controls the emphasis the model puts on debiasing vs. the original prediction task. In order to choose w_{KL} for each attribute[9], we introduce two methods of measuring the bias in the trained embeddings.

Note that all "tuning" results in this section (Figures 2, 3 and 4) are for the train (in sample) data. The motivation for this is that generally all entities appear in at least one triple in the train set (otherwise the model is not capable of producing an embedding for that entity). We wish to test whether the resulting trained embeddings of human entities contain sensitive information which could potentially be used in downstream tasks, including predicting new triples or as additional input to a language model etc. More precisely, we tune w_{KL} using the subset of human entities for which the triple (person, has_sensitive_attribute, sensitive_attribute) is in the training set. This ensures that even if this information is present in the training data, the debiasing is effective at removing it from the embedding.

To begin, we analyse the model's scores for each human entity when predicting each sensitive attribute (without the attribute vectors added on). The KL loss attempts to ensure that these scores are equalized. For example, the scores of (person1, gender, male) and (person1, gender, female) should be equal, so that we cannot predict a person's gender using the score function.

Figure 2: FB15K gender scores (in sample) for TransE model



In Figure 2, $S(F|F)$ denotes the score that a female entity is female, and $S(F|M)$ denotes the score a female entity is male. If the model is able to correctly identify female entities' gender from their embeddings, $S(F|F)$ should be greater than $S(F|M)$, as is clearly the case for the "Basic" model on the left.[10] For the "KL" model, shown on the right, the distributions of the scores overlap, as incentivized by the KL loss, indicating that the model now struggles to identify a person's gender.

To extend this analysis to all sensitive attributes, we calculate the difference between the score for a person's true attribute, and the top n false attributes. For example, in the case of a Catholic entity, we would calculate the score for the triple (person1, religion, catholic), and the scores (person1, religion, R) for all of the top 30 most frequent religions, R. We then calculate the difference between the true triple's score and the average score of the false triples.

Figure 3: Tuning of w_{KL} for FB15K, using the scores of triples with sensitive relations

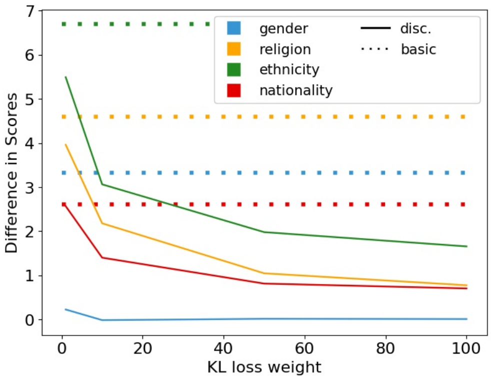


Figure 3 displays the results. The y-axis denotes the difference in scores, with the dotted horizontal lines giving the difference for the "Basic" model with no debiasing; the dotted line for gender therefore corresponds to the difference between the lighter and darker histograms on the left of Figure 2. The x-axis denotes the weight on the KL loss, w_{KL}. The solid coloured lines show the differences for the "KL" model. As we increase w_{KL}, more emphasis is put on reducing the sensitive information in the embeddings, leading to a reduction in the difference for all attributes.

For gender, it is relatively easy for the model to equalize the scores, as there are only two genders in FB15K. Equalization for TransE therefore corresponds to simply placing the sum of a human entity's embedding and the relation gender equidistant between the two gender embeddings. For the

---

[9] We can choose a different value of w_{KL} for gender, religion, ethnicity etc.

[10] The higher scores for female entities than male entities stems from a combination of the skewed distribution - there are more male entities than female entities in FB15K - and negative sampling. We are more likely to get unwanted positive triples in the negative samples for male entities, as there are more of them.

other three sensitive attributes, there are multiple rhs entities, and ensuring equidistance to each of them is no longer plausible. As a result, even as we increase w_{KL} to 100.0, the difference in scores approaches an asymptote. However, we can clearly see that the difference continues to decrease significantly for the higher values of w_{KL} for religion, ethnicity and nationality, suggesting a high weight is necessary.

As a second method of measuring the extent to which sensitive information remains in the trained embeddings, we train a feedforward neural network to try and predict the attributes of a human entity from their embedding alone. That is, the input to the network is the embedding of dimension d, and the output is a softmax distribution over labels (male and female for gender). We train the network using the cross-entropy loss between the output distribution and the correct class label. We use a single hidden layer of dimension 300 and ReLu activation function.

Figure 4: FB15K tuning of KL weight based on feedforward NN predictions

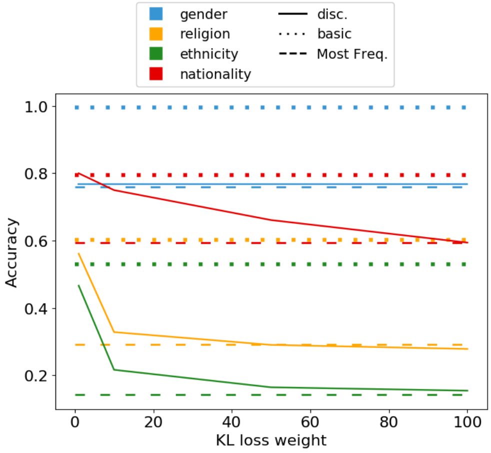

Figure 4 displays the results. The accuracy from predicting the most frequent class is illustrated with a dashed horizontal line. If the network is unable to extract any useful predictive information from the embedding, it will default to this. The accuracy when using the embeddings from the basic TransE model are shown with the horizontal dotted lines. For gender, we can see that the neural network achieves almost 100% accuracy in its predictions for the "basic" case. As before, a weight of 1.0 proves sufficient to remove the gender information from the embeddings. For religion, nationality and ethnicity a higher weight is needed, with the accuracy only approaching the most frequent case at weights of 50.0 and over.

The above methods of measuring the extent to which sensitive information remains in the embeddings suggest a high value of w_{KL} is necessary. However, this is not costless - a higher weight on the KL loss results in the model putting less emphasis on the original triple prediction task, and embeddings which are less informative. To illustrate, Table 1 shows the Mean Reciprocal Rank (MRR)[11] for both the KL only models and the KL + Attr. model on the FB15K test set, at different values of w_{KL}.

Table 1: MRR on FB15K test set for different KL loss weights

		Weight			
	Model	1.0	10.0	50.0	100.0
Biased	Basic	0.680			
Debiased	KL	0.673	0.660	0.658	0.654
	KL + Attr.	0.675	0.672	0.663	0.660

As we increase the weight, the MRR falls from the baseline of 0.680 to a minimum of 0.654 for the KL model. Part of this drop is regained in each case by the attribute vectors, but not the entire gap.

In light of Figures 3 and 4 we set w_{KL} to 1.0 for gender and to 100.0 for religion, ethnicity and nationality. That is, for the purposes of presenting our method in this paper, we tune w_{KL} to remove as much sensitive information as possible, using the results presented on the train set only. In practice w_{KL} should be tuned by the researcher for the specific dataset they are using and depending on the importance they place on debiasing vs. model accuracy. If this approach is taken, the validation set MRR should be monitored, and one may allow some bias to remain if validation MRR drops with high w_{KL}.

We note that the tuning step increases the computational cost significantly; a separate model has to be trained for each value of w_{KL} experimented with. However, the results presented here, and in Appendix A.4 for FB3M, suggest that this step is necessary, as the value of W_{KL} chosen varies across both sensitive attribute and datasets.

5 Experimental Details

5.1 Datasets

We evaluate our model on three datasets; FB15K, FB3M (both of which are subsets of the full Free-

---

[11] See Section 6.2 for a description of the MRR

base knowledge graph), and Wikidata. For FB3M there is no standard train/val/test split in the literature, so we randomly subsample 10,000 triples as a validation set, and 100,000 triples as a test set. Note that (as discussed at the start of Section 4.3) we use the train set for tuning W_{KL}, and as a result, do not use the validation splits in this paper, though they could be used by a practitioner for monitoring the MRR during tuning. For Wikidata, we first filtered out all triples which contained a string entity (as opposed to an entity with a wiki QID), and then removed all relations/entities which had fewer than 5 observations. This left a total of 283M triples, from which we randomly sampled a test set of size 200,000.

Table 2: Dataset statistics

Dataset	Ents	Rels	Train	Val	Test
FB15K	14.9K	1.3K	483K	50K	59K
FB3M	3M	6.6K	24M	10K	100K
Wikidata	20M	1.1K	283M	—	200K

As discussed in Section 4.2, our approach assumes that we will never predict the sensitive attributes of a person (their gender, ethnicity etc.) directly. To evaluate our model, we therefore remove all sensitive relations which provide these attributes from the validation and test datasets; roughly 2% of triples. We denote the resulting datasets as FB15K (filtered), FB3M (filtered) and Wikidata (filtered).

5.2 Hyperparameters

We use the AdaGrad (Duchi et al., 2011) optimizer with a learning rate of 0.1, and perform linear learning rate warmup over epoch 1. We train for 50 epochs for FB15K and FB3M and 10 for Wikidata. Training is implemented using the PyTorch-BigGraph library (Lerer et al., 2019). For the Bose and Hamilton (2019) comparison we use the author's opensource code and the same model (TransE) and hyperparameters as our work, with the filter network dimensions to the recommended levels, and a low value of gamma of 10.0, to try to match the accuracy of our model.

6 Results

We present results from three perspectives: speed (training time), accuracy (ability to predict correct triples given the embeddings), and debiasing (how much sensitive information remains in the trained embeddings).

6.1 Training Time

We present the training time per epoch relative to the basic TransE model. All models were trained using the PTBG framework on a desktop with an Intel Core i7-7700 CPU with 8 cores. Table 3 displays the results for FB15K. The "Basic" model takes 68 seconds per epoch (spe). For each debiased approach we use the whitelisted labels described in Section 4.2 to denote which entities need to be debiased.[12] The additional neural networks in (Bose and Hamilton, 2019) push the training time per epoch to 533.3 seconds, around an 8x increase.

Table 3: Per epoch model training times for FB15K

	Model	Seconds per epoch (spe)
Biased	Basic	68.4
	Bose & Ham.	533.3
Debiased	KL	71.0
	KL + Attr.	89.4

Next, we benchmark the speed of the discriminator and KL-loss only ("KL"). As this works through the model's own score function, we can group the training of the sensitive relations with existing batches of triples, meaning the hit to computation time is minimal, increasing to 71.0 spe.

Finally, we evaluate the model with the attribute vectors as well ("KL + Attr."), which we train concurrently. Despite being a simple calculation (addition of vectors), there is a computational cost from indexing which entities we need to add each additive vector to, resulting in a time of 89.4 spe.

Although these times are benchmarked on FB15K only, the relative differences in spe stays constant for the larger datasets, as time to read from/write to memory is negligible. Consequently, we are able to train our full model on the Wikidata knowledge graph for 10 epochs in a time of around 10 hours on a system with 64 cpus.

6.2 Triple Prediction

We evaluate the accuracy of the embeddings on the triple prediction problem, where we aim to predict the likelihood of a triple being correct by calculating its score relative to negative triples. As is common in the literature (Bordes et al., 2011, 2013) we report results in terms of the Mean Reciprocal Rank (MRR), hits@1, hits@10 and hits@50. For FB15K we replace either the lhs or rhs of the triple

---

[12] In general the majority of triples with humans require debiasing with respect to at least one sensitive attribute.

with all remaining entities, whereas for FB3M and Wikidata we randomly sample 50000 negative entities.

Throughout the remaining results, for FB15K we use the tuned values of w_{KL} described in Section 4.3. For FB3M and Wikidata, we found these values to be too small. Consequently, we increased the values for FB3M to 100.0 for gender and 500.0 for the other three attributes. See Appendix A.4 for a full discussion. For Wikidata, we didn't rerun the experiments due to the computational cost.

Table 4: Test set results for TransE embeddings

	Model	**MRR**	**h@1**	**h@10**	**h@50**
FB15K (filtered)					
Biased	Basic	0.680	0.555	0.871	0.937
Debiased	Bose & Ham.	0.426	0.300	0.655	0.821
	KL	0.671	0.534	0.853	0.924
	KL + Attr.	0.679	0.537	0.861	0.931
FB3M (filtered)					
Biased	Basic	0.684	0.612	0.794	0.843
Debiased	KL	0.682	0.611	0.792	0.840
	KL + Attr.	0.684	0.611	0.798	0.846
Wikidata (filtered)					
Biased	Basic	0.493	0.380	0.703	0.837
Debiased	KL	0.485	0.373	0.693	0.827
	KL + Attr.	0.495	0.383	0.705	0.837

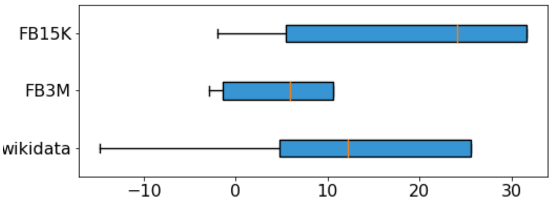
Table 4 displays the results. The "Basic" model achieves an MRR of 0.680 and hits@10 of 0.871 for FB15K. The neural network based filters approach of (Bose and Hamilton, 2019) significantly reduces these metrics, to 0.426 and 0.655 respectively. The "KL" approach leads to a much smaller drop in MRR and hits@10, to 0.671 and 0.853 respectively for FB15K, with a drop of similar magnitude for FB3M and Wikidata.

This result is expected; by limiting the model's ability to stereotype based on gender, religion, nationality and ethnicity, we expect to do worse at predicting both controversial relations such as profession, and whitelisted ones such as speaks_languages.

The aim when adding the attribute vectors ("KL + Attr.") for whitelisted relations is to recover some of this drop. We see a small increase of the MRR from 0.671 to 0.679, and of the hits@10 from 0.853 to 0.861 for FB15K, with similar results for the two larger datasets. We do not get back to the biased TransE accuracy for FB15K, but exceed it slightly for FB3M and Wikidata.

To understand if the attribute vectors are effective at increasing performance on the whitelisted relations, Figure 5 shows the distribution of the percentage changes in test set MRR for each whitelisted relation when we move from the "KL" model to the "KL + Attr." model[13]. That is, for each whitelisted relation, such as speaks_languages, we calculate the test set MRR **for this relation only** for both the "KL" model and the "KL + Attr." model, and take the percentage difference between the two scores. Figure 5 shows the distribution of these differences for all whitelisted relations, with the box spanning from the lower to upper quartiles, and the whiskers at the 5th and 95th percentiles.

Figure 5: Percentage increase in MRR for whitelisted relations when using attribute vectors



We see a substantial improvement in the model's ability to predict triples with whitelisted relations when adding the attribute vectors back in, with a median improvement of around 25% for FB15K, 6% for FB3M and 12% for Wikidata. With the KL loss only, it will be very hard to predict, for example, the languages that someone speaks when their embedding is independent of nationality. By adding the nationality information back in via an attribute vector, this prediction becomes simpler.

6.3 Debiasing

To evaluate the debiasing we present the same metrics introduced in Section 4.3, in which we tuned the values of w_{KL} for FB15K.[14] For (Bose and Hamilton, 2019), we give two sets of results. Firstly, denoted with [s], their model with just the single relevant filter network applied (the "gender" filter for the **Gender** column etc.), and secondly with all four filters applied, denoted [a]. For both variants, the scores of the correct attributes are consistently higher than the incorrect attributes, with the result particularly clear for the [a] variant. We discuss the reasons for this in Appendix A.1 .

---

[13] We include only the whitelisted relations that have more than 5 observations in the test datasets.

[14] As such the FB15K results in Tables 5 and 6 mirror those in Section 4.3.

In contrast, our model reduces the difference in scores for a human entity's true sensitive attributes and the alternatives (shown in Table 5) significantly for FB15K and FB3M. For Wikidata, we still see a notable gap between these scores (for example of 0.49 for gender), suggesting some information about these attributes remains in the embeddings.

Table 5: Difference in scores metric for debiasing

	Gender	Rel.	Ethn.	Nat.
FB15K (filtered)				
Basic	2.79	4.41	6.64	2.85
Bose & Ham. [s]	2.75	3.15	3.62	1.53

KL + Attr.	0.49	0.71	1.12	1.70

This conclusion is mirrored in Table 6, which shows the accuracy of a neural network trained to predict the sensitive attributes from the trained embeddings. For Bose and Hamilton (2019) we are still able to predict the correct sensitive attribute substantially more accurately than the Most Frequent baseline (we can predict a person's gender with 93.4% accuracy), indicating that despite the significant drop in model accuracy shown in 4, the model has not removed all bias. Our model, for FB15K and FB3M, reduces the accuracy of the neural network to very close to the most frequent class. For Wikidata, enough sensitive information remains to be able to predict some of the attributes very accurately. For example, we can predict a person's gender from their embedding with a 97.9% accuracy. These results suggest that higher values of w_{KL} would be suitable for Wikidata, if it is important that all sensitive information is removed.

A key component of our approach is that it operates through the model's usual score function, $g(.)$. This enables the fast training time relative to alternative methods, but raises a potential limitation; there is only an incentive via the KL loss to reduce sensitive information in the embeddings which can be detected by the (potentially very simple) function g. This is the motivation for introducing the neural network based method of measuring remaining sensitive information; to expose if information remains in the embedding which can be exposed by a more complicated (e.g. neural network based) function. Whilst the results in this paper suggest that this is not the case, care should be taken in practice to ensure that the function used for measuring the remaining sensitive information is as powerful as any downstream model for which the graph embeddings are an input.

Table 6: Accuracy of NN trained to predict sensitive attributes from embeddings

	Gender	Rel.	Ethn.	Nat.
FB15K (filtered)				
Most Frequent	0.767	0.292	0.142	0.594
Basic	0.990	0.552	0.534	0.799
Bose & Ham. [s]	0.933	0.406	0.391	0.732
Bose & Ham. [a]	0.934	0.423	0.472	0.736

FB3M (filtered)				
Most Frequent	0.778	0.256	0.227	0.380
Basic	0.990	0.756	0.686	0.844
KL + Attr.	0.788	0.306	0.431	0.435
Wikidata (filtered)				
Most Frequent	0.777	0.381	0.269	0.239
Basic	0.998	0.843	0.805	0.749
KL + Attr.	0.979	0.694	0.738	0.644

7 Summary

We have presented a novel method for debiasing knowledge graph embeddings, which is both significantly faster (allowing training on large knowledge graphs such as Wikidata in realistic timeframes) and less disruptive to accuracy than previous approaches. We demonstrated that the approach is also more effective in removing sensitive information from trained embeddings than previous methods, and through attribute vectors, give the user the flexibility to allow sensitive information to be used in predictions when desired.

A Appendices

A.1 Discussion of performance of (Bose and Hamilton, 2019) with multiple filters

To remove bias from an embedding, (Bose and Hamilton, 2019) propose a set of neural network filters, $f_k(.)$, which take as input the baseline (potentially biased) embedding, and output an embedding of the same dimension with the sensitive information removed. For each sensitive attribute (gender, religion etc.), they have a separate filter network. The "compositional" approach proposed suggests they can use multiple filter networks to allow the final embedding to be "invariant w.r.t. some set of sensitive attributes, $S \subseteq \{1, ..., K\}$". To do this, they compose the final debiased embedding as the averaged output of S filtered embeddings, as shown in Equation (6) of the paper:

$$C - ENC(u, S) = \frac{1}{|S|} \sum f_k(ENC(u))$$

where u is the input embedding, S, ENC is the encoder model [15] and S is the set of filters for each attribute k. We find that as each filter network $f_k(.)$ is trained to only remove a single sensitive attribute (for example, gender), when the outputs of multiple filters are combined, the remaining outputs (for example from the filters for religion, nationality and ethnicity), leak gender information back into the final representation. This explains the notable difference in Tables 5 and 6 between the [s] version of their model, in which we only use one filter network (and which is the version used to provide the debiasing results in the authors code), and the [a] versions, in which we apply all four filter networks.

A.2 Labelling of whitelisted relations and professions

In Section 4.2, we introduced the concept of whitelisted relations, such as "speaks_languages", for which we allow some sensitive information (in this case nationality) to be used by the model. For Freebase and Wikidata we labelled such relations by hand, and provide some examples in Table 7. In total we whitelisted 60 relations for Freebase and 88 for Wikidata.

Table 7: Example whitelisted relations

Freebase	
Gender	/music/opera_singer/voice_type
Religion	/religion/founding_figure/religion_founded
Ethnicity	/people/person/languages
Nationality	/people/person/place_of_birth

Wikidata	
Gender	P26 (spouse)
Religion	P119 (place of burial)
Ethnicity	P25 (mother)
Nationality	P102 (member of political party)

On top of this, for the relations "profession", we labelled each right hand side entity (i.e. each job type) with the sensitive attributes which could be used. For example, when predicting if someone is a nun, we allow the use of religious and gender information, whereas for predicting whether someone is a doctor, we allow the use of no sensitive information. We labelled the Freebase professions by hand, but for Wikidata there are around 12,000 professions, so we automated the process using keywords in the job description, wikidata subclasses, and properties.

For religion, a profession is whitelisted if any of the following three clauses apply:

1. Any of these keywords appear in professions definition:

   [religious, religion, divine]

2. The profession is a subclass (5 levels of inference) of any of these entities:

   [cleric, religious character, saint]

3. The profession has any of the following properties:

   [religion]

We use the same three clauses for gender, ethnicity and nationality, with different sets of keywords, subclasses and properties. We then filtered out false positives (there were less than five in total) manually.

Example professions are provided for each sensitive attribute in Table 8.

As mentioned in the paper, we do not suggest that the chosen relations/professions are complete/correct, and utilize them only as indicative of the types of relations/professions that may be used in practice, to demonstrate our debiasing approach.

A.3 Removing sensitive triples from training data

An obvious initial approach to attempting to make all entities neutral with respect to sensitive attributes is to simply take the sensitive relations

---

[15] TransE in this paper, which does not update the input embedding unlike more complex models.

Table 8: Example whitelisted professions

Freebase	
Gender	/m/05cyczs (Crown Princess)
Religion	/m/0djbw (Rabbi)
Ethnicity	/m/0df9z (Holy Roman Emperor)
Nationality	/m/07068 (Samurai)

Wikidata	
Gender	Q16511993 (Queen)
Religion	Q208762 (Chaplain)
Ethnicity	—
Nationality	Q636207 (United States Attorney General)

(gender, religion etc.) out of the training data. In this section, we show that doing so is not sufficient, and that active debiasing is required (which we carry out via the KL loss in our framework).

We use the neural network based measure of debiasing introduced in Section 4.3, in which we optimize a feedforward neural network to predict sensitive attributes from human entities embeddings post-training. If sensitive information remains in the embeddings, it will be possible for the network to be more accurate in its predictions than simply predicting the most frequent class.

Table 9: Accuracy of NN trained to predict sensitive attributes from embeddings for FB15K

	Gender	**Rel.**	**Ethn.**	**Nat.**
Most Frequent	0.767	0.292	0.142	0.594
Basic	0.990	0.552	0.534	0.799
Removed attributes	0.853	0.402	0.420	0.690

Table 9 shows the accuracy of the networks predictions for the most frequent class, the "Basic" TransE trained embeddings with no debiasing, and the "Removed attributes" model, in which we simply remove all sensitive relations from the training data. Although removing the sensitive relations lowers the accuracy of predictions relative to the "Basic" model, for each sensitive attribute it is possible to do better than the "Most Frequent" prediction, indicating that sensitive information remains.

Although we do not conduct a thorough investigation into the exact cause of this, it is likely due to relations which are highly correlated with the sensitive attributes remaining. For example, the relation "speaks_languages" provides information on the nationality a person is likely to have. In a more worrying example, the model may learn to infer, for example, gender, from the profession which somebody has (given the one-sided distribution of some professions in the datasets). In order to avoid this, active debiasing is required.

A.4 Additional FB3M Results

As discussed in Section 4.3, we tuned the values of w_{KL} on the FB15K dataset only, as tuning is computationally expensive in that it requires multiple repetitions. This resulted in a choice of w_{KL} of 1.0 for gender, and of 100.0 for religion, ethnicity and nationality.

Table 10: Difference in scores metric for debiasing

	Gender	**Rel.**	**Ethn.**	**Nat.**
FB3M (filtered)				
Basic	2.25	6.34	7.57	6.41
KL + Attr. (o)	0.44	2.40	2.72	2.09
KL + Attr.	0.01	0.78	1.87	1.46

However, when we used these same weights for FB3M, the model retained an ability to predict the sensitive attributes, as shown in Table 10, which is analogous to Table 5 in the main paper. The results with the original weights (tuned on FB15K) are denoted with an (o). For each sensitive attribute, the model is able to predict the correct attribute of a human entity using the discriminator relations, although the difference in scores is brought down significantly relative to the "Basic" method.

Table 11: Accuracy of NN trained to predict sensitive attributes from embeddings

	Gender	**Rel.**	**Ethn.**	**Nat.**
FB3M (filtered)				
Most Frequent	0.778	0.256	0.227	0.380
Basic	0.990	0.756	0.686	0.844
KL + Attr. (o)	0.979	0.588	0.334	0.608
KL + Attr.	0.788	0.306	431	0.435

This result is supported by Table 11, which indicates that a neural network can be trained to predict the correct attributes from a person's embedding with the original weights, getting, for example, a 97.9% accuracy in the case of gender.

In light of this result, we increased the values of w_{KL} for FB3M, to 100.0 for gender, and 500.0 for religion, ethnicity and nationality. These are the results which we presented in the main paper, and they are repeated in each of the Tables in this section. With the higher weights, the differential in scores is brought down, reaching close to zero in the case of gender, and it becomes much harder to predict the sensitive attributes from the trained embeddings.

Table 12: Test set results for TransE embeddings

	Model	**MRR**	**h@1**	**h@10**	**h@50**
FB3M (filtered)					
Biased	Basic	0.684	0.612	0.794	0.843
Deb.	KL (o)	0.688	0.619	0.793	0.840
	KL	0.682	0.611	0.792	0.840
	KL + Attr. (o)	0.693	0.624	0.797	0.845
	KL + Attr.	0.684	0.611	0.798	0.846

The increased emphasis on the KL loss comes at a cost of some accuracy however, as shown in Table 12. With the original weight, the hits at 10 and MRR remain at baseline levels, and we get a slightly higher than baseline performance once the attribute vectors are added in. As we increase the values of w_{KL}, the discriminator only results fall below the "Basic" model, with some of this regained by the attribute vectors, mirroring the results in the main paper.

Message Passing for Hyper-Relational Knowledge Graphs

Abstract

Hyper-relational knowledge graphs (KGs) (e.g., Wikidata) enable associating additional key-value pairs along with the main triple to disambiguate, or restrict the validity of a fact. In this work, we propose a message passing based graph encoder - STARE capable of modeling such hyper-relational KGs. Unlike existing approaches, STARE can encode an arbitrary number of additional information (*qualifiers*) along with the main triple while keeping the semantic roles of qualifiers and triples intact. We also demonstrate that existing benchmarks for evaluating link prediction (LP) performance on hyper-relational KGs suffer from fundamental flaws and thus develop a new Wikidata-based dataset - WD50K. Our experiments demonstrate that STARE based LP model outperforms existing approaches across multiple benchmarks. We also confirm that leveraging qualifiers is vital for link prediction with gains up to 25 MRR points compared to triple-based representations.

1 Introduction

The task of link prediction over knowledge graphs (KGs) has seen a wide variety of advances over the years (Ji et al., 2020). The objective of this task is to predict new links between entities in the graph based on the existing ones. A majority of these approaches are designed to work over triple-based KGs, where facts are represented as binary relations between entities. This data model, however, doesn't allow for an intuitive representation of facts with additional information. For instance, in Fig. 1.A, it is non-trivial to add information which can help disambiguate whether the two universities attended by `Albert Einstein` awarded him with the same degree.

This additional information can be provided in the form of key-value restrictions over instances of binary relations between entities in recent knowledge graph models (Vrandecic and Krötzsch, 2014; Pellissier-Tanon et al., 2020; Ismayilov et al., 2018). Such restrictions are known as *qualifiers* in the Wikidata statement model (Vrandecic and Krötzsch, 2014) or *triple metadata* in RDF* (Hartig, 2017) and RDF reification approaches (Frey et al., 2019). These complex facts with qualifiers can be represented as *hyper-relational* facts (See Sec. 3). In our example (Fig. 1.B), hyper-relational facts allow to observe that `Albert Einstein` obtained different degrees at those universities.

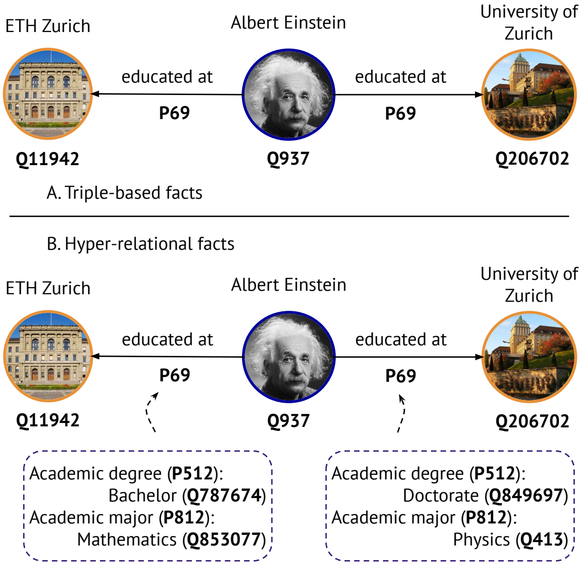

Figure 1: A comparison of triple-based and hyper-relational facts.

Existing representation learning approaches for such graphs largely treat a hyper-relational fact as an n-ary (n>2) composed relation (e.g., `educatedAt_academicDegree`) (Zhang et al., 2018; Liu et al., 2020) losing entity-relation attribution; ignoring the semantic difference between a triple relation (`educatedAt`) and qualifier relation (`academicDegree`) (Guan

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7346–7359,
November 16–20, 2020. ©2020 Association for Computational Linguistics

et al., 2019), or decomposing a hyper-relational instance into multiple quintuples comprised of a triple and one qualifier key-value pair (Rosso et al., 2020). In this work, we propose an alternate graph representation learning mechanism capable of encoding hyper-relational KGs with arbitrary number of qualifiers, while keeping the semantic roles of qualifiers and triples intact.

To accomplish this, we leverage the advances in Graph Neural Networks (GNNs), many of which are instances of the message passing (Gilmer et al., 2017) framework, to learn latent representations of nodes and edges of a given graph. Recently, GNNs have been demonstrated (Vashishth et al., 2020) to be capable of encoding mutli-relational (tripled based) knowledge graphs. Inspired by them, we further extend this framework to incorporate hyper-relational KGs, and propose STARE[1] , which to the best of our knowledge is the first GNN-based approach capable of doing so (see Sec. 4).

Furthermore, we show that WikiPeople (Guan et al., 2019), and JF17K (Wen et al., 2016) - two commonly used benchmarking datasets for LP over hyper-relational KGs exhibit some design flaws, which render them as ineffective benchmarks for the hyper-relational link prediction task (see Sec. 5). JF17K suffers from significant test leakage, while most of the qualifier values in WikiPeople are literals which are conventionally ignored in KG embedding approaches, rendering the dataset largely devoid of qualifiers. Instead, we propose a new hyper-relational link prediction dataset - WD50K extracted from Wikidata (Vrandecic and Krötzsch, 2014) that contains statements with varying amounts of qualifiers, and use it to benchmark our approach.

Through our experiments (Sec. 6), we find that STARE based model generally outperforms other approaches on the task of link prediction (LP) over hyper-relational knowledge graphs. We provide further evidence of the fact, independent of STARE, that triples enriched with qualifier pairs provide additional signal beneficial for the LP task.

2 Related Work

Early approaches for modelling hyper-relational graphs stem from conventional triple-based KG embedding algorithms, which often simplify complex property attributes (*qualifiers*). For instance, m-TransH (Wen et al., 2016) requires star-to-clique conversion which results in a permanent loss of entity-relation attribution. Later models, e.g., RAE (Zhang et al., 2018), HypE and HSimple introduced in (Fatemi et al., 2020), converted hyper-relational facts into *n-ary* facts with one abstract relation which is supposed to loosely represent a combination of all relations of the original fact.

Recently, GETD (Liu et al., 2020) extended TuckER (Balazevic et al., 2019) tensor factorization approach for n-ary relational facts. However, the model still expects only one relation in a fact and is not able to process facts of different arity in one dataset, e.g., 3-ary and 4-ary facts have to be split and trained separately.

NaLP (Guan et al., 2019) is a convolutional model that supports multiple entities and relations in one fact. However, every complex fact with k qualifiers has to be broken down into $k + 2$ key-value pairs with an artificial split of the main *(s,p,o)* triple into $(p_s : s)$ and $(p_o : o)$ pairs. Consequently, all key-value pairs are treated equally thus the model does not distinguish between the main triple and relation-specific qualifiers.

HINGE (Rosso et al., 2020) also adopts a convolutional framework for modeling hyper-relational facts. A main triple is iteratively convolved with every qualifier pair as a *quintuple* followed by min pooling over quintuple representations. Although it retains the hyper-relational nature of facts, HINGE operates on a triple-quintuple level that lacks granularity of representing a certain relation instance with its qualifiers. Additionally, HINGE has to be trained sequentially in a *curriculum learning* (Bengio et al., 2009) fashion requiring sorting all facts in a KG in an ascending order of the amount of qualifiers per fact which might be prohibitively expensive for large-scale graphs.

Instead, our approach directly augments a relation representation with any number of attached qualifiers properly separating auxiliary entities and relations from those in the main triple. Additionally, we do not force any restrictions on input order of facts nor on the amount of qualifiers per fact.

Parallel to our approach are the methods that work over hypergraphs, e.g., DHNE (Tu et al., 2018), Hyper-SAGNN (Zhang et al., 2020), and knowledge hypergraphs like HypE (Fatemi et al., 2020). We deem hyper-relational graphs and hypergraphs are conceptually different. As hyperedges contain multiple nodes, such hyperedges are

---

[1] The title is inspired by the RDF* (Hartig, 2017) ”RDF star” proposal for standardizing hyper-relational KGs

closer to *n-ary* relations $r(e_1, \ldots, e_n)$ with one abstract relation. The attribution of entities to the main triple or qualifiers is lost, and qualifying relations are not defined. Combining a certain set of main and qualifying relations into one abstract $r_k()$ would lead to a combinatorial explosion of typed hyperedges since, in principle, any relation could be used in a qualifier, and there the amount of qualifiers per fact is not limited. Therefore, modeling qualifiers in hypergraphs becomes non-trivial, and we leave such a study for future work.

3 Preliminaries

GNNs on Undirected Graphs: Consider an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ represents the set of nodes and $\mathcal{E}$ denotes the set of edges. Each node $v \in \mathcal{V}$ has an associated vector $\mathbf{h}_v$ and neighbourhood $\mathcal{N}(v)$. In the message passing framework (Gilmer et al., 2017), the node representations are learned iteratively via aggregating representations (messages) from their neighbors:

$$\mathbf{h}_v^{k+1} = \text{UPD}\left(\mathbf{h}_v^k, \underset{u \in \mathcal{N}(v)}{\text{AGGR}}\, \phi(\mathbf{h}_v^k, \mathbf{h}_u^k, \mathbf{e}_{vu})\right) \quad (1)$$

where AGGR$(\cdot)$ and UPD$(\cdot)$ are differentiable functions for neighbourhood aggregation and node update, respectively; $\mathbf{h}_v^{(k)}$ is the representation of a node v at layer k; $\mathbf{e}_{vu}$ is the representation of an edge between nodes v and u.

Different GNN architectures implement their own aggregation and update strategy. For example, in case of Graph Convolutional Networks (GCNs) (Kipf and Welling, 2017) the representations of neighbours are first transformed via a weight matrix $\mathbf{W}$ and then combined and passed through a non-linearity $f(\cdot)$ such as ReLU. A GCN layer k can be represented as:

$$\mathbf{h}_v^{(k)} = f\left(\sum_{u \in \mathcal{N}(v)} \mathbf{W}^{(k)} \mathbf{h}_u^{(k-1)}\right) \quad (2)$$

GCN and other seminal architectures such as GAT (Velickovic et al., 2018) and GIN (Xu et al., 2019) do not model relation embeddings explicitly and require further modifications to support multi-relational KGs.

GNN on Directed Multi-Relational Graphs: In case of a multi-relational graph $\mathcal{G} = (\mathcal{V}, \mathcal{R}, \mathcal{E})$ where $\mathcal{R}$ represents the set of relations r, and $\mathcal{E}$ denotes set of directed edges (s, r, o) where nodes $s \in \mathcal{V}$ and $o \in \mathcal{V}$ are connected via relation r. The GCN formulation by (Marcheggiani and Titov, 2017) assumes that the information in a directed edge flows in both directions. Thus for each edge (s, r, o), an inverse edge (o, r^{-1}, s) is added to $\mathcal{E}$. Further, self-looping relations (v, r^{self}, v), for each node $v \in \mathcal{V}$ are added to $\mathcal{E}$, enabling an update of a node state based on its previous one, and further improving normalization.

For directed multi-relational graphs, Equation 2 can be extended by introducing relation specific weights $\mathbf{W}_r$ (Marcheggiani and Titov, 2017; Schlichtkrull et al., 2018)

$$\mathbf{h}_v^{(k)} = f\left(\sum_{(u,r) \in \mathcal{N}(v)} \mathbf{W}_r^{(k)} \mathbf{h}_u^{(k-1)}\right) \quad (3)$$

However, such networks are known to be overparameterized. Instead, CompGCN (Vashishth et al., 2020) proposes to learn specific edge type vectors:

$$\mathbf{h}_v^{(k)} = f\left(\sum_{(u,r) \in \mathcal{N}(v)} \mathbf{W}_{\lambda(r)}^{(k)} \phi(\mathbf{h}_u^{(k-1)}, \mathbf{h}_r^{(k-1)})\right) \quad (4)$$

where $\phi(\cdot)$ is a composition function of a node u with its respective relation r, and $\mathbf{W}_{\lambda(r)}$ is a direction-specific shared parameter for incoming, outgoing, and self-looping relations. The composition $\phi : \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}^d$ can be any entity-relation function akin to TransE (Bordes et al., 2013) or DistMult (Yang et al., 2015).

Hyper-Relational Graphs: In case of a hyper-relational graph $\mathcal{G} = (\mathcal{V}, \mathcal{R}, \mathcal{E})$, $\mathcal{E}$ is a list $(e_1, \ldots, e_n)$ of edges with $e_j \in \mathcal{V} \times \mathcal{R} \times \mathcal{V} \times \mathcal{P}(\mathcal{R} \times \mathcal{V})$ for $1 \leq j \leq n$, where $\mathcal{P}$ denotes the power set. A hyper-relational fact $e_j \in \mathcal{E}$ is usually written as a tuple $(s, r, o, \mathcal{Q})$, where $\mathcal{Q}$ is the set of *qualifier pairs* $\{(qr_i, qv_i)\}$ with *qualifier relations* $qr_i \in \mathcal{R}$ and *qualifier values* $qv_i \in \mathcal{V}$. (s, r, o) is referred to as the *main triple* of the fact. We use the notation Q_j to denote the qualifier pairs of e_j. For example, under this representation scheme, one of the edges in Fig. 1.B would be `(Albert Einstein, educated at, University of Zurich, (academic degree, Doctorate), (academic major, Physics))`

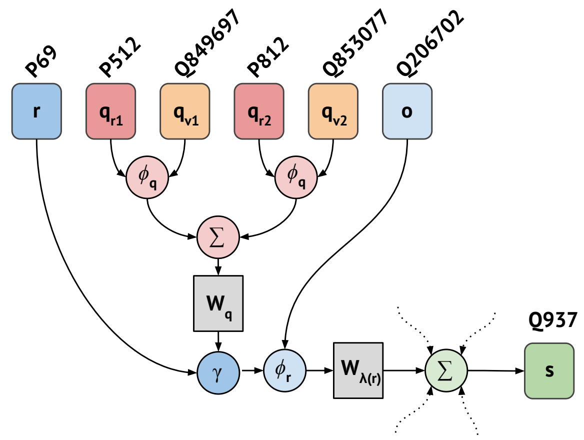

Figure 2: The mechanism in which StarE encodes a hyper-relational fact from Fig. 1.B. Qualifier pairs are passed through a composition function ϕ_q, summed and transformed by $\mathbf{W}_q$. The resulting vector is then merged via γ, and ϕ_r with the relation and object vector, respectively. Finally, node *Q937* aggregates messages from this and other hyper-relational edges.

4 StarE

In this section, we introduce our main contribution – StarE, and show how we use it for link prediction (LP). StarE (cf. Fig. 2 for the intuition) incorporates statement qualifiers $\{(qr_i, qv_i)\}$, along with the main triple (s, r, o) into a message passing process. To do this, we extend Equation 4 by combining the edge-type embedding $\mathbf{h}_r$ with a fixed-length vector $\mathbf{h}_q$ representing qualifiers associated with a particular relation r between nodes u and v. The resultant equation is thus:

$$\mathbf{h}_v = f\left(\sum_{(u,r)\in\mathcal{N}(v)} \mathbf{W}_{\lambda(r)}\phi_r(\mathbf{h}_u, \gamma(\mathbf{h}_r, \mathbf{h}_q)_{vu})\right) \tag{5}$$

where $\gamma(\cdot)$ is a function that combines the main relation representation with the representation of its qualifiers, e.g., concatenation $[\mathbf{h}_r, \mathbf{h}_q]$, element-wise multiplication $\mathbf{h}_r \odot \mathbf{h}_{rq}$, or weighted sum:

$$\gamma(\mathbf{h}_r, \mathbf{h}_q) = \alpha \odot \mathbf{h}_r + (1-\alpha) \odot \mathbf{h}_q \tag{6}$$

where α is a hyperparameter that controls the flow of information from qualifier vector $\mathbf{h}_q$ to $\mathbf{h}_r$.

Finally, the qualifier vector $\mathbf{h}_q$ is obtained through a composition ϕ_q of a qualifier relation $\mathbf{h}_{qr}$ and qualifier entity $\mathbf{h}_{qv}$. The composition function ϕ_q may be any entity-relation function akin to ϕ (Equation 4). The representations of different qualifier pairs are then aggregated via a position-invariant summation function and passed through a parameterized projection $\mathbf{W}_q$:

$$\mathbf{h}_q = \mathbf{W}_q \sum_{(qr,qv)\in Q_{jr_{vu}}} \phi_q(\mathbf{h}_{qr}, \mathbf{h}_{qv}) \tag{7}$$

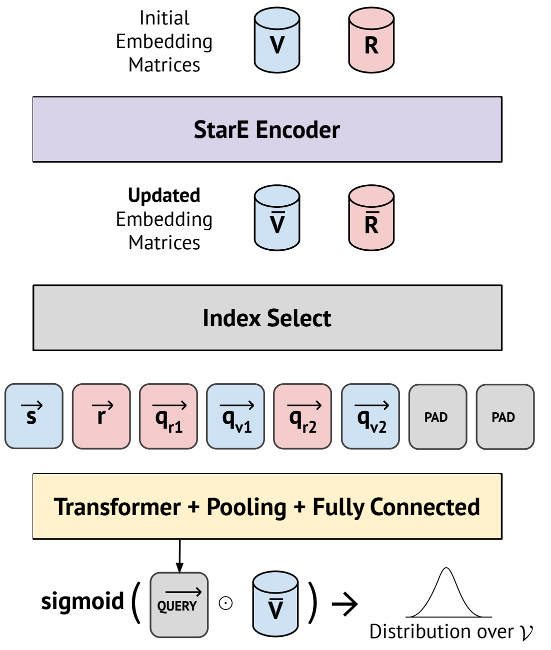

Figure 3: Architecture of a StarE based link prediction model. StarE updates the $\bar{\mathbf{V}}, \bar{\mathbf{R}}$ matrices, which are then used to encode the relations in a given query before passing them through the Transformer, Pooling and fully connected layers. The fixed-dimensional output is then compared to $\bar{\mathbf{V}}$, the result of which is passed through a sigmoid function to yield a probability distribution over entities.

This formalisation allows to (i) incorporate an arbitrary number of qualifier pairs and (ii) can take into account whether entities/relations occur in the main triple or the qualifier pairs. StarE is the first GNN model for representation learning of hyper-relational KGs that has these characteristics.

StarE for Link Prediction. StarE is a general representation learning framework for capturing the structure of hyper-relational graphs, and thus can be applied to multiple downstream tasks. In this work, we focus on LP and leave other tasks such as node classification for future work. In LP, given a query $(s, r, \mathcal{Q})$, the task is to predict an entity corresponding to the object position o.

Our link prediction model (see Fig. 3) is composed of two parts namely (i) a StarE based

Table 1: Datasets - E in quals (R in quals) denote the amount of entities (relations) appearing only in qualifiers.

Dataset	Statements	w/ Quals (%)	Entities	Relations	E in quals	R in quals	Train	Valid	Test
WD50K	236,507	32,167 (13.6%)	47,156	532	5460	45	166,435	23,913	46,159
WD50K (33)	102,107	31,866 (31.2%)	38,124	475	6463	47	73,406	10,568	18,133
WD50K (66)	49,167	31,696 (64.5%)	27,347	494	7167	53	35,968	5,154	8,045
WD50K (100)	31,314	31,314 (100%)	18,792	279	7862	75	22,738	3,279	5,297

JF17K	100,947	46,320 (45.9%)	28,645	322	3652	180	76,379	-	24,568

encoder, and (b) a Transformer (Vaswani et al., 2017) based decoder similar to CoKE (Wang et al., 2019a), which are jointly trained. We initialize two embedding matrices $\mathbf{R}, \mathbf{V}$ corresponding to relations ($\mathcal{R}$), and entities ($\mathcal{V}$) present in the dataset[2]. In every iteration, StarE updates the embeddings ($\bar{\mathbf{R}}$, $\bar{\mathbf{V}}$) by message passing across every edge in the training set. In the decoding step, we first linearize the given query, and use the updated embeddings ($\bar{\mathbf{R}}$, $\bar{\mathbf{V}}$) to encode the entities and relations within it. Then, this linearized sequence is passed through the Transformer block, whose output is averaged to get a fixed-dimensional vector representation of the query. The vector is then passed through a fully-connected layer, multiplied with $\bar{\mathbf{V}}$ and then passed through a sigmoid, to obtain a probability distribution over all entities. Thereafter, it is trivial to retrieve the top n candidate entities for the o position in the query.

Note that we can use different decoders in this architecture. An explanation and evaluation of few decoders is provided in Appendix D.

5 WD50K Dataset

Recent approaches (Guan et al., 2019; Liu et al., 2020; Rosso et al., 2020) for embedding hyper-relational KGs often use WikiPeople and JF17K as benchmarking datasets. We advocate that those datasets can not fully capture the task complexity.

In WikiPeople, about 13% of statements contain at least one literal. Literals (e.g. numeric values, date-time instances or other strings, etc) in KGs are conventionally ignored (Rosso et al., 2020) by embedding approaches, or are incorporated through specific means (Kristiadi et al., 2019). However, after removing statements with literals, less than 3% of the remaining statements contain any qualifier pairs. Out of those, about 80% possess only one qualifier. This fact renders WikiPeople less sensitive to hyper-relational models as performance on triple-only facts dominates the overall score.

The authors of JF17K reported[3] the dataset to contain redundant entries. In our own analysis, we detected that about 44.5% of the test statements share the same main (s, r, o) triple as the train statements. We consider this fact as a major data leakage which allows triple-based models to memorize subjects and objects appearing in the test set.

To alleviate the above problems, we propose a new dataset, WD50K, extracted from Wikidata statements. The following steps are used to sample our dataset from the Wikidata RDF dump of August 2019 [4]. We begin with a set of seed nodes corresponding to entities from FB15K-237 having a direct mapping in Wikidata (`P646` "Freebase ID"). Then, for each seed node, all statements whose *main* object and *qualifier* values correspond to `wikibase:Item` are extracted. This step results in the removal of all literals in object position. Similarly, all literals are filtered out from the qualifiers of the obtained statements. To increase the connectivity in the statements graph, all the entities mentioned less than twice are dropped.

All the statements of WD50K are randomly split into the train, test, and validation sets. To eliminate test set leakages we remove all statements from train and validation sets that share the same main triple *(s,p,o)* with test statements. Finally, we remove statements from the test set that contain entities and relations not present in the train or validation sets. WD50K contains 236,507 statements describing 47,156 entities with 532 relations where about 14% of statements have at least one qualifier pair. See Table 3, and Appendix A for further details. The dataset is publicly available[5].

---

[2] As mentioned in Section 3, while pre-processing, we add inverse and self-loop relations to the graph. Note, we retain the same set of qualifiers as in the original fact while generating inverse hyper-relational facts.

6 Experiments

In this section, we discuss the setup and results of multiple experiments conducted towards (i) assessing the performance of our proposed approach on the link prediction task, and (ii) analyzing the effects of including hyper-relational information during link prediction.

6.1 Evaluating StarE on the LP Task

In this experiment, we evaluate our proposed approach on the task of LP over hyper-relational graphs. We designed it to both compare StarE with the state of the art algorithms, and to better understand the contribution of the StarE encoder.

Datasets: We use WikiPeople[6] and JF17K[7], despite their design flaws (see Sec. 5) to illustrate the performance differences with existing approaches. We also provide a benchmark of our approach on the WD50K dataset introduced in this article. Note that as described by (Rosso et al., 2020), we drop all statements containing literals in WikiPeople. Further datasets statistics are presented in Table 1.

Baselines: In this experiment, we compare against previous hyper-relational approaches namely: (i) m-TransH (Wen et al., 2016), ii) RAE (Zhang et al., 2018), (iii) NaLP-Fix (an improved version of NaLP (Guan et al., 2019) as proposed in (Rosso et al., 2020)), and (iv) HINGE (Rosso et al., 2020).

To assess the significance of the StarE encoder, we also train a simpler model where the Transformer based decoder directly uses the randomly initialized embedding matrices without the StarE encoder. We call this model **Transformer (H)**, and the one with the StarE encoder **StarE (H) + Transformer (H)**. Here (H) represents that the input to the model is a hyper-relational fact. Later, we also experiment with triples as input and represent them with (T) (see Sec. 6.4).

Evaluation: For all the systems discussed above, we report various performance metrics when predicting the subject and object of hyper-relational facts. We adopt the *filtered* setting introduced in (Bordes et al., 2013) for computing mean reciprocal rank (MRR) and hits at 1, 5, and 10 (H@1, H@5, H@10). The metrics are computed for subject and object prediction separately and are then averaged.

Training: We train the model in 1-N setting using binary cross entropy loss with label smoothing as in (Dettmers et al., 2018; Vashishth et al., 2020) with Adam (Kingma and Ba, 2015) optimizer for 500 epochs on WikiPeople and for 400 epochs on JF17K and WD50K datasets. Hyperparameters were selected by manual fine tuning with further details in Appendix C. StarE is implementated with PyTorch Geometric (Fey and Lenssen, 2019) and is publicly available here[8].

Results and Discussion: The results of this experiment can be found in Table 2. We observe that the StarE encoder based model outperforms the other hyper-relational models across WikiPeople and JF17K. On JF17K, StarE (H) + Transformer (H) reports a gain of 11.3 (25%) MRR points, 13 (33%) H@1, and 7.8 (12%) H@10 points when

Table 3: Link prediction on WD50K graphs with different ratio of qualifiers. Best results are in **bold**.

Exp #	Dataset →	WD50K			WD50K (33)			WD50K (66)			WD50K (100)		
	Method ↓	MRR	H@1	H@10	MRR	H@1	H@10	MRR	H@1	H@10	MRR	H@1	H@10
4	Baseline (Transformer (T))	0.275	0.207	0.404	0.218	0.158	0.334	0.270	0.197	0.417	0.351	0.261	0.530
4	StarE (T) + Transformer(T)	0.308	0.228	0.465	0.246	0.173	0.388	0.297	0.212	0.470	0.380	0.276	0.584
4	NaLP-Fix	0.177	0.131	0.264	0.204	0.164	0.277	0.334	0.284	0.423	0.458	0.398	0.563
4	HINGE	0.243	0.176	0.377	0.253	0.190	0.372	0.378	0.307	0.512	0.492	0.417	0.636
1,2,4	Baseline (Transformer (H))	0.286	0.222	0.406	0.276	0.227	0.371	0.404	0.352	0.502	0.562	0.499	0.677
1,2,4	StarE (H) + Transformer(H)	**0.349**	**0.271**	**0.496**	**0.331**	**0.268**	**0.451**	**0.481**	**0.420**	**0.594**	**0.654**	**0.588**	**0.777**

compared to the next-best approach. Recall that JF17K suffers from a major test set leakage (Sec. 5), which we investigate in greater detail in Exp. 4 (Sec. 6.4) below. On WikiPeople, HINGE has a higher H@1 score than StarE (H) + Transformer (H). However, its H@10 is lower than H@5 of our approach, i.e., top five predictions of the StarE model are more likely to contain a correct answer than top 10 predictions of HINGE. We can thus claim our StarE based model to be competitive with, if not outperforming the state of the art on the task of link prediction over hyper-relational KGs, albeit on less-than-ideal baselines.

We further present the performance of our approach as a baseline on the WD50K dataset in Table 3. With an MRR score of 0.349, H@1 of 0.271, and H@10 of 0.496, we find that the task is far from solved, however, the StarE-based approaches provide effective, non-trivial baselines.

Note that Transformer (H) (without StarE) also performs competitively to HINGE. This suggests that the aforementioned gains in metrics of our approach cannot all be attributed to StarE's innate ability to effectively encode the hyper-relational information. That said, upon comparing the performance of StarE (H) + Transformer (H) and Transformer (H), we find that using StarE is consistently advantageous across all the datasets.

6.2 Impact of Ratio of Statements with and Without Qualifier Pairs

Based on the relatively high performance of Transformer (H) (without the encoder) in the previous experiment, we study the relationship between the amount of hyper-relational information (qualifiers), and the ability of StarE to incorporate it for the LP task. Here, we sample datasets from WD50K, with varying ratio of facts with qualifier pairs to the total number of facts in the KG. Specifically, we sample three datasets namely, *WD50K (33)*, *WD50K (66)*, and *WD50k (100)* containing approximately 33%, 66%, and 100% of such hyper-relational facts, respectively. We use the same experimental setup as the one discussed in the previous section. Table 3 presents the result of this experiment.

We observe that across all metrics, StarE (H) + Transformer (H) performs increasingly better than Transformer (H), as the ratio of qualifier pairs increases in the dataset. Concretely, the difference in their H@1 scores is 4.1, 6.8, and 8.9 points on *WD50K (33)*, *WD50K (66)*, and *WD50K (100)* respectively. These and the Sec. 6.1 results confirm that StarE is better suited to utilize the qualifier information available in the KG, (ii) which when leveraged by a transformer decoder, outperforms other hyper-relational LP approaches, and (iii) that StarE's positive effects increases as the amount of qualifiers in the task increases.

6.3 Impact of Number of Qualifiers per Statement

In WD50K, as in Wikidata, the number of qualifiers corresponding to a statement varies significantly (see Appendix A). In this experiment, we intend to quantify its effect on the model performance.

To do so, we create multiple variants of WD50K, each containing statements with up to n qualifiers($n \in [1, 6]$). In other words, for a given number n, we collect all the statements which have less than n qualifiers. If a statement contains more than n qualifiers, we arbitrarily choose n qualifiers amongst them. Thus, the total number of facts remains the same across these variants. Figure 4 presents the result of this experiment.

For all the datasets, we find that two qualifier pairs are enough for our model performance to saturate. This might be an attribute of the underlying characteristic of the dataset or the model's inability to aggregate information from longer statements. We leave the further analysis of this for the future work. However, we observe that in case of WD50K and other datasets, StarE (H) + Transformer (H)

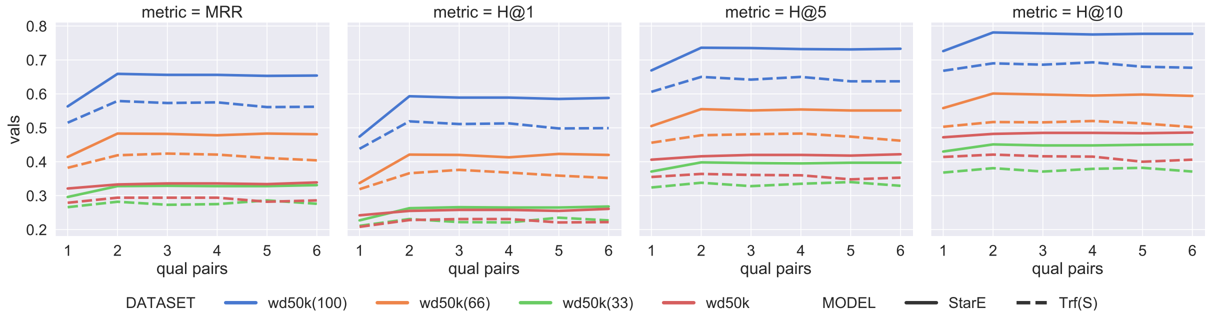

Figure 4: Statement length experiment. STARE (H) + Transformer (H) saturates after two qualifiers with slightly increase, whereas Transformer (H) is unstable in handling qualifiers.

slightly improves or remains stable with increase of statement length, while Transformer (H) shows degradation in performance.

6.4 Comparison to Triple Baselines

To further understand the role of qualifier information in the LP task, we design an experiment to gauge the performance difference between models on hyper-relational KG and triple-based KG. Concretely, we create a new triple-only dataset by pruning all qualifier information from the statements in WikiPeople, JF17K, and WD50K. That is, two statements that describe the same main fact $(s, r, o, \{(qr_1, qv_1), (qr_2, qv_2)\}$ and $(s, r, o, \{(qr_3, qv_3), (qr_4, qv_4)\})$ are reduced to one triple (s, r, o). Thus, the overall amount of distinct entities and relations is reduced, but the amount of subjects and objects in *main triples* for the LP task is the same.

We introduce **STARE (T) + Transformer (T)**, a model for this experiment. STARE (T) is similar to CompGCN (Vashishth et al., 2020), and can only model triple-based (s, r, o) facts. Since inputs to the Transformer decoder are linearized queries, we can trivially implement Transformer (T) by ignoring qualifier pairs during this linearization. The results are available in Table 2, and Table 3.

We observe that triple-only baselines yield competitive results on JF17K and WikiPeople compared to hyper-relational models (See Table 2). As WikiPeople contains less than 3% of hyper-relational facts, the biggest contribution to the overall performance is dominated by the triple-only performance. We attribute the strong performance of the triple-only baseline on JF17K to the identified data leakage pertaining to this dataset. In other words, JF17K in its hyper-relational form exhibits similar issues identified by (Akrami et al., 2020) as in FB15k and WN18 datasets proposed in (Bordes et al., 2013) for triple-based LP task. We thus perform another experiment after cleaning JF17K from the assumed data leakage and report the results in Table 4 below.

Table 4: StarE (H) + Transformer (H) denoted as (H) and Transformer (T) as (T) on the original JF17K and cleaned JF17K

	JF17K (original)		**JF17K (cleaned)**	
	H	T	H	T
MRR	0.574	0.534	0.376	0.334
H@1	0.496	0.471	0.278	0.242
H@5	0.658	0.602	0.485	0.428
H@10	0.725	0.661	0.582	0.514

We observe a drastic performance drop of about 20 MRR points in both models which provide experimental evidence of the flaws discussed in Sec. 5. We encourage future works in this domain to refrain from using these datasets in experiments.

In the case of WD50K (where about 13% of facts have qualifiers) the STARE (H) + Transformer (H) yields about 16%, 23%, and 11% of relative improvement over the best performing triple-only baseline across MRR, H@1 and H@10, respectively (see Table 3). Akin to the previous experiment, we observe that increasing the ratio of hyper-relational facts in the dataset leads to even higher performance boosts. In particular, on *WD50K (100)*, the H@1 of our hyper-relational model is higher than the H@10 of the triple baseline. This difference corresponds to 30 MRR and 32 H@1 points which is about 85% and 123% relative improvement, respectively.

Based on the above observations we therefore conclude, that information in hyper-relational facts indeed helps to better predict subjects and objects in the main triples of those facts.

7 Conclusion

We presented StarE, an instance of the message passing framework for representation learning over hyper-relational KGs. Experimental results suggest that StarE performs competitively on link prediction tasks over existing hyper-relational approaches and greatly outperforms triple-only baselines. In the future, we aim at applying StarE for node and graph classification tasks as well as extend our approach to large-scale KGs.

We also identified significant flaws in existing link prediction datasets and proposed WD50K, a novel, Wikidata-based hyper-relational dataset that is closer to real-world graphs and better captures the complexity of the link prediction task. In the future, we plan to enrich WD50K entities with class labels and probe it against node classification tasks.

A Further details on WD50K

In contrast with Freebase which is no longer supported nor updated, we choose Wikidata as the source KG for our dataset since it has an active community and has seen contributions from various companies that merge their knowledge with it. Additionally, many new NLP tasks (Xiong et al., 2020; Hayashi et al., 2019; Chakraborty et al., 2019), as well as datasets (Wang et al., 2019b; Mesquita et al., 2019; Dubey et al., 2019), are using Wikidata as a reference KG.

The combined statistics of our dataset are presented in Table 1. WD50k consists of 47,156 entities, and 532 relations, amongst which 5,460 entities and 45 relations are found only within qualifier (q_p, q_e) pairs. Fig. 5 illustrates how qualifiers are distributed among statements, i.e., 236,393 statements (99.9%) contain up to five qualifiers whereas remaining 114 statements in a long tail contain up to 20 qualifiers. Fig. 6 illustrates the in-degree distribution (with 50 bins, values higher than 1000 are omitted) of the WD50K graph structure where most of the nodes have in-degrees up to 200.

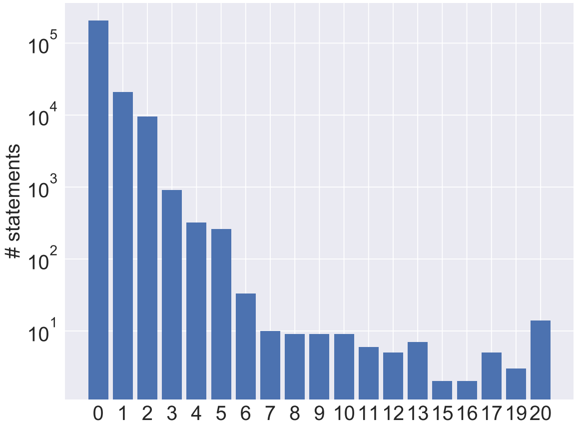

Figure 5: Number of qualifiers per statement

Recall that we augmented our dataset to reduce test set leakage by removing all instances from the train, and validation sets whose main triple (s, p, o) can be found in the test instances (Sec. 5). Another form of test leakage, as discovered in (Toutanova and Chen, 2015), may still persist in our dataset. To estimate this, we count the instances in the test set whose main triple's "direct" inverse (o, p, s), or "semantic" inverse (based on the relation P1696 in Wikidata, i.e., inverse of) is present in the train set. This amounts to less than 4% (1.6k out of 46k) instances in the test set.

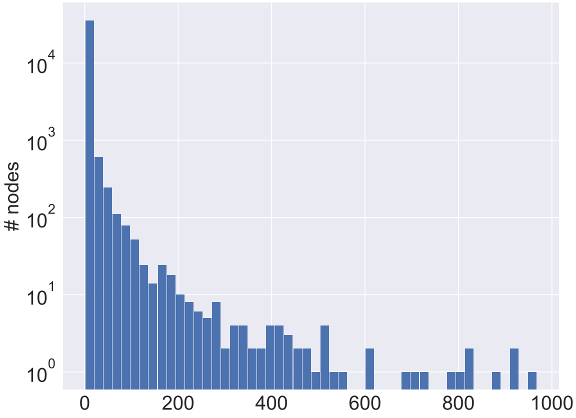

Figure 6: In-degree distribution

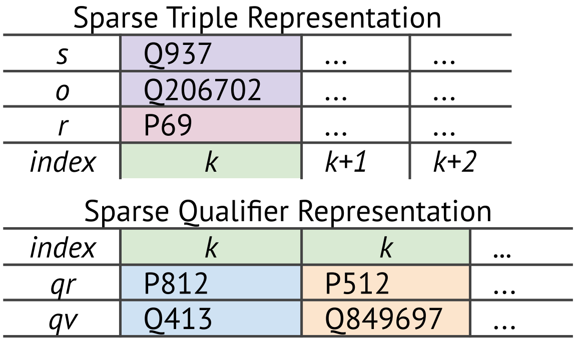
B Sparse Representation



Sparse Triple Representation

s	Q937	...	...
o	Q206702	...	...
r	P69	...	...
index	*k*	*k+1*	*k+2*

Sparse Qualifier Representation

index	*k*	*k*	...
qr	P812	P512	...
qv	Q413	Q849697	...

Figure 7: Sparse representation for hyper-relational facts. Each fact has a unique integer index k which is shared between two COO matrices, i.e., the first one is for main triples, the second one is for qualifiers. Qualifiers that belong to the same fact share the index k.

Storing full adjacency matrices of large KGs is impractical due to $O(|\mathcal{V}|^2)$ memory consumption. GNNs encourage using sparse matrix representations and adopting sparse matrices is shown (Cohen et al., 2020) to be scalable to graphs with millions of edges. As illustrated in Figure 7, we employ two sparse COO matrices to model hyper-relational KGs. The first COO matrix is of a standard format with rows containing indices of subjects, objects, and relations associated with the *main triple* of a hyper-relational fact.

In addition, we store index k that uniquely identifies each fact. The second COO matrix contains rows of qualifier relations qr and entities qe that are connected to their main triple (and the overall hyper-relational fact) through the index k, i.e., if a fact has several qualifiers those columns corresponding to the qualifiers of the fact will share the same index k. The overall memory consumption is therefore $O(|\mathcal{E}| + |\mathcal{Q}|)$ and scales linearly to the total number of qualifiers $|\mathcal{Q}|$. Given that most open-domain KGs rarely qualify each fact, e.g., as of August 2019, out of 734M Wikidata statements approximately 128M (17.4%) have at least one qualifier, this sparse qualifier representation saves limited GPU memory.

C Hyperparameters

We tuned the model (STARE encoder with Transformer decoder) on the validation set using the hyperparameters reported in Table 5. Implementations of mult, ccorr, and rotate functions in ϕ_q and ϕ_r correspond to DistMult (Yang et al., 2015), circular correlation (Nickel et al., 2016), and RotatE (Sun et al., 2019), respectively.

Table 5: This table reports the major hyperparameters of our approach, and their corresponding bounds. Note that ”Trf” refers to Transformers. Selected values are in **bold**.

Parameter	Value
STARE layers	{1, **2**}
Embedding dim	{100, **200**}
Batch size	{**128**, 256, 512}
Learning rate	{**0.0001**, 0.0005, 0.001}
ϕ_q	mult, ccorr, **rotate**
ϕ_r	mult, ccorr, **rotate**
γ	**weighted sum** concat, mul
Weighted sum α	$[0.0, 1.0]$ step 0.1
Quals aggregation	**sum**, mean
Trf layers	{1, **2**}
Trf hidden dim	{256, **512**, 768}
Trf heads	{2, **4**}
StarE dropout	{0.1, 0.2, **0.3**}
Trf dropout	{**0.1**, 0.2, 0.3}
Label smoothing	{0.0, **0.1**}

The selected hyperparameters include two STARE layers, embedding dimension of 200, batch size of 128, Adam optimizer with 0.0001 learning rate and 0.1 label smoothing. ϕ_r and ϕ_q are rotate functions, $\gamma(\cdot)$ is a weighted sum function with α of 0.8, qualifiers are aggregated using a simple summation, and 0.3 dropout rate. We use 2-layer Transformer block with the hidden dimension of 512, and 4 attention heads with 0.1 dropout rate as our decoder. For WD50K and JF17K datasets we set the maximum length of a hyper-relational fact to 15 (i.e., a statement can contain at most 6 qualifier pairs), and 7 for WikiPeople.

Infrastructure and Parameters. We train all models on one Tesla V100 GPU. Due to a large number of parameters, owing to large trainable embedding matrices, it is advisable to a GPU with at least 12GB of VRAM. Running STARE (H) + Transformer (H) models with the selected hyperparams on WD50K requires approximately 2 days to train and has 10.8M parameters[9]; on JF17k the model has 7.1M parameters and takes about 10 hours to train; on WikiPeople the model has 8.2M parameters which we run for 500 epochs and takes about 4 days.

StarE (H) + Transformer (H) models on reduced datasets: the model corresponding to WD50K (33) has 9M parameters and takes 20 hours to train while WD50K model has 6.8M parameters and takes about 9 hours to train. In case of WD50K (100), the model has 5M parameters and takes 5 hours to train.

D Decoders

As an additional experiment, we pair STARE with different decoders and evaluate them over WD50K datasets. Along with the main reported model denoted as **StarE + Trf**, we implemented two CNN-based decoders and another Transformer-based decoder. All models are trained with the same encoder hyperparameters as chosen in the main reported model.

StarE + ConvE relies on the ConvE (Dettmers et al., 2018)-like decoder but expanded for statements with qualifiers. Given a query *(s, r,* $\{(qr_i, qv_i), \ldots\}$*)*, we stack entities and relations embeddings row-wise and reshape the tensor into an *image* of size $H \times W$. For instance, for a statement with 6 qualifier pairs, i.e., query length of 14, and an embedding size of 200, we obtain *images* of size 40×70. We then apply a 2D convolutional layer with a 7×7 kernel for each image, apply ReLU, flatten the resulting tensor, and pass it through a fully-connected layer. We used 200 filters and the learning rate was set to 0.001.

StarE + ConvKB is based on the ConvKB (Nguyen et al., 2018)-like decoder adjusted for statements with qualifiers. Given a query *(s, r,* $\{(qr_i, qv_i), \ldots\}$*)*, we stack entities and relations embeddings row-wise and apply a 2D convolutional layer with a $L_Q \times 7$ kernel, e.g., for queries of length 14 the kernel size is 14×7. We then apply ReLU, flatten the resulting tensor, and

---

[9] According to a built-in PyTorch counter.

Table 6: Effect of different decoders on the link prediction task over WD50K, and its variations.

Dataset →	**WD50K**			**WD50K (33)**			**WD50K (66)**			**WD50K (100)**		
Method ↓	MRR	H@1	H@10	MRR	H@1	H@10	MRR	H@1	H@10	MRR	H@1	H@10
StarE + Trf	**0.349**	**0.271**	**0.496**	**0.331**	**0.268**	0.451	**0.481**	**0.420**	0.594	**0.654**	**0.588**	**0.777**
StarE + ConvE	0.341	0.260	**0.496**	0.323	0.254	**0.456**	0.460	0.392	0.590	0.627	0.550	0.772
StarE + ConvKB	0.323	0.241	0.479	0.316	0.247	0.448	0.448	0.377	0.584	0.621	0.544	0.763
StarE + MskTrf	0.341	0.262	0.489	0.324	0.260	0.446	0.479	0.417	**0.595**	0.649	0.579	0.774

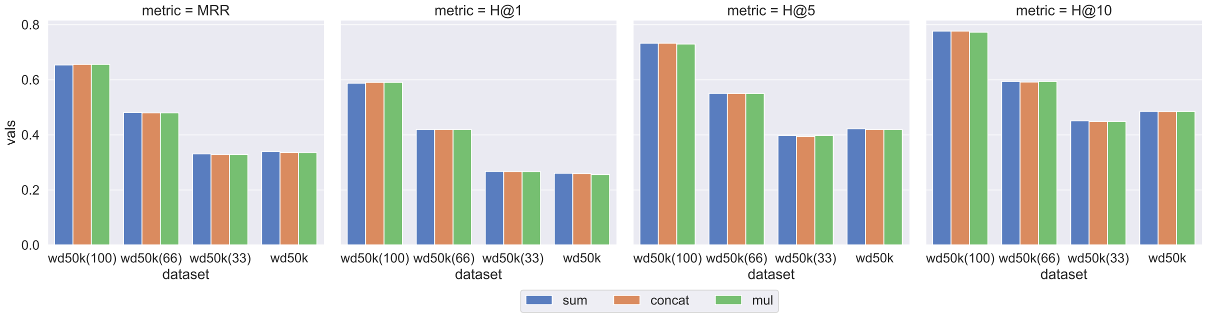


Figure 8: Gamma experiment.

pass it through a fully-connected layer. We used 200 filtersand the learning rate was set to 0.001.

StarE + MskTrf denotes a Transformer decoder with an explicit `[MASK]` token at the object position of each query. Given a query *(s, r,* $\{(qr_i, qv_i), \ldots\}$*)*, we extract relevant entities and relation embeddings and insert the `[MASK]` token, transforming it into *(s, r,* `[MASK]`*,* $\{(qr_i, qv_i), \ldots\}$*)*. We then pass it through the Transformer layers and retrieve the representation of the `[MASK]` token. Finally, the token representation is passed through a fully-connected layer. We trained the model with 0.0001 as the learning rate.

Table 6 reports link prediction results on a variety of WD50K datasets with with different decoders. The default **StarE + Trf** decoder generally attains superior results with biggest gains along H@1 metric.

E Relation-Qualifiers Aggregation

In this experiment, we measure the impact of the choice of $\gamma(\cdot)$ function which is used for aggregating representations of a relation and its qualifiers (see Eq. 5). To evaluate its impact we use StarE (H) + Transformer (H) models, on four WD50K datasets using three functions, i.e., concatenation $[\mathbf{h}_r, \mathbf{h}_q]$, element-wise multiplication $\mathbf{h}_r \odot \mathbf{h}_q$, and weighted sum $\alpha \odot \mathbf{h}_r + (1-\alpha) \odot \mathbf{h}_q$ where α is fixed to 0.8.

The results are presented in Fig.8. We find that all the three settings have similar performance indicating model's stability with respect to the choice of $\gamma(\cdot)$ function.

Relation-aware Graph Attention Networks with Relational Position Encodings for Emotion Recognition in Conversations

Taichi Ishiwatari **Yuki Yasuda** **Taro Miyazaki** **Jun Goto**
NHK Science and Technology Research Laboratories
{ishiwatari.t-fa, yasuda.y-hk, miyazaki.t-jw, goto.j-fw}@nhk.or.jp

Abstract

Interest in emotion recognition in conversations (ERC) has been increasing in various fields, because it can be used to analyze user behaviors and detect fake news. Many recent ERC methods use graph-based neural networks to take the relationships between the utterances of the speakers into account. In particular, the state-of-the-art method considers self- and inter-speaker dependencies in conversations by using relational graph attention networks (RGAT). However, graph-based neural networks do not take sequential information into account. In this paper, we propose *relational position encodings* that provide RGAT with sequential information reflecting the relational graph structure. Accordingly, our RGAT model can capture both the speaker dependency and the sequential information. Experiments on four ERC datasets show that our model is beneficial to recognizing emotions expressed in conversations. In addition, our approach empirically outperforms the state-of-the-art on all of the benchmark datasets.

♯	Speaker	Utterance	Emotion
1	A	I'm just so tired all the time.	Sad
2	B	Well have you been trying to get a job, look for a job or...?	Neutral
3	A	I've been looking for like eight months.	Frustrated
4	B	I know., It- It's really tough out there., It's really hard to find a job.	Frustrated
5	A	I'm tired of the same excuses., No, no you're not qualified enough, wish you had more education.	Frustrated
6	B	Well what are you looking for?, I mean–	Neutral
7	B	Well, okay. Well that's–	Neutral
8	A	Cause I went to Harvard.	Anger

Table 1: Example for contextual emotion analysis on the IEMOCAP dataset (Busso et al., 2008), which contains emotion-labeled utterances in multi-party conversations.

1 Introduction

Interest in emotion recognition in conversations (ERC) has been increasing in various fields (Picard, 2010), because it can be used to analyze user behaviors (Lee and Hong, 2016) and detect fake news (Guo et al., 2019). With the recent proliferation of social media platforms such as Facebook, Twitter, and YouTube, as well as conversational assistants such as Amazon Alexa, there is a need to study how emotions are expressed in natural conversation.

Recent research on ERC processes the utterances of dialogues in sequence by using recurrent neural network (RNN)-based methods (Hochreiter and Schmidhuber, 1997; Chung et al., 2014; Liu et al., 2016). However, these methods are not able to process long series of information (Bradbury et al., 2016). DialogueRNN tries to make up for this problem by using an attention mechanism to focus on the relevant utterances in the entire conversation (Majumder et al., 2019). However, these methods do not take self-dependency or inter-speaker dependency into account. Table 1 shows the importance of these dependencies, as illustrated by an example dialogue depicting an argument about a job search. Because speaker A has not been able to find a job for a long time, his emotional state is consistently negative. In this way, self-dependency is critical to understanding his own emotional transitions in the conversation. On the other hand, B's emotions shift at utterance ♯4 to commiserate on A's situation. This inter-speaker dependency captures how the utterances of other speakers affect emotions.

The state-of-the-art method, DialogueGCN (Ghosal et al., 2019), uses relational graph attention networks (RGAT) to take the dependency

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7360–7370,
November 16–20, 2020.

into account; it is inspired by relational graph convolutional networks (RGCN) (Schlichtkrull et al., 2018) and graph attention networks (GAT) (Veličković et al., 2017). This method takes into account the conversational context by using a directed graph, where the nodes denote individual utterances, the edges represent relationships between pairs of nodes (utterances), and the labels of the edges represent the types of relationships. However, graph-based neural networks do not take sequential information contained in utterances into account. Table 1 also represents the importance of the sequential information. B's emotional change at utterance ♯4 is caused by utterance ♯3 rather than ♯2 or ♯1. In this way, human emotions may depend on more immediate utterances in the temporal order, and thus it is essential to take the sequence of utterances into account.

A common response to this issue is to encode information about absolute position features (Vaswani et al., 2017) or relative position features (Shaw et al., 2018), where these encodings are added to nodes (utterances) or edges (relationships). However, in order to account for self- and inter-speaker dependency, our model focuses on relation types rather than nodes (utterances) and edges (relationships); thus, our position encoding also focuses on relation types.

In this paper, we propose novel position encodings (*relational position encodings*) that provide the RGAT model with sequential information reflecting relation types. By using the relational position encodings, our RGAT model can capture both the speaker dependency and the sequential information. Experiments on four ERC benchmark datasets showed that our relational position encoding outperformed baselines and state-of-the-art methods. In addition, our method outperformed both the absolute and relative position encodings.

In summary, our contributions are as follows: (1) For the first time, we apply position encodings to RGAT to account for sequential information. (2) We propose relational position encodings for the relational graph structure to reflect both sequential information contained in utterances and speaker dependency in conversations. (3) We conduct extensive experiments demonstrating that the graphical model with relational position encodings is beneficial and that our method outperforms state-of-the-art methods on four ERC datasets. (4) We also empirically demonstrate that our model is an effective representation of other positional variations with absolute or relative position encodings.

2 Related Work

Emotion Recognition in Conversation Several studies have tackled the ERC task. Hazarika et al. (2018a,b) used memory networks for recognizing humans emotion in conversation, where two distinct memory networks consider the inter-speaker interaction. DialogueRNN (Majumder et al., 2019) employs an attention mechanism for grasping the relevant utterance from the entire conversation. More related to our method is the DialogueGCN model proposed by Ghosal et al. (2019), in which RGAT is used for modeling both self-dependency and inter-speaker dependency. This model has achieved state-of-the-art performance on several conversational datasets. On the other hand, as a way of considering contextual information, Luo and Wang (2019) proposed to propagate each of the utterances into an embedded vector. Likewise, a pre-trained BERT model (Devlin et al., 2018) has been used for generating dialogue features to combine several utterances by inserting separate tokens (Yang et al., 2019).

Graph Neural Network Graph-based neural networks are used in various tasks. The fundamental model is the graph convolutional network (GCN) (Kipf and Welling, 2016), which uses a fixed adjacency matrix as the edge weight. Our method is based on RGCN (Schlichtkrull et al., 2018) and GAT (Veličković et al., 2017). The RGCN model prepares a different structure for each relation type and hence considers self-dependency and inter-speaker dependency separately. The GAT model uses an attention mechanism to attend to the neighborhood's representations of the utterances.

Position Encodings In our work, positional information is added to the graphical structure. Several studies add position encodings to several structures, such as self-attention networks (SANs) and GCN. SANs (Vaswani et al., 2017) perform the attention operation under the position-unaware assumption, in which the positions of the input are ignored. In response to this issue, the absolute position (Vaswani et al., 2017) or relative position (Shaw et al., 2018), or structure position (Wang et al., 2019) are used to capture the sequential order of the input. Similarly, graph-based neural net-

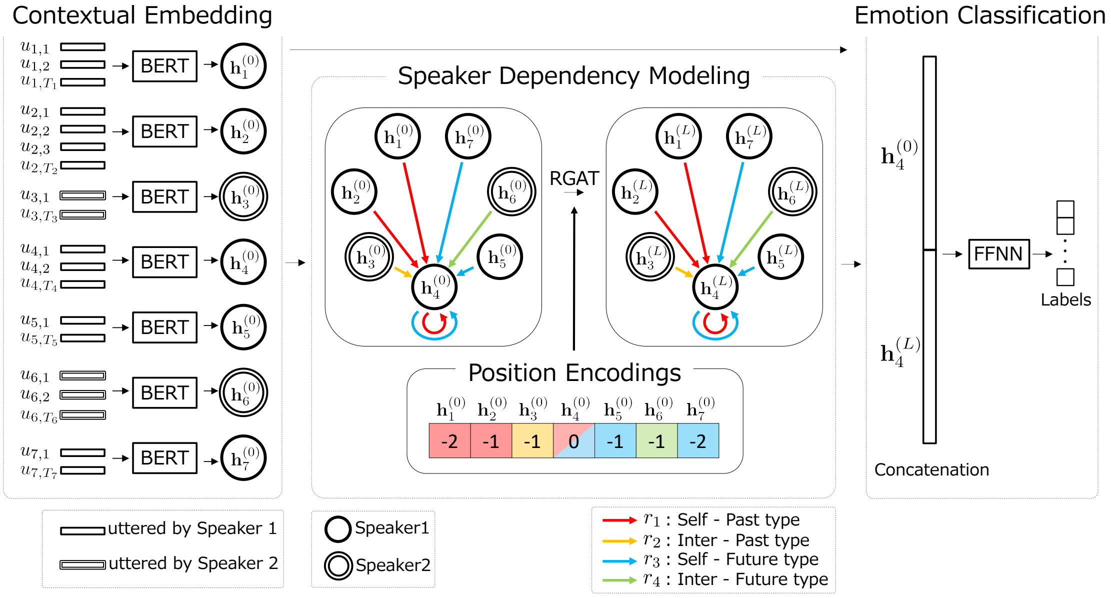

Figure 1: Our entire framework. First, we obtain a contextual embedding for each utterance by using BERT. Then, we modify this embedding by using RGAT to consider speaker dependency. The position encodings in the RGAT structure take sequential information into account. Finally, after concatenating the contextual embedding to the output embedding through RGAT, we classify the concatenated vector into emotion labels by using a fully connected feed-forward network.

works do not take sequential information. In the design of proteins, the relative spatial structure between proteins is modeled in order to account for the complex dependencies in the protein sequence and is applied to the edges of the graph representations (Ingraham et al., 2019).

3 Method

First, we define the problem of the ERC task. The task is to recognize emotion labels (*Happy*, *Sad*, *Neutral*, *Angry*, *Excited*, and *Frustrated*) of utterances $u_1, u_2, \cdots, u_N$, where N denotes the number of utterances in a conversation. Let s_m for $m = 1, \cdots, M$ be a collection of speakers in a given conversational dataset, where M denotes the number of speakers. The utterance u_i is uttered by speaker s_m, where m is the correspondence between the utterance and its speaker.

Our framework consists of three components - contextual utterance embedding, speaker dependency modeling with position encodings and emotion classification. The entire model architecture is shown in Figure 1. Although our method is based on the DialogueGCN (Ghosal et al., 2019) model, it considers the positional information contained in utterances in a sequential conversation as described in Section 3.2.3, whereas the DialogueGCN model does not.

3.1 Contextual Utterance Embedding

We generate contextual utterance features from the tokens by following the method in (Luo and Wang, 2019). First, every utterance $u_1, u_2, \cdots, u_N$ is tokenized by the BPE tokenizer (Sennrich et al., 2015), i.e., $u_i = (u_{i,1}, u_{i,2}, \cdots, u_{i,T_i})$, where T_i denotes the number of tokens. The tokens are embedded through WordPiece embeddings (Wu et al., 2016). The pre-trained *uncased BERT-Base*[1] model converts the token embeddings into contextualized token representations, which can be converted to the vector representations via max pooling, so that they are regarded as the contextual utterance embeddings $\mathbf{h}_i^{(0)} \in \mathbb{R}^{D_m}$ for $i = 1, \cdots, M$, where D_m denotes the dimension of the utterance embeddings. This BERT model is fine-tuned through a training process.

3.2 Speaker Dependency Modeling with Position Encodings

Graph-based neural networks are used to capture the speaker dependency features of conversations. We design relational graph attention net-

[1] See `https://github.com/google-research/bert` for details.

works to capture both self-dependency and inter-speaker dependency of utterances. In addition, we introduce an attention mechanism to attend to the neighborhood's representations of the utterances. Furthermore, novel position encodings (relational position encodings) are added to the graph to account for the sequential information contained in utterances.

3.2.1 Graphical Structure

We introduce the following notation: we denote directed and multi-graphs as $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$ with a node (utterance) $v_i \in \mathcal{V}$ and a labeled edge (relation) $(v_i, r, v_j) \in \mathcal{E}$, where $r \in \mathcal{R}$ is a relation type.

Nodes Representation Each utterance in a conversation is represented as a node $v_i \in \mathcal{V}$. Each node v_i is initialized with the contextual utterance embeddings $\mathbf{h}_i^{(0)}$. Through a stack of graphical layers, this embedding is modified by aggregating their neighborhood's representations, described as $\mathbf{h}_i^{(L)}$, where L denotes the number of graphical layers.

Labeled Edges Representation Following the state-of-the-art method (Ghosal et al., 2019), the labeled edges depend on two aspects: (a) speakers dependency - this depends upon both self-dependency and inter-speaker dependency. In detail, the former indicates how utterance u_i of speaker s_m influences s_m's other utterances (including itself). On the other hand, the latter describes how utterance u_i of speaker s_m influences the other speaker $s_{k \neq m}$'s utterances; (b) temporal dependency - this also depends on temporal turns in conversation. Namely, it relies upon whether one utterance u_j is uttered in the past or future of the target utterance u_i. While the future dependencies are not used in on-going conversation, the ERC task is an offline system. Furthermore, as past utterances plausibly influence future utterances, the converse may help the model fill in some missing information like the speaker's background. For these reasons, we take the converse influence into account, referring to (Ghosal et al., 2019).

Accordingly, there are four relation types of edges: (1) self - past type, (2) inter - past type, (3) self - future type, and (4) inter - future type, described as (r_1, r_2, r_3, r_4). Note that this is in contrast to the 8 types used by DialogueGCN[2].

In addition, the window sizes p and f represent the number of past or future utterances from a target utterance in a neighborhood where each utterance u_i has an edge with the p utterances (i.e. $u_{i-1}, u_{i-2}, \cdots, u_{i-p}$), the f utterances (i.e. $u_{i+1}, u_{i+2}, \cdots, u_{i+f}$), and itself. An appropriate window size has to be determined because a small window makes each utterance connect to too small a neighborhood while an immense window size makes the calculation very expensive. Although the window size can be different for each type, we determine the same window size for each relation.

3.2.2 Edge Weight

We introduce an edge weight by using an attention mechanism. Although our attention mechanism is based on the GAT (Veličković et al., 2017) model, it is independent for each relational type r:

$$\alpha_{ijr} = \text{softmax}_i\Big(\text{LRL}\big(\mathbf{a}_r^T[W_r\mathbf{h}_i || W_r\mathbf{h}_j]\big)\Big) \tag{1}$$

where α_{ijr} denotes the edge weight from a target utterance i to its neighborhood j under relational type r, W_r denotes a parametrized weight matrix for the attention mechanism, $\mathbf{a}_r$ denotes a parametrized weight vector, and $\cdot^T$ represents transposition. After applying LeakyReLU nonlinearity (LRL), a softmax function is used to obtain the incoming edges whose sum total weight is 1.

3.2.3 Position Encodings

We propose relational position encodings for the relational graph attention networks. Our position encodings are based on the relative position since it is appropriate for graph-based neural networks. The target utterance feature is connected to its neighborhood by an edge in the graph. Therefore, in order to account for the sequential information between them, we need to consider the distance from the target to its neighborhood, which is undoubtedly the relative distance between utterances. Furthermore, we follow the speaker dependency modeling described in 3.2.1 and use relational graph attention networks. It is necessary that the sequential information depends on the relation type r. In summary, we use a different relative distance for each relation type, which is re-

---

[2] The type of DialogueGCN depends on 2 distinct speakers and therefore implies 2×4 distinct relation types, which indicates that both the speaker dependency and the temporal dependency are prepared for each distinct speaker.

	$\mathbf{h}_1^{(0)}$	$\mathbf{h}_2^{(0)}$	$\mathbf{h}_3^{(0)}$	$\mathbf{h}_4^{(0)}$	$\mathbf{h}_5^{(0)}$	$\mathbf{h}_6^{(0)}$	$\mathbf{h}_7^{(0)}$	$\mathbf{h}_8^{(0)}$
Absolute Position	1	2	3	4	5	6	7	8
Relative Position	-3	-2	-1	0	1	2	3	4
Relational Position	-2	-1	-1	0	-1	-1	-2	-3

Figure 2: Example of relational positions. The relational position depends on each relational type, and the background color represents the relational type from the target utterance $\mathbf{h}_4$. These positions, which are based on the relative distance, are different for each relation.

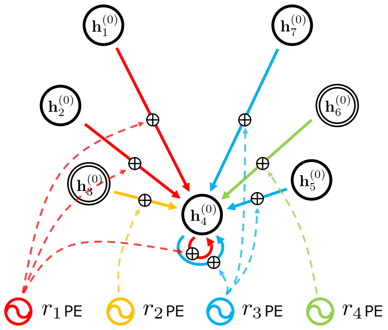

Figure 3: Illustration of relational position encodings. The encodings, which are composed of four representations, are added to the edges in a graph for each relation. "PE" denotes the position encodings.

ferred to as relational position encodings. Figure 2 illustrates the idea of relational positions.

We compare two types of relational position encoding, i.e., a fixed function and a learned representation (Gehring et al., 2017). As the fixed positional function, we define its representation as

$$PE_{ijr} = \begin{cases} max(-p, min(p, j-i)) & r = 1, where\ j \in \mathcal{N}^1(i) \\ max(-p, min(p, j-i)) & r = 2, where\ j \in \mathcal{N}^2(i) \\ max(-f, min(f, j-i)) & r = 3, where\ j \in \mathcal{N}^3(i) \\ max(-f, min(f, j-i)) & r = 4, where\ j \in \mathcal{N}^4(i) \end{cases} \tag{2}$$

where PE_{ijr} denotes the relational distance from a target utterance i to its neighborhood j under relational type r. The maximum relational position is clipped to a size of p or f, which denotes the window size of past or future utterances. $\mathcal{N}^r(i)$ denotes the neighborhood of the target i under relation type r. As the learned representations, we use one-layer feed-forward neural networks for positional embeddings, whose argument is the relational fixed function.

Our relational position is based on the relative position; thus, it can be added to the edge weight, as illustrated in Figure 3. We redefine the attention weight in (1) as

$$\alpha_{ijr} = \text{softmax}_i\Big(\text{LRL}\big(\mathbf{a}_r^T[W_r\mathbf{h}_i||W_r\mathbf{h}_j] + \text{PE}_{ijr}\big)\Big) \tag{3}$$

To add position encodings to the edge weight, our relational position has the same scalar dimension as the edge weight. Because it is a scalar value, it may have limited ability to express positional information. In future studies, we will increase the dimension of the position encodings.

3.2.4 RGAT

A graphical propagation module modifies the representation of a node $\mathbf{h}_i^{(l)}$ by aggregating representations of its neighborhood $\mathcal{N}^r(i)$, and an attention mechanism is used to attend to the neighborhood's representations. The features $\mathbf{h}_{ir}^{(l-1)}$ under relation r are summed to compose the output embedding of a node $\mathbf{h}_i^{(l)}$. Through a stack of graphical layers l, the representation of a node changes within its l-hop neighborhood. We define the propagation module as follows:

$$\mathbf{h}_{ir}^{(l-1)} = \sum_{j \in \mathcal{N}^r(i)} \alpha_{ijr}^{(l-1)} W_r^{(l-1)} \mathbf{h}_j^{(l-1)} \tag{4}$$

$$\mathbf{h}_i^{(l)} = \sum_{r=1}^{R} \mathbf{h}_{ir}^{(l-1)} \tag{5}$$

where $W_r^{(l-1)}$ denotes a learnable weight matrix for each relation r. In addition, We apply multi-head attention to the aggregation module in (4) and concatenate its outputs. After this propagation module in (5), we use layer normalization with learnable affine transform parameters.

3.3 Emotion Classification

After obtaining the representations $\mathbf{h}_i^{(L)}$ of each node through the speaker dependency modeling with relational position encodings, we concatenate the contextual utterance embeddings $\mathbf{h}_i^{(0)}$ and the representation of $\mathbf{h}_i^{(L)}$. The concatenated vector is classified by using a fully connected feed-forward network, which consists of two linear transformations with a ReLu activation between them:

$$\text{Classifier}(\mathbf{x}) = \max(0, \mathbf{x}W_1 + \mathbf{b}_1)W_2 + \mathbf{b}_2 \tag{6}$$

where W_1 and W_2 denote learnable weight matrixes, and $\mathbf{b}_1$ and $\mathbf{b}_2$ denote learnable bias vectors.

Datasets	Conversations			Utterances			Classes	Evaluation Metrics

Table 2: Dataset descriptions.

4 Experimental Settings

4.1 Datasets

We evaluated our method on four ERC benchmark datasets of various sizes. Training, validation, and test data distributions are reported in Table 2.

IEMOCAP (Busso et al., 2008) is an audio-visual database consisting of recordings of ten speakers in dyadic conversations. The utterances are annotated with one of six emotional labels: happy, sad, neutral, angry, excited, or frustrated.

MELD (Poria et al., 2018) is a multimodal multi-party emotional conversational database created from scripts of the TV series *Friends*. The utterances are annotated with one of seven labels: neutral, happiness, surprise, sadness, anger, disgust, or fear.

EmoryNLP (Zahiri and Choi, 2018) was also collected from *Friends*' TV scripts. It contains different sizes and different types of annotations from those of MELD. The emotion labels include neural, sad, mad, scared, powerful, peaceful, and joyful.

DailyDialog (Li et al., 2017) is a multi-turn daily dialogue dataset, which contains human-written daily communications. The emotion labels are the same as the ones used in MELD.

4.2 Evaluation Metrics

For DailyDialog, following (Zhong et al., 2019), we calculated the micro-averaged F1 score excluding the majority class (neutral), due to it being an extremely high majority (over 80% occupancy in both training and test sets). For the rest of the datasets, we followed (Zhong et al., 2019; Ghosal et al., 2019) and used the weighted-average F1 score.

4.3 Baselines and State-of-the-Art

For a comprehensive performance evaluation, we compared our model with the following baseline and state-of-the-art methods:

CNN (Kim, 2014) This is a convolutional neural network trained at the utterance-level without contextual information.

CNN+cLSTM (Poria et al., 2017) This model extracts utterance features by using a CNN and captures contextual information from surrounding utterances by using a bi-directional long short term memory (LSTM).

BERT_BASE (Devlin et al., 2018) This BERT-based model extracts contextual information from single sentences and uses it as input. After obtaining the sentence feature, it is classified with emotion labels. We used this model as a contextual utterance feature extractor (Section 3.1).

KET (Zhong et al., 2019) This is the state-of-the-art model for the EmoryNLP and DailyDialog benchmark datasets. KET considers contextual information by using hierarchical self-attention and leverages external commonsense knowledge by using a context-aware graph attention mechanism.

DialogueRNN (Majumder et al., 2019) This model uses a CNN to extract textual information. It uses three GRUs to account for the context and the speakers' features and track the emotional state.

DialogueGCN (Ghosal et al., 2019) This is the state-of-the-art model for the IEMOCAP and MELD datasets. DialogueGCN extracts textual utterance features by using a CNN and extracts sequential contextual features by using a GRU. Further, it captures self-dependency and inter-speaker dependency by using two-layer graph neural networks, which consists of one layer RGAT and one layer GCN.

4.4 Other Settings

We used cross entropy as a training loss for our approach on all datasets. The learning rate was decreased in accordance with a cosine annealing schedule (Loshchilov and Hutter, 2016). We set

Models	IEMOCAP	MELD	EmoryNLP	DailyDialog
CNN	48.18	55.86	32.59	49.34
CNN+cLSTM	54.95	56.87	32.89	50.24
BERT_BASE	53.31	56.21	33.15	53.12
KET	59.56	58.18	34.39	53.37
DialogueRNN	62.75	57.03	31.70	50.65
DialogueGCN	64.18	58.10	-	-
Ours	**65.22**	**60.91**	**34.42**	**54.31**

Table 3: Performance of our method, baseline, and state-of-the-art methods on the three test sets (the values in the table are in terms of the evaluation metrics listed in Table 2). Bold font denotes the best performance. "-" signifies that no results were reported for the given dataset. "Ours" denotes our methods, which are composed of a BERT model and RGAT with relational position encodings. The position representations were learned.

initial learning rates of $4e$-5 in the BERT structure and $2e$-3 in the RGAT structure and used the Adam optimizer (Kingma and Ba, 2014) under the scheduled learning rate with a batch size of 1. The number of dimensions of the contextual embeddings and utterance representations was set to 768, and the size of the internal hidden layer in the emotion classification module was set to 384. We used 8-head attention for calculating the edge weight of RGAT and set 0.1 as the dropout rate in the BERT structure. We also carried out experiments with different contextual past window sizes p and future window sizes f, $(1,1)$, $(2,2)$, $(3,3)$, $(10,10)$, (all, all), and RGAT layers, $1,2,3$. We selected either a concatenated function or a summation function as a mixing operation in the emotion classification module, as described in 3.3. We chose the hyper-parameter that achieved the best score on each dataset by using development data. All of the presented results are averages of 5 runs. We conducted all experiments on a CentOS server using Xeon(R) Gold 6246 CPU with 512GB of memory, and we used Quadro RTX 8000 GPU with 48GB of memory.

5 Results and Discussion

5.1 Comparison with Baselines and State-of-the-Art

We compared the performance of our approach with those of the baselines and state-of-the-art methods listed in Table 3. We have quoted the results for the baselines and state-of-the-art results reported in (Zhong et al., 2019; Ghosal et al., 2019), except for the results of BERT_BASE on IEMOCAP.

For IEMOCAP, our model obtained a weighted average F1 score of 65.22%, outperforming DialogueGCN by more than 1 point. Furthermore, it achieved a weighted average F1 score of 60.91% on the MELD dataset, outperforming DialogueGCN by more than 2 points. For EmoryNLP, it achieved a weighted average F1 score of 34.42%. It achieved a micro-averaged F1 score of 54.31% on the DailyDialog dataset, improving recognition performance over the baselines and KET model by around 1 point. From these results, we can see that adding our position encodings caused an improvement over the baselines, KET, and DialogueGCN on all datasets. Further, it is obvious that our approach is robust across datasets having varying training-data sizes, conversation lengths, and numbers of speakers.

5.2 Analysis of the Experimental Results

Let us investigate the importance of our model components by analyzing the predicted emotional labels, as shown in Table 4. The results of the model using BERT without speaker dependency modeling are listed on row ♯0, while the results of DialogueRNN, as described in Section 4.3, are on row ♯1. The results of DialogueGCN, as described in Section 4.3, are reported in ♯2. The results of the BERT and RGAT model without position encodings are on row ♯3, and those of our model are on ♯4. Note that DialogueGCN's RGAT differs from our model in terms of its graphical structure and relational types.

As shown in the table, our method did not achieve the best score for almost all labels. However, interestingly, it achieved a state-of-the-art average F1 score, which is the target metric on the dataset. A possible reason for this performance is that our method consists of effective components. Each component of BERT and RGAT with position encodings worked well for each label. As a result, these components led to a strong average performance. Each effective component is explained

♯	Models	Background Components		Happy	Sad	Neutral	Angry	Excited	Frustrated	Average
		Contextual Utterance Embedding	Speaker Dependency Modeling							
0	BERT_BASE	BERT	×	37.09	59.53	51.73	54.33	54.26	55.83	53.31
1	DialogueRNN	CNN, GRU		33.18	78.80	59.21	**65.28**	**71.86**	58.91	62.75
2	DialogueGCN	CNN, GRU	RGAT	42.75	**84.54**	63.54	64.19	63.08	**66.99**	64.18
3	Ours(without PE)	BERT	RGAT	50.69	76.78	**65.85**	59.66	64.04	62.37	64.36
4	Ours	BERT	RGAT with PE	**51.62**	77.32	65.42	63.01	67.95	61.23	**65.22**

Table 4: Weighted average F1 scores of ours (with or without PE), baseline, and state-of-the-art methods for each label in the IEMOCAP dataset. Bold font denotes the best performance. “Average” denotes the weighted average F1 score. The variations of their background components are shown in the third and fourth columns.

as follows:

Effect of Speaker Dependency We observed that DialogueGCN and ours (with or without PE) achieved an F1 score of more than 60% on *Frustrated*, higher than the other methods. This may be due to the well-functioning RGAT model. On the IEMOCAP dataset, the utterances often keep on influencing the other utterances through self and inter-speaker dependency; thus, the same label continues in these utterances. Most of the labels in this case are annotated with *Frustrated*. Because of the speaker dependency modeling, these consecutive utterances can be well classified using RGAT.

Effect of Contextual Information Ours (with or without PE) achieved an F1 score of more than 50% on *Happy*, outperforming the other baselines by around 10 points. On the dataset, the *Happy* label appears in several utterances including particular words like ’love’ or ’great’. The BERT model with RGAT may have led to better performance. Due to the representational power afforded by its bi-directional context modeling, the BERT model may have functioned well in these utterances. Note that the combination of BERT and RGAT is probably essential because the samples of *Happy* are also influenced by speaker dependency, as compared with ♯0.

Effect of Sequential Feature Our position encodings contributed to the strong performance on the *Sad* and *Angry* labels, our model with PE outperformed our model without PE (♯3 and ♯4). The two labels often appear in the utterances influenced by the other immediate utterances. As the RGAT with position encodings not only captures self and inter-speaker dependency but clearly distinguishes between immediate and far utterances; thus, it possibly performs well on these utterances. Despite its strong performance, our model did not outperform DialogueGCN and DialogueRNN on these labels (♯1, ♯2, and ♯4). A possible explanation is that these label’s utterances are mainly influenced by the immediately preceding utterances; thus, RNN-based models such as GRU may be more adequate for these two labels.

From these results, we can see that each component of our method functioned successfully on each label. Our method achieved a state-of-the-art average F1 score. Moreover, it was useful on any label; thus, it is a well-balanced method.

Other Analyses We analyzed other aspects of our models. We observed that our model misclassified some samples of *Excited* as *Happy*. The cause of this issue may be due to the similarity of the sentences these labels appear in. There is almost no difference in the meanings of sentences, so our method may have had difficulty distinguishing these labels. In future work, we will utilize additional audio and visual information to help our model by taking voice tones and facial expressions into account.

5.3 Model Variations

We evaluated the importance of our relational position encoding and studied the positional variations on the IEMOCAP dataset. The experimental results are reported in Table 5.

To make comparisons with the other position encoding methods, absolute and relative position representations were prepared; these are referred to as node-based position encodings and edge-based position encodings, respectively. Inspired by (Vaswani et al., 2017), we added node-based position encoding to the nodes (utterances) at the bottoms of the RGAT layers. Similarly, edge-based position encoding was added to the edges in the graph. We also compared two types of posi-

♯	Position Encodings (PE)	Type	Average
0	-	-	64.36
1	Node-based PE	*fixed*	63.95
2		*learn*	64.95
3	Edge-based PE	*fixed*	63.97
4		*learn*	64.59
5	Relational PE	*fixed*	63.99
6		*learn*	**65.22**

Table 5: Impact of various position encodings components on the IEMOCAP dataset. The base model using BERT and RGAT without position encodings is shown in ♯0. "*fixed*" and "*learn*" denote a fixed function and a learned representation respectively.

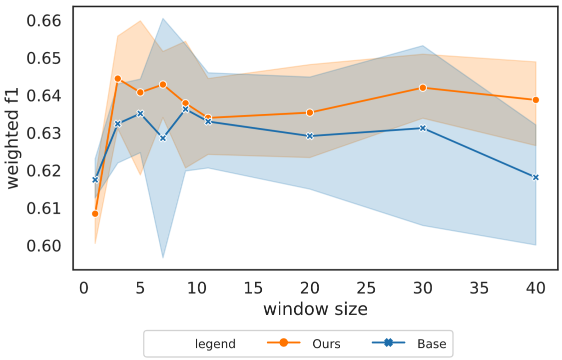

Figure 4: Effect of different window sizes on the weighted average F1 score of our method (Ours) and the baseline model (Base) on the IEMOCAP dataset. We plotted the scores by using a marker with a confidence interval of 95%, which was estimated using a bootstrap.

tion encoding, i.e., a fixed function and a learned representation.

The baseline model using BERT and RGAT without position encodings (♯0) had a recognition performance of 64.36%. We added various position encodings to the baseline model and selected fixed functions or learned representations as the position representation (from ♯1 to ♯6). The model using the relational position encodings with learned representations had a recognition performance of 65.22%, the best score and outperforming the base model by around 1 point. Our relational position encodings were more effective than the other position encodings.

We also found that the fixed functions in various positions resulted in a score lower than that of the baseline model. We can conclude that it is required to learn a position representation.

5.4 Effect of Varying the Window Size

We conducted another experiment to evaluate the key aspects of our framework. We carried out an experiment by increasing the past and future window sizes [(1,1), (3,3), (5,5), (7,7), (9,9), (11,11), (20,20), (30,30), and (40,40)] on the IEMOCAP dataset and compared the results with those of the baseline model using BERT and RGAT without positional information. The experimental results are illustrated in Figure 4.

As an illustration, it is clear that both models perform better with a window size around $3, 5, 7$. On the other hand, long utterance information may obstruct efficient recognition (see the results for a window size around $30, 40$). Although it is required to select a small window size, too small a size results in poor performance, no better than choosing a size of 1.

Furthermore, the proposed position encoding method is robust to a varying window size. As the window size increased, the baseline model's F1 score decreased, while our model maintained its performance even with a large window. One possible reason is that, as our position encodings clearly distinguish between immediate and far utterances, it can reduce the influence of these distant utterances.

6 Conclusion

We proposed relational position encodings for RGAT to recognize human emotions in textual conversation. We incorporated the relational position encodings in the RGAT structure to capture both speaker dependency and the sequential order of utterances. On four ERC datasets, our model improved recognition performance over those of the baselines and existing state-of-the-art methods. Additional experimental studies demonstrated that the relational position encoding approach outperformed the other position encodings and showed that it is robust to changes in window size.

In future studies, we plan to increase the number of dimensions of the relational position encodings, since a scalar value may not be able to express positional information adequately.

Acknowledgements

We would like to thank Dr. Ichiro Yamada, Dr. Rei Endo, and Hideya Mino for the valuable discussions. We also thank the anonymous reviewers for their helpful comments.

Abstract

Adjectives like *pretty*, *beautiful* and *gorgeous* describe positive properties of the nouns they modify but with different intensity. These differences are important for natural language understanding and reasoning. We propose a novel BERT-based approach to intensity detection for scalar adjectives. We model intensity by vectors directly derived from contextualised representations and show they can successfully rank scalar adjectives. We evaluate our models both intrinsically, on gold standard datasets, and on an Indirect Question Answering task. Our results demonstrate that BERT encodes rich knowledge about the semantics of scalar adjectives, and is able to provide better quality intensity rankings than static embeddings and previous models with access to dedicated resources.

1 Introduction

Scalar adjectives describe a property of a noun at different degrees of intensity. Identifying the scalar relationship that exists between their meaning (for example, the increasing intensity between *pretty*, *beautiful* and *gorgeous*) is useful for text understanding, for both humans and automatic systems. It can serve to define the sentiment and subjectivity of a text, perform inference and textual entailment (Van Tiel et al., 2016; McNally, 2016), build question answering and recommendation systems (de Marneffe et al., 2010), and assist language learners in distinguishing between semantically similar words (Sheinman and Tokunaga, 2009).

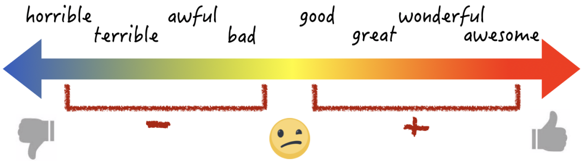

Figure 1: Full scale of adjectives describing positive and negative sentiment at different degrees from the SO-CAL dataset (Taboada et al., 2011).

We investigate the knowledge that the pre-trained BERT model (Devlin et al., 2019) encodes about the intensity expressed on an adjective scale. Given that this property is acquired by humans during language learning, we expect a language model (LM) exposed to massive amounts of text data during training to have also acquired some notion of adjective intensity. In what follows, we explore this hypothesis using representations extracted from different layers of this deep neural model. Since the scalar relationship between adjectives is context-dependent (Kennedy and McNally, 2005) (e.g., what counts as *tall* may vary from context to context), we consider the contextualised representations produced by BERT to be a good fit for this task. We also propose a method inspired by gender bias work (Bolukbasi et al., 2016; Dev and Phillips, 2019) for detecting the intensity relationship of two adjectives on the fly. We view intensity as a direction in the semantic space which, once identified, can serve to determine the intensity of new adjectives.

Our work falls in the neural network interpretation paradigm which explores the knowledge about language encoded in the representations of deep learning models (Voita et al., 2019a; Clark et al., 2019; Voita et al., 2019b; Tenney et al., 2019; Talmor et al., 2019). The bulk of this interpretation work addresses structural aspects of language such as syntax, word order, or number agreement (Linzen et al., 2016; Hewitt and Manning, 2019; Hewitt and Liang, 2019; Rogers et al., 2020); shallow semantic phenomena closely related to syntax such as semantic role labelling and coreference (Tenney et al., 2019; Kovaleva et al., 2019); or the symbolic reasoning potential of language model representations (Talmor et al., 2019). Our

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7371–7385,
November 16–20, 2020.

work makes a contribution towards the study of the knowledge pre-trained LMs encode about word meaning, generally overlooked until now in interpretation work.

We evaluate the representations generated by BERT against gold standard adjective intensity estimates (de Melo and Bansal, 2013; Wilkinson, 2017; Cocos et al., 2018) and apply them directly to a question answering task (de Marneffe et al., 2010). Our results show that BERT clearly encodes the intensity variation between adjectives on scales describing different properties. Our proposed method can be easily applied to new datasets and languages where scalar adjective resources are not available.[1]

2 Related Work

The analysis of scalar adjective relationships in the literature has often been decomposed into two steps: Grouping related adjectives together and ranking adjectives in the same group according to intensity. The first step can be performed by distributional clustering approaches (Hatzivassiloglou and McKeown, 1993; Pang et al., 2008) which can also address adjectival polysemy. *Hot*, for example, can be on the TEMPERATURE scale (a *warm* → *hot* → *scalding* drink), the ATTRACTIVENESS (a *pretty* → *hot* → *sexy* person) or the INTEREST scale (an *interesting* → *hot* topic), depending on the attribute it modifies.

Other works (Sheinman and Tokunaga, 2009; de Melo and Bansal, 2013; Wilkinson, 2017) directly address the second step, ranking groups of semantically related adjectives from lexicographic resources (e.g., WordNet) (Fellbaum, 1998). This ranking is the focus of this work. We show that BERT contextualised representations encode rich information about adjective intensity, and can provide high quality rankings of adjectives in a scale.

Adjective ranking has been traditionally performed using pattern-based approaches which extract lexical or syntactic patterns indicative of an intensity relationship from large corpora (Sheinman and Tokunaga, 2009; de Melo and Bansal, 2013; Sheinman et al., 2013; Shivade et al., 2015). For example, the patterns "*X, but not Y*" and "*not just X but Y*" provide evidence that X is an adjective less intense than Y. Another common approach is lexicon-based and draws upon a resource that maps adjectives to scores encoding sentiment polarity (positive or negative) and intensity. Such resources can be manually created, like the SO-CAL lexicon (Taboada et al., 2011), or automatically compiled by mining adjective orderings from star-valued product reviews where people's comments have associated ratings (de Marneffe et al., 2010; Rill et al., 2012; Sharma et al., 2015; Ruppenhofer et al., 2014). Cocos et al. (2018) combine knowledge from lexico-syntactic patterns and the SO-CAL lexicon with paraphrases in the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013; Pavlick et al., 2015).

Our approach is novel in that it does not need specified patterns or access to lexicographic resources. It, instead, relies on the knowledge about intensity encoded in scalar adjectives' contextualised representations. Our best performing method is inspired by work on gender bias which relies on simple vector arithmetic to uncover gender-related stereotypes. A gender direction is determined (for example, by comparing the embeddings of *she* and *he*, or *woman* and *man*) and the projection of the vector of a potentially biased word on this direction is then calculated (Bolukbasi et al., 2016; Zhao et al., 2018). We extend this method to scalar adjectives and BERT representations.

Kim and de Marneffe (2013) also consider vector distance in the semantic space to encode scalar relationships between adjectives. They specifically examine a small set of word pairs, and observe that the middle point in space between the word2vec (Mikolov et al., 2013) embeddings of two antonyms (e.g., *furious* and *happy*) falls close to the embedding of a mid-ranked word in their scale (e.g., *unhappy*). Their experiments rely on antonym pairs extracted from WordNet. We show that contextualised representations are a better fit for this task than static embeddings, encoding rich information about adjectives' meaning and intensity.

3 Data

We experiment with three scalar adjective datasets.

DEMELO (de Melo and Bansal, 2013).[2] Adjective sets were extracted from WordNet 'dumbbell' structures (Gross and Miller, 1990). The sets represent full-scales (e.g., from *horrible* to *awesome*) and are partitioned into half-scales (from *horrible* to *bad*, and from *good* to *awesome*) based on pattern-based evidence in the Google N-Grams cor-

[2] `http://demelo.org/gdm/intensity/`

Dataset	Adjective scale
DEMELO	[*soft* → *quiet* → *inaudible* → *silent*] [*thick* → *dense* → *impenetrable*]
CROWD	[*fine* → *remarkable* → *spectacular*] [*scary* || *frightening* → *terrifying*]
WILKINSON	[*damp* → *moist* → *wet*] [*dumb* → *stupid* → *idiotic*]

Table 1: Examples of scales in each dataset. '||' denotes a tie between adjectives of the same intensity.

pus (Brants and Franz, 2006). The dataset contains 87 half-scales with 548 adjective pairs, manually annotated for intensity relations ($<$, $>$, and $=$).

CROWD (Cocos et al., 2018).[3] The dataset consists of a set of adjective scales with high coverage of the PPDB vocabulary. It was constructed by a three-step process: Crowd workers were first asked to determine whether pairs of adjectives describe the same attribute (e.g., TEMPERATURE) and should, therefore, belong to the same scale. Sets of same-scale adjectives were then refined over multiple rounds. Finally, workers ranked the adjectives in each set by intensity. The final dataset includes 330 adjective pairs along 79 half-scales.

WILKINSON (Wilkinson and Oates, 2016).[4] This dataset was generated through crowdsourcing. Crowd workers were presented with small seed sets (e.g., *huge, small, microscopic*) and were asked to propose similar adjectives, resulting in twelve adjective sets. Sets were automatically cleaned for consistency, and then annotated for intensity by the crowd workers. The original dataset contains full scales. We use its division in 21 half-scales (with 61 adjective pairs) proposed by Cocos et al. (2018).

In the rest of the paper, we use the term "scale" to refer to the half-scales contained in these datasets. Table 1 shows examples from each one of them.

4 BERT Contextualised Representations

4.1 Sentence Collection

To explore the knowledge BERT has about relationships in an adjective scale s, we generate a contextualised representation for each $a \in s$ in the same context. Since such cases are rare in running text, we construct two sentence sets that satisfy this condition using the ukWaC corpus (Baroni et al., 2009)[5] and the Flickr 30K dataset (Young et al., 2014).[6] For every $s \in D$, a dataset from Section 3, and for each $a \in s$, we collect 1,000 instances (sentences) from each corpus.[7] We substitute each instance i of $a \in s$, with each $b \in s$ where $b \neq a$, creating $|s| - 1$ new sentences.[8] For example, for an instance of *thick* from the scale [*thick* → *dense* → *impenetrable*] in Table 1, we generate two new sentences where *thick* is substituted by each of the other adjectives in the same context.

4.2 Sentence Cleaning

Hearst patterns We filter out sentences where substitution should not take place, such as cases of specialisation or instantiation. In this way, we avoid replacing *deceptive* with *fraudulent* and *false* in sentences like "*Viruses and other deceptive software*", "*Deceptive software such as viruses*", "*Deceptive software, especially viruses*".[9] We parse the sentences with `stanza` (Qi et al., 2020) to reveal their dependency structure, and use Hearst lexico-syntactic patterns (Hearst, 1992) to identify sentences describing *is-a* relationships between nouns in a text. More details about this filtering are given in Appendix A.

Language Modelling criteria Adjectives that belong to the same scale might not be replaceable in all contexts. Polysemy can also influence their substitutability (e.g., *warm weather* is a bit *hot*, but a *warm smile* is *friendly*). In order to select contexts where $\forall a \in s$ fit, we measure the fluency of the sentences generated through substitution. We use a score assigned to each sentence by context2vec (Melamud et al., 2016) which reflects how well an $a \in s$ fits a context by measuring the cosine similarity between a and the context representation. We also experimented with calculating the

---

[5] http://u.cs.biu.ac.il/~nlp/resources/downloads/context2vec/

[6] Flickr contains crowdsourced captions for 31,783 images describing everyday activities, events and scenes. We consider objective descriptions to be a better fit for our task than subjective statements, which might contain emphatic markers. For example, *impossible* would be a bad substitute for *impractical* in the sentence "*What you ask for is too impractical*".

[7] ukWaC has perfect coverage. Flickr 30K covers 96.56% of the DEMELO scales and 86.08% of the CROWD scales. A scale s is not covered when no $a \in s$ is found in a corpus.

[8] We make a minor adjustment of the substituted data by replacing the indefinite article *a* with *an* when the adjective that follows starts with a vowel, and the inverse when it starts with a consonant.

[9] This would especially be a problem when considering adjectives with different polarity on a full scale (e.g., *deceptive* and *honest*).

perplexity assigned by BERT to a sentence generated through substitution, and with replacing the original a instance with the [MASK] token and getting the BERT probability for each $a \in s$ as a filler for that slot. context2vec was found to make better substitutability estimates.[10]

We use a 600-dimensional context2vec model in our experiments, pre-trained on ukWaC.[11] We calculate the context2vec score for all sentences generated for a scale s through substitution, and keep the ten with the lowest standard deviation (STD). Low STD for a sentence means that $\forall a \in s$ are reasonable choices in this context. For comparison, we also randomly sample ten sentences from all the ukWaC sentences collected for each scale. We call the sets of sentences ukWaC, Flickr and Random SENT-SETs.

We extract the contextualised representation for each $a \in s$ in the ten sentences retained for scale s, using the pre-trained `bert-base-uncased` model.[12] This results in $|s| * 10$ BERT representations for each scale. We repeat the procedure for every BERT layer. Examples of the obtained sentences are given in Appendix B.

5 Scalar Adjectives Ranking

5.1 Ranking with a Reference Point

In our first ranking experiment, we explore whether BERT encodes adjective intensity relative to a reference point, that is the adjective with the highest intensity (a_{ext}) in a scale s.

Method We rank $\forall a \in s$ where $a \neq a_{ext}$ by intensity by measuring the cosine similarity between their representation and that of a_{ext} in the ten ukWaC sentences retained for s, and in every BERT layer. For example, to rank [*pretty, beautiful, gorgeous*] we measure the similarity of the representations of *pretty* and *beautiful* to that of *gorgeous*. We then average the similarities obtained for each a and use these values for ranking. We refer to this method as BERTSIM.

Dataset	Metric	BERTSIM	FREQ	SENSE
DEMELO	P-ACC	$\mathbf{0.591}_{11}$	0.571	0.493
	τ	$\mathbf{0.364}_{11}$	0.304	0.192
	ρ_{avg}	$\mathbf{0.389}_{11}$	0.309	0.211
CROWD	P-ACC	$\mathbf{0.646}_{11}$	0.608	0.570
	τ	$\mathbf{0.498}_{11}$	0.404	0.428
	ρ_{avg}	0.494_{11}	0.499	**0.537**
WILKINSON	P-ACC	$\mathbf{0.913}_{9}$	0.739_{9}	0.739_{9}
	τ	$\mathbf{0.826}_{9}$	0.478	0.586
	ρ_{avg}	$\mathbf{0.724}_{9}$	0.345	0.493

Table 2: BERTSIM results on each dataset using contextualised representations from the ukWaC SENT-SET. Subscripts denote the best-performing BERT layer.

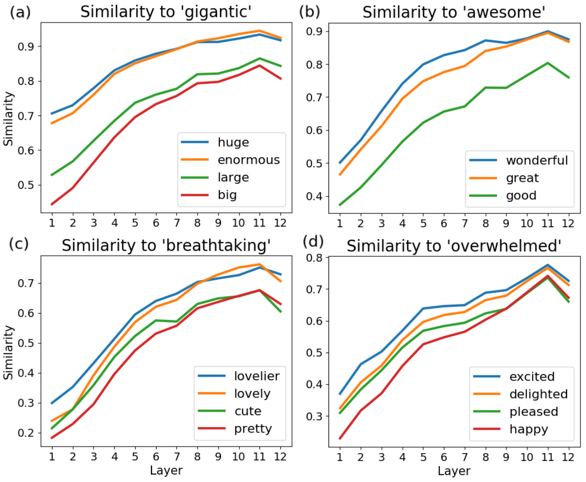

Figure 2: Examples of BERTSIM ranking predictions across layers using ukWaC sentences for four adjective scales: (a) [*big* → *large* → *enormous* → *huge* → *gigantic*], (b) [*good* → *great* → *wonderful* → *awesome*], (c) [*cute* → *pretty* → *lovely* → *lovelier* → *breathtaking*], (d) [*pleased* → *happy* → *excited* → *delighted* → *overwhelmed*]. (a) and (b) are from WILKINSON, (c) and (d) are from CROWD.

We evaluate the quality of the ranking for a scale by measuring its correlation with the gold standard ranking in the corresponding dataset D using Kendall's τ and Spearman's ρ correlation coefficients.[13] We also measure the model's pairwise accuracy (P-ACC) which shows whether it correctly predicted the relative intensity ($<, >, =$) for each pair a_i-$a_j \in s$ with $i \neq j$. During evaluation, we do not take into account scales where only one adjective is left ($|s| = 1$) after removing a_{ext} (26 out of 79 scales in CROWD; 9 out of 21 scales in WILKINSON).

Baselines We compare the BERTSIM method to two baselines which rank adjectives by frequency (FREQ) and number of senses (SENSE). We make

---

[10] We use as development set for this exploration a sample of 500 sentence pairs from the Concepts in Context (CoInCo) corpus (Kremer et al., 2014) that we will share along with our code. Details on the constitution of this sample are in Appendix B.

[11] `http://u.cs.biu.ac.il/~nlp/resources/downloads/context2vec/`

[12] When an adjective is split into multiple wordpieces (Wu et al., 2016), we average them to obtain its representation.

[13] We report correlations as a weighted average using the number of adjective pairs in a scale as weights.

the assumption that words with low intensity (e.g., *good, old*) are more frequent and polysemous than their extreme counterparts on the same scale (e.g., *awesome, ancient*). This assumption relies on the following two intuitions which we empirically validate: (a) Extreme adjectives tend to restrict the denotation of a noun to a smaller class of referents than low intensity adjectives (Geurts, 2010). We hypothesise that extreme adjectives denote more exceptional and less frequently encountered properties of nouns than low intensity adjectives on the same scale. This is also reflected in the directionality of their entailment relationship (e.g., *awesome* $\rightarrow$ *good*, *good* $\not\rightarrow$ *awesome*); low intensity adjectives should thus be more frequently encountered in texts. We test this assumption using frequency counts in Google Ngrams (Brants and Franz, 2006), and find that the least intense adjective is indeed more frequent than the most extreme adjective in 75% of the scales; (b) Since frequent words tend to be more polysemous (Zipf, 1945), we also expect that low intensity adjectives would have more senses than extreme ones. This is confirmed by their number of senses in WordNet: in 67% of the scales, the least intense adjective has a higher number of senses than its extreme counterpart.

Results We present the results of this evaluation in Table 2. Overall, similarities derived from BERT representations encode well the notion of intensity, as shown by the moderate to high accuracy and correlation in the three datasets. The good results obtained by the FREQ and SENSE baselines (especially on CROWD) highlight the relevance of frequency and polysemy for scalar adjective ranking, and further validate our assumptions.

Figure 2 shows ranking predictions made by BERTSIM in different layers of the model. Predictions are generally stable and reasonable across layers, despite not always being correct. For example, the similarly-intense *happy* and *pleased* are inverted in some layers but are not confused with adjectives further up the scale (*excited, delighted*). Note that *happy* and *pleased* are in adjacent positions in the CROWD ranking, and form a tie in the DEMELO dataset.

5.2 Ranking without Specified Boundaries

In real life scenarios, scalar adjective interpretation is performed without concrete reference points (e.g., a_{ext}). We need to recognize that a *great book* is better than a *well-written* one, without necessarily detecting their relationship to *brilliant*.

Method Our second adjective ranking method draws inspiration from word analogies in gender bias work, where a gender subspace is identified in word-embedding space by calculating the main direction spanned by the differences between vectors of gendered word pairs (e.g., $\overrightarrow{he}$ - $\overrightarrow{she}$, $\overrightarrow{man}$ - $\overrightarrow{woman}$) (Bolukbasi et al., 2016; Dev and Phillips, 2019; Ravfogel et al., 2020; Lauscher et al., 2020).

We propose to obtain an *intensity direction* by subtracting the representation of a mild intensity adjective a_{mild} from that of an extreme adjective a_{ext} on the same scale. By subtracting *pretty* from *gorgeous*, for example, which express a similar core meaning (they are both on the BEAUTY scale) but with different intensity, we expect the resulting $\overrightarrow{dVec} = \overrightarrow{gorgeous}$ - $\overrightarrow{pretty}$ embedding to represent this notion of intensity (or degree). We can then compare other adjectives' representations to $\overrightarrow{dVec}$, and rank them according to their cosine similarity[14] to this intensity vector: the closer an adjective is to $\overrightarrow{dVec}$, the more intense it is.

We calculate the $\overrightarrow{dVec}$ for each $s \in D$ (a dataset from Section 3) using the most extreme (a_{ext}) and the mildest (a_{mild}) words in s. We experiment with BERT embeddings from the SENT-SETs generated through substitution as described in Section 4, and with static word2vec embeddings (Mikolov et al., 2013) trained on Google News.[15] We build a $\overrightarrow{dVec}$ from every sentence (context) c in the set of ten sentences C for a scale s by subtracting the BERT representation of a_{mild} in c from that of a_{ext} in c. We average the ten $\overrightarrow{dVec}$'s obtained for s and construct a global $\overrightarrow{dVec}$ for the dataset D by averaging the vectors of $\forall s \in D$. For a fair evaluation, we perform a lexical split in the data used for deriving $\overrightarrow{dVec}$ and the data used for testing. When evaluating on CROWD, we calculate a $\overrightarrow{dVec}$ vector on DEMELO (DIFFVEC-DM) and one on WILKINSON (DIFFVEC-WK), omitting all scales where a_{ext} or a_{mild} are present in CROWD. We do the same for the other datasets.

To obtain the $\overrightarrow{dVec}$ of a s with static embeddings, we simply calculate the difference between the word2vec embeddings of a_{ext} and a_{mild} in s.

Results For evaluation, we use the same metrics as in Section 5.1. We compare our results to the

---

[14] We also tried the dot product of the vectors. The results were highly similar to the ones obtained using the cosine.

[15] We use the `magnitude` library (Patel et al., 2018).

Table 3: Results of our DIFFVEC adjective ranking method on the DEMELO, CROWD, and WILKINSON datasets. We report results with contextualised (BERT) representations obtained from different SENT-SETs (ukWaC, Flickr, Random) and with static (word2vec) vectors. We compare to the frequency (FREQ) and number of senses (SENSE) baselines, and to results from previous work (Cocos et al., 2018). Results for a dataset are missing (-) when the dataset was used for building the $\overrightarrow{dVec}$ intensity vector.

FREQ and SENSE baselines, and to the best results obtained by Cocos et al. (2018) who use information obtained from lexico-syntactic patterns, a lexicon annotated with intensity (SO-CAL) (Taboada et al., 2011), and paraphrases from PPDB.[16] Results are presented in Table 3. The DIFFVEC method gets remarkably high performance compared to previous results, especially when $\overrightarrow{dVec}$ is calculated with BERT embeddings. With the exception of Kendall's τ and pairwise accuracy on the DEMELO dataset, DIFFVEC outperforms results from previous work and the baselines across the board. We believe the lower correlation scores on the DEMELO dataset to be due to the large amount of ties present in this dataset: 44% of scales in DEMELO contain ties, versus 30% in CROWD and 0% in WILKINSON, where we obtain better results. Our models cannot easily predict ties using similarities which are continuous values. To check whether our assumption is correct, we make a simple adjustment to DIFFVEC so that it can propose ties if the vectors of two adjectives are similarly close to $\overrightarrow{dVec}$. Overall, this results in a small decrease in pairwise accuracy and a slight increase in correlation in DEMELO and CROWD. Complete results of this additional evaluation are given in Appendix C.

The composition of the SENT-SETs used for building BERT representations also plays a role on model performance. Overall, the selection method described in Section 4 offers a slight advantage over random selection, with ukWaC and Flickr sentences improving performance on different datasets. Note, however, that results for Flickr are calculated on the scales for which sentences were available (96.56% of DEMELO scales and 86.08% from CROWD).

The best-performing BERT layers are generally situated in the upper half of the Transformer network. The only exception is DIFFVEC-WK with the Flickr SENT-SET on DEMELO, where all layers perform similarly. The FREQ and SENSE baselines get lower performance than our method with BERT embeddings. SENSE manages to give results comparable to DIFFVEC with static embeddings and to previous work (Cocos et al., 2018) in one dataset (CROWD), but is still outperformed by DIFFVEC with contextualised representations.

We can also compare our results to those obtained by a purely pattern-based method on the same datasets, reported by Cocos et al. (2018). This method performs well on DEMELO ($\tau = 0.663$) because of its high coverage on this dataset, which was compiled by finding adjective pairs that also match lexical patterns. The performance of the pattern-based method is much lower than that of our models in the other two datasets ($\tau = 0.203$ on CROWD, $\tau = 0.441$ on WILKINSON), and its

---

[16] We do not report Spearman's ρ from Cocos et al. (2018) because it was calculated differently: They measure it a single time for each dataset, treating each adjective as a single data point.

		# Scales	deMelo P-ACC	 τ	 ρ_{avg}

Table 4: Results of DIFFVEC on deMelo and on Crowd using a single positive (1 (+)) or negative (1 (−)) $a_{ext} - a_{mild}$ pair, and five pairs (5).

coverage goes down to 11% on Crowd. This highlights the limitations of the approach, as well as the efficiency of our model which combines high performance and coverage.

5.3 Further Exploration of DIFFVEC

Given the high performance of the DIFFVEC method in the ranking task, we carry out additional experiments to explore the impact that the choice of scales and sentences has on the intensity vector quality. We test the method with a $\overrightarrow{dVec}$ vector built from a single $a_{ext} - a_{mild}$ pair of either positive (*awesome-good*) or negative (*horrible-bad*) polarity, that we respectively call DIFFVEC-1 (+)/(−). We also experiment with increasing the number of scales, adding *ancient-old*, *gorgeous-pretty* and *hideous-ugly* to form DIFFVEC-5. The scales are from Wilkinson, so we exclude this dataset from the evaluation.

Results are given in Table 4. We observe that a small number of word pairs is enough to build a $\overrightarrow{dVec}$ with competitive performance. Interestingly, DIFFVEC-1 (+) with random sentences obtains the best pairwise accuracy on deMelo. The fact that the method performs so well with just a few pairs (instead of a whole dataset as in Table 3) is very encouraging, making our approach easily applicable to other datasets and languages.

A larger number of scales is beneficial for the method with static word2vec embeddings, which seem to better capture intensity on the negative scale. For BERT, instead, intensity modeled using a positive pair gives best results across the board. The use of five pairs of mixed polarity improves results over a single negative pair, and has comparable performance to the single positive one.

Finally, we compare the performance of DIFFVEC-1 (+)/(−) and DIFFVEC-5 when the contextualised representations are extracted from a single sentence instead of ten. Our main observation is that reducing the number of sentences harms performance, especially when the sentence used is randomly selected. Detailed results are included in Appendix D.

6 Indirect Question Answering

We conduct an additional evaluation in order to assess how useful DIFFVEC adjective rankings can be in a real application. As in Cocos et al. (2018), we address Indirect Question Answering (QA) (de Marneffe et al., 2010). The task consists in interpreting indirect answers to YES/NO questions involving scalar adjectives. These do not straightforwardly convey a YES or NO answer, but the intended reply can be inferred. For example, if someone is asked "*Was it a good ad?*" and replies "*It was a great ad*", the answer is YES. This makes Indirect QA a good fit for scalar adjective ranking evaluation since it allows to directly assess a model's capability to detect the difference in intensity and direction (positive or negative) in an adjective pair.

We use the de Marneffe et al. (2010) dataset for evaluation, which consists of 125 QA pairs manually annotated with their implied answers (YES or NO). We adopt a decision procedure similar to the one proposed by de Marneffe et al. (2010). We compute the BERT embeddings of the adjective in the question (a_q) and the adjective in the answer (a_a). If a_a (e.g., *great*) has the same or higher intensity than a_q (e.g., *good*) the prediction

		$Previous_3$	0.642	0.710	0.683	0.684

Table 5: Results of our DIFFVEC method with contextualised (BERT) and static (word2vec) embeddings on the indirect QA task. We compare to the frequency, polysemy and majority baselines, and to results from previous work. $Previous_1$ stands for de Marneffe et al. (2010), $Previous_2$ for Kim and de Marneffe (2013) (the only result on 125 pairs), $Previous_3$ for Cocos et al. (2018).

is YES; otherwise, the prediction is NO. If the answer contains a negation, we switch YES to NO, and NO to YES. In previous work, indirect QA evaluation was performed on 123 or 125 examples, depending on whether cases labelled as "uncertain" were included (de Marneffe et al., 2010; Kim and de Marneffe, 2013; Cocos et al., 2018). We report all available results from previous work, and our scores on the 123 YES/NO examples as in the most recent work by Cocos et al. (2018). We report results using DIFFVEC with the adjustment for ties, where two adjectives are considered to be of the same intensity if they are similarly close to $\overrightarrow{dVec}$ ($diffsim$ = sim($\overrightarrow{dVec}$, $\overrightarrow{a_q}$) − sim($\overrightarrow{dVec}$, $\overrightarrow{a_a}$)). If the absolute value of $diffsim < 0.01$, we count them as a tie. We compare our method to previous results, to FREQ and SENSE, and to a baseline predicting always the majority label (YES). Results of this evaluation are given in Table 5. DIFFVEC with BERT embeddings outperforms the baselines and all previous approaches, and presents a clear advantage over DIFFVEC with static word2vec representations. Best performance is obtained when $\overrightarrow{dVec}$ is obtained from the Wilkinson dataset (DIFFVEC-WK). The $\overrightarrow{dVec}$ obtained from CROWD seems to be of lower quality. DIFFVEC-CD and DIFFVEC-DM improve over the baselines but do not achieve higher performance than the model of Kim and de Marneffe (2013).

7 Discussion

Our initial exploration of the knowledge encoded in BERT representations about scalar adjectives using BERTSIM (Section 5.1) showed they can successfully rank them by intensity. Then our DIFFVEC method (Sections 5.2 and 5.3) outperformed BERTSIM, providing even better ranking predictions with as few resources as a single adjective pair. This difference can be due to the composition of the vectors in the two cases. The a_{ext} representation in BERTSIM contains information about the meaning of the extreme adjective alongside its intensity, while the $\overrightarrow{dVec}$ vector is a cleaner representation of intensity: The subtraction of $\overrightarrow{a_{mild}}$ from $\overrightarrow{a_{ext}}$ removes the common core meaning expressed by their scale (e.g., BEAUTY, TEMPERATURE, SIZE). Consequently, $\overrightarrow{dVec}$ is a pure and general representation of intensity which can successfully serve to rank adjectives from any scale, as shown by our results. The DIFFVEC method can estimate adjectives' relative intensity on the fly, and performs better than the BERTSIM model which needs a reference point to propose a ranking. It does not use any external knowledge source – a requirement in previous approaches – and one of its highest performing variations (DIFFVEC-1 (+)) makes best quality predictions with a single adjective pair example.

Our assumption concerning the need for the sentences used for extracting BERT representations to be a good semantic fit for adjectives in a scale, has not been confirmed by our evaluation. Precisely, differences between our methods when relying on carefully vs randomly selected sentences are minor. This might be due to several reasons: One is that although BERT representations are contextualised, they also encode knowledge about the meaning and intensity of words acquired through pre-training, independent of the new context of use. Another possible explanation is that due to the skewed distribution of word senses (Kilgarriff, 2004; McCarthy et al., 2004), a high proportion of our randomly selected sentences might contain instances of the adjectives in their most frequent sense. If this is also the meaning of the corresponding scale, then the sentences are a good fit.

The DIFFVEC-1 (+) method, which uses a vector derived from a single positive pair, yields consistently better results than DIFFVEC-1 (−) which relies on a single negative pair. To better understand this difference in performance, we examine the composition of DEMELO and CROWD, specifically whether there is an imbalance in terms of polarity as reflected in the frequency of positive vs negative adjectives in the two datasets. We check the polarity of the adjectives in two sentiment lexicons: SO-CAL (Taboada et al., 2011) and AFINN-165 (Nielsen, 2011). The two lexicons cover a portion of the adjectives in DEMELO and CROWD: 68% and 79%, respectively. The DEMELO dataset is well-balanced in terms of positive and negative adjectives: 51% and 49% of the covered adjectives fall in each category. In CROWD, we observe a slight skew towards positive: 61% vs 39%. According to this analysis, the difference in performance between the two methods could only partially be explained by an imbalance in terms of polarity.

We perform an additional analysis based on the Google Ngram frequency of the positive and negative words that were used for deriving DIFFVEC. The adjectives *good* (276M) and *awesome* (10M) are more frequent than *bad* (65M) and *horrible* (4M). In fact, we find that the 1,000 most frequent positive words in SO-CAL and AFINN are, on average, much more frequent (18M) than the 1,000 most frequent negative words (8M). Word frequency has a direct impact on word representations, since having access to sparse information about a word's usages does not allow the model to acquire rich information about its linguistic properties as in the case of frequent words. The high frequency of *good* and *awesome* results in better quality representations than the ones obtained for their antonyms, and could explain to some extent the improved performance of DIFFVEC-1 (+) compared to DIFFVEC-1 (−) with BERT embeddings. However, this analysis does not explain the difference in the performance of DIFFVEC (+) and (−) between BERT and word2vec. This would require a better understanding of how words with different polarity (antonyms) are represented in BERT's space compared to word2vec, and how negation affects their representations. We leave these explorations for future work.

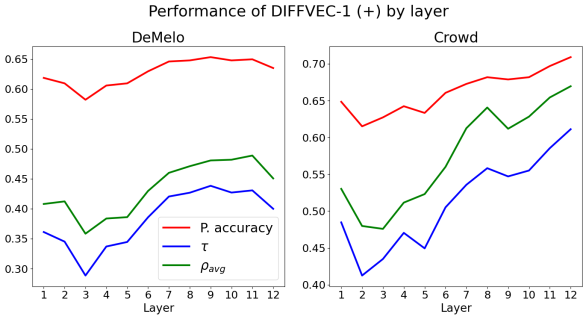

Figure 3: Performance of DIFFVEC-1 (+) with ukWaC sentences across BERT layers.

Regarding the performance of different BERT layers, we observe that knowledge relevant for scalar adjective ranking is situated in the last layers of the Transformer network. Figure 3 shows how the performance of DIFFVEC-1 (+) changes across different BERT layers: model predictions improve after layer 3, and performance peaks in one of the last four layers. This is in accordance with the findings of Tenney et al. (2019) that semantic information is mainly located in the upper layers of the model, but is more spread across the network than syntactic information which is contained in a few middle layers.

8 Conclusion

We have shown that BERT representations encode rich information about the intensity of scalar adjectives which can be efficiently used for their ranking. Although our method is simple and resource-light, solely relying on an intensity vector which can be derived from as few as a single example, it clearly outperforms previous work on the scalar adjective ranking and Indirect Question Answering tasks. Our performance analysis across BERT layers highlights that the lexical semantic knowledge needed for these tasks is mostly located in the higher layers of the BERT model.

In future work, we plan to extend our methodology to new languages, and experiment with multilingual and language specific BERT models. To create scalar adjective resources in new languages, we could either translate the English datasets or mine adjective scales from starred product reviews as in de Marneffe et al. (2010). Our intention is also to address adjective ranking in full scales (instead of half-scales) and evaluate the capability of contextualised representations to detect polarity.

A Hearst Patterns

Figure 4 illustrates the dependency structure of the following Hearst patterns:

- *[NP] and other [NP]*
- *[NP] or other [NP]*
- *[NP] such as [NP]*
- *Such [NP] as [NP]*
- *[NP], including [NP]*
- *[NP], especially [NP]*
- *[NP] like [NP]*

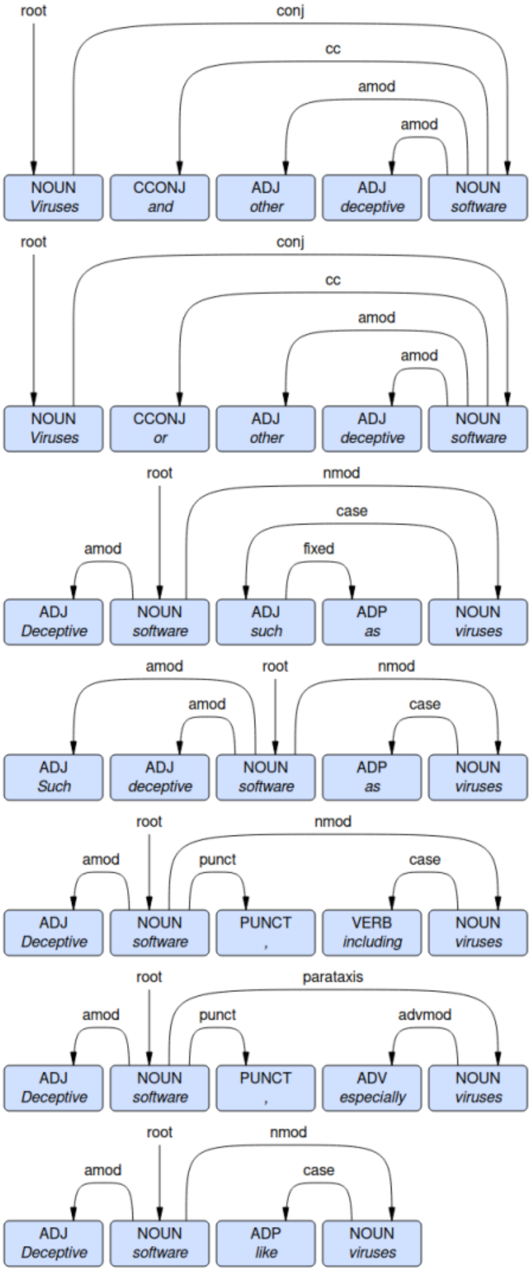

Figure 4: Dependency structure of Hearst patterns.

We use these patterns to detect sentences where adjective substitution should not take place, as described in Section 4.2 of the paper. We remove these sentences from our ukWaC and Flickr datasets.[17]

B Evaluation of Sentence Selection Methods

To identify the most appropriate method for selecting sentences where all adjectives in a scale fit, we use data from the Concepts in Context (CoInCo) corpus (Kremer et al., 2014). CoInCo contains sentences where content words have been manually annotated with substitutes which come with a frequency score indicating the number of annotators who proposed each substitute. We collect instances of adjectives, nouns and verbs in their base form.[18] For a word w, we form instance pairs (w_i-w_j with $i \neq j$) with similar meaning as reflected in their shared substitutes. We allow for up to two unique substitutes per instance, which we assign to the other instance in the pair with zero frequency. We keep instances with n substitutes, where $2 \leq n \leq 8$ (the lowest and highest number of adjectives in a scale). This results in 5,954 pairs.

We measure the variation in an instance pair in terms of substitutes using the *coefficient of variation* (VAR). VAR is the ratio of the standard deviation to the mean and is, therefore, independent from the unit used. A higher VAR indicates that not all substitutes are good choices in a context. We keep the 500 pairs with the highest VAR difference, where one sentence is a better fit for all substitutes than the other. For example, *private*, *individual* and *person* were proposed as substitutes for *personal* in "*personal insurance lines*", but *private* was the preferred choice for "*personal reasons*". The tested methods must identify which sentence in a pair is a better fit for all substitutes.

For sentence selection, we experiment with the three fluency calculation methods presented in Section 4.2: BERTPROB (the BERT probability of each substitute to be used in the place of the [MASK] token); BERTPPX (the perplexity assigned by BERT to the sentence generated through substitution); and CONTEXT2VEC (the cosine similarity between the context2vec representations of a substitute and the context).

We also test VAR and standard deviation (STD) as metrics for measuring variation in the fluency scores assigned to a sentence pair by the three methods. We evaluate the sentence selection methods and variation metrics on the 500 pairs retained from CoInCo. We report their accuracy, calculated as the proportion of pairs where a method correctly guesses the instance in a pair with the lowest variation. We compare results to those of a baseline that always proposes the first instance in a pair. The results in Table 6 show that the task is difficult for

---

[17] Graphs in Figure 4 were created with the visualisation tool available at `https://urd2.let.rug.nl/~kleiweg/conllu/`

[18] This filtering serves to control for morphological variation which could result in unnatural substitutions since CoInCo substitutes are in lemma form.

Method	Variation Metric	Accuracy
BERTPROB	STD	0.524
	VAR	0.488
BERTPPX	STD	0.518
	VAR	0.536
CONTEXT2VEC	STD	**0.594**
	VAR	0.588
1st sentence Baseline		0.506

Table 6: Accuracy of the three fluency calculation methods on the 500 sentence pairs collected from CoInCo. Comparison to a first sentence baseline.

all methods. Their accuracy is slightly higher than the baseline accuracy, which outperforms BERTPROB with VAR. The combination that gives best accuracy is CONTEXT2VEC with STD (0.594). We use this combination of metrics in our experiments.

Table 7 shows examples of sentences retained after this filtering for two adjective scales. CONTEXT2VEC tends to favour sentences where all adjectives in a scale fit well. We also give an example of a sentence randomly selected from ukWaC (Random) for a scale. These sentences usually reflect a frequent sense of a word in the scale.

C Adjustment for Ties

Table 8 contains results of the DIFFVEC method with the adjustment for ties. For two adjacent adjectives (a_i, a_j) in the ranking proposed by DIFFVEC, we check if their cosine similarities to $\overrightarrow{dVec}$ are very close ($diffsim$ = sim($\overrightarrow{dVec}$, $\overrightarrow{a_i}$) - sim($\overrightarrow{dVec}$, $\overrightarrow{a_j}$)). If the absolute value of $diffsim$ $<$ 0.01, we count them as a tie, meaning that a_i and a_j are considered to be situated at the same intensity level. Note that this procedure may give different results when the pairwise comparison starts at different ends of the proposed ranking. We establish ties starting from the a with lowest intensity in the ranking proposed by DIFFVEC.

D DIFFVEC with a Single Sentence

Table 9 contains results for DIFFVEC-1 $(+)$/$(-)$ and DIFFVEC-5 when using a single sentence for building $\overrightarrow{dVec}$.

Scale: *wrong* → *immoral* → *sinful* → *evil*

Method	Corpus	Sentences
context2vec-STD	ukWaC	I believe that war is *immoral*.
	Flickr	This boy was on the *wrong* end of this snowball fight.
Random	ukWaC	The author saw him and let him thru but not his mate as he had queued the *wrong* way.

Scale: *old* → *obsolete* \|\| *outdated*

Method	Corpus	Sentences
context2vec-STD	ukWaC	(...) Chekhov was misunderstood and frequently seen by critics as merely an irreverent recorder of an *obsolete* way of life (...)
	Flickr	Two preschool aged boys are looking at an *old* locomotive.
Random	ukWaC	(...) rustic dialogue and good *old* fashioned laughter (...)

Abstract

Adapting pre-trained language models (PrLMs) (e.g., BERT) to new domains has gained much attention recently. Instead of fine-tuning PrLMs as done in most previous work, we investigate how to adapt the features of PrLMs to new domains without fine-tuning. We explore unsupervised domain adaptation (UDA) in this paper. With the features from PrLMs, we adapt the models trained with labeled data from the source domain to the unlabeled target domain. Self-training is widely used for UDA, and it predicts pseudo labels on the target domain data for training. However, the predicted pseudo labels inevitably include noise, which will negatively affect training a robust model. To improve the robustness of self-training, in this paper we present class-aware feature self-distillation (CFd) to learn discriminative features from PrLMs, in which PrLM features are self-distilled into a feature adaptation module and the features from the same class are more tightly clustered. We further extend CFd to a cross-language setting, in which language discrepancy is studied. Experiments on two monolingual and multilingual Amazon review datasets show that CFd can consistently improve the performance of self-training in cross-domain and cross-language settings.

1 Introduction

Pre-trained language models (PrLMs) such as BERT (Devlin et al., 2019) and its variants (Liu et al., 2019c; Yang et al., 2019) have shown significant success for various downstream NLP tasks. However, these deep neural networks are sensitive to different cross-domain distributions (Quionero-Candela et al., 2009) and their effectiveness will be much weakened in such a scenario. How to adapt PrLMs to new domains is important. Unlike the most recent work that fine-tunes PrLMs on the unlabeled data from the new domains (Han and Eisenstein, 2019; Gururangan et al., 2020), we are interested in how to adapt the PrLM features without fine-tuning. To investigate this, we specifically study unsupervised domain adaptation (UDA) of PrLMs, in which we adapt the models trained with source labeled data to the unlabeled target domain based on the features from PrLMs.

Self-training has been proven to be effective in UDA (Saito et al., 2017), which uses the model trained with source labeled data to predict pseudo labels on the unlabeled target set for model training. Unlike the methods of adversarial learning (Ganin et al., 2016; Chen et al., 2018) and Maximum Mean Discrepancy (MMD) (Gretton et al., 2012) that learn domain-invariant features for domain alignment, self-training aims to learn discriminative features over the target domain, since simply matching domain distributions cannot make accurate predictions on the target after adaptation (Lee et al., 2019; Saito et al., 2017). To learn discriminative features for the target, self-training needs to retain a model's high-confidence predictions on the target domain which are considered correct for training. Methods like ensemble learning (Zou et al., 2019; Ge et al., 2020; Saito et al., 2017) which adopt multiple models to jointly make decisions on pseudo-label selections have been introduced to achieve this goal. Though these methods can substantially reduce wrong predictions on the target, there will still be noisy labels in the pseudo-label set, with negative effects on training a robust model, since deep neural networks with their high capacity can easily fit to corrupted labels (Arpit et al., 2017).

In our work, to improve the robustness of self-training, we propose to jointly learn discriminative features from the PrLM on the target domain to alleviate the negative effects caused by

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7386–7399,
November 16–20, 2020.

noisy labels. We introduce class-aware feature self-distillation (CFd) to achieve this goal (§4.2). The features from PrLMs have been proven to be highly discriminative for downstream tasks, so we propose to distill this kind of features to a feature adaptation module (FAM) to make FAM capable of extracting discriminative features (§4.2.1). Inspired by recent work on representation learning (van den Oord et al., 2018; Hjelm et al., 2019), we introduce mutual information (MI) maximization for feature self-distillation (Fd). We maximize the MI between the features from the PrLM and the FAM to make the two kinds of features more dependent. Since Fd can only distill features from the PrLM, it ignores the cluster information of data points which can also improve feature discriminativeness (Chapelle and Zien, 2005; Lee et al., 2019). Hence, for the features output by FAM, if the corresponding data points belong to the same class, we further minimize their feature distance to make the cluster more cohesive, so that different classes will be more separable. To retain high-confidence predictions, we re-rank the predicted candidates and balance the numbers of samples in different classes (§4.1).

We use XLM-R (Conneau et al., 2019) as the PrLM which is trained on over 100 languages. We also extend our method to cross-language, as well as cross-language and cross-domain settings using XLM-R, since it has already mapped different languages into a common feature space. We experiment with two monolingual and multilingual Amazon review datasets for sentiment classification: MonoAmazon for cross-domain and MultiAmazon for cross-language experiments. We demonstrate that self-training can be consistently improved by CFd in all settings (§5.3). Further empirical results indicate that the improvements come from learning lower errors of ideal joint hypothesis (§4.3,5.4).

2 Related Work

Adaptation of PrLMs. Recently, significant improvements on multiple NLP tasks have been enabled by pre-trained language models (PrLMs) (Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019c; Howard and Ruder, 2018; Peters et al., 2018). To enhance their performance on new domains, much work has been done to adapt PrLMs. Two main adaptation settings have been studied. The first is the same as what we study in this work: the PrLM provides the features based on which domain adaptation is conducted (Han and Eisenstein, 2019; Cao et al., 2019; Logeswaran et al., 2019; Ma et al., 2019; Li et al., 2020). In the second setting, the corpus for pre-training a language model has large domain discrepancy with the target domain, so in this scenario, we need the target unlabeled data to fine-tune the PrLM after which we train a task-specific model (Gururangan et al., 2020). For example, Lee et al. (2020) and Alsentzer et al. (2019) transfer PrLMs into biomedical and clinical domains. Instead of fine-tuning PrLMs with unlabeled data from the new domain as in most previous work (Rietzler et al., 2019; Han and Eisenstein, 2019; Gururangan et al., 2020), we are interested in the feature-based approach (Devlin et al., 2019; Peters et al., 2019) to adapt PrLMs, which does not fine-tune PrLMs. The feature-based approach is much faster, easier, and more memory-efficient for training than the fine-tuning-based method, since it does not have to update the parameters of the PrLMs which are usually massive especially the newly released GPT-3 (Brown et al., 2020).

Domain Adaptation. To perform domain adaptation, previous work mainly focuses on how to minimize the domain discrepancy and how to learn discriminative features on the target domain (Ben-David et al., 2010). Kernelized methods, e.g., MMD (Gretton et al., 2012; Long et al., 2015), and adversarial learning (Ganin et al., 2016; Chen et al., 2018) are commonly used to learn domain-invariant features. To learn discriminative features for DA, self-training is widely explored (Saito et al., 2017; Ge et al., 2020; Zou et al., 2019, 2018; He et al., 2018). To retain high-confidence predictions for self-training, ensemble methods like tri-training (Saito et al., 2017), mutual learning (Ge et al., 2020) and dual information maximization (Ye et al., 2019) have been introduced. However, the pseudo-label set will still have noisy labels which will negatively affect model training (Arpit et al., 2017; Zhang et al., 2017). Other methods on learning discriminative features include feature reconstruction (Ghifary et al., 2016), semi-supervised learning (Laine and Aila, 2017), and virtual adversarial training (Lee et al., 2019). Based on cluster assumption (Chapelle and Zien, 2005) and the relationship between decision boundary and feature representations, Lee et al. (2019) explore class information to learn discriminative features. Class information is also studied in distant supervision learning for relation extraction (Ye et al., 2017). In NLP, early work explores domain-invariant and

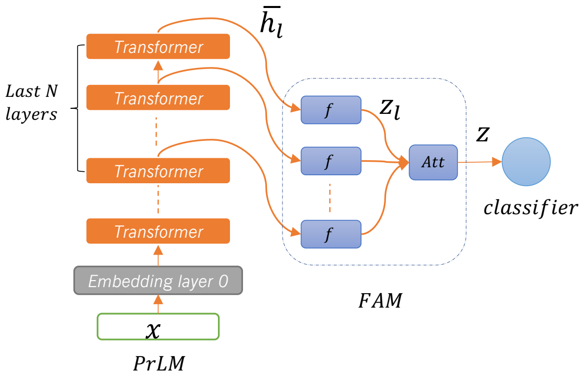

Figure 1: Illustration of our model architecture which includes a pre-trained language model, a feature adaptation module, and a classifier.

domain-specific words to reduce domain discrepancy (Blitzer et al., 2007; Pan et al., 2010; He et al., 2011).

3 Preliminary

In this section, we introduce the problem definition and the model architecture based on which we build our domain adaptation algorithm presented in the next section.

3.1 Unsupervised Domain Adaptation

In order to improve the feature adaptability of pre-trained transformers cross domains, we study unsupervised domain adaptation of pre-trained language models where we train models with labeled data and unlabeled data from the source and target domain respectively. We use the features from PrLMs to perform domain adaptation. Labeled data from the source domain are defined as $S = \{X_s, Y_s\}$, in which every sample $\mathbf{x}_s \in X_s$ has a label $\mathbf{y}_s \in Y_s$. The unlabeled data from the target domain are $T = \{X_t\}$. In this work, we comprehensively study domain adaptation in cross-domain and cross-language settings, based on the features from the multi-lingual PrLM where we adopt XLM-R (Conneau et al., 2019) for evaluation. By using XLM-R, different languages can be mapped into a common feature space. In this work, we evaluate our method on the task of sentiment classification using two datasets.

3.2 Model Architecture

As presented in Figure 1, our model consists of a pre-trained language model (PrLM), a feature adaptation module (FAM), and a classifier.

3.2.1 Pre-trained Language Model

Following BERT (Devlin et al., 2019), most PrLMs consist of an embedding layer and several transformer layers. Suppose a PrLM has $L+1$ layers, layer 0 is the embedding layer, and layer L is the last layer. Given an input sentence $\mathbf{x} = [w_1, w_2, \cdots, w_{|\mathbf{x}|}]$, the embedding layer of the PrLM will encode $\mathbf{x}$ as:

$$\mathbf{h}_0 = \text{Embedding}(\mathbf{x}) \tag{1}$$

where $\mathbf{h}_0 = [\mathbf{h}_0^1, \mathbf{h}_0^2, \cdots, \mathbf{h}_0^{|\mathbf{x}|}]$. After obtaining the embeddings of the input sentence, we compute the features of the sentence from the transformer blocks of PrLM. In layer l, we compute the transformer feature as:

$$\mathbf{h}_l = \text{Transformer}_l(\mathbf{h}_{l-1}) \tag{2}$$

where $\mathbf{h}_l = [\mathbf{h}_l^1, \mathbf{h}_l^2, \cdots, \mathbf{h}_l^{|\mathbf{x}|}]$ and $l \in \{1, 2, \cdots, L\}$. Using all the $|\mathbf{x}|$ features will incur much memory space. After experiments, we take the average of $\mathbf{h}_l$ as:

$$\bar{\mathbf{h}}_l = \frac{1}{|\mathbf{x}|} \sum_{i=1}^{|\mathbf{x}|} \mathbf{h}_l^i \tag{3}$$

and $\bar{\mathbf{h}}_l$ will be fed into the FAM.

3.2.2 Feature Adaptation Module

To transfer the knowledge from the source to the target domain, the features from PrLMs should be more transferable. Previous work points out that the PrLM features from the intermediate layers are more transferable than the upper-layer features, and the upper-layer features are more discriminative for classification (Hao et al., 2019; Peters et al., 2018; Liu et al., 2019b). By making a trade-off between speed and model performance, we combine the last N-layer features from the PrLM for domain adaptation, which is called the multi-layer representation of the PrLM.

Our FAM consists of a feed-forward neural network (followed by a $\tanh$ activation function) and an attention mechanism. We map $\bar{\mathbf{h}}_l$ from layer l into $\mathbf{z}_l$ with the feed-forward neural network:

$$\mathbf{z}_l = f(\bar{\mathbf{h}}_l) \tag{4}$$

Multi-layer Representation. Since feature effectiveness differs from layer to layer, we use an attention mechanism (Luong et al., 2015) to learn to weight the features from the last N layers. We get the multi-layer representation $\mathbf{z}$ of the PrLM as:

$$\begin{aligned} \mathbf{z} = E(\mathbf{x};\theta) &= \sum_{i=L-N+1}^{L} \alpha_i \mathbf{z}_i \\ \alpha_i &= \frac{e^{\tanh(\mathbf{W}_{att}\mathbf{z}_i)}}{\sum_{j=L-N+1}^{L} e^{\tanh(\mathbf{W}_{att}\mathbf{z}_j)}} \end{aligned} \tag{5}$$

in which $\mathbf{W}_{att}$ is a matrix of trainable parameters. Inspired by Berthelot et al. (2019), we want the model to focus more on the higher-weighted layers, so we further calculate the attention weight as:

$$\alpha_i = \frac{\alpha_i^{1/\tau}}{\sum_{j=L-N+1}^{L} \alpha_j^{1/\tau}} \tag{6}$$

where θ is a set of learnable parameters that includes the parameters from the feed-forward neural network and the attention mechanism.

3.2.3 Classifier

After obtaining the multi-layer representation $\mathbf{z}$, we train a classifier with the source domain labeled set S. We define the loss function for the task-specific classifier as:

$$\mathcal{L}_{pred}^{S} = \frac{1}{|S|} \sum_{\langle \mathbf{x},\mathbf{y}\rangle \in S} l\big(g(E(\mathbf{x};\theta);\phi),\mathbf{y}\big) \tag{7}$$

where g is a classifier that takes in the features out of E, and g is parameterized by ϕ. l is the loss function which is cross-entropy loss in our work.

4 Class-aware Feature Self-distillation for Domain Adaptation

In this section, we introduce our method for domain adaptation. Our domain adaptation loss function takes the form of:

$$\mathcal{L} = \mathcal{L}_{pred}^{S} + \mathcal{L}_{pred}^{T'} + \mathcal{L}_{CFd} \tag{8}$$

in which $\mathcal{L}_{pred}^{S}$ is for learning a task-specific classifier with the source labeled set S (Eq. 7), $\mathcal{L}_{pred}^{T'}$ is the self-training loss trained with the pseudo-label set T' (§4.1), and $\mathcal{L}_{CFd}$ is to enhance the robustness of self-training by learning discriminative features from the PrLM (§4.2), which is the main algorithm for domain adaptation in this work.

4.1 Self-training for Adaptation

We build our adaptation model based on self-training, which predicts pseudo labels on unlabeled target data. The predicted pseudo labels will be used for model training. In the training process, we predict pseudo labels on all the target samples in T. To retain high-confidence predictions from T, we introduce a simple but effective method called *rank-diversify* to build the pseudo-label set T' , which is a subset of T:

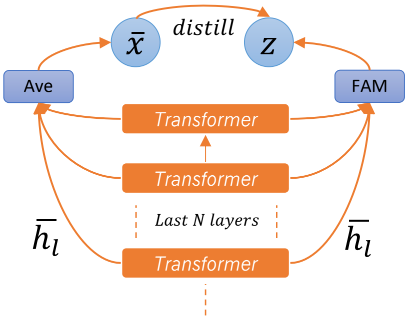

Figure 2: Illustration of feature self-distillation. We take the sum of the last N-layer features for distillation.

Rank. We calculate the entropy loss for every sample in T, specifically:

$$\begin{aligned} g(\mathbf{z}) &= Softmax\big(g(\mathbf{z})\big) \\ \mathcal{L}_e(\mathbf{z}) &= -\sum g(\mathbf{z})^T \log g(\mathbf{z}) \end{aligned} \tag{9}$$

in which $\mathbf{z}$ is the multi-layer feature and g is the classifier in Eq. 7. A lower entropy loss indicates a higher confidence of the model for the pseudo label. Then we use the entropy loss to re-rank T. However, after re-ranking, some classes may have too many samples in the top K candidates, which will bias model training, so we also need to diversify the pseudo labels in the top K list.

Diversify. We classify the samples into different classes with pseudo labels, and re-rank them with entropy loss in ascending order in every class. Samples are selected following the order from every class in turn until K samples are selected.

With the retained pseudo-label set T', we have the loss function for training as:

$$\mathcal{L}_{pred}^{T'} = \alpha \frac{1}{|T'|} \sum_{\langle \mathbf{x},\mathbf{y}\rangle \in T'} l\big(g(E(\mathbf{x};\theta);\phi),\mathbf{y}\big) \tag{10}$$

in which α is a hyper-parameter which will increase gradually in the training process.

4.2 Robust Self-training by Discriminative Feature Learning

To alleviate the negative effects caused by the noisy labels in the pseudo-label set T', we propose to learn discriminative features from the PrLM.

4.2.1 Feature Self-distillation

To maintain the discriminative power of PrLM features, we propose to self-distill the PrLM features into the newly added feature adaptation module (FAM). Similar to traditional knowledge distillation (Hinton et al., 2015), feature distillation in our work is to make the FAM (*student*) also capable of generating discriminative features for adaptation as the PrLM (*teacher*) does. Since the source domain already has the labeled data, there is no need for self-distillation on the source domain, and we apply feature self-distillation (Fd) to the target domain. Inspired by recent work on representation learning (van den Oord et al., 2018; Hjelm et al., 2019; Tian et al., 2020), we propose to use mutual information (MI) maximization for Fd.

MI for Feature Self-distillation. MI measures how different two random variables are. Maximizing the MI between them can reduce their difference. By maximizing the MI between the features from PrLM and FAM, we can make the two features more similar. We are interested in distilling the PrLM features into the multi-layer representation $\mathbf{z}$. We can distill the feature $\bar{\mathbf{h}}_l$ from any layer l into $\mathbf{z}$. However, only distilling one-layer feature of the PrLM may neglect the information from other layers, so we use the sum of the last N-layer features for distillation[1]:

$$\bar{\mathbf{x}} = \sum_{i=L-N+1}^{L} \bar{\mathbf{h}}_i \tag{11}$$

The distillation process is illustrated in Figure 2. Then we maximize the MI $I(\mathbf{z}, \bar{\mathbf{x}})$. We need to find its lower bound for maximization, since it is hard to directly estimate mutual information. Following van den Oord et al. (2018), we also use Noise Contrastive Estimation (NCE) to infer the lower bound as:

$$I(\mathbf{z}, \bar{\mathbf{x}}) \geq \mathcal{J}^{feat}_{NCE}(\mathbf{z}, \bar{\mathbf{x}}) \tag{12}$$

To estimate the NCE loss, we need a negative sample set in which the PrLM features are randomly sampled for the current $\mathbf{z}$. Given a negative sample set $\bar{X}^{neg} = \{\bar{\mathbf{x}}_i^{neg}\}_{i=1}^{|\bar{X}^{neg}|}$, we estimate $\mathcal{J}^{feat}_{NCE}$ as:

$$\mathcal{J}^{feat}_{NCE} = f(\mathbf{z}, \bar{\mathbf{x}}) - \frac{1}{|\bar{X}^{neg}|} \sum_{\bar{\mathbf{x}}_i^{neg} \in \bar{X}^{neg}} f(\mathbf{z}, \bar{\mathbf{x}}_i^{neg}) \tag{13}$$

$f(\mathbf{z}, \bar{\mathbf{x}}^*)$ is the similarity function, defined as:

$$f(\mathbf{z}, \bar{\mathbf{x}}^*) = \cos\big(\inf(\mathbf{z}), \bar{\mathbf{x}}^*\big) \tag{14}$$

where $\bar{\mathbf{x}}^* \in \{\bar{\mathbf{x}}\} \cup \bar{X}^{neg}$; $\inf(\cdot)$ is a trainable feed-forward neural network followed by the $\tanh$ activation, which is to resize the dimension of $\mathbf{z}$ to be equal to $\bar{\mathbf{x}}^*$. To obtain the negative sample set, we select one negative $\bar{\mathbf{x}}$ by randomly shuffling the batch of features which the negative $\bar{\mathbf{x}}$ is in, and this process is repeated $|\bar{X}^{neg}|$ times.

4.2.2 Class Information

Feature distillation can only maintain the discriminative power of PrLM features but ignores the class information present in class labels. To explore the class information, when performing feature self-distillation, we further introduce an intra-class loss to minimize the feature distance under the same class. By giving the pseudo-label set T' and the source labeled set S, we group the multi-layer features out of the FAM into different classes. For every class c, we calculate the center feature as $\mathbf{z}_c$. We define the intra-class loss as follows:

$$\mathcal{L}_{intra\_class} = \sum_{c \in C} \sum_{\mathbf{z}_i \in S_c \cup T'_c} \|\mathbf{z}_i - \mathbf{z}_c\|_2 \tag{15}$$

where C is the set of classes. The center feature $\mathbf{z}_c$ for class $c \in C$ is calculated as:

$$\mathbf{z}_c = \frac{1}{|S_c \cup T'_c|} \sum_{\mathbf{z}_j \in S_c \cup T'_c} \mathbf{z}_j \tag{16}$$

Before training for an epoch, the center features will be calculated and fixed during training. After one epoch of training, the center features will be updated. After the above analysis, our final CFd loss becomes:

$$\begin{aligned}\mathcal{L}_{CFd} = \mathcal{L}^{T}_{Fd} + \mathcal{L}^{S,T'}_{C} &= -\sum_{\mathbf{x} \in T} \mathcal{J}^{feat}_{NCE}(E(\mathbf{x};\theta), \bar{\mathbf{x}}) \\ &+ \lambda \sum_{\langle \mathbf{x}, \mathbf{y} \rangle \in S \cup T'} \mathcal{L}_{intra\_class}\end{aligned} \tag{17}$$

where λ is a hyper-parameter which controls the contribution of $\mathcal{L}^{S,T'}_{C}$.

4.3 Analysis

We provide a theoretical understanding for why CFd can enhance self-training based on the domain adaptation theory from Ben-David et al. (2010).

Theorem 1. (Ben-David et al., 2010) *Let $\mathcal{H}$ be the hypothesis space. With the generalization error δ_s and δ_t of a classifier $G \in \mathcal{H}$ on the source S and target T, we have:*

$$\delta_t(G) \leq \delta_s(G) + d_{\mathcal{H}\Delta\mathcal{H}}(S, T) + \epsilon \tag{18}$$

in which $d_{\mathcal{H}\Delta\mathcal{H}}$ measures the domain discrepancy and is defined as:

$$\begin{aligned} d_{\mathcal{H}\Delta\mathcal{H}}(S, T) = \sup_{h, h' \in \mathcal{H}} \big| &\mathbb{E}_{\mathbf{x} \in S}[h(\mathbf{x}) \neq h'(\mathbf{x})] \\ &- \mathbb{E}_{\mathbf{x} \in T}[h(\mathbf{x}) \neq h'(\mathbf{x})]\big| \end{aligned} \tag{19}$$

---

[1] Based on Eq.14, taking the sum or average of the last N-layer features will have the same effect.

Table 1: The cross-domain classification accuracy (%) results on MonoAmazon. Models are evaluated by 5 random runs except xlmr-tuning which is run for 3 times. We report the mean and standard deviation results. Best task performance is boldfaced. Results of DAS are taken from He et al. (2018).

DATA	train (S)	valid (S)	test (T)	unlabeled (T)	$\|C\|$
MonoAmazon	5,000	1,000	6,000	6,000	3
MultiAmazon	2,000	2,000	2,000	8,000	2

Table 2: The data splits for the experiments. $|C|$ is the number of classes. $(\cdot)$ denotes the domain which the data comes from.

and ϵ is the error of the ideal joint hypothesis which is defined as:

$$\epsilon = \delta_s(h^*) + \delta_t(h^*) \tag{20}$$

where $h^* = \arg\min_{h \in \mathcal{H}} \delta_s(h) + \delta_t(h)$.

From Ineq. 18, the performance of domain adaptation is bounded by the generalization error on the source domain, domain discrepancy, and the error of the ideal joint hypothesis (joint error). Self-training aims to learn a low joint error by learning discriminative features on the target domain, so that the adaptation performance can be improved (Saito et al., 2017). Our proposed CFd enhances the robustness of self-training by self-distilling the PrLM features and exploring the class information. In this way, the joint error can be further reduced compared to self-training (Fig. 3). Besides, by optimizing the intra-class loss, $d_{\mathcal{H}\Delta\mathcal{H}}$ in Ineq. 18 can be reduced since under the same class, the feature distance of samples from both the source and target domain is minimized (Fig. 4).

5 Experiments

5.1 Datasets

We use two Amazon review datasets for evaluation. One is monolingual and the other is multilingual.

MonoAmazon. This dataset consists of English reviews from He et al. (2018) and has four domains: Book (BK), Electronics (E), Beauty (BT), and Music (M). Each domain has 2,000 positive, 2,000 negative, and 2,000 neutral reviews.

MultiAmazon. This is a multilingual review dataset (Prettenhofer and Stein, 2010) in English, German, French, and Japanese. For every language, there are three domains: Book, Dvd, and Music. Each domain has 2,000 reviews for training and 2,000 for test, with 1,000 positive and 1,000 negative reviews in each set. 6,000 additional reviews form the unlabeled set for each domain. The source domains are only selected from the English corpus.

Table 2 shows the data split. To construct the unlabeled set for the target domain, we use reviews from the test set as the unlabeled data in MonoAmazon following He et al. (2018). For MultiAmazon, reviews from the training set and original unlabeled set both from the target domain are combined.

We also evaluate our model on the benchmark dataset of (Blitzer et al., 2007). The results are presented in Appendix B.

5.2 Experimental Setup

Model Settings. To enable cross-language transfer, we use XLM-R[2] (Conneau et al., 2019) which has 25 layers as the pre-trained language model. The dimension of its token embeddings is 1024 which is mapped into 256 by the FAM. Based on one transfer result, the last 10-layer features are used in FAM. λ for intra-class loss is set as 1 and 2 for MonoAmazon and MultiAmazon respectively. We set the size of negative sample set as 10 and we perform Fd training only in the target domain. τ for attention mechanism in Eq. 6 is set as 0.3. In the training process, we gradually increase the number of retained pseudo labels for self-training, in which we increase the number by 100 for MonoAmazon and 300 for MultiAmazon every epoch. α for $\mathcal{L}_{pred}^{T'}$ is the linear and quadratic function of epoch for MonoAmazon and MultiAmazon respectively. More details of the experimental settings are in Appendix A.

Table 3: The classification accuracy (%) results on MultiAmazon. Models are evaluated by 5 random runs except xlmr-tuning which is run for 3 times. Results of CLDFA and MAN-MoE are taken from Xu and Yang (2017) and Chen et al. (2019) respectively. More detailed transfer results are included in Appendix D.

Baselines. Since we are interested in adapting features of PrLMs without tuning, we mainly set up the baselines that use the features from XLM-R by freezing XLM-R. Trained on the source domain, **xlmr-1** directly tests on the target without domain adaptation and it only uses the last-layer features of XLM-R. **xlmr-10** is the same as xlmr-1, except that it uses the multi-layer representation of XLM-R with last 10-layer features. **KL** (Zhuang et al., 2015) uses the balanced Kullback-Leibler divergence loss to decrease the domain discrepancy for domain adaptation. **MMD** adopts the Maximum Mean Discrepancy loss (Gretton et al., 2012) in which Gaussian Kernel is implemented. **Adv** (Ganin et al., 2016; Chen et al., 2018) adversarially trains a domain classifier to learn domain-invariant features by reversing the gradients from the domain classifier following Ganin et al. (2016). **p** is our self-training method introduced in §4.1. **p+CFd** is our full model that uses CFd to enhance the robustness of self-training. **DAS** (He et al., 2018) uses semi-supervised learning. **CLDFA** (Xu and Yang, 2017) is a cross-lingual baseline which uses cross-lingual resources. **MAN-MoE** (Chen et al., 2019) studies multi-lingual transfer which has multiple languages in the source domain. MoE learns to focus on more transferable source domains for adaptation. xlmr-10, KL, MMD, Adv, p, and p+CFd are all based on the multi-layer representations with last 10-layer features. For KL, MMD, and Adv, to minimize domain discrepancy, we use an unlabeled set of the same size in the source domain as the target domain.

xlmr-tuning[3] first fine-tunes XLM-R with source labeled data using the representation from the final layer [CLS] and being fed to the classifier (Devlin et al., 2019), then tests on the target. By setting up this baseline, we want to see how well the feature-based approach works.

More detailed baseline settings can be found in Appendix A.3.

5.3 Main Results

We conduct experiments in cross-domain (CD), cross-language (CL), and both cross-language and cross-domain (CLCD) settings. Results of CD are evaluated on MonoAmazon (Table 1) and results of CL and CLCD are on MultiAmazon (Table 3). For CL, English is set as the source language. The domains in the source and target languages are the same, i.e., When German&book is the target, the source will be English&book. For CLCD, the sources are also only from English. For example, when the target is German&book, the source language is English and the source domain is dvd or music, in which two sources are set up: English&dvd and English&music, and the two adaptation results are averaged for German&book.

---

[3] Because of the limited computing resources, we cannot fine-tune XLM-R with unlabeled target data using LM loss.

Table 4: The classification accuracy (%) results of p+CFd and its ablations on MonoAmazon.

We have the following findings from Table 1 and 3 based on the overall average scores. **xlmr-10 vs. xlmr-tuning:** xlmr-10 is slightly better than xlmr-tuning which demonstrates the effectiveness of the feature-based approach. **xlmr-1 vs. xlmr-10:** xlmr-10 is much better than xlmr-1 which means our multi-layer representation of XLM-R is much more transferable than the last-layer feature. **xlmr-10 vs. p:** p is consistently better than xlmr-10 which shows our self-training method is effective. **p vs. p+CFd:** After using CFd, p can be consistently improved and p+CFd achieves the best performance among all the methods, which shows the effectiveness of CFd.

5.4 Further Analysis

Ablation Study. We conduct the ablation experiments to see the contributions of feature self-distillation (Fd) and class information (C), which are evaluated on MonoAmazon based on last 10-layer features. By ablating p+CFd, we have four baselines of p+C (w/o Fd), p+Fd (w/o C), CFd (w/o p) and Fd (w/o p+C). From the results in Table 4, p+Fd and p+C perform worse than p+CFd but still better than p, so feature self-distillation and class information both contribute to the improvements of p. Also, by removing the effects of p, CFd and Fd substantially outperform xlmr-10, which means CFd and Fd are both effective for domain adaptation, independent of the self-training method.

Joint errors. Here we study why CFd can enhance self-training and provide empirical results to demonstrate the theoretical understanding in §4.3. By testing on MonoAmazon based on last 10-layer features, Figure 3 presents the joint error results. For example, to find h^* in Eq. 20 for baseline p, following Liu et al. (2019a), we train a classifier using the combined source and target labeled data based on the fixed FAM trained by p. We note that p+Fd and p+C can achieve lower joint errors compared to p, and p+CFd has the best performance, which is consistent with our analysis in §4.3.

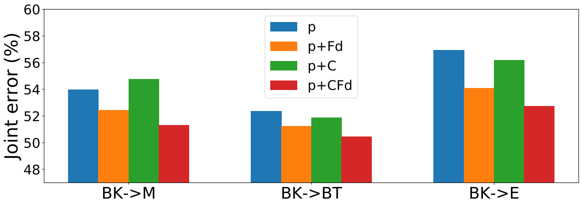

Figure 3: The errors of ideal joint hypothesis tested on MonoAmazon.

METHOD	M→BK	BK→E	M→E	BK→BT	M→BT	BK→M	Ave.
Super	77.54	74.56	74.08	75.66	75.48	72.88	75.03
Fd	76.34	72.44	72.44	74.35	73.15	74.12	73.81

Table 5: The classification accuracy (%) results of in-domain test evaluated on MonoAmazon.

Effects of Feature Self-distillation. We conduct an in-domain test to verify that Fd learns discriminative features from the PrLM. We build a sentiment classification model with in-domain data based on the last 10-layer features. From the same domain in MonoAmazon, we select 4,000 labeled pairs for training, 1,000 for validation, and 1,000 for test. We first pre-train the FAM by Fd using the entire 6,000 raw texts, then we freeze FAM and train a classifier with the training data with features out of FAM. We compare the results with the baseline that directly trains the FAM and classifier with training set (Super). From the results in Table 5, the performances of Fd are very close to Super, showing that the features out of FAM after Fd training are discriminative.

Effects of Class Information. Table 6 presents the average intra-class loss in the training process. By exploring class information, the intra-class loss can be dramatically minimized and accordingly the transfer performances are improved.

$\mathcal{A}$-distance. As an indicator of domain discrep-

BK→M	p	p+C	p+Fd	p+CFd
$\mathcal{L}_{intra\_class}$	966.38	**11.00**	327.72	**12.17**
Acc. (%)	66.59	**68.88**	70.16	**70.95**

Table 6: Effects of class information tested on MonoAmazon with last 10-layer features.

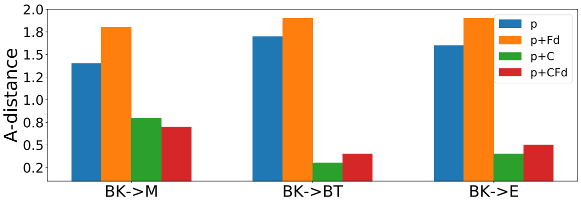

Figure 4: The $\mathcal{A}$-distance tested on MonoAmazon.

METHOD	One layer	last-10		last-20	
		AVE	ATT	AVE	ATT
BK→M	69.51	69.20	**70.07**	66.62	69.31
BK→BT	69.27	67.62	**69.34**	64.16	69.02
BK→E	66.35	64.62	66.71	62.90	**67.08**

Table 7: Study of our attention mechanism based on Fd baseline and tested on MonoAmazon.

ancy, following Saito et al. (2017), we calculate the $\mathcal{A}$-distance based on the last 10-layer features out of FAM trained by method of p or others, and train a classifier to classify the source and target domain data. $d_{\mathcal{A}}$ is equal to $2(1-\delta)$ and δ is the domain classification error. From Figure 4, p+C and p+CFd have much smaller $\mathcal{A}$-distance, which means that the intra-class loss reduces the domain discrepancy. p+Fd has larger $\mathcal{A}$-distance, probably because Fd learns domain-specific information from the target so the domain distance becomes larger.

Effects of Attention Mechanism. We further show whether combining the intermediate-layer features can enhance adaptation. In Table 7, one layer means only using one-layer features for transfer and the results are obtained by using the feature from the most transferable layer. We introduce the attention mechanism to combine the last N-layer features. We demonstrate that using last 10-layer features with attention can achieve better performances. AVE that averages the last N-layer features cannot improve the performance, since it lacks the ability to focus more on effective features.

We also study how the size of negative sample set affects feature distillation and the effects of sharpen on attention mechanism. The analysis is included in Appendix C.

6 Conclusion

In this paper, we study how to adapt the features from the pre-trained language models without tuning. We specifically study unsupervised domain adaptation of PrLMs, where we transfer the models trained in labeled source domain to the unlabeled target domain based on PrLM features. We build our adaptation method based on self-training. To enhance the robustness of self-training, we present the method of class-aware feature self-distillation to learn discriminative features. Experiments on sentiment analysis in cross-language and cross-domain settings demonstrate the effectiveness of our method.

A Experimental Settings

A.1 Datasets

We obtain the datasets from He et al. (2018) which can be downloaded online[4]. Then we follow He et al. (2018) to pre-process the datasets which only involves splitting the data into training, validation, and test sets.

A.2 Model Configuration

For MonoAmazon, the learning rate is 0.0001, and the batch size is 50 for classifier training and MI learning. We run 35 times for each baseline except xlmr-1 and xlmr-10 which are run 20 times and the batch size is 100. In epoch 0, we set to retain the top 950 high-confidence predictions for self-training and we increase the number of retained data by 100 every epoch. λ for Fd training is 1.

For MultiAmazon and Benchmark, the learning rate is 0.0005. The batch size for classifier learning is 50 and for MI training is 200. The training epoch is 20. λ for MultiAmazon and Benchmark is 2. In epoch 0, we set to retain the top 1000 high-confidence predictions for self-training. We increase by 150 retained samples every epoch for Benchmark, and by 300 for MultiAmazon.

α for $\mathcal{L}_{pred}^{T'}$ is the linear function of epoch for MonoAmazon, and the quadratic function for MultiAmazon and Benchmark. Adam (Kingma and Ba, 2015) is used for model training. In the training process, if the validation performance does not improve after 10 consecutive epochs, the learning rate will be halved.

For all the datasets, the size of negative sample set is set as 10. τ for attention mechanism is set as 0.3, tuned from $\{0.1, 0.3, 0.5, 0.8, 1.0\}$.

---

[4] `https://github.com/ruidan/DAS`

parameter	MonoAmazon	MultiAmazon	Benchmark
learning rate	0.0001	0.0005	0.0005
λ	1	2	2
α	linear function of epoch	quadratic function of epoch	quadratic function of epoch
Max epoch	35	20	20
Size of negative sample set	10	10	10

Table 8: Hyper-parameter settings for main experiments.

DATA	train (S)	valid (S)	test (T)	unlabeled (T)	$\|C\|$
Benchmark	1,600	400	400	6,000	2

Table 9: The data split for training, validation, test, and unlabeled set on Benchmark. $|C|$ is the number of classes.

A.3 Settings for Baselines

KL. The KL-divergence loss (Zhuang et al., 2015) is defined as:

$$\mathrm{KL} = D_{KL}(\xi_s || \xi_t) + D_{KL}(\xi_t || \xi_s) \tag{21}$$

where

$$\begin{aligned} \xi'_s &= \frac{1}{n}\sum_{i=1}^{n} \mathbf{z}_s^i \quad \xi_s = softmax(\xi'_s) \\ \xi'_t &= \frac{1}{n}\sum_{i=1}^{n} \mathbf{z}_t^i \quad \xi_t = softmax(\xi'_t) \end{aligned} \tag{22}$$

in which n is the batch size. We set the weight of KL loss as 500, tuned from {100, 500, 1000, 5000}.

MMD. We use the Gaussian kernel to implement the MMD loss (Gretton et al., 2012). The kernel number is 5. The weight for MMD loss is set to 1, tuned from {1, 0.1, 0.5}

Adv. We follow Ganin et al. (2016) to reverse the gradients from the domain classifier. We set the learning rate for Adv to be the same as the baselines, but set the weight for domain classifier as 0.01, tuned from {1, 0.1, 0.01, 0.001}.

xlmr-tuning. The fine-tuning baseline uses the first [CLS] token as the document representation. The learning rate is 1e-5 and the batch size for gradient update is 32. The fine-tuning models generally overfit the training data in 5 epochs.

B Results on Benchmark

Benchmark. This is a benchmark dataset for domain adaptation (Blitzer et al., 2007), whose reviews are also in English. Four domains are included: Book (B), DVDs (D), Electronics (E), and Kitchen (K). Each domain has 1,000 positive and 1,000 negative reviews. Following He et al. (2018), there are 4,000 unlabeled reviews for each domain. Table 9 summarizes the data split when training on Benchmark. The unlabeled set is the combination of the training set and the original unlabeled set. Table 10 shows the results on Benchmark.

C Further Analysis

Size of Negative Sample Set. We study how the size of negative sample set will affect Fd training. The results are shown in Fig. 5. The method used is xlmr-10+Fd. We find that using a size that is too small or too big is not a good strategy for Fd learning. Size of 10 is a good option for Fd learning.

Effects of Sharpen on Attention Mechanism. In Fig. 6, we show the effects of sharpen mechanism in our attention method which demonstrates that when not using sharpen (τ is ∞), the performance will drop and τ set as 0.3 is a good option for our attention method.

D Full Results on MultiAmazon

Table 11 shows the full results on MultiAmazon.

Abstract

In this paper we propose a novel data augmentation approach where guided outputs of a language generation model, e.g. GPT-2, when labeled, can improve the performance of text classifiers through an active learning process. We transform the data generation task into an optimization problem which maximizes the usefulness of the generated output, using Monte Carlo Tree Search (MCTS) as the optimization strategy and incorporating entropy as one of the optimization criteria. We test our approach against a Non-Guided Data Generation (NGDG) process that does not optimize for a reward function. Starting with a small set of data, our results show an increased performance with MCTS of 26% on the TREC-6 Questions dataset, and 10% on the Stanford Sentiment Treebank SST-2 dataset. Compared with NGDG, we are able to achieve increases of 3% and 5% on TREC-6 and SST-2.

1 Introduction

Active learning (AL) is a well applied approach in areas where unlabeled data is abundantly available, but labels are either scarce or costly to obtain (Settles, 2009). In AL, a classifier is improved upon through an iterative learning process; at each cycle, a subset of the original dataset with the most informative examples is selected to be labeled, typically by a human expert, before it is then added to the existing training data (Settles, 2009).

Previous active learning research on textual data to our knowledge has always assumed the availability of datasets containing large pools of unlabeled data. In cases where the available data is insufficient for active learning, the burden is transferred to the data collection process, where additional data must either be manually created, or collected from real world interactions. One strategy for creating data is to transform existing examples in certain ways in order to produce new data items and hence increase the size of the training dataset. This approach has been applied successfully in computer vision for example, by manipulating existing images while preserving the label to create additional data points (Shorten and Khoshgoftaar, 2019). However, in NLP, augmenting data is a very difficult task due to the complex nature of language (Wei and Zou, 2019). In this paper we assume a real-life scenario where the data at hand is insufficient for running a typical active learning algorithm. We introduce a method that enables us to automatically generate artificial text examples that complement an existing dataset. Our approach minimizes the human factor in data creation by automating the process through a guided searching procedure.

Once a set of examples is generated, it is required to be manually labeled before it is added to the original training set. The classifier is then retrained on the new, augmented training set. This procedure is repeated multiple times until the desired performance is either achieved or until performance no longer improves. We do this in active learning cycles, where only a subset of the generated data is used; this involves selecting examples in terms of how much information they would add to an existing classifier. In our experiments we use entropy as a measure of informativeness.

As our aim is to find the most informative examples, we tackle this problem by applying a search approach. Given that text examples are generated from an extremely large number of possible combinations, we apply the Monte Carlo Tree Search MCTS algorithm (Browne et al., 2012) to limit the

search space. Here MCTS is expected to guide a language generation model to output informative examples. In this context, MCTS assigns values to previously generated examples using a scoring function that incorporates the learning classifier of the previous active learning cycle, starting with a baseline classifier trained on the initial dataset for the first active learning run. In our experiments, we test MCTS with two different scoring functions: one that only measures the uncertainty of the generated examples through entropy, and another that combines the measure of uncertainty with a measure of diversity by computing the cosine similarity of every newly generated example with the previous content. These scores determine the text premise that is passed to the language model when generating newer examples.

We compare MCTS to Non-Guided Data Generation (NGDG), an approach where the knowledge of the learning classifier is not involved in the data generation process. Here, for each newly generated example, the text premise is always a token representing the beginning of a sentence, <bos>.

The remainder of this paper is organized as follows; Section 2 provides a background as well as an overview of related literature. Section 3 describes the proposed approach. Section 4 presents the experiments which were carried out. Section 5 gives conclusions and plans for future work.

2 Background

2.1 Active Learning

In this paper we consider the pool-based AL model, a commonly adapted approach in text classification problems (Hu et al., 2016; Krithara et al., 2006; Tong and Koller, 2001; Nigam and McCallum, 1998). This approach assumes the availability of all the data from the beginning of the process. We start with a set of data S_D, where a large pool of it is unlabeled S_U, leaving only a small subset S_L with labels $l_1, l_2, .., l_n \in L$. Hence, $S_D = S_U + S_L$. A classifier is first trained on S_L. Then, at each AL iteration, a selection strategy is applied to select a pool of data S_P from S_U to be labeled by the expert. Examples in S_P are chosen on the basis of being the most informative of S_U, such that, if added to the training data, an improvement in the classifier's performance is to be expected.

As described by Yoo and Kweon (2019); Siddiqui et al. (2019), there are three main selection strategies that can be applied to obtain S_P: uncertainty-based approaches, diversity-based approaches, and expected model change. In an uncertainty-based selection strategy, the active learner chooses the examples that it is most uncertain about. This assumes a probabilistic framework where the learner predicts a probability distribution $P = (p_1, p_2, ..., p_n)$ for labels $L = (l_1, l_2, ..., l_n)$ for a given example $e_i \in S_U$. In a binary classification setting, Lewis et al. presume that the most uncertain examples have a posterior probability closest to 0.5 for any label $l_i \in \{0, 1\} \forall i$ (Lewis and Gale, 1994; Lewis and Catlett, 1994). In a multi-class setting, a selection strategy could choose examples with the lowest posterior probability or be based on entropy (eq. 5) as in (Hwa, 2004; Settles and Craven, 2008; Joshi et al., 2009). Given that the difference in degree of certainty for similar examples can be small, uncertainty selections are prone to return similar examples (Wang et al., 2017). To address this issue, some works incorporate measures to exploit the diversity information of the examples in the selection process (Sener and Savarese, 2017; Wang et al., 2017; Sinha et al., 2019). Finally, expected-model change selects examples that would cause the greatest change to a model's output if their labels were known (Freytag et al., 2014; Roy and McCallum, 2001; Settles et al., 2008). This approach however, can be computationally expensive for big data and large feature spaces (Settles, 2009). Hence, this approach has not been very successful with deep learning models (Siddiqui et al., 2019).

In sum, research on active learning has focused on applications where a large pool of unlabeled data already exists. However, we are interested in real-life scenarios where this data may not be available. Other approaches such as Snorkel[1] use heuristics to generate data (Ratner et al., 2017) but this can prove impractical for text. In this paper we consider the case were the number of available data S_D is extremely small, so that typical active learning approaches become inapplicable due to the absence of S_U. Our aim is to generate synthetic data for S_U that can then be queried by an active learning algorithm to select an informative subset S_P for labeling. The selection process we apply can be classed as an uncertainty approach, except for the Diversity-Based MCTS (described in section 3.1.4) which incorporates a similarity check that could also be classed as a diversity approach.

2.2 Language Models

The year 2018 proved to be an exceptional one for the NLP community as research shifted rapidly from pretrained shallow embeddings to more complex pretrained language models adopted from the computer vision field. This is evident in developments such as Embeddings from Language Models (ELMO) (Peters et al., 2018), Universal Language Model Fine-tuning for Text Classification (ULMFIT) (Howard and Ruder, 2018), generative pretraining (Radford et al., 2018), Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2018) and many more.

In the same year, OpenAI released a transformer-based language model, GPT (Radford et al., 2018), which was trained with a traditional language modeling approach by predicting the next word in a sequence. In language modeling, the objective is to estimate the probability of a next token in a sequence conditioned on the context tokens (Bengio et al., 2003). In a unidirectional training approach such as GPT-2, the context is the history or past tokens. The probability of the sequence for tokens $w = w_1, ..., w_n$ can be defined as:

$$p(w) = \prod_{i=1}^{i=n} p(w_{(i)} | w_{(1)}, \ldots, w_{(i-1)}) \tag{1}$$

As such, given a set of sentences as input, the objective of the language model is to find the parameters θ that maximize the log-likelihood:

$$\theta^* = \arg\max_{\theta} \{\log p(w; \theta)\} \tag{2}$$

This training procedure did not give GPT the edge over other state-of-the-art models like BERT on classification tasks, possibly due to BERT taking advantage of a bidirectional architecture. However, this did not stop OpenAI's GPT from prevailing in other departments. As it turns out, compared to BERT, GPT is able to generate text sequences of higher quality (Wang and Cho, 2019). In 2019, OpenAI released a successor, GPT-2 (Radford et al., 2019) that included slight adjustments to the original GPT model and was trained on larger data collections. Although its architecture was very similar to its predecessor, GPT-2 presented significant progress in language generation. The main contribution of GPT-2 was its ability to scale up training parameters from 110 Million to 1.5 Billion. In our experiments we were able to achieve satisfactory results with the smallest version of the GPT-2 model; 12 hidden layers and 124M parameters.

2.3 Monte Carlo Tree Search MCTS

MCTS is a tree search method that attempts to find compelling solutions without having to run to completion. It does so by walking through random paths in the search space while constructing a tree using the results of a predefined reward function. Due its ability to find paths leading to an optimal solution when the search space is infinitely large, MCTS has been widely adopted by the AI gaming community (Arneson et al., 2010; Perez et al., 2013; Chang et al., 2016).

The longer MCTS runs, the stronger its moves get. This is because it manages to balance between two main criteria: exploring new search paths and exploiting paths that have been already explored. MCTS consists of four major steps: Selection, Expansion, Simulation, and Backpropagation (Chaslot et al., 2008). When applied to board games, MCTS constructs a tree to determine a winning strategy. In this setting, a node represents a board position, an edge represents a move, and a path represents a sequence of moves.

Selection: Starting from a root node R, the algorithm selects a move that leads to a node N that has no identified children. On the one hand, the selected move could be random, ignoring the scores of already visited paths; in this case, some paths are not visited. On the other hand, the selected move could be completely based on already visited nodes (e.g. by storing average wins for each node); here, the algorithm might miss other nodes that could lead to higher win rates. In order to balance between the benefits of exploration and exploitation, a selection policy such as the Upper Confidence Bound (UCB) can be used (Auer et al., 2002). UCB makes sure that as many nodes as possible are explored while still favouring branches that are visited more often than their counterparts. The selection is then done by choosing the nodes with the highest UCB value. In our implementation, given that the scoring criterion is an entropy value ranging between 0 and 1, we apply a small adjustment to the vanilla UCB policy, described in section 3.1.1:

$$UCB = \frac{W_i}{S_i} + C\sqrt{\frac{2 \times lnS_p}{S_i}} \tag{3}$$

where W_i is the number of simulations generated from node i which resulted with a win, S_i the total number of simulations generated from node i, S_p

the total number of simulations generated from the parent node, and C an exploration parameter.

Expansion: In this phase, a new child node is added to the node selected in the previous step. This new node is based on a random selection of one of the possible moves. The values for this new node are initialized to 0 wins out of 0 simulations where $W_i = 0$ and $S_i = 0$.

Simulation (Roll-out): A simulation is run from the root node R until a terminal node T is found. The terminal node will output a value that is then passed upwards in the backpropagation phase.

Backpropagation: A simulation stops when a terminal node T is reached. The values for each node leading to T are then updated by adding 1 to the number of visits S_i and number of wins W_i.

2.4 Related Work

In previous work, our group applied a similar framework to a private dataset, where instead of GPT-2, a recurrent neural network was used to generate words, and the reward function was solely based on entropy (Sankarpandi et al., 2019). Furthermore, experiments were based on a much larger initial training set, and there was an added burden on the user to manually correct ill-formed outputs. To our knowledge, the next closest work to ours is Anaby-Tavor et al. (2019), where GPT-2 and a classifier are applied to generate new weakly-labeled examples. This process involves fine-tuning GPT-2 on existing training examples while providing the class labels as part of the input. Examples are then selected and kept as training data based on the classifier's confidence score. Kumar et al. (2020) further explores this approach with different transformer based models (Vaswani et al., 2017) for data generation. This approach however, relies on GPT-2 to provide weak labels as it generates data. It also does not employ a guided search to generate the best examples at a given stage. By excluding the process of generating weak labels, this approach could be considered analogous to our Non-Guided Data Generation method in section 4.2.

Other data augmentation work in NLP relies on generating examples that are simply different forms of the existing text. Two approaches are word manipulation and the use of back-translations. Word manipulation involves techniques like randomly swapping words, replacing words with their synonyms, or deleting random words (Wei and Zou, 2019). In the same vein, Wang and Yang (2015) randomly replace words with neighboring ones from an embedding space. Kobayashi (2018) uses a bidirectional language model to randomly replace words with alternatives. Here the language model is fed the sentence input excluding the word at position x, to predict an alternative word at position x. Another word replacement approach is applied by Wang et al. (2018b) in a machine translation task, where words in both the source and target sentence are replaced with other random words. In back-translation, also known as round-trip translation (Aiken and Park, 2010), an input text is translated into an intermediate language and then the result is translated back to the original language. This technique is applied in the works of Sennrich et al. (2015); Aroyehun and Gelbukh (2018).

3 Proposed Method

In games, MCTS can be applied to predict moves in order to counter an opponent's strategy so that a winnable state is reached. However, text generation is more similar to a single player scenario, where decisions are based on which token to select when moving from one state to the other.

A language model calculates a probability distribution over a sequence of words. When passing over a stream of text, each vocabulary token is assigned a probability score for occurring next. Hence, tokens with higher probability scores are more likely to appear next in the sequence. In our setting, we are interested in multiple token candidates for all remaining words in the sequence. To achieve this we use a top-k sampling scheme as used by Fan et al. (2018). At each time step, each token in the vocabulary is assigned a probability score for coming next in the sequence. To get the top k candidates, vocabulary tokens are sorted by their probability scores and anything below the k'th token is then zeroed out. The probability mass is then redistributed among the k token candidates.

This process can be modeled as a tree where each node represents a token linked to k child nodes representing the top k candidate tokens that are likely to appear next in the sequence. Hence, this is similar to a board game where each board position is represented by a node: The root node corresponds to an empty board while a terminal node is where no further moves can be made. In our setting, we use a special token for both the root and terminal nodes. We represent the starting token with <bos>

and the ending token with <eos>.

As an example, a language model that is fine-tuned on a survey on pet adoption could be used to generate the tree of predictions in Figure 1. A full version of this tree would represent all the possible combinations of text that can be generated by the language model. In an ideal setting, we would search this tree for the paths that represent the most informative examples. However, given that the tree will grow exponentially as the number of next token candidates is increased, it would be computationally expensive to apply a brute force search algorithm where every path is examined. For this reason, we apply the Monte Carlo Tree Search (MCTS) algorithm in the data generation process, as discussed next.

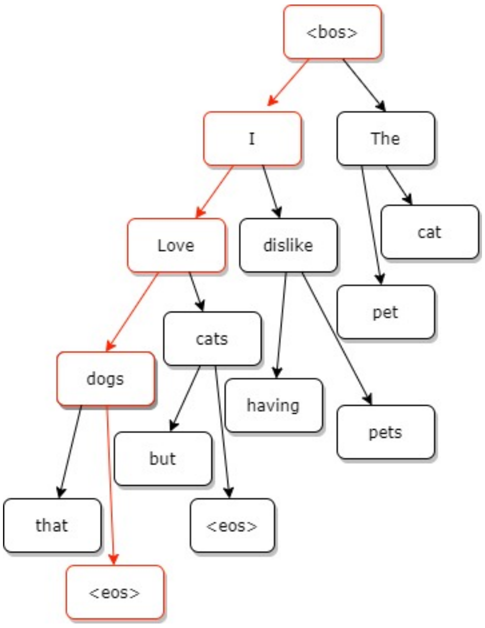

Figure 1: MCTS traverses down the tree as it creates paths spanning from the root node <bos> until a terminal node <eos> is reached. Tokens of the same path form a sentence when concatenated e.g. the path in red.

3.1 MCTS for Data Generation

In a typical MCTS application, a separate tree is formed for every decision. Applying this to our approach would require us to build a tree for each next word in the sequence. This would be computationally expensive due to the overhead of generating candidates and computing reward values. An alternative would be to construct a single tree only, while allowing MCTS to run for a longer period. This would result in a tree where each path is a possible output. However, given the nature of MCTS where the paths generated in the roll-out phase are not stored, we would be left with many incomplete paths which did not reach a terminal node (see Figure 1). To account for this, we keep track of all the simulations without impacting the selection policy. Thus we still have the same tree as in Figure 1, but we also have a record of the paths generated from non-terminal leaf nodes. The Selection, Expansion, Simulation and Backprogation phases for each MCTS iteration are described in the following sections.

3.1.1 Selection

The vanilla UCB function is mostly adopted in strategies where the outcome is chosen from a fixed set of categorical values, win, lose or tie. The objective is to reach a winnable state with the minimum number of visits. This is reflected in the UCB equation (eq. 3). By contrast, our purpose is to maximize the importance of nodes that lead to higher reward values (section 3.1.4), as shown in eq. 4, adopted from Chaudhry and Lee (2018):

$$UCB = max(N_i) + C\sqrt{\frac{2 \times lnS_p}{S_i}} \tag{4}$$

where $max(N_i)$ is the maximum reward at node i, C is an exploration constant, S_i is the total number of visits to node i, and P_i is the total number of visits to the parent node for node i.

3.1.2 Expansion

Once a node is selected, we add all its immediate child nodes. These are the allowed moves from a given state, that is the top k token candidates generated by a language model, given the state's context history. Figure 2 illustrates the process. For $k = 3$, the context history for the state at the root node is the token <bos>. When passed to a language generation model, the words "Where", "What" and "Who" are examples of the top three candidates to follow <bos>. Assume the node "Who" is picked in the selection phase at $i = 1$. Its state context history "<bos> Who" returns the candidate tokens "discovered", "is", and "invented"; these are added as child nodes in the expansion phase.

3.1.3 Simulation (Roll-out)

A simulation starts from the added child node in the expansion phase. During this process, a sequence is generated by picking at random a possible candidate for each next token until a terminal state is reached. Given that candidate tokens are generated over a probability distribution, we apply a

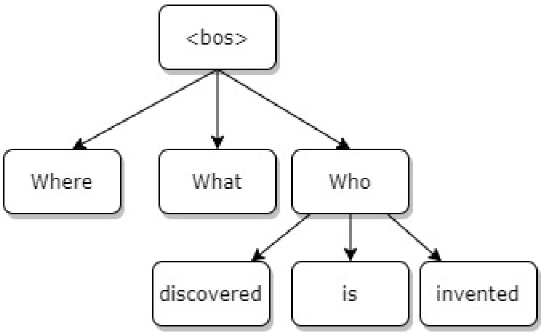

Figure 2: A possible MCTS output after 2 iterations

weighted choice method, enforcing non-uniform randomness. As explained earlier in 3.1, simulations are tracked without affecting the growth of the tree. Taking this into account, we are able to modify the value of k for the tokens, without affecting the functionality of MCTS. We will refer to this as K_s to distinguish it from the K in the expansion phase. If $K_s >> K$, we are able to achieve higher variance in the generated data while maintaining the width of the tree.

3.1.4 Backpropagation

Once an example is generated, its reward value is computed. The path of the expanded node is then updated by backpropagating the reward value and increasing the number of visits by one.

For the reward function, we implement two variants of MCTS, hereafter referred to as Uncertainty-Based MCTS and Diversity-Based MCTS, where the only difference is in the reward function.

In **Uncertainty-Based MCTS**, given the learning classifier's softmax probabilities over the possible class labels, we compute the normalized form of Shannon's entropy as shown in eq. 5:

$$H_n(P) = -\sum_{i=1}^{n} p_i \log_b p_i \cdot \frac{1}{\log_b n} \tag{5}$$

where P is a set of probabilities $P = \{p_i; i = 1, ..., n\}$, with $\sum_{i=1}^{n} p_i = 1$ for n labels, normalized by $log_b n$. We expect meaningless content in regions of higher entropy, and so limit the search space to a predefined value for maximum entropy, θ_{ent}. Examples with an entropy above this threshold become less important by returning a lowered reward value (e.g. 0), as shown in eq. 6.

$$f(x_{ent}) = \begin{cases} 0, & \text{if } x_{ent} \geq \theta_{ent} \\ x_{ent}, & \text{otherwise} \end{cases} \tag{6}$$

where x_{ent} is the entropy value for example x, and θ_{ent} the entropy cut-off threshold.

In **Diversity-Based MCTS**, in addition to entropy, we compute the cosine similarity between each generated candidate and a comparison list initialized with the classifier's training data. This is to ensure the diversity of the generated examples. If the similarity score is above a certain threshold θ_{sim}, the reward for the candidate will be set to 0, as shown in eq. 7. Conversely, if it is below θ_{sim}, the candidate is added to the comparison list, so that future candidates will be penalized if they are too similar to it.

$$f(x_{ent}, x_{sim}) = \begin{cases} 0, & \text{if } x_{ent} \geq \theta_{ent} \\ 0, & \text{if } x_{sim} > \theta_{sim} \\ x_{ent}, & \text{otherwise} \end{cases} \tag{7}$$

where x_{sim} is the maximum cosine similarity score between example x and the comparison list, and θ_{sim} the cosine similarity threshold.

3.2 Data Selection and Active Learning

Once MCTS reaches completion, all leaf nodes from the final tree are selected. Given that we have kept track of the generated simulations from a node, each non-terminal leaf node is now linked to a generated sequence of text. The final set of text examples is then sorted by the values from their corresponding nodes. The top n examples are selected, labeled by hand and appended to the original training set. We then retrain the learning classifier on the new dataset.

4 Experiments

4.1 Datasets

In our experiments, we attempt to emulate real life scenarios where training data is scarce. So from each dataset below, we create an initial training set by randomly selecting a very small subset of the available training data. We then fine-tune GPT-2 on the created subset and use our method from section 3 to generate new training examples. Once data is generated, we label the top n examples, sorted by the max reward value, as described in 3.2.

We study the effectiveness of our methods on two different tasks, question classification and sentiment analysis.

Question Classification: For this task we use the 6-label version of the TREC Questions dataset, TREC-6 (Li and Roth, 2002). TREC-6 divides questions into 6 categories: HUM, DESC, ENTY, LOC, NUM, and ABBR. From the available training data, we randomly select only 5 examples per label, making a total of 30 examples for training the baseline classifier. Evaluation is done over the provided test set of 500 questions.

Sentiment Analysis: For this task we use the Stanford Sentiment Treebank SST-2 Dataset (Socher et al., 2013), with sentiments divided into 2 labels, positive and negative. We use the data split from the GLUE SST task (Wang et al., 2018a), and evaluate on the provided development set. From the available training data, we only select 10 random examples per label and discard the rest.

4.2 Model Comparison

In our experiments we compare two variants of MCTS with only a minor difference in the reward function, one with the effect of θ_{sim} as described in section 3.1.4, and one without its effect. We further test the effectiveness of MCTS for data augmentation by comparing it to a data generation approach that does not optimize for a reward value. We refer to this approach as non-guided data generation (NGDG). Similar to MCTS, NGDG applies a top-k sampling procedure to generate candidate tokens. However, unlike MCTS, the selection of the next token is entirely based on the distribution of the candidate tokens. This is exactly the same procedure as the simulation phase in MCTS, but instead of constructing a tree search, simulations are run independently of one another. To emulate the flexibility of having higher variance over the latter parts of the generated text in MCTS (section 3.1.3), we increased k for the number of candidate tokens after the first n output tokens in the sequence. Here n is fixed at 3 in all our experiments. After the data is generated, we apply the classifier of the previous active learning cycle to compute an entropy value (eq. 5) for each example. Data is then sorted by the entropy, and the top n examples below θ_{ent} are then selected for labeling.

The classifier used for our experiments is a relu layer neural network with the Universal Sentence Encoder (USE) for the embedding layer. We implement this classifier using the Keras[2] toolkit. The classifier contains an embedding layer with 512 neurons, a 600-neuron fully-connected dense layer, a dropout layer with a 0.2 dropout rate, a softmax activation output and optimized using Adam (Kingma and Ba, 2014). We fixed the classifier's hyper-parameters following a hyperparameter search to a batch-size of 2, 0.0001 learning rate, and trained over 15 epochs.

4.3 Data Generation Parameters

We fix the MCTS UCB policy constant C to 2, θ_{ent} to 0.95, and θ_{sim} to 0.9 for all experiments. To achieve fairness in the comparison, when using the NGDG method (section 4.2), we discard examples with entropy above $\theta_{ent} = 0.95$ in the experiments.

4.4 Data Selection

For MCTS, as the learning classifier is part of the data generation process, the output examples are already mapped to their reward values and to the classifier's predicted labels. For NGDG, however, because the classifier does not take part in the generation process, it must be applied to the generated data afterwards, to predict labels and compute values for entropy. After classification, the data is sorted by entropy (for NGDG) or reward value (for MCTS), and the labels of the top n examples are corrected manually. Finally, to limit the effect of an imbalanced dataset, we restrict the number of the selected examples x_{max}, to the first 10 per label. In the event where all labels have more than 10 examples, x_{max} corresponds to the count of the label with the least number of examples.

4.5 Experiment 1: TREC-6 Question Data

For this experiment, we fixed the number of simulations at 3000 and the top n examples for labelling to 50 for both MCTS and NGDG. We set the number of candidate tokens K to 6 and K_s to 20. For NGDG, K changes from 6 to 20 after the first 3 tokens are generated from the sequence. Table 1 shows the average accuracy achieved over the 6 labels throughout 8 Active Learning runs on the TREC-6 test set, as well as giving the added number of examples after each AL cycle.

4.6 Experiment 2: SST-2 Sentiment Data

Similar to experiment 1, we kept the number of simulations at 3000 and top n at 50 for both MCTS and NGDG. Whereas, we set the number of candidate tokens $K = 15$ and $K_s = 30$ for MCTS. In NGDG, K changes from 15 to 30 after the first 3 tokens are generated. Results are in Table 2.

#	Example
1	Why did Einstein lose a fight with cancer?
2	Why did Lincole Ljungberg retire?
3	Why was Lorne L. Huntington's IQ so low?
4	What are three fundamental principles of socialism?
5	What is D.C.'s major metropolitan area?
6	When was Antarctica formed?
7	When did animals roam the earth?
8	Where can a geologist find fossils?
9	Where can an electrician find work?
10	How did Moses rule the ancient tribes?
11	How often have animals been killed by car crashes?
12	Which is Fordham's largest engineering college?

Table 4: Some examples generated on TREC-6 through the Diversity-Based MCTS for experiment 1.

4.7 Experiment 3: SST-2 Sentiment Data

We repeated experiment 2 with the same configurations, except that top n, is now 20 (not 50) for both MCTS and NGDG. Results are shown in Table 3.

4.8 Discussion

Table 4 shows twelve sentences generated by the Diversity-Based MCTS. These can give us insights concerning our approach and the role of GPT-2 in it. First, consider example 1 in the table ("Why did Einstein lose a fight with cancer?" – type DESC). In the initial training set, there is only one mention of Einstein ("What was Einstein's IQ?" – NUM), and one of cancer ("How do doctors diagnose bone cancer?" – DESC). Nevertheless, example 1 combines information from two different sentence types NUM and DESC in a coherent way. Example 3 again demonstrates a form of 'cross-type' learning: The Einstein training sentence above is the only mention of IQ and is of type NUM. Yet example 3 is a well-formed DESC sentence. For example 4, perhaps the most related training instances are "What are the four elements?" and "What are the chemicals used in glowsticks?". These are asking for lists but concerning elements and chemicals, not abstract concepts like socialism.

Interestingly, even though the training set contains no 'When' sentences, examples such as 6 and 7 could still be created; because MCTS pushes GPT-2 to generate novel sentences as it constructs the tree, those of the form "What kind, when..."

were created during the path traversal process. These were then corrected during the labeling stage. We did not witness this phenomenon with NGDG, possibly because MCTS is directed by a reward function that penalizes sentences of low entropy. This allows MCTS to search through the space of possible sentence combinations more efficiently.

Concerning the LOC examples 8 and 9, the only 'Where' training question is "Where do hyenas live?". Yet, in our experiments, we were able to expand on this by generating additional 'Where' questions which are very different from the hyenas and different from each other: A fossil is something which a geologist might find, while work is something which an electrician might find. Both are meaningful, while the sense of 'find' in each is quite distinct. Finally, while the remaining examples in table 4 could not be directly linked to relevant examples in the training data, this only confirms our purpose of using a pretrained model like GPT-2 that can make use of its external knowledge while remaining relevant to the target task.

In summary, by integrating GPT-2 with our methods, we gained substantial improvements over the baseline classifier. This shows how text generation can improve performance for tasks with scarce data. Even when starting with just a few examples per label, we were able to generate informative data that boosted the accuracy on TREC-6 from 65% to 91% with MCTS and 88% with NGDG, on SST-2 from 73% to 83% and 78% respectively, after 8 AL runs. Even when reducing the number of examples for labeling from 50 to 20 in experiment 3, we were still able to achieve an improvement of 81% with MCTS and 80% with NGDG. This suggests the effectiveness of our approach in solving real-world classification tasks when minimal data is available. Moreover, with MCTS we witnessed improvements in performance compared to NGDG on both the TREC-6 and SST-2 datasets. MCTS guides the growth of the tree by visiting more relevant nodes more frequently. Hence, relevancy is increased by the paths that maximize the reward function, those that correspond to high entropy values in our setting.

However, searching only for high entropy is more likely to incur noise in the final output such as ill-formed sentences or content that does not fall under the labeling criteria. Since ill-formed sentences are likely to incur high entropy values, the lack of a sentence quality measure can make MCTS prone to output meaningless sentences. For instance, "What kind!!??", "Which is the abbrev?", and "What does IQ be?" were outputs of MCTS in the TREC-6 experiments. This point is reflected in the lower overall number of added examples when comparing MCTS to NGDG over the 8 AL runs. Moreover, when MCTS over-exploits visited paths, it can get stuck in certain sub-trees, leading it to output examples with a high level of similarity. For instance, "good movie" and "good movie!" are identical examples with the only difference being the exclamation mark '!'. This issue is especially noticeable in the MCTS Uncertainty-Based experiment in Table 3, where due to the number of closely similar examples in the output, a lower proportion of the top 20 examples could be labeled. Hence, to diversify the generated output, we introduced θ_{sim} in the MCTS Diversity-Based approach.

Overall, the success of our approach relies on the quality of the search space, which is determined by the language model; if it performs less well, this can result in a noisier space. Hence, in our previous work (Sankarpandi et al., 2019), our group could not achieve comparable results. Moreover, additional user involvement was needed to make sense of ill-formed outputs, making the whole approach laborious and more prone to the user's bias.

5 Conclusion

In this paper we proposed a framework for improving a classifier's performance with synthetic data. We have shown in our experiments that even when starting with just a few examples, we are able to achieve noticeable improvements. We believe this approach is likely to work for any domain or language so long as the language model is able to generate meaningful output. In this work for instance, we did not need more than 20 examples to fine-tune GPT-2 for the SST-2 experiments, or 30 for the TREC-6 experiments. We expect even better results when more examples are provided or with the application of an improved language model like GPT-3. In future work, we plan to extend our approach to further improve the reward and policy functions, and to reduce the human-labeling factor.

“I’d rather just go to bed”: Understanding Indirect Answers

Abstract

We revisit a pragmatic inference problem in dialog: Understanding indirect responses to questions. Humans can interpret *‘I’m starving.’* in response to *‘Hungry?’*, even without direct cue words such as ‘yes’ and ‘no’. In dialog systems, allowing natural responses rather than closed vocabularies would be similarly beneficial. However, today’s systems are only as sensitive to these pragmatic moves as their language model allows. We create and release[1] the first large-scale English language corpus ‘Circa’ with 34,268 (polar question, indirect answer) pairs to enable progress on this task. The data was collected via elaborate crowdsourcing, and contains utterances with yes/no meaning, as well as uncertain, middle-ground, and conditional responses. We also present BERT-based neural models to predict such categories for a question-answer pair. We find that while transfer learning from entailment works reasonably, performance is not yet sufficient for robust dialog. Our models reach 82-88% accuracy for a 4-class distinction, and 74-85% for 6 classes.

1 Introduction

Humans produce and interpret complex utterances even in simple scenarios. For example, for the polar (yes/no) question *‘Want to get dinner?’*, there are many perfectly natural responses in addition to ‘yes’ and ‘no’, as in Table 1. How should a dialog system interpret these INDIRECT answers? Many can be understood based on the answer text alone, e.g. *‘I would like that’* or *‘I’d rather just go to bed’*. For others, the question is crucial, e.g. *‘Dinner would be lovely.’* is a positive reply here, but a negative answer to *‘Want to get lunch?’*. In this paper, we present the first large scale corpus and models for interpreting such indirect answers.

“Want to get some dinner together?”
“I know a restaurant we could get a reservation at.”
“I have already eaten recently.”
“I hope to make it home by supper but I’m not sure I can.”
“Dinner would be lovely.”
“I’d rather just go to bed.”
“There’s a few new restaurants we could go to.”
“I would like that.”
“We could do dinner this weekend.”
“I would like to go somewhere casual.”
“I’d like to try the new Italian place.”

Table 1: A polar question with 10 indirect responses, taken from our corpus.

Previous attempts to interpret indirect yes/no answers have been small scale and without data-driven techniques (Green and Carberry, 1999; de Marneffe et al., 2010). However, recent success on many language understanding problems (Wang et al., 2019), the impressive generation capabilities of modern dialog systems (Zhang et al., 2019; Adiwardana et al., 2020), as well as the huge interest in yes/no question-answering (Choi et al., 2018; Clark et al., 2019) have created a conducive environment for revisiting this hard task.

We introduce *Circa*, a new dataset with 34K pairs of polar questions and indirect answers in the English language. This high quality corpus consists of natural responses collected via crowd workers, and goes beyond binary yes/no meaning to include conditionals, uncertain, and middle-ground answers. Circa contains many phenomena of interest, although the first step, which we address here, is how to robustly classify a question-answer pair into one of the above meaning categories. We find that BERT (Devlin et al., 2019) fine-tuned on entailment data is an effective initial approach, mirroring the success in question-answering work involving yes/no questions (Clark et al., 2019). It reaches

[1] The corpus can be downloaded from `http://goo.gle/circa`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7411–7425,
November 16–20, 2020.

an accuracy of 85-88% for responses in the same situational context, and 6-10% lower accuracy on held-out scenarios. The answer text itself (as in *'I would like that'*) contains strong cues leading to 78-82% accuracy, however the best results come from jointly analyzing the question and the answer.

2 Related work

Indirect answers to polar questions are reasonably frequent and warrant deep study. Early work put the proportion at 13% in face-to-face and telephone conversations (Stenström, 1984), and at 27% in an instruction giving/following map task (Rossen-Knill et al., 1997; Hockey et al., 1997). For a more recent and larger analysis, consider the Cornell Movie Dialog Corpus (Danescu-Niculescu-Mizil and Lee, 2011). We heuristically mined yes/no questions and their following utterances, finding 6,327 pairs. Direct answers (i.e., answers with 'yes', 'no', 'maybe' and related terms such as 'okay', 'yup', etc.) only cover 53% of the pairs. This suggests that indirect responses could be even more frequent in natural open-domain dialogue.

Even when a direct answer is possible, speakers use indirect answers to be cooperative and address anticipated follow-up questions (Stenström, 1984), to provide explanations in the case of a negative answer (Stenström, 1984), to block misleading interpretations that may arise from a curt 'yes' or 'no' reply (Hirschberg, 1985), and since indirect answers may appear more polite (Brown and Levinson, 1978). But we lack a large corpus of such answers to study these multiple pragmatic functions. Our work aims to fill this gap.

On the computational side, there are impressive efforts towards planning, generation, and detection of indirect answers, albeit, on a small scale, and without data-driven approaches. Green and Carberry (1999)'s early work leverages discourse relations for generating indirect answers. For example, an 'elaboration' may be relevant for a 'yes' response, and a 'contrast' might help convey a 'no' answer. de Marneffe et al. (2009) reason about such answers using Markov Logic Networks. In subsequent work, de Marneffe et al. (2010) present one of the first data-driven studies into indirect answers containing scalar adjectives. They mine a set of 224 question-answer pairs from interview transcripts and dialog corpora. Using polarity information from review data, and manual coding of test samples, they achieve an accuracy of 71% on three classes 'yes', 'no' and 'uncertain'. Our work aims to collect a much larger and more diverse natural corpus, and demonstrates the first automatic approach using recent advances in natural language inference (NLI). de Marneffe et al. (2010) also demonstrated the first crowd annotation of indirect answers, and we draw on many aspects of their formulation for the creation of our corpus.

An unexpected limelight on yes/no questions has also arisen in recent question-answering (QA) work. Researchers have noticed that yes/no questions are complex and naturally arise (as high as 20%) when questions are posed one after the other in a conversation (Reddy et al., 2019; Choi et al., 2018). Their goal is to produce direct 'yes' or 'no' answers, but obtaining them requires inference against a paragraph or excerpt, an analogous task to our yes/no inference from indirect answers. Very recent work (Clark et al., 2019) has specifically sought to improve this ability in QA systems, by building a corpus of 16K yes/no factual questions paired with Wikipedia passages from which the yes/no answer can be inferred. Departing from factual texts, our focus is on single-turn *conversational* responses in everyday situations. The latter are faithful, cooperative, and grounded in world knowledge. Still, transfer learning from factual corpora could prove useful and we explore this too.

3 The Circa Corpus

Circa (meaning approximately) is our crowd-sourced corpus for research on indirect answers. It contains 34,268 question-answer pairs, comprising 3,431 unique questions with up to 10 answers to each. Each question-answer pair is also annotated with meaning based on a fixed set of categories.[2] We explain all aspects of the collection process below, but in the interest of space, further details (complete annotator instructions, interfaces, and examples) are in the Appendix.

Our data consists of very short dialogues, each containing a question and its indirect answer. The texts are varied in semantic and syntactic forms, and grounded in 10 different situational contexts. Table 2 presents some examples, showing that the answers go beyond binary yes/no distinctions. We created this data via an elaborate crowd-annotation exercise which comprised of *4 steps* described next.

---

[2] The data can be downloaded from `http://goo.gle/circa`

S1: Talking to a friend about food preferences. Q: "Do you like pizza?" A: "I like it when the toppings are meat, not vegetable."
S2: Talking to a friend about music preferences. Q: "Do you like guitars?" A: "I practice playing each weekend."
S3: Talking to a friend about weekend activities. Q: "Are you available this Sunday evening?" A: "What did you have in mind?"
S4: Talking to a friend about book preferences. Q: "Are you a fan of comic books?" A: "I read an Archie every time I have lunch."
S5. Your friend is visiting from out of town. Q: "Would you like to go out for dinner?" A: "I could go for some Mexican."
S6. Two colleagues leaving work on a Friday. Q: "Long week?" A: "I've had worse weeks."
S7. You friend is planning to buy a flat in New York. Q: "Does the flat's price fit your long-term budget?" A: "Well, if it doesn't I will definitely refinance my mortgage."
S8. Your friend is thinking of switching jobs. Q: "Do you have to travel far?" A: "My commute is about 10 minutes."
S9. Two childhood neighbours uexpectedly run into each other at a cafe. Q: "Are you going to the high school reunion in June?" A: "I forgot all about that."
S10. Meeting your new neighbour for the first time. Q: "Did you move from near-by?" A: "I am from Canada."

Table 2: Examples of questions and answers in our 10 dialogue scenarios.

3.1 Step 1: Dialog scenarios

We designed 10 diverse prompts to serve as situational contexts. These everyday situations can lead to productive dialog, and simple yes/no questions (i.e., they do not depend on elaborate prior context for initiating a conversation). We designed them manually to intentionally cover a number of situations that encourage variety in questions and responses. As only a small number were needed, and the desiderata are not trivial, a crowd task was not suitable for prompt development. In Table 2, S1–S10 are the titles of the 10 dialog scenarios (each also consisting of a longer description).

The rest of the data were collected using crowd workers. We ran pilots for each step of data collection, and perused their results manually to ensure clarity in guidelines, and quality of the data. We recruited native English speakers, mostly from the USA, and a few from the UK and Canada. We did not collect any further information about the crowd workers.

Annotator instructions
In this task, we will ask you to provide yes/no questions in a social dialogue situation.
Example: Suppose that you are trying to learn about a friend's movie preferences, but can only ask yes/no questions. Provide 5 useful questions that can be answered "Yes" or "No".
Note: (1) We are looking for variety in the questions. For instance:
'Have you watched Star Wars?'
'Do you like movies with a complicated plot?'
'Did you enjoy the last movie we saw together?'
'Want to go watch a thriller this weekend?'
'Are you into the Avengers series?'
Note that the questions have different forms as well as different content.
(2) Remember that the setting is a conversation with a friend (or neighbour or colleague). Please keep the questions casual, so they would be natural during an informal conversation.

Table 3: Annotator instructions for Step 2.

3.2 Step 2: Question collection

In this phase, we ask annotators to write yes/no questions for a given dialog scenario.

Table 3 shows the instructions displayed to annotators.[3] (Also see Figure 1 and Table 11.) 100 annotators each provided 5 questions per scenario, resulting in 5,000 questions.

Questions where annotators did not adhere to topic provided were removed. Of the remaining 4,710 questions, 84% were unique. Understandably, some scenarios had more repetitions than others: For food preferences, 76% of the questions were unique, as opposed to 95% when talking about a friend's job change. Below we show the most and least common questions in the food context.

Most common food questions	
25 times	Do you like spicy food?
11 times	Are you vegetarian?
10 times	Do you eat meat?
Sample of least common food questions	
1 time	Have you ever tried vegan cuisine?
1 time	Do you have a gluten allergy?
1 time	Are you familiar with Thai food?

The most common one *'Do you like spicy food?'* was suggested by 25 out of 100 annotators.

One important aspect of our design is that each annotator was asked to provide five questions at the same time. Obvious questions often showed up as the *first* question, with later questions becoming more complex and more interesting. Question properties such as length, inverse document frequency, and type-token ratio confirm this difference.

---

[3] In annotator instructions, we always use examples different from the actual scenarios in the exercise.

3.3 Step 3: Answer elicitation

We sampled 350 non-redundant questions per scenario, with an equal number from the 5 question positions (see previous section)[4]. Using a different set of annotators than Step 2, we then elicited 10 indirect answers for each question. The annotator instructions are provided in Table 4. For faster annotation, and to encourage diverse answers, we displayed five questions (in same situational context) simultaneously. The five questions were chosen to be diverse (based on cosine similarity between nouns and adjectives in the questions), and annotators were instructed to treat them independently.[5] See Figure 2 for an example display.

Importantly, a key design consideration was that we do *not* instruct annotators to produce an answer with a specific meaning. Rather the annotator composes a natural response without reflecting upon a required meaning. We believe this flexibility is important to ensure that varied meanings (even ambiguous ones) are present in our data. This is verified in our analysis in Section 3.6.

Table 1 provides example answers from this step. Note that the 10 answers have varied meanings departing from definite 'yes' and 'no'. The answers were high quality and diverse in form. 83% of answers appear only once in the corpus. At the same time, there are a few prototypical answers for the different meanings. Below we show the most repeated responses (and frequency) for 'yes' and 'no' meanings, and also for cases where the answer is conditional upon some situation, and middle ground responses.

	'yes' answers		**'no' answers**
59	I would love to	21	I don't drink
40	Let's do it	18	I prefer pop
40	That would be good	18	I wish!
	'conditional yes'		**'middle-ground'**
9	If the weather is nice	14	I'm not sure yet
6	If I can afford it	10	Which one?
6	Depends where you want to go	9	It's OK

These responses indicate that strong lexical signals for meaning are present in the answer.

3.4 Step 4: Marking interpretations

Finally, we ask a third set of annotators to mark interpretations for all the QA (question, indirect answer) pairs from Step 2. In particular, they are asked to judge how the question-seeker would interpret the answer provided. As in most NLP tasks, interpretations will vary, and so we obtain *five* annotations per pair.

Annotator Instructions
You will be given a social situation, for example, talking to your friend or neighbour.
Task: You will be asked to respond to a question from your friend/neighbour but without using the words 'yes' or 'no' (or similar words like 'yeah', etc). Please provide a possible answer, it does not have to be your real opinion. Rather you should provide a possible answer from which your friend will be able to infer whether you mean 'yes', 'no', 'maybe' or 'sometimes'.
Example: Here are three such answers to your friend's question about movies.
Do you like movies with sad endings?
(a) I often watch them. (Meaning=Yes)
(b) I prefer movies which make me laugh. (Meaning=No)
(c) When the plot is also good. (Meaning=Sometimes)

Table 4: Annotator instructions for Step 3.

Annotator instructions
You will be shown short dialogues between two friends/colleagues (X and Y) in a certain context. For example:
Context: X wants to know about Y's movie preferences.
X: "Do you like movies with sad endings?"
Y: "I often watch them."
In all the dialogues, X asks a simple 'Yes/No' question, and Y answers it with a short sentence or a phrase.
Task: We need your help to interpret Y's answer. Read the dialog and tell us how you think X will interpret Y's answer. Your options are: *X will think that Y means*
(1) 'yes'
(2) 'probably yes' / 'sometimes yes'
(3) 'yes, subject to some conditions'
(4) 'no'
(5) 'probably no'
(6) 'in the middle, neither yes nor no'
(7) 'I am not sure how X will interpret Y's answer'
If Y's response does not fit any of the above, please choose the option (8) 'Other', and leave a short comment.
For our example above, the likely interpretation is 'yes'.

Table 5: Annotator instructions for Step 4.

The correct label categories are not readily clear, but the variety of examples in our corpus made it certain that just 'yes' and 'no' will not suffice. Building on prior work by de Marneffe et al. (2010), and a pilot experiment, we identified categories that can be annotated reliably. These are shown in Table 5. The annotators were asked to assume the dialogs were co-operative and casual. They were advised to use 'probably yes/no' when they cannot infer a definite meaning. If X will not infer a 'yes' without some condition being met, then the class 'yes, subject to some conditions' was to be chosen. Detailed instructions with exact phrasing,

---

[4] For some scenarios, we obtained slightly fewer questions due to high repetitiveness at earlier question positions.

[5] Note that the 10 answers for each question in the Circa corpus are always from 10 different annotators.

Yes	**Probably yes / sometimes yes**	**Yes, subject to some conditions**
Q: Do you have any pets? A: My cat just turned one year old.	Q: Do you like mysteries? A: I have a few that I like.	Q: Do you enjoy drum solos? A: When someone's a master.
No	**Probably no**	**In the middle**
Q: Do you have a house? A: We are in a 9th floor apartment.	Q: Are you interested in fishing this weekend? A: It's supposed to rain.	Q: Did you find this week good? A: It was the same as always.

Table 6: Example question and answer pairs where all 5 annotators agreed on the label.

and practice questions are in the appendix (Figure 3, Tables 13 and 14). Annotators took an average of 23 seconds per question-answer pair.

Annotators were also given an option to flag improper content. We remove those QA pairs which were flagged by even one of the five annotators. The authors also read every question, and used a blacklist of words for additional filtering. The remaining 34,268 pairs comprise the final corpus.

3.5 Gold standard labels

Each (question, indirect answer) pair was marked by five annotators, so we use majority judgement as the gold standard, subject to *at least three* annotators making that judgement.

We use two aggregation schemes. The STRICT scheme keeps all eight class distinctions from Table 5. A more RELAXED label is computed by collapsing the uncertain classes with the definite ones: 'probably yes / sometimes yes' → 'yes', 'probably no' → 'no', and 'I am not sure how X will interpret Y's answer' → 'In the middle, neither yes nor no'. These classes were commonly confused by the raters. The 'Other' class was used mostly when the question was not polar (e.g, disjunctive ones such as *'Do you like to dine-in or take-out?'*). To illustrate the richness of the Circa corpus, Table 6 shows one QA pair from each class.

3.6 Label distributions

We now analyze the distribution of the gold standard labels. For STRICT labels (Table 7), only 8% of the examples (marked 'N/A') do not receive a majority vote. The most frequent class is 'yes' (42% of the data). 'No' is less frequent (32%). The third most frequent is 'conditional yes', indicating that conditional preferences may be common. The 'probably' classes are around 3-4%, each with over a thousand examples in the corpus. There is also a notable number of 'in the middle' examples. With the collapsed RELAXED labels (Table 8), the proportion of 'yes' and 'no' increase slightly, and 'N/A' examples drop to only 2%. These distributions reflect the rich patterns in our data.

Label	STRICT	
Yes	14,504	(42.3%)
No	10,829	(31.6%)
Probably yes / sometimes yes	1,244	(3.6%)
Yes, subject to some conditions	2,583	(7.5%)
Probably no	1,160	(3.4%)
In the middle, neither yes nor no	638	(1.9%)
I am not sure	63	(0.2%)
Other	504	(1.5%)
N/A	2,743	(8.0%)

Table 7: Distribution of STRICT gold standard labels. 'N/A' indicates lack of majority agreement.

Label	RELAXED	
Yes	16,628	(48.5%)
No	12,833	(37.5%)
Yes, subject to some conditions	2,583	(7.5%)
In the middle, neither yes nor no	949	(2.8%)
Other	504	(1.5%)
N/A	771	(2.2%)

Table 8: Distribution of RELAXED gold standard labels. 'N/A' indicates lack of majority agreement.

3.7 Annotator agreement

The Fleiss kappa scores are 0.61 for STRICT and 0.76 for RELAXED labels (p-values < 0.0001) indicating substantial agreement. In fact, full agreement, as in Table 6 where all five annotators agree on the STRICT class, occurs for 49% of pairs, a high proportion given the complexity of the task. When the labels are RELAXED, this reaches 71%. The full agreement distributions are:

Agreement	STRICT	RELAXED
5 annotators	49.1%	71.0%
4 annotators	23.8%	17.2%
3 annotators	19.1%	9.6%

3.8 Dialog scenarios and question type

As one would expect, different scenarios prompt different types of questions and answers, and hence different label distributions. For the 'friend switching jobs' scenario, 54.5% of elicited answers are have 'yes' meaning (RELAXED labels). For book preferences, this is only 42%.

Perhaps more unexpected is that a few questions have labels predominantly of the same kind. For example, all 10 answers to *'Ready for the weekend?'* receive a 'yes' label, and they are all 'no' for *'Are you offering the asking price?'*. While the first question is largely rhetorical, the second involves common sense: Most people negotiate real-estate prices. We found that 3% of questions (95) have all answers with the same label, and for another 20%, 8-9 answers have the same label. A model would still need to identify the label as either 'yes' or 'no', but these skews indicate that there may be some (weak) signals for the label in the question itself. After all, *who isn't ready for the weekend?*

3.9 Annotation Protocol

While our annotation method is comprehensive, one might wonder how alternative approaches would have fared. We have not performed controlled tests of different approaches but we briefly document our choices to aid future work.

We performed pilot annotations for each step of our process. Our goal was to start with less restrictive settings, where annotators are given minimal and simple instructions. If we did not receive quality responses, we intended to give more specific directions. For example, in an initial pilot, sometimes annotators gave long answers which may be unrealistic in conversations eg. *'I can tell you, without a shadow of a doubt, that there are very few things that I enjoy more than sitting in front of my computer.'* So in later annotations for all tasks, we added instructions 'to keep the conversation casual' which at least reminds annotators about this need. We performed spot checks on the results, but did not perform controlled tests.

For answer elicitation, our simple instruction pilot produced answers with diverse meanings. The distribution of meanings also varied according to the question (some questions had a mix of meanings, others were skewed towards a few meanings). So we decided against explicitly asking annotators to provide a certain meaning as that would create uniform meaning distributions, which may turn out unrealistic and miss dominant tendencies. We also considered that the explicit approach may reduce answer quality (for example, if a person who eats meat were to have to answer indirectly that they are vegetarian, they may be more likely to get their facts wrong, or try to rush through the task). In fixing our choice, we took care to ensure that quality was not affected, and answers were varied.

4 Learning Task

Obviously answers contain numerous cues for subsequent dialog flow, but in this first work we focus on meaning prediction. Specifically, given a question-answer pair, we classify it into one of the meaning categories in Tables 7 and 8.

We consider two experimental settings: In the *matched* setup, we assume that the response scenario is seen during training (randomly dividing our corpus examples into 60% training, 20% each for development/test). The *unmatched* setting is aimed at understanding the performance on unseen scenarios, i.e., whether models can learn the semantics of yes/no answers beyond the patterns specific to individual scenarios. As our data contains 10 scenarios, we carry out 10 leave-one-out tasks, each time holding out one scenario (for example, 'buying a flat in New York') as the test data, and use the remaining nine for training and development.

For both the *matched* and *unmatched* setting, we consider two variants of the classification problem: STRICT (with 6 different labels, namely all except 'other' and 'N/A' in Table 7) and RELAXED with 4 labels (Table 8). We ignore the examples without a majority label and also those marked 'unsure' or 'other'. Thus our experiment data sizes are:

Experimental Setting	**Train**	**Dev.**	**Test**
STRICT-matched	18,574	6,192	6,192
RELAXED-matched	19,795	6,599	6,599
STRICT-umatched	24,746	3,115	3,095
RELAXED-unmatched	26,404	3,289	3,299

For the *unmatched* setting, these sizes are the average across the 10 leave-one-out sets.

5 Models

Building upon recent NLI systems, our approach leverages representations from unsupervised pretraining, and finetunes a multiclass classifier over the BERT model (Devlin et al., 2019). However, we first consider other models for related tasks.

5.1 Related baselines and corpora

BOOLQ is a question-answering dataset focused on factual yes/no questions (Clark et al., 2019). Here yes/no questions from web search queries are paired with Wikipedia paragraphs that help answer the question. There are 9.4k train, 3.2k development, and 3.2k test set examples, with two target classes, namely 'yes' and 'no'. We train our own BOOLQ model with BERT pre-training. It reaches a development accuracy of 74.1%[6]. This model only predicts two classes 'yes' and 'no'.

MNLI. The MultiNLI corpus (Williams et al., 2018) is a large corpus for textual entailment. It consists of premise-hypothesis sentence pairs which are marked with three target classes 'entailment', 'contradiction' and 'neutral'. There are 392K train, 9K dev., and 9K test examples.

Although not applicable to all indirect answers, semantic consequence can be leveraged for interpreting some of them. For the question (Q) *'Do you like Italian food?'*, consider two possible answers (A) *'I love Tuscan food.'* and (B) *'I prefer Mexican cuisine.'* . Let Q' be the declarative (positive) sentence derived from Q i.e. Q' = *'I like Italian food'*. (Q' can be obtained by inverting the subject and auxiliary, and changing pronoun to first person). The meaning of A and B above, can then be obtained from an entailment system: $A \implies Q'$, hence 'yes', while B contradicts Q', hence 'no'.

We thus obtain predictions from an MNLI system, and map the predicted three NLI classes in a post-processing step: 'contradiction' → 'no', 'entailment' → 'yes', and 'neutral' → 'in the middle'. Note that this approach cannot predict all the classes in the corpus. Before prediction, we rewrite our questions into declarative form using syntactic rules on a constituency parse. Performance is much worse without this rewriting. Our models for the MNLI task start from a BERT checkpoint and reach a development accuracy of 84%.

This model improves with the syntactic rewriting of questions which we are able to do fairly accurately. We based the rewrite rules on 50 questions. On a different set of 50 questions, 38 were rewritten fully accurately (manual inspection). Some errors arose from incorrect parsing and some are due to deficient rules. For example, we do not handle verb re-inflection. So *'Did you enjoy the movie?'* gets rewritten into *'I did enjoy the movie.'* rather than *'I enjoyed the movie.'* This rewriting technique helped only the MNLI model. For other finetuning based models, which involve training, the models are able to learn from the question form itself.

Majority baseline. This method predicts the most frequent label, 'yes', for all examples.

5.2 Training with Question or Answer only

Answer only. In many cases, the answer to a question suffices for predicting the label (see Table 1 and Section 3.3); for example *"I would like that."* or *"I wish!"*. This *Answer only* model fine-tunes BERT to predict the class based only on the answer. Similar experiments are done on NLI datasets to test if the hypothesis alone is at times sufficient for entailment prediction (Poliak et al., 2018; Gururangan et al., 2018). Such results are problematic for entailment (since it is *defined* to depend on the truth of the premise). In contrast, our problem is primarily about the meaning of answers. This experiment will provide insight into the cues within indirect responses, an aspect not understood so far.

Question only. Some questions commonly elicit certain answers (see Section 3.8). These models test how well the question predicts the label.

5.3 Question-Answer Pair models

These models take both the question and the answer. They all finetune BERT checkpoints, and the question-answer pair is passed with a separator.

BERT-YN is BERT finetuned only on our Circa corpus (YN).

We also explore how to transfer the strength of parameters learned for three related inference tasks.

BERT-BOOLQ-YN finetunes a BOOLQ model checkpoint (see Section 5.1) on our corpus, with a new output layer. Since BOOLQ is a Yes/No question answering system, even if developed for a different domain, we expect to learn many semantics of yes/no answers from this data.

BERT-MNLI-YN is first fine-tuned on the MNLI corpus, followed by our YN data. This configuration tests if the signals we hoped to capture with the out-of-the-box MNLI model (Section 5.1) can be strengthened by training on our target task.

BERT-DIS-YN. As discussed, indirect answers also have discourse relations with the speaker's intent (Green and Carberry, 1999). We implement this idea via a discourse connective prediction task. Consider again the texts from Section 5.1: The likely connective between Q' and A is 'because' as in *'I like Italian food [because] I love Tuscan food.'*. For Q' and B, 'but' would be more reasonable: *'I like Italian food [but] I prefer Mexican cuisine.'*. We hypothesize that these discourse relations will help learn the yes/no meaning via transfer learning.

We use 400K examples (matching the MNLI data size) of explicit connectives and their arguments (a subset of Nie et al. (2019)). We aim to predict the 5 connectives (because, but, if, when,

---

[6] Clark et al. (2019) report 78% (dev.) with BERT-Large.

and) based on their arguments. This task itself can be done with a development accuracy of 82%. The best checkpoint is then finetuned on YN data.

6 Experiments

We use pre-trained BERT models (with 12 layers, 768 hidden units, and 12 attention heads, 110M parameters) for all our experiments. The experiments were done on a single Cloud TPU, and finetuning on our corpus takes under 30 minutes.

6.1 Setup and Hyperparameter Tuning

For the base models (MNLI, BOOLQ, and DIS), we tuned the learning rate (values 5e-5, 3e-5, 2e-5), the number of epochs (2, 3, 4), and train batch size (16, 32) in an exhaustive combination. For finetuning on yes/no data, we tune the learning rate while setting the epochs to 3 and training batch size to 32. We also perform three random restarts in each configuration. Performance was stable across the restarts (accuracy variation $\leq 1\%$). So we take the best model on the development set as our final model. The best hyperparameters are in the Appendix. For the unmatched setting, we do 10 leave-one-out tasks. Here we take the best parameters from the matched setting, and use that configuration to train all 10 experiments.

6.2 Results

We report the development accuracy and detailed test results in Table 9 (RELAXED setting) and Table 10 (STRICT setting). For the unmatched setting, we report the mean accuracy and standard deviation across the 10 folds, and the min and max values. We first discuss results for the RELAXED labels. The findings for STRICT are similar.

The majority baseline ('yes' class) leads to an accuracy of 49%. The MNLI to yes/no label mapping (no finetuning) is reasonable in terms of F-score for the 'no' class, but is poor for 'yes'. BOOLQ is the best baseline with 63% accuracy. However, there is no recall for labels other than 'yes' and 'no'.

The question-only and answer-only results are noteworthy. The question-only model outperforms the majority baseline. On the other hand, the answer text contains strong signals, with 82% accuracy, or about 20% better than the best baseline.

But models using both question and answer reach 5-6% greater accuracy and significantly outperform the answer-only model (McNemar's test, p-values $< 1e\text{-}6$). As expected, these joint models are necessary when a string is a possible answer to multiple questions. An answer-only model is easily misled in these cases, as the examples below show:

> (1) "Is there something you absolutely won't eat?" "I really dislike bananas."
> Answer-only prediction: 'No'
> Question+Answer prediction: 'Yes'
>
> (2) "Do you need a nap?"
> "I have plenty of energy."
> Answer-only prediction: 'Yes'
> Question+Answer prediction: 'No"

The best F-scores are obtained by an MNLI transfer task, reaching 88.2% accuracy in the matched setting. But it is not signficantly better than a no-transfer BERT-YN model (McNemar's test).

The unmatched setting shows that the models are worse when a scenario has not been seen in the training data. While it may not be possible for every conversational system to generalize across scenarios, a semantic classification such as yes/no should ideally be robust to such changes. Instead we see a 6-10% accuracy gap between the in-scenario test accuracies, and minimum out-of-scenario accuracy. The best accuracies are reached by a MNLI model. The highest accuracy on a scenario is 90% ('music preferences', 'weekend activities'), and lowest is 82% ('buying a flat in New York' and 'switching jobs'). The latter scenarios are quite different than the rest, indicating scope for improving the models.

The 'in the middle' class has much worse results compared to the rest. The class has low frequency but also comprises responses of different types. Uncertain responses such as *'I am not sure.'* appear easy to classify. But responses which do not take a stance: *'Do you know if it's raining outside? I'm prepared regardless.'* are harder. Sometimes, the interpretation is left to the judgement of the listener. Eg. *'travelling an hour away'* could be interpreted as 'far away' or 'close by' depending on the context and perceptions of the listener. These cases need models to deeply connect the question and answer, and are missed by our technique.

The general trends for STRICT labels is similar: The best accuracy is again reached with MNLI pretraining. It is 85% for the matched case, a small but significant gain over BERT-YN (McNemar's test, p-value < 0.02). The accuracy is 10% lower (74%) for hardest experiment in leave-one-out.

For STRICT labels, the 'probably no' class is hardest to predict even though it is as frequent as 'probably yes' and close to double the size of the 'in the middle' class. We found that 'probably no'

Model	Matched setting						Unmatched setting			
	Accuracy		Test F-Score				Test Accuracy			
	Dev.	Test	Yes	No	C.Yes	Mid	Mean	Std.	Min.	Max.
Baselines (no finetuning)

BERT-DIS-YN	83.8	83.3	87.9	50.2	90.5	84.1	21.2	**50.8**	81.5	4.5	73.1	86.3
BERT-BOOLQ-YN	83.1	83.4	88.2	51.2	89.1	84.5	**22.1**	43.7	81.1	4.3	73.3	85.8

Table 10: Performance on the **strict** labels. The highest value in each column is in bold.
BERT-YN is significantly better than 'Answer only' (McNemar's test, p-value $<$ 1e-6), and BERT-MNLI-YN is better than BERT-YN (p-value $<$ 0.02).

examples are heavily (69%) mis-predicted into the 'no' class. Utterances which explicitly convey uncertainty eg. (*'I don't believe so'*) or comparison (*'Is everything good? Not the greatest.'*) are somewhat easier to predict. On the other hand, in:

> "Have you ever bought a romance novel?" "I prefer to read horror books."
> Best model: "No"
> Gold standard: "Probably no"

The speaker prefers horror genre, but it does not preclude ever buying a romance novel. These subtleties are understandably harder for systems.

Overall, while MNLI based transfer learning has led to small improvements, incorporating the right information for the task remains a challenge.

7 Conclusion

We have presented a new dataset containing natural indirect yes/no answers, as well as other significant pragmatic moves in the form of conditionals and uncertain utterances. Our first approach towards automatic interpretation is promising, but there is a significant gap especially for examples outside training scenarios. Our model does not yet classify additional information in responses (*'Dinner? Let's go for Italian.'* indicates not only a 'yes' answer, but also a preference for Italian food.). Moreover, we have explored the phenomena in English. There are exciting avenues for multilingual work to account for language and cultural differences.

A Hyperparameter settings

For the base models (MNLI, BOOLQ, DIS), we tuned the learning rate (values 5e-5, 3e-5, 2e-5), the number of epochs (2, 3, 4), and train batch size (16, 32) in an exhaustive combination of these parameters. The best performance on development data was obtained with the following settings:

Model	**learning rate**	**no. epochs**	**batch size**
MNLI	2e-5	3	16
BOOLQ	3e-5	4	16
DIS	2e-5	2	32

For finetuning on yes/no data (matched setting), we tune the learning rate while setting the number of epochs to 3, and training batch size to 32. We also perform three random restarts in each configuration. Performance was stable across the restarts (accuracy variation $\leq 1\%$). We take the best model on the development set as our final model. The chosen learning rates are in the table below:

Model	STRICT	RELAXED
BERT-YN (Question only)	2e-5	3e-5
BERT-YN (Answer only)	2e-5	2e-5
BERT-YN	3e-5	3e-5
BERT-MNLI-YN	2e-5	5e-5
BERT-DIS-YN	3e-5	5e-5
BERT-BOOLQ-YN	3e-5	5e-5

For the unmatched setting, we do 10 leave-one-out experiments. Here we use the best parameters from the matched setting, and use the same configuration for training in all 10 experiments.

B Annotation Instructions

We now detail the complete instructions to annotators, along with interface examples, prompt texts, and practice items.

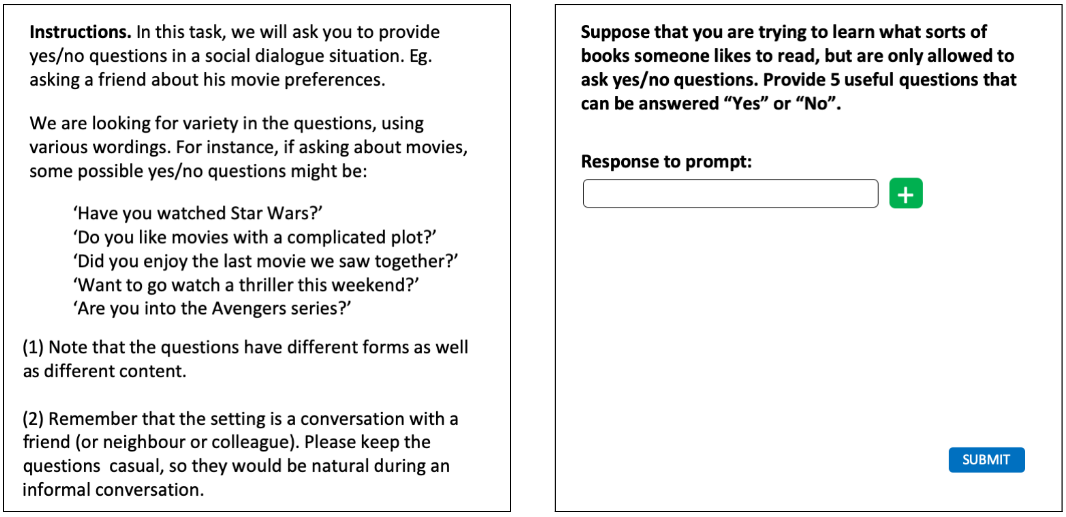
Question collection. In this step, an annotator is shown a scenario, and asked to provide five yes/no questions. The instructions, and interface for an example item are in Figure 1. The descriptions used for each of the 10 dialog scenarios are in Table 11.

Answer elicitation. Similarly, the instructions and interface for collecting answers are in Figure 2. Note that we show 5 questions on each screen, to reduce annotation time. The 5 questions are taken from the same scenario but such that they are not too similar. We enforce non-redundancy by keeping the pairwise similarity between any two questions on the same screen to less than 0.35 (measured by cosine similarity between the adjectives and nouns in the questions).

We have the same 10 scenarios but their descriptions are changed slightly to suit to the answer elicitation task. These prompts are in Table 12.

Marking interpretations. Finally, the question-answer pairs are annotated with meaning categories. Our complete instructions and annotator interface are in Figure 3. Again, the scenario descriptions are modified for the task, and are given in Table 13.

This step is fairly complex, so every annotator also worked through 8 practice questions before starting the annotation. After they answered them, the correct answers were shown along with an explanation. These examples are given in Table 14.



Instructions. In this task, we will ask you to provide yes/no questions in a social dialogue situation. Eg. asking a friend about his movie preferences.

We are looking for variety in the questions, using various wordings. For instance, if asking about movies, some possible yes/no questions might be:

'Have you watched Star Wars?'
'Do you like movies with a complicated plot?'
'Did you enjoy the last movie we saw together?'
'Want to go watch a thriller this weekend?'
'Are you into the Avengers series?'

(1) Note that the questions have different forms as well as different content.

(2) Remember that the setting is a conversation with a friend (or neighbour or colleague). Please keep the questions casual, so they would be natural during an informal conversation.

Suppose that you are trying to learn what sorts of books someone likes to read, but are only allowed to ask yes/no questions. Provide 5 useful questions that can be answered "Yes" or "No".

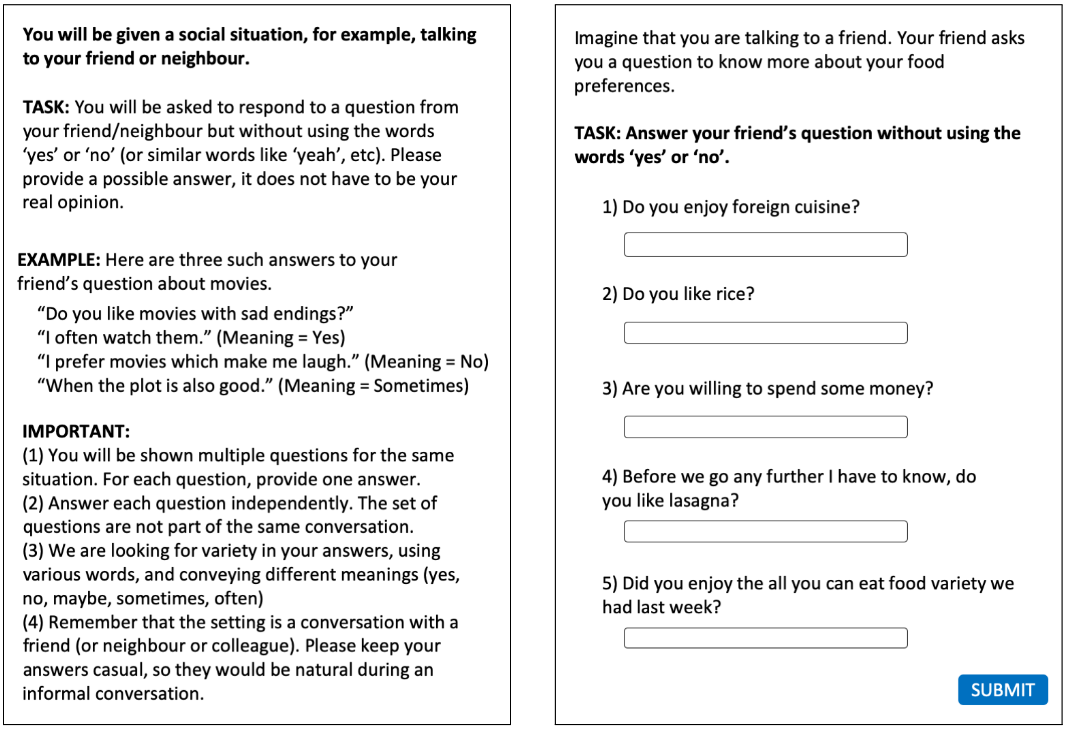
Response to prompt:

(a) Instructions (b) Example item

Figure 1: Annotator interface for question collection.

(1) Suppose that you are trying to learn about a friend's food preferences, so that you can recommend a local restaurant, but can only ask yes/no questions. Provide 5 useful questions that can be answered "Yes" or "No".	(5) On a Friday evening, you are leaving work and see your friend (and colleague) also at the door ready to leave. Provide 5 questions you might ask him/her that can be answered "Yes" or "No".
(2) Suppose that you are trying to learn what sorts of activities a friend likes to do during the weekend, so that you can recommend local activities that might interest them, but can only ask yes/no questions. Provide 5 useful questions that can be answered "Yes" or "No".	(6) Suppose that you are trying to learn about a friend's interests related to music. For instance, you could ask about music tastes, instruments played, events they go to, etc. You are only allowed to ask yes/no questions. Provide 5 questions you might ask.
(3) Suppose that you are trying to learn what sorts of books someone likes to read, but are only allowed to ask yes/no questions. Provide 5 questions you might ask about books that can be answered "Yes" or "No".	(7) Your friend has arrived from out of town to visit you. Provide 5 questions you might ask your friend when he/she arrives and during your time together. You are only allowed yes/no questions.
(4) Suppose that you are meeting your new neighbour for the first time. You want to find out more about him/her, but you are only allowed to ask yes/no questions. Provide 5 questions you might ask him/her that can be answered "Yes" or "No".	(8) Suppose that you are at a cafe, and you run into your childhood neighbour. You haven't seen each other or had any contact for many years. Ask a few questions of your childhood neighbour. You are only allowed yes/no questions. Provide 5 questions you might ask.
(9) Suppose that your friend tells you he is thinking of buying a flat in New York. In this context, provide 5 questions you might ask him/her. You are only allowed to ask yes/no questions.	(10) Your friend (not a colleague) is considering switching his/her job. You do not know much about the aspects of his/her job. Ask a few yes/no questions in this context. Provide 5 yes/no questions.

Table 11: Descriptions of the 10 scenarios in the question collection step.



You will be given a social situation, for example, talking to your friend or neighbour.

TASK: You will be asked to respond to a question from your friend/neighbour but without using the words 'yes' or 'no' (or similar words like 'yeah', etc). Please provide a possible answer, it does not have to be your real opinion.

EXAMPLE: Here are three such answers to your friend's question about movies.

"Do you like movies with sad endings?"
"I often watch them." (Meaning = Yes)
"I prefer movies which make me laugh." (Meaning = No)
"When the plot is also good." (Meaning = Sometimes)

IMPORTANT:
(1) You will be shown multiple questions for the same situation. For each question, provide one answer.
(2) Answer each question independently. The set of questions are not part of the same conversation.
(3) We are looking for variety in your answers, using various words, and conveying different meanings (yes, no, maybe, sometimes, often)
(4) Remember that the setting is a conversation with a friend (or neighbour or colleague). Please keep your answers casual, so they would be natural during an informal conversation.

Imagine that you are talking to a friend. Your friend asks you a question to know more about your food preferences.

TASK: Answer your friend's question without using the words 'yes' or 'no'.

1) Do you enjoy foreign cuisine?

2) Do you like rice?

3) Are you willing to spend some money?

4) Before we go any further I have to know, do you like lasagna?

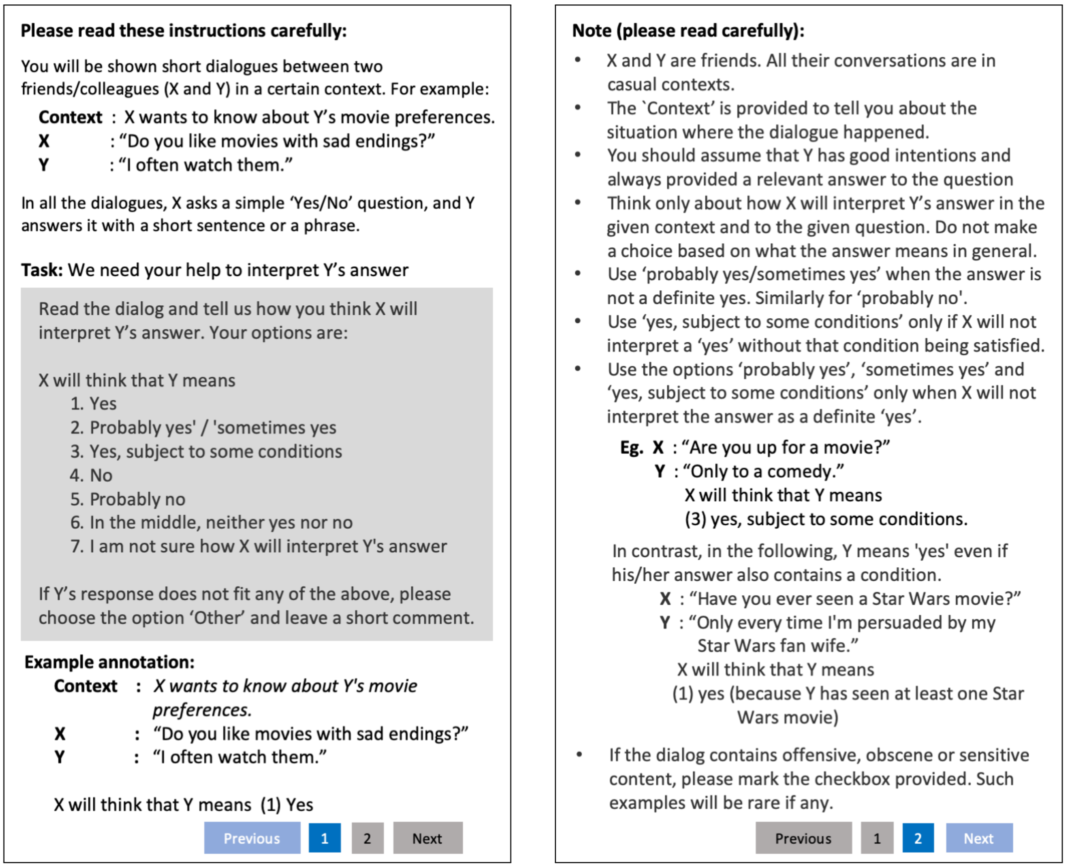
5) Did you enjoy the all you can eat food variety we had last week?

(a) Instructions (b) Example item

Figure 2: Annotator interface for answer elicitation.

(1) Imagine that you are talking to a friend. Your friend asks you a question to know more about your food preferences. Answer your friend's question without using the words 'yes' or 'no'.	(5) Imagine that at the end of the week you are leaving work and see your friend (and colleague) also at the door ready to leave. Your friend asks you a question. Answer your friend's question without using the words 'yes' or 'no'.
(2) Imagine that you are talking to a friend. Your friend asks you a question to know more about what activities you like to do during weekends. Answer your friend's question without using the words 'yes' or 'no'.	(6) Imagine you are talking to a friend. Your friend asks you a question to know more about your interests related to music. Answer your friend's question without using the words 'yes' or 'no'.
(3) Imagine that you are talking to a friend. Your friend asks you a question to know more about what sorts of books you like to read. Answer your friend's question without using the words 'yes' or 'no'.	(7) Imagine that you have just travelled from a different city to visit your friend. Upon your arrival, your friend asks you a question. Answer your friend's question without using the words 'yes' or 'no'.
(4) Imagine that you have just moved into a neighbourhood. One of your new neighbours is a friendly person, and asks you a question. Answer your neighbour's question without using the words 'yes' or 'no'.	(8) Imagine that you run into your childhood neighbour at a cafe. You haven't seen each other or had any contact for many years. Your childhood neighbour asks you a question. Answer your neighbour's question without using the words 'yes' or 'no'.
(9) Imagine that you have just told your friend that you are thinking of buying a flat in New York. Your friend asks you a question to know more about your plans. Answer your friend's question without using the words 'yes' or 'no'.	(10 Imagine that you have just told your friend that you are considering switching your job. Your friend asks you a question to know more about your plans. Answer your friend's question without using the words 'yes' or 'no'.

Table 12: Descriptions of the 10 scenarios as used in the answer elicitation step.



Please read these instructions carefully:

You will be shown short dialogues between two friends/colleagues (X and Y) in a certain context. For example:

Context : X wants to know about Y's movie preferences.
X : "Do you like movies with sad endings?"
Y : "I often watch them."

In all the dialogues, X asks a simple 'Yes/No' question, and Y answers it with a short sentence or a phrase.

Task: We need your help to interpret Y's answer

Read the dialog and tell us how you think X will interpret Y's answer. Your options are:

X will think that Y means

1. Yes
2. Probably yes' / 'sometimes yes
3. Yes, subject to some conditions
4. No
5. Probably no
6. In the middle, neither yes nor no
7. I am not sure how X will interpret Y's answer

If Y's response does not fit any of the above, please choose the option 'Other' and leave a short comment.

Example annotation:

Context : *X wants to know about Y's movie preferences.*
X : "Do you like movies with sad endings?"
Y : "I often watch them."

X will think that Y means (1) Yes

Note (please read carefully):

- X and Y are friends. All their conversations are in casual contexts.
- The `Context' is provided to tell you about the situation where the dialogue happened.
- You should assume that Y has good intentions and always provided a relevant answer to the question
- Think only about how X will interpret Y's answer in the given context and to the given question. Do not make a choice based on what the answer means in general.
- Use 'probably yes/sometimes yes' when the answer is not a definite yes. Similarly for 'probably no'.
- Use 'yes, subject to some conditions' only if X will not interpret a 'yes' without that condition being satisfied.
- Use the options 'probably yes', 'sometimes yes' and 'yes, subject to some conditions' only when X will not interpret the answer as a definite 'yes'.

Eg. X : "Are you up for a movie?"
Y : "Only to a comedy."
X will think that Y means
(3) yes, subject to some conditions.

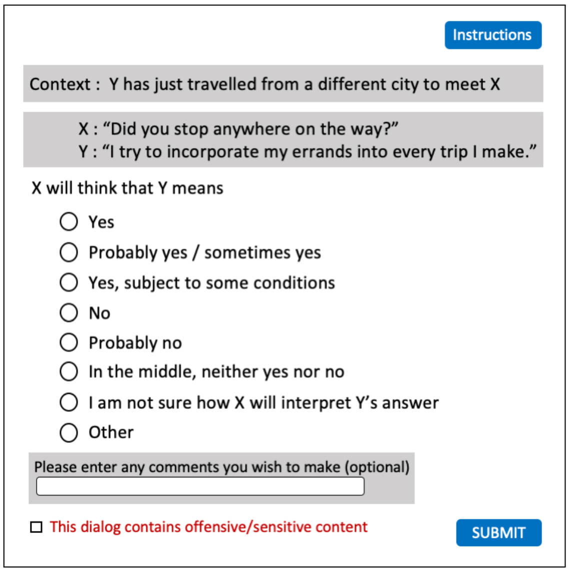
In contrast, in the following, Y means 'yes' even if his/her answer also contains a condition.

X : "Have you ever seen a Star Wars movie?"
Y : "Only every time I'm persuaded by my Star Wars fan wife."
X will think that Y means
(1) yes (because Y has seen at least one Star Wars movie)

- If the dialog contains offensive, obscene or sensitive content, please mark the checkbox provided. Such examples will be rare if any.

(a) Instructions

(b) Additional notes



Context : Y has just travelled from a different city to meet X

X : "Did you stop anywhere on the way?"
Y : "I try to incorporate my errands into every trip I make."

X will think that Y means

○ Yes
○ Probably yes / sometimes yes
○ Yes, subject to some conditions
○ No
○ Probably no
○ In the middle, neither yes nor no
○ I am not sure how X will interpret Y's answer
○ Other

Please enter any comments you wish to make (optional)

☐ This dialog contains offensive/sensitive content

(c) Example item

Figure 3: Annotator interface for marking interpretation.

(1) X wants to know about Y’s food preferences.	(5) X and Y are colleagues who are leaving work on a Friday at the same time.
(2) X wants to know what activities Y likes to do during weekends.	(6) X wants to know about Y’s music preferences.
(3) X wants to know what sorts of books Y likes to read.	(7) Y has just travelled from a different city to meet X.
(4) Y has just moved into a neighbourhood and meets his/her new neighbour X.	(8) X and Y are childhood neighbours who unexpectedly run into each other at a cafe.
(9) Y has just told X that he/she is thinking of buying a flat in New York.	(10) Y has just told X that he/she is considering switching his/her job.

Table 13: Descriptions of the 10 scenarios as used in the interpretation marking step.

(1) Context: X wants to know about Y’s food preferences.
X: “Do you eat red meat?”
Y: “I am a vegetarian.”
Answer: No (Vegetarians do not eat meat. So X will interpret it as a ‘no’ answer.)

---

(2) Context: X wants to know about Y’s food preferences.
X: “Have you had bulgogi?”
Y: “I am not sure.”
Answer: In the middle, neither yes nor no. (Here Y’s response is non-committal. So X’s best option is to interpret it as neither a ‘yes’ nor a ‘no’)

---

(3) Context: Y has just travelled from a different city to meet X.
X: “Did you stop anywhere on the way?”
Y: “I had to get gas a few times.”
Answer: Yes (X will infer a definite ‘yes’ because Y stopped for gas.)

---

(4) Context: Y has just travelled from a different city to meet X.
X: “Did you stop anywhere on the way?”
Y: “I try to incorporate my errands into every trip I make.”
Answer: Probably yes / sometimes yes (In response to the question, Y mentions that his general tendency is to do errands on the way. So it is likely that he did the same on this trip. Hence ‘probably yes’)

---

(5) Context: X wants to know about Y’s music preferences.
X: “Would you go to a punk rock show?”
Y: “It depends on who is playing.”
Answer: Yes, subject to some conditions (Y might go depending on the artist who is performing. Hence X will interpret that Y is posing a condition for going to the punk show.)

---

(6) Context: X wants to know about Y’s music preferences.
X: “Would you go to a punk rock show?”
Y: “I think I’d enjoy something less chaotic a little more.”
Answer: Probably no (Y’s indicates that he’d prefer some other activity. But he does not completely rule out the possibility of going to a punk show. Hence X will interpret it as ‘probably no’.)

---

(7) Context: X and Y are colleagues who are leaving work on a Friday at the same time.
X: “Is you department busy this time of year?”
Y: “We usually end up working overtime.”
Answer: Yes (Since Y is regularly working overtime, X will infer that Y’s department is busy.)

---

(8) Context: X and Y are colleagues who are leaving work on a Friday at the same time.
X: “Is your department busy this time of year?”
Y: “Just as busy as the rest of the year.”
Answer: In the middle, neither yes nor no (Since it is not known how busy Y’s department is in general, it is unclear if Y is busy at this time. In such cases pick ‘in the middle, neither yes nor no’. Note that if X had background knowledge that Y’s department is usually never busy, he could interpret the answer as a ‘no’ or vice versa. You do not have to assume such information is available when providing your answer.)

Table 14: The 8 practice questions used to train annotators for marking interpretations.

POWERTRANSFORMER: Unsupervised Controllable Revision for Biased Language Correction

Xinyao (Michelle) Ma[⋆] [◇] **Maarten Sap**[⋆] [◇] **Hannah Rashkin**[◇] **Yejin Choi**[◇][†]

Abstract

Unconscious biases continue to be prevalent in modern text and media, calling for algorithms that can assist writers with bias correction. For example, a female character in a story is often portrayed as passive and powerless ("*She daydreams about being a doctor*") while a man is portrayed as more proactive and powerful ("*He pursues his dream of being a doctor*").

We formulate **Controllable Debiasing**, a new revision task that aims to rewrite a given text to correct the implicit and potentially undesirable bias in character portrayals. We then introduce POWERTRANSFORMER as an approach that debiases text through the lens of *connotation frames* (Sap et al., 2017), which encode pragmatic knowledge of implied power dynamics with respect to verb predicates. One key challenge of our task is the lack of parallel corpora. To address this challenge, we adopt an unsupervised approach using auxiliary supervision with related tasks such as paraphrasing and self-supervision based on a reconstruction loss, building on pretrained language models.

Through comprehensive experiments based on automatic and human evaluations, we demonstrate that our approach outperforms ablations and existing methods from related tasks. Furthermore, we demonstrate the use of POWERTRANSFORMER as a step toward mitigating the well-documented gender bias in character portrayal in movie scripts.

1 Introduction

Narratives and news texts often reflect societal biases and stereotypes, such as the traditional gender role that women are passive and submissive (Lakoff, 1973; Fiske, 1993; Fast et al., 2016). The task of *controllable text revision*, i.e., rephrasing text to a targeted style or framing, can help correct for these biases by altering and equalizing the way people are described. For example, automatically rewriting *"Mey daydreamed about being a doctor"* as *"Mey pursued her dream to be a doctor"* portrays Mey with more authority and decisiveness (Figure 1). Such controllable revision methods could be used to help reshape how gender roles are portrayed in media (e.g., through machine-in-the-loop writing systems; Clark et al., 2018).

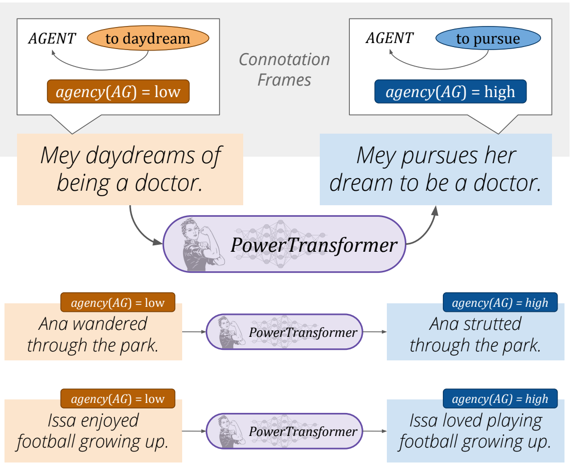

Figure 1: Examples of using connotation frames (Sap et al., 2017) for controllable revisions to portray characters with more agency and power. In the second example, "Ana strutted" implies that she is more active and decisive, compared to "Ana wandered" which portrays her as aimless and passive.

To edit such biases out of text, a controllable rewriting model faces three key challenges. First, a model should be able to make edits beyond surface-level paraphrasing, as simple paraphrasing will often not adequately debias the underlying events described. For example, Mey's portrayal in Figure 1 carries both overt bias (the choice of action) and subtle bias (the framing of the action), both of which require rewriting to be adequately debiased. Second, a model's debiasing revisions should

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7426–7441,
November 16–20, 2020. ©2020 Association for Computational Linguistics

be purposeful and precise and should not make unnecessary changes to the underlying meaning of the original text. Lastly, since parallel data does not exist, models must learn to revise and debias text without supervised data, thereby preventing straightforward machine translation-style modelling.

We formulate *Controllable Debiasing* as a new controllable text revision task that aims to correct the implicit and possibly unwanted bias against or towards a specific character portrayed in text (§2). As shown in Figure 1 (top), we study the portrayal biases through the lens of connotation frames of *power and agency* (Sap et al., 2017), which provide pragmatic knowledge about implied power and agency levels projected onto characters by a predicate.

We create POWERTRANSFORMER, an encoder-decoder model that rewrites sentences with a desired portrayal using agency connotation frames (§3). We combine a reconstruction and paraphrase objective into our model to overcome the lack of parallel supervised data, building off of the denoising autoencoder setup from Li et al. (2018a). To steer the revisions, we endow the model with connotation frame knowledge both at training time using control tokens, and at generation time using agency-based vocab boosting.

Our findings show that POWERTRANSFORMER is effective at rewriting sentences with desired agency connotations while only making minimal changes to their meaning, as measured through both human and automatic evaluations (§4). We also show that POWERTRANSFORMER significantly outperforms existing stylistic rewriting methods (Prabhumoye et al., 2018; Dathathri et al., 2020) on those metrics. Additionally, through ablations studies, we establish the usefulness of each component of the model, finding benefits from both the joint objective (47% gain in accuracy) and the agency scaling (12% gain in accuracy).

Finally, in §5, we apply Controllable Debiasing to a corpus of modern English movies (Gorinski and Lapata, 2015) as a step towards removing gender bias in character portrayal established by prior work (Sap et al., 2017). Using POWERTRANSFORMER, we revise the movie scripts and significantly increase the agency levels of female characters, thereby reducing the gender bias. Our findings show promise for using modern NLP tools to help mitigate societal biases in text. We release our preprocessed data and code at `http://maartensap.com/controllable-debiasing`.

2 Controllable Debiasing

Controllable Debiasing is a novel formalization of stylistic rewriting that aims to debias the portrayal of characters through controllable revision. To achieve the desired character portrayal, a system must be able to change the underlying meaning of events, unlike certain formalizations (e.g., politeness transfer; Rao and Tetreault, 2018) where full meaning preservation is required. Without this, systems run the risk of merely paraphrasing the biases in text. However, revisions must be precise and avoid unnecessary meaning changes, which can often occur in stylistic rewriting (e.g., reversing the sentiment of a review drastically changes its underlying meaning).

For our new rewriting task of changing portrayal bias, we focus on connotation frames that measure the *power* and *agency* ascribed to characters through the actions they take. Connotation frames (Rashkin et al., 2016; Sap et al., 2017) distill implicit relations between a verb, its agent, and its theme. In this work, we use the positive, neutral, and negative agency dimensions, where agency is defined as the capacity to intentionally make changes or act upon one's environment (Dennett, 1989). For example, illustrated in Figure 1, "X pursued Y" implies that X has positive agency.[1] Using machine-in-the-loop writing systems (e.g., Ghazvininejad et al., 2016, 2017; Clark et al., 2018, Textio[2]), models trained on this task could help authors write news, stories, or movies that portray characters in less biased ways, and thereby help mitigate the negative effects of stereotypical portrayals in media (Behm-Morawitz and Mastro, 2008; Field et al., 2019).

3 POWERTRANSFORMER

We present a new approach for Controllable Debiasing called POWERTRANSFORMER, which addresses two key challenges: the paucity of parallel supervised data for training and the difficulty of incorporating fine-grained control for steering the agency of the output. Our approach (Figure 2) jointly learns to reconstruct partially masked story

---

[1] Future work could explore using the power dimension instead of agency, or alternative operationalizations of biases, e.g., Social Bias Frames (Sap et al., 2020) or *regard* towards minorities as introduced by Sheng et al. (2019).

[2] `https://textio.com/`

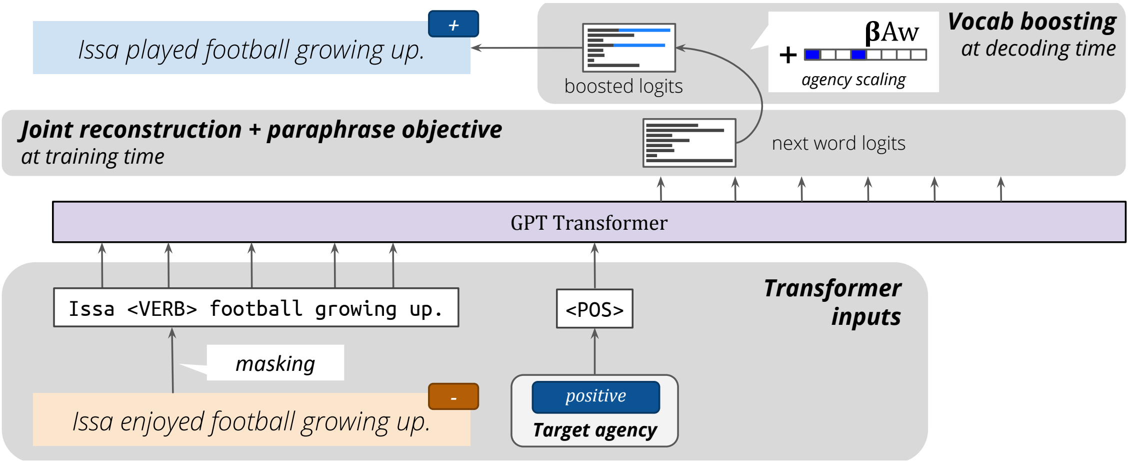

Figure 2: Overview of the full POWERTRANSFORMER model. An input sentence is masked for verb tokens indicative of agency. Masked inputs and target agency are used as GPT inputs. We use a joint objective using both paraphrase data and masked input sentences for training. At decoding time, we employ a vocab boosting technique to steer generations towards the target agency.

sentences while also learning to paraphrase from an external corpus of paraphrases (§3.2). At generation time, we also include a boosting method for fine-grained steering towards the desired agency level as described in §3.3.

3.1 Model Overview

POWERTRANSFORMER is an encoder-decoder style model with an OpenAI-GPT transformer model (Radford et al., 2018) as the base. The input sentence $\mathbf{x}$ is converted to a sequence of byte pair encodings (BPE) $\{x_1, ..., x_n\}$, and given to the encoder after being scrubbed of its agency markers as described below. To steer the model, we also give the encoder the target agency t, which we represent as one of three special tokens {`<Pos>`,`<Equal>`,`<Neg>`}.[3]

3.2 Joint Objective

We train our model on both a reconstruction and a paraphrasing task, for which inputs are masked and paraphrased versions of the output, respectively.

$$\mathcal{L}_{\text{joint}} = \mathcal{L}_{\text{recon}} + \mathcal{L}_{\text{para}} \tag{1}$$

Masking and Reconstructing Inspired by the delete-retrieve-generate model from Li et al. (2018a), this objective teaches the model to recover masked out agency-associated verbs in sentences. We first assign an agency level to an input sentence by counting verbs in the agency lexicon from Sap et al. (2017).[4] Then, we mask out all verbs indicative of the agency level, replacing them with a special `<VERB>` token. In this setup, the target output is the original sentence $\mathbf{x} = \{x_1, ..., x_n\}$, with the masked sentence $\hat{\mathbf{x}}$ and the target agency level t as inputs. During training, we minimize the cross entropy of the target output sentence given the inputs:

$$\mathcal{L}_{\text{recon}} = -\frac{1}{n}\sum_{i=1}^{n} \log p(x_i | x_{<i}, \hat{\mathbf{x}}, t) \tag{2}$$

Paraphrasing To go beyond reconstructing sentences, we add a paraphrasing objective using an out-of-domain paraphrase corpus (§4.1). We extract agency levels for each sentence and its paraphrase and mask out the agency verbs in the input, using the same methods as described above. Here, the inputs are the masked sentence $\hat{\mathbf{x}}$ and the target agency t, while the target output $\mathbf{y} = \{y_1, ..., y_m\}$ is the paraphrase. As with reconstruction, we minimize the cross entropy of the target output given the inputs:

$$\mathcal{L}_{\text{para}} = -\frac{1}{m}\sum_{i=1}^{m} \log p(y_i | y_{<i}, \hat{\mathbf{x}}, t) \tag{3}$$

3.3 Controlled Decoding with Vocab Boosting

We employ a vocab-boosting technique during generation to encourage models towards generating with the desired agency, inspired by Ghosh

---

[3] In earlier experiments, we also provided the original agency as an input to the model during training and decoding, but found that it made little difference in performance.

[4] For sentences that have multiple verbs, we assign the agency level that the most verbs in the sentence have (e.g., a sentence with two positive agency verbs and one negative agency verb will be assigned positive agency).

	Type	# Instances	Pos	Neutral	Neg
ROC	train	10721	3834	4151	2736
	dev	1803	633	710	460
	test	899	325	350	224
Para.	train	45000	16410	14153	14437
	dev	10000	3645	3328	3127

Table 1: Statistics for our main story sentences dataset (ROC) and for the external paraphrase corpus (Para.).

et al. (2017). At each decoding timestep i, we rescale the unnormalized token probabilities (logits $l_i \in \mathbb{R}^V$, where V is the vocabulary size) to boost the likelihood of predicting words with the target agency. The next token probabilities are then computed using the "boosted" logits:

$$P(y_i|y_{<i}, x, t) \propto \text{softmax}(l_i + \beta \cdot Aw) \qquad (4)$$

where A is a $\mathbb{R}^{V\times3}$ matrix that represents a 3-dimensional {positive, equal, and negative} agency embedding for each token in the vocabulary, w is a $\mathbb{R}^3$ one-hot vector denoting the target agency for the output, and β is a scalar hyperparameter representing the boosting strength. We create A manually using the verbs in the agency lexicon (Sap et al., 2017).[5] Used only at decoding time, this method effectively increases the likelihood of using a word with the target agency level.

4 Controllable Debiasing Experiments

In this section, we describe three experiments for investigating POWERTRANSFORMER performance. First, we evaluate performance of our full model and ablated baselines, using automatic metrics to quantify the effectiveness of each modelling component (§4.4). Next, we compare our full model to baselines from related work (§4.5). Lastly, given the limitations of automated metrics for evaluating generations (Liu et al., 2016; Mir et al., 2019), we obtain human judgments of model performance through crowdsourcing (§4.6). We additionally include examples of generations in Table 4.

4.1 Datasets

In our experiments, we use a dataset of short stories for the reconstruction task and a parallel corpus of paraphrases for both paraphrase and reconstruction tasks. We show data statistics in Table 1, with additional preprocessing details in Appendix A.

ROC story corpus The main focus of our study is controllable revision of story sentences; therefore, we select sentences from the ROC story corpus (ROC Mostafazadeh et al., 2016). After extracting agency levels for all sentences from the training stories, we sample roughly equal amounts of all three agency levels, and randomly split sentences into training, development, and test sets.[6]

Paraphrase corpus As additional training data, we use the corpus of automatically aligned paraphrases of TV subtitles (Creutz, 2018, Para.). As with the ROC story corpus, we extract agency levels for each sentence and its paraphrase, then sample roughly equal amounts of pairs with all different sentence-paraphrase agency combinations (further details in §A.2). We randomly split the data into 45k train and 10k dev. instances (Table 1).[7]

4.2 Metrics

In addition to human evaluations, we also use a variety of automated evaluation metrics to characterize different aspects of performance. We measure the accuracy of the change in agency by comparing the target agency level with that of the output (extracted using the connotation frames lexicon). As a measure of meaning preservation, we use BERTscore F1 metrics (Zhang et al., 2020) to compare the semantic similarity of the input sentence with the machine output.

As additional metrics, we measure the fluency, the repetitiveness, and diversity of the output. Following previous work (Dai et al., 2019), we measure fluency as perplexity (*PPL*) of the output sentence using a pre-trained GPT model that has not been fine-tuned for this task. As an additional metric of potential text degeneration, we compute the fraction of output sentences that have a bigram that is repeated two or more times (*w/ rep*). Finally, we compute the fraction of generations that are unique with respect to the rest of the output, to ensure diverse, input-specific generations (*unique*).

---

[5] Since our model operates on BPE tokens, we manually set the first BPE token of every tense of every verb to the desired agency. We also experimented with learning A from data, but found no improvement over manually setting it.

[6] We use a 80:13:7 train, development, test ratio.

[7] Since this is just additional training data, we do not test our models on this corpus, but do use the dev. set for selecting some hyperparameters.

Ablations using the Development Set

	Main Metrics		Additional Metrics		
	Agency	**Meaning**	**Fluency**	**Repetition**	**Diversity**
POWERTRANSFORMER variants	Acc (↑)	BertScore (↑)	PPL (↓)	w/ Rep (↓)	Unique (↑)
(*ParaOnly+noBoost*)	.30	.95	**58.76**	.002	.54
(*ParaOnly+Boost*)	.42	.90	76.25	**.001**	.59
(*Joint+noBoost*)	.77	**.96**	70.61	.007	.87
(*Joint+noBoost*)+*SupplyVerb*	.77	**.96**	94.54	.004	.92
FULL = (*Joint+Boost*)	**.89**	**.96**	76.78	.015	**.99**

Table 2: Ablation study results on the development set. We present separate metrics for evaluating the change in agency, the meaning preservation, fluency, repetitiveness and diversity of the output (bolding the best performance). (↑) indicates that higher is better and (↓) indicates that lower is better.

4.3 Experimental Setup

We randomize ROC story and paraphrase data, and use OpenAI GPT LM as our pretrained model. For decoding, we use top-p=0.4 nucleus sampling (Holtzman et al., 2020), and a boosting strength of β=5 (hyperparameters and details in §B.1).

4.4 Investigating Effectiveness of Approach

We first establish our model's effectiveness at Controllable Debiasing on our dev. set, and investigate the importance of various components in our approach through ablation analyses. For qualitative analyses, we also show example revisions in Table 4 (and Table 6 in the appendix).

4.4.1 Ablated Baselines

We first investigate the importance of the reconstruction objective, by comparing our joint objective model (*Joint*) with a model trained with just the paraphrasing objective (without masking, *ParaOnly*). Then, to quantify the effect of boosting, we compare models with (*Boost*) and without (*noBoost*) agency-specific vocab boosting. Note that *ParaOnly+noBoost* is equivalent to a GPT-based encoder-decoder model, similar to seq2seq frameworks commonly used in paraphrasing tasks (Cao et al., 2017; Li et al., 2018b; Prakash et al., 2016).

As a final comparison, we implement a model variant that more closely mirrors the delete-retrieve-generate paradigm (Li et al., 2018a) by adding a "retrieve" step in which we concatenate transformer input with a verb retrieved from the verb agency lexicon that is most similar to the masked out verb (*SupplyVerb*).[8]

4.4.2 Results

In Table 2, our results show that the full model (*Joint+Boost*) yields text revisions with the most accurate target agency and the most meaning preservation. In general, we find that both the joint objective and vocab boosting (*Boost*) substantially increase the target agency accuracy, as also illustrated in examples (d) and (e) in Table 4. However, unsurprisingly, vocab boosting also slightly lowers fluency, yielding higher perplexities than models' non-boosted counterparts. Our results also show that using the joint objective with boosting increases the diversity of output, but causes marginally more repetition of bigrams.

Counterintuitively, our ablations show that supplying a verb to the model as an explicit retrieval step (*SupplyVerb*) does not improve the agency or meaning metrics and actually hurts the fluency of the output (as measured by higher perplexities). Upon qualitative investigation (Table 6 in the appendix), the retrieved verb is often related to a different word sense of the masked verb, breaking the grammaticality of the sentence.

4.5 Comparison with External Approaches

To further validate our approach, we compare against two baselines from related style transfer and stylistic generation tasks. As these models were designed for binary style transfer, we only report our baseline and model results on the positive and negative agency portions of our data.

---

[8] We retrieve a verb from the Sap et al. (2017) lexicon that has the target agency and is most similar to the masked out verb, where similarity is defined as cosine distance between word embeddings using GloVe 300-d embeddings (Pennington et al., 2014).

Test Set Comparisons (pos-to-neg and neg-to-pos set)

	Main Metrics		Additional Metrics		
	Agency Acc (↑)	**Meaning** BertScore (↑)	**Fluency** PPL (↓)	**Repetition** w/ rep (↓)	**Diversity** unique (↑)
PPLM (Dathathri et al., 2020)	.13	.95	106.12	.053	**1.00**
BST (Prabhumoye et al., 2018)	**.88**	.83	**91.22**	.053	0.79
POWERTRANSFORMER	.86	**.96**	95.19	**.015**	**1.00**

Table 3: Performance of different re-writing methods on the neg-to-pos and pos-to-neg subsets of the test set (bolding the best performance). We evaluate the change in agency and the meaning preservation. As secondary metrics, we include fluency, repetitiveness, and diversity of the output.

4.5.1 Baselines

BST We compare to the backtranslation style transfer model from Prabhumoye et al. (2018). This model first translates input sentences to a pivot language (preserving the meaning but losing language-specific style), then relies on style-specific decoder-translators for generating the output sentence. We include set-up details in §B.3.

PPLM Recent work in controllable generation has introduced PPLM, a new plug-and-play technique with promising results for decoding stylistic text (Dathathri et al., 2020). This method operates on an underlying neural language model at decoding time. It uses backpropagation from a stylistic discriminator to update the past and present hidden representations to be more consistent with the targeted style or domain. We adapt the approach to controllable revision by replacing the base language model with an autoencoder trained on a reconstruction objective, described in detail in §B.2.

4.5.2 Results

We present results in Table 3. Our experiments show that POWERTRANSFORMER performs better than the baselines overall. Specifically, while the BST revisions obtain slightly higher accuracy on the output agency levels, these revisions have the both the lowest diversity and meaning preservation, suggesting the model ignores the input (Table 4). PPLM shows opposite trends, yielding the lowest accuracy with high meaning preservation and high diversity of generations. Illustrated in Table 4, this model often makes less purposeful and less concise alterations.

4.6 Evaluating with Human Judgements

To validate our automatic evaluations, we collect human judgments of the controllable revisions from several baselines and POWERTRANSFORMER (*Joint+Boost*).

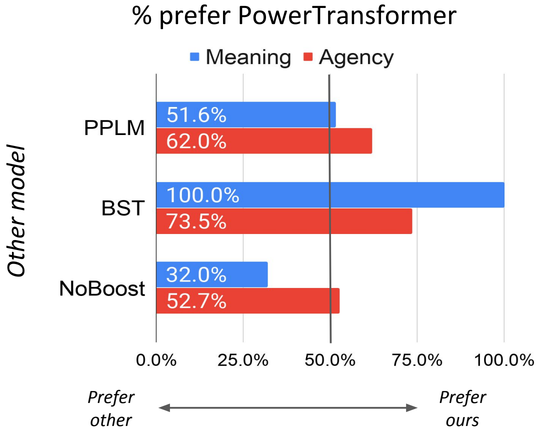

Figure 3: Human judgements of target agency and meaning preservation in POWERTRANSFORMER vs. three other model variants. Selection rates >50% indicate preference towards our model.

4.6.1 Human Evaluation Task

We design a head-to-head[9] crowdsourcing task on Amazon Mechanical Turk where we ask raters to compare two outputs from different models given the same input sentence and target agency (see Figure 5 in the appendix). We first ask them to judge whether either output is gibberish, then, in two questions, choose which revision has better targeted agency and which better preserves the meaning of the original sentence. For consistency, each pair is rated by three judges. To ensure the quality of our evaluations, we selected workers who could reliably distinguish high from low agency sentences in a qualification task (see Figure 6 in

---

[9] We use head-to-head evaluations as those have been shown to be more reliable than scale-rating evaluations (Kiritchenko and Mohammad, 2017).

dir.		Input	Model	Revised Sentence (out)	Agency(out)

Table 4: Example sentences from our dev. set, along with their revisions from various models and the achieved agency levels (Agency(out)). Examples (a)-(c) should be rewritten from high to low agency, and (d)-(f) from low to high agency. Confirming our quantitative results in Tables 2 and 3, PowerTransformer (*Joint+Boost*) is the most effective at making purposeful and precise changes to the input sentences to alter their agency while minimally changing their meaning. Revisions from more models are listed in Table 6 (in the appendix).

the appendix).

For this evaluation, we generate three revisions–one for each target agency level–for a random subset of 100 test examples. We compare the output of our full PowerTransformer model with two external baselines (PPLM and BST). For further comparison, we also include the most competitive ablated baseline from Table 2 (i.e., *Joint+noBoost*).

4.6.2 Results

In Figure 3, we show the percentages of times in which PowerTransformer was preferred over the three baseline models.[10] Percentages >50% indicate a preference towards PowerTransformer.

Overall, the sentence revisions by PowerTransformer are preferred over all of the baselines in obtaining the desired agency level. For meaning preservation, our model is always selected over BST, mirroring BertScores in Table 3. The difference is less stark when comparing to PPLM which sometimes makes no changes or irrelevant changes to the input sentence, and reversed when comparing to the ablated *noBoost*.

Additionally, BST revisions were marked as gibberish substantially more than those by other models (63% vs. 3-7%). While this seemingly contradicts BST's low perplexity scores, this is in line with previous work showing automatic fluency metrics can favor degenerate, bland, or repetitive language (Holtzman et al., 2020).

5 Gender Bias in Movies

As a proof-of-concept of Controllable Debiasing, we investigate whether gender biases in portrayals of movie characters can be mitigated using PowerTransformer.

---

[10] Judgments in our evaluation task had an average pairwise agreement of 75% (Krippendorf's α=.52).

5.1 Movie Scripts Corpus

We draw our data from the 767 modern English movie scripts by Gorinski and Lapata (2015), focusing on the narrations which describe characters and their actions (as opposed to the character's dialogue utterances). Described in further detail in §C in the appendix, we automatically extract characters and assign them a binary[11] gender (man, woman) using a list of highly gendered names (e.g., "Sarah", "William") and a list of gendered words (e.g., "waiter," "waitress"). Following previous work (Ramakrishna et al., 2017; Sap et al., 2017), we assign narration sentences to characters if their name appears in them.

Our corpus contains 16,763 characters from 767 different English movies. Of those characters, 68% are inferred to be men and only 32% to be women,[12] consistent with known gender skews in movie characters (Google, 2017). This bias in representation is also present at the narrative level. Specifically, female characters are only mentioned in $n_{narr,f}$ =27 narrations on average, compared to $n_{narr,m}$ =34 narrations for male characters (Cohen's $|d| = 0.13$, $p < 0.001$). Similarly, compared to their male counterparts, female characters are described in significantly fewer words ($n_{words,f} = 329$, $n_{words,m} = 435$, $|d| = 0.14$, $p < 0.001$) and with fewer verbs ($n_{verbs,f} = 41$, $n_{verbs,m} = 54$, $|d| = 0.13$, $p < 0.001$).

5.2 Debiasing Portrayal in Movies

Given the known bias that female characters are portrayed with less agency (Sap et al., 2017), our goal is to re-balance their agency levels to be more on par with those of male characters. Therefore, we revise only the sentences describing female characters to have higher agency, using POWERTRANSFORMER. Then we extract connotation frames of agency for revised script sentences, and aggregate per character. Shown in Figure 4, revisions successfully increase the instances of positive agency of female characters, and decrease their negative agency or passiveness.

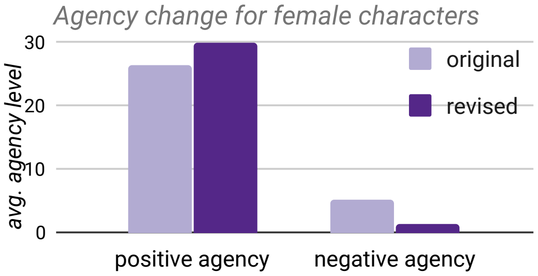

Figure 4: Average agency levels (i.e., number of agency verbs) for female characters in original and revised scripts. POWERTRANSFORMER can revise the portrayals of female characters in movies to give them higher positive agency and lower negative agency.

We further examine the change in gender association of positive and negative agency, to verify the effectiveness of Controllable Debiasing. We first count all the positive and negative agency verbs used to describe characters (in original or rewritten sentences). Following Sap et al. (2017), we then fit a logistic regression model to quantify the association between character's gender with their agency levels, controlling for their number of words, verbs, and narrations. For better interpretation of the β coefficients, we z-score all the continuous variables.

We confirm that indeed, Controllable Debiasing using POWERTRANSFORMER can reverse the bias in portrayal in movies. In original scripts, male characters were portrayed with significantly higher positive agency ($\beta_{\text{pos}} = 1.2$, $p < 0.001$) and lower negative agency ($\beta_{\text{neg}} = -0.3$, $p < 0.001$) than female characters. However, our model successfully reverses this gender bias, portraying women with significantly more positive agency ($\beta'_{\text{pos}} = -62.6$, $p < 0.001$) and significantly less negative agency ($\beta'_{\text{neg}} = 8.7$, $p < 0.001$).

Our findings on movie scripts show the promise of using Controllable Debiasing to successfully mitigate gender biases in portrayal of characters, which could be extended to other domains (e.g., news or fiction, Field and Tsvetkov, 2019; Fast et al., 2016). Additionally, future work could consider alternative views of portrayal biases (e.g., "regard" or bias directed at different demographic groups; Sheng et al., 2019; Sap et al., 2020), or use more holistic views of gender roles (e.g., "masculine default" cultures; Cheryan and Markus, 2020).

6 Related Work

Controllable Debiasing is a new formalization of the unsupervised stylistic rewriting task, contrasting with supervised approaches which benefit from

---

[11] Note that gender is a social construct that goes beyond the man-woman binary (Lorber et al., 1991), however more inclusive analyses (e.g., with non-binary genders) are not possible given the limited information about the individuals mentioned in our data.

[12] There were 2597 characters for which the gender could not be inferred.

parallel corpora (e.g., Xu et al., 2012, 2015; Rao and Tetreault, 2018; Pryzant et al., 2020). In unsupervised settings, a majority of work has dealt with the dearth of parallel data by using encoder-decoder setups paired with discriminators to disentangle style from content and steer generations (e.g., Shen et al., 2017; Zhang et al., 2018; Fu et al., 2018; Yang et al., 2018; Niu and Bansal, 2018; Romanov et al., 2019; Dai et al., 2019; John et al., 2019) or backtranslation setups (Prabhumoye et al., 2018; Lample et al., 2018). In contrast, Li et al. (2018a) introduce a modular approach (later adapted to transformer models by Sudhakar et al., 2019) that relies on drop-in replacement of attribute markers followed by language correction. POWERTRANSFORMER improves on this approach with an additional out-of-domain paraphrasing objective.

While a majority of related existing stylistic rewriting work defines style as sentiment (e.g., on reviews), a notable exception is Nogueira dos Santos et al. (2018), who use stylistic rewriting to make text less hateful or offensive. Similar in spirit, Controllable Debiasing is a novel formalization that aims to address and revise social biases expressed in text, but using the nuanced implications distilled in connotation frames of power and agency instead of binary offensiveness.

Our work also draws inspiration from controllable generation methods (e.g., Koncel-Kedziorski et al., 2016; Hu et al., 2017; Ficler and Goldberg, 2017). While those methods steer the generation output to contain desired attributes, controllable revision is constrained to revise an input sentence in addition to generating with desired attributes.

7 Conclusion

We introduce a new text revision task of Controllable Debiasing, to help debias the portrayal of characters through the lens of connotation frames of power and agency. To this end, we create POWERTRANSFORMER, a transformer-based encoder-decoder trained on a joint reconstruction and paraphrasing objective. Our approach demonstrates promising results to revise sentences with targeted power and agency, and outperforms ablations and baselines on both automatic and human evaluations. Finally, as a case study, we show the feasibility for Controllable Debiasing at debiasing the portrayal of characters in movie scripts. Our findings highlight the potential of neural models as a tool for editing out social biases in text.

Acknowledgements

The authors thank the anonymous reviewers and meta-reviewers for their helpful feedback. We also thank Aishwarya Nirmal and Kenta Takatsu for their preliminary exploration of this task. Additionally, we thank Ari Holtzman, Lucy Lin, Sofia Serrano, Elizabeth Clark, and other members of the UW NLP community for their thoughtful input. This research was supported in part by NSF (IIS-1524371, IIS-1714566), DARPA under the CwC program through the ARO (W911NF-15-1-0543), DARPA under the MCS program through NIWC Pacific (N66001-19-2-4031), and the National Science Foundation Graduate Research Fellowship Program under Grant No. DGE-1256082.

A Additional data description

A.1 ROC story corpus

This English corpus originally contains 100,000 five-sentence stories written by crowdworkers about realistic everyday scenarios. We select the data for our task by first extracting agency levels for each sentence, filtering out those with indeterminable agency. Additionally, we filter out sentences with four or more verbs, to prevent the sentence masking from deleting too many content words.

A.2 Paraphrase corpus

This corpus contains paraphrases of spoken dialogue extracted from movie and TV subtitles.[13] OpusParcus was created by automatically aligning the subtitles sentences using several probabilistic metrics, including likelihood under a round-trip translation paraphrasing model (Bannard and Callison-Burch, 2005) and pointwise mutual information. For our paraphrasing dataset, we apply the same filtering as with the ROC story corpus to the English portion of the OpusParcus training corpus and select the top 10% highest scoring paraphrases using the PMI scoring from the original paper. We extract agency levels for each pair of paraphrases, and select pairs to obtain roughly equal number of agency-level pairs (i.e., 1/9th positive-neutral, 1/9th positive-negative, etc.) We preprocess the text by stripping any leading periods and commas.

B Experimental details

We use the Hugging Face (Wolf et al., 2019) implementation of OpenAI's GPT model (117M parameters; Radford et al., 2018). our final setup uses AdamW (Loshchilov and Hutter, 2019) as our optimizer with a learning weight of 1e-5, batch size of 4 and maximum sequence length of 64. In preliminary results, we find that β=5 aptly steers the generation while avoiding repetition issues.

B.1 POWERTRANSFORMER details

All the experiments are performed on NVIDIA TITAN card and use the model hyperparameters listed in Table 5.

Hyperparameter	Value
Vocabulary Size	40486
Maximum Sequence Length	64
Training Batch Size	4
Embedding Size	768
# Attention Heads	12
# Attention Layers	12

Table 5: POWERTRANSFORMER hyperparameters.

B.1.1 POWERT$_{ParaOnly+None}$

We train this model for 10 epochs with each epoch taking approximately an hour. The learning rate is 1e-5 with AdamW optimizer, which is tuned manually in the [1e-6, 1e-3] range for 7 times. We use $p = 0.4$ for nucleus sampling and p is tuned manually in the [0.4, 0.9] range for 5 values.

B.1.2 POWERT$_{ParaOnly+Static}$

The POWERT$_{ParaOnly+Static}$ loads the trained model from POWERT$_{ParaOnly+None}$ and add re-scaling to the logits. The re-scaling factor, β was tuned manually tuned in the [0, 10] range. We try 8 βs and use 5 in the final model. We use the same p as POWERT$_{ParaOnly+None}$

B.1.3 POWERT$_{Joint+None}$

Similar to POWERT$_{ParaOnly+None}$, we train this model for 10 epochs with each epoch taking approximately an hour. The learning rate is 1e-5 with AdamW optimizer, which is tuned manually in the [1e-6, 1e-3] range for 7 times.We use the same p as POWERT$_{ParaOnly+None}$

B.1.4 POWERT$_{Joint+Static}$

The POWERT$_{Joint+Static}$ loads the trained model from POWERT$_{Joint+None}$ and add re-scaling to the logits. The re-scaling factor, β was tuned manually tuned in the [0, 10] range. We try 8 βs and use 5 in the final model. We use the same p as POWERT$_{ParaOnly+None}$

B.2 PPLM details

The PPLM decoding method can be used on top of any model, but their original codebase is for use with a pre-trained language model rather than a model for paraphrasing or style transfer. We augment their techniques for this task by replacing the base model in their code with a denoising autoencoder that was trained to reconstruct the input sentence. The denoising autoencoder was implemented using the base GPT2 model (to fit with their code library and be similar size to our model). It was trained on our ROC only training data with a

---

[13] From `http://www.opensubtitles.org`

reconstruction objective. In order to denoise the autoencoder, we randomly "dropout" about 50% of the tokens from the context by replacing them with mask tokens. This autoencoder is trained to reconstruct input sentences, but when used with the PPLM decoding method, the input gets dynamically updated to decode a sentence that is similar in meaning but more likely to have a positive/negative agency according to a discriminator that is trained on top of the autoencoder. The PPLM decoding method also has hyperparameters that control the strength of the target label. If set too high, then the output could be degenerate. We manually set the hyperparameters to be as strong possible without producing degenerate text, using a subset of the dev. set as a guide.

B.3 Backtranslation details

We use the code provided by Prabhumoye et al. (2018) for running this baseline. After lowercasing all the negative and positive agency examples in our training data (ROC and OpusParcus), we translate to French using the machine translation model provided in the code base. This baseline requires training a style classifier (agency) and two decoders (one for each agency level). Since the classifier essentially re-learns the agency lexicon, we do not search for hyperparameters, and simply set a learning rate of 5, and 6 epochs. For training the decoders, we perform grid search to find the best hyperparameters. We experiment with a learning rates of {0.5, 1, 2, 5}, {2, 3, 5} epochs, a classification-loss weight of {0.5, 1, 2}, and a word-loss weight of {0.5, 1, 2}, and select the configuration with the best word-level accuracy on the dev. set. We use SGD with a batch size of 64 for all experiments, and refer the reader to the code base for other default parameters.

C Gender Bias in Movies

C.1 Extracting gender from characters

The movie scripts mention characters in all caps, making it easy to identify and extract them. We then cross reference the name (or, description for unnamed characters, e.g., "the doorman") with a list of gendered names[14] and gendered words (e.g., "waitress," "policeman," "police woman"). To allow for better rewriting using our model, we split the narratives into sentences (using NLTK's sentence tokenizer Bird et al., 2009), and assign each sentence to a character if their name appears in the sentence.

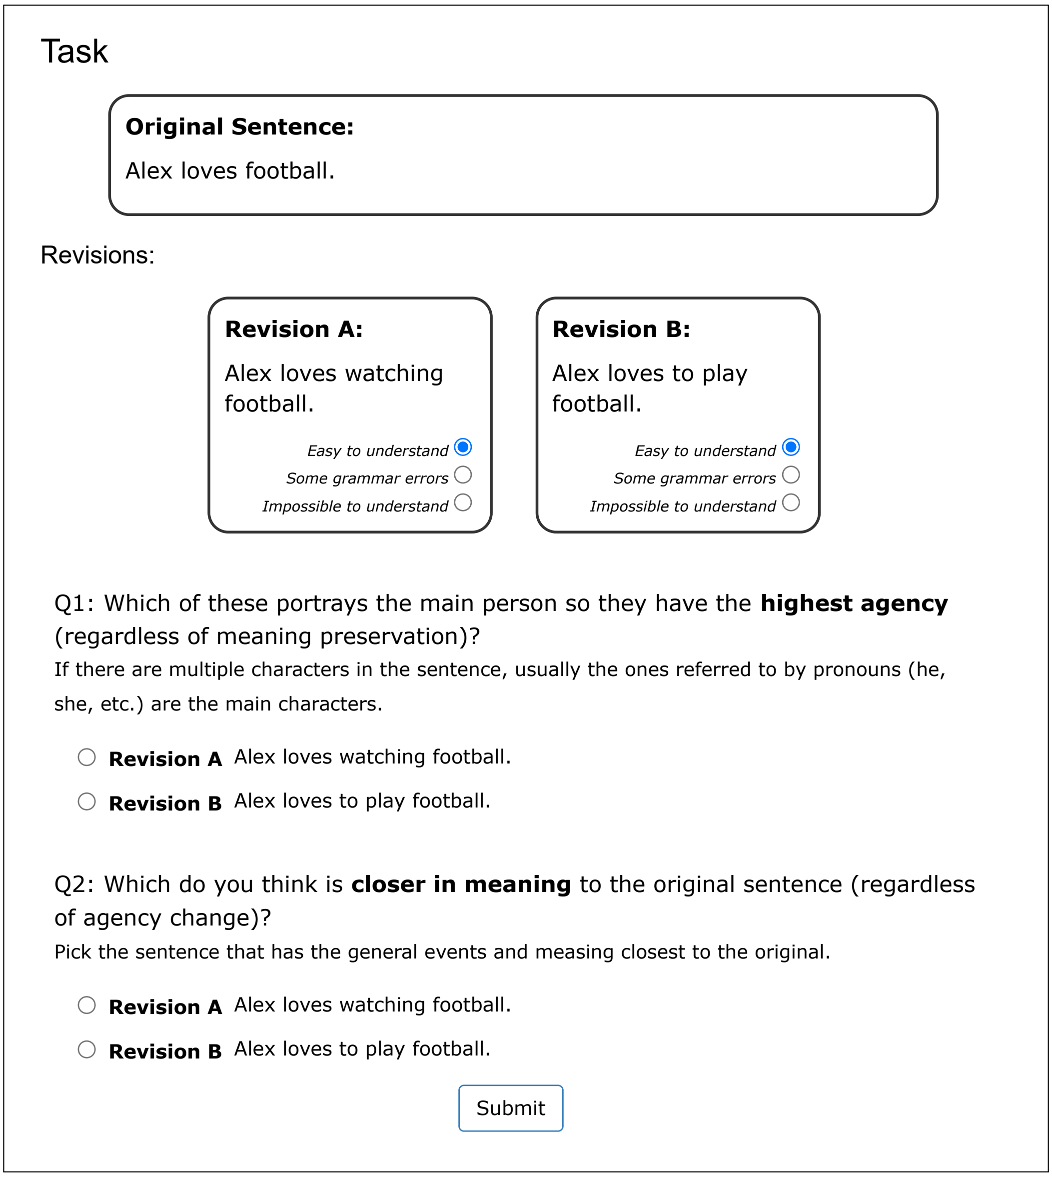
[14] http://www.cs.cmu.edu/Groups/AI/util/areas/nlp/corpora/names/0.html



Task

Original Sentence:

Alex loves football.

Revisions:

Revision A:

Alex loves watching football.

Easy to understand ●
Some grammar errors ○
Impossible to understand ○

Revision B:

Alex loves to play football.

Easy to understand ●
Some grammar errors ○
Impossible to understand ○

Q1: Which of these portrays the main person so they have the **highest agency** (regardless of meaning preservation)?

If there are multiple characters in the sentence, usually the ones referred to by pronouns (he, she, etc.) are the main characters.

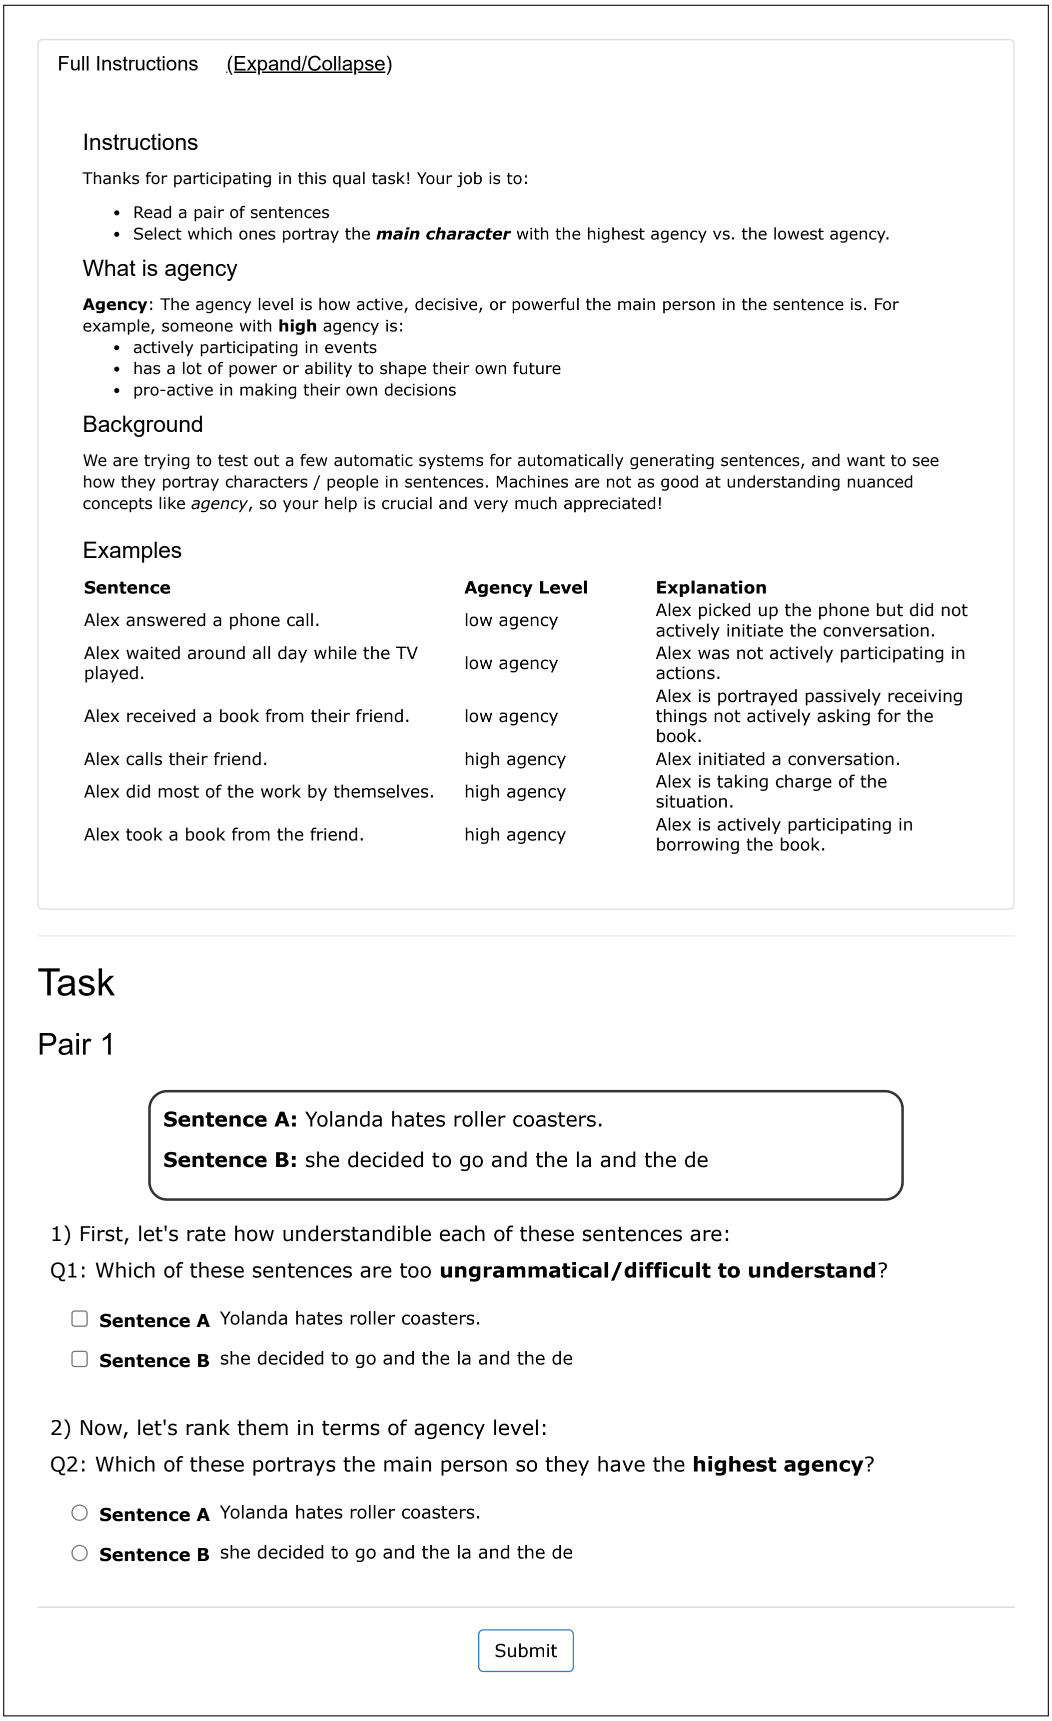
○ **Revision A** Alex loves watching football.
○ **Revision B** Alex loves to play football.

Q2: Which do you think is **closer in meaning** to the original sentence (regardless of agency change)?

Pick the sentence that has the general events and measing closest to the original.

○ **Revision A** Alex loves watching football.
○ **Revision B** Alex loves to play football.

Figure 5: Screenshot of the human evaluation annotation task.



Instructions

Thanks for participating in this qual task! Your job is to:

- Read a pair of sentences
- Select which ones portray the ***main character*** with the highest agency vs. the lowest agency.

What is agency

Agency: The agency level is how active, decisive, or powerful the main person in the sentence is. For example, someone with **high** agency is:

- actively participating in events
- has a lot of power or ability to shape their own future
- pro-active in making their own decisions

Background

We are trying to test out a few automatic systems for automatically generating sentences, and want to see how they portray characters / people in sentences. Machines are not as good at understanding nuanced concepts like *agency*, so your help is crucial and very much appreciated!

Examples

Sentence	**Agency Level**	**Explanation**
Alex answered a phone call.	low agency	Alex picked up the phone but did not actively initiate the conversation.
Alex waited around all day while the TV played.	low agency	Alex was not actively participating in actions.
Alex received a book from their friend.	low agency	Alex is portrayed passively receiving things not actively asking for the book.
Alex calls their friend.	high agency	Alex initiated a conversation.
Alex did most of the work by themselves.	high agency	Alex is taking charge of the situation.
Alex took a book from the friend.	high agency	Alex is actively participating in borrowing the book.

Task

Pair 1

Sentence A: Yolanda hates roller coasters.

Sentence B: she decided to go and the la and the de

1) First, let's rate how understandible each of these sentences are:

Q1: Which of these sentences are too **ungrammatical/difficult to understand**?

☐ **Sentence A** Yolanda hates roller coasters.

☐ **Sentence B** she decided to go and the la and the de

2) Now, let's rank them in terms of agency level:

Q2: Which of these portrays the main person so they have the **highest agency**?

○ **Sentence A** Yolanda hates roller coasters.

○ **Sentence B** she decided to go and the la and the de

Figure 6: Screenshot of the qualification task and its instructions. In the real task, workers rated three pairs of sentences, but only one is shown here.

Table 6: Full version of Table 4. Example revisions from various models for sentences from the dev. set. Columns are: the target change in agency from the original to the target agency, the input sentence, the model, generated output, and the actual agency level of the output measured by the connotation frame lexicon.

MEGA RST Discourse Treebanks with Structure and Nuclearity from Scalable Distant Sentiment Supervision

Patrick Huber and Giuseppe Carenini
Department of Computer Science
University of British Columbia
Vancouver, BC, Canada, V6T 1Z4
`{huberpat, carenini}@cs.ubc.ca`

Abstract

The lack of large and diverse discourse treebanks hinders the application of data-driven approaches, such as deep-learning, to RST-style discourse parsing. In this work, we present a novel scalable methodology to automatically generate discourse treebanks using distant supervision from sentiment-annotated datasets, creating and publishing MEGA-DT, a new large-scale discourse-annotated corpus. Our approach generates discourse trees incorporating structure and nuclearity for documents of arbitrary length by relying on an efficient heuristic beam-search strategy, extended with a stochastic component. Experiments on multiple datasets indicate that a discourse parser trained on our MEGA-DT treebank delivers promising inter-domain performance gains when compared to parsers trained on human-annotated discourse corpora.

1 Introduction

Discourse parsing is an important Natural Language Processing (NLP) task, aiming to uncover the hidden structure underlying coherent documents, as described by theories of discourse like Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) or PDTB (Prasad et al., 2008). Not only has discourse parsing been shown to enhance key downstream tasks, such as text classification (Ji and Smith, 2017), summarization (Gerani et al., 2014) and sentiment analysis (Bhatia et al., 2015; Nejat et al., 2017; Hogenboom et al., 2015), but it also appears to complement contextual embeddings, like BERT (Devlin et al., 2018), in tasks where discourse information is critical, such as argumentation analysis (Chakrabarty et al., 2019).

Traditionally, RST-style discourse parsing builds a complete, hierarchical constituency tree for a document (Morey et al., 2018), where leaf nodes are clause-like sentence fragments, called elementary-discourse-units (EDUs), while internal tree nodes are labelled with discourse relations (e.g., Evidence, Contrast). In addition, each node is given a nuclearity attribute, which encodes the importance of the node in its local context.

A key limitation for further research in RST-style discourse parsing is the scarcity of training data. Only a few human annotated discourse treebanks exist, each only containing a few hundred documents. Although our recent efforts using distant supervision from sentiment to generate large-scale discourse treebanks have already partly addressed this dire situation (Huber and Carenini, 2019), the previously proposed solution is still limited in: (i) Scope, by only building the RST constituency structure without nuclearity and relation labels; and (ii) Applicability, by relying on a non-scalable CKY solution, which cannot be applied to many real-world datasets with especially long documents.

In this work, we propose a significant extension to this line of research by introducing a scalable solution for documents of arbitrary length and further moving beyond just predicting the tree-structure by incorporating the nuclearity attribute, oftentimes critical in informing downstream tasks (Marcu, 2000; Ji and Smith, 2017; Shiv and Quirk, 2019). Inspired by the recent success of heuristic search in NLP tasks involving trees (e.g., Fried et al. (2017); Mabona et al. (2019)), we develop a beam-search strategy implementing an exploration-exploitation trade-off, as commonly used in reinforcement-learning (RL) (Poole and Mackworth, 2010).

Remarkably, by following this heuristic approach, any large corpus annotated with sentiment can be turned into a discourse treebank on which a domain/genre specific discourse parser can be trained. As a case study for this process, we annotate, evaluate and publicly release a new discourse-augmented Yelp '13 corpus (Tang et al., 2015)

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7442–7457,
November 16–20, 2020.

called MEGA-DT[1] (comprising ≈250,000 documents) with nuclearity attributed "silver-standard" discourse trees, solely leveraging the corpus' document-level sentiment annotation.

To evaluate the quality of our newly proposed MEGA-DT corpus, we conduct a series of experiments. We train the top-performing discourse parser by Wang et al. (2017) on MEGA-DT and compare its performance with the same parser trained on previously proposed treebanks. Specifically, we compare our discourse-annotated dataset against a smaller "silver-standard" treebank (Huber and Carenini, 2019) containing around ≈100,000 documents with ≤20 EDUs and two standard human annotated corpora in the news domain (RST-DT) (Carlson et al., 2002) and in the instructional domain (Subba and Di Eugenio, 2009).

Results indicate that while training a parser on MEGA-DT does not yet match the performance of training and testing on the same treebank (intra-domain), it does push the boundaries of what is possible with distant supervision. In most cases, training on MEGA-DT delivers statistically significant improvements on the arguably more difficult and useful task of inter-domain discourse prediction, where a parser is trained on one domain and tested/applied to another one.

Overall, this suggests that our new approach to distant supervision from sentiment can generate large-scale, high-quality treebanks, with MEGA-DT being the best publicly available resource for training a discourse parser in domains where no gold-standard discourse annotation is available.

2 Related Work

The most closely related line of work is RST-style discourse parsing, with the goal to obtain a complete discourse tree, including structure, nuclearity and relations. Based on the observation that these three aspects are correlated, most previous work has explored models to learn them jointly (e.g., Joty et al. (2015); Ji and Eisenstein (2014); Yu et al. (2018)). However, while this strategy seems intuitive, the state-of-the-art (SOTA) system on structure-prediction by Wang et al. (2017) applies a rather different strategy, first jointly predicting structure and nuclearity and then subsequently predicting relations. The main motivation behind this separation is the large number of possible output classes when predicting these three aspects together. The success of the system by Wang et al. (2017) on the widely used RST-DT corpus inspires us to also learn structure and nuclearity jointly, rather than combining all three aspects.

The second line of related work infers fine-grained information from coarse-grained supervision signals using machine learning. Due to the lack of annotated data in many domains and for many real-world tasks, methods to automatically generate reliable, fine-grained data-labels have been explored for many years. One promising approach in this area is Multiple Instance Learning (MIL) (Keeler et al., 1991). The general task of MIL is to retrieve fine-grained information (called instance-labels) from high-level supervision (called bag-labels), using correlations of discriminative features within and between bags to predict labels for instances. With the recent rise of deep-learning, neural MIL approaches have also been proposed (Angelidis and Lapata, 2018).

We previously combined the two lines of related work described above to create discourse structures from large-scale datasets, solely using document-level supervision (Huber and Carenini, 2019). When applied to the auxiliary task of sentiment analysis, we generated a "silver-standard" discourse structure treebank using the neural MIL model by Angelidis and Lapata (2018) in combination with a sentiment-guided CKY-style tree-construction algorithm, generating near-optimal discourse trees in bottom-up fashion (Jurafsky and Martin, 2014). Although our approach has shown clear benefits, it is inapplicable to many real-world datasets, as it does not scale to long documents and cannot predict nuclearity- and relation-labels. Addressing these limitations is a major motivation of this paper.

Further efforts to automatically generate discourse trees from auxiliary tasks have been mostly focused on latent tree induction, generating trees from text classification (Karimi and Tang, 2019) or summarization tasks (Liu et al., 2019). For both approaches, domain dependent discourse trees are induced during the neural training process. While either method has shown to improve the performance on the downstream task itself, subsequent research by Ferracane et al. (2019) indicates that the induced trees are often trivial and shallow, and

---

[1] Our new Discourse Treebank and the code to generate further "silver-standard" discourse treebanks can be found at: https://www.cs.ubc.ca/cs-research/lci/research-groups/natural-language-processing/

do not represent valid discourse structures.

The third stream of related work is on leveraging heuristic search algorithms in NLP tasks involving trees. For syntactic parsing, Vinyals et al. (2015) and Fried et al. (2017) show that a static, small beam size (e.g. 10) already achieves good performance, with Dyer et al. (2016) delivering promising results by using greedy decoding. As a recent example for discourse parsing, Mabona et al. (2019) successfully combine standard beam-search with shift-reduce parsing using two parallel beams for shift and reduce actions. Overall, recent work shows that beam-search approaches and their possible extensions can effectively address scalability issues in multiple parsing scenarios. In this paper, we extend the standard beam-search approach with a stochastic exploration-exploitation trade-off, as used in Reinforcement Learning, where signals also tend to be sparse and noisy.

3 Predicting Discourse from Sentiment

Previous work has shown that incorporating RST-style discourse trees can help to predict document-level sentiment (Bhatia et al., 2015; Nejat et al., 2017; Hogenboom et al., 2015). These findings give rise to the assumption that the sentiment of a document can also provide important information on its discourse structure. In the following sub-section, we shortly revisit our previous approach to exploit this assumption by solely relying on document-level sentiment annotations (Huber and Carenini, 2019). Afterwards, we will present our new approach to overcome scalability issues and jointly predict structure and nuclearity.

3.1 Predicting Discourse Structure for Short Documents

The discourse-structure tree of a document can be predicted from its global sentiment by combining Multiple Instance Learning (MIL) and the CKY algorithm. We will illustrate the process on the following negative sentiment example with a polarity of -0.5, pre-segmented into five EDUs: *[Bad poutine.]$_1$, [Fries were nice and thin,]$_2$, [had a good taste,]$_3$, [however, the gravy was cold]$_4$, [and the cheese was not melted.]$_5$*. The first step in generating the discourse structure for this example consist of assigning each EDU a sentiment polarity p_{EDU} within the interval of $[-1, 1]$ and an attention score a_{EDU} between $[0, 1]$, both learned through MIL from the overall document sentiment polarity.

To obtain the tuple $\{p_{EDU}, a_{EDU}\}$ for each EDU in a document, the neural MIL model (Angelidis and Lapata, 2018) is trained on a document-level sentiment dataset, with the goal to predict sentiment-labels for EDU-level instances. The model therefore generates a mapping from inputs (EDUs) to the respective outputs (sentiment-classes) by exploiting correlations between the appearance of EDUs in documents and the respective document gold-labels across a corpus. For example, the EDU *[had a good taste,]$_3$* will most likely appear predominantly in positive documents, allowing the MIL model to infer a positive EDU-level sentiment polarity p_{EDU} for this input. When applying the neural model by Angelidis and Lapata (2018), an attention mechanism is internally used to weight the importance of EDUs for the overall document sentiment. An attention-weight a_{EDU} is also extracted for each EDU and subsequently used as an importance score when aggregating subtrees using the CKY approach.

From those tuples $\{p_{EDU}, a_{EDU}\}$ assigned to leaf-nodes, the sentiment polarity p and attention score a for any internal node in an arbitrary constituency tree can be computed bottom-up by aggregating its two child nodes c_l, c_r. Out of the set of potential aggregation functions proposed in Huber and Carenini (2019), the best performing approach has shown to be:

$$p = \frac{p_{c_l} * a_{c_l} + p_{c_r} * a_{c_r}}{a_{c_l} + a_{c_r}} \qquad a = \frac{a_{c_l} + a_{c_r}}{2} \qquad (1)$$

By recursively applying this function from the leaf-nodes, we can compute the sentiment and attention of the root node, representing the full document.

The process of selecting the best discourse tree for a given document can be framed as finding the tree for which the sentiment of the root node (spanning the whole document) is the closest to the gold-standard sentiment annotation. A brute-force solution to this problem is to generate all possible discourse trees using the general CKY algorithm and selecting the best tree amongst all candidates. However, the computational complexity of this approach quickly explodes, as shown for our running example with 5 EDU leaf-nodes in Figure 1. From the decision-space of possible tree-structures, the tree with the shortest sentiment-distance from the gold-standard, computed at the root node, is selected.

Although this method has been shown to provide reasonably good trees when leveraged for

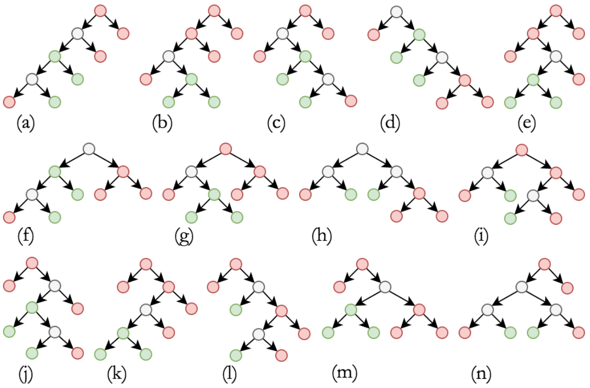

Figure 1: All 14 projective discourse trees annotated with sentiment for a 5 EDU document (using a simplified color-scheme, green = positive, red = negative, grey = neutral, omitting the attention attribute)

discourse-structure parsing, it is limited in two fundamental ways: (1) The approach is not scalable. Since its space complexity grows with the Catalan number $C_n = \frac{1}{n+1}\binom{2n}{n}$ for trees with $n + 1$ EDUs, it can only be applied to short ($\approx\leq$ 20 EDUs) documents (see bottom row in Table 1), making it impractical for many real-world datasets containing longer documents, such as the Yelp '13 (Tang et al., 2015), IMDB (Diao et al., 2014) or Amazon Review dataset (Zhang et al., 2015). (2) Due to the high computational complexity of the structure prediction itself, the inference of further RST-tree properties, such as nuclearity and relations, often critical for downstream tasks, are not feasible with this unconstrained CKY approach.

3.2 Predicting Discourse Structure and Nuclearity from Arbitrary Documents

Inspired by the recent success in applying beam-search to enhance the scalability of multiple NLP parsing tasks (Mabona et al., 2019; Fried et al., 2017; Dyer et al., 2016; Vinyals et al., 2015), we propose a novel heuristic beam-search approach that can automatically generate discourse trees containing structure- and nuclearity-attributes for documents of arbitrary length.

Stochastic Beam-Search In essence, the general CKY dynamic programming algorithm creates all possible binary trees covering the n EDUs by internally filling an $(n \times n)$ matrix, where each $cell(i, j)$ contains the information on all subtrees covering the text spans from EDU_i to EDU_j. Our heuristic beam-search solution limits the computational complexity of this process by reducing the number of subtrees stored in each cell to a constant beam-size B. This naturally raises the question on how to select the B subtrees to preserve in each cell. We follow the intuitive assumption that subtrees for which the sentiment diverges most from the overall document sentiment (the only available supervision for this task) can be safely discarded. Out of the set of possible subtrees T for a given cell, only the subset T' with $|T'| = B$ is kept, containing the B subtrees with the closest sentiment polarity p_{t_i} to the gold-label (gl) sentiment of the document. Formally:

$$T' = \underset{t_i \in T, |T'|=B}{\arg\min} \; |p_{t_i} - gl| \tag{2}$$

However, one limitation of this heuristic rule is that it strictly prefers subtrees with sentiment closer to the overall document sentiment, independent of their distance from the root node. This can be problematic when applied in early stages of the tree-generation process, where only a few EDUs are combined. For instance, a mostly positive document might still contain certain negative subtrees at its lowest levels, which also need to be aggregated appropriately.

Ideally, we would like to support a high degree of exploration on low levels of the tree, only loosely forcing the sentiment of subtrees in the beam to align with the overall document gold-label sentiment; while on higher levels of the tree, the requirement of closely reflecting the document's gold-standard sentiment should be strictly enforced (i.e., exploiting the distant supervision).

We implement this strategy through a stochastic beam-search approach, which relies on a softmax selection using the Boltzmann–Gibbs distribution (Poole and Mackworth, 2010). The temperature coefficient τ thereby modulates the exploration-exploitation trade-off (similar to previous work in RL), by influencing the divergence of the softmax outputs. We then sample from the resulting, categorical probability distribution $P = ((Prob(t_1), ..., Prob(t_n))$, computed for every local subtree $t_i \in T$ to obtain a subset T' of size B (as shown in equation 3).

$$Prob(t_i) = \frac{e^{\frac{1}{|p_{t_i} - gl|}/\tau}}{\sum\limits_{t_j \in T} e^{\frac{1}{|p_{t_j} - gl|}/\tau}} \tag{3}$$

$$\tau = f(n, c) = (n - c) + 1 \tag{4}$$

In this work, the parameter τ is defined as a linear function $f(n, c)$ parameterized by the number

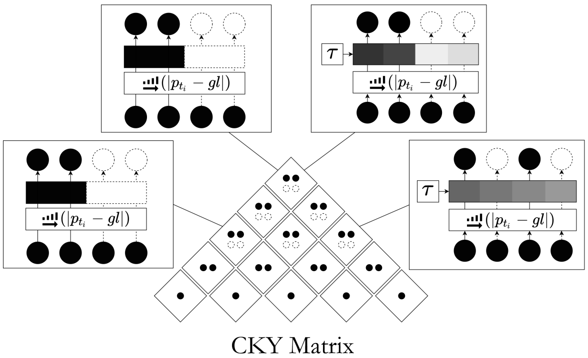

Figure 2: Standard beam-search approach (left) picking the top $B = 2$ tree-candidates with the smallest distance $|p_{t_i} - gl|$ in every CKY cell. Stochastic beam-search approach (right) calculating the Boltzmann–Gibbs distribution with the tree-coverage dependent temperature τ, modulating the subtree sampling process of the tree-candidates. (For readability, we only show a maximum of 4 subtrees per CKY cell)

of EDUs c covered under the subtree t_i as well as the total number of EDUs n (see equation 4). This way, τ influences equation 3 such that for larger values of c (at the top of the tree), τ gets close to 1 and the sampling is likely to select subtrees with low distance $|p_{t_i} - gl|$. For subtrees with a small coverage c (at the bottom of the tree), τ becomes $>>$ 1 and $Prob(t_i)$ resembles the uniform distribution, allowing for a high degree of exploration. For illustration, Figure 2 highlights the differences between the standard and the stochastic beam-search approach.

Analysis of Spacial Complexity The described system significantly reduces the spatial complexity, independent from whether a stochastic component is used. The complexity reduction can be easily observed by comparing the theoretical upper-bounds for the space consumption of the unrestricted CKY approach (eq. 5) against the upper-bounds for the heuristically constrained CKY method (eq. 6).

$$\sum_{i=1}^{n-1} \frac{4(n-i)}{i} \binom{2i-2}{i-1} \tag{5}$$

$$4n^2B + 4(n-1)B^2 \tag{6}$$

Beam	20 EDUs	30 EDUs	100 EDUs
1	1.6KB	3.7KB	40KB
10	24KB	48KB	440KB
100	920KB	1.5MB	7.9MB
∞	3.6GB	1.9PB	400SB

Table 1: Upper-bounds for growth of spatial complexity using different beam sizes and unconstrained CKY (∞), assuming 1Byte per unit in memory. KB = 10^3, MB = 10^6, GB = 10^9, PB = 10^{15}, SB = 10^{54}

In both equations, n represents the number of leaf-nodes (EDUs) in the discourse tree. In eq. 5, the number of generated trees at every level of the tree is bound by the Catalan number, while in eq. 6 the bound has a quadratic dependency on the input-size and the beam-size. For the equations shown, we assume that on every level of the tree, each of the possible subtrees is represented by 2 pointers to the child-nodes as well as a sentiment and attention value for the subtree itself. Table 1 compares the space capacities required with increasing document length, indicating that with a proper beam size, our heuristic strategy can deal with the tree structures for very long documents.

Integration of Nuclearity With this scalable solution, it is now possible to also take additional properties, like nuclearity, into account. The inherent advantage of generating nuclearity-attributed discourse trees becomes obvious when revisiting the definition in RST (Mann and Thompson, 1988), where the nuclearity-attribute encodes a notion of "importance" in the local context, with *Nucleus-Statellite (N-S)* and *Satellite-Nucleus (S-N)* attributions defining the directionality between two nodes, while the *Nucleus-Nucleus (N-N)* attribution implies equal importance (Morey et al., 2018). Expressing this notion of importance, it is not surprising that nuclearity-attribution is frequently critical in informing many downstream tasks like summarization and text categorization (e.g., Marcu (2000); Ji and Smith (2017); Shiv and Quirk (2019)).

Technically, we integrate the nuclearity attribute into the tree-generation process by assigning each subtree one of the three nuclearity classes *N-S*, *S-N* or *N-N*, following the assumption that the attention values a_{c_l}, a_{c_r} capture the nodes' relative importance in the tree. Starting from the leaf-node attention, extracted from MILNet, we propagate the attention values through the tree structure according to equation (1). More specifically, for a subtree where the attention value a_{c_l} is greater than the attention a_{c_r}, we will assign the *N-S* label, while *S-N* is assigned if the opposite is true. However, in this way, only two of the three possible nuclearity classes can be represented (namely *N-S* and *S-N*), as the attention values are distinct. To further account for the third class of *N-N*, we include

Treebank	#Documents	#EDUs*		
		min	avg	max
Instr-DT	176	2	33	248
RST-DT	385	2	56	240
Yelp13-DT	100,000	2	10	20
MEGA-DT	250,000	2	19	150

Table 2: Treebank size and distribution (*calculated on the training set)

an additional subtree at every merge in the CKY procedure, which averages not only the two attention values a_{c_l}, a_{c_r} (as shown in eq. 1) but also the child polarity scores p_{c_l}, p_{c_r}. This reflects the definition of the *N-N* nuclearity class according to RST, where an even importance for all child nodes is assumed in the multi-nucleus case. The additional complexity of doubling the number of trees in each cell is only manageable due to the use of our heuristic approach.

4 Evaluation

In this section, we evaluate our proposed method to generate the MEGA-DT discourse treebank by assessing the performance of a discourse parser when trained on MEGA-DT against our previously proposed "silver-standard" treebank (Huber and Carenini, 2019) as well as two commonly used, human-annotated, discourse corpora.

4.1 Treebanks

The two human-annotated treebanks are:
Instructional-DT (from here on called *Instr-DT*) by Subba and Di Eugenio (2009), which comprises of documents on home-repair instructions annotated with full RST-style discourse trees, separated into training- and test-set with a 90-10 split.
RST-DT by Carlson et al. (2002), containing news articles alongside with full RST-style discourse trees, in the standard 90-10 train-test split.

The two automatically annotated treebanks are:
Yelp13-DT, generated according to our previously proposed unconstrained CKY approach as described in Huber and Carenini (2019). We use the pre-segmented version of the Yelp'13 customer review dataset by Angelidis and Lapata (2018), separated into EDUs by applying the publicly available discourse segmenter proposed in Feng and Hirst (2014). Yelp13-DT contains short documents with $\leq$ 20 EDUs, only considering two nuclearity classes (namely N-S and S-N).
MEGA-DT, our novel treebank, is also generated from the original Yelp'13 corpus, akin to Yelp13-DT. However, due to our newly proposed, scalable solution, MEGA-DT is much larger and more comprehensive, integrating all three nuclearity classes. A comparison of the key dimensions of all treebanks used in this work is shown in Table 2.

4.2 Discourse Parsers

To interpret our results in the context of existing work, we consider a diverse set of top-performing discourse parsers. Previous work by Morey et al. (2017) compares a set of competitive parsers, including **DPLP** (Ji and Eisenstein, 2014), **gCRF** (Feng and Hirst, 2014), **CODRA** (Joty et al., 2015) and Li et al. (2016). We further add the **Two-Stage** discourse parser by Wang et al. (2017) and the neural approach by Yu et al. (2018) into our final evaluation. Due to the top performance of the parser by Wang et al. (2017) on the structure-prediction of the widely used RST-DT corpus, and even more importantly, due to the separation of the relation computation from the structure/nuclearity prediction, we use the parser by Wang et al. (2017) in our inter-domain experiments.

4.3 Preliminary Evaluation

We run a set of preliminary evaluations on a randomly selected subset containing 10,000 documents from the Yelp'13 dataset. In general, the preliminary evaluation suggests that (1) A beam-size of 10 delivers the best trade-off between computational complexity and performance (out of $\{1, 5, 10, 50, 100\}$), when tested according to the distance between gold-label sentiment and model prediction. (2) We employ a sentence-first aggregation strategy, using sentence-boundary predictions from the NLTK toolkit[2]. By not allowing inter-sentence connections, unless the complete sentence is already represented by a subtree, we reach superior results in the preliminary evaluation compared to exploring the complete CKY space. This is consistent with previous findings showing that sentence boundaries are key signals for tree aggregations (Joty et al., 2015).

4.4 Experiments and Results

We train the discourse parser by Wang et al. (2017)[3] on our newly generated MEGA-DT corpus as well as the Yelp13-DT and the original RST-DT and

Table 3: Results of the micro-averaged precision measure using the original Parseval method (Par.) and RST Parseval (R-Par.). Inter-domain subscripts identify the training set. Inter-domain results averaged over 10 independent runs. Models with stochastic components are averaged over 3 distinct generation processes. The best performance per sub-table is **bold**. * Results taken from Morey et al. (2017), † statistically significant with p-value $\leq$ .05 to the best inter-domain baseline (Bonferroni adjusted), – non-published values, × not feasible combinations

Instr-DT corpora[4]. To verify the ability of the training treebanks to support the discourse parser in extracting domain-independent features of general discourse, we evaluate the performance on the inter-domain discourse parsing task, training the Two-Stage discourse parser on one domain (e.g., Yelp user reviews in MEGA-DT) and evaluating it on documents in a different domain (e.g., news articles in RST-DT). We compare the obtained performances against the classic and arguably easier intra-domain measure (training and testing on documents within the same domain).

The results of the final evaluation are summarized and aggregated in three sets of experiments in Table 3. In the first set (on top of Table 3), we show the micro-averaged original Parseval performance (Par.) (Morey et al., 2017) as well as the RST-Parseval measures (R-Par.) of standard linguistic baselines for the structure- and nuclearity-prediction task. Regarding the structure prediction (left), we compare the performance when applying a strictly right- or left-branching tree to the data, as well as hierarchical versions of those (right-/left-branching trees on sentence-level combined by right-/left-branching trees on document level). The results indicate that the hierarchical right-branching tree resembles the original tree structure the closest on both metrics and either evaluation treebank[5]. As a baseline for the nuclearity prediction task, we compute the majority class on the training corpora. It is important to note that while the linguistic baselines for structure do not require available training data, the majority class measure depends on access to an annotated corpus in the target domain.

The second set of results shows the intra-domain performance of top performing discourse parsers, frequently evaluated against in the past. While all parsers except CODRA (Joty et al., 2015) have been only evaluated on RST-DT, we additionally train and evaluate the Two-Stage parser on the Instr-DT corpus. When comparing the intra-domain discourse parsing performance, the Two-Stage parser reaches the consistently best performance on RST-DT structure prediction, while the discourse parser by Yu et al. (2018) achieves the best results on the RST-DT nuclearity prediction using RST-Parseval. CODRA reaches the best performance on the Instr-

---

[5] Note that the performance of the Hierarchical Right-Branching baseline is higher than reported in Huber and Carenini (2019), because of an additional clean-up step required during data preprocessing. The competitive performance of this baseline is most likely attributed to the highly structured nature of the target domains.

Results averaged over 10 runs (using 3 distinct generation processes if a stochastic components is included). The best performance is **bold**.

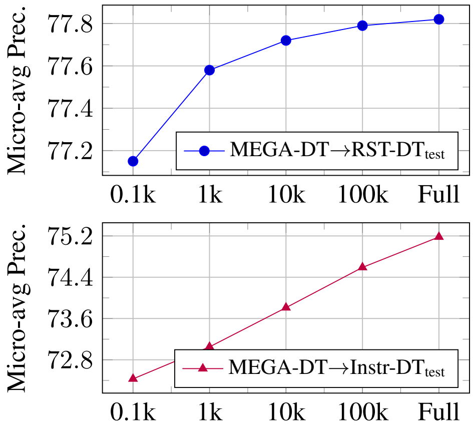

Figure 3: Performance-trend over increasingly large subsets tested on RST-DT (top) and Instr-DT (bottom). Each sample is generated as the average performance over 10 random subsets, drawn from 3 independently created treebanks.

DT corpus when evaluated with RST-Parseval.

The main contribution of this work is placed in the third set of results, where the Two-Stage discourse parser is trained and tested on different, non-overlapping domains (i.e., inter-domain). This task is arguably more useful and significantly more difficult than the task evaluated in the second set, which is reflected in the performance decrease for structure and nuclearity in the first two rows of the sub-table, confirming that the transfer of discourse-structures and -nuclearity between domains is a challenging task. The results presented in the third row of the sub-table show the performance of the Two-Stage parser when trained on Yelp13-DT, containing short documents with limited nuclearity annotations. The approach achieves consistently better performance compared to the first two rows on the inter-domain structure prediction task (For both, original Parseval and RST-Parseval), as we have previously shown in Huber and Carenini (2019). However, only considering two out of three nuclearity classes (N-S and S-N), the system performs rather poorly on the nuclearity classification task. The bottom row of the third sub-table displays the performance of the Two-Stage discourse parser when trained on our new MEGA-DT corpus. Training on MEGA-DT delivers statistically significant improvements over the best inter-domain baseline in all structure prediction tasks. Furthermore, our new system also achieves statistically significant gains on the Instr-DT nuclearity prediction, when evaluated according to the RST-Parseval metric. The nuclearity measure on RST-DT using RST-Parseval is statistically equivalent to the best baseline system. Overall, our MEGA-DT corpus appears to outperform previously published treebanks for inter-domain discourse parsing on every sub-task on at least one competitive metric.

In order to gain deeper insights into the effectiveness of our proposed treebank generation approach, we run a set of four additional evaluations. First, we evaluate the individual components of our system by showing an ablation study in Table 4, starting with the performance of the discourse parser trained with MEGA-DT-Base, a treebank generated with the standard beam-search approach and without integrating nuclearity. Adding each feature separately (+Stoch, +Nuc) we observe improvements on at least one of the sub-tasks; however, the combination of the two components produces the best performing MEGA-DT corpus. Second, we show the performance-trend over increasingly large subsets of MEGA-DT in Figure 3, tested on RST-DT (top) and Instr-DT (bottom). The two trends highlight consistent improvements with increasingly large dataset sizes, suggesting further possible gains with even larger treebanks. Third, we further analyze the nuclearity classification performance in Table 5, which presents four confusion matrices for the discourse parsing output of our MEGA-DT treebank, evaluated according to the original Parseval and RST-Parseval metrics on RST-DT and Instr-DT. The matrices show a potential explanation for the performance-gap between the original Parseval and the RST-Parseval metrics,

Gold \ Predicted	N-N	N-S	S-N
N-N	243	11	40
N-S	570	28	96
S-N	244	5	47

Gold \ Predicted	N	S
N	1947	186
S	1321	141

Gold	N-N	N-S	S-N
N-N	85	1	9
N-S	77	2	16
S-N	23	1	3

	N	S
N	470	30
S	149	7

Table 5: Confusion Matrices for the model trained on MEGA-DT, evaluated on RST-DT (top) and Instr-DT (bottom). Left: Original Parseval, Right: RST-Parseval

identifying the over-prediction of the N-N class, especially for gold-label N-S nuclearities. Further, we frequently misclassify the gold-label N-S nuclearity class as S-N. Lastly, we present an additional qualitative analysis in Appendix A to investigate the strength and potential weaknesses of trees in MEGA-DT. We therefore show three randomly selected trees that closely/poorly reflect the authors gold-label sentiment respectively (see Figure 4 for a teaser). In general, the qualitative analysis shows that trees in MEGA-DT are non-trivial, reasonably balanced, strongly linked to the EDU-level sentiment and mostly well-aligned with meaningful discourse-structures.

5 Conclusions and Future Work

In this work, we present a novel distant supervision approach to predict the discourse-structure and -nuclearity for documents of arbitrary length solely using document-level sentiment information. To deal with the increasing spatial complexity, we apply and compare heuristic beam-search strategies, including a stochastic variant inspired by RL techniques. Our results on the challenging inter-domain discourse-structure and -nuclearity prediction task strongly suggests that the heuristic approach taken (1) enhances the structure prediction task through more diversity in the early-stage tree selection, (2) allows us to effectively predict nuclearity and (3) helps to significantly reduce the complexity of the unrestricted CKY approach to scale for arbitrary length documents.

In conclusion, our new approach allows the NLP community to augment any existing sentiment-annotated dataset with discourse trees, enabling the automated generation of large-scale domain/genre-specific discourse treebanks. As a case study for the effectiveness of the approach, we annotate and publish our MEGA-DT corpus as a high quality RST-style discourse treebank, which has been shown to outperform previously proposed discourse treebanks (namely Yelp13-DT, RST-DT and Instr-DT) on most tasks of inter-domain discourse parsing. This suggests that parsers trained on our MEGA-DT corpus (or further domain-specific treebanks generated according to our approach) should be used to derive discourse trees in target domains where no gold-labeled data is available.

This work can be extended in several ways: (i) We plan to investigate into further functions for τ to enhance the exploration-exploitation trade-off. (ii) Additional strategies to assign nuclearity should be explored, considering the excessive N-N-classification shown in our evaluation. (iii) We plan to apply our approach to more sentiment datasets (e.g., Diao et al. (2014)), creating even larger treebanks. (iv) Our new and scalable solution can be extended to also predict discourse relations besides structure and nuclearity. (v) We also plan to use a neural discourse parser (e.g. Yu et al. (2018)) in combination with our large-scale treebank to fully leverage the potential of data-driven discourse parsing approaches. (vi) Taking advantage of the new MEGA-DT corpus, we want to revisit the potential of discourse-guided sentiment analysis, to enhance current systems, especially for long documents. (vii) Finally, more long term, we intend to explore other auxiliary tasks for distant supervision of discourse, like summarization, question answering and machine translation, for which plenty of annotated data exists (e.g., Nallapati et al. (2016); Cohan et al. (2018); Rajpurkar et al. (2016, 2018)).

A Qualitative Analysis of Generated Discourse Trees

The following examples are automatically generated trees from our MEGA-DT corpus. EDU leaf-nodes are enumerated and can be referenced with the discourse units in the description. The colour-saturation and -hue values represents the sentiment of the nodes, with a dark red (high saturation) representing a strongly negative subtree, white (low saturation) representing a neutral sentiment subtree and a dark green (high saturation) represents a strongly positive subtree. The thickness of edges and the size of nodes represent the attention of the subtree, which is strongly correlated with the subtree nuclearity.

Centering-based Neural Coherence Modeling with Hierarchical Discourse Segments

Sungho Jeon and **Michael Strube**
Heidelberg Institute for Theoretical Studies gGmbH
`{sungho.jeon, michael.strube}@h-its.org`

Abstract

Previous neural coherence models have focused on identifying semantic relations between adjacent sentences. However, they do not have the means to exploit structural information. In this work, we propose a coherence model which takes discourse structural information into account without relying on human annotations. We approximate a linguistic theory of coherence, Centering theory, which we use to track the changes of focus between discourse segments. Our model first identifies the focus of each sentence, recognized with regards to the context, and constructs the structural relationship for discourse segments by tracking the changes of the focus. The model then incorporates this structural information into a structure-aware transformer. We evaluate our model on two tasks, automated essay scoring and assessing writing quality. Our results demonstrate that our model, built on top of a pretrained language model, achieves state-of-the-art performance on both tasks. We next statistically examine the identified trees of texts assigned to different quality scores. Finally, we investigate what our model learns in terms of theoretical claims[1].

1 Introduction

Coherence describes the semantic relation between elements of a text. It identifies a text passage as either a unified whole or a collection of unrelated sentences. The most well-known formal theory, Centering theory, determines the most salient item in each sentence, the center or focus, and tracks the changes of the focus (Grosz et al., 1995). Prior studies of coherence have mainly focused on modeling local coherence in Centering theory (Barzilay and Lapata, 2008). They aim to identify the semantic relations between adjacent sentences. However, coherence arises not only at the local level, but also at the document level giving insight into the structure of the discourse.

Discourse structure represents the semantic organization of a text. Incorporating structural information into the model has been beneficial for diverse downstream tasks including text summarization (Marcu, 2000), translation (Guzmán et al., 2014), sentiment analysis (Bhatia et al., 2015), and text classification (Ji and Smith, 2017).

To identify discourse structure, earlier work adopts a supervised approach, relying on human annotations (Hernault et al., 2010; Wang et al., 2017). However, annotating discourse structure is time consuming and costly. It requires annotators to understand not only the local context surrounding the target sentence but also higher level relations. Learning latent structure has been proposed to alleviate this limitation. This approach induces the discourse structure from a text without annotations using an attention layer (Liu and Lapata, 2018). Recent work argues that, however, the learned trees have mostly little to no structure at the document level, and the model relies on specific linguistic cues (Ferracane et al., 2019).

In this paper, we propose a coherence model inspired by Centering theory which takes structural information into consideration. Our model does not rely on human annotations to identify this information. Our model consists of two components: (1) a discourse segments parser which constructs structural relationship for discourse segments by tracking the changes of the focus between discourse segments, and (2) a structure-aware transformer which exploits structural information to update sentence representations.

The discourse segments parser first identifies the hierarchical discourse segments of a text, building upon an approximation of Centering theory (Grosz et al., 1995). This theory first defines three data

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7458–7472,
November 16–20, 2020.

structures to describe the focus of a sentence, a list of forward-looking centers (*Cf*), the preferred center (*Cp*), and a single backward-looking center (*Cb*). *Cf* indicates the salient items of the sentence, that are candidates of the focus in the next sentence, and *Cp* indicates the most preferred item of *Cf*. *Cb* describes the focus of a sentence with regards to the previous context. The theory also defines centering transitions to describe the changes of focus by comparing two centers, *Cp* and *Cb*. We propose an algorithm to approximate this theory using a pretrained language model. Our algorithm first identifies the focus of sentences using multi-head attention scores provided by the pretrained language model and semantic similarity between vector representations. Our algorithm then constructs hierarchical discourse segments using a focus stack – inspired by the concept of Grosz and Sidner (1986) – to track the changes of the focus between discourse segments.

Secondly, we propose a structure-aware transformer to account for structural information. Vaswani et al. (2017) introduce the transformer, a model solely based on a self-attention mechanism. This mechanism relates all items to capture semantic relations in a sequence. In contrast, the self-attention of our transformer is restricted to considering sentences with regards to the identified hierarchical discourse segments. We first calculate document structure priors to allow self-attention to relate sentences connected in the identified structure. Then, the document structure attention is calculated by element-wise multiplication of the document structure priors and the self-attention of a naive transformer.

We evaluate our model on two tasks: automated essay scoring (AES) and assessing writing quality (AWQ). AES is the task of assigning a score for a given essay, aiming to replicate human scoring results (Dong and Zhang, 2016). This task has been used to evaluate coherence models (Burstein et al., 2010). Secondly, AWQ is the task of assigning labels of text quality recognized by human annotators. Coherence is one of the most essential aspects of text quality (Feng et al., 2014). We first show that a simple fine-tuned model, relying on a pretrained language model, outperforms the state of the art on both tasks. We then demonstrate that our model achieves state-of-the-art performance on both tasks. Our results indicate that the identified trees let the model assess text quality better by structure-aware coherence modeling. We then examine the identified trees to investigate differences of texts in writing quality. We finally inspect identified centers to investigate what our model learns in terms of theoretical claims.

2 Related Work

While unsupervised approaches for discourse parser have been developed (Marcu and Echihabi, 2002; Ji et al., 2015), earlier work mostly adopted a supervised approach to identify discourse structure relying on human annotations. Subba and Di Eugenio (2009) incorporate various linguistic features, including compositional semantics and part-of-speech information, to propose a discourse parser based on Inductive Logic Programming. Hernault et al. (2010) introduce a discourse parser which constructs discourse structure from a full input text. They train classifiers to identify discourse relations, and use them to build a tree structure of an input text. Feng and Hirst (2012) improve the tree building algorithm of this system by incorporating more linguistic features. Wang et al. (2017) introduce an SVM-based model that consists of two stages, one identifying discourse structure, and the other classifying types of relations between units.

More recently, neural models have been developed to recognize discourse structure. Li et al. (2014) present a simple model based on a recursive neural network. Li et al. (2016) claim that this model suffers from a vanishing gradient problem caused by long sequences, and propose an attention-based hierarchical neural network model. To alleviate the shortage of human annotations, Braud

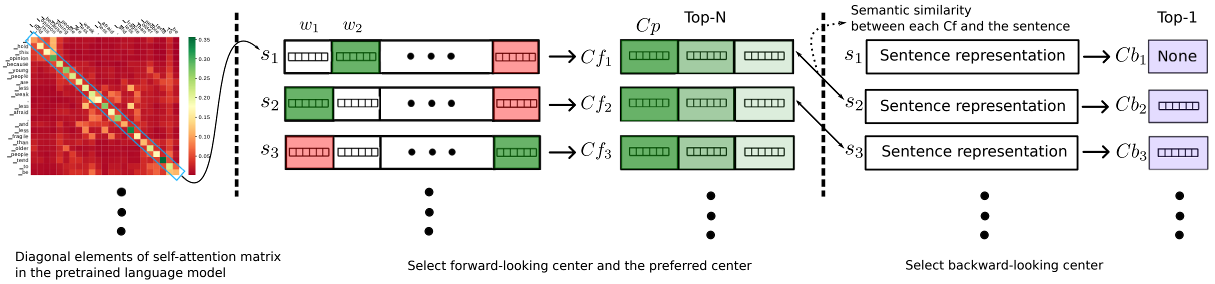

Figure 2: An overview of selecting forward-looking looking centers (*Cf*), preferred centers (*Cp*), and backward-looking centers (*Cb*).

et al. (2016) introduce a simple LSTM-based model which has a multi-view learning architecture. This model uses different views of the same data. Yu et al. (2018) extract syntactical representations by a neural syntax parser, and incorporate them into an RNN-based model.

Previous models of discourse parsing are mostly based on Rhetorical Structure Theory (Mann and Thompson, 1988). This theory represents a document as a tree structure built by connecting discourse units recursively through predefined discourse relations. Another line of work is based on the Penn Discourse Treebank (Webber et al., 2019), which annotates discourse structure in a lexically-grounded approach. These studies represent discourse structure with discourse relations. Unlike these studies, our model does not consider discourse relations but we investigate Centering theory to take structural relationships for discourse segments into account.

A supervised approach requires annotations for each task. To overcome the lack of a labeled dataset, recent work has investigated to learn latent structures, which induce the tree structure directly from a text. While Yogatama et al. (2017) and Choi et al. (2018) induce structure at the sentence level to learn syntax, Liu and Lapata (2018) propose a neural model which induces structural information without a labeled resource. They induce the non-projective dependency structure from a text by structured attention. More recently, however, Ferracane et al. (2019) claim that induced document-level structures do neither match human intuitions nor align with linguistic theories. Unlike latent structure learning, we identify hierarchical discourse segments using a pretrained language model. It lets our model identify the focus of a sentence by comparing semantic similarities between representations of sentences without relying on a resource of manually labeled discourse structure.

3 Our Model

Figure 1 presents the architecture of our coherence model. We first introduce input representations at the sentence level using a pretrained language model. We then describe the algorithm of the discourse segments parser. Finally, we present a structure-aware transformer and the document representation created.

3.1 Sentence Representations

We use a pretrained language model to obtain representations of sentences. In this work, we employ XLNet for the pretrained language model (Yang et al., 2019). XLNet not only outperforms BERT (Devlin et al., 2019), XLNet also has the advantage to model coherence because of its training objective. XLNet maximizes the expected likelihood over all permutations in the training.

We first encode an input document using XLNet to produce word representations. We obtain sentence representations by averaging all word representations in a sentence. We then feed the sentence representations to the discourse parser and the structure-aware transformer.

3.2 Discourse Segment Parser

Our discourse segment parser is inspired by Centering theory Grosz et al. (1995). We modify Centering theory to approximate it in a neural model. The theory considers entities as candidates of centers. To determine centers at the phrase level or the entity level, we would need to incorporate an external parser into the model to identify phrases or entities. The performance of the model then crucially would rely on how accurately the external parser would identify them. Hence, we determine centers at the word level so that our model is not affected by the performance of an external parser.

Figure 2 gives an overview of our approach to identify the focus of sentences. To represent

	$Cb(S_{i-1}) \approx Cb(S_i)$	$Cb(S_{i-1}) \neq Cb(S_i)$
$Cb(S_i)$ $\approx Cp(S_i)$	Continue	Shifting
$Cb(S_i)$ $\neq Cp(S_i)$	Retain	

Table 1: Three types of centering transitions.

the focus of a sentence, we model the backward-looking center and forward-looking centers using scores computed by multi-head self-attention in XLNet. Recent work shows that multi-head attention of a pretrained language model represents important linguistic notions of the input sequence (Clark et al., 2019; Vig and Belinkov, 2019; Sen et al., 2020). It also claims that self-attention might be biased to specialized tokens used in training, <SEP>, <CLS> and the token of a punctuation mark, hence we only consider actual items by filtering these tokens. Following previous work, we use the averaged scores of the multi-head self-attention extracted from the last layer of the model. To identify the salient items of sentences, we encode each sentence separately to identify centers of the sentence.

To determine the forward-looking centers of the sentence at the word level, we extract diagonal elements of the matrix representing multi-head self-attention of the encoded sentence. We then select the top-k vectors obtained by XLNet as the forward-looking centers in the extracted elements. The preferred center of a sentence is the top-1 item in the forward-looking centers. The backward-looking center of a sentence is the item most related to one of the forward-looking centers of the immediately preceding sentence (Brennan et al., 1987). We compare semantic similarity between the averaged word representations of the current sentence and each forward-looking center of the immediately preceding sentence. We use cosine similarity to measure semantic similarity.

Previous work introduces concepts to describe the changes of focus. Grosz et al. (1995) describe three types of centering transitions: *Continue*, *Retain*, and *Shifting*, as shown in Table 1. *Continue* maintains the current focus, and *Retain* intends to change the focus to an item recognized in the current sentence. *Shifting* indicates that the focus is different from the previous sentence. Grosz and Sidner (1986) introduce a focus stack which stores discourse segments related to the current focus.

In this work, we propose an algorithm to construct the hierarchical discourse segments of a text using these concepts (Algorithm 1). For each sentence, we iterate the process until the focus stack is empty or we find a change of the focus. For *Continue*, we add the current sentence to the current segment without changing the stack (line 9-10). For *Retain*, we push the current segment to the stack, which results in connecting the discourse segment of the top item in the stack to the current segment (line 11-13). For *Shifting*, we pop the discourse segment from the stack, and iterate the process for the next sentence (line 16-17). If the process is completed because of an empty stack, then we push s_i as a new segment to process the next sentence (line 20-23). During the process, we build an adjacency matrix to represent the changes of the focus stack. Finally, we connect the adjacent sentences in the discourse segment.

Algorithm 1 The discourse segment parser.

```
 1: procedure PARSER($S$, $Cb$, $Cp$, $t_{sim}$)
 2:     $Seg \leftarrow \{\}$ ▷ A list for the current segment
 3:     for $s_i \leftarrow s_1$ to $s_n$ do
 4:         $Seg \leftarrow Seg + s_i$
 5:         while $f\_stack \neq \oslash$ do
 6:             $sim_{Cb_{i-1},Cb_i}$ = $Sim(Cb_{i-1}, Cb_i)$
 7:             $sim_{Cb_i,Cp_i}$ = $Sim(Cb_i, Cp_i)$
 8:             if $sim_{Cb_i,Cb_{i-1}} > t_{sim}$ then
 9:                 if $sim_{Cp_i,Cb_i} > t_{sim}$ then
10:                     $isCont \leftarrow True$
11:                 else
12:                     Push($f\_stack$, $Seg$)
13:                     $Seg \leftarrow \{\}$
14:                 end if
15:                 break                ▷ Exit the loop
16:             else
17:                 Pop($f\_stack$)
18:                 $isCont \leftarrow False$
19:             end if
20:         end while
21:         if $\sim isCont$ and $f\_stack = \oslash$ then
22:             Push($f\_stack$, $Seg$)
23:             $Seg \leftarrow \{\}$
24:         end if
25:     end for
26:     $Adj\_Mat$ = Gen_Ad_Mat(Adj_List)
27:     return $Adj\_Mat$
28: end procedure
```

3.3 Structure-aware Transformer

To take structural information into account, we propose a structure-aware transformer. Our structure-aware transformer is inspired by the Tree-Transformer (Wang et al., 2019), which updates its hidden representations by inducing a tree-structure from a document. The Tree-Transformer generates constituent priors by calculating neighboring attention which represents the probability whether adjacent items are in the same constituent. The constituent priors constrain the self-attention of the transformer to follow the induced structure. Instead of inducing a tree structure, our model uses input structural information to generate document structure priors, which guide the self-attention of the transformer. The sentences which are not connected in the structure are constrained to not attend each other. Document structure priors are then used to calculate structure-aware attention.

We calculate structure-aware attention scores using the identified hierarchical discourse segments. We compute the score $s_{i,j}$ to relate s_i and s_j by the scaled dot-product attention: $s_{i,j} = (q_i^{ds} \cdot k_j^{ds})/d$. We use $(q_i^{ds} \cdot k_j^{ds})$ to represent the semantic relation between s_i and s_j, where q^{ds} is a query matrix and k^{ds} is a key matrix of document structure attention. We represent hierarchical discourse segments by an adjacency matrix. To let the model learn attention with the structural information, we mask scores by the adjacency matrix: $\hat{S} = mask(S, adj)$ where adj is the adjacency matrix representing document structure. We apply a softmax function to each row of the score matrix to represent the probability that s_i attends to other connected sentences: $p_i = softmax(\hat{s}_i)$. To make a symmetric matrix, we calculate the structure-aware attention score: $\hat{a} = \sqrt{p_{i,j} \times p_{j,i}}$. We follow Wang et al. (2019) to cover more relations at the higher level by applying a hierarchical constraint. This restricts a_k^l to be larger than $a_k^l - 1$ for layer l and sentence index k: $a_k^l = a_k^{l-1} + (1 - a_k^{l-1})\hat{a}_k^l$.

We then calculate document structure priors $(D_{i,j})$ using a log-sum instead of multiplication to calculate it efficiently:

$$D_{i,j} = e^{\sum_{k=i}^{j-1} \log(a_k)} \qquad (1)$$

Finally, the attention score (E) of the structure-aware transformer is calculated by element-wise multiplication of the document structure priors and the self-attention of a naive transformer:

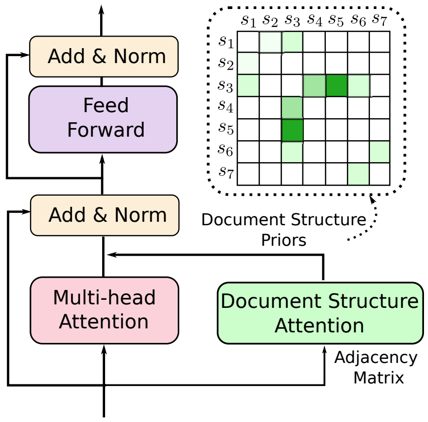

Figure 3: Structure-Aware Transformer.

$$E = D \odot softmax(\frac{QK^T}{d}) \qquad (2)$$

where Q is query vectors, K is key vectors with dimension d_k in the naive transformer.

3.4 Document Representation

In the last layer of our model, we apply document attention to produce the weighted sum of all the updated sentence representations. The document attention identifies relative weights of updated sentence representations which enables our model to handle any document length. Finally, a feed-forward network is applied to the representation to produce the output value.

4 Experiments

4.1 Implementation Details

We implement our model using the PyTorch library and use the Stanford Stanza library[2] for sentence tokenization. We employ XLNet for the pretrained-language model. For the baselines that do not use the pretrained language model, we use Glove for word embeddings, the pretrained word embeddings trained on Google News (Pennington et al., 2014). We set the top-n for selecting *Cf* to 3 and the semantic threshold to compare vector representations to 0.945 (see Appendix B for more training details and parameters).

Due to memory constraints, we encode each sentence separately using XLNet instead of the whole document at once. Our dataset consists of long documents i.e., journal articles with more than 3,000 tokens. For employing the pretrained model, it is

Table 2: TOEFL Accuracy performance comparison on the test sets (see Appendix D for more details).

practically infeasible to encode all words in a document at once due to memory limitations. We use 46GB GPU memory of two NVidia P40s for each run.

We re-implemented all baselines to compare on the same deep-learning framework, PyTorch. We then used our re-implementation to report the performance of models with 10 runs with different random seeds. We verified statistical significance (p-value<0.01) in both a one-sample t-test, which verifies the reproducibility of the performance of each model, and a two-sample t-test, which verifies that the performance of our model is statistically significant compared to other models. To fulfill the request for fairer comparisons between neural models (Dodge et al., 2019), we also report validation performance and standard deviation of the performance (see Appendix D for more details).

4.2 Baselines

We first compare against the latent learning model for discourse parsing by Liu and Lapata (2018). While their model induces structure at both the sentence level and the document level, we only induce structure at the document level due to memory constraints for large documents. We then compare against a neural coherence model. Mesgar and Strube (2018) propose a local coherence model inspired by Centering Theory. This model finds the two most similar RNN outputs to determine the most salient part of sentences to connect adjacent sentences. This model is evaluated on the AES task as well as the task of assessing readability.

To investigate the influence of a pretrained language model on this task, we implement two models for baselines. We first develop a simple fine-tuned model relying on the pretrained language model (Averaged-XLNet). This simple model encodes an input document at the sentence level and averages the encoded representations. We also implement a second model which combines a state-of-the-art latent tree learning model and the pretrained language model (XLNet+Wang et al. (2019)). This model encodes an input document at the sentence level and updates representations using the Tree-Transformer (Wang et al., 2019). Instead of averaging, document attention is applied to produce a weighted-sum vector representation.

For AES, we also compare against the state of the art for this task. Dong et al. (2017) introduce a model which consists of a convolutional layer followed by a recurrent layer and an attention layer (Bahdanau et al., 2015).

4.3 Automated Essay Scoring

Datasets. To examine the effectiveness of our model on AES, we evaluate our model on the Test of English as a Foreign Language (TOEFL) dataset. TOEFL has overall higher quality of essays compared to essays in the frequently used dataset for AES, the Automated Student Assessment Prize (ASAP) dataset[3]. The prompts in ASAP are written by students in grade levels 7 to 10 of US middle schools. Many essays in ASAP consist of only a few sentences. In contrast, the prompts in TOEFL are submitted for the standard English test for the entrance to universities by non-native students. The prompts in TOEFL do not vary so much, the student population is more controlled, and the essays have a similar length (see Appendix A for more details).

Evaluation Setup. We follow the evaluation setup of previous work on AES (Taghipour and Ng, 2016). For TOEFL, we evaluate performance with accuracy for the three-class classification problem with 5-fold cross-validation. We deploy the cross-entropy loss for training. We use the ADAM optimizer with a learning rate of 0.003. We evaluate performance for 20 epochs on the validation set. The model which reaches the best accuracy on the validation set is then applied to the test set. We use a mini-batch size of 32 with random shuffle.

Figure 4: Accuracy per score in TOEFL (see Appendix D for more details).

	NYT
Liu and Lapata (2018)-reported	82.69 (1.36)
Liu and Lapata (2018)-ours	54.35 (1.00)
Averaged-XLNet	67.53 (3.48)
XLNet+Wang et al. (2019)	71.79 (0.77)
Our Model	**75.12 (1.10)**

Table 3: Mean (standard deviation) accuracy performance of assessing writing quality on the test sets in NYT. We compare the performance of Liu and Lapata (2018), reported in Ferracane et al. (2019) which uses an embedding layer trained on NYT and our implementation which uses a pretrained Glove embedding layer.

Results. Table 2 shows the performance on TOEFL. Dong et al. (2017), the state of the art on AES, show significantly better performance than the model of discourse structure parsing and the neural model of coherence. Interestingly, the simple model relying on the pretrained language model outperforms these three models. XLNet+Wang et al. (2019) then shows better performance. Since we encode a text at the sentence level and not the whole document at once, encoded representations do not include any structural information at the document level. Hence, this indicates that structural information improves the performance of this model compared to Averaged-XLNet. Finally, our model achieves state-of-the-art performance.

To better understand how the model works, we conduct an error analysis. This analysis shows that uneven label distributions cause biased predictions in the model of Liu and Lapata (2018). The TOEFL dataset has an uneven label distribution, 11.0%/54.3%/34.7% for low, mid, and high scores, respectively. In contrast, all models built upon pretrained language models generally predict different scores in an unbiased fashion. XLNet+Wang et al. (2019) shows, however, more bias toward the middle score than Averaged-XLNet. This indicates that, as the model of Liu and Lapata (2018), the baseline model predicts the uneven distribution which leads to better performance. Our model mostly predicts the low and the high score better. This suggests that our model does not take advantage of the uneven distribution but assesses essay quality by modeling coherence.

4.4 Assessing Writing Quality

Datasets. Louis and Nenkova (2013) use a dataset of scientific articles from the New York Times (NYT) for assessing writing quality. They assign each article to one of two classes by a semi-supervised approach: typical or good. Though articles included in both classes are of good quality generally, Louis and Nenkova (2013) show that linguistic features can distinguish different classes of writing quality. Ferracane et al. (2019) use this dataset to evaluate the model of Liu and Lapata (2018).

Evaluation Setup. For NYT, we follow the setup used in previous work. Louis and Nenkova (2013) and Ferracane et al. (2019) undersample the dataset to alleviate the bias of the uneven label distribution. We partition the dataset following Ferracane et al. (2019), into 80% training, 10% validation, and 10% test set, respectively. We use the ADAM optimizer with a learning rate of 0.001. For training, we evaluate performance for 20 epochs and use a mini-batch size of 128 with random shuffle.

Results. We first compare against the state-of-the-art model in latent learning on NYT. Ferracane et al. (2019) show the performance of the latent learning model in Liu and Lapata (2018) on NYT[4].

Table 4: Statistics for learned trees as labels by our model described as mean (standard deviation).

They report the performance of this model with an embedding layer trained on the NYT corpus itself[5]. To ensure fair comparison of the model across different datasets, we use a pretrained Glove embedding layer.

Table 3 reports performance of models on the NYT test set. The model of Liu and Lapata (2018) with the pretrained Glove embedding layer shows significantly lower performance than the same model with the embedding layer trained on NYT. Averaged-XLNet performs better, which shows that employing a pretrained language model is beneficial, and XLNet+Wang et al. (2019) outperforms this model. Our model achieves state-of-the-art performance on NYT among the models using the pretrained embedding layer, but it still shows lower performance than the model using the embedding layer trained on the target corpus. This suggests that linguistic cues have the potential to improve this model further.

4.5 Learned Discourse Structure

We next statistically examine the discourse structure identified by our parser. Ferracane et al. (2019) evaluate the induced structure learned by the model of Liu and Lapata (2018) using four measures: the average height of trees, the proportion of leaf nodes, the normalized arc length, and the ratio of vacuous trees. They define a vacuous tree as a shallow tree whose nodes are connected to the root directly.

We report statistics on the trees identified by our parser as shown in Table 4. We modify two measures, the normalized tree height and the ratio of small trees. We normalize the tree height by the number of nodes to take the length of documents into account. Since there are no vacuous trees in our trees, we report the ratio of small trees, defined as a tree whose normalized tree height is smaller than 0.2 and whose height is smaller than 3. In addition, we report the proportion of the nodes at the top level.

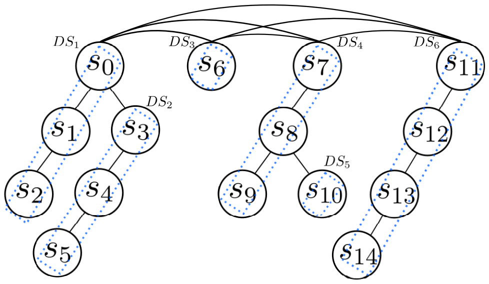

Figure 5: Example of the identified hierarchical discourse segments where DS is a discourse segment and s is a sentence: An essay of high score whose essay-id is 913590 in TOEFL (see Appendix E for more details).

Ferracane et al. (2019) show that trees learned by the model of Liu and Lapata (2018) mostly are vacuous or shallow trees, whose proportion of leaf nodes is greater than 0.9. In contrast, the measures confirm that our model finds differences in the structure of texts of different score levels. The trees are not shallow trees, there is even no small tress, and the proportion of leaf nodes is less than 15%. The normalized arc length is high in our trees, which indicates that there is content connected to the root in the late part of a document. We suspect that this is the result of modeling the changes of focus instead of being biased to the focus captured in the beginning a document.

Figure 5 visualizes an example essay in TOEFL. If texts are scored lower, trees are higher with more leaf nodes, and the proportion of nodes at the top level is lower. In NYT, we observe that the trees are more similar according to the four measures. However, we still observe texts of lower quality in NYT have higher trees and more leaf nodes. These trees are more skewed. This suggests that the focus is more biased to specific content in the texts of lower quality. In our manual examination, we also observe a few cases that texts of lower quality show very shallow trees. This suggests that the focus changes less frequently than in texts of higher quality.

4.6 Centering Analysis

We finally inspect the identified centers to investigate what our model learns with regard to the most preferred centers in Centering theory. We explore two questions, (1) whether the identified centers are related to the given topic of a text and (2) whether the centers rely on function words.

While all essays submitted to a prompt in TOEFL have the same topic, articles in NYT have different topics. Hence, we inspect centers at the prompt level in TOEFL and for each document in NYT.

We first examine the proportion of most preferred centers. Table 5 shows that our discourse structure parser indeed identifies centers related to the topic of prompts in TOEFL and to the title of each document in NYT. For instance, the given topic of prompt 1 in TOEFL is "Is it better to have a broad knowledge of many academic subjects than to specialize in one specific subject?", and we observe that preferred centers are related to their topic. However, we also observe a few types of undesirable cases when interpreting centers. The most common case is that the identified centers are related to the topic but also are redundant to other centers. They indicate the same meaning, but they have a different form, such as different tense or grammatical number. Another undesirable case is when centers are subword-level tokens which are produced by subword tokenization deployed in the pretrained language model. It not only makes us difficult to interpret centers intuitively, but also the model might capture a focus different from the author's intention.

We then verify whether our model determines function words as centers. Table 6 shows the proportion of function words determined as centers and the average proportion among all centers. It shows that the proportion of function word is less or comparable to other centers. Hence, this analysis indicates that our model does not exploit function words to capture focus.

5 Conclusions

We propose a neural model of coherence inspired by Centering theory. The intuition is that it describes coherence by tracking the changes of the focus between discourse segments. Our model identifies the hierarchy of discourse segments without human annotations, and incorporates structural information into the model. We demonstrate that the identified hierarchical discourse segments improve performance of the model on two tasks, automated essay scoring and assessing writing quality. Interestingly, we find statistical differences of trees generated from texts of different quality.

A Data Description Details

Table 7 describes statistics on two datasets, TOEFL[6] and NYT[7]. We split a text at the sentence level by Stanford Stanza library, and tokenize them by the XLNet tokenizer. Table 8 describes the topic of each prompt in TOEFL. They are all open-ended tasks, that do not have given context but require students to submit their opinion.

Dataset	#Texts	Avg len (Std)	Max len	Scores
T-P1	1,656	401 (97)	902	1-3
T-P2	1,562	423 (97)	902	1-3
T-P3	1,396	407 (102)	837	1-3
T-P4	1,509	405 (99)	852	1-3
T-P5	1,648	424 (101)	993	1-3
T-P6	960	425 (101)	925	1-3
T-P7	1,686	396 (87)	755	1-3
T-P8	1,683	407 (92)	795	1-3
NYT	8,512	1,841 (1,221)	18,728	1-2

Table 7: Dataset statistics on tokenization: each TOEFL prompt (T-P) and NYT.

B Training and Parameters

For TOEFL, we use a mini-batch size of 32 with random-shuffle. For NYT, we use a mini-batch size of 128 with random-shuffle. For both datasets, we train models with a learning rate of 0.003 and epsilon of 1e-4. We use the ADAM optimizer with a learning rate of 0.003. We evaluate performance for 20 epochs. For the baseline models which do not use a pretrained language model, we use Glove pretrained embeddings with 100-dimensional for TOEFL and with 50-dimensional for NYT. We clip gradients by 1.0 excepts for the latent learning model of discourse parsing. To update sentence representations obtained by a pretrained language model, we use the same dimension of the pretrained language model on a structure-aware transformer. We manually tune hyperparameters.

We use 46GB GPU memory of two NVidia P40s for each run. For training our model, it takes approximately 0.3 days on TOEFL and 11 days on NYT. It takes less processing time to train other two baselines relying on the pretrained language model.

C Scores on Muti-head Attention

Figure 6 visualizes multi-head self-attention scores obtained by XLNet for the example which consists of four sentences as follows. The visualization shows that multi-head self-attention scores capture salient items such as a piano or a home, or linguistic notions such as he or it.

Prompt 1	Agree or Disagree: It is better to have broad knowledge of many academic subjects than to specialize in one specific subject.
Prompt 2	Agree or Disagree: Young people enjoy life more than older people do.
Prompt 3	Agree or Disagree: Young people nowadays do not give enough time to helping their communities.
Prompt 4	Agree or Disagree: Most advertisements make products seem much better than they really are.
Prompt 5	Agree or Disagree: In twenty years, there will be fewer cars in use than there are today.
Prompt 6	Agree or Disagree: The best way to travel is in a group led by a tour guide.
Prompt 7	Agree or Disagree: It is more important for students to understand ideas and concepts than it is for them to learn facts.
Prompt 8	Agree or Disagree: Successful people try new things and take risks rather than only doing what they already know how to do well.

Table 8: Topic description: TOEFL.

- s_1: Peter wants to play the piano.
- s_2: He went to the piano store to buy one.
- s_3: It was closed.
- s_4: So, he went home.

D Experiments Details

We report not only performance of models on test sets, also performance on validation sets, and standard deviation in 10 runs as shown in Table 9-10. These results indicate that our model achieves state-of-the-art performance on both validation sets and test sets. Figure 7 shows the error analysis on TOEFL.

Keeping Up Appearances: Computational Modeling of Face Acts in Persuasion Oriented Discussions

Ritam Dutt **Rishabh Joshi** **Carolyn Penstein Rosé**
Language Technologies Institute
Carnegie Mellon University
{rdutt, rjoshi2, cprose}@cs.cmu.edu

Abstract

The notion of *face* refers to the public self-image of an individual that emerges both from the individual's own actions as well as from the interaction with others. Modeling face and understanding its state changes throughout a conversation is critical to the study of maintenance of basic human needs in and through interaction. Grounded in the politeness theory of Brown and Levinson (1978), we propose a generalized framework for modeling *face acts* in persuasion conversations, resulting in a reliable coding manual, an annotated corpus, and computational models. The framework reveals insights about differences in face act utilization between asymmetric roles in persuasion conversations. Using computational models, we are able to successfully identify face acts as well as predict a key conversational outcome (e.g. donation success). Finally, we model a latent representation of the conversational state to analyze the impact of predicted face acts on the probability of a positive conversational outcome and observe several correlations that corroborate previous findings.

1 Introduction

Politeness principles, displayed in practice in day-to-day language usage, play a central role in shaping human interaction. Formulations of politeness principles are related to basic human needs that are jointly met in and through interaction (Grice et al., 1975; Brown et al., 1987; Leech, 2016). Natural language offers various ways to enact politeness. One of the most influential politeness theories from linguistics is proposed in (Brown and Levinson, 1978), in which a detailed exposition is offered of the individual actions whose cumulative effect results in *saving face* and *losing face*, along with a consideration of cost. Using this framework, it is possible to analyze how interlocutors make decisions about where and how these devices should be used based on an intricate cost-benefit analysis (Brown et al., 1987). We refer to these component actions here as **face acts**.

The idea of *face acts* appears quite attractive from a computational standpoint for their potential role in understanding what is "meant" from what is "said" (Grice et al., 1975; Brown et al., 1987; Leech, 2016). Consequently, politeness has been widely researched in various domains of language technologies (Walker et al., 1997; Gupta et al., 2007; Wang et al., 2012; Abdul-Mageed and Diab, 2012; Danescu-Niculescu-Mizil et al., 2013) in addition to foundational work in pragmatics and sociolinguistics (Brown et al., 1987; Grice et al., 1975; Leech, 2016). However, much prior work modeling politeness reduces the problem to a rating task or binary prediction task, separating polite and impolite behavior. Consequently, what the models end up learning is mainly overt markers of politeness or rudeness, rather than the underlying indirect strategies for achieving politeness or rudeness through raising or attacking face, even in the indirect case where no overt markers of rudeness or politeness might be explicitly displayed.

In contrast, the main contribution of this work is the investigation of eight major face acts, similar to dialogue acts, including an investigation of their usage in a publicly available corpus of Wang et al. (2019). In the selected corpus, a persuader (**ER**) is tasked with convincing a persuadee (**EE**) to donate money to a charity. The nature of the task prompts frequent utilization of face acts in interaction, and thus these face acts are abundantly present in the chosen dataset. We also provide a generalized framework for operationalizing face acts in conversations as well as design an annotation scheme to instantiate these face acts in the context of persuasion conversations (§2.1, §2.3). We offer the annotations we have added to this public dataset as another contribution of this work

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7473–7485,
November 16–20, 2020.

(§2.2). Additionally, we develop computational models to identify face acts (§3.1) as well as construct a latent representation of conversational state to analyze the impact of face acts on conversation success (§3.2). We achieve 0.6 F1 on classifying face acts (§5.1), and 0.67 F1 in predicting donation outcome (§5.2). We observe that the predicted face acts significantly impact the local probability of donation (§5.3)[1].

2 Framework

2.1 Face Representation

Face, based on the politeness theory of Brown et al. (1987), reflects the 'public self-image' that every rational adult member of society claims for themselves. It can be subdivided into *positive face*, referring to one's want to be accepted or valued by society, and *negative face*, referring to one's right to freedom of action and freedom from imposition.

We refer to 'face acts' as utterances/speech acts that alter the positive and/or the negative face of the participants in a conversation. We hereby refer to the acts that attack one's face as Face Threatening Acts (FTA) and those acts that raise one's face as Face Saving Acts (FSA). For example, criticizing an individual is an attack on the other's positive face, whereas refusing to comply with someone's wishes, raises one's own negative face. We also note that a single utterance or act can simultaneously affect the face of one or both participants in a conversation. For example, a refusal to donate to a charity because they do not trust the charity involves asserting one's negative face as well as decreasing the charity's positive face.

The implication of a face act between the participants is governed by several factors such as 'power' and relative 'social distance', as well as the relative threat ('ranking') of the face act (Brown and Levinson, 1978). For example, refusing to comply with the orders of one's superior is more threatening than requesting a friend for some change.

Moreover, face acts need to be contextualized for a particular situation based on the rights and obligations of the individual participants, such as in compliance-gaining episodes (Wilson et al., 1998). For example, a teacher has the responsibility and right to assign homework to the students. Such an action cannot be perceived as an attack on negative face, even though the student is reluctant to do so.

Based on the definition of face and face acts, we design a generalized annotation framework to capture the face dynamics in conversation. We instantiate our framework on a publicly-available corpus on persuasion dialogues.

2.2 Dataset Description

We use the pre-existing persuasion corpus of Wang et al. (2019). Each conversation comprises a series of exchanges where the persuader (ER) has to convince the persuadee (EE) to donate a part of their task earnings to the charity, *Save the Children*. This selected corpus is well-situated for our task since each conversation is guaranteed to have a potential face threat (i.e., a request for money) and hence, we can expect face act exchanges between the two participants. It also sets itself apart from other goal-oriented conversations such as restaurant reservations and cab booking (Budzianowski et al., 2018) since in those cases the hearer is obligated to address what might otherwise come across as an FTA (request/ booking), and thus in those cases non-compliance can be assumed to be due to logistic issues rather than an unwillingness to co-operate.

In the selected corpus, the participants are Amazon Mechanical Turk workers who are anonymous to each other, which controls for the 'social distance' variable. Moreover, the participants have similar 'power', with one role having some appearance of authority in that it represents an organization, but the other role representing possession of some desired object (i.e., money). Thus, we argue that although ER imposes an FTA by asking for donation, EE is equally at liberty to refuse. Moreover, ER does not incur a penalty for failing to persuade. In fact the corpus includes some conversations that do not talk about donation at all. We also emphasize that the task was set up in a manner such that EE come into the interaction blind to the fact that ER have been tasked with asking them to donate.

We assess the success of a conversation based on whether EE agrees to donate to the charity. We label successful conversations as *donor* conversations and *non-donor* conversation otherwise. We refer the reader to Wang et al. (2019) for more details about the dataset.

2.3 Annotation Framework

In a two-party conversation, a face act can either raise (+) or attack (-) the positive face (Pos) or

---

[1] We include our annotation framework in Appendix and the annotated dataset and code is publicly available at `https://github.com/ShoRit/face-acts`

Face Act	Description
SPos+	(i) S posit that they are **virtuous** in some aspects or they are **good**. (ii) S **compliment the brand or item they represent or endorse** and thus project their credibility. (iii) S state their **preference or want**, something that they like or value.
SPos-	(i) S **confess** or apologize for being unable to do something that is expected of them. (ii) S **criticise or humiliate themselves**. They damage their reputation or values by either saying they are not so virtuous or criticizes some aspect of the brand/item they endorse or support.
HPos+	(i) **S compliment H** either for H's virtues, efforts, likes or desires. It also extends to S **acknowledging the efforts of H** and **showing support for H**. (ii) S can also provide an **implicit compliment to incentivize H** to do something good. (iii) S **empathize** / sympathize or in general **agree with H**. (iv) S is **willing to do the FTA** as imposed by H (implying that the FTA is agreeable to S.)
HPos-	(i) S voice **doubts or criticize H** or the product/brand that H endorses. (ii) S **disagree with H** over some stance, basically contradicting their viewpoint. (iii) S is either **unaware** or **indifferent** to H's wants or preferences.
SNeg+	(i) S **reject** or are unwilling to do the **FTA.** Stating the reason does not change the circumstances of non-compliance but sometimes helps to mitigate the face act.
SNeg-	(i) S **offer to assist H**.
HNeg+	(i) S seek to **decrease the imposition of the FTA** on H by either decreasing the inconvenience such as providing alternate, simpler ways to carry out the FTA or decrease the threat associated with the FTA. (ii) S **apologize for the FTA** to show that S understood the inconvenience of imposing the request but they have to request nevertheless.
HNeg-	(i) S **impose an FTA on the H**. The FTA is some act which H would not have done on their own. (ii) S **increase the threat** or ranking of the FTA (iii) S **ask/request H** for assistance?

Table 1: Generalized framework for situating and operationalizing face acts in conversations. The predicates for each of the face act are highlighted in bold.

negative face (Neg) of either the speaker (S) or the hearer (H), leading to 8 possible different outcomes. For example, *HPos+* means raising the positive face of the hearer. We provide a generalized framework in Table 1 for labelling a speech act / utterance with one or more face acts, building upon the politeness theory of Brown and Levinson (1978). The framework is designed to be explicit enough to ensure the creation of a reliable coding manual for classifying face-acts, as opposed to the simple classification of requests and other directives as intrinsic FTAs (Brown and Levinson, 1978). Moreover, since we also seek to operationalize FSA, we make some departure from the original classification of directives. For example, we feel that compliments directed at the hearer, should be *HPos+* rather than *HNeg-* (as observed in Brown et al. (1987)) since an appreciation for someone's efforts is more desirable.

We highlight the predicates that result in a particular face act in bold in Table 1. For example, S claiming to be virtuous or doing some good deed amounts to raising their own positive face (*SPos+*). Although the framework is designed to be generalizable across domains, the predicates themselves need to be instantiated based on the domain of choice. For example, in this particular corpus, the act of requesting someone for donation counts as an FTA. We refer the readers to Table S3 in Appendix A which outlines how the face acts are instantiated for the specific persuasion dataset.

Each conversation in the dataset consists of 10 or more turns per participant with one or more utterances per turn. Each utterance is labeled with one or more face acts according to our annotation framework. Otherwise we label the utterance as 'Other' if no face act can be identified, or if the utterance contains no task-specific information (Eg: small talk). We consider ER to be a representative of the charity since ER advocates for donations on their behalf. We show the flowchart detailing the annotation framework in Figure S3 of Appendix A.

Validating the annotation scheme: Two authors of the paper annotated 296 conversations in total. The annotation scheme underwent five revisions, each time with three different conversations, eventually yielding a high Cohen's Kappa score of 0.85 across all face acts (Cohen, 1960). The revised scheme was then used to annotate the remaining conversations. We show an annotated conversation snippet in Table 4.

2.4 Summary Statistics

Our annotated dataset comprises 231 donor conversations and 65 non-donor conversations. Table 2 shows the distributions of different face acts employed by ER and EE respectively for both donor and non-donor conversations. We also note that certain face-acts do not occur in our corpus, such as *SPos-* for ER, presumably because ER does not have a reason to debase themselves or the charity they endorse. We provide a detailed explanation of the occurrence of such acts in the supplementary section. We observe multiple statistically significant differences in face act prevalence based on whether EE is a donor or non-donor. Some findings are intuitive, such as an increase in *HPos+* for Donor conversations (for both ER and EE). We argue that EE had acknowledged the efforts of the charity and was willing to donate, and was thus rewarded with compliments from ER. Likewise, *SNeg+* occurs significantly more in Non-donor situations, due to a refusal to comply. We note that a majority of the turns labeled 'Other' involve greetings or conversation exchanges unrelated to the main business of the conversations.

Face Acts	ER		EE	
	D	N	D	N
SPos+	19.95	23.03	8.29	6.51
SPos-	0.00	0.00	0.18	0.96^{*}
HPos+	23.08^{***}	16.24	36.17^{***}	21.07
HPos-	0.70	2.65^{*}	4.37	10.73^{**}
SNeg+	0.00	0.00	3.85	11.97^{***}
HNeg+	5.50	4.81	0.00	0.00
HNeg-	10.47	10.85	9.20	13.03
Other	40.31	42.42	37.94	35.73

Table 2: Distribution of different face acts for the donor (D) and non-donor (N) for ER and EE. *, **, and *** signify that the specific act is statistically significant for D and N according to the independent t-test with p-values $\leq 0.05, 0.01$, and 0.001 respectively.

3 Methodology

3.1 Face act prediction

We model the task of computationally operationalizing face acts as a dialogue act classification task. Given an dialogue with n utterances, $D = [u_1, u_2, ..., u_n]$, we assign labels $y_1, y_2 ... y_n$ where $y_i \in Y$ represents one of 8 possible face acts or 'Other'. Although, we acknowledge that an utterance can have multiple face acts, we observe that multi-labeled utterances comprise only 2% of our dataset, and thus adopt the simplification of predicting a single face-act for each utterance[2]. Several tasks in the dialogue domain, such as emotion recognition (Majumder et al., 2019; Jiao et al., 2019), dialogue act prediction (Chen et al., 2018; Raheja and Tetreault, 2019) and open domain chit-chat (Zhang et al., 2018b; Kumar et al., 2020), have achieved state-of-the-art results using a hierarchical sequence labelling framework. Consequently, we also adopt a modified hierarchical neural network architecture of Jiao et al. (2019) that leverages both the contextualized utterance embedding and the previous conversational context for classification. We hereby adopt this as the foundation architecture for our work and refer to our instantiation of the architecture as BERT-HIGRU.

Architecture of BERT-HIGRU: An utterance u_j is composed of tokens $[w_0, w_1, ..., w_K]$, which are represented by their corresponding embeddings $[e(w_0), e(w_1), ..., e(w_K)]$. In BERT-HIGRU, we obtain these using a pre-trained BERT model (Devlin et al., 2019). We pass these contextualized word representations through a BiGRU to obtain the forward $\overrightarrow{h_k}$ and backward $\overleftarrow{h_k}$ hidden states of each word, before passing them into a Self-Attention layer. This gives us corresponding attention outputs, $\overrightarrow{ah_k}$ and $\overleftarrow{ah_k}$. Finally, we concatenate the contextualized word embedding with the GRU hidden states and Attention outputs in our *fusion layer* to obtain the final representation of the word. We perform max-pooling over the fused word embeddings to obtain the j^{th} utterance embedding, $e(u_j)$. Formally,

$$\begin{aligned}
\overrightarrow{h_k} &= \mathrm{GRU}\left(e\left(w_k\right), \overrightarrow{h_{k-1}}\right) \\
\overleftarrow{h_k} &= \mathrm{GRU}\left(e\left(w_k\right), \overleftarrow{h_{k+1}}\right) \\
\overrightarrow{ah_k} &= \mathrm{SelfAttention}(\overrightarrow{h_k}) \\
\overleftarrow{ah_k} &= \mathrm{SelfAttention}(\overleftarrow{h_k})
\end{aligned}$$

$$e_c(w_k) = \tanh(W_w[\overrightarrow{ah_k}; \overrightarrow{h_k}; e(w_k); \overleftarrow{h_k}; \overleftarrow{ah_k}] + b_w)$$

$$e(u_j) = \max(e_c(w_1), e_c(w_2), ... e_c(w_K)) \quad (1)$$

Similarly, we calculate the contextualized representation of an utterance $e_c(u_j)$ using the conversation context. In departure from Jiao et al. (2019), we pass $e(u_j)$ through a uni-directional GRU that yields the forward hidden state $\overrightarrow{H_j}$. Masked Self-Attention over the previous hidden states, yields $\overrightarrow{AH_j}$. We fuse $e(u_j)$, $\overrightarrow{H_j}$ and $\overrightarrow{AH_j}$ before passing it through a linear layer with tanh activation to obtain $e_c(u_j)$. This ensures that current $e_c(u_j)$ is not influenced by future utterances, enabling us to observe change in donation probability over time

---

[2] For each utterance with multiple labels, one is randomly select from that set to be treated as the Gold label.

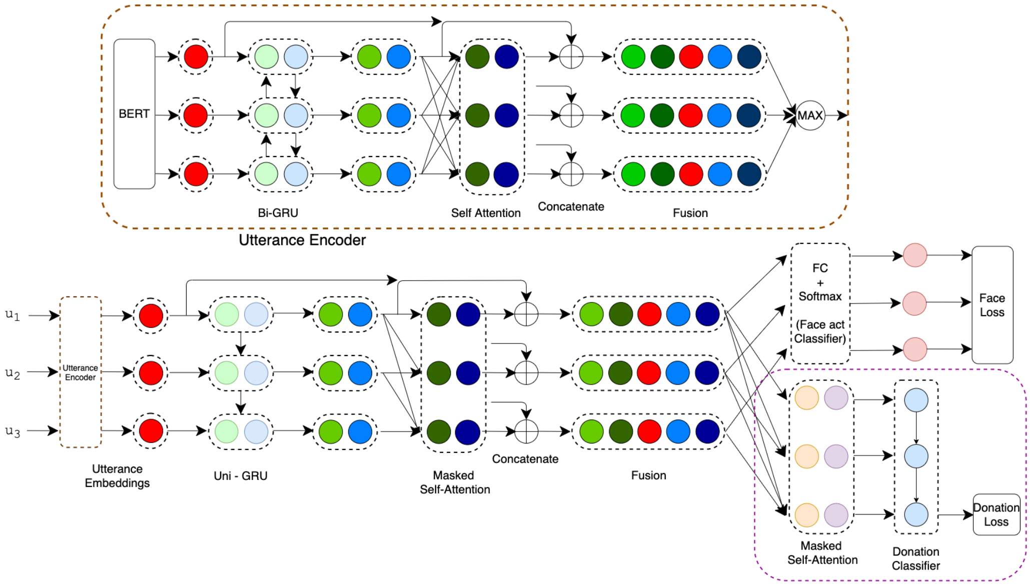

Figure 1: Overview of BERT-HiGRU. We first encode the utterances by passing the BERT representations of the token through a BiGRU layer followed by Self Attention. The BERT, BiGRU and Self-Attention outputs are then fused to get the final token representation before max pooling. This utterance representation is passed through a uni-directional GRU followed by Masked-Self-Attention and fusion. One part of the model uses the face classifier to predict the face-act of each utterance while the other model uses another layer of Masked-Self-Attention to predict the donation probability. The details are in Section 3

in Section 3.2

$$\overrightarrow{H_j} = \text{GRU}\left(e\left(u_j\right), \overrightarrow{H_{j-1}}\right)$$

$$\overrightarrow{AH_j} = \text{MaskSelfAttention}(\overrightarrow{H_j})$$

$$e_c(u_j) = \tanh(W_u[\overrightarrow{AH_j}; \overrightarrow{H_j}; e(u_j)] + b_u) \quad (2)$$

We explore different hierarchical architecture variants which differ in the creation of contexualized embeddings $e_c(w_k)$ and $e_c(u_j)$ in Equation 1 and 2. (1) BERT-HiGRU includes only the final hidden state $\overrightarrow{H_j}$; (2) BERT-HiGRU-f additionally employs the utterance embedding $e_(u_j)$; and (3) BERT-HiGRU-sf, which also includes the attention vector $\overrightarrow{AH_j}$.

We feed the final contextualized utterance embedding $e_c(u_j)$ through a FC layer with dropout and project it onto the state space of face-acts. We then apply softmax to obtain a probability distribution over the face-acts, with negative logarithmic loss as the loss function. Given the true labels y and the predicted labels y', the loss is computed for all n utterances in a conversation as:

$$L_f = -\sum_{i=1}^{n} \sum_{y_j \epsilon Y} y_j log(y'_j) \quad (3)$$

3.2 Impact of face acts on donation

Donation Outcome Prediction: Brown et al. (1987) notes that the exchange of face acts contributes towards an evolving conversational state. We seek to view the evolving state representation within our sequence model and analyze its impact on conversation success. The best reflection of what the evolving conversational state accomplishes in the context of persuasion is whether a donation occurs or not. We thus add the prediction task as supervision and interpret the resulting conversation state based on how the probability of donation changes. We accomplish the supervision by incorporating another loss, called donation loss, in addition to the loss obtained for face acts.

For each utterance u_j, we apply masked self attention over the set of contextual utterance embeddings $e_c(u_j)$ till the j^{th} utterance and project it through a linear layer with tanh activation to obtain the donation score don_j. The tanh non-linearity ensures that the donation score remains between -1 and 1 and intuitively denotes the delta change in scores from the previous step. We finally compute the probability of donation o'_j at the j^{th} step, by applying sigmoid activation over the sum of probability at the previous step and the delta change don_j. This ensures that the o'^{th}_j probability is restricted between 0 and 1. We obtain the donation loss L_d similar to Yang et al. (2019) by taking the mean squared error of the donation probability at the last step o'_n and the actual donation outcome o_n. o_n is 1 if successful, otherwise 0. We also experiment with Binary Cross Entropy loss and obtain similar results.

$$
\begin{aligned}
e_d(u_j) &= \text{MaskSelfAttention}(e_c(u_j)) \\
don_j &= \tanh(W_d[e_d(u_j)] + b_d) \\
o'_j &= \sigma(o'_{j-1} + don_j) \\
L_d &= (o'_n - o_n)^2
\end{aligned}
$$

The donation loss is combined with the original face-act loss in a weighted fashion using some hyperparameter α, such that $\alpha \epsilon [0, 1]$.

$$L_{tot} = \alpha L_f + (1 - \alpha) L_d \tag{4}$$

Correlating face acts with donation outcome: The aforementioned formulation enables us to obtain the donation probability at any given step and assess the impact of difference in conversational state (due to a specific face act) on the local assessment of the probability of donation. To quantify the impact, we perform linear regression with the donation probability at each time step (y_i) as the dependent variable. The independent variables includes the predicted face acts for that step (f_i^k) and the donation probability at the previous step y_{i-1}.

$$y_i = \beta_0 * y_{i-1} + \sum_{f^k} \beta_k * f_i^k \tag{5}$$

Here, β_k represents the coefficient of the corresponding face-act and β_0 the coefficient for y_{i-1}.

4 Experimental Setup

We describe the baselines and evaluation metrics here. We present the additional experimental details of our model in Appendix Table S1.

4.1 Baselines

Face act prediction: We employ different variants of BERT-HiGRU described in Section 3, namely the vanilla BERT-HiGRU, BERT-HiGRU-f (with residual connections (fusion)) and BERT-HiGRU-sf with self-attention and fusion.

To observe the effect of incorporating conversation context, we pass the utterance embedding $e(u_j)$ obtained from the utterance encoder directly into the face act classifier. We denote the different variants of utterance encoder employed as BERT-BiGRU, BERT-BiGRU-f, and BERT-BiGRU-sf with the same notation as the hierarchical variants.

To explore the impact of embedding choice on model performance, we experiment with pretrained Glove embeddings (Pennington et al., 2014) in addition to BERT tokens. We denote the hierarchical models with GloVe embeddings as HiGRU and those without conversation context as BiGRU.

Donation Outcome Prediction: We use the baselines mentioned above for predicting face acts and augment them with the donation loss component. We explore different values of α for weighing the two losses as described in Equation 4.

4.2 Evaluation Metrics

Face act prediction: We observe the model performance in predicting the face acts for (i) only the persuader (ER), (ii) only the persuadee (EE), and (iii) both ER and EE (All). We perform five-fold cross-validation due to the paucity of annotated data. We report performance in terms of mean accuracy as well as macro F1-scores across the five folds due to the high class imbalance.

Donation Outcome Prediction: For a given conversation, we observe the probability of donation at the final step as o'_n. We choose an appropriate threshold on o'_n across the five validation folds, such that a conversation with (o'_n) greater than the threshold is considered successful and vice versa. The F1 score is then computed on the binarized outcome. We choose macro F1-score as the evaluation metric due to the highly skewed distribution of the number of donor and non-donor conversations.

Correlating face acts with donation outcome: We quantify the impact of face acts on donation probability for both ER and EE through the corresponding coefficients obtained from the regression framework. A positive coefficient implies that the face act is positively correlated with the local donation probability and vice versa. We also note the fraction of times a particular face act contributed to a local increase in donation probability and denote it by *Frac*. A value of *Frac* > 0.5 for an act implies that the act increased the local donation probability more number of times than it decreased it.

5 Results

In this section we put forward the following research questions and attempt to answer the same.

Q1. How well does BERT-HiGRU predict face acts? (Section 5.1)

Q2. How well are we able to predict the outcome of the conversation? (Section 5.2)

Q3. How do individual face acts correlate with donation probability? (Section 5.3)

5.1 Face Act Prediction

Model Performance: We present the results of our models for face act prediction in Table 3 and glean several insights. Firstly, we observe that all models consistently perform better for ER than EE due to the more skewed distribution of EE and the presence of an extra face act (6 for ER vs 7 for EE). The difference in F1 is less noticeable between EE and All, despite an additional face act (8 for All), possibly due to the increase in labelled data.

Model	ER		EE		All	
	Acc	F1	Acc	F1	Acc	F1
BiGRU	0.68	0.58	0.59	0.49	0.62	0.49
BiGRU-f	0.69	0.57	0.59	0.50	0.62	0.49
BiGRU-sf	0.69	0.57	0.60	0.51	0.62	0.51
HiGRU	0.68	0.56	0.62	0.52	0.63	0.49
HiGRU-f	0.70	0.57	0.62	0.52	0.64	0.49
HiGRU-sf	0.69	0.59	0.62	0.56	0.64	0.52
BERT-BiGRU	0.73	0.63	0.66	0.57	0.67	0.56
BERT-BiGRU-f	0.72	0.62	0.66	0.58	0.66	0.57
BERT-BiGRU-sf	0.72	0.62	0.65	0.56	0.66	0.56
BERT-HiGRU	**0.74**	**0.63**	0.66	0.54	0.68	0.57
BERT-HiGRU-f	0.73	**0.63**	**0.67**	**0.61**	**0.69**	**0.60**
BERT-HiGRU-sf	0.73	0.62	**0.67**	0.60	0.68	0.59

Table 3: Performance of the various models on face act prediction. The best results are shown in bold.

Adding conversational context aids model performance as observed by the average increase of 1.3 in F1 scores across all model configurations (BiGRU to HiGRU). The highest gains are observed for BERT-HiGRU-sf and HiGRU-sf which attends over the set of previous utterances and thus can better reason about the current utterance.

The greatest boost, however, comes from incorporating BERT embeddings as opposed to pre-trained GloVe, which bears testimony to the efficacy of contextualized embeddings for several dialogue tasks (Yu and Yu, 2019; Lai et al., 2019).

In fact, with the inclusion of BERT, BERT-HiGRU-f performs as competitively as BERT-HiGRU-sf. We also note that the performance of BERT-HiGRU-f and BERT-HiGRU-sf are statistically significant as compared to the other baselines according to the McNemar's test (McNemar, 1947) with p-value ≤ 0.001.

Error Analysis: We present the confusion matrix of face act prediction for the BERT-HiGRU-f model for both ER and EE in Figures 2 and 3 respectively. We observe that a majority of the misclassification errors occurs when a face-act is predicted as 'Other' since it is the most frequent class and also shares a commonality with the remaining classes.

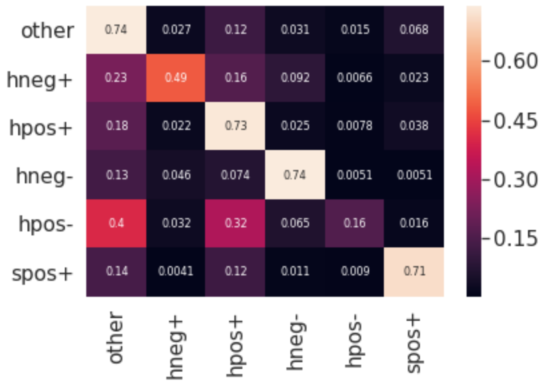

Figure 2: Confusion matrix for Persuader (ER)

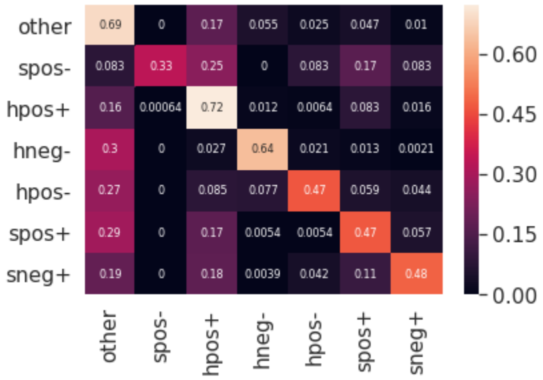

Figure 3: Confusion matrix for Persuadee (EE)

Some instances of misclassification errors for ER involves the labels *HPos+* and *HNeg+*. For example, utterances like "Every little bit will help the children we are trying to save." or "Anyways, even 50 cents goes a long way you know?" seek to decrease the imposition of the face threat by letting EE choose the donation amount, but also simultaneously provides EE with an opportunity to raise their face. For EE, the face act *SNeg+* is frequently misclassified as *SPos+* or *HPos+*, since a refusal to donate is often accompanied by EE stating their preference ("there are other charities I'd like to donate to over this one") or acknowledging the efforts of ER and the charity ("I appreciate you informing about this but I'll be donating at a later time"). The greatest misclassification happens for *HPos-* for ER and *SPos-* for EE, since they account for $\approx 1\%$ and $\approx 0.3\%$ of the dataset respectively. Consequently, they are often misclassified as *HPos+* and *SPos+* respectively since they affect the same face.

5.2 Donation Outcome Prediction

We use BERT-HiGRU-f as the model since it achieves the highest performance on face act prediction. Experiments with different values of alpha

Role	Utterance	True Face	Pred Face	Don Prob
ER	Hi	other	other	0.268
EE	hello	other	other	0.324
ER	How's it going	other	other	0.337
EE	it's going good so far this morning for me.	other	other	0.340
EE	what about you?	other	other	0.340
ER	Another day in paradise	other	other	0.340
EE	haha.	other	other	0.340
EE	do you live in the states ?	other	other	0.791
ER	Great state of Texas.	other	other	0.448
ER	How about you?	other	other	0.365
EE	chicago.	other	other	0.346
EE	so what is this about anyway?	other	other	0.792
EE	it says a child's charity.	other	other	0.448
EE	I am lost.	other	other	0.365
ER	I guess I'm supposed to persuade you to donate your bonus to the save the children charity.....	hneg-	other	0.346
ER	I want you to keep your bonus obviously	hneg-	other	0.342
EE	it would help to know what childrens charity as well with some information about it.	hpos+	other	0.341
EE	usually thats how you persuade ppl to donate.	other	other	0.341
EE	show a pic of a kid etc.	other	other	0.340
ER	How much do you like to donate to the charity now?	hneg-	hneg-	0.340
ER	Your donation will be directly deducted from your task payment.	hneg+	other	0.791
ER	You can choose any amount from $0 to all your payment	hneg+	other	0.856
EE	I do not wish to donate.	sneg+	sneg+	0.464
EE	I've been given no info about the charity.	hpos-	sneg+	0.369
ER	They help children in warzones and other poor nations to get food and clothes	spos+	spos+	0.797
EE	oh ok, who is they?	hneg-	hneg-	0.449
EE	what is the organization ?	hneg-	hneg-	0.365
ER	Save The Children is the name	spos+	other	0.796
EE	no, I do not wish to donate at this time.	sneg+	sneg+	0.449
EE	there are other charities I'd like to donate to over this one.	spos+	sneg+	0.802
EE	I'm sorry.	hpos+	spos-	0.858
EE	I don't have a lot to work with either.	sneg+	sneg+	0.464
ER	Think of the poor kids in Syria who could get so much for the price of a coffee in Chicago.	other	hpos+	0.812
ER	Do you really need all you have when they have nothing at all?	hpos-	other	0.453
EE	I don't have much money for myself either which is why I consider this to be my part time job.	sneg+	sneg+	0.366
EE	I already work full-time to make ends meet.	sneg+	sneg+	0.346
EE	I'm sorry	hpos+	spos-	0.793
ER	But you have a full time job, food, shelter and I'm sure you have family and friends.	hpos+	other	0.857
ER	These kids families were murdered and they live in rubble that used to be their home, nobody to care for them and they only eat what they can find off the street from the dead.	other	hpos+	0.464
ER	If they eat at all	hpos-	hpos+	0.369
EE	that is very sad.	hpos+	hpos+	0.797
EE	I'd like to look into this charity more before I donate as well.	sneg+	other	0.857
EE	I'd like to see how the money is dispersed in the company	hneg-	other	0.464

Table 4: An example conversation consisting of true and predicted face acts, along with donation probabilities. The persuader was unsuccessful in convincing the EE to donate. The utterances of the EE are in cyan.

reveal that $\alpha = 0.75$ achieves the highest F1 score on both face acts (0.591) and donation outcome (0.672). The F1-score for face acts is comparable to the best performing model in 5.1 but the performance for donation outcome increases significantly from 0.545 to 0.672. When $\alpha = 1.0$, the donation outcome prediction is similar to random choice. On the other extreme, when $\alpha = 0$, i.e. in the absence of L_f, the donation outcome behaves like random choice since, the model is unable to learn an appropriate latent state representation.

5.3 Correlation of face acts with donation.

We present the coefficients of face acts for ER and EE obtained from the regression framework 5 and the corresponding fraction (Frac) of times the face act increased the donation probability in Table 5.

We observe several face acts which are statistically significant based on the corresponding p-value of the coefficients (highlighted in bold).

	ER		EE	
Face Act	Frac	Coeff	Frac	Coeff
HPos-	0.464	-0.036	0.661	0.003
HPos+	0.646	0.004	0.605	-0.007
HNeg+	0.753	**0.029***	-	-
HNeg-	0.709	**0.023***	0.744	**0.043*****
SPos+	0.504	**-0.052*****	0.553	**-0.026***
SPos-	-	-	1.000	0.002
Other	0.742	**0.031*****	0.717	**0.023***
SNeg+	-	-	0.435	**-0.038***

Table 5: Coefficients of the face acts, for ER and EE obtained from linear regression. A positive coefficient implies positive correlation. *, *** indicate statistical significance with p values ≤ 0.05 and 0.001.

We observe unsurprisingly a positive correlation (0.029) for *HNeg+* for ER since decreasing the imposition of the FTA is likely to influence donation. Likewise, a criticism of EE (*HPos-*), decreases the likelihood of donation and thus has a negative correlation (-0.036). We also observe a negative coefficient for *SPos+* (-0.052) which corroborates the finding of Wang et al. (2019), that appealing to the credibility of the organization correlates negatively with donation outcome.

Similarly, for EE, asserting one's face / independence (*SNeg+*) corresponds to a decrease in the donation probability (-0.038). Likewise, *HNeg+* corresponds to an increase in donation probability (0.043) since these face acts increase user engagement. We attribute the negative correlation for *SPos+* (-0.026) and *HPos+* (-0.007) to the fact that they often occur along with *SNeg+* and hence decreases the outcome probability. Nevertheless, *SPos+* and *HPos+* increase the donation probability 60.5% and 55.3% of the times. However, the learned model errs in assuming that *HPos-* (for EE) and *HNeg-* (for ER) increases the donation probability and requires further investigation

We illustrate the effect of face act on the local donation probability through a conversation snippet in Table 4. We observe a noticeable reduction in donation probability associated with *SNeg+* (for EE) and *HPos-* (for ER). Likewise, face acts corresponding to *HNeg+* (for ER) and *HPos+* (for EE) result in an increase in donation probability.

6 Related Work

Although politeness derailment and politeness evolution in dialogue have been previously investigated in the NLP literature (Chang and Danescu-Niculescu-Mizil, 2019; Danescu-Niculescu-Mizil et al., 2013), the prior work is distinguished from our own in that they do not explicitly model face changes of both parties over time. Rather, Danescu-Niculescu-Mizil et al. (2013) utilizes requests annotated for politeness to create a framework specifically to relate politeness and social power. Other previous work attempt to computationally model politeness, using politeness as a feature to identify conversations that appear to go awry in online discussions (Zhang et al., 2018a). Previous work has also explored indirect speech acts as potential sources of face-threatening acts through blame (Briggs and Scheutz, 2014) and as face-saving acts in parliamentary debates (Naderi and Hirst, 2018).

The closest semblance of our work is with Klüwer (2011, 2015), which builds upon the notion of face provided by Goffman (1967) and invents its own set of face acts specifically in the context of "small-talk" conversations. In contrast, our work specifically operationalizes the notion of the positive and negative face of Brown et al. (1987); Brown and Levinson (1978), which is well established in the Pragmatics literature and heavily acknowledged in the NLP community (Danescu-Niculescu-Mizil et al., 2013; Zhang et al., 2018a; Wang et al., 2012; Musi et al., 2018). Moreover, we focus on analysing the effects of face acts in a "goal-oriented" task like persuasion, where there is an explicit threat or attack on face as opposed to small-talk scenarios, where the goal is building rapport or passing the time. Thus our work can be considered to be complementary to the prior work of Klüwer (2011) and Klüwer (2015). It also enables us to draw insights from recent work in persuasion strategy to analyze face act exchanges in persuasion (Wang et al., 2019; Yang et al., 2019).

7 Conclusion and Future Work

In this paper, we present a generalized computational framework based on the notion of *face* to operationalize face dynamics in conversations. We instantiate these face act exchanges in the context of persuasion and propose a dataset of 296 conversations annotated with face acts. We develop computational models for predicting face acts as well as observe the impact of these predicted face acts on the donation outcome.

One important limitation of the current work is the assumption that all face acts have the same intensity/ranking. We seek to rectify this by separating the content and style of these face acts. We also wish to expand the current face framework to a more comprehensive politeness framework that incorporates notions of power and social distance between the interlocutors. We believe that our work may be extended to language generation in chatbots for producing more polite language to mediate face threats. Moreover, we intend to instantiate our proposed framework to other domains such as teacher/student conversations and other types of discourse such as social media narratives.

Abstract

We present our HABERTOR model for detecting hatespeech in large scale user-generated content. Inspired by the recent success of the BERT model, we propose several modifications to BERT to enhance the performance on the downstream hatespeech classification task. HABERTOR inherits BERT's architecture, but is different in four aspects: (i) it generates its own vocabularies and is pre-trained from the scratch using the largest scale hatespeech dataset; (ii) it consists of *Quaternion-based factorized* components, resulting in a much smaller number of parameters, faster training and inferencing, as well as less memory usage; (iii) it uses our proposed multi-source ensemble heads with a pooling layer for separate input sources, to further enhance its effectiveness; and (iv) it uses a regularized adversarial training with our proposed fine-grained and adaptive noise magnitude to enhance its robustness. Through experiments on the large-scale real-world hatespeech dataset with 1.4M annotated comments, we show that HABERTOR works better than **15** state-of-the-art hatespeech detection methods, including fine-tuning Language Models. In particular, comparing with BERT, our HABERTOR is 4∼5 times faster in the training/inferencing phase, uses less than 1/3 of the memory, and has better performance, even though we pre-train it by using less than 1% of the number of words. Our generalizability analysis shows that HABERTOR transfers well to other unseen hatespeech datasets and is a more efficient and effective alternative to BERT for the hatespeech classification.

1 Introduction

The occurrence of hatespeech has been increasing (Barna, 2019). It has become easier than before to reach a large audience quickly via social media, causing an increase of the temptation for inappropriate behaviors such as hatespeech, and potential damage to social systems. In particular, hatespeech interferes with civil discourse and turns good people away. Furthermore, hatespeech in the virtual world can lead to physical violence against certain groups in the real world[1][2], so it should not be ignored on the ground of freedom of speech.

To detect hatespeech, researchers developed human-crafted feature-based classifiers (Chatzakou et al., 2017; Davidson et al., 2017; Waseem and Hovy, 2016; MacAvaney et al., 2019), and proposed deep neural network architectures (Zampieri et al., 2019; Gambäck and Sikdar, 2017; Park and Fung, 2017; Badjatiya et al., 2017; Agrawal and Awekar, 2018). However, they might not explore all possible important features for hatespeech detection, ignored pre-trained language model understanding, or proposed uni-directional language models by reading from left to right or right to left.

Recently, the BERT (Bidirectional Encoder Representations from Transformers) model (Devlin et al., 2019) has achieved tremendous success in Natural Language Processing . The key innovation of BERT is in applying the transformer (Vaswani et al., 2017) to language modeling tasks. A BERT model pre-trained on these language modeling tasks forms a good basis for further fine-tuning on supervised tasks such as machine translation and question answering, *etc*.

Recent work on hatespeech detection (Nikolov and Radivchev, 2019) has applied the BERT model and has shown its prominent results over previous hatespeech classifiers. However, we point out its two limitations in hatespeech detection domain. First, the previous studies (ElSherief et al., 2018b,a) have shown that a hateful corpus owns distinguished linguistic/semantic characteristics compared to a non-hateful corpus. For instance, hatespeech sequences are often informal or even in-

[2] https://www.washingtonpost.com/nation/2018/11/30/how-online-hate-speech-is-fueling-real-life-violence

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7486–7502,
November 16–20, 2020.

tentionally mis-spelled (ElSherief et al., 2018a; Arango et al., 2019), so words in hateful sequences can sit in a long tail when ranking their uniqueness, and a comment can be hateful or non-hateful using the same words (Zhang and Luo, 2019). For example, "dick" in the sentence "Nobody knew dick about what that meant" is non-hateful, but "d1ck" in "You are a weak small-d1cked keyboard warrior" is hateful [3]. Thus, to better understand hateful vocabularies and contexts, it is better to pre-train on a mixture of both hateful and non-hateful corpora. Doing so helps to overcome the limitation of using BERT models pre-trained on non-hateful corpora like English Wikipedia and BookCorpus. Second, even the smallest pre-trained BERT "base" model contains 110M parameters. It takes a lot of computational resources to pre-train, fine-tune, and serve. Some recent efforts aim to reduce the complexity of BERT model with the knowledge distillation technique such as DistillBert (Sanh et al., 2019) and TinyBert (Jiao et al., 2019). In these methods, a pre-trained BERT-alike model is used as a teacher model, and a student (smaller) model (i.e. TinyBERT, DistilBERT, *.etc*) is trained to produce similar output to that of the teacher model. Unfortunately, while their complexity is reduced, the performance is also degraded in NLP tasks compared to BERT. Another direction is to use cross-layer parameter sharing, such as ALBERT (Lan et al., 2020). However, ALBERT's computational time is similar to BERT, since the number of layers remains the same as BERT; likewise, its inference is equally expensive.

Based on the above observation and analysis, we aim to investigate whether it is possible to achieve a better hatespeech prediction performance than state-of-the-art machine learning classifiers, including classifiers based on publicly available BERT model, while significantly reducing the number of parameters compared with the BERT model. By doing so, we believe that performing pre-training tasks from the ground up and on a hatespeech-related corpus would allow the model to understand hatespeech patterns better and enhance the predictive results. However, while language model pretraining tasks require a large scale corpus size, available hatespeech datasets are normally small: only 16K$\sim$115K annotated comments (Waseem and Hovy, 2016; Wulczyn et al., 2017). Thus, we introduce a large annotated hatespeech dataset with 1.4M comments extracted from Yahoo News and Yahoo Finance. To reduce the complexity, we reduce the number of layers and hidden size, and propose Quaternion-based Factorization mechanisms in BERT architecture. To further improve the model effectiveness and robustness, we introduce a multi-source ensemble-head fine-tuning architecture, as well as a target-based adversarial training.

The major contributions of our work are:

- We reduce the number of parameters in BERT considerably, and consequently the training/inferencing time and memory, while achieving better performance compared to the much larger BERT models, and other state-of-the-art hatespeech detection methods.
- We pre-train from the ground up a hateful language model with our proposed Quaternion Factorization methods on a large-scale hatespeech dataset, which gives better performance than fine tuning a pretrained BERT model.
- We propose a flexible classification net with multi-sources and multi-heads, building on top of the learned sequence representations to further enhance our model's predictive capability.
- We utilize adversarial training with a proposed fine-grained and adaptive noise magnitude to improve our model's performance.

2 Related Work

Some of the earlier works in hatespeech detection have applied a variety of classical machine learning algorithms (Chatzakou et al., 2017; Davidson et al., 2017; Waseem and Hovy, 2016; MacAvaney et al., 2019). Their intuition is to do feature engineering (i.e. manually generate features), then apply classification methods such as SVM, Random Forest, and Logistic Regression. The features are mostly Term-Frequency Inverse-Document-Frequency scores or Bag-of-Words vectors, and can be combined with additional features extracted from the user account's meta information and network structure (i.e., followers, followees, *etc*). Those methods are suboptimal as they mainly rely on the quality and quantity of the human-crafted features.

Recent works have used deep neural network architectures for hatespeech detection (Zampieri

---

[3] **It is important to note that this paper contains hate speech examples, which may be offensive to some readers. They do not represent the views of the authors. We tried to make a balance between showing less number of hate speech examples and illustrating the challenges in real-world applications.**

et al., 2019; Mou et al., 2020) such as CNN (Gambäck and Sikdar, 2017; Park and Fung, 2017), RNN (i.e. LSTM and GRU) (Badjatiya et al., 2017; Agrawal and Awekar, 2018), combining CNN with RNN (Zhang et al., 2018), or fine tuning a pretrained language models (Indurthi et al., 2019).

Another direction focuses on the testing generalization of the current hatespeech classifiers (Agrawal and Awekar, 2018; Dadvar and Eckert, 2018; Gröndahl et al., 2018), where those methods are tested in other datasets and domains such as Twitter data (Waseem and Hovy, 2016), Wikipedia data (Wulczyn et al., 2017), Formspring data (Reynolds et al., 2011), and YouTube comment data (Dadvar et al., 2014).

Unlike previous works, we pre-train a hateful language model, then build a multi-source multi-head hatespeech classifier with regularized adversarial training to enhance the model's performance.

3 Problem Definition

Given an input text sequence $s = [w_1, w_2, ..., w_n]$ where $\{w_1, w_2, .., w_n\}$ are words and $n = |s|$ is the maximum length of the input sequence s. The hatespeech classification task aims to build a mapping function $f : s = [w_1, w_2, ..., w_n] \longrightarrow \mathcal{R} \in [0, 1]$, where f inputs s and returns a probability score $P(y = 1|s) \in [0, 1]$, indicating how likely s is classified as hatespeech. In this paper, we approximate f by a deep neural classifier, where we first pretrain f with unsupervised language modeling tasks to enhance its language understanding. Then, we train f with the hatespeech classification task to produce $P(y = 1|s)$.

4 Our approach – HABERTOR

4.1 Tokenization

BERT model relies on WordPiece (WP) (Wu et al., 2016), a Google's internal code that breaks down each word into common sub-word units ("wordpieces"). These sub-words are like character n-grams, except that they are automatically chosen to ensure that each of these sub-words is frequently observed in the input corpus. WP improves handling of rare words, such as intentionally misspelled abusive words, without the need for a huge vocabulary. A comparable implementation that is open sourced is SentencePiece (SP) (Kudo and Richardson, 2018). Like WP, the vocab size is predetermined. Both WP and SP are unsupervised learning models. Since WP is not released in public, we train a SP model using our training data, then use it to tokenize input texts.

4.2 Parameter Reduction with Quaternion Factorization

Denote V the vocab size, E the embedding size, H the hidden size, L the number of layers, and F the feed-forward/filter size. In BERT, F = 4H, E = H, and the number of attention heads is $H/64$. Encoding the vocabs takes VH parameters. Each BERT layer contains three parts: (i) attention, (ii) filtering/feedforward, and (iii) output. Each of the three parts has 4H^2 parameters. Thus, a BERT layer has 12H^2 parameters and a BERT-base setting with 12 layers has VH$\,+\,$144H^2 parameters. Please refer to Section A.3 in the Appendix for details.

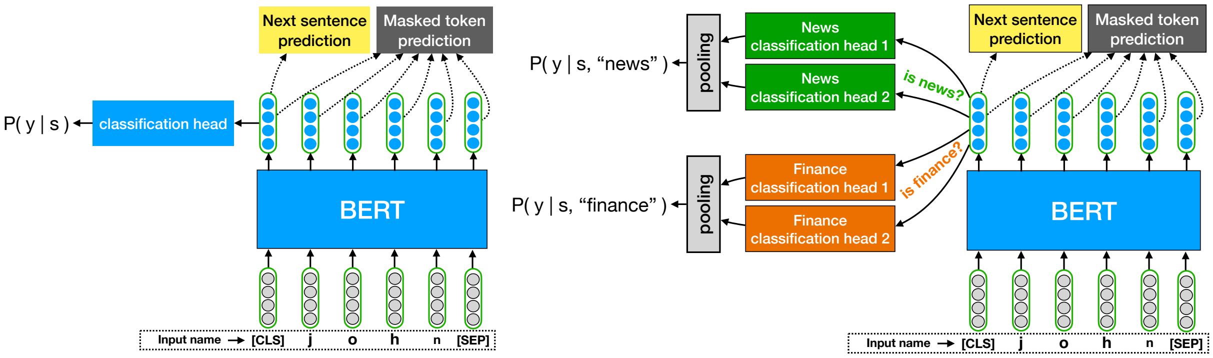
Recently, Quaternion representations have shown its benefits over Euclidean representations in many neural designs (Parcollet et al., 2019; Tay et al., 2019): (i) a Quaternion number consists of a real component and three imaginary components, encouraging a richer extent of expressiveness; and (ii) a Quaternion transformation reduces 75% parameters compared to the traditional Euclidean transformation because of the weight sharing using the Hamilton product. Hence, we propose Quaternion fatorization strategies to significantly reduce the model's parameters as follows:

Vocab Factorization (VF): Inspired by Lan et al. (2020), we encode V vocabs using Quaternion representations with an embedding size E≪H. Then, we apply a Quaternion transformation to transform E back to H, and concatenate all four parts of a Quaternion to form a regular Euclidean embedding. This leads to a total of VE + EH/4 parameters, compared to VE + EH in ALBERT.

Attention Factorization (AF): If the input sequences have length N, the output of the multi-head attention is N×N, which does not depend on the hidden size H. Hence, it is unnecessary to produce the attention Query, Key, and Value with the same input hidden size H and cost 3H^2 parameters per a layer. Instead, we produce the attention Query, Key, and Value in size C≪H using linear Quaternion transformations, leading to 3CH/4 parameters.

Feedforward Factorization (FF): Instead of linearly transforming from H to 4H (i.e. $4H^2$ parameters), we apply Quaternion transformations from H to I, and from I to 4H, with I≪H is an intermediate size. This leads to a total of (HI/4 + IH) parameters.

Output Factorization (OF): We also apply



(a) Traditional Fine-tuning BERT. (b) HABERTOR with two sources and ensemble of 2 heads.

Figure 1: Architecture comparison of traditional fine-tuned BERT and HABERTOR multi-source ensemble heads.

Quaternion transformations from 4H to I, then from I to H. This results in (HI + IH/4) parameters, compared to $4H^2$ in BERT.

When we apply all the above compression techniques together, the total parameters are reduced to VE + EH/4 + L(3CH/4 + H^2 + 5HI/2). Particularly, with BERT-base settings of V=32k, H=768, L=12, if we set E=128, C=192, and I=128, the total of parameters is reduced from 110M to **only 8.4M**.

4.3 Pretraining tasks

Similar to BERT, we pre-train our HABERTOR with two unsupervised learning/*language modeling* tasks: (i) masked token prediction, and (ii) next sentence prediction. We describe some modifications that we made to the original BERT's implementation as follows:

4.3.1 Masked token prediction task

BERT generates only one masked training instance for each input sequence. Instead, inspired by Liu et al. (2019), we generate τ training instances by randomly sampling with replacement masked positions τ times. We refer to τ as a *masking factor*. Intuitively, this helps the model to learn differently combined patterns of tokens in the same input sequence, and boosts the model's language understanding. This small modification works especially well when we have a smaller pre-training data size, which is often true for a domain-specific task (e.g., hatespeech detection).

4.3.2 Next sentence prediction task

In BERT, the two input sentences are already paired and prepared in advanced. In our case, we have to preprocess input text sequences to prepare paired sentences for the next sentence prediction task. We conduct the following preprocessing steps:

Step 1: We train an unsupervised sentence tokenizer from *nltk* library. Then we use the trained sentence tokenizer to tokenize each input text sequence into (splitted) sentences.

Step 2: In BERT, 50% of the chance two consecutive sentences are paired as *next*, and 50% of the chance two non-consecutive sentences are paired as *not next*. In our case, our input text sequences can be broken into one, two, three, or more sentences. For input text sequences that consist of only one tokenized sentence, the only choice is to pair with another random sentence to generate a *not next* example. By following our 50-50 rule described in the Appendix, we ensure generating an equal number of *next* and *not next* examples.

4.4 Training the hatespeech prediction task

For hatespeech prediction task, we propose a multi-source multi-head HABERTOR classifier. The architecture comparison of the traditional fine-tuning BERT and our proposal is shown in Figure 1. We note two main differences in our design as follows.

First, as shown in Figure 1b, our HABERTOR has separated classification heads/nets for different input sequences of different sources but with a shared language understanding knowledge. Intuitively, instead of measuring the same probabilities $P(y|s)$ for all input sequences, it injects additional prior source knowledge of the input sequences to measure $P(y|s$, "news") or $P(y|s$, "finance").

Second, in addition to multi-source, HABERTOR with an *ensemble* of h heads provides even more capabilities to model data variance. For each input source, we employ ensemble of several classification heads (i.e. two classification heads for each source in the Figure 1b) and use a pooling layer on top to aggregate results from those classification heads. We use three pooling functions: *min, max, mean*. *min* pooling indicates that HABERTOR classifies an input comment as a hateful one if all of the heads classify it as hatespeech, which put a more stringent requirement on classifying hatespeech. On the other hand, HABERTOR will predict an input comment as a normal comment if at least one of the heads recognizes the input comment as a normal one, which is less strict. Similarly, using *max* pooling will put more restriction on declaring comments as normal, and less restriction on declaring hatespeech. Finally, *mean* pooling considers the average voting from all heads.

Note that our design generalizes the traditional fine-tuning BERT architecture when h=1 and the two classification nets share the same weights. Thus, HABERTOR is more flexible than the conventional fine-tuning BERT. Also, HABERTOR can be extended trivially to problems that have q sources, with h separated classification heads for q different sources. When predicting input sequences from new sources, HABERTOR averages the scores from all separated classification nets.

4.5 Parameter Estimation

Estimating parameters in the pretraining tasks in our model is similar to BERT, and we leave the details in the Appendix due to space limitation.

For hatespeech prediction task, we use the transformed embedding vector of the *[CLS]* token as a summarized embedding vector for the whole input sequence. Let $\boldsymbol{S}$ be a collection of sequences s_i. Note that s_i is a normal sequence, not corrupted or concatenated with another input sequence. Given that $\boldsymbol{y}_i$ is the supervised ground truth label for the input sequence, and $\hat{\boldsymbol{y}}_i = P(\boldsymbol{y}_i|s_i,$ "news") (Figure 1b, 1b) where s_i is a *news* input sequence, or $\hat{\boldsymbol{y}}_i = P(\boldsymbol{y}_i|s_i,$"finance") when s_i is a *finance* input sequence. The hateful prediction task aims to minimize the following binary cross entropy loss:

$$\mathcal{L}_{hs} = \underset{\theta}{\text{argmin}} \; -\sum_{i=1}^{|\boldsymbol{S}|} \boldsymbol{y}_i \log\left(\hat{\boldsymbol{y}}_i\right) + (1-\boldsymbol{y}_i) \log\left(1-\hat{\boldsymbol{y}}_i\right)$$

Regularize with adversarial training: To make our model more robust to perturbations of the input embeddings, we further regularize our model with adversarial training. There exist several state-of-the-art *target*-based adversarial attacks such us Fast Gradient Method (*FGM*) (Miyato et al., 2017), Basic Iterative Method (Kurakin et al., 2016), and Carlini L2 attack (Carlini and Wagner, 2017). We use the *FGM* method as it is effective and efficient according to our experiments.

In *FGM*, the noise magnitude is a scalar value and is a manual input hyper-parameter. This is sub-optimal, as different adversarial directions of different dimensions are scaled similarly, plus, manually tuning the noise magnitude is expensive and not optimal. Hence, we propose to extend *FGM* with a *learnable* and *fine-grained* noise magnitude, where the noise magnitude is parameterized by a learnable vector, providing different scales for different adversarial dimensions. Moreover, the running time of our proposal compared to *FGM* is similar.

The basic idea of the adversarial training is to add a small perturbation noise δ on each of the token embeddings that makes the model misclassify hateful comments as normal comments, and vice versa. Given the input sequence $s_i = [w_1^{(i)}, w_2^{(i)}, ..., w_u^{(i)}]$ with ground truth label y_i, let $\tilde{y}_i$ be the adversarial target class of s_i such that $\tilde{y}_i \neq y_i$. In the hatespeech detection domain, our model is a binary classifier. Hence, when $y_i = 1$ (s_i is a hateful comment), $\tilde{y}_i = 0$ and vice versa. Then, the perturbation noise δ is learned by minimizing the following cost function:

$$\mathcal{L}_{adv} = \underset{\delta,\delta\in[a,b]}{\text{argmin}} \; -\sum_{i=1}^{|\boldsymbol{S}|} logP\big(\tilde{\boldsymbol{y}}_{\boldsymbol{i}} \,|s_i+\delta_i;\hat{\theta}\big) \qquad (1)$$

Note that in Eq. (1), δ is constrained to be less than a predefined noise magnitude scalar in the traditional FGM method. In our proposal, δ is constrained within a range $[a, b]$ (i.e. $min(\delta) \geq$ a $\wedge$ $max(\delta) \leq$ b). Solving Eq. (1) is expensive and not easy, especially with complicated deep neural networks. Thus, we approximate each perturbation noise δ_i for each input sequence s_i by linearizing partial loss $-logP\big(\tilde{\boldsymbol{y}}_{\boldsymbol{i}} \,|s_i+\delta_i;\hat{\theta}\big)$ around s_i. Particularly, δ_i is measured by:

$$\delta_i = -\epsilon \times \frac{\nabla_{s_i}\big(-logP(\tilde{\boldsymbol{y}}_{\boldsymbol{i}} \,|s_i;\hat{\theta})\big)}{\|\nabla_{s_i}\big(-logP(\tilde{\boldsymbol{y}}_{\boldsymbol{i}} \,|s_i;\hat{\theta})\big)\|_2} \qquad (2)$$

In Eq. (2), ϵ is a *learnable vector*, with the same dimensional size as δ_i. Solving the constraint $\delta_i \in [a, b]$ in Eq. (1) becomes restricting $\epsilon \in [a, b]$, which is trivial by projecting ϵ in $[a, b]$.

Finally, HABERTOR aims to minimize the following cost function:

$$\mathcal{L} = \mathcal{L}_{hs} + \lambda_{adv}\mathcal{L}_{adv} - \lambda_{\epsilon}||\epsilon||_2, \qquad (3)$$

where $||\epsilon||_2$ is an additional term to force the model to learn robustly as much as possible, and λ_ϵ is a hyper-parameter to balance its effect. Note that, we first learn the optimal values of all token embeddings and HABERTOR's parameters before learning adversarial noise δ. Also, regularizing adversarial training only increases the training time, but not the inferencing time since it does not introduce extra parameters for the model during the inference.

Table 1: Statistics of the three datasets.

Statistics/Datasets	Yahoo	Twitter	Wiki
Total	1.4M	16K	115K
# Hateful	100K	5K	13K
% of hatespeech	7%	31%	12%

5 Empirical Study

5.1 Experiment Setting

Dataset: Our primary dataset was extracted from user comments on Yahoo News and Finance for five years, and consisted of 1,429,138 labeled comments. Among them, 944,391 comments are from Yahoo News and 484,747 comments are from Yahoo Finance. There are 100,652 hateful comments. The 1.4M labeled data was collected as follows (Nobata et al., 2016): comments that are reported as "abusive" for any reason by users of Yahoo News and Finance are sent to in-house trained raters for review and labeling.

To further validate the generalizability of HABERTOR, we perform transfer-learning experiments on other two publicly available hatespeech datasets: Twitter (Waseem and Hovy, 2016), and Wikipedia (i.e. Wiki) (Wulczyn et al., 2017). The Twitter dataset consists of 16K annotated tweets, including 5,054 hateful tweets (i.e., 31%). The Wiki dataset has 115K labeled discussion comments from English Wikipedia talk's page, including 13,590 hateful comments (i.e., 12%). The statistics of 3 datasets are shown in Table 1.

Train/Dev/Test split: We split the dataset into train/dev/test sets with a ratio 70%/10%/20%. We tune hyper-parameters on the dev set, and report final results on the test set. Considering critical mistakes reported at Arango et al. (2019) when building machine learning models (i.e. extracting features using the entire dataset, including testing data, *etc*), we generate vocabs, pre-train the two language modeling tasks, and train the hatespeech prediction task using **only the training set**.

Baselines, our Models and hyper-parameter Settings: We compare our models with 15 state-of-the-art baselines: Bag of Words (BOW) (Dinakar et al., 2011; Van Hee et al., 2015), NGRAM, CNN (Kim, 2014), VDCNN (Conneau et al., 2017), FastText (Joulin et al., 2016), LSTM (Cho et al., 2014), att-LSTM, RCNN (Lai et al., 2015), att-BiLSTM (Lin et al., 2017), Fermi (best hatespeech detection method as reported in Basile et al. (2019)) (Indurthi et al., 2019), Q-Transformer (Tay et al., 2019), Tiny-BERT (Jiao et al., 2019), DistilBERT-base (Sanh et al., 2019), ALBERT-base (Lan et al., 2020), and BERT-base (Devlin et al., 2019; Nikolov and Radivchev, 2019). We are aware of other recent language models such as Transformer-XL (Dai et al., 2019), RoBERTa(Liu et al., 2019), DialoGPT (Zhang et al., 2020), to name a few. However, as these models are even heavier than BERT-base, we do not compare with them. The detailed description of the baselines and hyper-parameter settings is described in the Appendix.

Table 2: Parameters Comparison between *HABERTOR-VAFOQF* vs. other LMs. "–" indicates not available.

Statistics	HABERTOR -VAFOQF	AL-BERT	Tiny-BERT	Distil-BERT	BERT-base
Layers (L)	**6**	12	4	6	12
Attention heads	**6**	12	12	12	12
Attention size (C)	**192**	–	–	–	–
Embedding (E)	**128**	128	–	–	–
Hidden (H)	**384**	768	312	768	768
Intermediate size (I)	**128**	–	–	–	–
Feedforward size	**1,536**	3072	1,200	3,072	3,072
Vocab (V)	**40k**	30k	30k	30k	30k
Parameters	**7.1M**	12M	14.5M	65M	110M

Our models: We denote *HABERTOR* as our model without using any factorization, *HABERTOR-VQF* as *HABERTOR* + Vocab Quaternion Factorization, *HABERTOR-VAQF* as *HABERTOR* + Vocab + Attention Quaternion Factorization, *HABERTOR-VAFQF* as *HABERTOR* + Vocab + Attention + Feedforward Quaternion Factorization, and *HABERTOR-VAFOQF* as *HABERTOR* + Vocab + Attention + Feedforward + Output Quaternion Factorization.

Measurement: We evaluate models on seven metrics: Area Under the Curve (*AUC*), Average Precision (*AP*), False Positive Rate (FPR), False Negative Rate (FNR), F1 score[4]. In real world, for imbalanced datasets, we care more about FPR and FNR. Thus, we report FPR at 5% of FNR (FPR@5%FNR), meaning we allow 5% of hateful texts to be misclassified as normal ones, then report FPR at that point. Similarly, we report FNR at 5% of FPR (FNR@5%FPR). Except for AUC and AP, the other metrics are reported using an optimal threshold selected by using the development set.

Model size comparison: *HABERTOR* has 26M of parameters. *HABERTOR-VQF* and *HABERTOR-VAQF* have 16.2M and 13.4M of parameters, respectively. *HABERTOR-VAFQF* and *HABERTOR-VAFOQF* have 10.3M and 7.1M of parameters, respectively. The size of all five models is much

---

[4] Both AP and F1 account for Precision and Recall so we do not further report Precision and Recall for saving space.

smaller than BERT-base (i.e. 110M of parameters). The configuration comparison of HABERTOR-VAFOQF and other pretrained language models is given in Table 2. *HABERTOR-VAFOQF* has less than 2 times compared to TinyBERT's parameters, less than 9 times compared to Distil-BERT's size, and is equal to 0.59 AlBERT's size.

5.2 Experimental results

5.2.1 Performance comparison

Table 3 shows the performance of all models on Yahoo dataset. Note that we train on the Yahoo training set that contains both Yahoo News and Finance data, and report results on Yahoo News and Finance separately, and report only AUC and AP on both of them (denoted as column "Yahoo" in Table 3). We see that Fermi worked worst among all models. It is mainly because Fermi transfers the pre-trained embeddings from the USE model to a SVM classifier without further fine-tuning. This limits Fermi's ability to understand domain-specific contexts. Q-Transformer works the best among non-LM baselines, but worse than LM baselines as it is not pretrained. BERT-base performed the best among all baselines. Also, distilled models worked worse than BERT-base due to their compression nature on BERT-base as the teacher model.

Next, we compare the performance of our proposed models against each other. Table 3 shows that our models' performance is decreasing when we compress more components (*p-value* < 0.05 under the directional Wilcoxon signed-rank test). We reason it is a trade-off between the model size and the model performance as factorizing a component will naturally lose some of its information.

Then, we compared our proposed models with BERT-base – the best baseline. Table 3 shows that except our *HABERTOR-VAFOQF*, our other proposals outperformed BERT-base, improving by an average of 1.2% and 1.5% of F1-score in Yahoo News and Yahoo Finance, respectively (*p-value* $<$ 0.05). Recall that in addition to improving hate-speech detection performance, our models' size is much smaller than BERT-base. For example, *HABERTOR* saved 84M of parameters from BERT-base, and *HABERTOR-VAFQF* saved nearly 100M of parameters from BERT-base. Interestingly, even our smallest *HABERTOR-VAFOQF* model (7.1M of parameters) achieves similar results compared to BERT-base (i.e. the performance difference between them is not significant under the directional Wilcoxon signed-rank test). Those results show the effectiveness of our proposed models against BERT-base, the best baseline, and consolidate the need of pretraining a language model on a hateful corpus for a better hateful language understanding.

5.2.2 Running time and memory comparison

Running time: Among LM baselines, TinyBERT is the fastest. Though ALBERT has the smallest number of parameters by adopting the cross-layer weight sharing mechanism, ALBERT has the same

Table 4: Generalizability of *HABERTOR* and top baselines. Report AUC, AP, and F1 on each test set.

	Twitter			Wiki		
Model	AUC	AP	F1	AUC	AP	F1
Fermi	89.03	79.23	74.52	96.59	84.26	75.51
TinyBERT	92.23	83.88	78.33	97.10	87.64	79.70
DistilBERT	92.13	80.21	77.89	97.23	88.16	80.21
ALBERT	92.55	86.51	78.76	97.66	88.91	80.66
BERT	93.21	86.67	79.68	97.75	89.23	80.73
HABERTOR	**93.52**	**88.57**	**81.22**	97.46	88.65	**80.81**
HABERTOR-VQF	**93.94**	**88.45**	**81.21**	97.40	88.64	80.66
HABERTOR-VAQF	**93.57**	**87.66**	**80.23**	97.45	88.61	80.63
HABERTOR-VAFQF	**93.51**	**87.38**	**80.16**	97.37	88.21	80.23
HABERTOR-VAFOQF	**93.49**	**87.14**	**80.06**	97.23	87.94	79.61

number of layers as BERT-base, leading to a similar computational expense as BERT-base.

Our *HABERTOR-VQF* and *HABERTOR-VAQF* have a very similar parameter size with *TinyBERT* and their train/inference time are similar. Interestingly, even though *HABERTOR* has 26M of parameters, its runtime is also competitive with *TinyBERT*. This is because among 26M of parameters in *HABERTOR*, 15.4M of its total parameters are for encoding 40k vocabs, which are not computational parameters and are only updated sparsely during training. *HABERTOR-VAFQF* and *HABERTOR-VAFOQF* significantly reduce the number of parameters compared to TinyBERT, leading to a speedup during training and inference phases. Especially, our experiments on 4 K80 GPUs with a batch size of 128 shows that *HABERTOR-VAFOQF* is 1.6 times faster than TinyBERT.

Memory consumption: Our experiments with a batch size of 128 on 4 K80 GPUs show that among LM baselines, TinyBERT and ALBERT are the most lightweight models, consuming 13GB of GPU memory. Compared to TinyBERT and ALBERT, *HABERTOR* takes an additional 4GB of GPU memory, while *HABERTOR-VQF*, *HABERTOR-VAQF* hold a similar memory consumption, *HABERTOR-VAFQF* and *HABERTOR-VAFOQF* reduces 1$\sim$3 GB of GPU memory.

Compared to BERT-base: In general, *HABERTOR* is 4$\sim$5 times faster, and 3.1 times GPU memory usage smaller than BERT-base. Our most lightweight model *HABERTOR-VAFOQF* even reduces 3.6 times GPU memory usage, while remains as effective as BERT-base. The memory saving in our models also indicates that we could increase the batch size to perform inference even faster.

5.2.3 Generalizability analysis

We perform hatespeech Language Model transfer learning on other hateful Twitter and Wiki datasets to understand our models' generalizability. We use our models' pre-trained language model checkpoint learned from Yahoo hateful datasets, and fine tune them on Twitter/Wiki datasets. Note that the fine-tuned training also includes regularized adversarial training for best performance. Next, we compare the performance of our models with Fermi and four LM baselines – best baselines reported in Table 3.

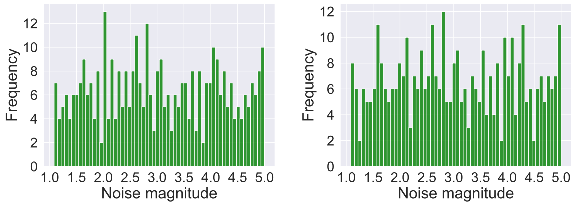
Table 5: Comparison of the **traditional** FGM with a *fixed* and *scalar* noise magnitude, compared to the FGM with **our** proposed *fine-grained* and *adaptive* noise magnitude. Better results are in **bold**.

		Twitter			Wiki		
Model	Type	AUC	AP	F1	AUC	AP	F1
HABERTOR	traditional	93.54	87.88	79.84	97.50	88.14	80.13
	ours	93.52	**88.57**	**81.22**	97.46	**88.65**	**80.81**
HABERTOR-VQF	traditional	93.62	88.09	80.26	97.44	88.19	80.11
	ours	93.94	**88.45**	**81.21**	97.40	**88.64**	**80.66**
HABERTOR-VAQF	traditional	93.03	86.77	79.56	97.44	88.15	80.16
	ours	93.57	**87.66**	**80.23**	97.45	**88.61**	**80.63**
HABERTOR-VAFQF	traditional	92.89	86.42	79.64	97.42	88.08	79.71
	ours	93.51	**87.38**	**80.16**	97.37	**88.21**	**80.23**
HABERTOR-VAFOQF	traditional	93.08	86.67	79.33	97.28	87.40	79.19
	ours	93.49	**87.14**	**80.06**	97.23	**87.94**	**79.61**

Table 4 shows that BERT-base performed best compared to other fine-tuned LMs, which is consistent with our reported results on Yahoo datasets in Table 3. When comparing with BERT-base's performance (i.e. best baseline) on the Twitter dataset, all our models outperformed BERT-base. On Wiki dataset, interestingly, our models work very competitively with BERT-base, and achieve similar F1-score results. Recall that BERT-base has a major advantage of pre-training on 2,500M Wiki words, thus potentially understands Wiki language styles and contexts better. In contrast, HABERTOR and its four factorized versions are pre-trained on 33M words from Yahoo hatespeech dataset. As shown in the ablation study (refer to *AS2* in Section A.6 of the Appendix), a larger pre-training data size leads to better language understanding and a higher hatespeech prediction performance. Hence, if we acquire larger pre-training data with more hateful representatives, our model's performance can be further boosted. All of those results show that our models generalize well on other hatespeech datasets compared with BERT-base, with significant model complexity reduction.

5.2.4 Ablation study

Effectiveness of the adversarial attacking method FGM with our fined-grained and adaptive noise magnitude: To show the effectiveness of the FGM attacking method with our proposed fine-grained and adaptive noise magnitude, we



(a) Twitter (b) Wiki.

Figure 2: Histogram of the learned noise magnitude when performing Language Model transfer learning of HABERTOR on (a) Twitter, and (b) Wiki datasets.

compare the performance of HABERTOR and its four factorized versions when (i) using a fixed and scalar noise magnitude as in the *traditional* FGM method, and (ii) using a fine-grained and adaptive noise magnitude in *our* proposal. We evaluate the results by performing the Language Model transfer learning on Twitter and Wiki datasets and present results in Table 5. Note that, the noise magnitude range is set in [1, 5] for both two cases (i) and (ii) for a fair comparison, and we manually search the optimal value of the noise magnitude in the *traditional* FGM method using the development set in each dataset. We observe that in all our five models, learning with our modified FGM produces better results compared to learning with a traditional FGM, confirming the effectiveness of our proposed fine-grained and adaptive noise magnitude.

We also plot the histogram of the learned noise magnitude of HABERTOR on Twitter and Wiki datasets. Figure 2 shows that different embedding dimensions are assigned with different learned noise magnitude, showing the need of our proposed fine-grained and adaptive noise magnitude, that automatically assigns different noise scales for different embedding dimensions.

Additional Ablation study: We conduct several ablation studies to understand HABERTOR's sensitivity. Due to space limitation, we summarize the key findings as follows, and leave detailed information and additional study results in the Appendix: (i) A large *masking factor* in HABERTOR is helpful to improve its performance; (ii) Pretraining with a larger hatespeech dataset or a more fine-grained pretraining can improve the hatespeech prediction performance; and (iii) Our fine-tuning architecture with multi-source and ensemble of classification heads helps improve the performance.

5.2.5 Further application discussion

Our proposals were designed for the hatespeech detection task, but in an extent, they can be applied for other text classification tasks. To illustrate the point, we experiment our models (i.e. all our pretraining and fine-tuning designs) on a sentiment classification task. Particularly, we used 471k Amazon-Prime-Pantry reviews (McAuley et al., 2015), which is selected due to its reasonable size for fast pretraining, fine-tuning and result attainment. After some preprocessings (i.e. duplicated reviews removal, convert the reviews with rating scores ≥ 4 as positive, rating ≤ 2 as negative, and no neutral class for easy illustration), we obtained 301k reviews and splited into 210k-training/30k-development/60k-testing with a ratio 70/10/20. Next, we pretrained our models on 210k training reviews which contain 5.06M of words. Then, we fine-tuned our models on the 210k training reviews, selected a classification threshold on the 30k development reviews, and report AUC, AP, and F1 on the 60k testing reviews. We compare the performance of our models with fine-tuned BERT-base and ALBERT-base – two best baselines. We observe that though pretraining on only 5.06M words of 210k training reviews, HABERTOR performs very similarly to BERT-base, while improving over ALBERT-base. Except HABERTOR-VAFOQF with a little bit smaller F1-score compared to ALBERT-base, our other three compressed models worked better than ALBERT-base, showing the effectiveness of our proposals.

Table 6: Application of our models on the sentiment classification task using Amazon Prime Pantry reviews.

Model	AUC	AP	F1
ALBERT-base	98.77	99.77	97.95
BERT-base	99.16	99.84	98.42
HABERTOR	99.10	99.83	98.39
HABERTOR+VQF	99.09	99.83	98.27
HABERTOR+VAQF	98.90	99.80	98.07
HABERTOR+VAFQF	98.87	99.79	98.05
HABERTOR+VAFOQF	98.61	99.75	97.78

6 Conclusion

In this paper, we presented the *HABERTOR* model for detecting hatespeech. *HABERTOR* understands the language of the hatespeech datasets better, is 4-5 times faster, uses less than 1/3 of the memory, and has a better performance in hatespeech classification. Overall, *HABERTOR* outperforms 15 state-of-the-art hatespeech classifiers and generalizes well to unseen hatespeech datasets, verifying not only its efficiency but also its effectiveness.

A Appendix

A.1 Parameter Estimation for pretraining HABERTOR with language model tasks

Given the following input sentences $s_i = [w_1^{(i)}, w_2^{(i)}, ..., w_u^{(i)}]$ and $s_j = [w_1^{(j)}, w_2^{(j)}, ..., w_v^{(j)}]$, let the text sequence be $c_l = s_{ij} = [w_1^{(i)}, w_2^{(i)}, ..., w_u^{(i)}, w_1^{(j)}, w_2^{(j)}, ..., w_v^{(j)}]$=$[w_1, ..., w_n]$ $(n = u + v)$ with label y_l where we already paired the sentences to generate a *next* (i.e $y_l = 1$) or *not next* (i.e. $y_l = 0$) training instance. Let $\bar{c}_l$ be a corrupted sequence of c_l, where we masked some tokens in c_l. Denote $\boldsymbol{C}$ a collection of such training text sequences c_l. The masked token prediction task aims to reconstruct each $c_l \in \boldsymbol{C}$ given the corrupted sequence $\bar{c}_l$. In another word, the masked token prediction task maximizes the following log-likelihood:

$$\mathcal{L}_1 = \underset{\theta}{\text{argmax}} \sum_{l=1}^{|\boldsymbol{C}|} log\ p_\theta(c_l|\bar{c}_l)$$
$$\approx \sum_{l=1}^{|\boldsymbol{C}|} \sum_{t=1}^{n} \mathbb{1}_t\ log\ p_\theta(w_t|\bar{c}_l)$$

where $\mathbb{1}_t$ is an indicator function and $\mathbb{1}_t$ = 1 when the token t^{th} is a *[MASK]* token, otherwise $\mathbb{1}_t$ = 0. θ refers to all the model's learning parameters, w_t is the ground truth token at position t^{th}. Denote $H_\theta(c_l) = [H_\theta(c_l)_1, H_\theta(c_l)_2, ..., H_\theta(c_l)_n]$ as the sequence of transformed output embedding vectors obtaining at the final layer of corresponding n tokens in the sequence c_l. $H_\theta(c_l)_t \in \mathcal{R}^d$ with d is the embedding size. By parameterizing a linear layer with a transformation $W_1 \in \mathcal{R}^{V \times d}$ (with V refers to the vocabulary size) as a decoder, we can rewrite $\mathcal{L}_1$ as follows:

$$\mathcal{L}_1 = \underset{\theta}{\text{argmin}} - \sum_{i=1}^{|\boldsymbol{C}|} \sum_{t=1}^{n} \mathbb{1}_t \log \frac{\exp\Big(\big[W_1 H_\theta(\bar{c}_l)_t\big]_t\Big)}{\sum_{k=1}^{V} exp\Big(\big[W_1 H_\theta(\bar{c}_l)_t\big]_k\Big)}$$

where $[\cdot]_t$ refers to the output value at position t.

For the next sentence prediction task, the objective is to minimize the following binary cross entropy loss function:

$$\mathcal{L}_2 = \underset{\theta}{\text{argmin}}\ - \sum_{i=1}^{|\boldsymbol{C}|} y_l\ \log\big(\sigma(W_2 H_\theta(c_l)_1)\big) +$$
$$(1 - y_l) \log\big(\sigma(W_2 H_\theta(c_l)_1)\big)$$

where $W_2 \in \mathcal{R}^d$ and $H_\theta(c_l)_1$ refers to the embedding vector of the first token in the sequence c_l, or the *[CLS]* token. The intuition behind this is that the *[CLS]*'s embedding vector summarizes information of all other tokens via the attention Transformer network (Vaswani et al., 2017).

Then, pretraining with two language modeling tasks aims to minimize both loss functions $\mathcal{L}_1$ and $\mathcal{L}_2$ by: $\mathcal{L}_{LM} = \text{argmin}_\theta\ \big(\mathcal{L}_1 + \mathcal{L}_2\big)$

A.2 Quaternion

In mathematics, Quaternions[5] are a hypercomplex number system. A Quaternion number P in a Quaternion space $\mathbb{H}$ is formed by a real component (r) and three imaginary components as follows:

$$P = r + a\boldsymbol{i} + b\boldsymbol{j} + c\boldsymbol{k}, \tag{4}$$

where $\boldsymbol{ijk} = \boldsymbol{i^2} = \boldsymbol{j^2} = \boldsymbol{k^2} = -1$. The non-commutative multiplication rules of quaternion numbers are: $\boldsymbol{ij} = \boldsymbol{k}$, $\boldsymbol{jk} = \boldsymbol{i}$, $\boldsymbol{ki} = \boldsymbol{j}$, $\boldsymbol{ji} = -\boldsymbol{k}$, $\boldsymbol{kj} = -\boldsymbol{i}$, $\boldsymbol{ik} = -\boldsymbol{j}$. In Equa (4), r, a, b, c are real numbers $\in \mathbb{R}$. Note that r, a, b, c can also be extended to a real-valued vector $\in \mathbb{R}$ to obtain a Quaternion embedding, which we use to represent each word-piece embedding.

Algebra on Quaternions: We present the Hamilton product on Quaternions, which is the heart of the linear Quaternion-based transformation. The Hamilton product (denoted by the $\otimes$ symbol) of two Quaternions $P \in \mathbb{H}$ and $Q \in \mathbb{H}$ is defined as:

$$\begin{aligned} P \otimes Q =& (r_P r_Q - a_P a_Q - b_P b_Q - c_P c_Q) + \\ & (r_P a_Q + a_P r_Q + b_P c_Q - c_P b_Q)\boldsymbol{i} + \\ & (r_P b_Q - a_P c_Q + b_P r_Q + c_P a_Q)\boldsymbol{j} + \\ & (r_P c_Q + a_P b_Q - b_P a_Q + c_P r_Q)\boldsymbol{k} + \end{aligned} \tag{5}$$

Activation function on Quaternions: Similar to (Tay et al., 2019; Parcollet et al., 2019), we use a *split activation function* because of its stability and simplicity. *Split activation function* β on a Quaternion P is defined as:

$$\beta(P) = f(r) + f(a)\boldsymbol{i} + f(b)\boldsymbol{j} + f(c)\boldsymbol{k} \tag{6}$$

, where f is any standard activation function for Euclidean-based values.

Why does a linear Quaternion transformation reduce 75% of parameters compared to the linear Euclidean transformation? Figure 3 shows a comparison between a traditional linear Euclidean transformation and a linear Quaternion-based transformation.

In Euclidean space, the same input will be multiplied with different weights to produce different

---

[5] https://en.wikipedia.org/wiki/Quaternion

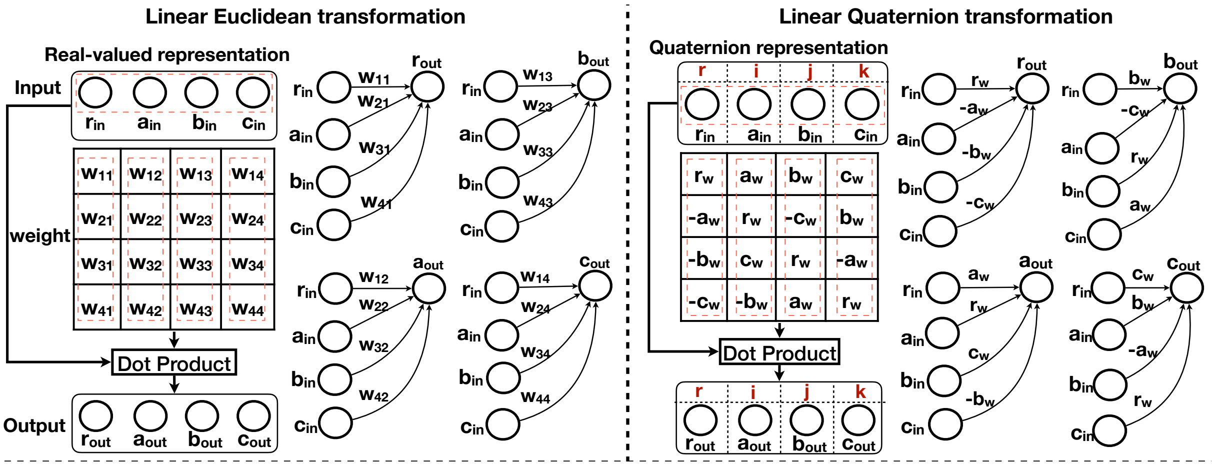

Figure 3: Comparison between linear Euclidean transformation (Left) and linear Quaternion transformation (Right). The Hamilton product in Quaternion space is replaced with an equivalent dot product in real space for an easy reference. Computing each output dimension in real-valued transformation (left) always need 4 new parameters, resulting in 16 degrees of freedom. In contrast, only 4 parameters are used and shared in producing all 4 output dimensions in Quaternion transformation, leading to a better inter-dependency encoding and a 75% of parameter saving.

output dimensions. Particularly, given a real-valued 4-dimensional vector $[r_{in}, a_{in}, b_{in}, c_{in}]$, we need to parameterize a weight matrix of 16 parameters (i.e. 16 degrees of freedom) to transform the 4-dimensional input vector into a 4-dimensional output vector $[r_{out}, a_{out}, b_{out}, c_{out}]$. However, with Quaternion transformation, the input vector now is represented with 4 components, where r_{in} is the value of the real component, a_{in}, b_{in}, c_{in} are the corresponding value of the three imaginary parts $\boldsymbol{i}$, $\boldsymbol{j}$, $\boldsymbol{k}$, respectively. Because of the weight sharing nature of Hamilton product, different output dimensions take different combinations with the same input with exactly same 4 weighting parameters $\{r_w, a_w, b_w, c_w\}$. Thus, the Quaternions transformation reduces 75% of the number of parameters compared to the real-valued representations in Euclidean space.

Quaternion-Euclidean conversion: Another excellent property of using Quaternion representations and Quaternion transformations is that converting from Quaternion to Euclidean and vice versa are convenient. To convert a real-valued based vector $v \in \mathcal{R}^d$ into a Quaternion-based vector, we consider the first $d/4$ dimensions of v as the value of the real component, and the corresponding next three $d/4$ dimensions are for the three imaginary parts, respectively. Similarly, to convert a Quaternion vector $v \in \mathcal{H}^d$ into a real-valued vector, we simply concatenate all four components of the Quaternion vector, and treat the concatenated vector as a real-valued vector in Euclidean space.

A.3 Analysis on the BERT's Parameters

Figure 4 presents a general view of the BERT architecture. Each BERT layer contains three parts: (i) attention, (ii) filtering, and (iii) output.

The *attention* part parameterizes three weight transformation matrices H×H to form key, query, and value from the input, and another weight matrix H×H to transform the output attention results. The total parameters of this part are $4H^2$. The *filtering* part parameterizes a weight matrix H×4H to transform the output of the *attention* part, leading to a total of $4H^2$ parameters. The *output* part parameterizes a weight matrix 4H×H to transform the output of the *filtering* part from 4H back to H, resulting in $4H^2$ parameters.

Thus, a BERT layer has $12H^2$ parameters, and a BERT-base setting with 12 layers has $144H^2$ parameters. By taking into account the number of parameters for encoding V vocabs, the total parameters of BERT is VH + $144H^2$.

A.4 50-50 Rule

To ensure the 50-50 rule, we perform the following method: Let M be the number of input text sequences that we can split into multiple sentences, and N be the number of input sequences that can be tokenized into only one sentence. We want the number of sentences to be generated as *next* sentence pairs (sampling with probability p_1) to be roughly equal to the number of sentences to be formed as *not next* sentence pairs (sampling with probability p_2). In another word,

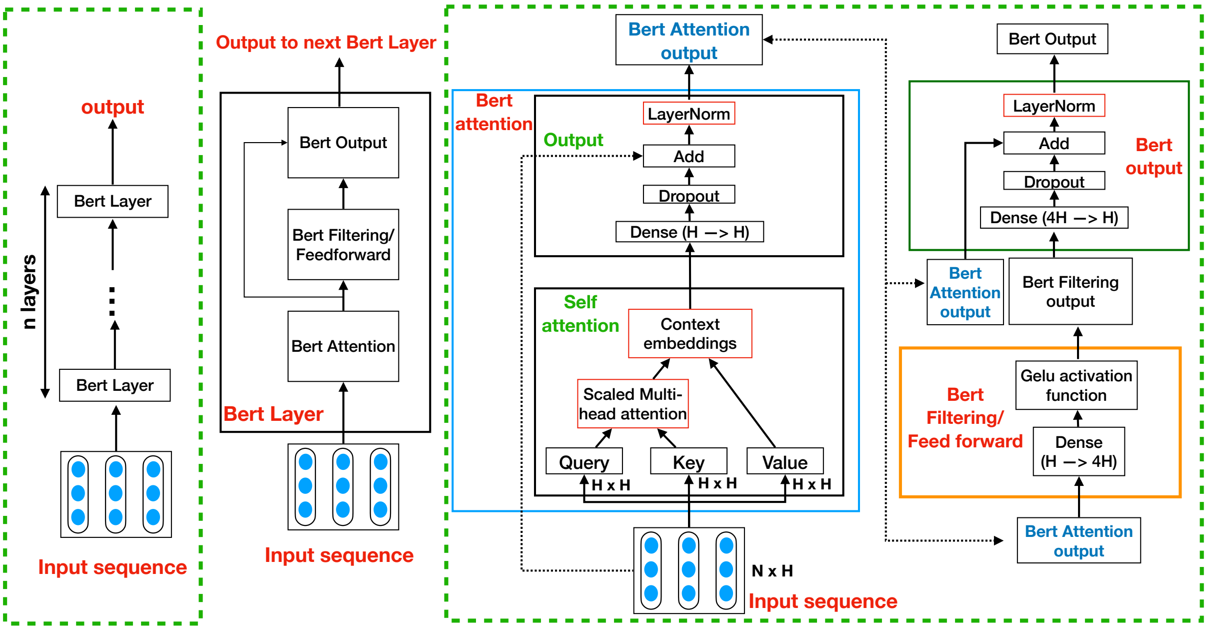

Figure 4: General view of the BERT architecture. Uncovering the architecture from left to right.

$M \times p_1 = (M+N) \times p_2$ or $\frac{p_1}{p_2} = \frac{(M+N)}{M}$. Since $p_1 + p_2 = 1$, replacing $p_2 = 1 - p_1$, we have: $M \times p_1 = (M+N)(1-p_1) \longrightarrow p_1 = \frac{(M+N)}{(2M+N)}$. With p_1 established, we set p_1 as the probability for a sentence to be paired with another consecutive sentence in a same input sequence to generate a *next* sentence example.

A.5 Baselines and Hyper-parameter Settings

15 Baselines are described as follows:

- **BOW**: Similar to Dinakar et al. (2011); Van Hee et al. (2015), we extract bag of words features from input sequences, then a traditional machine learning classifier is built on top of the extracted features.
- **NGRAM**: It is similar to BOW model, except using n-gram features of the input sequence.
- **CNN** (Kim, 2014): It is a state-of-the-art word based CNN neural network model.
- **VDCNN** (Conneau et al., 2017): It is a character based CNN model with a deeper architecture and optional shortcut between layers.
- **FastText** (Joulin et al., 2016): An extension of the Word2Vec model, where it represents each word as an n-gram of characters to provide embeddings for rare words.
- **LSTM** (Cho et al., 2014): We use: (i) the last LSTM output vector, and (ii) a pooling layer (*max* and *mean*) to aggregate LSTM output vectors and report only the best results.
- **att-LSTM**: A LSTM model with an attention layer to aggregate LSTM hidden state vectors.
- **RCNN** (Lai et al., 2015): A combination between a bi-directional recurrent structure to capture contextual information and a *max* pooling layer to extract key features.
- **att-BiLSTM** (Lin et al., 2017): It is a self-attentive Bidirectional LSTM model.
- **Fermi** (Indurthi et al., 2019): The best hate-speech detection method, as reported in (Basile et al., 2019). It built a SVM classifier on top of the pretrained embeddings from Universal Sentence Encoder (USE) (Cer et al., 2018) model.
- **Q-Transformer** (Tay et al., 2019): It is a Quaternion Transformer. It replaces all Euclidean embeddings and linear transformations by Quaternion emddings and Quaternion linear transformation. We use the *full* version of Q-Transformer due to its high effectiveness.
- **Tiny-BERT** (Jiao et al., 2019): It is a compressed model of BERT-base by performing knowledge distillation on BERT-base during its pretraining phase with smaller number of layers and embedding sizes. We adopt the Tiny-BERT 4 layers with 14.5M of parameters.
- **DistilBERT-base** (Sanh et al., 2019): another knowledge distillation of the BERT-base model during the BERT's pre-training phase.
- **ALBERT-base** (Lan et al., 2020): a light-

weight version of BERT-base model with parameters sharing strategies and an inter-sentence coherence pretraining task.

- **BERT-base** (Devlin et al., 2019): Similar to Nikolov and Radivchev (2019), we use pre-trained BERT with 12 layers and uncased (our experiments show uncased works better than cased vocab) to perform fine-tuning for the hate-speech detection.

For baselines that require word embeddings, to maximize their performances, we initialize word embeddings with both GloVe pre-trained word embeddings (Pennington et al., 2014) and random initialization and report their best results. We implement BOW and NGRAM with Naive Bayes, Random Forest, Logistic Regression, and Xgboost classifiers, and then report the best results.

By default, our vocab size is set to 40k. The number of pretraining epochs is set to 60, and the batch size is set to 768. The learning rate is set to 5e-5 for the masked token prediction and next sentence prediction tasks, which are the two pretraining tasks, and 2e-5 for the hatespeech prediction task, which is the fine-tuning task. The default design of HABERTOR is given at Figure 1b, with one separated classification net with an ensemble of 2 heads for each input source. The *masking factor* τ is set to 10. The noise magnitude's bound constraint $[a, b] = [1, 2]$ in Yahoo dataset, and $[a, b] = [1, 5]$ in Twitter and Wiki datasets. λ_{adv}=1.0, and λ_{ϵ}=1 in all three datasets. We use *min* pooling function to put a more stringent requirement on classifying hatespeech comments, as the number of hatespeech-labeled comments is the minority. All the pre-trained language models are fined-tuned with the Yahoo train set. For all other baselines, we vary the hidden size from {96, 192, 384} and report their best results. We build VDCNN with 4 convolutional blocks, which have 64, 128, 256 and 512 filters with a kernel size of 3, and 1 convolution layer. Each convolutional block includes two convolution layers. For FastText, we find that 1,2,3-grams and 1,2,3,4,5-character grams give the best performance. All models are optimized using Adam optimizer (Kingma and Ba, 2014).

A.6 Ablation Study

Effectiveness of regularized adversarial training and masking factor τ (AS1): Recall that by default, HABERTOR has 2 classification nets, each of the two nets has an ensemble of 2 classification heads, *masking factor* $\tau = 10$, and is trained with regularized adversarial training. HABERTOR - *adv* indicates HABERTOR without regularized adversarial training, and HABERTOR - *adv* + τ=1 indicates HABERTOR without regularized adversarial training and *masking factor* τ of 1 instead of 10. Comparing HABERTOR with HABERTOR - *adv*, we see a drop of AP by 1.16%, F1-score by 1.16%, and the average error rate increases by 0.78% (i.e. average of FPR@5%FNR and FNR@5%FPR). This shows the effectiveness of additional regularized adversarial training to make HABERTOR more robust. Furthermore, comparing HABERTOR - *adv* (with default τ=10) with HABERTOR - *adv* + $\tau = 1$, we observe a drop of AP by 0.92%, F1-score by 0.24%, and an increment of average error rate by 1.01%. This shows the need of both regularized adversarial training with our proposed fine-grained and adaptive noise magnitude, and a large *masking factor* in HABERTOR.

Is pretraining with a larger domain-specific dataset helpful? (AS2): We answer the question by answering a reverse question: does pretraining with smaller data reduce performance? We pre-train HABERTOR with 250k Yahoo comments data (4 times smaller), and 500k Yahoo comments data (2 times smaller). Then, we compare the results of HABERTOR - *adv* + $\tau = 1$ with HABERTOR - *adv* + $\tau = 1$ under 250k data, and HABERTOR - *adv* + $\tau = 1$ under 500k data. Table 7 shows the results. We observe that pretraining with a larger data size increases the hatespeech prediction performance. We see a smaller drop when pretraining with 1M data vs 500k data (AP drops 0.6%), and a bigger drop when pretraining with 500k data vs 250k data (AP drops 4.4%). We reason that when the pretraining data size is too small, important linguistic patterns that may exist in the test set are not fully observed in the training set. In short, pretraining with larger hatespeech data can improve the hatespeech prediction performance. Note that BERT-base is pre-trained on 3,300M words, which are 106 times larger than HABERTOR (only 31M words). Hence, the performance of HABERTOR can be boosted further when pre-training a hate-speech language model with a larger number of hateful representatives.

Usefulness of separated source prediction and ensemble heads (AS3): We compare HABERTOR from *Default* settings to using *single source*

Table 7: Ablation study of HABERTOR on Yahoo dataset (i.e. both Yahoo News + Finance, to save space). Default results are in bold. Better results compared to the default one are underlined.

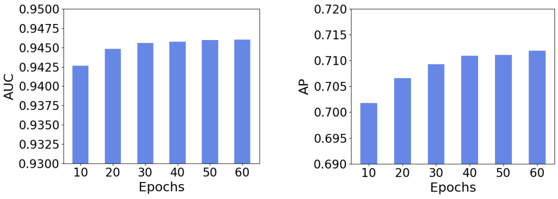
Goal	Model	Yahoo				
		AUC	AP	FPR@ 5%FNR	FNR@ 5%FPR	F1
	Default	**94.77**	**72.35**	**26.11**	**25.08**	**66.18**
AS1	- adv	94.60	71.19	26.97	25.78	65.02
	- adv + $\tau = 1$	94.32	70.27	28.08	26.69	64.78
AS2	- adv + $\tau = 1$ under 250k data	92.61	64.71	36.43	32.51	60.13
	- adv + $\tau = 1$ under 500k data	94.04	69.11	29.82	27.99	63.34
AS3	+ single source + single head	94.70	71.82	26.82	25.55	65.16
	+ single head	94.70	72.15	26.66	25.20	65.59
	+ ensemble 4	94.78	72.18	26.29	24.97	65.78
	+ ensemble 8	94.71	72.06	26.13	25.08	65.56
AS4	- adv + $\tau = 1$ - pretraining	92.48	65.26	36.47	32.10	60.66
AS5	+ 3 layers	94.54	71.25	27.15	25.90	64.98
	+ 4 layers	94.67	71.53	26.25	25.50	65.38
	+ 192 hidden size	94.57	71.00	26.56	25.93	65.05
	+ 3 att heads	94.69	72.00	26.72	25.43	65.75
	+ 4 att heads	94.69	72.06	26.61	25.22	65.80
	+ 12 att heads	94.70	72.01	26.28	25.14	65.64

+ *single source* (i.e. one classification head for all data sources, see Figure 1a), *single head* (i.e. multi-source and each source has a single classification head, see Figure 1b), and using more ensemble heads (i.e. multi-source + more ensemble classification heads, see Figure 1b). Table 7 shows that the overall performance order is *multi-source + ensemble of 2 heads > multi-source + single head > single source + single head*, indicating the usefulness of our multi-source and ensemble of classification heads architecture in the fine-tuning phase. However, when the number of ensemble heads $\geq$ 4, we do not observe better performance.

Is pretraining two language modeling tasks helpful for the hatespeech detection task? (AS4) We compare HABERTOR-*adv* + $\tau = 1$ with HABERTOR-*adv* + $\tau = 1$ - *pretraining*, where we ignore the pretraining step and consider HABERTOR as an attentive network for pure supervised learning with random parameter initialization. In Table 7, the performance of HABERTOR without the language model pretraining is highly downgraded: AUC drops ~-2%, AP drops ~-5%, FPR and FNR errors are ~+9% and ~+5% higher, respectively, and F1 drops -4%. These results show a significant impact of the pretraining tasks for hatespeech detection.

Is HABERTOR sensitive when varying its number of layers, attention heads, and embedding size? (AS5) In Table 7, we observe that HABERTOR+*3 layers* and HABERTOR+*4 layers* work worse than HABERTOR (6 layers), indicating that a deeper model does help to improve hatespeech detection. However, when we increase the number of attention heads from 6 to 12, or decrease the number of attention heads from 6 to 4, we observe that the performance becomes worse. We reason that when we set the number of attention heads to 12, since there is no mechanism to constrain different attention heads to attend on different information, they may end up focusing on the similar things, as shown in (Clark et al., 2019). But when reducing the number of attention heads to 4, the model is not complex enough to attend on more relevant information, leading to worse performance. Similarly, when we reduce the embedding size from 384 in HABERTOR to 192, the performance is worse. Note that we could not perform experiments with larger embedding sizes and/or more number of layers due to high running time and memory consumption. However, we can see in Table 7 performance of smaller HABERTOR with 3 layers, 4 layers, or 192 hidden size still obtain slightly better than BERT-base results reported in Table 3. This again indicates the need for pretraining language models on hatespeech-related corpus for the hatespeech detection task.

Effectiveness of fine-grained pretraining



(a) AUC. (b) AP.

Figure 5: AUC and AP of HABERTOR without regularized adversarial training on Yahoo dataset when varying the number of epochs for the pretraining task.

(AS6)? Since the pretraining phase is unsupervised, a question is how much fine-grained pretraining should we perform to get a good hatespeech prediction performance? Or how many pretraining epochs are good enough? To answer the question, we vary the number of the pretraining epochs from $\{10, 20, 30, ..., 60\}$ before performing the fine-tuning phase with hatespeech classification task. We report the changes in AUC and AP of fine-tuned HABERTOR on the Yahoo dataset without performing regularized adversarial training in Figure 5. We observe that a more fine-grained pretraining helps to increase the hatespeech prediction results, which is similar to a recent finding at Liu et al. (2019), especially from 10 epochs to 40 epochs. However, after 40 epochs, the improvement is smaller.

An Empirical Study on Large-Scale Multi-Label Text Classification Including Few and Zero-Shot Labels

Abstract

Large-scale Multi-label Text Classification (LMTC) has a wide range of Natural Language Processing (NLP) applications and presents interesting challenges. First, not all labels are well represented in the training set, due to the very large label set and the skewed label distributions of LMTC datasets. Also, label hierarchies and differences in human labelling guidelines may affect graph-aware annotation proximity. Finally, the label hierarchies are periodically updated, requiring LMTC models capable of zero-shot generalization. Current state-of-the-art LMTC models employ Label-Wise Attention Networks (LWANs), which (1) typically treat LMTC as flat multi-label classification; (2) may use the label hierarchy to improve zero-shot learning, although this practice is vastly understudied; and (3) have not been combined with pre-trained Transformers (e.g. BERT), which have led to state-of-the-art results in several NLP benchmarks. Here, for the first time, we empirically evaluate a battery of LMTC methods from vanilla LWANs to hierarchical classification approaches and transfer learning, on frequent, few, and zero-shot learning on three datasets from different domains. We show that hierarchical methods based on Probabilistic Label Trees (PLTs) outperform LWANs. Furthermore, we show that Transformer-based approaches outperform the state-of-the-art in two of the datasets, and we propose a new state-of-the-art method which combines BERT with LWAN. Finally, we propose new models that leverage the label hierarchy to improve few and zero-shot learning, considering on each dataset a graph-aware annotation proximity measure that we introduce.

1 Introduction

Large-scale Multi-label Text Classification (LMTC) is the task of assigning a subset of labels from a large predefined set (typically thousands) to a given document. LMTC has a wide range of applications in Natural Language Processing (NLP), such as associating medical records with diagnostic and procedure labels (Mullenbach et al., 2018; Rios and Kavuluru, 2018), legislation with relevant legal concepts (Mencia and Fürnkranzand, 2007; Chalkidis et al., 2019b), and products with categories (Lewis et al., 2004; Partalas et al., 2015).

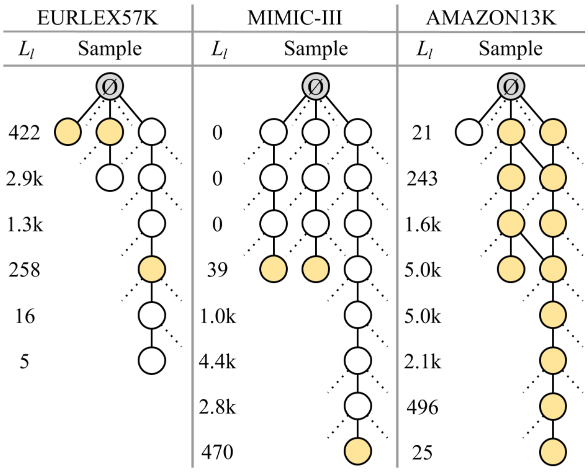

Figure 1: Examples from LMTC label hierarchies. $\emptyset$ is the root label. L_l is the number of labels per level. Yellow nodes denote gold label assignments. In EURLEX57K, documents have been tagged with both leaves and inner nodes (GAP: 0.45). In MIMIC-III, only leaf nodes can be used, causing the label assignments to be much sparser (GAP: 0.27). In AMAZON13K, documents are tagged with leaf nodes, but it is assumed that all the parent nodes are also assigned, leading to dense label assignments (GAP: 0.86).

Apart from the large label space, LMTC datasets often have skewed label distributions (e.g., some labels have few or no training examples) and a label hierarchy with different labelling guidelines (e.g., they may require documents to be tagged only with leaf nodes, or they may allow both leaf and other nodes to be used). The latter affects graph-aware annotation proximity (GAP), i.e., the proximity of the gold labels in the label hierarchy (see Section 4.1). Moreover, the label set and the hierarchies are periodically updated, thus requiring zero- and few-shot learning to cope with

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7503–7515,
November 16–20, 2020. ©2020 Association for Computational Linguistics

newly introduced labels. Figure 1 shows a sample of label hierarchies, with different label assignment guidelines, from three standard LMTC benchmark datasets: EUR-LEX (Chalkidis et al., 2019b), MIMIC-III (Johnson et al., 2017), and AMAZON (McAuley and Leskovec, 2013)).

Current state-of-the-art LMTC models are based on Label-Wise Attention Networks (LWANs) (Mullenbach et al., 2018), which use a different attention head for each label. LWANs (1) typically do not leverage structural information from the label hierarchy, treating LMTC as flat multi-label classification; (2) may use the label hierarchy to improve performance in few/zero-shot scenario, but this practice is vastly understudied; and (3) have not been combined with pre-trained Transformers.

We empirically evaluate, for the first time, a battery of LMTC methods, from vanilla LWANs to hierarchical classification approaches and transfer learning, in frequent, few, and zero-shot learning scenarios. We experiment with three standard LMTC datasets (EURLEX57K; MIMIC-III; AMAZON13K). Our contributions are the following:

- We show that hierarchical LMTC approaches based on Probabilistic Label Trees (PLTs) (Prabhu et al., 2018; Khandagale et al., 2019; You et al., 2019) outperform flat neural state-of-the-art methods, i.e., LWAN (Mullenbach et al., 2018) in two out of three datasets (EURLEX57K, AMAZON13K).
- We demonstrate that pre-trained Transformer-based approaches (e.g., BERT) further improve the results in two of the three datasets (EURLEX57K, AMAZON13K), and we propose a new method that combines BERT with LWAN achieving the best results overall.
- Finally, following the work of Rios and Kavuluru (2018) for few and zero-shot learning on MIMIC-III, we investigate the use of structural information from the label hierarchy in LWAN. We propose new LWAN-based models with improved performance in these settings, taking into account the labelling guidelines of each dataset and a graph-aware annotation proximity (GAP) measure that we introduce.

2 Related Work

2.1 Advances and limitations in LMTC

In LMTC, deep learning achieves state-of-the-art results with LWANs (You et al., 2018; Mullenbach et al., 2018; Chalkidis et al., 2019b), in most cases comparing to naive baselines (e.g., vanilla CNNs or vanilla LSTMs). The computational complexity of LWANs, however, makes it difficult to scale them up to extremely large label sets. Thus, Probabilistic Label Trees (PLTs) (Jasinska et al., 2016; Prabhu et al., 2018; Khandagale et al., 2019) are preferred in Extreme Multi-label Text Classification (XMTC), mainly because the linear classifiers they use at each node of the partition trees can be trained independently considering few labels at each node. This allows PLT-based methods to efficiently handle extremely large label sets (often millions), while also achieving top results in XMTC. Nonetheless, previous work has not thoroughly compared PLT-based methods to neural models in LMTC. In particular, only You et al. (2018) have compared PLT methods to neural models in LMTC, but without adequately tuning their parameters, nor considering few and zero-shot labels. More recently, You et al. (2019) introduced ATTENTION-XML, a new method primarily intended for XMTC, which combines PLTs with LWAN classifiers. Similarly to the rest of PLT-based methods, it has not been evaluated in LMTC.

2.2 The new paradigm of transfer learning

Transfer learning (Ruder et al., 2019; Rogers et al., 2020), which has recently achieved state-of-the-art results in several NLP tasks, has only been considered in legal LMTC by Chalkidis et al. (2019b), who experimented with BERT (Devlin et al., 2019) and ELMO (Peters et al., 2018). Other BERT variants, e.g. ROBERTA (Liu et al., 2019), or BERT-based models have not been explored in LMTC so far.

2.3 Few and zero-shot learning in LMTC

Finally, few and zero-shot learning in LMTC is mostly understudied. Rios and Kavuluru (2018) investigated the effect of encoding the hierarchy in these settings, with promising results. However, they did not consider other confounding factors, such as using deeper neural networks at the same time, or alternative encodings of the hierarchy. Chalkidis et al. (2019b) also considered few and zero-shot learning, but ignoring the label hierarchy.

Our work is the first attempt to systematically compare flat, PLT-based, and hierarchy-aware LMTC methods in frequent, few-, and zero-shot learning, and the first exploration of the effect of transfer learning in LMTC on multiple datasets.

3 Models

3.1 Notation for neural methods

We experiment with neural methods consisting of: (i) a *token encoder* ($\mathcal{E}_w$), which makes token embeddings (w_t) context-aware (h_t); (ii) a *document encoder* ($\mathcal{E}_d$), which turns a document into a single embedding; (iii) an optional *label encoder* ($\mathcal{E}_l$), which turns each label into a label embedding; (iv) a *document decoder* ($\mathcal{D}_d$), which maps the document to label probabilities. Unless otherwise stated, tokens are words, and $\mathcal{E}_w$ is a stacked BIGRU.

3.2 Flat neural methods

BIGRU-LWAN: In this model (Chalkidis et al., 2019b),[1] $\mathcal{E}_d$ uses one attention head per label to generate L document representations d_l:

$$a_{lt} = \frac{\exp(h_t^\top u_l)}{\sum_{t'} \exp(h_{t'}^\top u_l)}, \; d_l = \frac{1}{T} \sum_{t=1}^{T} a_{lt} h_t \quad (1)$$

T is the document length in tokens, h_t the context-aware representation of the t-th token, and u_l a trainable vector used to compute the attention scores of the l-th attention head; u_l can also be viewed as a label representation. Intuitively, each head focuses on possibly different tokens of the document to decide if the corresponding label should be assigned. In this model, $\mathcal{D}_d$ employs L linear layers with sigmoid activations, each operating on a different label-wise document representation d_l, to produce the probability of the corresponding label.

3.3 Hierarchical PLT-based methods

In PLT-based methods, each label is represented as the average of the feature vectors of the training documents that are annotated with this label. The root of the PLT corresponds to the full label set. The label set is partitioned into k subsets using k-means clustering, and each subset is represented by a child node of the root in the PLT. The labels of each new node are then recursively partitioned into k subsets, which become children of that node in the PLT. If the label set of a node has fewer than m labels, the node becomes a leaf and the recursion terminates. During inference, the PLT is traversed top down. At each non-leaf node, a multi-label classifier decides which children nodes (if any) should be visited by considering the feature vector of the document. When a leaf node is visited, the multi-label classifier of that node decides which labels of the node will be assigned to the document.

PARABEL, BONSAI: We experiment with PARABEL (Prabhu et al., 2018) and BONSAI (Khandagale et al., 2019), two state-of-the-art PLT-based methods. PARABEL employs binary PLTs ($k = 2$), while BONSAI uses non-binary PLTs ($k > 2$), which are shallower and wider. In both methods, a linear classifier is used at each node, and documents are represented by TF-IDF feature vectors.

ATTENTION-XML: Recently, You et al. (2019) proposed a hybrid method that aims to leverage the advantages of both PLTs and neural models. Similarly to BONSAI, ATTENTION-XML uses non-binary trees. However, the classifier at each node of the PLT is now an LWAN with a BILSTM token encoder ($\mathcal{E}_w$), instead of a linear classifier operating on TF-IDF document representations.

3.4 Transfer learning based LMTC

BIGRU-LWAN-ELMO: In this model, we use ELMO (Peters et al., 2018) to obtain context-sensitive token embeddings, which we concatenate with the pre-trained word embeddings to obtain the initial token embeddings (w_t) of BIGRU-LWAN. Otherwise, the model is the same as BIGRU-LWAN.

BERT, ROBERTA: Following Devlin et al. (2019), we feed each document to BERT and obtain the top-level representation h_{CLS} of BERT's special CLS token as the (single) document representation. $\mathcal{D}_d$ is now a linear layer with L outputs and sigmoid activations which operates directly on h_{CLS}, producing a probability for each label. The same arrangement applies to ROBERTA (Liu et al., 2019).[2]

BERT-LWAN: Given the large size of the label set in LMTC datasets, we propose a combination of BERT and LWAN. Instead of using h_{CLS} as the document representation and pass it through a linear layer with L outputs (as with BERT and ROBERTA), we pass all the top-level output representations of BERT into a label-wise attention mechanism. The entire model (BERT-LWAN) is jointly trained, also fine-tuning the underlying BERT encoder.

---

[1] The original model was proposed by Mullenbach et al. (2018), with a CNN token encoder ($\mathcal{E}_w$). Chalkidis et al. (2019b) show that BIGRU is a better encoder than CNNs. See also the supplementary material for a detailed comparison.

[2] Unlike BERT, ROBERTA uses dynamic masking, it eliminates the next sentence prediction pre-training task, and uses a larger vocabulary. Liu et al. (2019) reported better results in NLP benchmarks using ROBERTA.

3.5 Zero-shot LMTC

C-BIGRU-LWAN is a zero-shot capable extension of BIGRU-LWAN. It was proposed by Rios and Kavuluru (2018), but with a CNN encoder; instead, we use a BIGRU. In this method, $\mathcal{E}_l$ creates u_l as the *centroid* of the token embeddings of the corresponding label descriptor. The label representations u_l are then used by the attention heads.

$$v_t = \tanh(W h_t + b) \tag{2}$$

$$a_{lt} = \frac{\exp(v_t^\top u_l)}{\sum_{t'} \exp(v_{t'}^\top u_l)}, \quad d_l = \frac{1}{T} \sum_{t=1}^{T} a_{lt} h_t \tag{3}$$

Here h_t are the context-aware embeddings of $\mathcal{E}_w$, a_{lt} is the attention score of the l-th attention head for the t-th document token, viewed as v_t (Eq. 2), d_l is the label-wise document representation for the l-th label. $\mathcal{D}_d$ also relies on the label representations u_l to produce each label probability p_l.

$$p_l = \operatorname{sigmoid}(u_l^\top d_l) \tag{4}$$

The centroid label representations u_l of both encountered (during training) and unseen (zero-shot) labels remain unchanged, because the token embeddings in the centroids are not updated. This keeps the representations of unseen labels close to those of similar labels encountered during training. In turn, this helps the attention mechanism (Eq. 3) and the decoder (Eq. 4) cope with unseen labels that have similar descriptors with encountered labels.

GC-BIGRU-LWAN: This model, originally proposed by Rios and Kavuluru (2018), applies graph convolutions (GCNs) to the label hierarchy.[3] The intuition is that the GCNs will help the representations of rare labels benefit from the (better) representations of more frequent labels that are nearby in the label hierarchy. $\mathcal{E}_l$ now creates graph-aware label representations u_l^3 from the corresponding label descriptors (we omit the bias terms for brevity) as follows:

$$u_l^1 = f\Big(W_s^1 u_l + \sum_{j \in N_{p,l}} \frac{W_p^1 u_j}{|N_{p,l}|} + \sum_{j \in N_{c,l}} \frac{W_c^1 u_j}{|N_{c,l}|}\Big) \tag{5}$$

$$u_l^2 = f\Big(W_s^2 u_l^1 + \sum_{j \in N_{p,l}} \frac{W_p^2 u_j^1}{|N_{p,l}|} + \sum_{j \in N_{c,l}} \frac{W_c^2 u_j^1}{|N_{c,l}|}\Big) \tag{6}$$

$$u_l^3 = [u_l; u_l^2] \tag{7}$$

where u_l is again the centroid of the token embeddings of the descriptor of the l-th label; W_s^i, W_p^i, W_c^i are matrices for self, parent, and children nodes of each label; $N_{p,l}$, $N_{c,l}$ are the sets of parents and children of the the l-th label; and f is the tanh activation. The label-wise document representations d_l are again produced by $\mathcal{E}_d$, as in C-BIGRU-LWAN (Eq. 2–3), but they go through an additional dense layer with tanh activation (Eq. 8). The resulting document representations $d_{l,o}$ and the graph-aware label representations u_l^3 are then used by $\mathcal{D}_d$ to produce a probability p_l for each label (Eq. 9).

$$d_{l,o} = \tanh(W_o d_l + b_o) \tag{8}$$

$$p_l = \operatorname{sigmoid}\left((u_l^3)^\top d_{lo}\right) \tag{9}$$

DC-BIGRU-LWAN: The stack of GCN layers in GC-BIGRU-LWAN (Eq. 5–6) can be turned into a plain two-layer Multi-Layer Perceptron (MLP), unaware of the label hierarchy, by setting $N_{p,l} = N_{c,l} = \emptyset$. We call DC-BIGRU-LWAN the resulting (deeper than C-BIGRU-LWAN) variant of GC-BIGRU-LWAN. We use it as an ablation method to evaluate the impact of the GCN layers on performance.

DN-BIGRU-LWAN: As an alternative approach to exploit the label hierarchy, we used a recent improvement of NODE2VEC (Grover and Leskovec, 2016) by Kotitsas et al. (2019) to obtain alternative hierarchy-aware label representations. NODE2VEC is similar to WORD2VEC (Mikolov et al., 2013), but pre-trains node embeddings instead of word embeddings, replacing WORD2VEC's text windows by random walks on a graph (here the label hierarchy).[4] In a variant of DC-BIGRU-LWAN, dubbed DN-BIGRU-LWAN, we simply replace the initial centroid u_l label representations of DC-BIGRU-LWAN in Eq. 5 and 7 by the label representations g_l generated by the NODE2VEC extension.

DNC-BIGRU-LWAN: In another version of DC-BIGRU-LWAN, called DNC-BIGRU-LWAN, we replace the initial centroid u_l label representations of DC-BIGRU-LWAN by the concatenation $[u_l; g_l]$.

GNC-BIGRU-LWAN: Similarly, we expand GC-BIGRU-LWAN with the hierarchy-aware label representations of the NODE2VEC extension. Again, we replace the centroid u_l label representations of GC-BIGRU-LWAN in Eq. 5 and 7 by the label representations g_l of the NODE2VEC extension. The resulting

---

[3] The original model uses a CNN token encoder ($\mathcal{E}_w$), whereas we use a BIGRU encoder, which is a better encoder. See the supplementary material for a detailed comparison.

[4] The NODE2VEC extension we used also considers the textual descriptors of the nodes, using an RNN encoder operating on token embeddings.

model, GNC-BIGRU-LWAN, uses both NODE2VEC and the GCN layers to encode the label hierarchy, thus obtaining knowledge from the label hierarchy both in a self-supervised and a supervised fashion.

4 Experimental Setup

4.1 Graph-aware Annotation Proximity

In this work, we introduce *graph-aware label proximity* (GAP), a measure of the topological proximity (on the label hierarchy) of the gold labels assigned to documents. GAP turns out to be a key factor in the performance of hierarchy-aware zero-shot capable extensions of BIGRU-LWAN. Let $G(L, E)$ be the graph of the label hierarchy, where L is the set of nodes (label set) and E the set of edges. Let $L_d \subseteq L$ be the set of gold labels a particular document d is annotated with. Finally, let $G_d^+(L_d^+, E_d^+)$ be the minimal (in terms of $|L_d^+|$) subgraph of $G(L, E)$, with $L_d \subseteq L_d^+ \subseteq L$ and $E_d^+ \subseteq E$, such that for any two nodes (gold labels) $l_1, l_2 \in L_d$, the shortest path between l_1, l_2 in the full graph $G(L, E)$ is also a path in $G_d^+(L_d^+, E_d^+)$. Intuitively, we extend L_d to L_d^+ by including additional labels that lie between any two assigned labels l_1, l_2 on the shortest path that connects l_1, l_2 in the full graph. We then define $\text{GAP}_d = \frac{|L_d|}{|L_d^+|}$. By averaging GAP_d over all the documents d of a dataset, we obtain a single GAP score per dataset (Fig. 1). When the assigned (gold) labels of the documents are frequently neighbours in the full graph (label hierarchy), we need to add fewer labels when expanding the L_d of each document to L_d^+; hence, GAP $\rightarrow 1$. When the assigned (gold) labels are frequently remote to each other, we need to add more labels ($|L_d^+| \gg |L_d|$) and GAP $\rightarrow 0$.

GAP should not be confused with *label density* (Tsoumakas and Katakis, 2009), defined as $\text{D} = \frac{1}{N}\sum_{d=1}^{N}\frac{|L_d|}{|L|}$, where N is the total number of documents. Although label density is often used in the multi-label classification literature, it is graph-unaware, i.e., it does not consider the positions (and distances) of the assigned labels in the graph.

4.2 Data

EURLEX57K (Chalkidis et al., 2019b) contains 57k English legislative documents from EUR-LEX.[5] Each document is annotated with one or more concepts (labels) from the 4,271 concepts of EUROVOC.[6] The average document length is approx. 727 words. The labels are divided in *frequent* (746 labels), *few-shot* (3,362), and *zero-shot* (163), depending on whether they were assigned to $n > 50$, $1 < n \leq 50$, or no training documents. They are organized in a 6-level hierarchy, which was not considered in the experiments of Chalkidis et al. (2019b). The documents are labeled with concepts from all levels (Fig. 1), but in practice if a label is assigned, none of its ancestor or descendent labels are assigned. The resulting GAP is 0.45.

MIMIC-III (Johnson et al., 2017) contains approx. 52k English discharge summaries from US hospitals. The average document length is approx. 1.6k words. Each summary has one or more codes (labels) from 8,771 leaves of the ICD-9 hierarchy, which has 8 levels (Fig. 1).[7] Labels are divided in *frequent* (4,112 labels), *few-shot* (4,216 labels), and *zero-shot* (443 labels), depending on whether they were assigned to $n > 5$, $1 < n \leq 5$, or no training documents. All discharge summaries are annotated with leaf nodes (5-digit codes) only, i.e., the most fine-grained categories (Fig. 1), causing the label assignments to be much sparser compared to EURLEX57K (GAP 0.27).

AMAZON13K (Lewis et al., 2004) contains approx. 1.5M English product descriptions from Amazon. Each product is represented by a title and a description, which are on average 250 words when concatenated. Products are classified into one or more categories (labels) from a set of approx. 14k. Labels are divided in *frequent* (3,108 labels), *few-shot* (10,581 labels), *zero-shot* (579 labels), depending on whether they were assigned to $n > 100$, $1 < n \leq 100$, or no training documents. The labels are organized in a hierarchy of 8 levels. If a product is annotated with a label, all of its ancestor labels are also assigned to the product (Fig. 1), leading to dense label assignments (GAP 0.86).

4.3 Evaluation Measures

The most common evaluation measures in LMTC are label precision and recall at the top K predicted labels ($P@K$, $R@K$) of each document, and $nDCG@K$ (Manning et al., 2009), both averaged over test documents. However, $P@K$ and $R@K$ unfairly penalize methods when the gold labels of a document are fewer or more than K, respectively. R-Precision@K ($RP@K$) (Chalkidis et al., 2019b), a top-K version of R-Precision (Manning et al.,

Table 1: Results (%) of experiments across base methods for all, frequent, and few label groups. All base methods are incapable of zero-shot learning. The best overall results are shown in bold. The best results in each zone are shown underlined. We show results for K close to the average number of labels L_{AVG}.

2009), is better; it is the same as *P@K* if there are at least *K* gold labels, otherwise *K* is reduced to the number of gold labels. When the order of the top-*K* labels is unimportant (e.g., for small *K*), *RP@K* is more appropriate than *nDCG@K*.

4.4 Implementation Details

We implemented neural methods in TENSORFLOW 2, also relying on the HuggingFace Transformers library for BERT-based models.[8] We use the BASE versions of all models, and the Adam optimizer (Kingma and Ba, 2015). All hyper-parameters were tuned selecting values with the best loss on the development data.[9] For all PLT-based methods, we used the code provided by their authors.[10]

5 Results

5.1 Overall predictive performance

PLTs vs. LWANs: Interestingly, the TF-IDF-based PARABEL and BONSAI outperform the best previously published neural LWAN-based models on EURLEX57K and AMAZON13K, while being comparable to ATTENTION-XML, when all or frequent

---

labels are considered (Table 1). This is not the case with MIMIC-III, where BIGRU-LWAN and ATTENTION-XML have far better results for all and frequent labels. The poor performance of the two TF-IDF-based PLT-based methods on MIMIC-III seems to be due to the fact that their TF-IDF features ignore word order and are not contextualized, which is particularly important in this dataset. To confirm this, we repeated the experiments of BIGRU-LWAN on MIMIC-III after shuffling the words of the documents, and performance dropped by approx. 7.7% across all measures, matching the performance of PLT-based methods.[11] The dominance of ATTENTION-XML in MIMIC-III further supports our intuition that word order is particularly important in this dataset, as the core difference of ATTENTION-XML with the rest of the PLT-based methods is the use of RNN-based classifiers that use word embeddings and are sensitive to word order, instead of linear classifiers with TF-IDF features, which do not capture word order. Meanwhile, in both EURLEX57K and AMAZON13K, the performance of ATTENTION-XML is competitive with both TF-IDF-based PLT-based methods and BIGRU-LWAN, suggesting that the bag-of-words assumption holds in these cases. Thus, we can fairly assume that word order and global context (long-term dependencies) do not play a drastic role when predicting labels (concepts) on these datasets.

Effects of transfer learning: Adding context-aware ELMO embeddings to BIGRU-LWAN (BIGRU-LWAN-ELMO) improves performance across all datasets by a small margin, when considering all or frequent labels. For EURLEX57K and AMAZON13K, larger performance gains are obtained by fine-tuning BERT-BASE and ROBERTA-BASE. Our proposed new method (BERT-BASE-LWAN) that employs LWAN on top of BERT-BASE has the best results among all methods on EURLEX57K and AMAZON13K, when all and frequent labels are considered. However, in both datasets, the results are comparable to BERT-BASE, indicating that the multi-head attention mechanism of BERT can effectively handle the large number of labels.

Method	$\hat{\mathrm{T}}$	$\hat{\mathrm{F}}$	$nDCG@15$
ATTENTION-XML (You et al., 2019)	full-text	-	**73.4**
BERT-BASE (Devlin et al., 2019)	512	1.51	58.1
ROBERTA-BASE (Liu et al., 2019)	512	1.45	58.9
CLINICAL-BERT (Alsentzer et al., 2019)	512	1.60	58.6
SCI-BERT (Beltagy et al., 2019)	512	1.35	60.5
HIER-SCI-BERT (new)	4096	1.35	61.9

Table 2: Performance of BERT and its variants compared to ATTENTION-XML on MIMIC-III. $\hat{\mathrm{T}}$ is the maximum number of (possibly sub-word) tokens used per document. $\hat{\mathrm{F}}$ is the fragmentation ratio, i.e., the number of tokens (BPEs or wordpieces) per word.

Poor performance of BERT on MIMIC-III: Quite surprisingly, all three BERT-based models perform poorly on MIMIC-III (Table 1), so we examined two possible reasons. First, we hypothesized that this poor performance is due to the distinctive writing style and terminology of biomedical documents, which are not well represented in the generic corpora these models are pre-trained on. To check this hypothesis, we employed CLINICAL-BERT (Alsentzer et al., 2019), a version of BERT-BASE that has been further fine-tuned on biomedical documents, including discharge summaries. Table 2 shows that CLINICAL-BERT performs slightly better than BERT-BASE on the biomedical dataset, partly confirming our hypothesis. The improvement, however, is small and CLINICAL-BERT still performs worse than ROBERTA-BASE, which is pre-trained on larger generic corpora with a larger vocabulary. Examining the token vocabularies (Gage, 1994) of the BERT-based models reveals that biomedical terms are frequently over-fragmented; e.g., 'pneumonothorax' becomes ['p', '##ne', '##um', '##ono', '##th', '##orax'], and 'schizophreniform becomes ['s', '##chi', '##zo', '##ph', '##ren', '##iform']. This is also the case with CLINICAL-BERT, where the original vocabulary of BERT-BASE was retained. We suspect that such long sequences of meaningless sub-words are difficult to re-assemble into meaningful units, even when using deep pre-trained Transformer-based models. Thus we also report the performance of SCI-BERT (Beltagy et al., 2019), which was pre-trained from scratch (including building the vocabulary) on scientific articles, mostly from the biomedical domain. Indeed SCI-BERT performs better, but still much worse than ATTENTION-XML.

A second possible reason for the poor performance of BERT-based models on MIMIC-III is that they can process texts only up to 512 tokens long, truncating longer documents. This is not a problem in EURLEX57K, because the first 512 tokens contain enough information to classify EURLEX57K documents (727 words on average), as shown by Chalkidis et al. (2019b). It is also not a problem in AMAZON13K, where texts are short (250 words on average). In MIMIC-III, however, the average document length is approx. 1.6k words and documents

---

[11] By contrast, the drop was less significant in the other datasets (4.5% in EURLEX57K and 2.8% in AMAZON13K).

	EURLEX57K ($K = 5$)		MIMIC-III ($K = 15$)		AMAZON13K ($K = 5$)	
	FEW ($n < 50$)	ZERO	FEW ($n < 5$)	ZERO	FEW ($n < 100$)	ZERO
BIGRU-LWAN (Chalkidis et al., 2019b)	61.7	-	14.3	-	**73.6**	-
C-BIGRU-LWAN (Rios and Kavuluru, 2018)	51.0	33.5	15.0	31.5	9.9	20.8

GNC-BIGRU-LWAN (new)	**62.6**	36.3	18.4	34.2	45.3	**51.9**

Table 3: Results (%) of experiments performed with zero-shot capable extensions of BIGRU-LWAN. All scores are *nDCG@K*, with the same *K* values as in Table 1. Best results shown in bold. Best results in each zone shown underlined. n is the number of training documents assigned with a label. Similar conclusions can be drawn when evaluating with *RP@K* (See the appendix).

are severely truncated.[12] To check the effect of text truncation, we employed a hierarchical version of SCI-BERT, dubbed HIER-SCI-BERT, similar to the hierarchical BERT of Chalkidis et al. (2019a).[13] This model encodes consecutive segments of text (each up to 512 tokens) using a shared SCI-BERT encoder, then applies max-pooling over the segment encodings to produce a final document representation. HIER-SCI-BERT outperforms SCI-BERT, confirming that truncation is an important issue, but it still performs worse than ATTENTION-XML. We believe that a hierarchical BERT model pre-trained from scratch on biomedical corpora, especially discharge summaries, with a new BPE vocabulary, may perform even better in future experiments.

5.2 Zero-shot Learning

In Table 1 we intentionally omitted zero-shot labels, as the methods discussed so far, except GC-BIGRU-LWAN, are incapable of zero-shot learning. In general, any model that relies solely on trainable vectors to represent labels cannot cope with unseen labels, as it eventually learns to ignore unseen labels, i.e., it assigns them near-zero probabilities. In this section, we discuss the results of the zero-shot capable extensions of BIGRU-LWAN (Section 3.5).

In line with the experiments of Rios and Kavuluru (2018), Table 3 shows that GC-BIGRU-LWAN (with GCNs) performs better than C-BIGRU-LWAN in zero-shot labels on all three datasets. These two zero-shot capable extensions of BIGRU-LWAN also obtain better few-shot results on MIMIC-III comparing to BIGRU-LWAN; GC-BIGRU-LWAN is also comparable to BIGRU-LWAN in few-shot learning on EURLEX57K, but BIGRU-LWAN is much better than its two zero-shot extensions on AMAZON13K. The superior performance of BIGRU-LWAN on EURLEX57K and AMAZON13K, compared to MIMIC-III, is due to the fact that in the first two datasets few-shot labels are more frequent ($n \leq 50$, and $n \leq 100$, respectively) than in MIMIC-III ($n \leq 5$).

Are graph convolutions a key factor? It is unclear if the gains of GC-BIGRU-LWAN are due to the GCN encoder of the label hierarchy, or the increased depth of GC-BIGRU-LWAN compared to C-BIGRU-LWAN. Table 3 shows that DC-BIGRU-LWAN is competitive to GC-BIGRU-LWAN, indicating that the latter benefits mostly from its increased depth, and to a smaller extent from its awareness of the label hierarchy. This motivated us to search for alternative ways to exploit the label hierarchy.

Alternatives in exploiting label hierarchy: Table 3 shows that DN-BIGRU-LWAN, which replaces the centroids of token embeddings of the label descriptors of DC-BIGRU-LWAN with label embeddings produced by the NODE2VEC extension, is actually inferior to DC-BIGRU-LWAN. In turn, this suggests that although the NODE2VEC extension we employed aims to encode both topological information from the hierarchy and information from the label descriptors, the centroids of word embeddings still capture information from the label descriptors that the NODE2VEC extension misses. This also indicates that exploiting the information from the label descriptors is probably more important than the topological information of the label hierarchy for few and zero-shot learning generalization.

DNC-BIGRU-LWAN, which combines the centroids with the label embeddings of the NODE2VEC extension, is comparable to DC-BIGRU-LWAN, while being better overall in few-shot labels. Combining the GCN encoder and the NODE2VEC extension (GNC-BIGRU-LWAN) leads to a large im-

---

[12] In BPEs, the average document length is approx. 2.1k, as many biomedical terms are over-fragmented, thus only the 1/4 of the document actually fit in practice in BERT-based models.

[13] This model is 'hierarchical' in the sense that a first layer encodes paragraphs, then another layer combines the representations of paragraphs (Yang et al., 2016). It does not use the label hierarchy.

provement in zero-shot labels (46.1% to 51.9% *nDCG@K*) on AMAZON13K. On EURLEX57K, however, the original GC-BIGRU-LWAN still has the best zero-shot results; and on MIMIC-III, the best zero-shot results are obtained by the hierarchy-unaware DC-BIGRU-LWAN. These mixed findings seem related to the GAP of each dataset (Fig. 1).

The role of graph-aware annotation proximity: When gold label assignments are dense, neighbouring labels co-occur more frequently, thus models can leverage topological information and learn how to better cope with neighbouring labels, which is what both GCNs and NODE2VEC do. The denser the gold label assignments, the more we can rely on more distant neighbours, and the better it becomes to include graph embedding methods that conflate larger neighbourhoods, like NODE2VEC (included in GNC-BIGRU-LWAN) on AMAZON13K (GAP 0.86), when predicting unseen labels.

For medium proximity gold label assignments, as in EURLEX57K (GAP 0.45), it seems preferable to rely on closer neighbours only; hence, it is better to use only graph encoders that conflate smaller neighbourhoods, like the GCNs which apply convolution filters to neighbours up to two hops away, as in GC-BIGRU-LWAN (excl. NODE2VEC extension).

When label assignments are sparse, as in MIMIC-III (GAP 0.27), where only non-neighbouring leaf labels are assigned in the same document, leveraging the topological information (e.g., knowing that a rare label shares an ancestor with a frequent one) is not always helpful, which is why encoding the label hierarchy shows no advantage in zero-shot learning in MIMIC-III; however, it can still be useful when we at least have few training instances, as the few-shot results of MIMIC-III indicate.

Overall, we conclude that the GCN label hierarchy encoder does not always improve LWANs in zero-shot learning, compared to equally deep LWANs, and that depending on the proximity of label assignments (based on the label annotation guidelines) it may be preferable to use additional or no hierarchy-aware encodings for zero-shot learning.

6 Conclusions

We presented an extensive study of LMTC methods in three domains, to answer three understudied questions on (1) the competitiveness of PLT-based methods against neural models, (2) the use of the label hierarchy, (3) the benefits from transfer learning. A condensed summary of our findings is that (1) TF-IDF PLT-based methods are definitely worth considering, but are not always competitive, while ATTENTION-XML, a neural PLT-based method that captures word order, is robust across datasets; (2) transfer learning leads to state-of-the-art results in general, but BERT-based models can fail spectacularly when documents are long and technical terms get over-fragmented; (3) the best way to use the label hierarchy in neural methods depends on the proximity of the label assignments in each dataset. An even shorter summary is that no single method is best across all domains and label groups (all, few, zero) as the language, the size of documents, and the label assignment strongly vary with direct implications in the performance of each method.

In future work, we would like to further investigate few and zero-shot learning in LMTC, especially in BERT models that are currently unable to cope with zero-shot labels. It is also important to shed more light on the poor performance of BERT models in MIMIC-III and propose alternatives that can cope both with long documents (Kitaev et al., 2020; Beltagy et al., 2020) and domain-specific terminology, reducing word over-fragmentation. Pretraining BERT from scratch on discharge summaries with a new BPE vocabulary is a possible solution. Finally, we would like to combine PLTs with BERT, similarly to ATTENTION-XML, but the computational cost of fine-tuning multiple BERT encoders, one for each PLT node, would be massive, surpassing the training cost of very large Transformer-based models, like T5-3B (Raffel et al., 2019) and MEGATRON-LM (Shoeybi et al., 2019) with billions of parameters (30-100x the size of BERT-BASE).

A Additional Implementation Details

All experiments were run in NVIDIA GT1080TI GPU cards, in a single GPU fashion. In Table 6, we report the size of the models and the elapsed training time. Hyper-parameters were tuned using HYPEROPT,[14] selecting values with the best loss on development data. Table 4 shows the hyper-parameters search space and the selected values. We use 200-D pretrained GLOVE embeddings (Pennington et al., 2014) for EURLEX57K and AMAZON13K, and 200-D WORD2VEC embeddings pretrained on PUBMED[15] (McDonald et al., 2018) for MIMIC-III. For BERT-based methods we tuned only the learning rate, considering the values $\{2e\text{-}5, 3e\text{-}5, 5e\text{-}5\}$, selecting $2e$-5 for EURLEX57K and AMAZON13K, and $5e$-5 for MIMIC-III. Finally, for PARABEL and BONSAI we tuned the n-gram order in the range $\{1, 2, 3, 4, 5\}$, and the number of n-gram features in the range {100k, 200k, 300k, 400k}. When $n > 1$ we use n-grams up to order n, e.g. for $n = 3$ we use 1-grams, 2-grams and 3-grams. In all datasets the optimal values were 200k features for $n = 5$.

B BIGRUs vs. CNNs

Chalkidis et al. (2019b) showed that BIGRUs are better encoders than CNNs in EURLEX57K. We confirm these findings across all datasets (Table 5). BIGRU-LWAN, C-BIGRU-LWAN and GC-BIGRU-LWAN outperform CNN-LWAN, C-CNN-LWAN and GC-CNN-LWAN by 3.5 to 16.5 percentage points.

C Additional Results

Table 7 shows *RP@K* results of the zero-shot capable methods. As with *nDCG@K*, we conclude that the GCN label hierarchy encoder of Rios and Kavuluru (2018) does not always improve LWANs in zero-shot learning, compared to equally deep LWANs, and that depending on the proximity of label assignments, it may be preferable to use additional or no encodings of the hierarchy for zero-shot learning. Also, the zero-shot capable methods outperform BIGRU-LWAN in all, frequent, and few labels, but no method is consistently the best.

Which *BERT? A Survey Organizing Contextualized Encoders

Patrick Xia **Shijie Wu** **Benjamin Van Durme**
Johns Hopkins University
`{paxia, vandurme}@cs.jhu.edu, shijie.wu@jhu.edu`

Abstract

Pretrained contextualized text encoders are now a staple of the NLP community. We present a survey on language representation learning with the aim of consolidating a series of shared lessons learned across a variety of recent efforts. While significant advancements continue at a rapid pace, we find that enough has now been discovered, in different directions, that we can begin to organize advances according to common themes. Through this organization, we highlight important considerations when interpreting recent contributions and choosing which model to use.

1 Introduction

A couple years ago, Peters et al. (2018, ELMo) won the NAACL Best Paper Award for creating strong performing, task-agnostic sentence representations due to large scale unsupervised pretraining. Days later, its high level of performance was surpassed by Radford et al. (2018) which boasted representations beyond a single sentence and finetuning flexibility. This instability and competition between models has been a recurring theme for researchers and practitioners who have watched the rapidly narrowing gap between text representations and language understanding benchmarks. However, it has not discouraged research. Given the recent flurry of models, we often ask: "**What, besides state-of-the-art, does this newest paper contribute? Which encoder should *we* use?**"

The goals of this survey are to outline the areas of progress, relate contributions in text encoders to ideas from other fields, describe how each area is evaluated, and present considerations for practitioners and researchers when choosing an encoder. This survey does not intend to compare specific model metrics, as tables from other works provide comprehensive insight. For example, Table 16 in Raffel et al. (2019) compares the scores on a large suite of tasks of different model architectures, training objectives, and hyperparameters, and Table 1 in Rogers et al. (2020) details early efforts in model compression and distillation. We also recommend other closely related surveys on contextualized word representations (Smith, 2019; Rogers et al., 2020; Liu et al., 2020a), transfer learning in NLP (Ruder et al., 2019), and integrating encoders into NLP applications (Wolf et al., 2019). Complementing these existing bodies of work, we look at the ideas and progress in the scientific discourse for text representations from the perspective of discerning their differences.

We organize this paper as follows. §2 provides brief background on encoding, training, and evaluating text representations. §3 identifies and analyzes two classes of pretraining objectives. In §4, we explore faster and smaller models and architectures in both training and inference. §5 notes the impact of both quality and quantity of pretraining data. §6 briefly discusses efforts on probing encoders and representations with respect to linguistic knowledge. §7 describes the efforts into training and evaluating multilingual representations. Within each area, we conclude with high-level observations and discuss the evaluations that are used and their shortcomings.

We conclude in §8 by making recommendations to researchers: publicizing negative results in this area is especially important owing to the sheer cost of experimentation and to ensure evaluation reproducibility. In addition, probing studies need to focus not only on the models and tasks, but also on the pretraining data. We pose questions for users of contextualized encoders, like whether the compute requirement of a model is worth the benefits. We hope our survey serves as a guide for both NLP researchers and practitioners, orienting them to the current state of the field of contextualized encoders and differences between models.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7516–7533,
November 16–20, 2020.

2 Background

Encoders Pretrained *text encoders* take as input a sequence of tokenized[1] text, which is encoded by a multi-layered neural model. The representation of each (sub)token, x_t, is either the set of hidden weights, $\{h_t^{(l)}\}$ for each layer l, or its weight on just the top layer, $h_t^{(-1)}$. Unlike fixed-sized word, sentence, or paragraph representations, the produced *contextualized representations* of the text depends on the length of the input text. Most encoders use the Transformer architecture (Vaswani et al., 2017).

Transfer: The Pretrain-Finetune Framework While text representations can be learned in any manner, ultimately, they are evaluated using specific *target tasks*. Historically, the learned representations (e.g. word vectors) were used as initialization for task-specific models. Dai and Le (2015) are credited with using *pretrained* language model outputs as initialization, McCann et al. (2017) use pretrained outputs from translation as frozen word embeddings, and Howard and Ruder (2018) and Radford et al. (2018) demonstrate the effectiveness of *finetuning* to different target tasks by updating the full (pretrained) model for each task. We refer to the embeddings produced by the pretrained models (or encoders) as contextualized text representations. As our goal is to discuss the encoders and their representations, we do not cover the innovations in finetuning (Liu et al., 2015; Ruder et al., 2019; Phang et al., 2018; Liu et al., 2019c; Zhu et al., 2020, *inter alia*).

Evaluation Widely adopted evaluations of text representations relate them to downstream natural language understanding (NLU) benchmarks. This full-stack process necessarily conflates representation power with finetuning strategies. Common language understanding benchmarks include (1) a diverse suite of sentence-level tasks covering paraphrasing, natural language inference, sentiment, and linguistic acceptability (GLUE) and its more challenging counterpart with additional commonsense and linguistic reasoning tasks (SuperGLUE) (Wang et al., 2019c,b; Clark et al., 2019a; De Marneffe et al., 2019; Roemmele et al., 2011; Khashabi et al., 2018; Zhang et al., 2018; Dagan et al., 2006; Bar Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009; Pilehvar and Camacho-Collados, 2019; Rudinger et al., 2018; Poliak et al., 2018; Levesque et al., 2011); (2) crowdsourced questions derived from Wikipedia articles (Rajpurkar et al., 2016, 2018, SQuAD); and (3) multiple-choice reading comprehension (Lai et al., 2017, RACE).

3 Area I: Pretraining Tasks

To utilize data at scale, pretraining tasks are typically self-supervised. We categorize the contributions into two types: *token prediction* (over a large vocabulary space) and *nontoken prediction* (over a handful of labels). In this section, we discuss several empirical observations. While token prediction is clearly important, less clear is which variation of the token prediction task is the best (or whether it even matters). Nontoken prediction tasks appear to offer orthogonal contributions that marginally improve the language representations. We emphasize that in this section, we seek to outline the primary efforts in pretraining objectives and not to provide a comparison on a set of benchmarks.[2]

3.1 Token Prediction

Predicting (or generating) the next word has historically been equivalent to the task of language modeling. Large language models perform impressively on a variety of language understanding tasks while maintaining their generative capabilities (Radford et al., 2018, 2019; Keskar et al., 2019; Brown et al., 2020), often outperforming contemporaneous models that use additional training objectives.

ELMo (Peters et al., 2018) is a BiLSTM model with a language modeling objective for the next (or previous) token given the forward (or backward) history. This idea of looking at the full context was further refined as a cloze[3] task (Baevski et al., 2019), or as a denoising Masked Language Modeling (MLM) objective (Devlin et al., 2019, BERT). MLM replaces some tokens with a `[mask]` symbol and provides both right and left contexts (bidirectional context) for predicting the masked tokens. The bidirectionality is key to outperforming a unidirectional language model on a large suite of natural language understanding benchmarks (Devlin et al., 2019; Raffel et al., 2019).

The MLM objective is far from perfect, as the use of `[mask]` introduces a pretrain/finetune vo-

---

[1] Unlike traditional word-level tokenization, most works decompose text into *subtokens* from a fixed vocabulary using some variation of byte pair encoding (Gage, 1994; Schuster and Nakajima, 2012; Sennrich et al., 2016)

[2] See Raffel et al. (2019) for comprehensive experiments.

[3] A cloze task is a fill-in-the-blank task.

cabulary discrepancy. Devlin et al. (2019) look to mitigate this issue by occasionally replacing `[mask]` with the original token or sampling from the vocabulary. Yang et al. (2019) convert the discriminative objective into an autoregressive one, which allows the `[mask]` token to be discarded entirely. Naively, this would result in unidirectional context. By sampling permutations of the factorization order of the joint probability of the sequence, they preserve bidirectional context. Similar ideas for permutation language modeling (PLM) have also been studied for sequence generation (Stern et al., 2019; Chan et al., 2019; Gu et al., 2019). The MLM and PLM objectives have since been unified architecturally (Song et al., 2020; Bao et al., 2020) and mathematically (Kong et al., 2020).

ELECTRA (Clark et al., 2020) replaces `[mask]` through the use of a small generator (trained with MLM) to sample a real token from the vocabulary. The main encoder, a discriminator, then determines whether each token was replaced.

A natural extension would mask units that are more linguistically meaningful, such as rarer words,[4] whole words, or named entities (Devlin et al., 2019; Sun et al., 2019b). This idea can be simplified to *random* spans of texts (Yang et al., 2019; Song et al., 2019). Specifically, Joshi et al. (2020) add a reconstruction objective which predicts the masked tokens using only the span boundaries. They find that masking random spans is more effective than masking linguistic units.

An alternative architecture uses an encoder-decoder framework (or denoising autoencoder) where the input is a corrupted (masked) sequence the output is the full original sequence (Wang et al., 2019d; Lewis et al., 2020; Raffel et al., 2019).

3.2 Nontoken Prediction

Bender and Koller (2020) argue that for the goal of natural language understanding, we cannot rely purely on a language modeling objective; there must be some grounding or external information that relates the text to each other or to the world. One solution is to introduce a secondary objective to directly learn these biases.

Self-supervised discourse structure objectives, such as text order, has garnered significant attention. To capture relationships between two *sentences*,[5] Devlin et al. (2019) introduce the next sentence prediction (NSP) objective. In this task, either sentence `B` follows sentence `A` or `B` is a random negative sample. Subsequent works showed that this was not effective, suggesting the model simply learned topic (Yang et al., 2019; Liu et al., 2019d). Jernite et al. (2017) propose a sentence order task of predicting whether `A` is before, after, or unrelated to `B`, and Wang et al. (2020b) and Lan et al. (2020) use it for pretraining encoders. They report that (1) understanding text order does contribute to improved language understanding; and (2) harder-to-learn pretraining objectives are more powerful, as both modified tasks have lower intrinsic performance than NSP. It is still unclear, however, if this is the best way to incorporate discourse structure, especially since these works do not use real sentences.

Additional work has focused on effectively incorporating multiple pretraining objectives. Sun et al. (2020a) use multi-task learning with *continual pretraining* (Hashimoto et al., 2017), which incrementally introduces newer tasks into the set of pretraining tasks from word to sentence to document level tasks. Encoders using visual features (and evaluated only on visual tasks) jointly optimize multiple different masking objectives over both token sequences and regions of interests in the image (Tan and Bansal, 2019).[6]

Prior to token prediction, discourse information has been used in training sentence representations. Conneau et al. (2017, 2018a) use natural language inference sentence pairs, Jernite et al. (2017) use discourse-based objectives of sentence order, conjunction classifier, and next sentence selection, and Nie et al. (2019) use discourse markers. While there is weak evidence suggesting that these types of objectives are less effective than language modeling (Wang et al., 2019a), we lack fair studies comparing the relative influence between the two categories of objectives.

3.3 Comments on Evaluation

We reviewed the progress on pretraining tasks, finding that token prediction is powerful but can be improved further by other objectives. Currently, successful techniques like span masking or arbitrarily sized "sentences" are linguistically unmotivated. We anticipate future work to further incorporate

---

[4] Clark et al. (2020) report negative results for rarer words.

[5] *Sentence* unfortunately refers to a text segment containing no more than a fixed number of subtokens. It may contain any (fractional) number of real sentences.

[6] Table 5 in Su et al. (2020) provides a recent summary of efforts in visual-linguistic representations.

more meaningful linguistic biases in pretraining.

Our observations are informed by evaluations that are compared across different works. **These benchmarks on downstream tasks do not account for ensembling or finetuning and can only serve as an approximation for the differences between the models.** For example, Jiang et al. (2020) develop a finetuning method over a supposedly weaker model which leads to gains in GLUE score over reportedly stronger models. Furthermore, these evaluations aggregate vastly different tasks. Those interested in the best performance should first carefully investigate metrics on their specific task. Even if models are finetuned on an older encoder,[7] it may be more cost-efficient and enable fairer future comparisons to reuse those over restarting the finetuning or reintegrating new encoders into existing models when doing so does not necessarily guarantee improved performance.

4 Area II: Efficiency

As models perform better but cost more to train, some have called for research into efficient models to improve deployability, accessibility, and reproducibility (Amodei and Hernandez, 2018; Strubell et al., 2019; Schwartz et al., 2019). Encoders tend to scale effectively (Lan et al., 2020; Raffel et al., 2019; Brown et al., 2020), so efficient models will also result in improvements over inefficient ones of the same size. In this section, we give an overview of several efforts aimed to decrease the computation budget (time and memory usage) during training and inference of text encoders. While these two axes are correlated, reductions in one axis do not always lead to reductions in the other.

4.1 Training

One area of research decreases wall-clock training time through more compute and larger batches. You et al. (2020) reduce the time of training BERT by introducing the LAMB optimizer, a large batch stochastic optimization method adjusted for attention models. Rajbhandari et al. (2020) analyze memory usage in the optimizer to enable parallelization of models resulting in higher throughput in training. By reducing the training time, models can be practically trained for longer, which has also been shown to lead to benefits in task performance (Liu et al., 2019d; Lan et al., 2020, *inter alia*).

Another line of research reduces the compute through attention sparsification (discussed in §4.2) or increasing the convergence rate (Clark et al., 2020). These works report hardware and estimate the reduction in floating point operations (FPOs).[8] These kinds of speedup are orthogonal to hardware parallelization and are most encouraging as they pave the path for future work in *efficient* training.

Note that these approaches do not necessarily affect the latency to process a single example nor the compute required during inference, which is a function of the size of the computation graph.

4.2 Inference

Reducing model size without impacting performance is motivated by lower inference latency, hardware memory constraints, and the promise that naively scaling up dimensions of the model will improve performance. Size reduction techniques produce smaller and faster models, while occasionally improving performance. Rogers et al. (2020) survey BERT-like models and present in Table 1 the differences in sizes and performance across several models focused on inference efficiency.

Architectural changes have been explored as one avenue for reducing either the model size or inference time. In Transformers, the self-attention pattern scales quadratically in sequence length. To reduce the asymptotic complexity, the self-attention can be sparsified: each token only attending to a small "local" set (Vaswani et al., 2017; Child et al., 2019; Sukhbaatar et al., 2019). This has further been applied to pretraining on longer sequences, resulting in sparse contextualized encoders (Qiu et al., 2019; Ye et al., 2019; Kitaev et al., 2020; Beltagy et al., 2020, *inter alia*). Efficient Transformers is an emerging subfield with applications beyond NLP; Tay et al. (2020) survey 17 Transformers that have implications on efficiency.

Another class of approaches carefully selects weights to reduce model size. Lan et al. (2020) use low-rank factorization to reduce the size of the embedding matrices, while Wang et al. (2019f) factorize other weight matrices. Additionally, parameters can be shared between layers (Dehghani et al., 2019; Lan et al., 2020) or between an encoder and decoder (Raffel et al., 2019). However, models that employ these methods do not always have *smaller* computation graphs. This greatly reduces the usefulness of parameter sharing compared to other

---

[7] This the case with retrieval-based QA (Guu et al., 2020; Herzig et al., 2020), which builds on BERT.

[8] We borrow this terminology from Schwartz et al. (2019).

methods that additionally offer greater speedups relative to the reduction in model size.

Closely related, model pruning (Denil et al., 2013; Han et al., 2015; Frankle and Carbin, 2018) during training or inference has exploited the overparameterization of neural networks by removing up to 90%-95% parameters. This approach has been successful in not only reducing the number of parameters, but also improving performance on downstream tasks. Related to efforts for pruning deep networks in computer vision (Huang et al., 2016), layer selection and dropout during both training and inference have been studied in both LSTM (Liu et al., 2018a) and Transformer (Fan et al., 2020) based encoders. These also have a regularization effect resulting in more stable training and improved performance. There are additional novel pruning methods that can be performed during training (Guo et al., 2019; Qiu et al., 2019). These successful results are corroborated by other efforts (Gordon et al., 2020) showing that low levels of pruning do not substantially affect pretrained representations. Additional successful efforts in model pruning directly target a downstream task (Sun et al., 2019a; Michel et al., 2019; McCarley, 2019; Cao et al., 2020a). Note that pruning does not always lead to speedups in practice as sparse operations may be hard to parallelize.

Knowledge distillation (KD) uses an overparameterized teacher model to rapidly train a smaller student model with minimal loss in performance (Hinton et al., 2015) and has been used for translation (Kim and Rush, 2016), computer vision (Howard et al., 2017), and adversarial examples (Carlini and Wagner, 2016). This has been applied to ELMo (Li et al., 2019) and BERT (Tang et al., 2019; Sanh et al., 2019; Sun et al., 2020b, *inter alia*). KD can also be combined with adaptive inference, which dynamically adjusts model size (Liu et al., 2020b), or performed on submodules which are later substituted back into the full model (Xu et al., 2020).

Quantization with custom low-precision hardware is also a promising method for both reducing the size of models and compute time, albeit it does not reduce the number of parameters or FPOs (Shen et al., 2020; Zafrir et al., 2019). This line of work is mostly orthogonal to other efforts specific to NLP.

4.3 Standardizing Comparison

There has yet to be a comprehensive and fair evaluation across all models. The closest, Table 1 in Rogers et al. (2020), compares 12 works in model compression. **However, almost no two papers are evaluated against the same BERT with the same set of tasks.** Many papers on attention sparsification do not evaluate on NLU benchmarks. We claim this is because finetuning is itself an expensive task, so it is not prioritized by authors: works on improving model efficiency have focused only on comparing to a BERT on a few tasks.

While it is easy for future research on pretraining to report model sizes and runtimes, it is harder for researchers in efficiency to report NLU benchmarks. We suggest extending versions of the leaderboards under different resource constraints so that researchers with access to less hardware could still contribute under the resource-constrained conditions. Some work has begun in this direction: the SustaiNLP 2020 Shared Task is focused on the energy footprint of inference for GLUE.[9]

5 Area III: (Pretraining) Data

Unsurprisingly for our field, increasing the size of training data for an encoder contributes to increases in language understanding capabilities (Yang et al., 2019; Raffel et al., 2019; Kaplan et al., 2020). At current data scales, some models converge before consuming the entire corpus. In this section, we identify a weakness when given *less* data, advocate for better data cleaning, and raise technical and ethical issues with using web-scraped data.

5.1 Data Quantity

There has not yet been observed a ceiling to the amount of data that can still be effectively used in training (Baevski et al., 2019; Liu et al., 2019d; Yang et al., 2019; Brown et al., 2020). Raffel et al. (2019) curate a 745GB subset of Common Crawl (CC),[10] which starkly contrasts with the 13GB used in BERT. For multilingual text encoding, Wenzek et al. (2020) curate 2.5TB of language-tagged CC. As CC continues to grow, there will be even larger datasets (Brown et al., 2020).

Sun et al. (2017) explore a similar question for computer vision, as years of progress iterated over 1M labeled images. By using 300M images, they improved performance on several tasks with a basic model. We echo their remarks that we should be cognizant of data sizes when drawing conclusions.

---

[9] `https://sites.google.com/view/sustainlp2020/shared-task`

[10] `https://commoncrawl.org/` scrapes publicly accessible webpages each month.

Is there a floor to the amount of data needed to achieve current levels of success on language understanding benchmarks? As we decrease the data size, LSTM-based models start to dominate in perplexity (Yang et al., 2019; Melis et al., 2020), suggesting there are challenges with either scaling up LSTMs or scaling down Transformers. While probing contextualized models and representations is an important area of study (see §6), prior work focuses on pretrained models or models further pretrained on domain-specific data (Gururangan et al., 2020). We are not aware of any work which probes identical models trained with decreasingly less data. How much (and which) data is necessary for high performance on probing tasks?[11]

5.2 Data Quality

While text encoders should be trained on language, large-scale datasets may contain web-scraped and uncurated content (like code). Raffel et al. (2019) ablate different types of data for text representations and find that naively increasing dataset size does not always improve performance, partially due to data quality. This realization is not new. Parallel data and alignment in machine translation (Moore and Lewis, 2010; Duh et al., 2013; Xu and Koehn, 2017; Koehn et al., 2018, *inter alia*) and speech (Peddinti et al., 2016) often use language models to filter out misaligned or poor data. Sun et al. (2017) use automatic data filtering in vision. These successes on other tasks suggest that improved automated methods of data cleaning would let future models consume more *high-quality* data.

In addition to high quality, data uniqueness appears to be advantageous. Raffel et al. (2019) show that increasing the repetitions (number of epochs) of the pretraining corpus hurts performance. This is corroborated by Liu et al. (2019d), who find that random, unique masks for MLM improve over repeated masks across epochs. These findings together suggest a preference to seeing more *new* text. We suspect that representations of text spans appearing multiple times across the corpus are better shaped by observing them in unique contexts.

Raffel et al. (2019) find that differences in domain mismatch in pretraining data (web crawled vs. news or encyclopedic) result in strikingly different performance on certain challenge sets, and Gururangan et al. (2020) find that continuing pretraining on both domain and task specific data lead to gains in performance.

5.3 Datasets and Evaluations

With these larger and cleaner datasets, future research can better explore tradeoffs between size and quality, as well as strategies for scheduling data during training.

As we continue to scrape data off the web and publish challenge sets relying on other web data, we need to cautiously construct our training and evaluation sets. For example, the domains of many benchmarks (Wang et al. (2019c, GLUE), Rajpurkar et al. (2016, 2018, SQuAD), Wang et al. (2019b, SuperGLUE), Paperno et al. (2016, LAMBADA), Nallapati et al. (2016, CNN/DM)) now overlap with the data used to train language representations. Section 4 in Brown et al. (2020) more thoroughly discuss the effects of overlapping test data with pretraining data. Gehman et al. (2020) highlight the prevalance of toxic language in the common pretraining corpora and stress the important of pretraining data selection, especially for deployed models. We are not aware of a comprehensive study that explores the effect of leaving out targeted subsets of the pretraining data. We hope future models note the domains of pretraining and evaluation benchmarks, and for future language understanding benchmarks to focus on more diverse *genres* in addition to diverse *tasks*.

As we improve models by training on increasing sizes of crawled data, these models are also being picked up by NLP practitioners who deploy them in real-world software. These models learn biases found in their pretraining data (Gonen and Goldberg, 2019; May et al., 2019, *inter alia*). **It is critical to clearly state the source[12] of the pretraining data and clarify appropriate uses of the released models.** For example, crawled data can contain incorrect facts about living people; while webpages can be edited or retracted, publicly released "language" model are frozen, which can raise privacy concerns (Feyisetan et al., 2020).

6 Area IV: Interpretability

While it is clear that the performance of text encoders surpass human baselines, it is less clear what knowledge is stored in these models; how do they make decisions? In their survey, Rogers et al. (2020) find answers to the first question and also

---

[11] Conneau et al. (2020a) claim we need a few hundred MiB of text data for BERT.

[12] How was the data generated, curated, and processed?

raise the second. Inspired by prior work (Lipton, 2018; Belinkov and Glass, 2019; Alishahi et al., 2019), we organize here the major probing *methods* that are applicable to all encoders in hopes that future work will use comparable techniques.

6.1 Probing with Tasks

One technique uses the learned model as initialization for a model trained on a *probing task* consisting of a set of targeted natural language examples. The probing task's format is flexible as additional, (simple) diagnostic classifiers are trained on top of a typically frozen model (Ettinger et al., 2016; Hupkes et al., 2018; Poliak et al., 2018; Tenney et al., 2019b). Task probing can also be applied to the embeddings at various layers to explore the knowledge captured at each layer (Tenney et al., 2019a; Lin et al., 2019; Liu et al., 2019a). Hewitt and Liang (2019) warn that expressive (nonlinear) diagnostic classifiers can learn more arbitrary information than constrained (linear) ones. This revelation, combined with the differences in probing task format and the need to train, leads us to be cautious in drawing conclusions from these methods.

6.2 Model Inspection

Model inspection directly opens the metaphorical black box and studies the model weights without additional training. For examples, the embeddings themselves can be analyzed as points in a vector space (Ethayarajh, 2019). Through visualization, attention heads have been matched to linguistic functions (Vig, 2019; Clark et al., 2019b). These works suggest inspection is a viable path to debugging specific examples. In the future, methods for analyzing and manipulating attention in machine translation (Lee et al., 2017; Liu et al., 2018b; Bau et al., 2019; Voita et al., 2019) can also be applied to text encoders.

Recently, interpreting attention as explanation has been questioned (Serrano and Smith, 2019; Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Clark et al., 2019b). The ongoing discussion suggests that this method may still be insufficient for uncovering the rationale for predictions, which is critical for real-world applications.

6.3 Input Manipulation[13]

Input manipulation draws conclusions by recasting the probing task format into the form of the pre-training task and observing the model's predictions. As discussed in §3, word prediction (cloze task) is a popular objective. This method has been used to investigate syntactic and semantic knowledge (Goldberg, 2019; Ettinger, 2020; Kassner and Schütze, 2019). For a specific probing task, Warstadt et al. (2019) show that cloze and diagnostic classifiers draw similar conclusions. As input manipulation is not affected by variables introduced by probing tasks and is as interpretable than inspection, we suggest more focus on this method: either by creating new datasets (Warstadt et al., 2020) or recasting existing ones (Brown et al., 2020) into this format. A disadvantage of this method (especially for smaller models) is the dependence on both the pattern used to elicit an answer from the model and, in the few-shot case where a couple examples are provided first, highly dependent on the examples (Schick and Schütze, 2020).

6.4 Future Directions in Model Analysis

Most probing efforts have relied on diagnostic classifiers, yet these results are being questioned. Inspection of model weights has discovered what the models learn, but cannot explain their causal structure. We suggest researchers shift to the paradigm of input manipulation. By creating cloze tasks that assess linguistic knowledge, we can both observe decisions made by the model, which would imply (lack of) knowledge of a phenomenon. Furthermore, it will also enable us to directly interact with these models (by changing the input) without additional training, which currently introduces additional sources of uncertainty.

Bender and Koller (2020) also recommend a top-down view for model analysis that focuses on the end-goals for our field over hill-climbing individual datasets. While language models continue to outperform each other on these tasks, they argue these models do not learn *meaning*.[14] If not meaning, what are these models learning?

We are overinvesting in BERT. While it is fruitful to understand the boundaries of its knowledge, we should look more across (simpler) models to see *how* and *why* specific knowledge is picked up as our models both become increasingly complex and perform better on a wide set of tasks. For example, how many parameters does a Transformer-based model need to outperform ELMo or even rule-based baselines?

---

[13] This is analogous to the "few-shot" and "zero-shot" analysis in Brown et al. (2020).

[14] A definition is given in §3 of Bender and Koller (2020).

7 Area V: Multilinguality

The majority of research on text encoders has been in English.[15] Cross-lingual shared representations have been proposed as an efficient way to target multiple languages by using multilingual text for pretraining (Mulcaire et al., 2019; Devlin et al., 2019; Lample and Conneau, 2019; Liu et al., 2020c, *inter alia*). For evaluation, researchers have devised multilingual benchmarks mirroring those for NLU in English (Conneau et al., 2018b; Liang et al., 2020; Hu et al., 2020). Surprisingly, without any explicit cross-lingual signal, these models achieve strong zero-shot cross-lingual performance, outperforming prior cross-lingual word embedding-based methods (Wu and Dredze, 2019; Pires et al., 2019).

A natural follow-up question to ask is why these models learn cross-lingual representations. Some answers include the shared subword vocabulary (Pires et al., 2019; Wu and Dredze, 2019), shared Transformer layers (Conneau et al., 2020b; Artetxe et al., 2020) across languages, and depth of the network (K et al., 2020). Studies have also found the geometry of representations of different languages in the multilingual encoders can be aligned with linear transformations (Schuster et al., 2019; Wang et al., 2019e, 2020c; Liu et al., 2019b), which has also been observed in independent monolingual encoders (Conneau et al., 2020b). These alignments can be further improved (Cao et al., 2020b).

7.1 Evaluating Multilinguality

All of the areas discussed in this paper are applicable to multilingual encoders. However, progress in training, architecture, datasets, and evaluations are occurring concurrently, making it difficult to draw conclusions. We need more comparisons between competitive multilingual and monolingual systems or datasets. To this end, Wu and Dredze (2020) find that monolingual BERTs in low-resource languages are outperformed by multilingual BERT. Additionally, as zero-shot (or few-shot) cross-lingual transfer has inherently high variance (Keung et al., 2020), **the variance of models should also be reported**.

We anticipate cross-lingual performance being a new dimension to consider when evaluating text representations. For example, it will be exciting to discover how a small, highly-performant monolingual encoder contrasts against a multilingual variant; e.g., what is the minimum number of parameters needed to support a new language? Or, how does model size relate to the phylogenetic diversity of languages supported?

8 Discussion

8.1 Limitations and Recommendations

This survey, like others, is limited to only what has been shared publicly so far. The papers of many models described here highlight their best parts, where potential flaws are perhaps obscured within tables of numbers. Leaderboard submissions that do not achieve first place may never be published. Meanwhile, encoders are expensive to work with, yet they are a ubiquitous component in most modern NLP models. We strongly encourage more **publication and *publicizing* of negative results** and limitations. In addition to their scientific benefits,[16] publishing negative results in contextualized encoders can avoid significant externalities of rediscovering what doesn't work: time, money, and electricity. Furthermore, we ask leaderboard owners to **periodically publish surveys** of their received submissions.

The flourishing research in improving encoders is rivaled by research in interpreting them, mainly focused on discovering the boundary of what knowledge is captured by the models. For investigations that aim to sharpen the boundary, it is logical to build off of these prior results. However, we raise a concern that these encoders are all trained on similar data and have similar sizes. Future work in **probing should also look across different sizes and domains of training data**, as well as study the effect of model size. This can be further facilitated by model creators who release (data) ablated versions of their models.

We also raise a concern about reproducibility and accessibility of evaluation. Already, several papers focused on model compression do not report full GLUE results, possibly due to the expensive finetuning process for each of the nine datasets. Finetuning currently requires additional compute and infrastructure,[17] and the specific methods used impact task performance. As long as finetuning is still an essential component of evaluating encoders, de-

---

[15] Of the monolingual encoders in other languages, core research in modeling has only been performed so far for a few non-English languages (Sun et al., 2019b, 2020a).

[16] An EMNLP 2020 workshop is motivated by better science (`https://insights-workshop.github.io/`).

[17] Pruksachatkun et al. (2020) is a library that reduces some infrastructural overhead of finetuning.

vising **cheap, accessible, and reproducible metrics for encoders is an open problem**.

Ribeiro et al. (2020) suggest a practical solution to both probing model errors and reproducible evaluations by creating tools that quickly generate test cases for linguistic capabilities and find bugs in models. This task-agnostic methodology may be extensible to both challenging tasks and probing specific linguistic phenomenon.

8.2 Which *BERT should we use?

Here, we discuss tradeoffs between metrics and synthesize the previous sections. We provide a series of questions to consider when working with encoders for research or application development.

Task performance vs. efficiency An increasingly popular line of recent work has investigated knowledge distillation, model compression, and sparsification of encoders (§4.2). These efforts have led to significantly smaller encoders that boast competitive performance, and under certain settings, non-contextual embeddings alone may be sufficient (Arora et al., 2020; Wang et al., 2020a). For downstream applications, ask: **Is the extra iota of performance worth the significant costs of compute?**

Leaderboards vs. real data As a community, we are hill-climbing on curated benchmarks that aggregate dozens of tasks. Performance on these benchmarks does not necessarily reflect that of specific real-world tasks, like understanding social media posts about a pandemic (Müller et al., 2020). Before picking the best encoder determined by average scores, ask: **Is this encoder the best for our specific task? Should we instead curate a large dataset and pretrain again?** Gururangan et al. (2020) suggest continued pretraining on in-domain data as a viable alternative to pretraining from scratch.

For real-world systems, practitioners should be especially conscious of the datasets on which these encoders are pretrained. **There is a tradeoff between task performance and possible harms contained within the pretraining data.**

Monolingual vs. Multilingual For some higher resource languages, there exist monolingual pretrained encoders. For tasks in those languages, those encoders are a good starting point. However, as we discussed in §7, multilingual encoders can, surprisingly, perform competitively, yet these metrics are averaged over multiple languages and tasks. Again, we encourage looking at the relative **performance for a specific task and language**, and whether **monolingual encoders (or embeddings) may be more suitable.**

Ease-of-use vs. novelty With a constant stream of new papers and models (without peer review) for innovating in each direction, we suggest using and building off **encoders that are well-documented with reproduced or reproducible results**. Given the pace of the field and large selection of models, unless aiming to reproduce prior work or improve underlying encoder technology, we recommend proceeding with caution when reimplementing ideas from scratch.

9 Conclusions

In this survey we categorize research in contextualized encoders and discuss some issues regarding its conclusions. We cover background on contextualized encoders, pretraining objectives, efficiency, data, approaches in model interpretability, and research in multilingual systems. As there is now a large selection of models to choose from, we discuss tradeoffs that emerge between models. We hope this work provides some assistance to both those entering the NLP community and those already using contextualized encoders in looking beyond SOTA (and Twitter) to make more educated choices.

Acknowledgments

We especially thank the (meta-)reviewers for their insightful feedback and criticisms. In addition, we thank Sabrina Mielke, Nathaniel Weir, Huda Khayrallah, Mitchell Gordon, and Shuoyang Ding for discussing several drafts of this work. This work was supported in part by DARPA AIDA (FA8750-18-2-0015) and IARPA BETTER (#2019-19051600005). Abstract

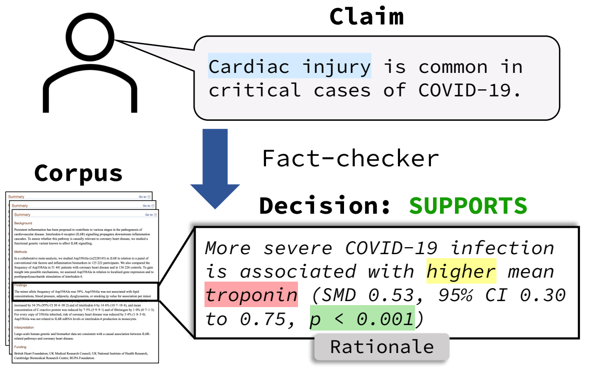
We introduce scientific claim verification, a new task to select abstracts from the research literature containing evidence that Supports or Refutes a given scientific claim, and to identify rationales justifying each decision. To study this task, we construct SciFact, a dataset of 1.4K expert-written scientific claims paired with evidence-containing abstracts annotated with labels and rationales. We develop baseline models for SciFact, and demonstrate that simple domain adaptation techniques substantially improve performance compared to models trained on Wikipedia or political news. We show that our system is able to verify claims related to COVID-19 by identifying evidence from the CORD-19 corpus. Our experiments indicate that SciFact will provide a challenging testbed for the development of new systems designed to retrieve and reason over corpora containing specialized domain knowledge. Data and code for this new task are publicly available at https://github.com/allenai/scifact. A leaderboard and COVID-19 fact-checking demo are available at https://scifact.apps.allenai.org.

1 Introduction

Due to rapid growth in the scientific literature, it is difficult for researchers – and the general public even more so – to stay up to date on the latest findings. This challenge is especially acute during public health crises like the current COVID-19 pandemic, due to the extremely fast rate at which new findings are reported and the risks associated with making decisions based on outdated or incomplete information. As a result, there is a need for automated tools to assist researchers and the public in evaluating the veracity of scientific claims.



Cardiac injury is common in critical cases of COVID-19.

More severe COVID-19 infection is associated with higher mean troponin (SMD 0.53, 95% CI 0.30 to 0.75, p < 0.001)

Figure 1: A scientific claim, supported by evidence identified by our system. To correctly verify this claim, the system must possess background knowledge that *troponin* is a protein found in cardiac muscle and that elevated levels of *troponin* are a marker of *cardiac injury*. In addition, it must be able to reason about directional relationships between scientific processes: replacing *higher* with *lower* would cause the rationale to Refute the claim rather than Support it. Finally, the system should interpret $p < 0.001$ as an indication that the reported finding is statistically significant.

Fact-checking – a task in which the veracity of an input *claim* is verified against a corpus of documents that *support* or *refute* the claim – has been studied to combat the proliferation of misinformation in political news, social media, and on the web (Thorne et al., 2018; Hanselowski et al., 2019). However, verifying scientific claims poses new challenges to both dataset construction and effective modeling. While political claims are readily available on fact-checking websites and can be verified by crowd workers, annotators with extensive domain knowledge are required to generate and verify scientific claims.

In addition, NLP systems for scientific claim verification must possess additional capabilities beyond those required to verify factoid claims. For instance, to verify the claim shown in Figure 1, a

Claim 1: Lopinavir / ritonavir have exhibited favorable clinical responses when used as a treatment for coronavirus.

Supports: …*Interestingly, after lopinavir/ritonavir (Kaletra, AbbVie) was administered, β-coronavirus viral loads significantly decreased and no or little coronavirus titers were observed.*

Refutes: *The focused drug repurposing of known approved drugs (such as lopinavir/ritonavir) has been reported failed for curing SARS-CoV-2 infected patients.* It is urgent to generate new chemical entities against this virus …

Claim 2: The coronavirus cannot thrive in warmer climates.

Supports: *...most outbreaks display a pattern of clustering in relatively cool and dry areas...This is because the environment can mediate human-to-human transmission of SARS-CoV-2, and unsuitable climates can cause the virus to destabilize quickly...*

Refutes: *...significant cases in the coming months are likely to occur in more humid (warmer) climates, irrespective of the climate-dependence of transmission and that summer temperatures will not substrantially limit pandemic growth.*

Table 1: Evidence identified by our system as supporting and refuting two claims concerning COVID-19.

system must have the ability to access scientific background knowledge, reason over increases and decreases in quantities or measurements, and make sense of specialized statistical language.

In this paper, we introduce the task of scientific claim verification to evaluate the veracity of scientific claims against a scientific corpus. Table 1 presents some examples. To facilitate research on this task, we construct SciFact, an expert-annotated dataset of 1,409 scientific claims accompanied by abstracts that support or refute each claim, and annotated with rationales (Lei et al., 2016) justifying each Supports / Refutes decision. To create the dataset, we develop a novel annotation protocol in which annotators re-formulate naturally occurring claims in the scientific literature – *citation sentences* – into atomic scientific claims. Using citation sentences as a source of claims both speeds the claim generation process and guarantees that the topics discussed in SciFact are representative of the research literature. In addition, citation links indicate the exact documents likely to contain evidence necessary to verify a given claim.

We establish performance baselines on SciFact with an approach similar to DeYoung et al. (2020a), which achieves strong performance on the Fever claim verification dataset (Thorne et al., 2018). Our baseline is a pipeline system which retrieves abstracts related to an input claim, uses a BERT-based (Devlin et al., 2019) sentence selector to identify rationale sentences, and labels each abstract as Supports, Refutes, or NoInfo with respect to the claim. We demonstrate that our baseline can benefit from training on claims from domains including Wikipedia articles and politics.

We showcase the ability of our model to verify expert-written claims concerning the novel coronavirus COVID-19 against the newly-released CORD-19 corpus (Wang et al., 2020). Expert annotators judge retrieved evidence to be plausible for 23 of 36 claims.[1] Our results and analyses demonstrate the importance of the new task and dataset to support significant future research in this domain.

In summary, our contributions include: (1) We introduce and formalize the scientific claim verification task. (2) We develop a novel annotation protocol to generate and verify 1.4K naturally-occurring claims about scientific findings. (3) We establish strong baselines on this task, and identify substantial opportunities for improvement at all stages of the modeling pipeline. (4) We demonstrate the efficacy of our system in a real-world case study verifying claims about COVID-19 against the research literature.

2 Background and task definition

As illustrated in Figure 1, scientific claim verification is the task of identifying evidence from the research literature that Supports or Refutes a given scientific claim. Table 1 shows the results of our system applied to claims about the novel coronavirus COVID-19. For each claim, the system identifies relevant scientific abstracts, and labels the relation of each abstract to the claim as either Supports or Refutes. Verifying scientific claims is challenging and requires domain-specific background knowledge – for instance, in order to identify the evidence supporting Claim 1 in Table 1, the system must determine that a reduction in coronavirus viral load indicates a favorable clinical response, even though this fact is never mentioned.

Scientific claims In SciFact, a scientific claim is an *atomic verifiable statement* expressing a finding

---

[1] We emphasize that our model is a *research prototype* and should not be used to make any medical decisions whatsoever.

about one aspect of a scientific entity or process, which can be verified from a single source.[2] For instance, "*The R_0 of the novel coronavirus is 2.5*" is valid, but opinion-based statements like "*The government should require people to stand six feet apart to stop coronavirus*" are not. Compound claims like "*Aerosolized coronavirus droplets can travel at least 6 feet and can remain in the air for 3 hours*" should be split into two atomic claims.

Claims in SciFact are *natural* – they are derived from citation sentences, or *citances* (Nakov et al., 2004), that occur naturally in scientific articles. This is similar to political fact-checking datasets such as UKP Snopes (Hanselowski et al., 2019), which use political fact-checking websites as a source of natural claims. On the other hand, claims in the popular Fever dataset (Thorne et al., 2018) are *synthetic*, since they are created by annotators by mutating sentences from the Wikipedia articles that will serve as evidence.

Supporting and refuting evidence In most fact-checking work, claims are assigned a global truth label based on the entirety of the available evidence. For example in Fever, the claim "*Barack Obama was the* 44th *President of the United States*" can be verified using Wikipedia as an evidence source.

While SciFact claims are indeed verifiable assertions about scientific findings, accurately assigning a global truth label to a scientific claim (given a fixed scientific corpus) requires a systematic review by a team of experts. In this work we focus on the simpler task of assigning Supports or Refutes relations to individual *claim-abstract pairs*.

Each Supports or Refutes relation between claim and abstract must be justified by at least one *rationale*. A rationale is a minimal collection of sentences which, taken together as premises in the context of the abstract, can reasonably be judged by a domain expert as implying the claim. Rationales facilitate the development of *interpretable models* which not only have the ability to make label predictions, but can also identify the exact sentences that are necessary for their decisions.

3 The SciFact dataset

The SciFact dataset consists of 1,409 scientific claims[3] verified against a corpus of 5,183 abstracts.

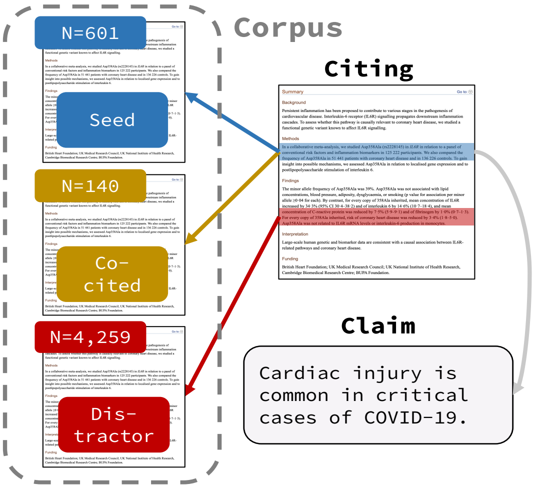

Figure 2: Corpus construction. Citing abstracts are identified for each seed document. A claim is written based on the source citance in the citing abstract.

Abstracts that support or refute each claim are annotated with rationales. We describe our corpus creation and annotation process.

3.1 Data source and corpus construction

To construct SciFact, we use S2ORC (Lo et al., 2020), a publicly-available corpus of millions of scientific articles. To ensure that documents in our dataset are of high quality, we randomly sample articles from a manually curated collection of well-regarded journals spanning domains from basic science (e.g., *Cell*, *Nature*) to clinical medicine (e.g., *JAMA*, *BMJ*). The full list of journals is included in Appendix C.1. We restrict to articles with at least 10 citations. The resulting collection is referred to as our *seed* set. We use the S2ORC citation graph to sample *source citances* from *citing articles* which cite these seed articles. If a citance cites other articles not in the seed set, we refer to these as *co-cited* articles and add them to the corpus, as depicted in Figure 2. The content of the cited abstracts encompasses a diverse array of topics within biomedicine, as shown in Figure 3. The majority of citances used for SciFact cite only the seed article (no co-cited articles), as we found in initial annotation experiments that these citances tended to yield specific, easy-to-verify claims.

To expand the corpus, we identify five papers cited in the same paper as each source citance but in a different paragraph, and add these to the corpus as *distractor abstracts*. These abstracts often

---

[2] Requiring annotators to search multiple sources increases cognitive burden and decreases annotation quality.

[3] SciFact is comparable in size to recent scientific datasets for tasks such as QA (e.g. PubMedQA (Jin et al., 2019) has 1,000 questions), and information extraction (e.g. SciERC (Luan et al., 2018) has 500 annotated abstracts).

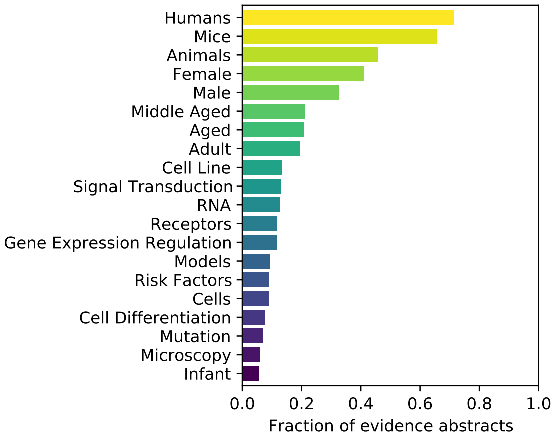

Figure 3: Most frequently occurring Medical Subject Headings (MeSH) terms (y-axis) among cited abstracts. MeSH is a controlled vocabulary used for indexing articles in PubMed. Topics range from clinical trial reports ("Humans", "Risk Factors") to molecular biology ("Cell Line", "RNA").

discuss similar topics to the evidence documents, increasing the difficulty of abstract retrieval and making our metrics more accurately reflect the system's performance on a large research corpus.

3.2 Claim writing

Annotation Annotators are shown a source citance in the context of an article, and are asked to write up to three claims based on the content of the citance; see Appendix C.2 for an example. This results in *natural* claims because the annotator does not see the cited article's abstract – the *cited abstract* – at the time of claim writing. Annotators are asked to skip citances that do not make statements about specific scientific findings.

The claim writers included four experts with background in scientific NLP, fifteen undergraduates studying the life sciences, and four graduate students (doctoral or medical) in the life sciences. Detailed information on the annotator training process can be found in Appendix C.3. The claim-writing interface is shown in Appendix D.

Claim negation Unless the authors of the source citance were mistaken, cited articles should provide supporting evidence for the claims made in a citance. To obtain examples where an abstract REFUTES a claim, an NLP expert wrote negations of existing claims, taking precautions not to bias the negations by using obvious keywords like "not" (Schuster et al., 2019; Gururangan et al., 2018). In §6.1, we demonstrate that a "claim-only" verification model performs poorly, suggesting that the negation process did not introduce severe artifacts.

3.3 Claim verification

Annotation For each claim, all of the claim's cited abstracts are annotated for evidence. Annotators are shown a single claim - cited abstract pair, and asked to label the pair as SUPPORTS, REFUTES, or NOINFO. Although our task definition allows for a single claim to be both supported and refuted (by different abstracts) – an occurrence we observe on real-world COVID-19 claims (§6.3) – this never occurs in our dataset. Each claim has a single label. Counts for each label are shown in Table 2a. Overall, the annotators found evidence in 63% of cited abstracts. If the annotator assigns a SUPPORTS or REFUTES label, they must also identify all rationales as defined in §2. Table 2b provides statistics on the number of sentences per rationale, the number of rationales per claim / abstract pair, and the number of evidence abstracts per claim. No abstract has more than 3 rationales for a given claim, and all rationales consist of at most three sentences. Rationales in SCIFACT are mutually exclusive. 28 rationales contain non-contiguous sentences.

The verifiers included three NLP experts, five life science undergraduates, and five graduate students studying life sciences. Annotators verified claims that they did not write themselves. Annotation guidelines are provided in Appendix D.

SCIFACT claims are verified against abstracts rather than full articles since (1) abstracts can be annotated more scalably, (2) evidence is found in the abstract in more than 60% of cases, and (3) previous attempts at full-document annotation suffered from low annotator agreement (§7).

Quality We assign 232 claim-abstract pairs for independent re-annotation. The label agreement is 0.75 Cohen's κ, comparable with the 0.68 Fleiss' κ reported in Thorne et al. (2018), and 0.70 Cohen's κ reported in Hanselowski et al. (2019). To measure rationale agreement, we treat each sentence as either classified as "part of a rationale" or "not part of a rationale" and compute sentence-level agreement. The resulting Cohen's κ is 0.71.

4 The SCIFACT task

Task Formulation The inputs to our task are a scientific claim c and a corpus of abstracts $\mathcal{A}$. All abstracts $a \in \mathcal{A}$ are labeled as $y(c, a) \in \{$SUPPORTS, REFUTES, NOINFO $\}$ with respect to a claim c.

Fold	SUPPORTS	NOINFO	REFUTES	All
Train	332	304	173	809
Dev	124	112	64	300
Test	100	100	100	300
All	556	516	337	1409

(a) Distribution of claim labels in SCIFACT.

	0	1	2	3+
Cited abstracts per claim	-	1278	86	45
Evidence abstracts per claim	516	830	37	26
Rationales per abstract	-	552	290	153
Sentences per rationale	-	1542	92	11

(b) Evidence counts at various levels of granularity. For example, Column 2 of the row "Rationales / abstract" indicates that 290 claim / abstract pairs are supported by 2 distinct rationales.

Table 2: Statistics on claim labels, and the number of evidence abstracts and rationales per claim.

The abstracts that either SUPPORT or REFUTE c are referred to as *evidence abstracts* for c, denoted as $\mathcal{E}(c)$. Each evidence abstract $a \in \mathcal{E}(c)$ is annotated with rationales. A single rationale R_i is a collection of sentences $\{r_1(c,a), \ldots, r_m(c,a)\}$, where m is the number of sentences in rationale R_i. We denote the set of all rationales as $\mathcal{R}(c,a) = \{R_1(c,a), \ldots, R_n(c,a)\}$.

Given a claim c and a corpus $\mathcal{A}$, the system must predict a set of evidence abstracts $\widehat{\mathcal{E}}(c)$. For each abstract $a \in \widehat{\mathcal{E}}(c)$, it must predict a label $\widehat{y}(c,a)$, and a collection of *rationale sentences* $\widehat{S}(c,a) = \{\widehat{s}_1(c,a), \ldots, \widehat{s}_\ell(c,a)\}$. Note that although the gold annotations may contain multiple separate rationales, to simplify the prediction task we only require the model to predict a single collection of *rationale sentences*; these sentences may encompass multiple gold rationales.

Task Evaluation We evaluate the task at two levels of granularity. For *abstract-level* evaluation, we assess the model's ability to identify the abstracts that support or refute the claim. For *sentence-level* evaluation, we evaluate the model's performance at identifying the sentences sufficient to justify the abstract-level predictions. We conduct evaluations in both the "Open" FEVER-style (Thorne et al., 2018) setting where the evidence abstracts must be retrieved, and the "Oracle abstract" ERASER-style (DeYoung et al., 2020a) setting where the gold evidence abstracts $\mathcal{E}(c)$ are provided.

Abstract-level evaluation is inspired by the FEVER score. Given a claim c, a predicted evidence abstract $a \in \widehat{\mathcal{E}}(c)$ is *correctly labeled* if (1) a is a gold evidence abstract for c, and (2) The predicted label is correct: $\widehat{y}(c,a) = y(c,a)$. It is *correctly rationalized* if, in addition, the predicted rationale sentences contain a gold rationale, i.e., there exists some gold rationale $R_i(c,a) \subseteq \widehat{S}(c,a)$.

Like FEVER, which limits the maximum number of predicted rationale sentences to five, SCIFACT limits to three predicted rationale sentences. Overall performance is measured by the micro-F1 of the precision and recall over the correctly-labeled and correctly-rationalized evidence abstracts. We refer to these evaluations as $\text{Abstract}_{\text{Label-Only}}$ and $\text{Abstract}_{\text{Label+Rationale}}$, respectively.

Sentence-level evaluation measures performance in identifying individual rationale sentences. Unlike the abstract-level metrics, this evaluation penalizes the prediction of extra rationale sentences.

A predicted rationale sentence $\widehat{s}(c,a)$ is correctly *selected* if (1) It is a member of some gold rationale $R_i(c,a)$, (2) all other sentences from the same gold rationale $R_i(c,a)$ are among the predicted $\widehat{S}(c,a)$, and (3) $\widehat{y}(c,a) \neq$ NOINFO[4]. It is correctly *labeled* if, in addition, the abstract a is correctly labeled: $\widehat{y}(c,a) = y(c,a)$.

Overall performance is measured by the micro-F1 of the precision and recall of correctly-selected and correctly-labeled rationale sentences, denoted $\text{Sentence}_{\text{Selection-Only}}$ and $\text{Sentence}_{\text{Selection+Label}}$. For sentence-level evaluation, we do not limit the number of predicted rationale sentences, since the evaluation penalizes models that over-predict.

5 VERISCI: Baseline model

We develop a baseline (referred to as VERISCI) that takes a claim c and corpus $\mathcal{A}$ as input, identifies evidence abstracts $\widehat{\mathcal{E}}(c)$, and predicts a label $\widehat{y}(c,a)$ and rationale sentences $\widehat{S}(c,a)$ for each $a \in \widehat{\mathcal{E}}(c)$. Following the "BERT-to-BERT" model presented in DeYoung et al. (2020a); Soleimani et al. (2019), VERISCI is a pipeline of three components:

1. ABSTRACTRETRIEVAL retrieves k abstracts with highest TF-IDF similarity to the claim.
2. RATIONALESELECTION identifies rationale sentences $\widehat{S}(c,a)$ for each abstract.
3. LABELPREDICTION makes the final label prediction $\widehat{y}(c,a)$.

Rationale selection Given a claim c and abstract a, we train a model to predict $z_i \triangleq$

---

[4] Condition (3) eliminates rationale sentences which were identified by the rationale selector, but proved insufficient to justify a final SUPPORTS / REFUTES decision

$\mathbb{1}[a_i \text{ is a rationale sentence}]$ for each sentence a_i in a. For each sentence, we encode the concatenated sequence $w_i = [a_i, \text{SEP}, c]$ using a BERT-style language model and predict a score $\tilde{z}_i = \sigma[f(\text{CLS}(w_i))]$, where σ is the sigmoid function, f is a linear layer and $\text{CLS}(w_i)$ is the CLS token from the encoding of w_i. We train the model on pairs of claims and their cited abstracts and minimize cross-entropy loss between z_i and $\tilde{z}_i$. For each claim, we use cited abstracts labeled NOINFO, as well as non-rationale sentences from abstracts labeled SUPPORTS and REFUTES as negative examples. To make predictions, we select all sentences a_i with $\tilde{z}_i > t$ as rationale sentences, where $t \in [0, 1]$ is tuned on the dev set (Appendix A.1).

Label prediction Sentences identified by the rationale selector are passed to a separate BERT-based model to make the final labeling decision. Given a claim c and abstract a, we concatenate the claim and the predicted rationale sentences $u = [\widehat{s}_1(c, a), \ldots \widehat{s}_\ell(c, a), \text{SEP}, c]$[5], and predict $\tilde{y}(c, a) = \phi[f(\text{CLS}(u))]$, where ϕ is the softmax function, and f is a linear layer with three outputs representing the $\{$SUPPORTS, REFUTES, NOINFO $\}$ labels. We minimize the cross-entropy loss between $\tilde{y}(c, a)$ and the true label $y(c, a)$.

We train the model on pairs of claims and their cited abstracts using gold rationales as input. For cited abstracts labeled NOINFO, we choose the k sentences from the cited abstract with highest TF-IDF similarity to the claim as input rationales. For prediction, we use the predicted rationale sentences $\widehat{S}(c, a)$ as input and predict $\hat{y}(c, a) = \text{argmax}\ \tilde{y}(c, a)$. NOINFO is predicted for abstracts with no rationale sentences.

We experimented with a label prediction model which encodes entire abstracts via the Longformer (Beltagy et al., 2020), and makes predictions using the document-level CLS token. Performance was not competitive with our pipeline setup, likely because the label predictor struggles to identify relevant information when given full abstracts.

6 Experiments

In our experiments, we (1) analyze the performance of each individual component of VERISCI, (2) evaluate full task performance in both the "Oracle abstract" and "Open" settings, (3) present promising results verifying claims about COVID-19 using VERISCI, and (4) discuss some modeling challenges presented by the dataset.

	RATIONAL-SELECT.			LABEL-PRED.

Abstract-only	60.1	60.9	60.5	53.3

Table 3: Comparison of different training datasets, encoders, and model inputs for RATIONALESELECTION and LABELPREDICTION, evaluated on the SCIFACT dev set. The claim-only model cannot select rationales.

6.1 Pipeline components

We examine the effects of different training datasets, sentence encoders, and model inputs on the performance of the RATIONALESELECTION and LABELPREDICTION modules. The RATIONALESELECTION module is evaluated on its ability to select rationale sentences given gold abstracts[6]. The LABELPREDICTION module is evaluated on its 3-way label classification accuracy given gold rationales from cited abstracts. Cited abstracts labeled NOINFO are included in the evaluation. These abstracts have no gold rationale sentences; as in §5, we provide the k most similar sentences from the abstract as input (more details in Appendix A).

Training Data We train on (1) FEVER, (2) UKP Snopes, (3) SCIFACT, and (4) FEVER pretraining followed by SCIFACT fine-tuning. RoBERTa-large (Liu et al., 2019) is used as the sentence encoder.

Sentence encoder We fine-tune SCIBERT (Beltagy et al., 2019), BioMedRoBERTa (Gururangan et al., 2020), RoBERTa-base, and RoBERTa-large. SCIFACT is used as training data.

Model Inputs We examine the performance of "claim-only" and "abstract-only" models trained on SCIFACT, using RoBERTa-large as the sentence encoder. The claim-only model makes label predic-

---

[5] We truncate the rationale input if it exceeds the BERT token limit. c is never truncated.

[6] Our FEVER-trained RATIONALESELECTION module achieves 79.9 sentence-level F1 on the FEVER test set, virtually identical to 79.6 reported in DeYoung et al. (2020a).

			Sentence-level						Abstract-level

Table 4: Test set performance on SciFact, according to the metrics from §4. For the "Oracle abstract" rows, the system is provided with gold evidence abstracts. "Oracle rationale" rows indicate that the gold rationales are provided as input. "Zero-shot" indicates zero-shot performance of a verification system trained on Fever. Additionally, standard deviations are reported as subscripts for all F1 scores. See Appendix B for standard deviations on all reported metrics.

tions based on the claim text alone, without access to evidence abstracts. The abstract-only model selects rationale sentences and makes label predictions without access to the claim.

Results The results are shown in Table 3. For LabelPrediction, the best performance is achieved by training first on the large Fever dataset and then fine-tuning on the smaller in-domain SciFact training set. To understand the benefits of Fever pretraining, we examined the claim / evidence pairs where the Fever + SciFact- trained model made correct predictions but the SciFact- trained model did not. In 36 / 44 of these cases, the SciFact-trained model predicts NoInfo. Thus pretraining on Fever appears to improve the model's ability to recognize textual entailment relationships between evidence and claim – particularly relationships indicated by non-domain-specific cues like "is associated with" or "has an important role in".

For RationaleSelection, training on SciFact alone produces the best results. We examined the rationales that the SciFact- trained model identified but the Fever- trained model missed, and found that they generally contain science-specific vocabulary. Thus, training on additional out-of-domain data provides little benefit.

RoBERTa-large exhibits the strongest performance on label prediction, while SciBERT has a slight edge on rationale selection. The "claim-only" model exhibits very poor performance, which provides some reassurance that the claim negation procedure described in §3.2 does not introduce obvious statistical artifacts. Similarly, the poor performance of the "abstract-only" model indicates that the model needs access to the claim being verified in order to identify relevant evidence.

6.2 Full task

Experimental setup Based on the results from §6.1, we use the RationaleSelection module trained on SciFact only, and the LabelPrediction module trained on Fever + SciFact for our final end-to-end system VeriSci. Although SciBERT performs slightly better on rationale selection, using RoBERTa-large for both RationaleSelection and LabelPrediction gave the best full-pipeline performance on the dev set, so we use RoBERTa-large for both components. For the AbstractRetrieval module, the best dev set full-pipeline performance was achieved by retrieving the top $k = 3$ documents.

Model comparisons We report performance of three model variants. For the "Oracle rationale" setting, the RationaleSelection module is replaced by an oracle which outputs gold rationales for correctly retrieved documents, and no rationales for incorrect retrievals. The "Zero-shot" setting reports the zero-shot generalization performance of a model trained on Fever (the results on UKP Snopes were slightly worse). VeriSci reports the performance of our best system.

Results The results are shown in Table 4. In the oracle abstract setting, the abstract-level F1 scores are roughly comparable to label classification accuracies, and the $\text{Abstract}_{\text{Label+Rationale}}$ score in Row 3 implies an end-to-end classification accuracy of roughly 70%, given gold abstracts.

Access to in-domain data during training clearly improves performance. Despite the small size of SciFact, training on these data

Reasoning type	**Example**	
Science background	**Claim:**	Rapamycin slows aging in fruit flies.
	Evidence:	. . . *feeding rapamycin to adult Drosophila produces life span extension . . .*
	Gold Verdict:	SUPPORTS
	Reasoning:	Drosophila is a type of fruit fly.
Directionality	**Claim:**	Inhibiting glucose-6-phospate dehydrogenase impairs lipogenesis
	Evidence:	. . . *suppression of 6PGD increased lipogenesis*
	Gold Verdict:	REFUTES
	Reasoning:	A decrease (not increase) in lipogenesis would indicate lipogenesis impairment.
Numerical reasoning	**Claim:**	Bariatric surgery improves resolution of diabetes.
	Evidence:	*Strong associations were found between bariatric surgery and the resolution of T2DM, with a HR of 9.29 (95% CI 6.84-12.62)...*
	Gold Verdict:	SUPPORTS
	Reasoning:	A HR (hazard ratio) that is greater than 1 with 95% confidence indicates improvement.
Cause and effect	**Claim:**	Major vault protein (MVP) functions to decrease tumor aggression.
	Evidence:	*Knockout of MVP leads to miR-193a accumulation...inhibiting tumor progression*
	Gold Verdict:	REFUTES
	Reasoning:	Knocking out (removing) MVP inhibits tumor progression → MVP increases tumor aggression.
Coreference	**Claim:**	Low saturated fat diets have adverse effects on the development of infants
	Evidence:	*Neurological development of children in the intervention group was at least as good as ... the control group*
	Gold Verdict:	REFUTES
	Reasoning:	The intervention group in this study was placed on a low saturated fat diet.

Table 5: Reasoning types required to verify SciFact claims which are classified incorrectly by our modeling baseline. Words crucial for correct verification are highlighted.

leads to relative improvements of 47% on open $\text{Sentence}_{\text{Selection+Label}}$, and 28% on open $\text{Abstract}_{\text{Label+Rationale}}$ over FEVER alone (Row 6 vs. Row 5). The three pipeline components make similar contributions to the overall model error. Replacing RATIONALESELECTION with an oracle leads to a roughly 20-point rise in $\text{Sentence}_{\text{Selection+Label}}$ F1 (Row 6 vs. Row 4). Replacing ABSTRACTRETRIEVAL with an oracle as well leads to a gain of roughly 20 more points (Row 4 vs. Row 1).

Nearly all correctly-labeled abstracts are supported by at least one rationale. There is only a two-point difference in F1 between $\text{Abstract}_{\text{Label-Only}}$ and $\text{Abstract}_{\text{Label+Rationale}}$ in the oracle setting (Row 3), and a one-point difference in the open setting (Row 6). The differences between $\text{Sentence}_{\text{Selection-Only}}$ and $\text{Sentence}_{\text{Selection+Label}}$ are larger, caused by examples where the model finds the evidence but fails to predict its relationship to the claim. We examine these in §6.4.

We evaluate the statistical robustness of our results by generating 10,000 bootstrap-resampled versions of the test set (Dror et al., 2018) and computing the standard deviation of all performance metrics. Table 4 shows the standard deviations in F1 score. Uncertainties on all metrics for both the dev and test set can be found in Appendix B. The results indicate that the observed differences in model performance are statistically robust and cannot be attributed to random variation in the dataset.

6.3 Verifying claims about COVID-19

We conduct exploratory experiments using our system to verify claims concerning COVID-19. We tasked a medical student to write 36 COVID-related claims. For each claim c, we used VERISCI to predict evidence abstracts $\widehat{\mathcal{E}}(c)$. The annotator examined each $(c, \widehat{\mathcal{E}}(c))$ pair. A pair was labeled *plausible* if $\widehat{\mathcal{E}}(c)$ was nonempty, and at least half of the evidence abstracts in $\widehat{\mathcal{E}}(c)$ were judged to have reasonable rationales and labels. For 23 / 36 claims, the response of VERISCI was deemed plausible by our annotator, demonstrating that VERISCI is able to successfully retrieve and classify evidence in many cases. Two examples are shown in Table 1. In both cases, our system identifies both supporting *and* refuting evidence.

6.4 Error analysis

To better understand the errors made by VERISCI, we conduct a manual analysis of test set predictions where an evidence abstract was correctly retrieved, but where the model failed to identify any relevant rationales or predicted an incorrect label. We identify five modeling capabilities required to correct these mistakes (Table 5 provides examples):

Science background includes knowledge of domain-specific lexical relationships.

Directionality requires understanding increases or decreases in scientific quantities.

Numerical reasoning involves interpreting numerical or statistical findings.

Cause and effect requires reasoning about counterfactuals.

Coreference involves drawing conclusions using context stated outside of a rationale sentence.

7 Related work

Fact checking and rationalized NLP models Fact-checking datasets include PolitiFact (Vlachos and Riedel, 2014), Emergent (Ferreira and Vlachos, 2016), LIAR (Wang, 2017), SemEval 2017 Task 8 RumorEval (Derczynski et al., 2017), Snopes (Popat et al., 2017), CLEF-2018 Check-That! (Barrón-Cedeño et al., 2018), Verify (Baly et al., 2018), Perspectrum (Chen et al., 2019), FEVER (Thorne et al., 2018), and UKP Snopes (Hanselowski et al., 2019). Hanselowski et al. (2019) provides a thorough review. To our knowledge, there are no existing data sets for scientific claim verification. We refer to our task as "claim verification" rather than "fact-checking" to emphasize that our focus is to help researchers make sense of scientific findings, not to counter disinformation.

Fact-checking is one of a number of tasks where a model is required to justify a prediction via *rationales* from the source document. The ERASER dataset (DeYoung et al., 2020a) provides a suite of benchmark datasets (including SCIFACT) for evaluating rationalized NLP models.

Related scientific NLP tasks The *citation contextualization* task (Cohan et al., 2015; Jaidka et al., 2017) is to identify spans in a cited document that are relevant to a particular citation in a citing document. Unlike SCIFACT, these citations are not re-written into atomic claims and are therefore more difficult to verify. Expert annotators achieved very low (21.7%) inter-annotator agreement on the BioMedSumm dataset (Cohen et al., 2014), which contains 314 citations referencing 20 papers.

Biomedical question answering datasets include BioASQ (Tsatsaronis et al., 2015) and PubMedQA (Jin et al., 2019), which contain 855 and 1,000 "*yes / no*" questions respectively (Gu et al., 2020). Claim verification and question answering are both knowledge intensive tasks which require an understanding of the relationship between an input query and relevant supporting text.

Automated evidence synthesis (Marshall and Wallace, 2019; Beller et al., 2018; Tsafnat et al., 2014; Marshall et al., 2017) seeks to automate the process of creating *systematic reviews* of the medical literature[7] – for instance, by extracting PICO snippets (Nye et al., 2018) and inferring the outcomes of clinical trials (Lehman et al., 2019; DeYoung et al., 2020b). We hope that systems for claim verification will serve as components in future evidence synthesis frameworks.

8 Conclusion and future work

Claim verification allows us to trace the sources and measure the veracity of scientific claims. These abilities have emerged as particularly important in the context of the current pandemic, and the broader reproducibility crisis in science. In this article, we formalize the task of scientific claim verification, and release a dataset (SCIFACT) and models (VERISCI) to support work on this task. Our results indicate that it is possible to train models for scientific fact-checking and deploy them with reasonable efficacy on real-world claims related to COVID-19.

Scientific claim verification presents a number of promising avenues for research on models capable of incorporating background information, reasoning about scientific processes, and assessing the strength and provenance of various evidence sources. This last challenge will be especially crucial for future work that seeks to verify scientific claims against sources other than the research literature – for instance, social media and the news. We hope that the resources presented in this paper encourage future research on these important challenges, and help facilitate progress toward the broader goal of scientific document understanding.

A Model implementation details

All models are implemented using the Huggingface Transformers package (Wolf et al., 2019).

A.1 Parameters for the final VERISCI system

For the ABSTRACTRETRIEVAL module, VERISCI retrieves the top $k = 3$ documents ranked by TF-IDF similarity using unigram + bigram features. These parameters are tuned on the SCIFACT development set.

When making predictions using the RATIONALESELECTION module described in §5, we find that the usual decision rule of predicting $\hat{z}_i = 1$ when $\tilde{z}_i \geq 0.5$ works well for models trained on SCIFACT. However, for models trained on FEVER and UKP Snopes, we achieve better performance by tuning the classification threshold t, such that $\hat{z}_i = 1$ when $\tilde{z}_i \geq t$, on the SCIFACT dev set. The best threshold was $t = 0.025$ when training on FEVER, and $t = 0.75$ when training on UKP Snopes.

A.2 Training the RATIONALESELECTION module

We experiment with various learning rates when training SCIBERT, BioMedRoBERTa, RoBERTa-base, and RoBERTa-large. Below we describe the setting for training RoBERTa-large.

For models trained on SCIFACT, we use an initial learning rate of 1e-5 on the transformer base and 1e-3 on the linear layer. For FEVER + SCIFACT, the learning rate is set to 1e-5 for the entire model for pre-training on FEVER and fine-tuning on SCIFACT. We use a batch size of 256 through gradient accumulation and apply cosine learning rate decay over 20 epochs to find the best performing model on the dev set.

For models trained on FEVER, we set the learning rate to 5e-6 for the transformer base and 5e-5 for the linear layer. For models trained on UKP Snopes, we set the learning rate 1e-5 for the transformer base and 1e-4 for the linear layer. We find that these learning rates help the models converge. We only train the model for 3 epochs on FEVER and 5 epochs on UKP Snopes because they are larger datasets and the models converged within early epochs.

A.3 Training the LABELPREDICTION module

We adopt similar settings as we used for the RATIONALESELECTION module and only change the learning rate to 1e-5 for the transformer base and 1e-4 for the linear layer for models trained on SCIFACT, FEVER, and UKP Snopes. When training on claim / cited abstract pairs labeled NOINFO, we use the k sentences in the abstract with greatest similarity to the claim as rationales (§5). k is sampled from $\{0, 1\}$ with uniform probability.

A.4 Additional training details

All models are trained using a single Nvidia P100 GPU on Google Colabortoary Pro platform.[8] For the RATIONALESELECTION module, it takes about 150 minutes to train on SCIFACT for 20 epochs. 120 minutes on UKP Snopes for 5 epochs, and 700 minutes on FEVER for 3 epochs. For the LABELPREDICTION module, it takes about 130 minutes to train on SCIFACT for 20 epochs, 160 minutes on UKP Snopes for 5 epochs, and 640 minutes on FEVER for 3 epochs.

A.5 Hyperparameter search

The learning rate, batch size, and number of epochs are the most important hyperparameters. We perform manual tuning and select the hyperparameters that produce the highest F1 on the development set. For the learning rate, we experiment with 1e-3, 1e-4, 5e-5, 1e-5, and 5e-6. For batch size, we experiment with 64 and 256. The number of epochs are cutoff after the model converges.

B Statistical analysis

We assess the uncertainty in the results reported in the main results (Table 4) using a simple bootstrap approach (Dror et al., 2018; Berg-Kirkpatrick et al., 2012; Efron and Tibshirani, 1993). Given our test set with $n_{\text{test}} = 300$ claims, we generate $n_{\text{boot}} = 10,000$ bootstrap-resampled test sets by resampling (uniformly, with replacement) n_{test} claims from the test set. For each resampled test set, we compute the metrics in Table 4. Table 6 reports the mean and standard deviation of these metrics, computed over the bootstrap samples. Table 7 reports dev set metrics. Our conclusion that training on SCIFACT improves performance is robust to the uncertainties presented in these tables.

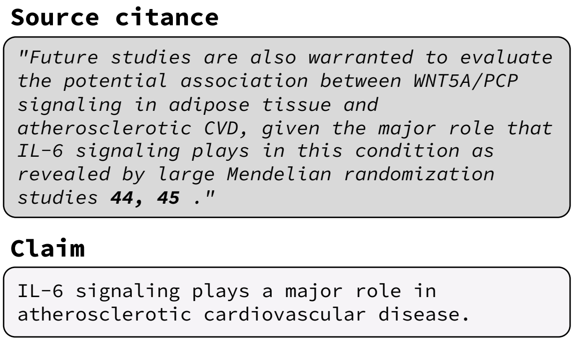
Table 8: Number of cited documents by journal. Some co-cited articles (§3.1) come from journals outside our curated set; these are indicated by "Other".

C Dataset collection and corpus statistics

C.1 Corpus

Source journals Table 8 shows the number of cited abstracts from each of our selected journals. The "Other" category includes "co-cited" (§3.1) abstracts that came from journals not among our pre-defined set.

Distractor abstracts In §3.1, we mention how we increase the size of the corpus by adding *distractor abstracts*. The reason why we do not use the entirety of a large research corpus like S2ORC as our fact-checking corpus is that doing so would introduce many *false negative retrievals*: abstracts containing evidence relevant to a given claim, but not mentioned in the claim's source citance. This can occur either because the citance authors simply were not aware of these abstracts, or because the abstracts were published after the citance was written. These retrievals would be incorrectly marked wrong by our evaluation metrics.



Source citance

*"Future studies are also warranted to evaluate the potential association between WNT5A/PCP signaling in adipose tissue and atherosclerotic CVD, given the major role that IL-6 signaling plays in this condition as revealed by large Mendelian randomization studies **44, 45** ."*

Claim

IL-6 signaling plays a major role in atherosclerotic cardiovascular disease.

Figure 4: A claim written based on a citance. Material unrelated to the citation is removed. The acronym "CVD" is expanded to "cardiovascular disease".

Distractor abstracts as defined in §3.1 have two qualities that make them a good addition to the SciFact corpus: (1) They are cited in the same articles as our evidence abstracts, meaning that they often discuss similar topics and increase the difficulty of abstract retrieval methods based on lexical similarity. (2) The authors of our citances were aware of the distractor abstracts, and chose not to mention them in the citances used to generate claims. This makes them unlikely to be a source of false negative retrievals.

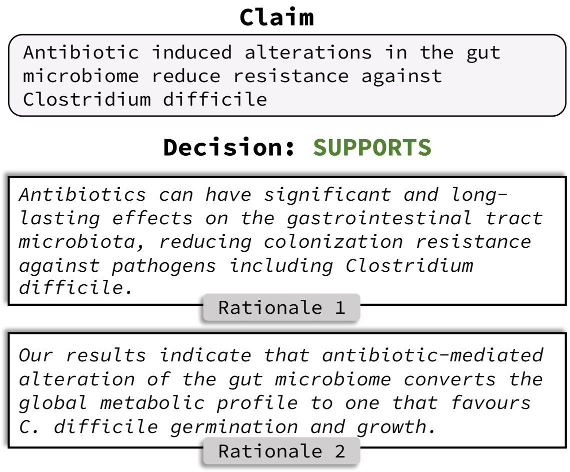
C.2 Annotation examples

Converting citances to claims Figure 4 shows an example of a citance re-written as a claim. The citance discusses the relationship between "atherosclerotic CVD" and "IL-6", and cites two papers (**44** and **45**) as evidence. To convert to a claim, the acronym "CVD" is expanded to "cardiovascular disease", irrelevant information is removed, and the claim is written as an atomic factual statement.

Multiple rationales Figure 5 shows a claim supported by two rationales from the same abstract. The text of each rationale on its own is sufficient to entail the claim.

C.3 Annotators and quality control

Claim writing Student claim writers attended an in-person training session where they were introduced to the task and received in-person feedback from the four experts. Following training, student annotators continued writing claims remotely. The expert annotators monitored claims for quality during the remote annotation process, and provided



Claim

Antibiotic induced alterations in the gut microbiome reduce resistance against Clostridium difficile

Decision: **SUPPORTS**

Antibiotics can have significant and long-lasting effects on the gastrointestinal tract microbiota, reducing colonization resistance against pathogens including Clostridium difficile.

Rationale 1

Our results indicate that antibiotic-mediated alteration of the gut microbiome converts the global metabolic profile to one that favours C. difficile germination and growth.

Rationale 2

Figure 5: A claim supported by two rationales from the same abstract. The text of each rationale on its own provides sufficient evidence to verify the claim.

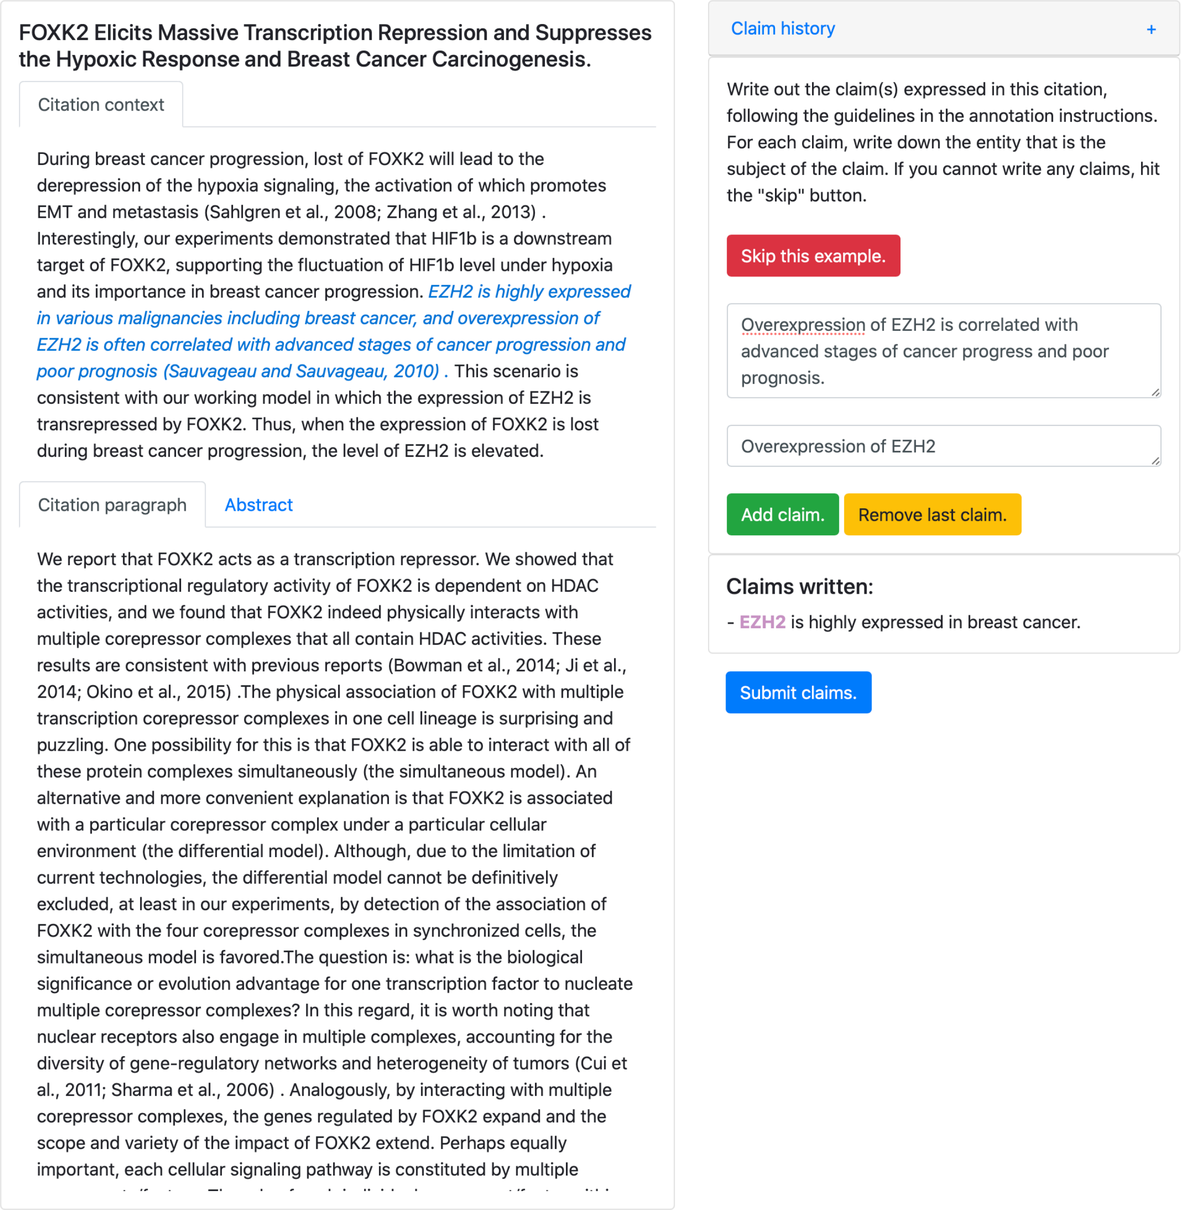
feedback when necessary; low-quality claims were returned to the annotators for re-writing. As a final check, all submitted claims were proofread (and edited if necessary) by an undergraduate whose claims were deemed especially high-quality by the expert annotators.

Claim negations As mentioned in §3.2, an expert annotator wrote claim negations to introduce cases where an abstract REFUTES a claim. The annotator skipped claims that could only be negated by adding obvious triggers like “not”. The majority of claim negations involved a reversal of effect direction; for instance “*A high microerythrocyte count protects against severe anemia*” can be negated as “*A high microerythrocyte count raises vulnerability to severe anemia*”.

Claim verification Annotations were performed remotely through a web interface. Annotators were required to pass a 10-question “quiz” before annotating their own claims. After passing the quiz, subsequent submissions were reviewed by an NLP expert until that expert deemed the annotator reliable. Approved annotators were then assigned to review each others’ submissions. In general, graduate students were assigned to review annotations from undergraduates.

D Annotation interfaces and guidelines

We show a screenshot of the claim writing interface in Figure 6, and the claim verification interface in Figure 7. The complete annotation guide for claim verification is available at the following URL: `https://scifact.s3-us-west-2.amazonaws.com/doc/evidence-annotation-instructions.pdf`.



FOXK2 Elicits Massive Transcription Repression and Suppresses the Hypoxic Response and Breast Cancer Carcinogenesis.

During breast cancer progression, lost of FOXK2 will lead to the derepression of the hypoxia signaling, the activation of which promotes EMT and metastasis (Sahlgren et al., 2008; Zhang et al., 2013) . Interestingly, our experiments demonstrated that HIF1b is a downstream target of FOXK2, supporting the fluctuation of HIF1b level under hypoxia and its importance in breast cancer progression. *EZH2 is highly expressed in various malignancies including breast cancer, and overexpression of EZH2 is often correlated with advanced stages of cancer progression and poor prognosis (Sauvageau and Sauvageau, 2010) .* This scenario is consistent with our working model in which the expression of EZH2 is transrepressed by FOXK2. Thus, when the expression of FOXK2 is lost during breast cancer progression, the level of EZH2 is elevated.

We report that FOXK2 acts as a transcription repressor. We showed that the transcriptional regulatory activity of FOXK2 is dependent on HDAC activities, and we found that FOXK2 indeed physically interacts with multiple corepressor complexes that all contain HDAC activities. These results are consistent with previous reports (Bowman et al., 2014; Ji et al., 2014; Okino et al., 2015) .The physical association of FOXK2 with multiple transcription corepressor complexes in one cell lineage is surprising and puzzling. One possibility for this is that FOXK2 is able to interact with all of these protein complexes simultaneously (the simultaneous model). An alternative and more convenient explanation is that FOXK2 is associated with a particular corepressor complex under a particular cellular environment (the differential model). Although, due to the limitation of current technologies, the differential model cannot be definitively excluded, at least in our experiments, by detection of the association of FOXK2 with the four corepressor complexes in synchronized cells, the simultaneous model is favored.The question is: what is the biological significance or evolution advantage for one transcription factor to nucleate multiple corepressor complexes? In this regard, it is worth noting that nuclear receptors also engage in multiple complexes, accounting for the diversity of gene-regulatory networks and heterogeneity of tumors (Cui et al., 2011; Sharma et al., 2006) . Analogously, by interacting with multiple corepressor complexes, the genes regulated by FOXK2 expand and the scope and variety of the impact of FOXK2 extend. Perhaps equally important, each cellular signaling pathway is constituted by multiple

IL-6 signaling plays a major role in atherosclerotic cardiovascular disease.

Interleukin-6 receptor pathways in coronary heart disease: a collaborative meta-analysis of 82 studies

BACKGROUND Persistent inflammation has been proposed to contribute to various stages in the pathogenesis of cardiovascular disease. Interleukin-6 receptor (IL6R) signalling propagates downstream inflammation cascades. 3 To assess whether this pathway is causally relevant to coronary heart disease, we studied a functional genetic variant known to affect IL6R signalling.

METHODS In a collaborative meta-analysis, we studied Asp358Ala (rs2228145) in IL6R in relation to a panel of conventional risk factors and inflammation biomarkers in 125,222 participants. We also compared the frequency of Asp358Ala in 51,441 patients with coronary heart disease and in 136,226 controls. To gain insight into possible mechanisms, we assessed Asp358Ala in relation to localised gene expression and to postlipopolysaccharide stimulation of interleukin 6.

FINDINGS The minor allele frequency of Asp358Ala was 39%. Asp358Ala was not associated with lipid concentrations, blood pressure, adiposity, dysglycaemia, or smoking (p value for association per minor allele ≥0·04 for each). 9 By contrast, for every copy of 358Ala inherited, mean concentration of IL6R increased by 34·3% (95% CI 30·4-38·2) and of interleukin 6 by 14·6% (10·7-18·4), and mean concentration of C-reactive protein was reduced by 7·5% (5·9-9·1) and of fibrinogen by 1·0% (0·7-1·3). 10 For every copy of 358Ala inherited, risk of coronary heart disease was reduced by 3·4% (1·8-5·0). Asp358Ala was not related to IL6R mRNA levels or interleukin-6 production in monocytes.

INTERPRETATION Large-scale human genetic and biomarker data are consistent with a causal association between IL6R-related pathways and coronary heart disease.

FUNDING British Heart Foundation; UK Medical Research Council; UK National Institute of Health Research, Cambridge Biomedical Research Centre; BUPA Foundation.

P INTERPRETATION Large-scale human genetic and biomarker data are consistent with a causal association between IL6R-related pathways and coronary heart disease.

Abstract

We reduce the task of (span-based) PropBank-style semantic role labeling (SRL) to syntactic dependency parsing. Our approach is motivated by our empirical analysis that shows three common syntactic patterns account for over 98% of the SRL annotations for both English and Chinese data. Based on this observation, we present a conversion scheme that packs SRL annotations into dependency tree representations through joint labels that permit highly accurate recovery back to the original format. This representation allows us to train statistical dependency parsers to tackle SRL and achieve competitive performance with the current state of the art. Our findings show the promise of syntactic dependency trees in encoding semantic role relations within their syntactic domain of locality, and point to potential further integration of syntactic methods into semantic role labeling in the future.

1 Introduction

Semantic role labeling (SRL; Palmer et al., 2010) analyzes texts with respect to predicate argument structures such as "*who* did *what* to *whom*, and *how*, *when* and *where*". These generic surface semantic representations provide richer linguistic analysis than syntactic parsing alone and are useful in a wide range of downstream applications including question answering (Shen and Lapata, 2007; Khashabi et al., 2018), open-domain information extraction (Christensen et al., 2010), clinical narrative understanding (Albright et al., 2013), automatic summarization (Khan et al., 2015) and machine translation (Liu and Gildea, 2010; Xiong et al., 2012; Bazrafshan and Gildea, 2013), among others.

It is commonly acknowledged that syntax and semantics are tightly coupled with each other (Levin and Hovav, 2005). In some forms of linguistic theories (Baker, 1996, 1997), semantic arguments are even hypothesized to be assigned under consistent and specific syntactic configurations. As a matter of practice, annotations of semantic roles (Palmer et al., 2005, *inter alia*) are typically based on existing syntactic treebanks as an additional annotation layer. Annotators are instructed (Babko-Malaya et al., 2006; Bonial et al., 2015) to identify semantic arguments within the predicates' domain of locality,[1] respecting the strong connection between syntax and semantics.

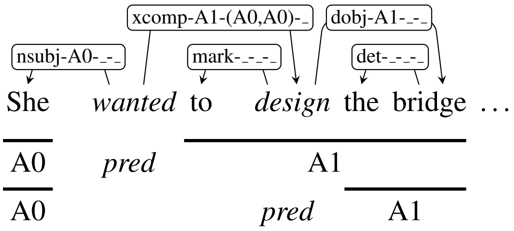

Figure 1: An example sentence with SRL annotations (below) and our joint syntacto-semantic dependency relations (above; described in §3). The two representations can be converted from one to the other. A0 and A1 are short for SRL relations ARG0 and ARG1.

Empirically, syntax has indeed been shown to be helpful to SRL in a variety of ways. Earlier SRL systems have successfully incorporated syntactic parse trees as features and pruning signals (Punyakanok et al., 2008). Recently, neural models with shared representations trained to predict both syntactic trees and predicate-argument structures in a multi-task learning setting achieve superior performance to syntax-agnostic models (Strubell et al., 2018; Swayamdipta et al., 2018), reinforcing the utility of syntax in SRL.

However, researchers are yet to fully leverage

---

[*] Work done during an internship at Bloomberg L.P.

[1] The arguments can potentially be traces and null elements. If a trace is selected as an argument, it is automatically chained to its surface constituent after syntactic movement.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7551–7571,
November 16–20, 2020.

all the theoretical linguistic assumptions and the dataset annotation conventions surrounding the tight connections between syntax and SRL. To do so, ideally, one must perform deep syntactic processing to capture long-distance dependencies and argument sharing. One solution is to introduce traces into phrase-structure trees, which, unfortunately, is beyond the scope of most statistical constituency parsers partially due to their associated increased complexity (Kummerfeld and Klein, 2017). Another solution is to use richer grammar formalisms with feature structures such as combinatory categorial grammar (CCG; Steedman, 2000) and tree adjoining grammar (TAG; Joshi et al., 1975) that directly build syntactic relations within the predicates' *extended* domain of locality. It is then possible to restrict the semantic argument candidates to only those "local" dependencies (Gildea and Hockenmaier, 2003; Liu, 2009; Liu and Sarkar, 2009; Konstas et al., 2014; Lewis et al., 2015). However, such treebank data are harder to obtain, and their parsing algorithms tend to be less efficient than parsing probabilistic context-free grammars (Kallmeyer, 2010).

On the other hand, syntactic dependency trees directly encode bilexical governor-dependent relations among the surface tokens, which implicitly extend the domain of locality (Schneider, 2008). Dependency parsing (Kübler et al., 2008) is empirically attractive for its simplicity, data availability, efficient and accurate parsing algorithms, and its tight connection to semantic analysis (Reddy et al., 2017). Despite ample research community interest in joint models for dependency parsing and SRL (Surdeanu et al., 2008; Hajič et al., 2009; Henderson et al., 2013), a precise characterization of the mapping between semantic arguments and syntactic configurations has been lacking.

In this paper, we provide a detailed empirical account of PropBank-style SRL annotations on both English and Chinese data. We show that a vast majority (over 98%) of the semantic relations are characterized by one of three basic dependency-based syntactic configurations: the semantic predicate 1) directly dominates, 2) is directly dominated by, or 3) shares a common syntactic governor with the semantic argument. The latter two cases are mostly represented by syntactic constructions including relativization, control, raising, and coordination.

Based on our observations, we design a back-and-forth conversion algorithm that embeds SRL relations into dependency trees. The SRL relations are appended to the syntactic labels to form joint labels, while the syntactic governor for each token remains unaltered. The algorithms reach over 99% F1 score on English and over 97% on Chinese data in oracle back-and-forth conversion experiments. Further, we train statistical dependency parsing models that simultaneously predict SRL and dependency relations through these joint labels. Experiments show that our fused syntacto-semantic models achieve competitive performance with the state of the art.

Our findings show the promise of dependency trees in encoding PropBank-style semantic role relations: they have great potential in reducing the task of SRL to dependency parsing with an expanded label space. Such a task reduction facilitates future research into finding an empirically adequate granularity for representing SRL relations. It also opens up future possibilities for further integration of syntactic methods into SRL as well as adaptations of extensively-studied dependency parsing techniques to SRL, including linear-time decoding, efficiency-performance tradeoffs, multilingual knowledge transfer, and more. We hope our work can inspire future research into syntactic treatment of other shallow semantic representations such as FrameNet-style SRL (Baker et al., 1998; Fillmore et al., 2003). Our code is available at `https://www.github.com/bloomberg/emnlp20_depsrl`.

Contribution Our work (1) provides a detailed empirical analysis of the syntactic structures of semantic roles, (2) characterizes the tight connections between syntax and SRL with three repeating structural configurations, (3) proposes a back-and-forth conversion method that supports a fully-syntactic approach to SRL, and (4) shows through experiments that dependency parsers can reach competitive performance with the state of the art on span-based SRL. Additionally, (5) all our analysis, methods and results apply to two languages from distinctive language families, English and Chinese.

2 Syntactic Structures of Semantic Roles

It has been widely assumed in linguistic theories that the semantic representations of arguments are closely related to their syntactic positions with respect to the predicates (Gruber, 1965; Jackendoff, 1972, 1992; Fillmore, 1976; Baker, 1985; Levin, 1993).[2] This notion is articulated as linguistic hypotheses underlying many syntactic theories:

(1) *Universal Alignment Hypothesis:* There exist principles of Universal Grammar which predict the initial [grammatical] relation borne by each nominal in a given clause from the meaning of the clause. (Perlmutter and Postal, 1984, p. 97)

(2) *The Uniformity of Theta Assignment Hypothesis:* Identical thematic relationships between items are represented by identical structural relationships between those items at the level of D[eep]-structure. (Baker, 1985, p. 57)

For theories that posit one-to-one correspondence between semantic roles and syntactic structures (Baker, 1996, 1997), SRL can be treated purely as a syntactic task. However, doing so would require deep structural analysis (Bowers, 2010) that hypothesizes more functional categories than what current syntactic annotations cover.

Nonetheless, the Proposition Bank (PropBank; Kingsbury and Palmer, 2002; Palmer et al., 2005) annotations do capture the domain of locality that is implicitly assumed by these linguistic theories. PropBank defines the domain of locality for verbal predicates to be indicated by "clausal boundary markers" and the annotators are instructed to limit their semantic role annotations to "the sisters of the verb relation (for example, the direct object) and the sisters of the verb phrase (for example, the subject)" (Bonial et al., 2017, p. 746). In cases of syntactically-displaced arguments, the annotators are asked to pick the empty elements that are within the domain of locality, and then syntactic coindexation chains are used to reconstruct the surface semantic role relations. Recognizing displaced arguments is crucial to SRL, so taking full advantage of locality constraints would also require modeling empty elements and movement, for which current NLP systems still lack accurate, efficient, and high-coverage solutions (Gabbard et al., 2006; Kummerfeld and Klein, 2017).

From an empirical perspective, most syntactic realizations for semantic arguments follow certain common patterns even when they are displaced. Indeed, this is partially why syntax-based features and candidate pruning heuristics have been successful in SRL (Gildea and Palmer, 2002; Gildea and Jurafsky, 2002; Sun et al., 2008). Full parsing might not be necessary to account for the majority of cases in the annotations. Thus, knowing the empirical distributions of the arguments' syntactic positions would be highly useful for deciding how detailed the syntactic analysis needs to be for the purpose of SRL. In this section, we provide such a characterization.

Our analysis is based on dependency syntax and complements prior constituent-based characterizations (Palmer et al., 2005). One advantage of syntactic dependencies over phrase-structure trees for the purposes of this paper is that the dependents are often more directly connected to the syntactic governors without intervening intermediate constituents. For example, when a verb has multiple adjunct modifiers, each would create an additional intermediate VP constituent in the argument structure, leading to further separation between the verb and the external argument (subject). In contrast, in a dependency representation, the subject is always directly dominated by the verbal predicate.

2.1 Material

We use the training splits of the CoNLL 2012 shared task data (Pradhan et al., 2012) on both English and Chinese; sentences are originally from OntoNotes 5.0 (Hovy et al., 2006). The SRL annotations are based on English and Chinese PropBank (Kingsbury and Palmer, 2002; Palmer et al., 2005; Xue and Palmer, 2003; Xue, 2008), which are extensively used in SRL research. We choose not to use the SRL-targeted CoNLL 2005 shared task (Carreras and Màrquez, 2005) data since earlier versions of PropBank (Babko-Malaya, 2005) contain many resolvable mismatches between syntactic and semantic annotations (Babko-Malaya et al., 2006). Updated annotation guidelines (Bonial et al., 2015) have fixed most of the identified issues. We convert the Penn TreeBank (PTB; Marcus et al., 1993) and the Penn Chinese TreeBank (CTB; Xue et al., 2005) phrase-structure trees into Stanford Dependencies (SD; de Marneffe et al., 2006) for English (de Marneffe and Manning, 2008; Silveira et al., 2014) and for Chinese (Chang et al., 2009) respectively.[3] SD is semantically-friendly as noted by Schuster and Manning (2016, p. 2371), "Since its first version, SD representation has had the status of being both

---

[2] This is often termed *linking theory* in linguistics (See Levin and Hovav (2005) for a survey).

[3] During conversion, we set copular verbs to be heads, since PropBank marks some copular verbs as predicates.

	Pattern	Example	Percentage English	Percentage Chinese
(D)	pred arg	nsubj *She* *designed* the bridge …	87.5%	82.7%
(C)	arg pred	nsubj xcomp *She* wanted to *design* the bridge …	6.1%	10.4%
(R)	arg pred	rcmod The *bridge*, which is *designed* by her, …	4.7%	5.7%
	arg pred	nsubj xcomp conj *She* wanted to design and *build* the bridge …	1.1%	1.0%
Others			0.5%	0.2%

Table 1: The most common structural relations in the training data between the *predicates* (pred) and the *arguments* (arg). Appendix §C and §D include more examples as well as Chinese data.

a syntactic and a shallow semantic representation", thus it is suited for the development of our joint modeling of syntactic and semantic structures. Indeed, Universal Dependencies (UD; Nivre et al., 2016), which builds upon SD, has been compared with and aligned to meaning representations including UCCA (Hershcovich et al., 2019) and AMR (Szubert et al., 2018).[4]

2.2 Observations

We categorize the syntactic configurations between predicates and arguments and present the results in Table 1. For both English and Chinese, the vast majority, more than 98%, of the predicate-argument relations fall into one of three major categories: the semantic argument is a syntactic child, sibling, or parent of the semantic predicate. Next, we give a brief account of our linguistic observations on the English data associated with each category. See Appendix §C and §D for more examples from both English and Chinese.

pred → arg (D) The predicate directly (D) dominates the semantic argument in the syntactic tree. Not surprisingly, this straightforward type of relation is the most prevalent in the PropBank data, accounting for more than 87% (82%) of all English (Chinese) predicate-argument relations.

arg ← → pred (C) The predicate and the argument share a common (C) syntactic parent. There are two major types of constructions resulting in this kind of configuration: 1) the common parent is a control or raising predicate, creating an open clausal complement (xcomp) relation and 2) there is a coordination structure between the predicate and the common parent and both predicates share a same argument in the semantic structure. Both cases are so common that they are converted to direct dependencies in the enhanced Stanford Dependencies (Schuster and Manning, 2016).

arg → pred (R) The dominance relation between the predicate and the argument is reversed (R). This type of relations is frequently realized through relative clauses (rcmod) and verb participles (e.g., *broken glass*).

Other constructions Many other constructions can be analyzed as combinations of the previously mentioned patterns.[5] For example, a combination of (C)+(C) through control and coordination would derive the structural configuration of the fourth most frequent case in Table 1.

3 Reducing SRL to Dependency Parsing

3.1 Joint Labels

Building on the insights obtained from our analysis, we design a joint label space to encode both syntactic and SRL relations. The joint labels have four components: one syntactic relation and three semantic labels, each corresponding to one of the three most common structural patterns in Table 1.

---

[4] Our choice of SD instead of UD is motivated by the flexibility in conversion to set copular verbs as syntactic heads.

[5] Combinations of (D), (C), and (R) can theoretically account for all possible predicate-argument configurations. However, for a lossless back-and-forth conversion with our proposed joint labels (§3), there are constraints on the argument structures of all the intermediate predicates along the shortest dependency path between the predicate and the argument. See Table 2 for an estimation of how many semantic relations may be decomposed as combinations of the three common structural patterns empirically given our conversion method.

Formally, for a length-n input sentence $w = w_1, \ldots, w_n$, we denote the head of token w_i in the syntactic dependency tree t to be w_{h_i}, or h_i for short. The dependency tree also specifies a dependency relation labeled r_i between each (h_i, w_i) pair. To encode both syntactic and SRL information, we define a dependency tree t', keeping all the h_i's same as in t, but we modify relation r_i to be $r'_i := r_i^{\text{SYN}}\text{-}r_i^{\text{(D)}}\text{-}r_i^{\text{(C)}}\text{-}r_i^{\text{(R)}}$, a concatenation of four labels: $r_i^{\text{SYN}} = r_i$ is the syntactic relation; $r_i^{\text{(D)}}$ describes the SRL relation directly between the predicate h_i and the argument headed by w_i; $r_i^{\text{(R)}}$ specifies the reverse situation where w_i is the predicate and h_i the head of the argument; $r_i^{\text{(C)}}$ encodes the parent-sharing pattern connecting the two predicates and is in the form of a tuple (a, b), corresponding to the case where the SRL argument with label a for predicate h_i is an SRL argument labeled b with respect to predicate w_i.[6] If there exist no such semantic relations, the component labels can be left unspecified, denoted as "_".

In the example of Fig. 1, the joint label between *wanted* and *design* is xcomp-ARG1-(ARG0,ARG0)-_. We can break the joint label into four parts: "xcomp" describes the syntactic relation between the two tokens; "ARG1" indicates that the subtree *to design the bridge* is an argument labeled "ARG1" for predicate *wanted*; (ARG0,ARG0) establishes the argument sharing strategy that ARG0 *she* of *wanted* is an ARG0 for the predicate *design*; finally, "_" indicates there is no argument headed by *wanted* for the predicate *design*.

3.2 Back-and-Forth Conversion

The joint labels encode both syntactic and semantic relations, and it is straightforward to convert/recover the separate dependency and SRL annotations to/from the joint representations.

In the forward conversion (separate → joint), we first extract the syntactic heads of all SRL arguments. Then we enumerate all predicate-argument pairs, and for each pair falling into one of the three most common patterns as listed in Table 1, we insert the SRL argument label in the corresponding slot in the joint label. For predicates sharing more than one argument, we observe that most cases are due to the two predicates sharing all their ARGM relations, so we augment the (C) label with a binary indicator of whether or not to propagate all ARGM arguments. When the two predicates share more than one core argument, which occurs for around 2% of the argument-sharing predicates, we randomly select and record one of the shared arguments in $r_i^{\text{(C)}}$. A more systematic assignment in such cases in future work may lead to further improvement.

As for the backward conversion (joint → separate), the syntactic dependencies can be directly decoupled from the joint label, and we build the SRL relations in three steps: we first identity all the (D) and (R) dependency relations; then, with a top-down traversal of the tree, we identify the shared argument relations through (C) labels; finally, we rebuild the span boundaries using a rule-based approach. Top-down traversal is necessary to allow further propagation of arguments. It allows us to cover some of the less common cases through multiple argument sharings, e.g., the fourth example in Table 1. When a (C) label (a, b) is invalid[7] in that the syntactic governor does not have an argument with label a, we simply ignore this (C) label. In reconstructing the span boundaries, we distinguish among different types of arguments. For (D)-type arguments, we directly take the entire subtrees dominated by the head words of the arguments. For (R)-type arguments, we adopt language-specific heuristics:[8] in English, when the argument (syntactic head) is to the left of the predicate (syntactic child), as commonly happens in relative clause structures, we include all of the argument's children subtrees to the left of the predicate; when the argument is to the right, which usually happens when the predicate is in participle form, we define the right subtree of the argument as its span. For (C)-type arguments, we reuse the span boundaries of the shared arguments.

Table 2 shows the oracle results of our back-and-forth conversion strategies on the training data. We take gold-standard syntactic and SRL annotations and convert them into joint-label representations. Then, we reconstruct the SRL relations through our backward conversion and measure span-based

---

[6] This assumes that the argument must also be an argument to the predicate h_i. In cases where there exists no such relation, we insert a dummy relation $\emptyset$ that gets removed during post-processing between h_i and the argument, and the (C) label between h_i and w_i then becomes $(\emptyset, b)$.

[7] This should not happen in the oracle conversion but may occur in model predictions.

[8] The simple subtree approach does not apply to reconstructing (R)-type arguments since, by definition, the subtree of an (R)-type argument will contain its predicate, which contradicts data annotations. Our heuristics are designed to support a span-based evaluation, and span reconstruction can be omitted if one focuses on a dependency-based evaluation.

Table 2: Oracle back-and-forth conversion results on the training splits.

exact match metrics. Our procedures can faithfully reconstruct most of the SRL relations for both English and Chinese data.[9] English sees a higher oracle score than Chinese. We attribute this result to the synchronization effort between the syntactic and SRL annotations during the evolution of English PropBank (Babko-Malaya et al., 2006; Bonial et al., 2017).

3.3 Models

Given that SRL can be reduced to a dependency parsing task with an extended label space, our model replicates and adapts that of a dependency parser. We follow the basic design of Dozat and Manning (2017), but instead of using LSTMs as input feature extractors, we opt for Transformer encoders (Vaswani et al., 2017), which have previously been shown to be successful in constituency parsing (Kitaev and Klein, 2018; Kitaev et al., 2019), dependency parsing (Kondratyuk and Straka, 2019), and SRL (Tan et al., 2018; Strubell et al., 2018). Next, we score all potential attachment pairs and dependency and SRL relations with the token-level representations through deep biaffine transformation (Dozat and Manning, 2017). After the dependency parsing decoding process, we retrieve the syntactic parse trees and SRL structures via our backward conversion algorithm.

Formally, we associate each token position with a context-sensitive representation by

$$[\mathbf{x_0}, \mathbf{x_1}, \ldots, \mathbf{x_n}] = \text{Transformer}\left(w_0, w_1, \ldots, w_n\right),$$

where w_0 denotes the root symbol for the dependency parse tree, and the inputs to the Transformer network are pretrained GloVe embeddings (Pennington et al., 2014). Alternatively, we can finetune a pre-trained contextualized feature extractor such as BERT (Devlin et al., 2019):[10]

$$[\mathbf{x_0}, \mathbf{x_1}, \ldots, \mathbf{x_n}] = \text{BERT}\left(\texttt{[CLS]}, w_1, \ldots, w_n\right).$$

Next, the same representations $\mathbf{x}$ serve as inputs to five different scoring modules, one for dependency attachment, one for syntactic labeling, and three modules for the newly-introduced SRL-related labels. All of the scoring modules use a deep biaffine (DBA) scoring function introduced by Dozat and Manning (2017) that is widely used in syntactic parsing (Dozat et al., 2017; Shi et al., 2017; Shi and Lee, 2018), semantic dependency parsing (Dozat and Manning, 2018) and SRL (Strubell et al., 2018). For an ordered pair of input vectors $\mathbf{x_i}$ and $\mathbf{x_j}$, an r-dimensional DBA transforms each vector into a d-dimensional vector with multi-layer perceptrons and then outputs an r-dimensional vector $\mathbf{z}_{ij} = \text{DBA}(\mathbf{x_i}, \mathbf{x_j})$, where

$$\mathbf{z}_{ijk} = \left[\text{MLP}^I(\mathbf{x_i}); 1\right]^\top \mathbf{U}_k \left[\text{MLP}^J(\mathbf{x_j}); 1\right],$$

$\mathbf{U} \in \mathbb{R}^{r\times(d+1)\times(d+1)}$, $[; 1]$ appends an element of 1 to the end of the vector, and MLP^I and MLP^J are two separate multi-layer perceptrons with nonlinear activation functions. Following Dozat and Manning (2017), we model dependency attachment probabilities with a 1-dimensional DBA function:

$$P(h_j = i) \propto \exp(\text{DBA}^{\text{ATT}}(\mathbf{x_i}, \mathbf{x_j})).$$

For syntactic labels from vocabulary V^{SYN}, we use a $|V^{\text{SYN}}|$-dimensional DBA function:

$$P(r_j^{\text{SYN}} = V_t^{\text{SYN}}) \propto \exp(\text{DBA}_t^{\text{SYN}}(\mathbf{x_{h_j}}, \mathbf{x_j})).$$

The three semantic label components $r^{(\text{D})}$, $r^{(\text{C})}$, and $r^{(\text{R})}$ are modeled similarly to r^{SYN}.

All the above components are separately parameterized but they share the same feature extractor (Transformer or BERT). We train them with locally-normalized log-likelihood as objectives. During inference, we use a projective[11] maximum spanning tree algorithm (Eisner, 1996; Eisner and Satta, 1999) for unlabeled dependency parsing and then select the highest-scoring component label for each predicted attachment and each component.[12]

---

[9] The English oracle F1 score is higher than the combined (D)+(C)+(R) occurrences of 98%. This is because (1) our method is precision-focused to minimize error propagation in prediction; recall loss of 1.7% is a direct reflection of the unaccounted less-frequent structures, and (2) many arguments, e.g., the fourth most frequent case in Table 1, can be reconstructed through the propagation of (C)-type labels.

[10] In this case, we use the final-layer vector of the last subword unit for each word as its representation and the vector from the prepended `[CLS]` token for the root symbol.

[11] The choice of a projective decoder is motivated by the empirical fact that both English and Chinese dependency trees are highly projective. One may consider a non-projective decoder when adapting to other languages.

[12] Structured and global inference that considers the interactions among all relation labels is a promising future direction.

4 Experiments

We evaluate on two datasets from OntoNotes 5.0 (Hovy et al., 2006) on English and Chinese. Similar to §2, we adopt the CoNLL 2012 dataset splits. To isolate the effects of predicate identification and following most existing work on SRL, we provide our models with pre-identified predicates. We report median performance across 5 runs of different random initialization for our models and our replicated reference models. Implementation details are provided in Appendix §A.

Main Results Table 3 reports the evaluation results. We compare our method with multiple state-of-the-art methods, including BIO-tagging (Tan et al., 2018; Peters et al., 2018), span-based (Ouchi et al., 2018; Li et al., 2019), semi-Markov CRF (Swayamdipta et al., 2018) and structured tuning (Li et al., 2020). We also implement a strong BIO-tagging model trained with a CRF loss as our baseline model (BIO-CRF), which has identical feature extractors as our proposed method.[13] Results show that our models are competitive with the state-of-the-art models, even though our method reduces SRL to syntactic dependency parsing. Our models slightly underperform the BIO-CRF baseline models on English, and the gap is larger on Chinese.[14] This can be attributed to the higher back-and-forth conversion loss on the Chinese data. We observe no significant difference in dependency parsing accuracy when training the Dozat and Manning's (2017) parser alone versus jointly training with our SRL labels.

Additionally, our models make predictions for all predicates in a given sentence at the same time through $O(n)$ joint syntacto-semantic labels with identical features, while most other competitive methods either use different features extracted for different predicates (Tan et al., 2018; Ouchi et al., 2018; Swayamdipta et al., 2018), effectively requiring executing feature extraction multiple times, or require scoring for all $O(n^2)$ or $O(n^3)$ possible predicate-argument pairs[15] (Strubell et al., 2018; Li et al., 2019). In our experiments, our models are 40% faster than the BIO-CRF baseline on average.

Results Broken Down by Argument Type Table 4 presents per-label F1 scores comparing our baseline model with our proposed method. Our method exhibits a similar overall performance to the baseline BIO-CRF model. Most of the difference is materialized on ARG2 and ARGM-ADV. Previous work in the literature finds that these labels are highly predicate-specific and known to be hard to predict (He et al., 2017). We further observe that pretrained feature extractors (BERT) tend to improve the most with respect to these two labels.

Effect of Different Components Table 5 summarizes the results when one or more components of our models are replaced by gold-standard labels.

---

[13] See, for example, He et al. (2017) for a BIO-tagging formulation of SRL.

[14] An anonymous reviewer hypothesizes that the accuracy loss may also be explained by the label sparsity introduced by our joint label scheme.

[15] $O(n^3)$ results from considering all combinations of predicates, span start points and end points. In practice, however, Li et al. (2019) apply pruning to reduce number of candidates.

Setting	F1 Score	
	GloVe	BERT
All predicted	83.0	85.9
+ Gold syntax	88.9	90.0
+ Gold (D)	97.2	97.3
+ Gold (R) (C)	90.1	91.1
Upperbound (Oracle)	98.9	

Table 5: F1 performance on the English dev set if parts of the components are replaced by oracle, as an indicator of potential further gains from each component.

As expected, it is crucial to predict the syntactic trees correctly: failure to do so amounts to 35% or 29% of errors with or without pretrained feature extractors. Accuracy of (D)-type SRL relations has an even larger impact on the overall performance: it is responsible for half of the errors. This indicates that argument labeling is a harder sub-task than syntactic parsing. Further, we observe that the benefits of pretrained feature extractors mostly stem from improved accuracies of the syntactic component. Even with pretrained BERT features, semantic components remain challenging.

5 Related Work

SRL and syntax From the time the SRL task was first introduced (Gildea and Jurafsky, 2002; Gildea and Palmer, 2002; Màrquez et al., 2008; Palmer et al., 2010), syntax has been shown to be a critical factor in system performance. Most models use syntactically-derived features (Pradhan et al., 2005; Punyakanok et al., 2005; Swanson and Gordon, 2006; Johansson and Nugues, 2008; Toutanova et al., 2008; Xue, 2008; Zhao et al., 2009, *inter alia*) and syntax-based candidate pruning (Punyakanok et al., 2008). There have been many approaches for joint syntactic parsing and SRL models, including approximate search (Johansson, 2009) and dual decomposition (Lluís et al., 2013) to resolve feature dependencies, and synchronous parsing to simultaneously derive the (disjoint) syntactic and SRL structures (Henderson et al., 2008; Li et al., 2010; Henderson et al., 2013; Swayamdipta et al., 2016). In contrast, our work unifies the two representations into common structures.

Joint labels The idea of using joint labels for performing both syntactic and semantic tasks is similar to that of function parsing (Merlo and Musillo, 2005; Gabbard et al., 2006; Musillo and Merlo, 2006). Ge and Mooney (2005) use joint labels for semantic parsing as well. Earlier approaches for SRL have considered joint syntactic and semantic labels. Due to lack of characterization of the common structures, most work either focuses on the subtask of argument identification (Yi and Palmer, 2005), predicts the set of all SRL labels for each argument and links them to predicates in a second stage (Merlo and Musillo, 2008), or models joint labels independently for each predicate (Samuelsson et al., 2008; Lluís and Màrquez, 2008; Morante et al., 2009; Rekaby Salama and Menzel, 2019). Instead, our work aims at extracting all predicate-argument structures from a sentence. Our joint label design is related to that of Qiu et al. (2016). They annotated a Chinese SRL corpus from scratch with a similar label scheme, while in this paper, we show that it is possible to extract such joint labels from existing data annotations.

Tree approximation In the task of semantic dependency parsing (Oepen et al., 2014), dependency structures are used to model more aspects of semantic phenomena than predicate-argument structures, and the representations are more general directed acyclic graphs. These graphs can be approximated by trees (Du et al., 2014; Schluter et al., 2014; Schluter, 2015) such that tree-based parsing algorithms become applicable. Unlike this line of research, we limit ourselves to the *given* syntactic trees, as opposed to finding the *optimal approximating* trees, and we focus on the close relations between syntax and SRL.

Dependency-based SRL Although predicate-argument structures are traditionally defined in constituency terms, dependency-based predicate-argument analysis (Hacioglu, 2004; Fundel et al., 2007) has been popularized through the CoNLL 2008 and 2009 shared tasks (Surdeanu et al., 2008; Hajič et al., 2009) and has been adopted by recent proposals of decompositional semantics (White et al., 2017). Choi and Palmer (2010) consider reconstructing constituency-based representations from dependency-based analysis. We confirm their findings that through a few heuristics, the reconstruction can be done faithfully.

Neural SRL The application of neural models to SRL motivates the question of whether modeling syntax is still necessary for the task (He et al., 2017). Similar to non-neural models, syntactic trees are used to construct features (Roth and Lapata, 2016; Kasai et al., 2019; Wang et al., 2019; Xia et al., 2019b; Zhang et al., 2019) and to prune candidates (Täckström et al., 2015; He et al., 2018b, 2019). Alternatively, they are used to determine network structures (Marcheggiani and Titov, 2017; Li et al., 2018), including tree-LSTM, graph convolutional networks (Niepert et al., 2016) and syntax-aware LSTM (Qian et al., 2017). On the other hand, syntax-agnostic models (Collobert and Weston, 2007; Zhou and Xu, 2015; Cai et al., 2018; He et al., 2018a; Tan et al., 2018; Li et al., 2019) have shown competitive results. Our results contribute to the ongoing debate by adding further evidence that the two tasks are deeply-coupled. Future work may further explore how much syntactic knowledge has been implicitly obtained in the apparently syntax-agnostic models.

Multi-task learning Our models share neural representations across the syntactic and the SRL labelers. This is an instance of multi-task learning (MTL; Caruana, 1993, 1997). MTL has been successfully applied to SRL (Collobert and Weston, 2008; Collobert et al., 2011; Shi et al., 2016) in many state-of-the-art systems (Strubell et al., 2018; Swayamdipta et al., 2018; Cai and Lapata, 2019; Xia et al., 2019a). A potential future extension is to learn multiple syntactic (Søgaard and Goldberg, 2016) and semantic representations (Peng et al., 2017; Hershcovich et al., 2018) beyond dependency trees and PropBank-style SRL at the same time.

6 Conclusion

Linguistic theories assume a close relationship between the realization of semantic arguments and syntactic configurations. This work provides a detailed analysis of the syntactic structures of PropBank-style SRL and reveals that three common syntactic patterns account for 98% of annotated SRL relations for both English and Chinese data. Accordingly, we propose to reduce the task of SRL to syntactic dependency parsing through back-and-forth conversion to and from a joint label space. Experiments show that dependency parsers achieve competitive results on PropBank-style SRL with the state of the art.

This work shows promise of a syntactic treatment of SRL and opens up possibilities of applying existing dependency parsing techniques to SRL. We invite future research into further integration of syntactic methods into shallow semantic analysis in other languages and other formulations, such as frame-semantic parsing, and other semantically-oriented tasks.

A Implementation Details

We use two types of encoders in our models: randomly-initialized Transformer (Vaswani et al., 2017) networks and pre-trained BERT (Devlin et al., 2019). For Transformer networks, the input representations are concatenations of 100-dimensional randomly-initialized word embeddings, 100-dimensional pre-trained GloVe (Pennington et al., 2014) embeddings, 16-dimensional predicate indicator embeddings and 128-dimensional positional embeddings. The Transformer networks have 8 self-attention and feed-forward layers. Each self-attention layer has 8 attention heads, and each feed-forward layer has a dimensionality of 2048. For BERT models, we fine-tune the pretrained BASE model by Devlin et al. (2019) and Wolf et al. (2019).

The decoders consist of an unlabeled attachment scorer and several labeling components for the syntactic dependencies and SRL relations. The design and hyperparameters follow that of Dozat and Manning (2017). The biaffine scoring function for the unlabeled attachment scorer has a dimensionality of 400, while each labeling component has 100 dimensions. For our baseline, we build on top of Tan et al.'s (2018) BIO tagging model and further add a CRF-based decoding layer following Yang et al. (2018). Contextualized representation at each token's position is passed through a multi-layer perceptron with one hidden layer consisting of 256 hidden units and PReLU (He et al., 2015) activation function to obtain the scores for each tag.

64 training instances (16 when using BERT) are grouped into a minibatch, and the gradients are clipped (Pascanu et al., 2013) at 5.0. We use Adam (Kingma and Ba, 2015) optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1 \times 10^{-8}$. When using GloVe embeddings and Transformers, we set the learning rate to be 1×10^{-4}; when fine-tuning BERT, the learning rate is lowered to 1×10^{-5}. Learning rates are multiplied by 0.1 once the development performance stops increasing for 5 epochs. All the models are trained until the learning rates are lowered three times and the performance plateaus on the development sets. Our implementation is based on PyTorch (Paszke et al., 2017).

On a single V100 GPU, the baseline BIO-CRF model parses 96.4 sentences/sec and our proposed model processes at 159.1 sentences/sec on average.

Throughout our experiments, all the hyperparameters are taken directly from relevant suggestions in previous literature (Dozat and Manning, 2017; Tan et al., 2018; Kitaev et al., 2019) without tuning. An extensive hyperparameter search may lead to further accuracy improvements.

	Trained with	P	R	F
Oracle	Gold	99.7	98.2	98.9
	Predicted	99.6	93.2	96.3
GloVe	Gold	83.2	82.9	83.0
	Predicted	84.7	80.6	82.6
BERT	Gold	86.2	85.5	85.8
	Predicted	86.9	83.2	85.1

Table 6: English back-and-forth oracle and dev set results using *gold-standard* dependency trees versus *predicted* trees as *training* data.

B Additional Model Analysis

B.1 Training without Gold Syntactic Trees

Our method leverages the gold-standard dependency trees in the *training* data to design high-fidelity back-and-forth conversion algorithms. Table 6 considers a scenario where we do not have access to such gold trees during *training*: we jackknife the data into 8 folds, train parsers using 7 folds and predict trees on the remaining fold. Our models show similar F1 scores under this condition as that of using gold trees, while the recall is traded for precision since our conversion method is precision-focused.

This is not a realistic scenario given that existing PropBank-style SRL annotations are all based on syntax, so as a matter of practice we always have access to gold trees during *training*. Nonetheless, these experiments point to the viability of using predicted trees in practice without incurring a significant loss in F1 scores.

B.2 Accuracies by SRL Relation Types

In Table 7, we break down the accuracies by the syntactic patterns of the SRL relations. Compared with our baseline, a replication of Tan et al. (2018), our models achieves higher or competitive results on (D)-type and (R)-type SRL relations. These two types establish a direct or reverse semantic relation with respect to the syntactic structure. In contrast, the (C)-type relations require accurate predictions of sibling relations as well as at least two SRL-related labels and are thus more prone to error propagation. We hypothesize that global scoring of the dependency structures can alleviate

Type	English		Chinese	
	Baseline	Ours	Baseline	Ours
(D)	88.1	88.1	82.8	83.4
(C)	80.3	76.6	53.3	50.0
(R)	78.7	79.3	46.3	46.8
Overall	83.5	83.0	74.1	72.9

Table 7: Per-pattern F1 scores on the dev sets.

	GloVe			BERT		
	Base.	Ours	Δ	Base.	Ours	Δ
10%	71.3	72.4	+1.1	82.3	81.5	−0.8
3%	59.9	62.0	+2.1	78.2	77.6	−0.6
1%	47.5	48.7	+1.2	69.3	73.2	+3.9

Table 8: English dev F1 scores, when trained with different percentages of the training data.

this issue, and we leave that to future work.

B.3 Learning Curve

In Table 8, we train the models with varying amounts of training data. With GloVe embeddings, our models exhibit higher performance when training data is limited, as compared with the corresponding baselines. When the pre-trained BERT feature extractor is used, both the baseline and our model require far less data to reach similar levels of performance. Our model shows significant improvement when the amount of training data is extremely limited (1%), and the baseline edges out for the other two settings (3% and 10%).

C Additional English Data Analysis

Among the three common patterns, (D)-type SRL relations are the most frequent and easiest to understand. In this section, we provide additional examples to shed light on (C)-type and (R)-type relations. We also show some sentences with more complex syntactic phenomena than what can be handled by our joint-label scheme. In all the examples, we boldface the predicates, underline the head words of the arguments, and highlight only the shortest dependency paths connecting them.

C.1 (C)-Type Relations

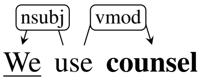
The (C)-type relations are most frequently used in ARG0 (55%) and ARG1 (19%) relations, in contrast to (D)-type relations, where the percentages are much lower (34% and 17% respectively). This can be explained by the fact that a lot of (C)-type relations are used in control and raising verb constructions. A second major construction associated with (C)-type relations is conjunction, which shares either core or peripheral arguments among the conjuncts. The most common dependency relation labels connecting the common parents and the predicates are: “xcomp” (39%), “conj” (37%), “vmod” (9%), and “dep” (6%).

“xcomp” signifies control/raising structures. Popular common parent words (the control/raising verbs) include “want”, “expect”, “continue”, “begin”, etc.

“conj” represents a coordination structure. Since the first conjunct is a syntactic head of other conjuncts in Stanford Dependencies, any shared argument will result in a (C)-type relation.

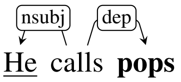
“vmod” denotes non-finite verbal modifiers whose missing subjects can often be found in the main clauses. For example:

(3) We use all wisdom to **counsel** every person.



A lot of problematic instances of “dep” can be attributed to failures of constituency-to-dependency conversion, where it should have been recognized as a relation corresponding to another construction. For example:

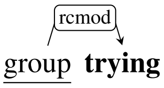
(4) He calls . . . and **pops** in every once in a while.



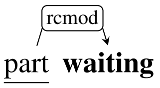
C.2 (R)-Type Relations

(R)-type relations are frequently used in relative clauses, as “rcmod” accounts for 47% of the syntactic relations connecting the predicates and the arguments. For examples:

(5) . . . another group that is always **trying** to . . .

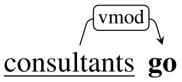


(6) . . . outer part of the nursery where we were **waiting** . . .

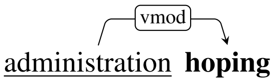


The second most common construction involves "vmod" (28%). Different from the "vmod" relations involved in (C)-type relations, the non-finite clauses usually modify noun phrases in (R)-type relations. For examples:

(7) . . . developed . . . management consultants to **go** out . . .

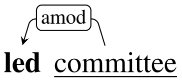


(8) The administration, **hoping** to de-escalate the violence, is appealing to both sides.



The third most common type of cases involves participial adjectives, using "amod" syntactic relation (17%). Since the verb is modifying the noun as an adjective, the syntactic dependency and the semantic relation are reversed. For example:

(9) . . . a fact finding American **led** committee . . .

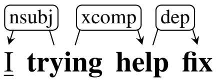


C.3 Others

The other constructions besides the three most common patterns are a mixture of data annotation errors, constituency-to-dependency failures, and combinations of the frequent patterns.

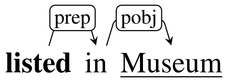
If the argument is shared with other predicates along the dependency path, then our conversion algorithm can recover the SRL relation through multiple (C)-type labels. For example, in the following sentence, the argument "I" is shared across three predicates "trying", "help" and "fix" as ARG0's.

(10) I've been **trying** to **help** him **fix** . . .



Annotation inconsistencies can result in rare patterns beyond the scope of the current design of our joint label. For example, in the following sentence, the SRL annotation decides that "the Museum of Modern Art" is ARGM-LOC of "listed", making the predicate a grandparent of the argument. A simple fix that simply includes the preposition "in" as part of the argument span (as is annotated in most other examples) will change this case into a (D)-type relation.

(11) Now your name is **listed** in the Museum of Modern Art.



D Chinese Data Analysis

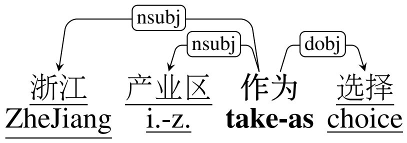
Despite the fact that Chinese and English are very different languages from two distinctive language families, they exhibit similar distributions of patterns when it comes to the syntactic patterns of SRL relations. The three most common types, (D)-, (C)- and (R)-type relations, account for over 98% of all annotated predicate-argument relations. In the following examples, BA denotes a *ba* construction, DE refers to a *de* particle, and CLASSIFIER represents Chinese measure words for quantity expressions (Huang et al., 2008).

D.1 (D)-Type Relations

Similarly to English, most Chinese SRL relations parallel the syntactic counterparts. For example, in the following sentence, each of the three arguments of the predicate corresponds to a direct dependent in the dependency structure.

(12) 浙江 把 特色 产业区
ZheJiang BA featured industrial-zones
作为 经济 发展 的 战略
take-as economic development DE strategic
选择
choice

"Zhejiang uses its featured industrial zones as a strategic choice for economic development."

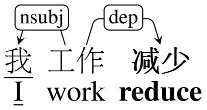


"i.-z." is short for "industrial-zones".

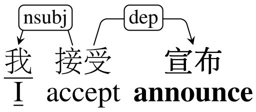
D.2 (C)-Type Relations

In a (C)-type relation, the most frequent syntactic labels between the common parent and the predicate are "dep" (37.5%), "conj" (34.4%) and "mmod" (9.6%). "conj" denotes coordinations, as discussed in the English data analysis section. Unlike English data, the Chinese annotations use a large percentage of "dep" relations. A closer inspection reveals that most of the instances correspond to open clausal complements ("xcomp") and coordinations ("conj"). (See English data analysis section for analysis.)

(13) 我 真的 非常 努力 地 工作 . . . 以
I really very diligently DE work . . . to
减少 . . .
reduce . . .
"I work very diligently to reduce . . . "

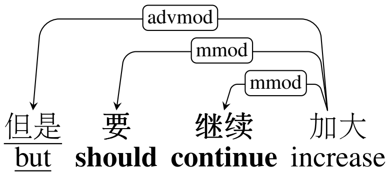


(14) 我 能 接受 这个 , 并且 能 **宣布** 它
I can accept this , and can **announce** it
"I can accept this and announce it"



"mmod" is a dependency relation specific to Chinese. This label represents modal verb modifiers. In the Chinese SRL data, many of the modal verbs are annotated as predicates, resulting in (C)-type patterns. Additionally, "mmod" is frequently overloaded with conversions from some multi-verb constructions. The following sentence shows a common argument of two predicates. The first one ("should") is a modal verb, while the second one ("continue") is often treated as a standalone verb in a multi-verb construction (Li and Thompson, 1989).

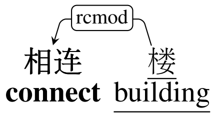
(15) 但是 **要** **继续** 加大 改革
but **should continue** increase reform
力度
strength
"but we should continue to strengthen the reforms"



D.3 (R)-Type Relations

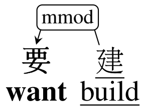
Similar to English, (R)-type relations are frequently used in relative clauses in Chinese as well. "rcmod" accounts for 64% of the syntactic relations connecting the predicates and the arguments. For example:

(16) 一 栋 众多 商户 **相连** 的
a CLASSIFIER many merchants **connect** DE
商业 楼
commercial building
"a commercial building that connects many merchants"



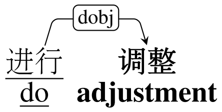
Other common constructions include "mmod" (12.9%), "dep" (6.6%) and "dobj" (5.9%). Complements of modal verbs can result in (R)-type patterns, illustrated as follows:

(17) 上海 **要** 建 四 个 中心
Shanghai **want** build four CLASSIFIER center
"Shanghai wants to build itself as four centers"



In (R)-type patterns, "dobj" commonly corresponds to light verb constructions where the object nouns are nominalized predicates while the syntactic heads are light verbs without much semantic meaning. Here we show an example:

(18) 进行 适当 **调整**
do adequate **adjustment**
"adjust adequately"



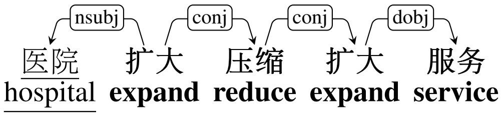
Finally, cases involving "dep" relations include miscellaneous data annotation errors and constituency-to-dependency conversion errors.

D.4 Others

Similar to English, many of the unaccounted Chinese syntactic patterns of SRL relations are combinations of the three basic patterns. The following sentence illustrates propagation of an argument through multiple (C)-type structures.

(19) 医院 **扩大** 药品 和 医疗
hospital **expand** medicine and medical
仪器 采购 规模 从而 **压缩**
equipment purchase scale in-order-to **reduce**
单位 成本 、 **扩大** **服务**
unit cost , **expand service**

“Hospitals expand the scale of purchasing medicines and medical equipments in order to reduce unit costs and to expand their service”



PARADE: A New Dataset for Paraphrase Identification Requiring Computer Science Domain Knowledge

Yun He, Zhuoer Wang, Yin Zhang, Ruihong Huang, James Caverlee
Department of Computer Science and Engineering, Texas A&M University
`{yunhe, wang, zhan13679, huangrh, caverlee}@tamu.edu`

Abstract

We present a new benchmark dataset called PARADE for paraphrase identification that requires specialized domain knowledge. PARADE contains paraphrases that overlap very little at the lexical and syntactic level but are semantically equivalent based on computer science domain knowledge, as well as non-paraphrases that overlap greatly at the lexical and syntactic level but are not semantically equivalent based on this domain knowledge. Experiments show that both state-of-the-art neural models and non-expert human annotators have poor performance on PARADE. For example, BERT after fine-tuning achieves an F1 score of 0.709, which is much lower than its performance on other paraphrase identification datasets. PARADE can serve as a resource for researchers interested in testing models that incorporate domain knowledge. We make our data and code freely available.[1]

1 Introduction

Paraphrases are sentences that express the same (or similar) meaning by using different wording (Bhagat and Hovy, 2013). Automatically identifying paraphrases and non-paraphrases has proven useful for a wide range of natural language processing (NLP) applications, including question answering, semantic parsing, information extraction, machine translation, textual entailment, and semantic textual similarity.

Paraphrase identification (PI) is typically formalized as a binary classification problem: given two sentences, determine if they roughly express the same meaning. Traditional paraphrase identification approaches (Mihalcea et al., 2006; Kozareva and Montoyo, 2006; Wan et al., 2006; Das and Smith, 2009; Xu et al., 2014) mainly rely on lexical and syntactic overlap features to measure the semantic similarity between the two sentences. Examples include string-based features (e.g., whether two sentences share the same words), part-of-speech features (e.g., whether shared words have the same POS tags), and dependency-based features (e.g., whether two sentences have similar dependency trees).

s1: the lowest level of code made up of 0s and 1s.
s2: binary instructions used by the cpu.
Label: paraphrase (both describe “Machine Code”)

s3: a graph representation that uses a 2d array such that if arr[i][j] == 1, there is an edge between **vertices** i and j
s4: a matrix which records the number of direct links between **vertices**
Label: paraphrase (both describe “Adjacency Matrix”)

s5: how **the optimal solution** to **a linear programming problem** changes as the <u>problem data</u> are modified.
s6: how changes in the <u>coefficients</u> of **a linear programming problem** affect **the optimal solution**
Label: non-paraphrase

Table 1: Examples of paraphrases and non-paraphrases from the computer science domain. Judgments are made based on domain knowledge rather than lexical or syntactic features. Overlapping words (other than stop-words) are in bold and key different words are underlined.

However, these shallow lexical and syntactic overlap features may not effectively capture the domain-specific semantics of the two sentences. A typical situation where models based on these overlap features may fail is *a pair of sentences that overlap very little at the lexical and syntactic level but are semantically equivalent* ***based on domain knowledge***. Consider the two paraphrases s1 and s2 in Table 1. Both describe *machine code* though they have very little overlap. In order to correctly identify paraphrases like this pair, it is necessary to have specialized domain knowledge that a processor (CPU) can only understand binary instructions made up of 0s and 1s. On the other hand, *a pair*

---

[1] `https://github.com/heyunh2015/PARADE_dataset`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7572–7582,
November 16–20, 2020.

of sentences that overlap greatly at the lexical and syntactic level but are not semantically equivalent ***based on domain knowledge*** can also confuse both non-expert annotators and NLP models. Consider the non-paraphrase of s5 and s6 in Table 1 as an example. Sentence s5 is about a sensitivity analysis between the problem data and the optimal solution while s6 is about a sensitivity analysis between the coefficients and the optimal solution; these two cases are fundamentally different, requiring specialized domain knowledge of linear programming to distinguish the two. These examples highlight the importance of **specialized domain knowledge** for identifying paraphrases and non-paraphrases correctly.

Recent neural models (Nie and Bansal, 2017; Parikh et al., 2016; Chen et al., 2017) that go beyond traditional approaches based on lexical and syntactic features have demonstrated state-of-the-art performance on paraphrase identification. For example, BERT and its variants (Devlin et al., 2018; Liu et al., 2019; Yang et al., 2019; Lan et al., 2019; Raffel et al., 2019) have achieved the best results on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018) on two paraphrase identification datasets: the Microsoft Research Paraphrase Corpus (MRPC) and Quora Question Pairs (QQP). Using massive pre-training data and a flexible bidirectional self-attention mechanism, BERT and its variants are able to better model the semantic relationship between sentences. Moreover, two recent studies (Petroni et al., 2019; Davison et al., 2019) observe that BERT without fine-tuning can even capture world knowledge and can answer factual questions like "place of birth" and "who developed the theory of relativity." Naturally, we are curious to know if these neural models can correctly identify paraphrases that require specialized domain knowledge like the examples shown in Table 1.

Hence, our overarching research goal is to create new datasets and enable new models for high-quality *paraphrase identification based on domain knowledge*. Because previous paraphrase datasets (Dolan and Brockett, 2005; Dolan et al., 2004; Xu et al., 2014; Lan et al., 2017; Iyer et al., 2017; Zhang et al., 2019) were not originally designed and constructed from the perspective of domain knowledge, to date there is no such dataset that requires specialized domain knowledge to discern the quality of two candidate sentences as paraphrases. As a first step, we focus in this paper on the computer science domain. Specifically, we require a dataset of paraphrases that overlap very little but are semantically equivalent, and of non-paraphrases that have overlap greatly but are not semantically equivalent based on computer science domain knowledge. Correspondingly, there is a research gap in understanding if modern neural models can achieve exemplary performance on such a dataset, especially in comparison with existing paraphrase identification datasets (that lack such specialized domain knowledge). In sum, this paper makes four contributions:

- First, we propose a novel extensible framework for inexpensively collecting domain-specific sentential candidate paraphrases that are characterized by specialized knowledge. The key idea is to leverage large-scale online collections of *user-generated flashcards*. We treat definitions on each flashcard's back side that correspond to a common entity on the front side (e.g., "machine code") as candidate paraphrases.

- Due to the noise in user-generated flashcards and heterogeneity in the aspects in the candidate paraphrases, our second contribution is a refinement strategy coupled with annotation by domain experts to create a new gold dataset called PARADE (**PARA**phrase identification based on **D**omain knowledg**E**). PARADE contains 4,778 (46.9%) paraphrases and 5,404 (53.1%) non-paraphrases that describe 788 distinct entities from the computer science domain and is the *first publicly available benchmark* for paraphrase identification based on domain knowledge.

- Third, we evaluate the quality of state-of-the-art paraphrase identification models on PARADE and existing paraphrase identification datasets like MRPC and QQP. We find that both state-of-the-art neural models (which have shown strong performance on existing PI datasets) and non-expert human annotators have poor performance on PARADE. For example, BERT after fine-tuning only achieves 0.709 in terms of F1 on PARADE compared to 0.893 on MRPC and 0.877 on QQP. Such a gap indicates the need for new models that can better exploit specialized domain knowledge.

- Finally, we show that incorporating external domain knowledge into the training of models like BERT offers the potential for improvements on PARADE. Concretely, we find that SciBERT – a BERT variant pre-trained on a corpus of computer science papers – improves the accuracy from 0.729 to 0.741. This improvement is encouraging, and suggests the need for further enhancements in incorporating domain knowledge into NLP models.

2 Related Work

Framework for Collecting Paraphrases: The basic idea of collecting a paraphrase dataset is to connect parallel data that are related to the same reference, like different news articles reporting the same event (MRPC) (Dolan and Brockett, 2005; Dolan et al., 2004), multiple descriptions of the same video clip (Chen and Dolan, 2011), multiple phrasal paraphrases on the web to describe the same concept (Hashimoto et al., 2011), different translations of a foreign novel (Barzilay and Elhadad, 2003), and multiple tweets that relate to the same topic (Xu et al., 2014) or contain the same URL (Lan et al., 2017).

In this paper, we propose a novel framework to collect sentential paraphrases from online user-generated flashcards, where different definitions (on the back of flashcards) of the same entity (on the front of flashcards) are probably paraphrases. The main advantage of this framework is that it can easily collect domain-specific paraphrases. Since flashcard websites like Quizlet are mainly used by students to prepare for quizzes and exams, these flashcards are often organized by subject, providing a rich source of domain-specific paraphrases.

Datasets for Paraphrase Identification: To our best knowledge, there are five publicly available sentential paraphrase identification datasets: Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005; Dolan et al., 2004) contains 5,801 pairs of sentences from news articles, PIT-2015 (Xu et al., 2014) contains 18,762 pairs of tweets on 500 distinct topics, Twitter-URL (Lan et al., 2017) contains 51,524 pairs of tweets containing 5,187 distinct URLs, Quora Question Pairs (QQP) (Iyer et al., 2017) contains 400K[2] pairs of question pairs on Quora and PAWS (Zhang et al., 2019) contains 53,402 pairs of sentences by using word scrambling methods based on QQP. These datasets were not originally designed and constructed from the perspective of domain knowledge. Hence, we present PARADE, the first sentential dataset for paraphrase identification based on domain knowledge as shown in Table 1, as a complement to these previous efforts.

Domain-Specific Phrasal Paraphrases: Some previous work aims to extract domain-specific **phrasal** paraphrases (Pavlick et al., 2015; Zhang et al., 2016; Ma et al., 2019), like "head" and "skull" in the Biology domain. In this paper, we focus on sentential paraphrases rather than phrasal paraphrases, which require models that consider context and domain knowledge.

Pre-trained Language Models with Domain Knowledge: Recently, some works have sought to incorporate domain knowledge into pre-trained language models such as BERT. For example, SciBERT (Beltagy et al., 2019) uses the same architecture as BERT-base but is pre-trained over a corpus of 1.14M papers, with 18% of papers from the computer science domain and 82% from the biomedical domain. It has been reported that SciBERT outperforms BERT-base which is pre-trained over Wikipedia and bookscorpus on a variety of tasks like named entity recognition in the both domains.

3 Collecting Domain-Specific Paraphrases from Online Flashcards

In this section, we propose a novel framework that constructs a domain-specific paraphrase corpus from online user-generated flashcards. We choose *computer science* as the target domain in this paper as a first step. The framework can be easily applied to construct datasets of other domains.

Many web platforms provide flashcards like Quizlet, StudyBlue, AnkiWeb, and CRAM. Each flashcard generated by a user is made up of an entity on the front and a definition describing or explaining the entity on the back. The purpose of flashcards is to help users to understand and remember concepts like "machine code."

Our core idea is that two different definitions probably express the same meaning if they have the same entity on the front. Hence, they can be paired as a candidate paraphrase. Our framework can collect arbitrarily many definitions generated by users independently, leading to broad coverage of how native speakers are likely to describe an entity in a specialized domain. By pairing the va-

---

[2] The size of QQP is much larger than other datasets but its authors claim that the ground-truth labels are not guaranteed to be perfect.

riety of definitions about concepts (like "machine code"), paraphrases and non-paraphrases that requires specialized domain (e.g., computer science) knowledge to discern are generated and collected.

3.1 Collecting Entity-Definition Pairs Related to Specialized Domains

We first collect domain-specific terminology and then collect entity-definition pairs from a popular flashcard website.

Domain-specific terminology: Ren et al. (2014) presented a dataset of 55,171 research papers in the computer science domain, collected from 2,414 conferences or journals, covering sub-fields like artificial intelligence, computer architecture, networking, and so on. Naturally, high document frequency phrases from these papers can be regarded as computer science terminology. Therefore, 3,813 phrases with document frequency higher than 20 are extracted from these papers, where examples are shown in Table 2:

Table 2: Examples of Computer Science Terminology with Document Frequency (DF)

Phrases	DF	Phrases	DF
sensor networks	939	mobile devices	425
information retrieval	688	source code	375
data structures	467	data structure	348
query processing	429	software systems	341

Next, we use these phrases as queries to search flashcards related to computer science from Quizlet, a well-known online flashcards website with a convenient search API.[3] To ensure paraphrases generated from the flashcards are related to the target domain, we only keep the flashcards where the entity on the front is drawn from our computer science terminology set (of size 3,813). Some example flashcards are presented in Table 3.

For each flashcard, we extract the entity from the front and the definition from the back to form an entity-definition pair. Since there are many duplicate entities and definitions on Quizlet flashcards, we merge the same definitions and group unique definitions by entities. Further, we only keep entities and definitions in English and in the form of pure text (some definitions contain images) and remove entities with fewer than 5 unique definitions. Finally, 30,917 unique entity-definition pairs are obtained.

Table 3: Examples of Flashcards Related to Computer Science Domain

Entity (Front)	Definition (Back)
Artificial Intelligence	s1: simulating logical thoughts, patterns and responses
Artificial Intelligence	s2: simulates human thinking and behavior, such as the ability to reason and learn
Artificial Intelligence	s3: the ability of a computer or a robot to learn from new information
Artificial Intelligence	s4: machines that can apply and acquire knowledge

3.2 Generating Candidate Paraphrases

For the definitions that describe or explain the same entity, it is not guaranteed that any two of them will form a paraphrase because the definitions might focus on different aspects or facets of the entity. An example is shown in Table 3, where the first two definitions s1 and s2 focus on the aspect of "simulation" while the other two definitions s3 and s4 focus on "learning new knowledge." Two definitions on different aspects of the entity are probably not a paraphrase. As a consequence, a random pair of definitions about the same entity has a low probability of expressing the same meaning.

Clusters of Definitions: Hence, we propose to cluster definitions of each entity to group entity-definition pairs that are likely to be on the same aspect. Intuitively, definitions that focus on the same aspect often share some overlapping terms and are likely to be grouped into the same cluster, and pairs of definitions from the same cluster are more likely to be a paraphrase, like s1 and s2, and s3 and s4 in Table 3. The definitions are first preprocessed with tokenization and lemmatization.[4] K-means is applied to cluster the definitions for each entity, where each definition is represented by the average of 300-dimensional word2vec (Mikolov et al., 2013) token embeddings trained over these definitions. Empirically, we set the number of clusters be half the number of definitions for each entity. Such a large number of clusters is helpful to filter out some noisy data like meaningless or ill-formed definitions because they are likely to be grouped into a single definition's cluster that can be discarded.

Sampling Candidate Paraphrases: Then, every two of the definitions from the same cluster are paired as a candidate paraphrase. Following Lan et al. (2017), we also filter out paraphrases where

---

[4] The tokenizer and lemmatizer are from NLTK.

Table 4: Annotation Criteria

3- Completely equivalent: they clearly describe the same computer science concept with same details; **Example of label 3:** Text 1: its software that is freely available and its source code is also available. Text 2: typically free software where source code is made freely available Reason: the two sentences are clearly about the same concept ("open source software") with similar details.
2 - Mostly equivalent: as they clearly describe the same computer science concept but some unimportant information differ. Unimportant information include two categories: (1) some examples to explain the entity; and (2) some details can be inferred (based on computer science knowledge) from the overlapping part of the two texts; **Example of label 2:** Text 1: moves packets between computers on different networks. routers operate at this layer. ip and ipx operate at this layer. Text 2: osi layer that moves packets between computers on different networks. routers & ip operate at this level. Reason: they are talking about the same concept: "network layer", only some unimportant information differ (the detail "osi layer" in Text 2 can be inferred based on computer science knowledge: network layer is one of the layers in OSI model).
1 - Roughly equivalent: as they describe the same computer science concept but some important information differs or is missing; Important information here include any details except for the two categories in the previous criterion of label 2; **Example of label 1:** Text 1: term for when a scan fails to find real vulnerabilities. leaves unidentified risk in the code. Text 2: malicious activity goes undetected. Reason: the two sentences might be talking about the same concept: "false negatives", but some important information differ (the detail "...risk in the code..." in Text 1 cannot be inferred from Text 2 based on computer science knowledge).
0 - Not equivalent: as they describe two different computer science concepts; **Example of label 0:** Text 1: test without knowledge of system internals. Text 2: attacker has no knowledge of the network environment (external attack). Reason: the first sentence is talking about "system test" while the second one is about "system attack."

the two definitions are very similar like they only differ in punctuation or some typos, or one definition is a sub-string of the other. After that, we collect all candidate paraphrases and obtain a dataset with 10,182 pairs.

4 PARADE Dataset

In Section 3, we introduced our framework for generating domain-specific candidate paraphrases. Although each one of the candidate paraphrases is focused on the same topic (entity), we still need to confirm that the two definitions express the same meaning. In this section, we introduce our annotation strategy for candidate paraphrases and formally present the PARADE dataset for paraphrase identification based on domain knowledge.

4.1 Annotators with Domain Expertise

As discussed in Section 1, candidate paraphrases in our dataset can not be annotated correctly without specialized domain knowledge. Hence, unlike most previous works (Lan et al., 2017; Xu et al., 2015, 2014; Chen and Dolan, 2011) that hire workers from crowdsourcing platforms like Amazon Mechanical Turk, we invited students majoring in computer science as the annotators for this dataset. The 40 invited annotators include 5 Ph.D. students, 18 masters students, and 17 upper-level undergraduates. All have finished courses that cover almost all of the entities (topics) introduced in Section 3.1.

4.2 Annotation Criteria

Since the annotators have domain expertise, we expect them to provide more specific judgments than just true paraphrase or not. The annotation criteria are presented in Table 4: Completely equivalent (3), Mostly equivalent (2), Roughly equivalent (1), and Not equivalent (0). Labels of 3 and 2 are considered paraphrases, while 0 and 1 are non-paraphrases.

4.3 Annotation Quality Control

Annotators are asked to carefully read the annotation criteria before starting annotations. Each pair is randomly assigned to three annotators; the final ground-truth is decided by majority vote. We evaluate annotation quality of each annotator via Cohen's Kappa score (Artstein and Poesio, 2008) against the ground-truth. The average Cohen's Kappa score of the annotators is 0.65. Following Lan et al. (2017), we re-assign the data instances that were assigned to 2 annotators with low annotation quality (Cohen's Kappa score$<$0.4) to the best 5 annotators (Cohen's Kappa score$>$0.75) and ask them to re-label (give labels without seeing old labels) these data instances.

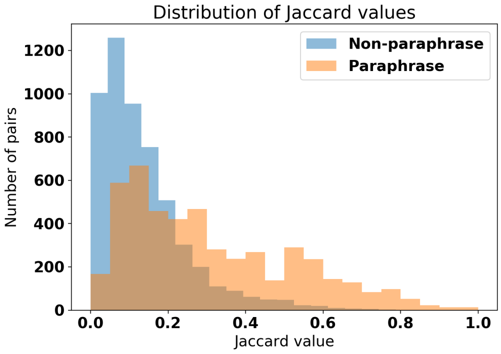

Figure 1: Distributions of Jaccard similarity for paraphrases and non-paraphrases in PARADE.

4.4 Dataset Description

Finally, we construct the first gold dataset for paraphrase identification based on domain knowledge, with 10,182 pairs of definitions that describe 788 distinct entities in the computer science domain. Among them, 4,778 (46.9%) are paraphrases and 5,404 (53.1%) are non-paraphrases. The average length of the definitions is 17.1 words and the maximum length is 30. An example from PARADE is shown in Table 5. Note that entities like "machine code" are also provided with definitions. However, these entities are not used in training and testing models for paraphrase identification tasks; otherwise the models will just learn the answers.

Table 5: An example of PARADE

Entity: Machine Code
Definition 1: the lowest level of code made up of 0s and 1s.
Definition 2: binary instructions used by the cpu.
Label: paraphrase

We calculate the Jaccard similarity for each pair to measure the lexical overlap[5] between the two definitions. In Figure 1, we illustrate the distributions of Jaccard similarity for paraphrases and non-paraphrases. It can be observed that PARADE contains lots of paraphrases that overlap very little at the lexical level but are semantically equivalent. PARADE also contain a few non-paraphrases that overlap a lot but are not semantically equivalent.

In Section 5, we present a qualitative analysis of PARADE on the cases where BERT give wrong predictions, which indicates that PARADE is truly enriched with domain knowledge.

5 Experiments

In this section, we present experiments that aim to answer the following research questions (RQs):

- RQ1: How do BERT and other neural models perform on PARADE? Better or worse than their performance on traditional PI datasets?
- RQ2: What kinds of domain knowledge are captured by PARADE? And how well do non-experts identify paraphrases that contain this domain knowledge?
- RQ3: Can we achieve high-quality identification by augmenting BERT-like models with a collection of domain-specific resources?

5.1 Experimental Setup

We first introduce our experimental setup here, including paraphrase identification models, other PI datasets and their partition and reproducibility.

Models for Binary Paraphrase Identification: We test seven different approaches on PARADE. The Decomposable Attention Model (**DecAtt**, 380K parameters) (Parikh et al., 2016) is one of the earliest models to apply attention for modeling sentence pairs. It computes the word pair interaction between the two sentences in a candidate paraphrase. The Pairwise Word Interaction Model (**PWIM**, 2.2M parameters) (He and Lin, 2016) uses Bi-LSTM to model the context of each word and then uses cosine similarity, Euclidean distance and dot product together to model word pair interactions. The Enhanced Sequential Inference Model (**ESIM**, 7.7M parameters) (Chen et al., 2017) first encodes sentences by using Bi-LSTM and then also calculates the word pair interaction between the two sentences like DecAtt. The Shortcut-Stacked Sentence Encoder (**SSE**, 140M parameters) (Nie and Bansal, 2017) applies a stacked Bi-LSTM with skip connections as the sentence encoder. Recently, the Bidirectional Encoder Representations from Transformer (**BERT**) (Devlin et al., 2018) obtains the state-of-the-art performance on many NLP tasks, including paraphrase identification. We evaluate **BERT-base** (12 layers and 768 hidden embedding size with 108M parameters) and **BERT-large** (24 layers and 1024 hidden embedding size with 334M parameters) on PARADE. We also adopt **ALBERT**, which compresses the architecture of BERT by factorized embedding parameterization

---

[5] Stopwords and punctuation were removed; words were stemmed.

and cross-layer parameter sharing, to obtain a substantially higher capacity than BERT. We choose the maximum version ALBERT-xxlarge (12 layers and 4096 hidden embedding size with 235M parameters).

Datasets and Their Partition: For PARADE, we randomly split it by entities into three parts: 7,550 with 560 distinct entities in the training set, 1,275 with 110 distinct entities in the validation set and 1,357 with 118 distinct entities in the testing set. For paraphrase datasets MRPC[6], PAWS[7], Twitter-URL[8] and PIT-2015[9], we follow the data partitioning strategy of their authors. For QQP[10], the labels for its test set at GLUE are private, so we treat its validation set at GLUE as the test set and sample another part from its training set as the validation set. Details of these previous PI datasets can be found in Section 2.

Reproducibility: PARADE and its split in this paper is released.[11] For BERT, we use a widely used pytorch implementation[12] and Adam optimizer with batch size 32 and learning rate 2e-5. We fine-tuned BERT for 20 epochs. We selected the BERRT hyper-parameters from the range as recommended in Devlin et al. (2018) and based on the performance in terms of F1 on the validation set. The implementations[13] of the other neural models are from Lan and Xu (2018), and we use the same hyper-parameters as recommended by Lan and Xu (2018).

5.2 RQ1: Paraphrase Identification Comparison

We first present the performance of BERT-large on PARADE and previous PI datasets in Table 6. Compared to datasets that lack domain knowledge, we observe that BERT yields the lowest performance on PARADE across all metrics. For example, BERT obtains 0.709 in terms of F1, which is much lower than its performance on the other datasets. Both the precision and the recall are relatively low, which indicates that identifying paraphrases in PARADE is non-trivial even for BERT.

Table 6: Performance of BERT on paraphrase identification datasets

BERT-large	Accuracy	F1	Precision	Recall
MRPC	0.853	0.893	0.866	0.922
QQP	0.908	0.877	0.866	0.889
PWAS	0.939	0.933	0.923	0.944
Twitter-URL	0.905	0.770	0.728	0.817
PIT-2015	0.901	0.746	0.803	0.697
PARADE	0.736	0.709	0.669	0.753

Table 7: Performance of Neural Models on PARADE

	Accuracy	F1	Precision	Recall
DecAtt	0.540	0.530	0.519	0.541
ESIM	0.595	0.646	0.556	0.770
PWIM	0.701	0.687	0.689	0.686
SSE	0.689	0.702	0.649	0.764
BERT-base	0.729	0.708	0.687	0.731
BERT-large	0.736	0.709	0.669	0.753
ALBERT-xxlarge	0.753	0.741	0.738	0.745

Additionally, we present the results of BERT-base, BERT-large, ALBERT-xxlarge and other neural models on PARADE in Table 7. We observe that the other neural models have lower performance than BERT-family models. Among the BERT-family models, BERT-large is slightly better than BERT-base, and ALBERT-xxlarge is the best due to its large learning capacity. However, the best performance is still relatively low on this dataset.

A possible reason is that these general neural net models do not sufficiently capture specialized knowledge of the computer science domain. BERT is pre-trained on two corpora: BooksCorpus (800M words) (Zhu et al., 2015) and English Wikipedia (2,500M words), which leads to some world knowledge learned as reported in Petroni et al. (2019); Davison et al. (2019). However, BooksCorpus[14] does not contain computer science books. While Wikipedia does contain articles on computer science, BERT may not pay enough attention to this subject since Wikipedia is such a huge corpus and computer science is just one branch.

5.3 RQ2: Domain Knowledge

As discussed in Section 5.2, BERT and other neural models face key challenges in paraphrase identi-

[14] This corpus has 11,038 books like *American Psycho* and *No Country for Old Men.*

fication with domain knowledge as in PARADE. A possible reason is that PARADE has a lot of domain knowledge, which is beyond the lexical, syntactic features, or even commonsense knowledge captured by these models. To confirm the presence of domain knowledge, we first conduct a qualitative analysis of PARADE.

Table 8: A case where BERT predict incorrectly

Entity: Type Inference
Definition 1: variables don't need explicit statements about their type unlike in **java**. **haskell** can automatically tell that **1** is of type **int**.
Definition 2: allows the **compiler** to deduce the proper type for you automatically, instead of you having to say it.

BERT Prediction: non-paraphrase
Ground-truth: paraphrase

Qualitative Analysis: We qualitatively analyzed 277 cases (171 paraphrase and 106 non-paraphrases) where BERT predicts the wrong results. From the perspective of domain knowledge, we count the occurrences of each phenomenon in the following categories: **Specialized Terminology.** Examples in the computer science domain include java, haskell and compiler in Table 8. **Acronyms and Abbreviations:** Examples include "int" for integer in Table 8, OS (operating system), OSI (Open Systems Interconnection) model and so on. **Numbers and Equations:** These have special meaning like "port: 80", "arr[i][j] == 1" and "an m-ary tree with m = 2". **Inference:** These non-overlapping sentences may be paraphrases based on domain-specific inference. For example in Table 8, definition 1 does not mention "compiler" in definition 2 but domain experts can infer that based on context and domain knowledge that the compiler is responsible for identifying the type. **Examples:** Non-overlapping paraphrases use examples to support the main idea, like the example of "haskell" in the definition 1 in Table 8. Although definition 2 does not have this example, they still express the concept of "type inference."

A typical example of the cases where these phenomena occur together is shown in Table 8. We report the number of occurrences of each phenomenon in Table 9 and observe that the cases where BERT fails have a high frequency of these domain knowledge phenomena, further supporting the assertion that PARADE is enriched with domain knowledge.

Table 9: Number of domain knowledge phenomena in the 277 cases where BERT mis-labels

Phenomenon	Count	Frequency
Specialized Terminology	150	0.54
Acronyms and Abbreviations	30	0.11
Numbers and Equations	31	0.11
Inference	114	0.41
Examples	78	0.28
Cases that have one phenomenon at least	197	0.71

Table 10: Performance of Non-Experts on Paraphrase Identification

Human	Accuracy	F1	Precision	Recall
MRPC	0.70	0.75	0.77	0.74
QQP	0.74	0.61	0.50	0.77
PAWS	0.90	0.88	0.86	0.90
Twitter-URL	0.90	0.71	0.67	0.75
PIT-2015	0.90	0.76	0.80	0.73
PARADE	0.62	0.56	0.45	0.73

Performance of Non-Experts without Domain Knowledge: To further confirm the presence of domain knowledge, we invite three college students who are **not** majoring in computer science to label PARADE and other datasets. Before evaluation, we ask the students to carefully read the annotation criteria of each dataset and 100 sampled cases with labels from the training set from each dataset. After that, 100 cases without ground-truth are randomly sampled from the test set of each dataset for evaluating the quality of non-expert annotators.

The results are presented in Table 10. We observe that non-experts without domain knowledge obtain abysmal performance on PARADE like 0.56 in terms of F1. However, on other datasets, these non-experts can achieve much better results like 0.88 in terms of F1 on PAWS. By interviewing these students, we believe they can correctly identify paraphrases based on lexical, syntactic and commonsense knowledge on all datasets except for PARADE, where the lack of specialized domain knowledge made the task too challenging.

5.4 RQ3: Incorporating Domain Knowledge

As shown in Section 5.2 and Section 5.3, both widely used neural models and non-expert human annotators have poor performance on PARADE. To corroborate the importance and possibility to enhance a model for PARADE by incorporating specialized domain knowledge, we ran an off-the-shelf model, SciBERT[15] (Beltagy et al., 2019), that

---

[15] `https://huggingface.co/allenai/scibert_scivocab_uncased`

uses the same architecture as BERT-base and is pretrained using 1.14M papers from Semantic Scholar (Ammar et al., 2018) with 18% of papers from the computer science domain and 82% from the biomedical domain. As shown in Table 11, SciBERT outperforms BERT consistently over all the metrics. This experiment shows that simply using corpora of a target domain for model training does lead to some improvements on PARADE. Further improvements may be achieved by methods that can more effectively infuse domain knowledge into NLP models.

Table 11: Results of Enhancing BERT by incorporating domain knowledge

	Accuracy	F1	Precision	Recall
BERT-base	0.729	0.708	0.687	0.731
SciBERT	0.741↑	0.723↑	0.707↑	0.740↑

6 Conclusion and Future Work

We have presented PARADE, a new dataset for sentential paraphrase identification requiring domain knowledge. We conducted extensive experiments and analysis showing that both state-of-the-art neural models and non-expert human annotators perform poorly on PARADE. In the future, we will continue to investigate effective ways to obtain domain knowledge and incorporate it into enhanced models for paraphrase identification. In addition, since PARADE provides entities like "machine code" for definitions, this new dataset could also be useful for other tasks like entity linking (Shen et al., 2014), entity retrieval (Petkova and Croft, 2007) and entity or word sense disambiguation (Navigli, 2009).

Causal Inference of Script Knowledge

Noah Weber [1], **Rachel Rudinger** [2,3], **Benjamin Van Durme** [1]

Abstract

When does a sequence of events define an everyday scenario and how can this knowledge be induced from text? Prior works in inducing such *scripts* have relied on, in one form or another, measures of correlation between instances of events in a corpus. We argue from both a conceptual and practical sense that a purely correlation-based approach is insufficient, and instead propose an approach to script induction based on the causal effect between events, formally defined via interventions. Through both human and automatic evaluations, we show that the output of our method based on causal effects better matches the intuition of what a script represents.

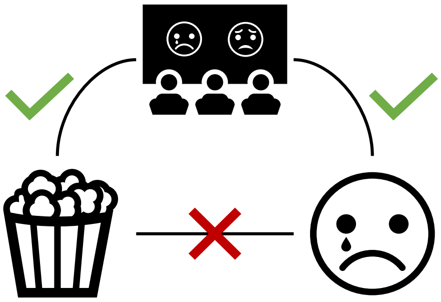

Figure 1: The events of *Watching a sad movie*, *Eating popcorn*, and *Crying*, may highly co-occur in a hypothetical corpus. What distinguishes valid event pair inferences (event pairs linked in a commensense scenario; noted by checkmarks above) versus invalid inferences (noted by a 'X')?

1 Introduction

Commonsense knowledge of everyday situations, as defined in terms of prototypical sequences of events, has long been held to play a major role in text comprehension and understanding (Minsky, 1974; Schank and Abelson, 1975, 1977; Bower et al., 1979; Abbott et al., 1985). Naturally, this has motivated a large body of work looking to learn such knowledge, such *scripts*,[1] from text corpora through data-driven approaches.

A minimal and often implicit requirement for any such approach is to resolve for any pair of events e_1 and e_2 what quantitative measure should be used to determine whether e_2 should "follow" e_1 in script. That is, documents may serve as descriptions of events that occur in the same situation as other events: what function may we compute over the raw presence or absence of events in documents that is most useful for script induction?

Chambers and Jurafsky (2008; 2009) adopted point-wise mutual information (PMI) (Church and Hanks, 1990) between event mentions. Others employed probabilities from a language model over event sequences (Jans et al., 2012; Rudinger et al., 2015; Pichotta and Mooney, 2016; Peng and Roth, 2016; Weber et al., 2018b), or other measures of event co-occurrence (Balasubramanian et al., 2013; Modi and Titov, 2014).

In this work we ask: do measures rooted in co-occurrence best capture the notion of whether one event should follow another in a script? We posit that it does not, that while observed correlations between events indicate relatedness, relatedness is not the only factor in determining whether events form a meaningful script.

Consider the example of Ge et al. (2016): *hurricane* events are prototypically connected with events of *donations* coming in. Likewise, *hurricane* events are connected to *evacuation* events. However, while *donation* and *evacuation* events are not conceptually connected in the same sense, there will exist strong statistical associations between the two. Figure 1 provides a second example: *eating popcorn* is not conceptually associated with *crying*,

---

[1] For simplicity we will refer to these 'prototypical event sequences' as scripts throughout the paper, though it should be noted scripts as originally proposed contain further structure not captured in this definition.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7583–7596,
November 16–20, 2020.

but they might co-occur in a hypothetical corpus describing situations of *watching a sad movie*.

What do strict co-occurrence measures miss? In both examples the 'invalid' inferences arise from the same issue: an event such as *eating popcorn* may raise the probability of the event *crying*, but it does so only through a shared association with a *movie watching* context: the increase in probability is **not** due to the *eating popcorn* itself. In other words, what is lacking is a direct *causal effect* between these events, a quantity that can be formally defined using tools from the causal inference literature (Hernan and Robins, 2019).

In this work we demonstrate how a measure based on causal effects can be derived, computed, and employed for the extraction of script knowledge. Using crowdsourced human evaluations and a variant of the automatic cloze evaluation, we show how this definition better captures the notion of scripts as compared to prior standard measures, PMI and event sequence language models. Code and data available at `github.com/weberna/causalchains`.

2 Motivation

Does that fact that event e_2 is often observed after e_1 in the data (i.e. $p(e_2|e_1)$ is "high") mean that e_2 prototypically follows e_1, in the sense of being part of a script? In this section we argue that observed associations are not sufficient for the purpose of extracting script knowledge from text. We argue from a conceptual standpoint that some notion of causal relevance is required. We then give examples showing the practical pitfalls that may arise from ignoring this component. Finally, we propose our intervention based definition for script events, and show how it both explicitly defines a notion of 'causal relevance,' while simultaneously fixing the aforementioned practical pitfalls.

2.1 The Significance of Causal Relevance

The original works defining scripts are unequivocal about the importance of causal linkage between script events,[2] and other components of the original script definition (e.g. what-ifs, preconditions, postconditions, etc.) are arguably causal in nature. Early rule-based works on inducing scripts heavily used causal concepts in their schema representations (DeJong, 1983; Mooney and DeJong, 1985), as do related works in psychology (Black and Bower, 1980; Trabasso and Sperry, 1985).

But any measure based solely on $p(e_2|e_1)$ is agnostic to notions of causal relevance. Does this matter in practice? A high $p(e_2|e_1)$ indicates either: (1) a causal influence of e_1 on e_2, or (2) a common cause e_0 between them, meaning the relation between e_1 and e_2 is spurious. In the latter case, e_0 acts as a *confounder* between e_1 and e_2.

Ge et al. (2016) acknowledges that the associations picked up by correlational measures may often be spurious. Their solution relies on using trends of words in a temporal stream of newswire data, and hence is fairly domain specific.

2.2 Defining Causal Relevance

Early works such as Schank and Abelson (1975) are vague with respect to the meaning of "causally chained." Can one say that *watching a movie* has causal influence on the subsequent event of *eating popcorn* happening? Furthermore, can this definition be operationalized in practice?

We argue that both of these questions may be elucidated by taking a *manipulation*-based view of causation. Roughly speaking, this view holds that a causal relationship is one that is "*potentially exploitable for the purposes of manipulation and control*" – Woodward (2005). In other words, a causal relationship between *A* and *B* means that (in some cases) manipulating the value of *A* should result in a change in the value of *B*. A primary benefit of this view is that the meaning of a causal claim can be clarified by specifying what these 'manipulations' are exactly. We take this approach below to clarify what exactly is meant by 'causal relevance' between script events.

Imagine an agent reading a discourse. After reading a part of the discourse, the agent has some expectations for events that might happen next. Now imagine that, before the agents reads the next passage, we surreptitiously replace it with an alternate passage in which the event e_1 happens. We then allow the agent to continue reading. If e_1 is *causally relevant* to e_2, then this replacement should, in some contexts, raise the agents degree of belief in e_2 happening next (contra the case where we didn't intervene to make e_1 happen).

So, for example, if we replaced a passage such that e_1 = *watching a movie* was true, we could expect on average that the agent's degree of belief that e_2 = *eating popcorn* happens next will be

---

[2] "*...a script is not a simple list of events but rather a linked causal chain*" (Schank and Abelson, 1975)

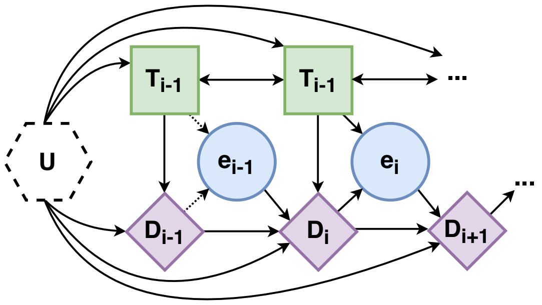

Figure 2: The diagram for our causal model up to time step i. Intervening on e_{i-1} acts to remove the dotted edges. See 3.1 for a description of the variables.

higher. In this way, we say these events are causally relevant, and are for our purposes, script events.

With this little 'story,' we have clarified the conceptual notion of causal relevance in our problem. In the next section, we formalize this story and its notion of intervention into a causal model.

3 Method

We would like to compute the effect of forcing an event of a certain type to occur in the text. The event types that get the largest increase in probability due to this are held to be 'script' events. Computing these quantities falls within the domain of causal inference, and hence will require its tools be used. There are three fundamental steps in causal inference we will need to work through to accomplish this: (1) **Define a Causal Model**: Identify the variables of interest in the problem, and define causal assumptions regarding these variables, (2) **Establish Identifiability**: With the given model, determine whether the causal quantity can be computed as a function of observed data. If it can, derive this function and move to (3) **Estimation**: Estimate this function using observed data. We go through each step in the next three subsections.

To best contrast with prior work, we use the event representation of Chambers and Jurafsky (2008) and others (Jans et al., 2012; Rudinger et al., 2015). A description of this representation is provided in the Supplemental.

3.1 Step 1: Define a Causal Model

A causal model defines a set of causal assumptions on the variables of interest in a problem. While there exists several formalisms that accomplish this, in this paper we make use of causal Bayesian networks (CBN) (Spirtes et al., 2000; Pearl, 2000). CBNs model dependencies between variables graphically in a manner similar to Bayesian networks; the key distinction being that the edges in a CBN posits a direction of *causal* influence between the variables [3].

We will define our causal model from a top down, data generating perspective in a way that aligns with our conceptual story from the previous section. Below we describe the four types of variables in our model, as well as their causal dependencies.

The World, *U*: The starting point for the generation of our data is the real world. This context is explicitly represented by the unmeasured variable U. This variable is unknowable and in general unmeasurable: we don't know how it is distributed, nor even what 'type' of variable it is. This variable is represented by the hexagonal node in Figure 2.

The Text, *T*: The next type of variable represents the text of the document. For indexing purposes, we segment the text into chunks T_1,...,T_N, where N is the number of realis events explicitly mentioned in the text. The variable T_i is thus the text chunk corresponding to the i^{th} event mentioned in text. These chunks may be overlapping, and may skip over certain parts of the original text.[4] The causal relationship between various text chunks is thus ambiguous. We denote this by placing bidirectional arrows between the square text nodes in Figure 2. The context of the world also causally influences the content of the text, hence we include an arrow from U to all text variables, T_i.

Event Inferences, *e*: In our story in Section 2, an agent reads a chunk of text and infers the type of event that was mentioned in the piece of text. This inference is represented (for the i^{th} event in text) in our model by the variable $e_i \in E$ where E is the set of possible atomic event types (described at the end of this section).[5]

---

[3] See Pearl (2000); Bareinboim et al. (2012) for a comprehensive definition of CBNs and their properties.

[4] Keeping with prior work, we use the textual span of the event predicate syntactic dependents as the textual content of an event. The ordering of variables T_i corresponds to the positions of the event predicates in the text.

[5] For this study we use the output of information extraction tools as a proxy for the variable e_i (see supplemental). As such, it is important to note that there will be bias in computations due to *measurement error*. Fortunately, there do exists methods in the causal inference literature that can adjust for this bias (Kuroki and Pearl, 2014; Miao et al., 2018). Wood-Doughty et al. (2018) derive equations in a case setting related to ours (i.e. with measurement bias on the variable being intervened on). Dealing with this issue will be an important next step for future work.

The textual content of T_i causally influences the inferred type e_i, hence directional connecting arrows in Figure 2.

Discourse Representation, *D* The variable e_i represent a high level abstraction of part of the semantic content found in T_i. Is this information about events used for later event inferences by an agent reading the text? Prior results in causal network/chain theories of discourse processing (Black and Bower, 1980; Trabasso and Sperry, 1985; Van den Broek, 1990) seem to strongly point to the affirmative. In brief, these theories hold that the identities of the events occurring in the text – and the causal relations among them – are a core part of how a discourse is represented in human memory while reading, and more-so, that this information significantly affects a reader's event based inferences(Trabasso and Van Den Broek, 1985; Van den Broek and Lorch Jr, 1993). Thus we introduce a *discourse representation* variable, D_i, itself a combination of two sub-variables, D_i^I and D_i^O.

The variable $D_i^I \in E^*$ is a sequence[6] of events that were explicitly stated ***in the text***, up to step i. After each step, the in-text event inferred at i (the variable e_i) is appended to D_{i+1}^I. The causal parents of D_{i+1}^I are thus e_i and D_i^I (which is simply copied over). We posit that the information in D_i^I provides information in the inference of e_i, and thus draw an arrow from D_i^I to e_i.

Unstated events not found in the text but inferred by the reader also have an effect on event inferences (McKoon and Ratcliff, 1986, 1992; Graesser et al., 1994). We thus additionally take this into consideration in our causal model by including an ***out of text*** discourse representation variable, $D_i^O \in 2^{|E|}$. This variable is a bag of events that a reader may infer implicitly from the text chunk T_i using common sense. Its causal parents are thus both the text chunk T_i, as well as the world context U; its causal children are e_i. Obtaining this information is done via human annotation and discussed later. D_i is thus equal to (D_i^I, D_i^O), and inherits the incoming and outgoing arrows of both in Figure 2.

3.2 Step 2: Establishing Identifiability

Our goal is to compute the effect that intervening and setting the preceding event e_{i-1} to $k \in E$ has on the distribution over the subsequent event e_i. Now that we have a causal model in the form of Fig. 2, we can now define this effect. Using the notation of Pearl (2000), we write this as:

$$p(e_i | do(e_{i-1} = k)) \tag{1}$$

The semantics of $do(e_{i-1} = k)$ are defined as an 'arrow breaking' operation on Figure 2 which deletes the incoming arrows to e_{i-1} (the dotted arrows in Figure 2) and sets the variable to k. Before a causal query such as Eq. 1 can be estimated we must first establish identifiability (Shpitser and Pearl, 2008): can the causal query be written as a function of (only) the observed data?

Eq. 1 is identified by noting that variables T_{i-1} and D_{i-1} meet the 'back-door criterion' of Pearl (1995), allowing us to write Eq. 1 as the following:

$$\mathbb{E}_{T_{i-1}, D_{i-1}} \Big[p(e_i | e_{i-1} = k, D_{i-1}, T_{i-1}) \Big] \tag{2}$$

Our next step is to estimate the above equation. If one has an estimate for the conditional $p(e_i | e_{i-1}, D_{i-1}, T_{i-1})$, then one may "plug it into" Eq. 2 and use a Monte Carlo approximation of the expectation (using samples of (T, D)). This simple *plug in* estimator is what we use here

It is important to be aware of the fact that This estimator, specifically when plugging in machine learning methods, is quite naive (e.g. Chernozhukov et al. (2018)), and will suffer from an asymptotic (first order) bias. [7] which prevents one from constructing meaningful confidence intervals or performing certain hypothesis tests. That said, in practice these machine learning based plug in estimators can achieve quite reasonable performance (see for example, the results in Shalit et al. (2017)), and since our current use case can be validated empirically, we save the usage of more sophisticated estimators (and proper statistical inference) for future work[8].

3.3 Step 3: Estimation

Eq. 2 depends on the conditional, $p_{e_i} = p(e_i | e_{i-1}, D_{i-1}, T_{i-1})$, which we estimate via stan-

---

[6] We don't explicitly model the causal structure between events in D_i, the importance of which is a key finding in the above referenced literature. While this wouldn't change the structure of our causal model, it would impact the estimation stage, and would be an interesting line of future work.

[7] See Fisher and Kennedy (2018) for an introduction on how this bias manifests.

[8] Semiparametric estimation of equations such as Eq. 2 involving high dimensional variables (like text) is an open problem that we do not address here. See (D'Amour et al., 2020; Kennedy, 2016; Chernozhukov et al., 2018) for an analysis of some of the problems that arise in both high dimensional causal inference and semiparametric estimation (ie estimation without full parametric assumptions). See Keith et al. (2020) for an overview of problems that arise particularly when dealing with text.

dard ML techniques with a dataset of samples drawn from $p(e_i, e_{i-1}, D_{i-1}, T_{i-1})$. There are two issues: (1) How do we deal with out-of-text events in D_{i-1}?, and (2) What form will p_{e_i} take?

Dealing with Out-of-Text Events Recall that D_i is combination of the variables D_i^I and D_i^O. To learn a model for p_{e_i} we require samples from the full joint. Out of the box however, we only have access to $p(e_i, e_{i-1}, D_{i-1}^I, T_{i-1})$. If, for the samples in our current dataset, we could draw samples from $p_D = p(D_{i-1}^O | e_i, e_{i-1}, D_{i-1}^I, T_{i-1})$, then we would have access to a dataset with samples drawn from the full joint.

In order to 'draw' samples from p_D we employ human annotation. Annotators are presented with a human readable form of $(e_i, e_{i-1}, D_{i-1}^I, T_{i-1})$[9] and are asked to annotate for possible events belonging in D_{i-1}^O. Rather than opt for noisy annotations obtained via freeform elicitation, we instead provide users with a set of 6 candidate choices for members of D_{i-1}^O. The candidates are obtained from various knowledge sources: ConceptNet (Speer and Havasi, 2012), VerbOcean (Chklovski and Pantel, 2004), and high PMI events from the NYT Gigaword corpus (Graff et al., 2003). The top two candidates are selected from each source.

In a scheme similar to Zhang et al. (2017), we ask users to rate candidates on an ordinal scale and consider candidates rated at or above a 3 (out of 4) to be considered within D_{i-1}^O. We found annotator agreement to be quite high, with a Krippendorf's α of 0.79. Under this scheme, we crowdsourced a dataset of 2000 fully annotated examples on the Mechanical Turk platform. An image of our annotation interface is provided in the Appendix.

The Conditional Model We use neural networks to model p_{e_i}. In order to deal with the small amount of fully annotated data available, we employ a finetuning paradigm. We first train a model on a large dataset that does not include annotations for D_{i-1}^O. This model consists of a single layer, 300 dimensional GRU encoder which encodes $[D_{i-1}^I, e_{i-1}]$ into a vector $v_e \in R^d$ and a CNN-based encoder which encodes T_{i-1} into a vector $v_t \in R^d$. The term p_{e_i} is modeled as:

$$p_{e_i} \propto Av_e + Bv_t$$

for matrices A and B of dimension $|E| \times d$. We then finetune this model on the 2000 annotated examples including D_{i-1}^O. We add a new parameter matrix, C, to the previously trained model (allowing it to take D_{i-1}^O as input) and model p_{e_i} as:

$$p_{e_i} \propto Av_e + Bv_t + Cv_o$$

The input v_o is the average of the embeddings for the events found in D_{i-1}^O. The parameter matrix C is thus the only set of parameters trained 'from scratch,' on the 2000 annotated examples. The rest of the parameters are initialized and finetuned from the previously trained model. See Appendix for further training details.

3.4 Extracting Script Knowledge

Provided a model of the conditional p_{e_i} we can approximate Eq. 2 via Monte Carlo by taking our annotated dataset of $N = 2000$ examples and computing the following average:

$$\hat{P}_k = \frac{1}{N} \sum_{j=1}^{N} p(e_i | e_{i-1} = k, D_j, T_j) \qquad (3)$$

This gives us a length $|E|$ vector $\hat{P}_k$ whose l^{th} component, $\hat{P}_{kl}$ gives $p(e_i = l | do(e_{i-1} = k))$. We compute this vector for all values of k. Note that this computation only needs to be done once.

There are several ways one could extract script-like knowledge using this information. In this paper, we define a normalized score over intervened-on events such that the script compatibility score between two concurrent events is defined as:

$$S(e_{i-1} = k, e_i = l) = \frac{\hat{P}_{kl}}{\sum_{j=1}^{E} \hat{P}_{jl}} \qquad (4)$$

We term this as the 'Causal' score in the eval below.

4 Experiments and Evaluation

Automatic evaluation of methods that extract script-like knowledge is an open problem that we do not attempt to tackle here,[10] relying foremost on crowd-sourced human evaluations to validate our method.

However, as we aim to provide a contrast to prior script-induction approaches, we perform an experiment looking at a variant of the popular automatic narrative cloze evaluation.

---

[9] In the final annotation experiment, we found it easier for annotators to be only provided the text T_{i-1}, given that many events in D_{i-1}^I are irrelevant.

[10] See discussions by Rudinger et al. (2015) and Chambers (2017).

4.1 Dataset

For these experiments, we use the Toronto Books corpus (Zhu et al., 2015; Kiros et al., 2015), a collection of fiction novels spanning multiple genres. The original corpus contains 11,040 books by unpublished authors. We remove duplicate books from the corpus (by exact file match), leaving a total of 7,101 books. The books are assigned randomly to train, development, and test splits in 90%-5%-5% proportions. Each book is then run through a pipeline of tokenization with CoreNLP 3.8 (Manning et al., 2014), parsing with CoreNLP's universal dependency parser (Nivre et al., 2016) and coreference resolution (Clark and Manning, 2016b), before feeding the results into PredPatt (White et al., 2016). We additionally tag the events with factuality predictions from Rudinger et al. (2018b) (we only consider factual events). The end result is a large dataset of event chains centered around a single protagonist entity, similar to (Chambers and Jurafsky, 2008). We make this data public to facilitate further work in this area. See the Appendix for a full detailed overview of our pipeline.

4.2 Baselines

In this paper, we compare against the two dominant approaches for script induction (under a atomic event representation[11]): PMI (similar to Chambers and Jurafsky (2008, 2009)) and LMs over event sequences (Rudinger et al., 2015; Pichotta and Mooney, 2016). We defer definitions for these models to the cited papers, below we provide the relevant details for each baseline, with further training details provided in the Appendix.

For computing PMI we follow many of the details from (Jans et al., 2012). Due to the nature of the evaluations, we utilize their 'ordered' PMI-variant. Also like Jans et al. (2012), we use skip-bigrams with a window of 2 to deal with count sparsity. Consistent with prior work we additionally employ the discount score of Pantel and Ravichandran (2004). For the LM, we use a standard, 2 layer, GRU-based neural network language model, with 512 dimensional hidden states, trained on a log-likelihood objective.

Method	Average Score	Average Rank (1-6)
Causal	49.71	4.10
LM	35.95	3.39
PMI	34.92	3.02

Table 1: Average Annotator Scores in Pairwise annotation experiment

X radioed	*X made*	*X fostered*	*X ordered*

Table 2: Examples from each system, each of which outputs a previous event that maximizes the score/likelihood that the Targeted event follows in text.

4.3 Eval I: Pairwise Event Associations

Any system aimed at extracting script-like knowledge should be able to answer the following *abductive* question: given an event e_i happened, what previous event e_{i-1} best explains why e_i is true? In other words, what e_{i-1}, if it were true, would maximize my belief that e_i was true. We evaluate each method's ability to do this via a human evaluation.

On each task, annotators are presented with six event pairs (e_{i-1}, e_i), where e_i is the same for all pairs, but e_{i-1} is generated by one of the three systems. Similar to the human evaluation in Pichotta and Mooney (2016), we filter out outputs in the top-20 most frequent events list for all systems. For each system, we pick the top two events that maximize $S(\cdot, e_i)$, $PMI(\cdot, e_i)$, and $p_{lm}(\cdot, e_i)$, for the Causal, PMI, and LM systems respectively, and present them in random order. For each pair, users are asked to provide a scalar annotation (from 0%-100%, via a slider bar) on the chance that e_i is *true afterwards or happened as a result of* e_{i-1}. The annotation scheme is modeled after the one presented in Sakaguchi and Van Durme (2018), and shown to be effective for paraphrase evaluation in Hu et al. (2019). Example outputs for systems are provided for several e_1 choices for this task in Table 2.

The evaluation is done for 150 randomly[12] chosen instances of e_i, each with 6 candidate e_{i-1}. We

---

[11] There are also a related class of methods based on creating compositional event embeddings (Modi, 2016; Weber et al., 2018a). Since the event representation used here is atomic it makes little sense to use them here.

[12] Note that we do manually filter out of the initial random list events which we judge as difficult to understand

Method	Average Score	Average Rank (1-3)
Causal	60.12	2.19
LM	57.40	2.12
PMI	44.26	1.68

Table 3: Average Annotator Scores in Chain annotation experiment

have two annotators provide annotations for each task, and similar to Hu et al. (2019), average these annotations together for a gold annotation.

In Table 1 we provide the results of the experiment, providing both the average annotation score for the outputs of each system, as well as the average relative ranking (with a rank of 6 indicating the annotators ranked the output as the highest/best in the task, and a rank of 1 indicating the opposite). We find that annotators consistently rated the Causal system higher. The differences (in both Score and Rank) between the Causal system and the next best system are significant under a Wilcoxon signed-rank test ($p < 0.01$).

4.4 Eval II: Event Chain Completion

Of course, while pairwise knowledge between events is a minimum prerequisite, we would also like to generalize to handle chains of events containing multiple events. In this section, we look at each system's ability to provide an intuitive completion to an event chain. More specifically, the model is provided with a chain of three context events, (e_1, e_2, e_3), and is tasked with providing a suitable e_4 that might follow given the first three events. We evaluate each method's ability to do this via a human evaluation.

Since both PMI and the Causal model [13] work only as pairwise models, we adopt the method of Chambers and Jurafsky (2008) for chains. For both the PMI and Causal model, we pick the e_4 that maximizes $\frac{1}{3}\sum_{i=1}^{3} Score(e_i, e_4)$, where $Score$ is either PMI or Eq 4. The LM model chooses an e_4 that maximizes the joint over all events.

Our annotation task is similar to the one in 4.3, except the pairs provided consist of a context (e_1, e_2, e_3) and a system generated e_4. Each system generates its top choice for e_4, giving annotators 3 pairs[14] to annotate for each task (i.e. each context). On each task, human annotators are asked to provide a scalar annotation (from 0%-100%, via a slider) on the chance that e_4 is *true afterwards or happened as a result of* the chain of context events. The evaluation is done for 150 tasks, with two annotators on each task. As before, we average these annotations together for a gold annotation.

In Table 3 we provide results of the experiment. Note the the rankings are now from 1 to 3 (higher is better). We find annotators usually rated the Causal system higher, though the LM model is much closer in this case. The differences (in both Score/Rank) between the Causal and LM system outputs are not significant under a Wilcoxon signed-rank test, though the differences between the Causal and PMI system is ($p < 0.01$). The fact that the pairwise Causal model is still able to (at minimum) match the full sequential model on a chain-wise evaluation speaks to the robustness of the event associations mined from it, and further motivates work in extending the method to the sequential case.

4.5 Diversity of System Outputs

But what type of event associations are found from the Causal model? As noted both in Rudinger et al. (2015) and in Chambers (2017), PMI based approaches can often extract intuitive event relationships, but may sometimes overweight low frequency events or suffer problems from count sparsity. LM based models, on the other hand, were noted for their preference towards boring, uninformative, high frequency events (like 'sat' or 'came'). So where does the Causal model lay on this scale?

We study this by looking at the percentage of unique words used by each system in the previous evaluations, presented in Table 5. Unsurprisingly, we find that PMI chooses a new word to output often (77%-84% of the time), while the LM model very rarely does (only 7%-13%). The Causal model, while not as adventurous as the PMI system, tends to produce very diverse output, generating a new output 60%-76% of the time. Both the PMI and Causal system produce relatively less diverse output on the chain task, which is expected due to the averaging scheme used by each to select events.

4.6 Infrequent Narrative Cloze

The narrative cloze task, or some variant of it, has remained a popular automatic test for systems aiming to extract 'script' knowledge. The task is usually formulated as follows: given a chain of events $e_1, ...e_{n-1}$ that occurs in the data, predict the held out next event that occurs in the data, e_n. There

---

[13] Generalizing the Causal model to multiple interventions, though out of scope here, is a clear next step for future work.

[14] We found providing six pairs per task to be overwhelming given the longer context

Method	Pairwise	Chain
Causal	*X awoke* (2%) *X parried* (1%)	*X collided* (4%) *pinched X* (3%)
LM	*X came* (30%) *X sat* (27%)	*X made* (23%) *X came* (15%)
PMI	*X lurched* (1%) *X patroled* (1%)	*bribed X* (3%) *X swarmed* (2%)

Table 4: Two most used output events (and % of times it is used) for each system, for each human evaluation

Method	Pairwise	Chain
Causal	76.0%	60.1%
LM	7.30%	13.3%
PMI	84.0%	77.6%

Table 5: % of times a system outputs a new event it previously had not used before.

exists various measures to calculate a models ability to perform in this task, but arguably the most used one is the Recall@N measure introduced in Jans et al. (2012). Recall@N works as follows: for a cloze instance, a system will return the top N guesses for e_n. Recall@N is the percentage of times e_n is found anywhere in the top N list.

The automatic version of the cloze task has notable limitations. As noted in Rudinger et al. (2015), the cloze task is essentially a language modeling task; it measures how well a model *fits* the data. The question then becomes whether data fit implies valid script knowledge was learned. The work of Chambers (2017) casts serious doubts on this, with various experiments showing automatic cloze evaluations are biased to high frequency, uninformative events, as opposed to informative, *core*, script events. They further posit human annotation as a necessary requirement for evaluation.

In this experiment, we provide another datapoint for the inadequacy of the automatic cloze, while simultaneously showing the relative robustness of the knowledge extracted from our Causal system. For the experiment, we make the following assumptions: (1) Highly frequent events tend to appear in many scenarios, and hence are less likely to be an informative 'core' event for a script, and (2) Less frequent events are more likely to appear only in specific scenarios, and are thus more likely to be informative events. If these are true, then a system that has extracted useful script knowledge should keep (or even improve) cloze performance when the correct answer for e_n is a less frequent event.

We thus propose a Infrequent Cloze task. In this task we create a variety of different cloze datasets (each with 2000 instances) from our test set. Each set is indexed by a value C, such that the indicated dataset does not include instances from the top C most frequent events ($C = 0$ is the normal cloze setting). We compute a Recall@100 cloze task on 7 sets of various C and report results in Table 6.

At $C = 0$, as expected, the LM model is vastly superior. The performance of the LM model drastically drops however, as soon as C increases, indicating an overreliance on prior probability. The LM performance drops below 2% once $C = 200$, indicating almost no ability in predicting informative events such as *drink* or *pay*, both of which occur in this set in our case. The PMI and Causal model's performance on the other hand, steadily improve while C increases, with the Causal model consistently outperforming PMI. This result, *when combined with* the results of the human evaluation, give further evidence towards the relative robustness of the Causal model in extracting informative core events. The precipitous drop in performance of the LM further underscores problems that a naive automatic cloze evaluation may cover up.

5 Related Work

Our work looks at script like associations between events in a manner similar to Chambers and Jurafsky (2008), and works along similar lines (Jans et al., 2012; Pichotta and Mooney, 2016). Related lines of work exist, such as work using generative models to induce probabilistic schemas(Chambers, 2013; Cheung et al., 2013; Ferraro and Van Durme, 2016), work showing how script knowledge may be mined from user elicited event sequences (Regneri et al., 2010; Orr et al., 2014), and approaches take advantage of hand coded schematic knowledge (Mooney and DeJong, 1985; Raskin et al., 2003). The cognitive linguistics literature is rich with work studying the role of causal semantics in linguistic constructions and argument structure (Talmy, 1988; Croft, 1991, 2012), as well as the causal semantics of lexical items themselves (Wolff and Song, 2003). Work in the NLP literature on extracting causal relations has benefited from this line of work, utilizing the systematic way in which causation in expressed in language to mine relations (Girju and Moldovan, 2002; Girju, 2003; Riaz and Girju, 2013; Blanco et al., 2008; Do et al., 2011; Bosselut et al., 2019). This line work aims to extract

Method	Exclusion Threshold						
	< 0	< 50	< 100	< 125	< 150	< 200	< 500
Causal	5.60	7.10	7.00	**7.49**	**7.20**	**8.20**	**9.10**
LM	**65.3**	**28.1**	**9.70**	6.30	3.60	1.70	0.25
PMI	1.80	3.30	3.36	4.10	4.00	4.90	7.00

Table 6: Recall@100 Narrative Cloze Results. $< C$ indicates that instances whose cloze answer is one of the top C most frequent events are not evaluated on

causal relations between events that are in some way explicitly expressed in the text (e.g. through the use of particular constructions).Taking advantage of how causation is expressed in language may benefit our causal model, and is a potential path for future work.

6 Conclusions and Future Work

In this work we argued for a causal basis in script learning. We showed how this causal definition could be formalized and used in practice utilizing the tools of causal inference, and verified our method with human and automatic evaluations. In the current work, we showed a method calculating the 'goodness' of a script in the simplest case: between pairwise events, which we showed still to be quite useful. A causal definition is in no way limited to this pairwise case, and future work may generalize it to the sequential case or to event representations that are compositional. Having a causal model shines a light on the assumptions made here, and indeed, future work may further refine or overhaul them, a process which may further shine a light on the nature of the knowledge we are after.

A Appendix

A.1 Event Representation

To best contrast with prior work, we use the event representation of Chambers and Jurafsky (2008) and others (Jans et al., 2012; Rudinger et al., 2015). Each event is a pair (p, d), where p is the event predicate (e.g. *hit*), and d is the dependency relation (e.g. *nsubj*) between the predicate and the *protagonist* entity. The protagonist is the entity that participates in every event in the considered event chain, e.g., the ‘Bob’ in the chain ‘Bob sits, Bob eats, Bob pays.’

A.2 Data Pre-Processing

For these experiments, we use the Toronto Books corpus (Zhu et al., 2015; Kiros et al., 2015), a collection of fiction novels spanning multiple genres. The original corpus contains 11,040 books by unpublished authors. We remove duplicate books from the corpus (by exact file match), leaving a total of 7,101 books; a distribution by genre is provided in Table 7. The books are assigned randomly to train, development, and test splits in 90%-5%-5% proportions (6,405 books in train, and 348 in development and test splits each). Each book is then sentence-split and tokenized with CoreNLP 3.8 (Manning et al., 2014); these sentence and token boundaries are observed in all downstream processing.

A.2.1 Narrative Chain Extraction Pipeline

In order to extract the narrative chains from the Toronto Books data, we implement the following

Adventure	390	Other	284
Fantasy	1,440	Romance	1,437
Historical	161	Science Fiction	425
Horror	347	Teen	281
Humor	237	Themes	32
Literature	289	Thriller	316
Mystery	512	Vampires	131
New Adult	702	Young Adult	117

Table 7: Distribution of books within each genre of the deduplicated Toronto Books corpus.

pipeline. First, we note that coreference resolution systems are trained on documents much smaller than full novels (Pradhan et al., 2012); to accommodate this limitation, we partition each novel into non-overlapping windows that are 100 sentences in length, yielding approximately 400,000 windows in total. We then run CoreNLP's universal dependency parser (Nivre et al., 2016; Chen and Manning, 2014), part of speech tagger (Toutanova et al., 2003), and neural coreference resolution system (Clark and Manning, 2016a,b) over each window of text. For each window, we select the longest coreference chain and call the entity in that chain the "protagonist," following Chambers and Jurafsky (2008).

We feed the resulting universal dependency (UD) parses into PredPatt (White et al., 2016), a rule-based predicate-argument extraction system that runs over universal dependency parses. From PredPatt output, we extract predicate-argument edges, i.e., a pair of token indices in a given sentence where the first index is the head of a predicate, and the second index is the head of an argument to that predicate. Edges with non-verbal predicates are discarded.

At this stage in the pipeline, we merge information from the coreference chain and predicate-argument edges to determine which events the protagonist is participating in. For each predicate-argument edge in every sentence, we discard it if the argument index does not match the head of a protagonist mention. Each of the remaining predicate-argument edges therefore represents an event that the protagonist participated in.

With a list of PredPatt-determined predicate-argument edges (and their corresponding sentences), we are now able to extract the narrative event representations, (p, d) For p, we take the lemma of the (verbal) predicate head. For d, we take the dependency relation type (e.g., *nsubj*) between the predicate head and argument head indices (as determined by the UD parse); if a direct arc relation does not exist, we instead take the unidirectional dependency path from predicate to argument; if a unidirectional path does not exist, we use a generic "arg" relation.

To extract a factuality feature for each narrative event (i.e. whether the event happened or not, according to the meaning of the text), we use the neural model of Rudinger et al. (2018a).As input to this model, we provide the full sentence in which the event appears, as well as the index of the event predicate's head token. The model returns a factuality score on a $[-3, 3]$ scale, which is then discretized using the following intervals: $[1, 3]$ is "positive" $(+)$, $(-1, 1)$ is "uncertain," and $[-3, -1]$ is "negative" $(-)$.

From this extraction pipeline, we yield one sequence of narrative events (i.e., narrative chain) per text window.

A.3 Training and Model Details - Causal Model

A.3.1 RNN Encoder

We use a single layer GRU based RNN encoder with a 300 dimensional hidden state and 300 dimensional input event embeddings to encode the previous events into a single 300 dimensional vector.

A.3.2 CNN Encoder

We use a CNN to encode the text into a 300 dimensional output vector. The CNN uses 4 filters with ngram windows of $(2, 3, 4, 5)$ and max pooling.

A.3.3 Training Details - Pretraining

The conditional for the Causal model is trained using Adam with a learning rate of 0.001, gradient clipping at 10, and a batch size of 512. The model is trained to minimize cross entropy loss. We train the model until loss on the validation set does not go down after three epochs, afterwhich we keep the model with the best validation performance, which in our case was epoch 4

A.3.4 Training Details - Finetuning

The model is then finetuned on our dataset of 2000 annotated examples. We use the same objective as above, training using Adam with a learning rate of 0.00001, gradient clipping at 10, and a batch size of 512. We split our 2000 samples into a train set of

"Tavi ducked under a curved blade"

3. If you read the above sentence in a story, then it is ⌄ that the following statement was true previously in the story:

Tavi jumped (something or someone)

"Tavi ducked under a curved blade"

4. If you read the above sentence in a story, then it is ⌄ that the following statement was true previously in the story:

Tavi headed (something or someone)

"Tavi ducked under a curved blade"

5. If you read the above sentence in a story, then it is ⌄ that the following statement was true previously in the story:

Tavi feinted (something or someone)

"Tavi ducked under a curved blade"

6. If you read the above sentence in a story, then it is ⌄ that the following statement was true previously in the story:

Tavi parried (something or someone)

Figure 3: The annotation interface for the out-of-text events annotation.

1800 examples and a dev set of 200 examples. We train the model in a way similar to above, keeping the best validation model (at epoch 28).

A.4 Training and Model Details - LM Baseline

We use a 2 layer GRU based RNN encoder with a 512 dimensional hidden state and 300 dimensional input event embeddings as our baseline event sequence LM model.

A.4.1 Training Details

The LM model is trained using Adam with a learning rate of 0.001, gradient clipping at 10, and a batch size of 64. We found using dropout at the embedding layer and the output layers to be helpful (with dropout probability of 0.1). The model is trained to minimize cross entropy loss. We train the model until loss on the validation set does not go down after three epochs, afterwhich we keep the model with the best validation performance, which in our case was epoch 5.

A.5 Annotation Interfaces

To get an idea for about the annotation set ups used here, we also provide screen shots of the annotation suites for all three annotation experiments. The out-of-text annotation experiment of Section 3.3 is shown in Figure 3. The pairwise annotation evaluation of Section 4.3 is shown in Figure 4. The chain completion annotation evaluation of Section 4.4 is shown in Figure 5.

Abstract

NLU models often exploit biases to achieve high dataset-specific performance without properly learning the intended task. Recently proposed debiasing methods are shown to be effective in mitigating this tendency. However, these methods rely on a major assumption that the types of bias should be *known* a-priori, which limits their application to many NLU tasks and datasets. In this work, we present the first step to bridge this gap by introducing a self-debiasing framework that prevents models from mainly utilizing biases without knowing them in advance. The proposed framework is general and complementary to the existing debiasing methods. We show that it allows these existing methods to retain the improvement on the challenge datasets (i.e., sets of examples designed to expose models' reliance on biases) without specifically targeting certain biases. Furthermore, the evaluation suggests that applying the framework results in improved overall robustness.[1]

1 Introduction

Neural models often achieve impressive performance on many natural language understanding tasks (NLU) by leveraging *biased features*, i.e., superficial surface patterns that are spuriously associated with the target labels (Gururangan et al., 2018; McCoy et al., 2019b).[2] Recently proposed *debiasing* methods are effective in mitigating the impact of this tendency, and the resulting models are shown to perform better beyond training distribution. They improved the performance on *challenge test sets* that are designed such that relying on the *spurious association* leads to incorrect predictions.

Prevailing debiasing methods, e.g., example reweighting (Schuster et al., 2019), confidence regularization (Utama et al., 2020), and model ensembling (He et al., 2019; Clark et al., 2019; Mahabadi et al., 2020), are agnostic to model's architecture as they operate by adjusting the training loss to account for biases. Namely, they first identify *biased examples* in the training data and down-weight their importance in the training loss so that models focus on learning from harder examples.[3]

While promising, these *model agnostic* methods rely on the assumption that the *specific* types of biased features (e.g., lexical overlap) are *known* a-priori. This assumption, however, is a limitation in various NLU tasks or datasets because it depends on researchers' intuition and task-specific insights to *manually* characterize the spurious biases, which may range from simple word/n-grams co-occurrence (Gururangan et al., 2018; Poliak et al., 2018; Tsuchiya, 2018; Schuster et al., 2019) to more complex stylistic and lexico-syntactic patterns (Zellers et al., 2019; Snow et al., 2006; Vanderwende and Dolan, 2006). The existing datasets or the newly created ones (Zellers et al., 2019; Sakaguchi et al., 2020; Nie et al., 2019b) are, therefore, still very likely to contain biased patterns that remain *unknown* without an in-depth analysis of each individual dataset (Sharma et al., 2018).

In this paper, we propose a new strategy to enable the existing debiasing methods to be applicable in settings where there is minimum prior information about the biases. Specifically, models should automatically identify potentially biased examples without being pinpointed at a specific bias in advance. Our work makes the following novel contributions in this direction of automatic bias mitigation.

First, we analyze the learning dynamics of a

[2] E.g., in several textual entailment datasets, negation words such as "never" or "nobody" are highly associated with the *contradiction* label.

[3] We refer to biased examples as examples that can be solved using *only* biased features.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7597–7610,
November 16–20, 2020.

large pre-trained model such as BERT (Devlin et al., 2019) on a dataset injected with a synthetic and controllable bias. We show that, in very small data settings, models exhibit a distinctive response to synthetically biased examples, where they rapidly increase the accuracy ($\rightarrow 100\%$) on biased test set while performing poorly on other sets, indicating that they are mainly relying on biases.

Second, we present a self-debiasing framework within which two models of the same architecture are pipelined to address the *unknown* biases. Using the insight from the synthetic dataset analysis, we train the first model to be a *shallow* model that is effective in automatically identifying potentially biased examples. The shallow model is then used to train the main model through the existing debiasing methods, which work by down-weighting the potentially biased examples. These methods present a caveat in that they may lose useful training signals from the down-weighted training examples. To account for this, we also propose an *annealing mechanism* which helps in retaining models' in-distribution performance (i.e., evaluation on the test split of the original dataset).

Third, we experiment on three NLU tasks and evaluate the models on their existing challenge datasets. We show that models obtained through our self-debiasing framework gain equally high improvement compared to models that are debiased using specific prior knowledge. Furthermore, our cross-datasets evaluation suggests that our general framework that does not target only a particular type of bias results in better overall robustness.

Terminology This work relates to the growing number of research that addresses the effect of dataset biases on the resulting models. Most research aims to mitigate different types of bias on varying parts of the training pipeline (e.g., dataset collection or modeling). Without a shared definition and common terminology, it is quite often that the term "bias" discussed in one paper refers to a different kind of bias mentioned in the others. Following the definition established in the recent survey paper by Shah et al. (2020), the dataset bias that we address in this work falls into the category of **label bias**. This bias emerges when the conditional distribution of the target label given certain features in the training data diverges substantially at test time. These features that are associated with the label bias may differ from one classification setting to the others, and although they are predictive, relying on them for prediction may be harmful to fairness (Elazar and Goldberg, 2018) or generalization (McCoy et al., 2019b). The instances of these features may include protected socio-demographic attributes (gender, age, etc.) in automatic hiring decision systems; or surface-level patterns (negation words, lexical overlap, etc.) in NLU tasks. Further, we consider the label bias to be **unknown** when the information about the characteristics of its associated features is not precise enough for the existing debiasing strategies to identify potentially biased examples.

MNLI synthetic:
premise: What's truly striking, though, is that Jobs has never really let this idea go.
orig. hypo.: Jobs never held onto an idea for long.
biased: 0 Jobs never held onto an idea for long.
anti-biased: 1 Jobs never held onto an idea for long.
label: 0 (contradiction)

Figure 1: Synthetic bias datasets are created by appending an artificial feature to the input text that allows models to use it as a shortcut to the target label. For each example in MNLI, a number-coded label (`contradiction`: 0, `entailment`: 1, `neutral`: 2) is appended to the hypothesis sentences.

2 Motivation and Analysis

Debiasing NLU models Recent NLU tasks are commonly formulated as multi-class classification problems (Wang et al., 2018), in which the goal is to predict the semantic relationship label $y \in \mathcal{Y}$ given an input sentence pairs $x \in \mathcal{X}$. For each example x, let $b(x)$ be the biased features that happen to be predictive of label y in a specific dataset. The aim of a debiasing method for an NLU task is to learn a debiased classifier f_d that does not mainly use $b(x)$ when computing $p(y|x)$.

Model-agnostic debiasing methods (e.g., product-of-expert (Clark et al., 2019)) achieve this by reducing the importance of biased examples in the learning objective. To identify whether an example is biased, they employ a shallow model f_b, a simple model trained to directly compute $p(y|b(x))$, where the features $b(x)$ are hand-crafted based on the task-specific knowledge of the biases. However, obtaining the prior information to design $b(x)$ requires a dataset-specific analysis (Sharma et al., 2018). Given the ever-growing number of new datasets, it would be a time-consuming and

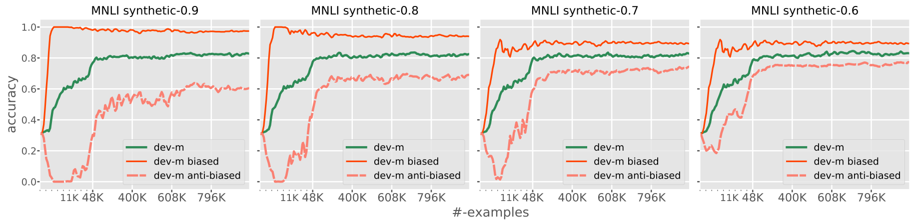

Figure 2: The learning trajectory of a BERT model on MNLI datasets that are synthetically biased with different proportions: 0.9, 0.8, 0.7, and 0.6. All settings show models' tendency to rely on biases after seeing only a small number of training examples (accuracy goes up rapidly on "biased" while goes down on "anti-biased" after less than 10K training steps).

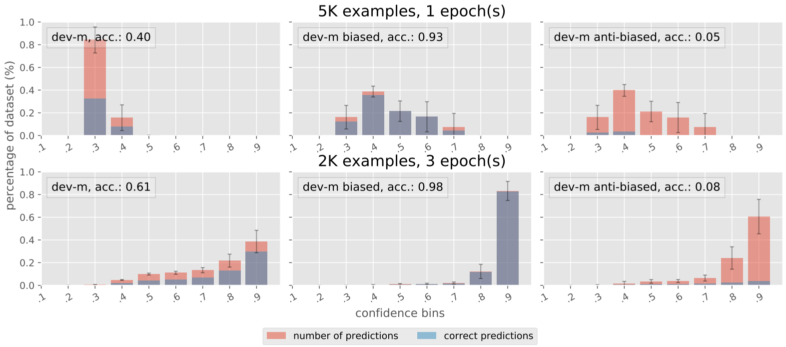

Figure 3: Histogram of probabilities assigned by synthetic MNLI models to their predicted labels. Top: model trained on 5K examples for 1 epoch. Bottom: model trained on 2K for 3 epochs. Blue areas indicate the proportion of the correct predictions within each bin.

costly process to identify biases before applying the debiasing methods.

In this work, we propose an alternative strategy to automatically obtain f_b to enable existing debiasing methods to work with no precise prior knowledge. This strategy assumes a connection between large pre-trained models' reliance on biases with their tendency to operate as a *rapid surface learner*, i.e., they tend to quickly overfit to surface form information especially when they are fine-tuned in a small training data setting (Zellers et al., 2019). This tendency of deep neural network to exploit simple patterns in the early stage of the training is also well-observed in other domains of artificial intelligence (Arpit et al., 2017; Liu et al., 2020). Since biases are commonly characterized as simple surface patterns, we expect that models' rapid performance gain is mostly attributed to their reliance on biases. Namely, they are likely to operate similarly as f_b after they are exposed to only a small number of training instances, i.e., achieving high accuracy on the *biased* examples while still performing poorly on the rest of the dataset.

Synthetic bias We investigate this assumption by analyzing the comparison between models' performance trajectory on *biased* and *anti-biased* ("counterexamples" to the biased shortcuts) test sets as more examples are seen during the training. Our goal is to obtain a fair comparison without the confounds that may result in performance differences on these two sets. Specifically, the examples from the two sets should be similar except for the presence of a feature that is biased in one set and anti-biased in the other. For this reason, we construct a synthetically biased data based on the MNLI dataset (Williams et al., 2018) using a procedure illustrated in Figure 1. A synthetic bias is injected by appending an artificial feature to 30% of the original examples. We simulate the presence of bias by controlling m portion of these manipulated examples such that their artificial feature is associated with the ground truth label ("biased"), whereas, in the remaining $(1 - m)$, the feature is disassociated with the label ("anti-biased").[4] Using a similar injection procedure we can produce both fully *biased* and *anti-biased* test sets in which 100% of the examples contain the synthetic features. Models that blindly predict based on the artificial feature are guaranteed to achieve 0% ac-

---

[4] The remaining 70% of the dataset remain the same. The biased and anti-biased examples refer to the fraction within the other 30% that are injected with the artificial feature.

curacy on the anti-biased test.

Model's performance trajectory We finetune a `bert-base-uncased` model (Wolf et al., 2019) on the *whole* MNLI datasets that are partially biased with different proportions ($m = \{0.9, 0.8, 0.7, 0.6\}$). We evaluate each model on the original as well as the two fully biased and anti-biased test sets. Figure 2 shows the performance trajectory in all settings. As expected, the models show the tendency of relying on biases after only seeing a small fraction of the dataset. Specifically, at an early point during training, models achieve 100% accuracy on the biased test and drop to almost 0% on the anti-biased test. This behavior is more apparent as the proportion of biased examples is increased by adjusting m from 0.6 to 0.9.

Training a shallow model The analysis suggests that we can obtain a substitute f_b by taking a checkpoint of the main model early in the training, i.e., when the model has only seen a small portion of the training data. However, we observe that the resulting model makes predictions with rather low confidence, i.e., assigns a low probability to the predicted label. As shown in Figure 3 (top), most predictions fall in the 0.4 probability bin, only slightly higher than a uniform probability (0.3). We further find that by training the model for multiple epochs, we can obtain a confident f_b that overfits biased features from a smaller sample size (Figure 3, bottom). We show in Section 3 that overconfident f_b is particularly important to better identify biased examples.

3 Self-debiasing Framework

We propose a self-debiasing framework that enables existing debiasing methods to work without requiring a precise dataset-specific knowledge about the biases' characteristics. Our framework consists of two stages: (1) automatically identifying biased examples using a shallow model; and (2) using this information to train the main model through the existing debiasing methods, which are augmented with our proposed annealing mechanism.

3.1 Biased examples identification

First, we train a shallow model f_b, which approximates the behavior of a simple hand-crafted model that is commonly used by the existing debiasing methods to identify biased examples. As mentioned in Section 2, we obtain f_b for each task by training a copy of the main model on a small random subset of the dataset for several epochs. The model f_b is then used to make predictions on the remaining *unseen* training examples. Given a training example $\{x^{(i)}, y^{(i)}\}$, we denote the output of the shallow model as $f_b(x^{(i)}) = p_b^{(i)}$.

Probabilities p_b are assigned to each training instance to indicate how likely that it contains biases. Specifically, the presence of biases can be estimated using the scalar probability value of $p_b^{(i)}$ on the correct label, which we denote as $p_b^{(i,c)}$, where c is the index of the correct label. We can interpret $p_b^{(i,c)}$ by the following: when the model predicts an example $x^{(i)}$ correctly with high confidence, i.e., $p_b^{(i,c)} \to 1$, $x^{(i)}$ is potentially biased. Conversely, when the model makes an overconfident error, i.e., $p_b^{(i,c)} \to 0$, $x^{(i)}$ is likely to be a harder example from which models should focus on learning.

3.2 Debiased training objective

We use the obtained p_b to train the main model f_d parameterized by θ_d. Specifically, p_b is utilized by the existing model-agnostic debiasing methods to down-weight the importance of biased examples in the training objective. In the following, we describe how the three recent model-agnostic debiasing methods (example reweighting (Schuster et al., 2019), product-of-expert (He et al., 2019; Clark et al., 2019; Mahabadi et al., 2020), and confidence regularization (Utama et al., 2020)) operate within our framework:

Example reweighting This method adjusts the importance of a training instance by directly assigning a scalar weight that indicates whether the instance exhibits a bias. Following Clark et al. (2019), this weight scalar is computed as $1 - p_b^{(i,c)}$. The individual loss term is thus defined as:

$$\mathcal{L}(\theta_d) = -(1 - p_b^{(i,c)}) y^{(i)} \cdot \log p_d$$

Where p_d is the softmax output of f_d. This formulation means that the contribution of an example to the overall loss is steadily decreased as the shallow model assigns a higher probability to the correct label (i.e., more confident prediction).

Product-of-expert In this method, the main model f_d is trained in an ensemble with the shallow model f_b, by combining their softmax outputs. The ensemble loss on each example is defined as:

$$\mathcal{L}(\theta_d) = -y^{(i)} \cdot \log \texttt{softmax}(\log p_d + \log p_b)$$

During the training, we only optimize the parameters of f_d while keeping the parameters of f_b fixed. At test time, we use only the prediction of f_d.

Confidence regularization This method works by regularizing model confidence on the examples that are likely to be biased. Utama et al. (2020) use a self-distillation training objective (Furlanello et al., 2018; Hinton et al., 2015), in which the supervision by the teacher model is scaled down using the output of the shallow model. The loss on each individual example is defined as a cross entropy between p_d and the scaled teacher output:

$$\mathcal{L}(\theta_d) = -\mathtt{S}(p_t, p_b^{(i,c)}) \cdot \log p_d$$

Where f_t is the teacher model (parameterized identically to f_d) that is trained using a standard cross entropy loss on the full dataset, and $f_t(x) = p_t$. This "soft" label supervision provided by the scaled teacher output discourages models to make overconfident predictions on examples containing biased features.

3.3 Annealing mechanism

Our shallow model f_b is likely to capture multiple types of bias, leading to more examples being down-weighted in the debiased training objectives. As a result, the effective training data size is reduced even more, which leads to a substantial in-distribution performance drop in several debiasing methods (He et al., 2019; Clark et al., 2019). To mitigate this, we propose an *annealing mechanism* that allows the model to gradually learn from all examples, including ones that are detected as biased. This is done by steadily lowering $p_b^{(i,c)}$ as the training progresses toward the end. At training step t, the probability vector $p_b^{(i)}$ is scaled down by re-normalizing all probability values that have been raised to the power of α_t: $p_b^{(i,j)} = \frac{p_b^{(i,j)^{\alpha_t}}}{\sum_{k=1}^{K} p_b^{(i,k)^{\alpha_t}}}$, where K is the number of labels and index $j \in \{1, ..., K\}$. The value of α_t is gradually decreased throughout the training using a linear schedule. Namely, we set the value of α_t to range from the maximum value 1 at the start of the training to the minimum value a in the end of the training: $\alpha_t = 1 - t\frac{(1-a)}{T}$, where T is the total number of training steps. In the extreme case where a is set to 0, p_b vectors are scaled down closer to uniform distribution near the end of the training. This results in a more equal importance of all examples, which is equivalent to the standard cross entropy loss.

We note that since this mechanism gradually exposes models to potentially biased instances, it presents the risk of model picking up biases and adopting back the baseline behavior. However, our results and analysis suggest that when the parameter a is set to a value close to 1, the annealing mechanism can still provide an improvement on the in-distribution data while retaining a reasonably well performance on the challenge test sets.

4 Experimental Setup

4.1 Evaluation Tasks

We perform evaluations on three NLU tasks: natural language inference, fact verification, and paraphrase identification. We *simulate* a setting where we have not enough information about the biases for training a debiased model, and thus biased examples should be identified automatically. Therefore, we only use the existing challenge test set for each examined task strictly for evaluation and do not use the information about their corresponding bias types during training. In the following, we briefly discuss the datasets used for training on each task as well as their corresponding challenge test sets to evaluate the impact of debiasing methods:

Natural language inference We use the English Multi-Genre Natural Language Inference (MNLI) dataset (Williams et al., 2018) which consists of 392K pairs of premise and hypothesis sentences annotated with their textual entailment information. We test NLI models on lexical overlap bias using HANS evaluation set (McCoy et al., 2019b). It contains examples, in which premise and hypothesis sentences that consist of the same set of words may not hold an entailment relationship, e.g., "cat caught a mouse" vs. "mouse caught a cat". Since word overlapping is biased towards entailment in MNLI, models trained on this dataset often perform close to a random baseline on HANS.

Paraphrase identification We experiment with the Quora Question Pairs dataset.[5] It consists of 362K questions pairs annotated as either *duplicate* or *non-duplicate*. We perform an evaluation using PAWS dataset (Zhang et al., 2019) to test whether

Table 1: Models' performance when evaluated on MNLI, Fever, QQP, and their corresponding challenge test sets. The `known-bias` results for MNLI and FEVER are taken from Utama et al. (2020)(♭), Clark et al. (2019)(‡), Mahabadi et al. (2020)(†), and Schuster et al. (2019)(♣). The results of the proposed framework are indicated by `self-debias`. (♠) indicates the training with our proposed *annealing mechanism*. Boldface numbers indicate the highest challenge test set improvement for each debiasing setup on a particular task.

the resulting models perform the task by relying on lexical overlap biases.

Fact verification We run debiasing experiments on the FEVER dataset (Thorne et al., 2018). It contains pairs of claim and evidence sentences labeled as either *support*, *refutes*, and *not-enough-information*. We evaluate on the FeverSymmetric test set (Schuster et al., 2019), which is collected to reduced claim-only biases (e.g., negative phrases such as "refused to" or "did not" are associated with the *refutes* label).

4.2 Main Model

We apply our self-debiasing framework on the BERT model (Devlin et al., 2019), which performs very well on the three considered tasks.[6] It also shows substantial improvements on the corresponding challenge datasets when trained through the existing debiasing methods (Clark et al., 2019; He et al., 2019). For each examined debiasing method, we show the comparison between the results when it is applied within our framework and when it is trained using prior knowledge to detect training examples with a specific bias. For the second scenario, MNLI and QQP models are debiased using a lexical overlap bias prior, whereas FEVER model is debiased using hand-crafted claim-only biased features. We use the results reported in their corresponding papers. Additionally, we train a baseline BERT model with a standard cross entropy loss.

4.3 Hyperparameters

The hyperparameters of our framework include the number of training samples and epochs to train the shallow model f_b as well as parameter a to schedule the annealing process. We only use the training data, and no information about the challenging sets, for tuning these parameters. Based on the insight from our synthetic bias analysis (Section 2), we choose the sample size and the number of epochs which result in f_b that satisfies the following conditions: (1) its accuracy on the unseen training examples is around 60% to 70%; (2) More than 90% of their predictions fall into the high confidence bin (> 0.9). These variables vary for each task depending on their diversity and difficulty. For instance, it takes 2000 examples and 3 epochs of training for MNLI, and only 500 examples and 4 epochs for an easier task such as QQP.[7] For the annealing mechanism, we set $a = 0.8$ as the minimum value of α_t for all experiments across the three tasks. Although this may not be an optimal configuration for all tasks, it still allows us to observe how gradually increasing the importance of "biased" examples may affect the overall performance.

5 Results and Discussion

Main results We experiment with several training methods for each task: the baseline training, debiased training with prior knowledge, and the debiased training using our self-debiasing framework (with and without annealing mechanism). We

---

[6] We use the pre-trained `bert-base-uncased` model available at `https://huggingface.co/transformers/pretrained_models.html`.

[7] We perform a search on all combinations of $1, 2, 3, 4$, and 5 epochs and $500, 1000, 1500$, and 2000 examples.

Table 2: Accuracy results of self-debias confidence regularization on cross-dataset evaluation.

present the results on the three tasks in Table 1. Each model is evaluated both in terms of their in-distribution performance on the original development set and their out-of-distribution performance on the challenge test set. For each setting, we report the average results across 5 runs.

We observe that: (1) models trained through self-debiasing framework obtain equally high improvements on challenge sets of the three tasks compared to their corresponding debiased models trained with a prior knowledge (indicated as `known-bias`). In some cases, the existing debiasing methods can even be more effective when applied using the proposed framework, e.g., `self-debias` example reweighting obtains 52.3 F1 score improvement over the baseline on the non-duplicate subset of PAWS (compared to 33.6 by its `known-bias` counterpart). This indicates that the framework is equally effective in identifying biased examples without previously needed prior knowledge; (2) Most improvements on the challenge datasets come at the expense of the in-distribution performance (dev column) except for the confidence regularization models. For instance, the `self-debias` product-of-expert (PoE) model, without annealing, performs 2.2pp lower than the `known-bias` model on MNLI dev set. This indicates that self-debiasing may identify more potentially biased examples and thus effectively omit more training data; (3) Annealing mechanism (indicated by ♠) is effective in mitigating this issue in most cases, e.g., improving PoE by 0.5pp on FEVER dev and 1.2pp on MNLI dev while keeping relatively high challenge test accuracy. Self-debias reweighting augmented with annealing mechanism even achieves the highest HANS accuracy in addition to its improved in-distribution performance.

Cross-datasets evaluation Previous work demonstrated that targeting a specific bias to optimize performance in the corresponding challenge dataset may bias the model in other unwanted directions, which proves to be counterproductive in improving the overall robustness (Nie et al., 2019a; Teney et al., 2020). One way to evaluate the impact of debiasing methods on the overall robustness is to train models on one dataset and evaluate them against other datasets of the same task, which may have different types and amounts of biases (Belinkov et al., 2019a). A contemporary work by Wu et al. (2020) specifically finds that debiasing models based on only a single bias results in models that perform significantly worse upon cross-datasets evaluation for the reading comprehension task.

Motivated by this, we perform similar evaluations for models trained on MNLI through the three debiasing setups: `known-bias` to target the HANS-specific bias, `self-debiasing`, and `self-debiasing` augmented with the proposed annealing mechanism. We do not tune the hyperparameters for each target dataset and use the models that we previously reported in the main results. As the target datasets, we use 4 NLI datasets: Scitail (Khot et al., 2018), SICK (Marelli et al., 2014), GLUE diagnostic set (Wang et al., 2018), and 3-way version of RTE 1, 2, and 3 (Dagan et al., 2005; Bar-Haim et al., 2006; Giampiccolo et al., 2007).[8]

We present the results in Table 2. We observe that the debiasing with prior knowledge to target the specific lexical overlap bias (indicated by $\texttt{known}_{\text{HANS}}$) can help models to perform better on SICK and Scitail. However, its resulting models under-perform the baseline in RTE sets and GLUE diagnostic, degrading the accuracy by 0.5 and 0.6pp. In contrast, the self-debiased models, with and without annealing mechanism, outperform the baseline on all target datasets, both achieving additional 1.1pp on average. The gains by the two self-debiasing suggest that while they are effective in mitigating the effect of one particular bias (i.e., lexical overlap), they do not result in models learning other unwanted patterns that may hurt the performance on other datasets. These results also extend the findings of Wu et al. (2020) to the NLU settings in that addressing multiple biases at once, as done by our general debiasing method, leads to a better overall generalization.

Analyzing the annealing mechanism In previous experiments, we show that setting the mini-

---

[8] We compiled and reformated the dataset files which are available at `https://nlp.stanford.edu/projects/contradiction/`.

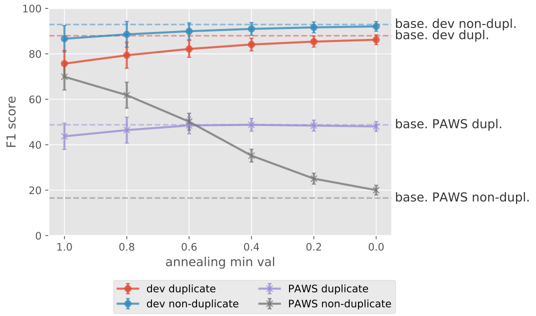

Figure 4: Analysis of the annealing mechanism using different values of minimum α_t.

mum α_t to only slightly lower than 1 (i.e., $a = 0.8$) results in improvements on the in-distribution without substantial degradation on challenge datasets scores. We question whether this behavior persists once we set a closer to 0. Specifically, do models fall back to the baseline performance when the loss gets more equivalent to the standard cross-entropy at the end of the training?

We run additional experiments using the self-debiased example reweighting on QQP $\Rightarrow$ PAWS evaluations. We consider the following values to set the minimum α_t: $1.0, 0.8, 0.6, 0.4, 0.2$, and 0.0. For each experiment, we report the average scores across multiple runs. As we see in Figure 4, the challenge test scores decrease as we set minimum a to lower values. Annealing can still offer a reasonable trade-off between in-distribution and challenge test performances up until $a = 0.6$, before falling back to baseline performance at $a = 0$. These results suggest that models are still likely to learn spurious shortcuts from biased examples that they are exposed to even at the end of the training. Consequently, the annealing mechanism should be used cautiously by setting the minimum α_t to moderate values, e.g., 0.6 or 0.8.

Impact on learning dynamics We previously show (Figure 2) that baseline models tend to learn easier examples more rapidly, allowing them to make correct predictions by relying on biases. As the self-debiasing framework manages to mitigate this fallible reliance, we expect some changes in models' learning dynamics. We are, therefore, interested in characterizing these changes by analyzing their training loss curve. In particular, we examine the individual losses on each training batch and measure their variability using percentiles (i.e., 0th, 25th, 50th, 75th, and 100th percentile). Figure 5 shows the comparison of the individual loss variability between the baseline and the self-debiased models when trained on MNLI. We observe that the median loss of the baseline model converges faster than the self-debiased counterpart (dotted solid lines). However, examples below its 25th percentile already have losses smaller than 10^{-1} when the majority of the losses are still high (darker shadow area). This indicates that unregularized training optimizes faster on certain examples, possibly due to the presence of biases. On the contrary, self-debiased training maintains relatively less variability of losses throughout the training. This result suggests that overconfident predictions (unusually low loss examples) can be an indication of the model utilizing biases. This is in line with the finding of Utama et al. (2020), which shows that regularizing confidence on biased examples leads to improved robustness against biases.

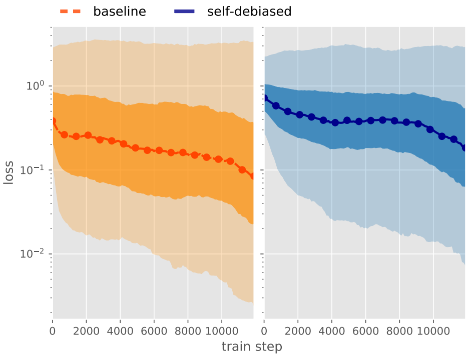

Figure 5: Training loss curves for the first 15K steps by the baseline and self-debias example reweighting training (shown in log scale). Solid lines indicate the median loss within each training batch. The dark and light shadow areas represent the range between 25th to 75th percentile and the range between 0th (minimum) and 100th percentile (maximum), respectively.

Bias identification stability Researchers have recently observed large variability in the generalization performance of fine-tuned BERT model (Mosbach et al., 2020; Zhang et al., 2020), especially in the out-of-distribution evaluation settings (McCoy et al., 2019a; Zhou et al., 2020). This may raise concerns on whether our shallow models, which are trained on the sub-sample of the training data, can consistently learn to rely mostly on biases. We, therefore, train 10 instances of shallow models on the MNLI dataset using different random seeds (for classifier's weight initialization and training sub-sampling). For evaluation, we perform two different partitionings of MNLI dev set based on the output of two simple hand-crafted models, which

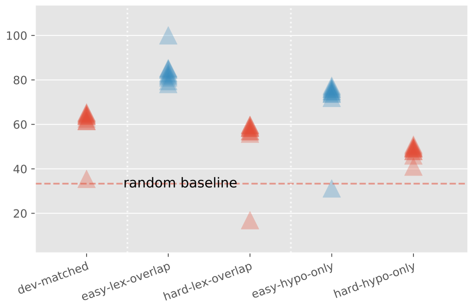

Figure 6: Evaluation of 10 shallow model instances on easy/hard partitioning of MNLI dev based on the presence of lexical overlap and hypothesis-only biases. The results suggest the stability of shallow models in capturing the two biases.

use lexical overlap and hypothesis-only features (Gururangan et al., 2018), respectively. The stability of bias utilization across the runs is evaluated by measuring their performance on *easy* and *hard* subsets of each partitioning, where examples that simple models predicted correctly belong to *easy* and the rest belong to *hard*.[9]

Figure 6 shows the results. We observe small variability in the overall dev set performance which ranges in 61-65% accuracy. Similarly, the models obtain consistently higher accuracy on the easy subsets over the hard ones: 79-85% vs. 56-59% on the lexical-overlap partitioning and 72-77% vs. 48-50% on the hypothesis-only partitioning. The results indicate that: 1) the bias-reliant behavior of shallow models is stable; and 2) shallow models capture multiple types of bias. However, we also observe one rare instance of the shallow model that fails to converge during training and is stuck at making random predictions (33% in MNLI). This may indicate that the biased examples are undersampled in that particular run. In that case, we can easily spot this undesired behavior, discard the model, and perform another sampling.

6 Related Work

The artifacts of large scale dataset collections result in dataset biases that allow models to perform well without learning the intended reasoning skills. In NLI, models can perform better than chance by only using the partial input (Gururangan et al., 2018; Poliak et al., 2018; Tsuchiya, 2018) or by basing their predictions on whether the inputs are highly overlapped (McCoy et al., 2019b; Dasgupta et al., 2018). Similar phenomena exist in various tasks, including argumentation mining (Niven and Kao, 2019), reading comprehension (Kaushik and Lipton, 2018), or story cloze completion (Schwartz et al., 2017; Cai et al., 2017). To allow a better evaluation of models' reasoning capabilities, researchers constructed challenge test sets composed of "counterexamples" to the spurious shortcuts that models may adopt (Jia and Liang, 2017; Glockner et al., 2018; Zhang et al., 2019; Naik et al., 2018). Models evaluated on these sets often fall back to random baseline performance.

There has been a flurry of work in dynamic dataset construction to systematically reduce dataset biases through adversarial filtering (Zellers et al., 2018; Sakaguchi et al., 2020; Bras et al., 2020) or human in the loop (Nie et al., 2019b; Kaushik et al., 2020; Gardner et al., 2020). While promising, researchers also show that newly constructed datasets may not be fully free of hidden biased patterns (Sharma et al., 2018). It is thus crucial to complement the data collection efforts with learning algorithms that are more robust to biases, such as the recently proposed product-of-expert (Clark et al., 2019; He et al., 2019; Mahabadi et al., 2020), confidence regularization (Utama et al., 2020), or other training strategies (Belinkov et al., 2019b; Yaghoobzadeh et al., 2019; Tu et al., 2020). Despite their effectiveness, these methods are limited by their assumption on the availability of information about the task-specific biases. Our framework aims to alleviate this limitation and enable them to address *unknown* biases.

7 Conclusion

We present a general self-debiasing framework to address the impact of unknown dataset biases by omitting the need for thorough dataset-specific analysis to discover the types of biases for each new dataset. We adopt the existing debiasing methods into our framework and enable them to obtain equally high improvements on several *challenge test sets* without targeting a specific bias. The evaluation also suggests that our framework results in better overall robustness compared to the bias-specific counterparts. Based on our analysis, future work in the direction of automatic bias mitigation may include identifying potentially biased examples in an *online* fashion and discouraging models from exploiting them throughout the training.

---

[9] Although this may seem to be against the spirit of not using prior knowledge about the biases, we believe that this step is necessary to show the stability of the shallow models and to validate if they indeed capture the intended biases.

A Natural Language Inference

Main model We finetune the BERT base model for all settings (baseline, known-bias, and self-debiasing) using default parameters: 3 epochs of training with learning rate 5^{-5}. An exception is made for product-of-expert and confidence regularization, where we follow He et al. (2019) to run the training longer, i.e. 5 epochs.

Shallow model The shallow model for MNLI is trained on 2K of examples for 3 epochs using the default learning rate of 5^{-5}.

B Fact verification

Main model We follow Schuster et al. (2019) in finetuning the BERT base model on FEVER dataset using the following parameters: learning rate 2^{-5} and 3 epochs of training.

Shallow model The shallow model can be trained in lesser amount of data, 500 examples. We train the model for 5 epochs with the same learning rate, 2^{-5}.

C Paraphrase Identification

Main model We follow Utama et al. (2020) in setting the parameters for training a QQP model: learning rate 2^{-5} and 3 epochs of training.

Shallow model Similar to FEVER, we train the shallow model using only 500 examples. It converges in 4 epochs using the same learning rate, 2^{-5}.

D Synthetic MNLI Results

We report the final accuracy of models when trained on our synthetic bias datasets. We show that the anti-biased accuracy correlates negatively with the proportion of the biased examples. We present the results in Table 3.

Bias prop.	**test sets**		
	original	biased	anti-biased
0.9	83.6 ⇐	97.1 ⟹	61.7 ⟸
0.8	83.7 ⇐	95.3 ⟹	70.4 ⟸
0.7	83.9 ⇐	92.8 ⇒	75.5 ⇐
0.6	84.1 =	90.9 ⇒	78.5 ⇐

Table 3: Final accuracy of models trained on synthetic bias datasets.

E Detailed HANS Results

HANS dataset (McCoy et al., 2019b) consist of three subsets, covering different inference phenomena which happen to have lexical overlap: (a) Lexical overlap e.g., "*The doctor was paid by the actor*" vs. "*The doctor paid the actor*"; (b) Subsequence, e.g., "*The doctor near the actor danced*" vs. "*The actor danced*"; and (c) Constituent e.g., "*If the artist slept, the actor ran*" vs. "*The artist slept*". Each subset contains examples of both entailment and non-entailment. The 3-way predictions on MNLI is mapped to HANS by taking max pool between neutral and contradiction labels. We present the results of our experiments in Table 4.

Method	**HANS all sets (Acc.)**					
	Lex	**Lex.**	**Sub.**	**Sub.**	**Con.**	**¬Con.**
BERT-base	96.0	51.8	99.5	7.4	99.4	14.5
Rew. $_{\textbf{self-debias}}$	81.3	73.3	94.7	34.5	92.8	42.3
Rew. ♠ $_{\textbf{self-debias}}$	84.7	77.1	96.0	30.5	95.3	37.4
PoE $_{\textbf{self-debias}}$	77.0	73.6	92.1	42.2	89.3	49.8
PoE ♠ $_{\textbf{self-debias}}$	78.5	67.7	91.3	28.6	95.4	45.1
Conf-reg $_{\textbf{self-debias}}$	81.8	78.2	93.7	31.7	95.1	31.5
Conf-reg ♠ $_{\textbf{self-debias}}$	87.4	74.5	96.3	27.4	95.1	26.6

Table 4: Models' performance on HANS challenge test set (McCoy et al., 2019b). Column `lex.`, `con.`, and `sub.` stand for lexical overlap, constituency, and subsequence, respectively. The (¬) symbol indicates the non-entailment subset.

On the Role of Supervision in Unsupervised Constituency Parsing

Abstract

We analyze several recent unsupervised constituency parsing models, which are tuned with respect to the parsing F_1 score on the *Wall Street Journal* (WSJ) development set (1,700 sentences). We introduce strong baselines for them, by training an existing supervised parsing model (Kitaev and Klein, 2018) on the same labeled examples they access. When training on the 1,700 examples, or even when using only 50 examples for training and 5 for development, such a few-shot parsing approach can outperform all the unsupervised parsing methods by a significant margin. Few-shot parsing can be further improved by a simple data augmentation method and self-training. This suggests that, in order to arrive at fair conclusions, we should carefully consider the amount of labeled data used for model development. We propose two protocols for future work on unsupervised parsing: (i) use fully unsupervised criteria for hyperparameter tuning and model selection; (ii) use as few labeled examples as possible for model development, and compare to few-shot parsing trained on the same labeled examples.[1]

1 Introduction

Recent work has considered neural unsupervised constituency parsing (Shen et al., 2018a; Drozdov et al., 2019; Kim et al., 2019b, *inter alia*), showing that it can achieve much better performance than trivial baselines. However, many of these approaches use the gold parse trees of all sentences in a development set for either early stopping (Shen et al., 2018a, 2019; Drozdov et al., 2019, *inter alia*) or hyperparameter tuning (Kim et al., 2019a). In contrast, models trained and tuned without any labeled data (Kim et al., 2019b; Peng et al., 2019) are much less competitive.

Are the labeled examples important in order to obtain decent unsupervised parsing performance? How well can we do if we *train* on these labeled examples rather than merely using them for tuning? In this work, we consider training a supervised constituency parsing model (Kitaev and Klein, 2018) with very few examples as a strong baseline for unsupervised parsing tuned on labeled examples.

We empirically characterize unsupervised and few-shot parsing across the spectrum of labeled data availability, finding that (i) tuning based on a few (as few as 15) labeled examples is sufficient to improve unsupervised parsers over fully unsupervised criteria by a significant margin; (ii) unsupervised parsing with supervised tuning does outperform few-shot parsing with fewer than 15 labeled examples, but few-shot parsing quickly dominates once there are more than 55 examples; and (iii) when few-shot parsing is combined with a simple data augmentation method and self-training (Steedman et al., 2003; Reichart and Rappoport, 2007; McClosky et al., 2006, *inter alia*), only 15 examples are needed for few-shot parsing to begin to dominate.

Based on these results, we propose the following two protocols for future work on unsupervised parsing:

1. Derive and use fully unsupervised criteria for hyperparameter tuning and model selection.
2. Use as few labeled examples as possible for model development and tuning, and compare to few-shot parsing models trained on the used examples as a strong baseline.

We suggest future work to tune and compare models under each protocol separately.

In addition, we present two side findings on unsupervised parsing: (i) the vocabulary size in unsupervised parsing, which has not been widely considered as a hyperparameter and varies across

prior work, greatly affects the performance of all unsupervised parsing models tested; and (ii) self-training can help improve all investigated unsupervised parsing (Shen et al., 2018a, 2019; Drozdov et al., 2019; Kim et al., 2019a) and few-shot parsing models, and thus can be considered as a post-processing step in future work.

2 Related Work

Unsupervised parsing. During the past two decades, there has been a lot of work on both unsupervised constituency parsing (Klein and Manning, 2002, 2004; Bod, 2006a,b; Seginer, 2007; Snyder et al., 2009, *inter alia*) and unsupervised dependency parsing (Klein and Manning, 2004; Smith and Eisner, 2006; Spitkovsky et al., 2011, 2013, *inter alia*). Recent work has proposed several effective models for unsupervised or distantly supervised constituency parsing, optimizing either a language modeling objective (Shen et al., 2018a, 2019; Kim et al., 2019b,a, *inter alia*) or other downstream semantic objectives (Li et al., 2019; Shi et al., 2019). Some of them are tuned with labeled examples in the WSJ development set (Shen et al., 2018a, 2019; Htut et al., 2018; Drozdov et al., 2019; Kim et al., 2019a; Wang et al., 2019) or other labeled examples (Jin et al., 2018, 2019).

Data augmentation. Data augmentation is a strategy for automatically increasing the amount and variety of data for training models, without actually collecting any new data. Such methods have been found helpful on many NLP tasks, including text classification (Kobayashi, 2018; Samanta et al., 2019), relation classification (Xu et al., 2016), and part-of-speech tagging (Şahin and Steedman, 2018). Part of our approach also falls into the category of data augmentation, applied specifically to constituency parsing from very few examples.

Few-shot parsing. Sagae et al. (2008) show that a supervised dependency parsing model trained on 100 examples can work surprisingly well. Recent work has demonstrated the potential of few-shot dependency parsing on multiple languages (Aufrant et al., 2018; Meechan-Maddon and Nivre, 2019; Vania et al., 2019, *inter alia*). Our approach (§3) can be viewed as few-shot constituency parsing.

3 Few-Shot Constituency Parsing

We apply Benepar (§3.1; Kitaev and Klein, 2018) as the base model for few-shot parsing. We present a simple data augmentation method (§3.2) and an iterative self-training strategy (§3.3) to further improve the performance. We suggest that such an approach should serve as a strong baseline for unsupervised parsing with supervised tuning.

3.1 Parsing Model

The Benepar parsing model consists of (i) word embeddings, (ii) transformer–based (Vaswani et al., 2017) word-span embeddings, and (iii) a multi-layer perceptron to compute a score for each labeled span.[2] The score of an arbitrary tree is defined as the sum of all of its internal span scores. Given a sentence and its ground-truth parse tree T^*, the model is trained to satisfy $\mathit{score}(T^*) \geq \mathit{score}(T) + \Delta(T^*, T)$ for any tree T $(T \neq T^*)$, where Δ denotes the Hamming loss on labeled spans. The label-aware CKY algorithm is used to obtain the tree with the highest score. More details can be found in Kitaev and Klein (2018).

3.2 Data Augmentation

We introduce a data augmentation method, subtree substitution (SUB; Figure 1), to automatically improve the diversity of data in the few-shot setting.

We start with a set of sentences with N unlabeled parse trees $\mathcal{S} = \{\langle s_i, \mathcal{T}_i \rangle\}_{i=1}^N$; $s_i = \langle w_{i1}, w_{i2}, \ldots, w_{iL_i} \rangle$ denotes a sentence with L_i words, where w_{ik} denotes a word; $\mathcal{T}_i = \{\langle b_{ij}, e_{ij} \rangle\}_{j=1}^{C_i}$ denotes the unlabeled parse tree of s_i with C_i nonterminal nodes; b_{ij} and e_{ij} denotes the beginning and ending index of a constituent.

The augmented dataset $\mathcal{S}'$ is initialized to $\mathcal{S}$. At each step, we draw a sentence s_i and its parse tree $\mathcal{T}_i$ uniformly from $\mathcal{S}'$, and draw a constituent $\langle b_{ij}, e_{ij} \rangle \in \mathcal{T}_i$ uniformly from $\mathcal{T}_i$. After that, we replace $\langle b_{ij}, e_{ij} \rangle$ with a random $\langle b_{kh}, e_{kh} \rangle \in t_k$; that is, we replace a constituent with another one from the training set. We let s_i' and $\mathcal{T}_i'$ denote modified sentence and its parse tree, assign $\mathcal{S}' \leftarrow \mathcal{S}' \cup \{(s_i', \mathcal{T}_i')\}$, and repeat the above procedure until $\mathcal{S}'$ reaches the desired size.

3.3 Self-Training

Steedman et al. (2003), Reichart and Rappoport (2007) and McClosky et al. (2006) have shown that

---

[2] In this work, there are only two labels: (i) NT denotes a constituent and (ii) $\emptyset$ denotes non-constituent. The label $\emptyset$ enables the parser to output non-binary trees; details can be found in Kitaev and Klein (2018). Almost all existing unsupervised parsing models do not use the nonterminal categories in the development set, so we propose to train such unlabeled constituency parsing models as their baselines.

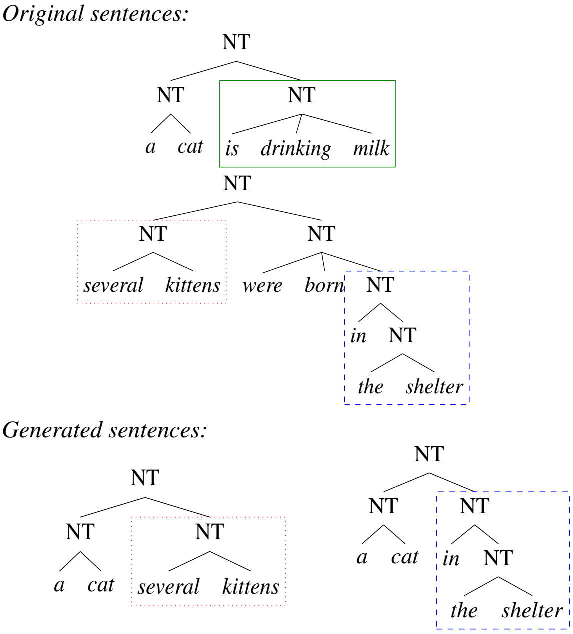

Figure 1: Illustration of the proposed data augmentation approach for improving few-shot parsing: we create new sentences by subtree substitution (e.g., substituting the subtree in the solid box by the ones in the dotted or dashed box), whether the created sentences are grammatical or not. NT denotes nonterminal nodes.

self-training (ST) on unseen sentences can improve a parsing model. Inspired by this, we apply an iterative self-training strategy after obtaining each supervised or unsupervised parsing model.

Concretely, we start with an arbitrary parsing model $\mathcal{M}_0$. At the i^{th} step of self-training, we (i) use the trained model from the previous step (i.e., $\mathcal{M}_{i-1}$) to predict parse trees for sentences in the WSJ training set and those in the WSJ development set, and (ii) train a supervised parsing model $\mathcal{M}_i$ (Kitaev and Klein, 2018) to fit the prediction of $\mathcal{M}_{i-1}$. No gold labels are used in self-training.

4 Experiments

4.1 Dataset and Training Details

We use the WSJ portion of the Penn Treebank corpus (Marcus et al., 1993) to train and evaluate the models, replace all number tokens with a special token, and split standard train/dev/test sets following Kim et al. (2019b).[3] For each criterion, we tune the hyperparameters of each model with respect to its performance on the development set. To solve the problem of vocabulary sparsity in the few-shot parsing setting (§3), we initialize the word embeddings of Benepar (Kitaev and Klein, 2018) with the word embeddings from an LSTM–based (Hochreiter and Schmidhuber, 1997) language model trained on the WSJ training set. During training, models are able to access all sentences (without parse trees) in the WSJ training set; for few-shot parsing or unsupervised parsing with supervised tuning, some unlabeled parse trees in the WSJ development set are available as well. We augment the training set to 10,000 examples for few-shot parsing with SUB, and apply 5-step self-training when applicable.

We evaluate the unlabeled F_1 score of all models using `evalb`,[4] discarding punctuation. More details can be found in the supplementary material.

4.2 Models and Tuning Criteria

We investigate four recently proposed models: PRPN (Shen et al., 2018a), ON-LSTM (Shen et al., 2019), DIORA (Drozdov et al., 2019), and Compound PCFG (Kim et al., 2019a).

PRPN and ON-LSTM are left-to-right neural language models, where syntactic distance (Shen et al., 2018b) between consecutive words is computed from the model output and used to infer the constituency parse tree. DIORA learns text-span representations and span-level scores by optimizing a masked language modeling objective. The compound PCFG uses a neural parameterization of a PCFG, as well as a per-sentence latent vector which introduces context sensitivity. Both DIORA and the Compound PCFG use the CKY algorithm to infer the parse tree of a given sentence.

As fully unsupervised tuning criteria, we use perplexity on the development set for PRPN and ON-LSTM, and the upper bound of perplexity for the Compound PCFG, following Shen et al. (2018a, 2019) and Kim et al. (2019a) respectively. For DIORA, we use its reconstruction loss on the development set.[5]

4.3 Comparison between Unsupervised Parsing and Few-Shot Parsing

We compare unsupervised parsing against few-shot parsing (Table 1 and Figure 2): when there are 55 or more labeled examples available, few-shot

---

[3] For analysis purposes (§4.5 and Figure 2), we use WSJ Section 24, instead of the standard development set (Section 22) as we train few-shot parsing on part of it. We do not use the standard test split (Section 23) to avoid tuning on the test set, hence our analysis numbers are not directly comparable with those reported in original papers.

[4] https://nlp.cs.nyu.edu/evalb/

[5] Drozdov et al. (2019) did not evaluate any unsupervised tuning criteria for DIORA. We choose reconstruction loss because it is what DIORA minimizes during training.

Model $\backslash\|\mathcal{D}_{label}\|$	0	15	55	1,700
PRPN	42.4	44.6	44.7	44.9
DIORA	**46.6**	47.7	47.6	48.0
Compound PCFG	39.2	39.2	39.2	39.2
ON-LSTM	39.0	**51.5**	**51.1**	**52.0**
Few-Shot	N/A	42.1	55.5	81.2
Few-Shot + SUB	N/A	52.5	58.5	82.6
Few-Shot + SUB + ST	N/A	**53.4**	**61.2**	**85.1**

Table 1: Unlabeled F_1 scores on the standard WSJ test set (Section 23). We keep all tokens, resulting in a vocabulary size $|V| = 35K$. $|\mathcal{D}_{label}| = 0$ means using fully unsupervised criteria (§4.2); otherwise we use the first $|\mathcal{D}_{label}|$ labeled examples in WSJ Section 22. For few-shot parsing (§3), we divide the available labeled examples into 10/5, 50/5, and 1,600/100 respectively for training and development. We use boldface for the best unsupervised parsing result and the best few-shot parsing result in each column.

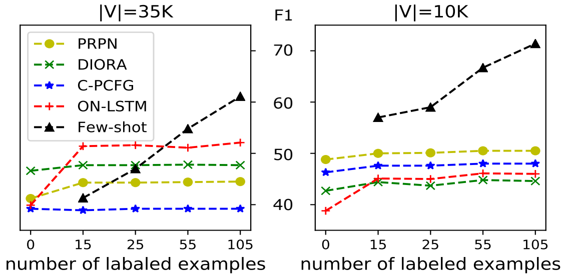

Figure 2: Performance of models with vocabulary size 35K (left) and 10K (right) on WSJ Section 24. C-PCFG denotes the Compound PCFG. The F_1 scores are averaged over 5 runs with the same hyperparameters, different random seeds, and different sets of labeled examples when applicable.

Model	WSJ$_{train}$	+ WSJ$_{dev}$ SUB
PRPN	44.9	**46.1**
DIORA	48.0	**48.2**
Compound PCFG	39.2	**42.2**
ON-LSTM	**52.0**	48.2

Table 2: Unlabeled F_1 scores on the standard WSJ test set. WSJ$_{train}$ denotes models trained with the 40K sentences in the WSJ training set, and + WSJ$_{dev}$ SUB denotes models trained with the union of WSJ training sentences and 10K sentences augmented from 1,700 WSJ development sentences. The best number in each row is bolded.

parsing (§3) consistently outperforms all unsupervised parsing models; with SUB and self-training or a smaller vocabulary size ($|V| = 10K$), few-shot parsing begins to dominate even when only 15 labeled examples are available.

On the other hand, we find that a few labeled examples are consistently helpful for most models to achieve better results than fully unsupervised parsing. In addition, models tuned on a very small number (e.g., 15) of labeled examples can achieve similar performance to those tuned on 1,700 labeled examples; that is, we need far fewer labeled examples than existing unsupervised parsing approaches have used to obtain very similar results.

To test if SUB can also help improve unsupervised parsing models, we generate 10K sentences from the 1,700 sentences in the WSJ development set with SUB (Figure 1), and add them to the 40K-sentence WSJ training set. We compare unsupervised parsing models trained on the original WSJ training set and the augmented one (Table 2). We find that SUB can sometimes help, but not by a large margin, and all numbers in Table 2 are far below the performance of few-shot parsing with the same data availability (82.6; Table 1). Few-shot parsing with data augmentation is a strong baseline for unsupervised parsing with data augmentation.

4.4 The Importance of Vocabulary Size

We notice that the result of the Compound PCFG in Table 1 is much worse than that reported by Kim et al. (2019a).[6] The only major difference between their approach and ours is the vocabulary size: instead of keeping all words, they keep the most frequent 10K words in the WSJ corpus and replace others with a special token. To analyze the importance of this choice, we compare the performance of the models with vocabulary size 35K vs. 10K (Figure 2), tuning models separately in the two settings. We find that the vocabulary size, which has not been widely considered a hyperparameter and varies across prior work, greatly affects the performance of all models tested. One possible reason is that a large portion (79.9%) of the low-frequency (i.e., outside the 10K vocabulary) word tokens are nouns or adjectives – some models (e.g., PRPN and Compound PCFG) may benefit from collapsing these tokens to a single form, as it may be a beneficial kind of word clustering. This suggests that we should consider tuning the vocabulary size

---

[6] Our DIORA result also differs from that reported by Drozdov et al. (2019); however, our number is not directly comparable to theirs due to different data settings—they use a different training set and apply ELMo (Peters et al., 2018) for model initialization.

Model	#ST-steps		
	0	1	5
PRPN	44.7	44.7	45.1
DIORA	46.7	48.7	49.1
Compound PCFG	41.1	41.8	42.2
ON-LSTM	50.2	51.3	52.1
Few-Shot	44.3	44.5	45.0
Few-Shot + SUB	53.3	55.5	56.6

Table 3: F_1 score on WSJ Section 24 of different models, where the base models are those used to report results in Table 1 with $|\mathcal{D}_{label}| = 15$.

as a hyperparameter, or fix the vocabulary size for fair comparison in future work.

4.5 Self-Training Improves all Models

Inspired by the fact that self-training boosts the performance of few-shot parsing (Table 1), we apply iterative self-training to the unsupervised parsing models as well, and find that it improves all models (Table 3).[7] It is worth noting that 5-step self-training is better than 1-step self-training for all base models we experimented with. Our results suggest that iterative (e.g., 5-step) self-training may be considered as a standard post-hoc processing step for unsupervised parsing.

5 Discussion

While many state-of-the-art unsupervised parsing models are tuned on all labeled examples in a development set (Drozdov et al., 2019; Kim et al., 2019b; Wang et al., 2019, *inter alia*), we have demonstrated that, given the same data, few-shot parsing with simple data augmentation and self-training can consistently outperform all of these models by a large margin. We suggest that one possibility for future work is to focus on fully unsupervised criteria, such as language model perplexity (Shen et al., 2018a, 2019; Kim et al., 2019b; Peng et al., 2019; Li et al., 2020) and model stability across different random seeds (Shi et al., 2019), for model selection, as discussed in unsupervised learning work (Smith and Eisner, 2005, 2006; Spitkovsky et al., 2010a,b, *inter alia*). An alternative is to use as few labeled examples in the development set as possible, and compare to few-shot parsing trained on the used examples as a strong baseline. In addition, we find that self-training is a useful post-processing step for unsupervised parsing.

Our work does not necessarily imply that unsupervised parsers produce poor parses; they may be producing good parses that clash with the conventions of treebanks (Klein, 2005). If this is the case, then extrinsic evaluation of parsers in downstream tasks (Shi et al., 2018), e.g., machine translation (DeNero and Uszkoreit, 2011; Neubig et al., 2012; Gimpel and Smith, 2014), may better show the potential of unsupervised methods.

Appendices

A Training Details

A.1 Datasets and Standard Splits

We summarize the details for the dataset, i.e., the Penn Treebank (Marcus et al., 1993) in Table 4.[8] We follow Kim et al. (2019b) to preprocess the original dataset, removing all noterminals indicating syntactic movement (e.g., the -NONE- category) as well as all sub-categories of nonterminal nodes (e.g., NP-SBJ → NP).

A.2 Hyperparameter Tuning

We modify the original code to fit our experiments. All models requires PyTorch (Paszke et al., 2017) for automatic differentiation. We train all of our models except ON-LSTM with an Adam optimizer (Kingma and Ba, 2015), and use stochastic gradient descent (SGD) for ON-LSTM.[9] We make the batch size as large as possible to make efficient use of GPU memory. We use grid search (i.e., enumerate all possible combinations of hyperparameters) to tune models, where the considered hyperparameters of models and values are as follows. We evaluate on the development set after every epoch. For hyperparameter tuning, we let each model run for 10 epochs (i.e., see the training set for 10 times) and select the best group of hyperparameters with respect to each criterion (see paper for details). We tune the hyperparameters with the vocabulary size $|V| = 35K$, and we use the selected best performing hyperparameters to train models with $|V| = 10K$.

hidden layer size	100, 200, 400

hyperparameter search trials $= 3 \times 3 \times 3 \times 3 = 81$.

Compound PCFG (Kim et al., 2019a).[14]

Hyperparameter	Considered Values
learning rate	$1 \times 10^{-3}, 5 \times 10^{-4}, 1 \times 10^{-4}$
#nonterminal	20, 30, 40
#preterminal	50, 60

hyperparameter search trials $= 3 \times 3 \times 2 = 18$.

A.3 Model Selection

All experiments are done on a Titan X GPU or a Titan RTX GPU when large GPU memory is required. After selecting the best hyperparameter set for each model under each criterion, we let the model run for at most 100 epochs and at most 96 hours.[15] We evaluate on the development set after every epoch, with respect to each (fully unsupervised or few labeled examples based) criterion. The best performing hyperparameter set is summarized in Table 5.

A.4 Run Time

We report the running time and number of epochs within the allowed running time (i.e., 96h) of each best-performing model in Table 6.

A.5 Hyperparameters for Self-Training

We use the following hyperparameters for all self-training experiments. Other possible hyperparameters are identical to the default ones. Please see the code attached for details.

Hyperparameter	Value
learning rate	5×10^{-5}
hidden layer size	1024
number of hidden layers	2

B Evaluation parameters

We report the used `evalb` parameters in Table 7. We modify the original COLLINS.prm to let it evaluate unlabeled F_1 score,[16] ignoring punctuation when testing.[17]

C Standard Deviation w.r.t. Different Small Development Sets

In the main content of the paper (Figure 2), We show the average WSJ Section 24 performance (in terms of F_1 score) of models with different random seeds and different development set (if applicable),

Abstract

The scarcity of large parallel corpora is an important obstacle for neural machine translation. A common solution is to exploit the knowledge of language models (LM) trained on abundant monolingual data. In this work, we propose a novel approach to incorporate a LM as prior in a neural translation model (TM). Specifically, we add a regularization term, which pushes the output distributions of the TM to be probable under the LM prior, while avoiding wrong predictions when the TM "disagrees" with the LM. This objective relates to knowledge distillation, where the LM can be viewed as teaching the TM about the target language. The proposed approach does not compromise decoding speed, because the LM is used only at training time, unlike previous work that requires it during inference. We present an analysis on the effects that different methods have on the distributions of the TM. Results on two low-resource machine translation datasets show clear improvements even with limited monolingual data.

1 Introduction

Neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) relies heavily on large parallel corpora (Koehn and Knowles, 2017) and needs careful hyper-parameter tuning, in order to work in low-resource settings (Sennrich and Zhang, 2019). A popular approach for addressing data scarcity is to exploit abundant monolingual corpora via data augmentation techniques, such as back-translation (Sennrich et al., 2016). Although back-translation usually leads to significant performance gains (Hoang et al., 2018), it requires training separate models and expensive translation of large amounts of monolingual data. However, when faced with lack of training data, a more principled approach is to consider exploiting prior information.

Language models (LM) trained on target-side monolingual data have been used for years as priors in statistical machine translation (SMT) (Brown et al., 1993) via the noisy channel model. This approach has been adopted to NMT, with the neural noisy channel (Yu et al., 2017; Yee et al., 2019). However, neural noisy channel models face a computational challenge, because they model the "reverse translation probability" $p(x|y)$. Specifically, they require multiple passes over the source sentence x as they generate the target sentence y, or sophisticated architectures to reduce the passes.

LMs have also been used in NMT for re-weighting the predictions of translation models (TM), or as additional context, via LM-fusion (Gulcehre et al., 2015; Sriram et al., 2018; Stahlberg et al., 2018). But, as the LM is required during decoding, it adds a significant computation overhead. Another challenge is balancing the TM and the LM, whose ratio is either fixed (Stahlberg et al., 2018) or requires changing the model architecture (Gulcehre et al., 2015; Sriram et al., 2018).

In this work, we propose to use a LM trained on target-side monolingual corpora as a weakly informative prior. We add a regularization term, which drives the output distributions of the TM to be probable under the distributions of the LM. This gives flexibility to the TM, by enabling it to deviate from the LM when needed, unlike fusion methods that change the decoder's distributions, which can introduce translation errors. The LM "teaches" the TM about the target language similar to knowledge distillation (Bucila et al., 2006; Hinton et al., 2015). This method works by simply changing the training objective and does not require any changes to the model architecture. Importantly, the LM is separated from the TM, which means that it is needed only during training, therefore we can decode faster than fusion or neural noisy channel. We also note that this method is not intended as a replacement

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7622–7634,
November 16–20, 2020. ©2020 Association for Computational Linguistics

to other techniques that use monolingual data, such as back-translation, but is orthogonal to them.

We make the following contributions:

1. We propose a simple and principled way for incorporating prior information from LMs in NMT, by adding an extra regularization term (§ 3). Also, this approach enables fast decoding, by requiring the LM only during training.
2. We report promising results (§ 4.2) in two low-resource translation datasets. We find that the proposed LM-prior yields clear improvements even with limited monolingual data.
3. We perform an analysis (§ 5) on the effects that different methods have on the output distributions of the TM, and show how this can lead to translation errors.

2 Background

NMT models trained with maximum likelihood estimation, model directly the probability $p(\boldsymbol{y}|\boldsymbol{x})$ of the target sentence $\boldsymbol{y}$ given the source sentence $\boldsymbol{x}$:

$$\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y}} \log p(\boldsymbol{y}|\boldsymbol{x})$$

Modeling directly $p(\boldsymbol{y}|\boldsymbol{x})$ requires large amounts of parallel sentences to learn a good model and NMT lacks a principled way for leveraging monolingual data. In this section we review approaches that exploit prior information encoded in LMs or the signal from the language modeling task.

Noisy Channel Model SMT (Koehn, 2010) employs Bayes' rule which offers a natural way for exploiting monolingual data, using a target-side LM based on the so called "noisy channel" model (Shannon and Weaver, 1949). Instead of directly modeling $p(\boldsymbol{y}|\boldsymbol{x})$, it models the "reverse translation probability" $p(\boldsymbol{x}|\boldsymbol{y})$, by rewriting $p(\boldsymbol{y}|\boldsymbol{x}) \propto p(\boldsymbol{x}|\boldsymbol{y}) \times p(\boldsymbol{y})$. It selects words that are both *a priori* likely with $p(\boldsymbol{y}_i)$ and "explain well" the input with $p(\boldsymbol{x}|y_i)$. This idea has been adopted to NMT with neural noisy channel, but it has two fundamental limitations. First, during decoding the model has to alternate between generating the output and scoring the input (Yu et al., 2017, 2019) or perform multiple forward passes (Yee et al., 2019) over $\boldsymbol{x}$. And crucially, since the LM is part of the network it has to also be used during inference, which adds a computational constraint on its size.

Fusion Gulcehre et al. (2015) proposed to incorporate pretrained LMs in NMT, using *shallow*- and *deep-fusion*. In *shallow-fusion*, the LM re-weights the TM's scores via log-linear interpolation:

$$\begin{aligned}\log p(\boldsymbol{y}_t) =&(1-\beta)\ \log p_{\mathrm{TM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t},\boldsymbol{x})\\ &+\beta\ \log p_{\mathrm{LM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t})\end{aligned}$$

In *deep fusion*, they alter the model architecture to include the hidden states of a RNN-LM (Mikolov et al., 2011) as additional features for predicting the next word in the decoder, which are weighted with a controller mechanism (i.e., gating). In both approaches, the TM and LM are first trained independently and are combined later. Sriram et al. (2018) extend these ideas with *cold-fusion*, where they train the TM from scratch with the LM, using its logits as features, instead of its LM hidden states. Stahlberg et al. (2018) simplify this, by training a TM together with a fixed LM, using combinations of the TM's and LM's outputs. By training the TM with the assistance of the LM, the motivation is that the TM will rely on the LM for fluency, whereas the TM will be able to focus on modeling the source. They report the best results with the POSTNORM method, outperforming other LM-fusion techniques. POSTNORM parameterizes $p(\boldsymbol{y}_t)$ as follows:

$$p(\boldsymbol{y}_t)=\mathrm{softmax}(\log p_{\mathrm{TM}}(\boldsymbol{y}_t|y_{<t},\boldsymbol{x})+\log p_{\mathrm{LM}}(\boldsymbol{y}_t))$$

It is practically the same as *shallow-fusion*, but with the LM used *also* during training, instead of used just in inference, and interpolating with λ=1.

Fusion methods face the same computational limitation as noisy channel, since the LM needs to be used during inference. Also, probability interpolation methods, such as shallow fusion or POSTNORM, use a fixed weight for all time-steps, which can lead to translation errors. Gated fusion (Gulcehre et al., 2015; Sriram et al., 2018) is more flexible, but requires changing the network architecture.

Other Approaches Transfer-learning is another approach for exploiting pretrained LMs. Ramachandran et al. (2017), first proposed to use LMs trained on monolingual corpora to initialize the encoder and decoder of a TM. Skorokhodov et al. (2018) extended this idea to Transformer architectures (Vaswani et al., 2017). This approach requires the TM to have identical architecture to the LM, which can be a limitation if the LM is huge.

Domhan and Hieber (2017) used language modeling as extra signal, by training the decoder of a TM also as a LM on target-side monolingual data. Sennrich et al. (2016) replaced the source with a NULL token, while training on monolingual data. Both, reported mixed results, with marginal gains.

3 Language Model Prior

We propose to move the LM out of the TM and use it as a prior over its decoder, by employing posterior regularization (PR) (Ganchev et al., 2010). PR incorporates prior information, by imposing soft constraints on a model's posterior distributions, which is much easier than putting Bayesian priors over all the parameters of a deep neural network.

$$\mathcal{L} = \sum_{t=1}^{N} -\log p_{\text{TM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t},\boldsymbol{x}) + \lambda\, D_{\text{KL}}(p_{\text{LM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t}) \,\|\, p_{\text{TM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t},\boldsymbol{x})) \qquad (1)$$

The first term is the standard translation objective $\mathcal{L}_{\text{MT}}$ and the second is the regularization term $\mathcal{L}_{\text{KL}}$, which we interpret as a weakly informative prior over the TM's distributions p_{TM}, that expresses partial information about $\boldsymbol{y}$. $\mathcal{L}_{\text{KL}}$ is defined as the Kullback-Leibler divergence between the output distributions of the TM and the LM, weighted by λ.

This formulation gives flexibility to the model, unlike probability interpolation, such as in fusion methods. For example, POSTNORM multiplies the probabilities of the LM and TM, which is the same as applying a logical AND operation, where only words that are probable under *both* distributions will receive non-negligible probabilities. This prevents the model from generating the correct word when there is a large "disagreement" between the TM and the LM, which is inevitable as the LM is not aware of the source sentence (i.e., unconditional). However, by using the LM-prior we do *not* change the outputs of the TM. $\mathcal{L}_{\text{KL}}$ pushes the TM to stay *on average* close to the prior, but crucially, it enables the TM to deviate from it when needed, for example to copy words from the source.

Secondly, the LM is no longer part of the network. This means that we can do inference using only the TM, unlike fusion or neural noisy channel, which require the LM for both training and decoding. By lifting this computational overhead, we enable the use of large pretrained models LMs (BERT; Devlin et al. (2019), GPT-2; Radford et al. (2019)), without compromising speed or efficiency.

3.1 Relation to Knowledge Distillation

The regularization term in Eq. (1) resembles knowledge distillation (KD) (Ba and Caruana, 2014; Bucila et al., 2006; Hinton et al., 2015), where the soft output probabilities of a big teacher model are used to train a small compact student model, by minimizing their D_{KL}. However, in standard KD the teacher is trained on the *same* task as the student, like in KD for machine translation (Kim and Rush, 2016). However, the proposed LM-prior is trained on a different task that requires only monolingual data, unlike TM teachers that require parallel data.

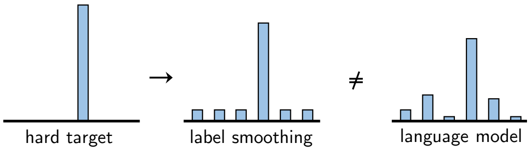

Figure 1: Targets with LS and LM-prior.

We exploit this connection to KD and following Hinton et al. (2015) we use a softmax-temperature parameter $\tau \geq 1$ to control the smoothness of the output distributions $p_i = \frac{\exp(s_i/\tau)}{\sum_j \exp(s_j/\tau))}$, where s_i is the un-normalized score of each word i (i.e., logit). Higher values of τ produce smoother distributions. Intuitively, this controls how much information encoded in the tail of the LM's distributions, we expose to the TM. Specifically, a well trained LM will generate distributions with high probability for a few words, leaving others with probabilities close to zero. By increasing τ we expose extra information to the TM, because we reveal more low-probability words that the LM found similar to the predicted word.

We use $\tau > 1$ *only* for computing the D_{KL} between the distributions of the TM and the LM and is the same for both. The magnitude of D_{KL} scales as $1/\tau^2$, so it is important to multiply its output with τ^2 to keep the scale of the $\mathcal{L}_{\text{KL}}$ loss invariant to τ. Otherwise, this would implicitly change the weight to λ applied to $\mathcal{L}_{\text{KL}}$. Finally, we re-write the regularization term of Eq. (1) as follows:

$$\mathcal{L}_{\text{KL}} = \boldsymbol{\tau}^2 D_{\text{KL}}(p_{\text{LM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t};\boldsymbol{\tau}) \| p_{\text{TM}}(\boldsymbol{y}_t|\boldsymbol{y}_{<t},\boldsymbol{x};\boldsymbol{\tau}))$$

3.2 Relation to Label Smoothing

Label smoothing (LS) (Szegedy et al., 2016) is a "trick" widely used in machine translation that also uses soft targets. Specifically, the target distribution at each step is the weighted average between the one-hot distribution y_k of the ground-truth label and a uniform distribution over all other K labels, parameterized by a smoothing parameter α: $y_i^{\text{LS}} = y_i(1-\alpha) + \alpha/K$. The purpose of LS is to penalize confidence (i.e., low-entropy distributions).

Table 2: Hyperparameters of the TMs and LMs.

language	3M (PPL↓)	30M (PPL↓)
English	29.70	**25.02**
German	22.71	**19.22**
Turkish	**22.78**	–

Table 3: Perplexity scores for LMs trained on each language's monolingual data, computed on a small held-out validation set per language.

We note that LS differs from the LM-prior in two ways. First, LS encourages the model to assign *equal* probability to all incorrect words (Müller et al., 2019), which can be interpreted as a form of uninformative prior (Fig. 1). By contrast, the distributions of the LM are informative, because they express the beliefs of the LM at each step. Second, LS *changes* the target distribution (i.e., first term in Eq. (1)), whereas the LM-prior involves an additional term, hence the two methods are orthogonal.

4 Experiments

Datasets We use two low-resource language pairs (Table 1): the English-German (EN-DE) News Commentary v13 provided by WMT (Bojar et al., 2018) [1] and the English-Turkish (EN-TR) WMT-2018 parallel data from the SETIMES2[2] corpus. We use the official WMT-2017 and 2018 test sets as the development and test set, respectively.

As monolingual data for English and German we use the News Crawls 2016 articles (Bojar et al., 2016) and for Turkish we concatenate *all* the available News Crawls data from 2010-2018, which contain 3M sentences. For English and German we subsample 3M sentences to match the Turkish data, as well as 30M to measure the effect of stronger LMs. We remove sentences longer than 50 words.

Pre-processing We perform punctuation normalization and truecasing and remove pairs, in which either of the sentences has more than 60 words or length ratio over 1.5. The text is tokenized with sentencepiece (SPM; Kudo and Richardson (2018)) with the "unigram" model. For each language we learn a separate SPM model with 16K symbols, trained on its respective side of the parallel data. For English, we train SPM on the concatenation of the English-side of the training data from each dataset, in order to have a single English vocabulary and be able to re-use the same LM.

Model Configuration In all experiments, we use the Transformer architecture for both the LMs and TMs. Table 2 lists all their hyperparameters. For the TMs we found that constraining their capacity and applying strong regularization was crucial, otherwise they suffered from over-fitting. We also found that initializing all weights with *glorot-uniform* (Glorot and Bengio, 2010) initialization and using pre-norm residual connections (Xiong et al., 2020; Nguyen and Salazar, 2019), improved stability. We also tied the embedding and the output (projection) layers of the decoders (Press and Wolf, 2017; Inan et al., 2017).

We optimized our models with Adam (Kingma and Ba, 2015) with a learning rate of 0.0002 and a linear warmup for the first 8K steps, followed by inverted squared decay and with mini-batches with 5000 tokens per batch. We evaluated each model on the dev set every 5000 batches, by decoding using greedy sampling, and stopped training if the BLEU score did not increase after 10 iterations.

For the LM training we followed the same optimization process as for the TMs. However, we use Transformer-large configuration, in order to obtain a powerful LM-prior. Crucially, we did not apply LS during the LM pretraining, because, as discussed, it pushes the models to assign equal probability to all incorrect words (Müller et al., 2019), which will make the prior less informative. In Table 3 we report the perplexities achieved by each LM on different scales of monolingual data.

We developed our models in PyTorch (Paszke et al., 2019) and we used the Transformer implementation from JoeyNMT (Kreutzer et al., 2019). We make our code publically available[3].

Table 4: BLEU scores of each model. Mean and stdev of 3 runs reported. The top section contains the main results, where all methods use LMs trained on the *same* amount of data (3M). The bottom section compares different configurations of the LM-prior. Underlined scores denote gains over the "Base + Prior (3M)" model.

4.1 Experiments

We compare the proposed LM-prior with other approaches that incorporate a pretrained LM or regularize the outputs of the TM. First, we consider a vanilla NMT baseline without LS. Next, we compare with fusion techniques, namely *shallow-fusion* (Gulcehre et al., 2015) and POSTNORM (Stahlberg et al., 2018), which in the original paper outperformed other fusion methods. We also separately compare with label smoothing (LS), because it is another regularization method that uses soft targets. We report detokenized case-sensitive BLEU using sacre-BLEU (Post, 2018)[4], and decode with beam search of size 5. The LMs are *fixed* during training for both POSTNORM and the prior.

We tune the hyper-parameters of each method on the DE→EN dev-set. We set the interpolation weight for *shallow-fusion* to β=0.1, the smoothing parameter for LS to $\alpha = 0.1$. For the LM-prior we set the regularization weight to λ=0.5 and the temperature for $\mathcal{L}_{\text{KL}}$ to τ=2.

4.2 Results

First, we use in all methods LMs trained on the *same* amount of monolingual data, which is 3M sentences. We used the total amount of available Turkish monolingual data (3M) as the lowest common denominator. This is done to remove the effects of the size of monolingual data from the final performance of each method, across language-pairs and translation directions. The results are shown in the top section of Table 4. We also report results with recurrent neural networks (RNN) based on the attentional encoder-decoder (Bahdanau et al., 2015) architecture in appendix A.

Overall, adding the LM-prior consistently improves performance in all experiments. Specifically, it yields up to +1.8 BLEU score gains over the strongest baseline "Base+LS" (DE→EN and EN→DE). This shows that the proposed approach yields clear improvements, even with limited monolingual data (3M). As expected, LS proves to be very effective for mitigating over-fitting in such low-resource conditions. However, simply penalizing confidence helps up to a point, which is shown by the performance gap between "Base+LS" and "Base+prior". We explore this further next (§ 5).

Shallow-fusion achieves consistent but marginal improvements in all language-pairs. It works by making small (local) changes to p_{TM}, which primarily helps improve fluency when the TM is very unsure about what to generate next. Surprisingly, when training the TM with the POSTNORM objective, it barely reaches the baseline. As we show in our analysis (§ 5), under POSTNORM the TM generates very sharp distributions, which is a result of how it combines p_{TM} and p_{LM}[5]. We identify two potential reasons for this result. First, in (Stahlberg et al., 2018) POSTNORM was only tested with LS, which to some extend hid the issue of low-entropy outputs. To verify this, we trained POSTNORM with LS. We observed that in this case, the scores improve significantly, but it still falls short in comparison with the other methods. Second, we note that the LMs used in the original paper were also trained with LS. We hypothesize that by using an LM that emitted smoother distribution, it implicitly down-weighted the contribution of p_{LM}, that is

---

[4] Signature "BLEU+c.mixed+#.1+s.exp+tok.13a+v.1.4.2"

[5] By multiplying the probabilities of p_{TM} and p_{LM}, or adding their log-probabilities, very small subset of tokens that have non-negligible probability in *both* of them, will be assigned very large probability in the final distribution

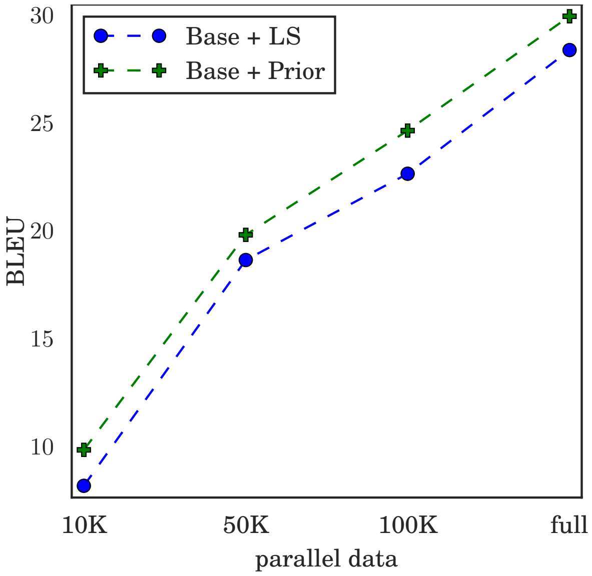

Figure 2: BLEU scores (mean of 3 runs) on the DE→EN test set with different scales of parallel data, using the LM trained on 30M English sentences.

similar to the small weight used in *shallow-fusion*, which works better in our experiments.

Stronger LMs Next, we test how different variations of the LM-prior affect the translation quality (bottom section of Table 4). First, we lift the monolingual data constraint, in order to evaluate the impact of stronger LM-priors. Specifically, for English and German we use LMs trained on 30M sentences. We observe that the stronger LMs yield improvements only in the EN→DE direction. This could partially be explained by the fact that German has richer morphology than English. Therefore, it is harder for the decoder to avoid grammatical mistakes in low-resource settings while translating into German, and a stronger prior is more helpful for X→DE than X→EN.

However, it is still surprising that the stronger English LM does not boost performance. We hypothesize that this might be related to the limited capacity of the TMs we used. Specifically, in the KD literature it has been found that the student's performance is affected by the difference between the capacities of the student and teacher networks (Cho and Hariharan, 2019; Zhou et al., 2020). In preliminary experiments we also used big LMs pretrained on generic large-scale data, such as GPT-2 (Radford et al., 2019), but we failed to achieve any measurable improvements over the baseline. Besides the discrepancy in the capacity between the LM and the TM, we suspect that another obstacle in this case is the large vocabulary size used in GPT-2 (50K symbols). In particular, Sennrich and Zhang (2019) showed that in low-resource NMT, using a very small vocabulary (2K-10K symbols) is the most important factor that affects translation performance. A potential solution could be to finetune GPT-2 on the small vocabulary of the TM (Zhao et al., 2019) and then use it as a prior, but we leave this exploration for future work.

Prior + LMs We also evaluate a combination of the LM-prior with LS. We observe that in most experiments it has small but additive effects. This implicitly suggests that the two approaches are complementary to each other. LS smooths the one-hot target distribution, which penalizes confidence, whereas the LM-prior helps improve fluency. We further explore their differences in our analysis (§. 5), by showing the effects each method has on the TM's distributions.

4.3 Extremely Low-Resource Experiments

We also conducted experiments that measure the effect of the LM-prior on different scales of parallel data. Specifically, we emulate more low-resource conditions, by training on subsets of the EN→DE parallel data. In Fig. 2 we compare the BLEU scores of the "Base+LS" and the "Base+Prior (30M)".

Overall, we observe that adding the LM-prior yields consistent improvements, even with as little as 10K parallel sentences. The improvements have a weak correlation with the size of parallel data. We hypothesize that by exposing the TM to a larger sample of target-side sentences, it has the opportunity to extract more information from the prior. However, we anticipate that in more high-resource settings the improvements will start to diminish.

5 Analysis

The main results show that LS, that simply penalizes confidence, is a very effective form of regularization in low-resource settings. We conduct a quantitative comparison to test whether the improvements from the proposed LM-prior are due to penalizing confidence, similar to LS, or from actually using information from the LM. Specifically, we evaluate each model on the DE→EN test-set and for each target token we compute the entropy of each model's distribution. In Fig. 3 we plot for each model the density[6] over all its entropy values.

---

[6] We fit a Gaussian kernel with bandwidth 0.3 on the entropy values of each model. Density plots are more readable

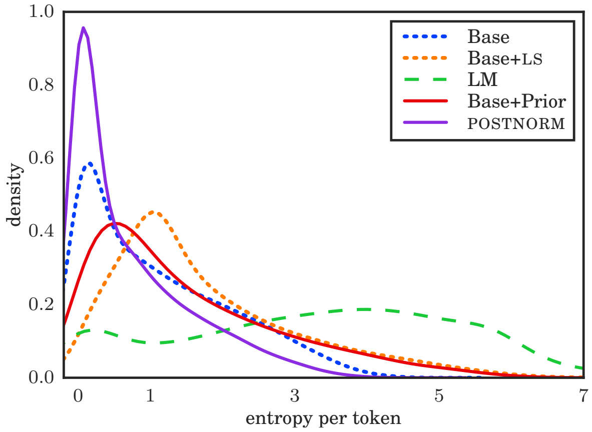

Figure 3: Densities of the entropies of the output distributions of each model on the DE→EN test set.

First, we observe that the un-regularized “Base” model generates very confident (low-entropy) distributions, which suggests that it overfits on the small parallel data. As expected, the LS regularization successfully makes the TM less confident and therefore more robust to over-fitting. For additional context, we plot the entropy density of the LM and observe that, unsurprisingly, it is the most uncertain, since it is unconditional.

Interestingly, the model trained with the LM-prior emits *more* confident distributions than the “Base+LS” model, although it also achieves significantly better performance. This clearly shows that the gains cannot be explained just from smoothing the distributions of the TM and suggests that the model indeed exploits information from the LM.

Next, we focus on the “Base+POSTNORM” model and observe that it generates the most confident predictions. Note that, this finding aligns with a similar analysis in the original paper, where it was shown that under POSTNORM the TM generates low-entropy distributions. However, even though this method might improve fluency, it can hurt translation quality in certain cases. As described in Sec. 3, by multiplying the two distributions, only a small subset of words will have non-zero probability in the final distribution. This means that when there are “disagreements” between the TM and LM this can lead to wrong predictions. We illustrate this with a concrete example in Fig. 4. Although the TM predicted the correct word, the multiplication with the LM distribution caused the model to finally make a wrong prediction. Also, the final distribution assigns a relatively high probability to a word (“more”), which is not among the top predictions of neither the LM or the TM. By contrast, the LM-prior does *not* change the TM’s predictions, and the model has the flexibility to deviate from the prior.

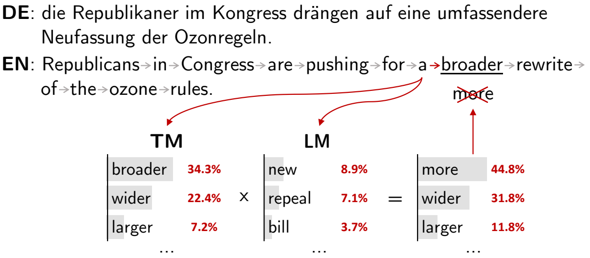

Figure 4: Example of failure of probability interpolation between LM and TM, while translating DE→EN.

5.1 $\mathcal{L}_{\text{KL}}$ Sensitivity Analysis

The proposed regularization uses two different hyper-parameters in $\mathcal{L}_{\text{KL}}$, the weight λ that controls the strength of the regularization, and the temperature τ that controls how much information from the long-tail of the LM to expose to the TM. We do a pairwise comparison between them, in order to measure how sensitive the model is to their values. In Fig. 5 we plot a heatmap of the BLEU scores achieved by models trained on the DE→EN dev-set with various combinations.

Overall, we observe a clear pattern emerging of how the LM-prior affects performance, which suggests that (1) using $\tau > 1$ indeed helps the TM to acquire more of the knowledge encoded in the prior, and (2) increasing the strength of the regularization up to a point yields consistent improvements. We find that the performance is less sensitive to the value of τ, compared to λ and that

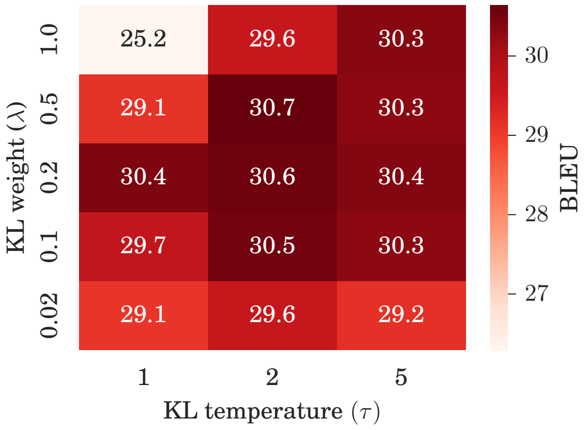

Figure 5: BLEU scores on the DE-EN dev set of models trained with different λ and τ for the $\mathcal{L}_{\text{KL}}$. Mean of 3 runs for each combination reported.

---

compared to plotting overlapping histograms.

by setting $\tau > 1$, the model becomes also more robust to λ. Our explanation is that for $\tau > 1$, the TM tries to match a larger part of the LM's distribution and focuses less on its top-scoring words. Therefore, it is reasonable to observe that in the extreme case when we set equal weight to the $\mathcal{L}_{\text{MT}}$ and $\mathcal{L}_{\text{KL}}$ ($\lambda = 1$) and $\tau = 1$ the performance starts to degrade, because we strongly push the TM to match only the top-scoring predictions of the LM, that is unconditional. This forces the TM to pay less attention to the source sentence, which leads to translation errors.

6 Related Work

Most recent related work considers large pretrained models, either via transfer-learning or feature-fusion. Zhu et al. (2020); Clinchant et al. (2019); Imamura and Sumita (2019) explore combinations of using BERT as initialization for NMT, or adding BERT's representations as extra features. Yang et al. (2019) address the problem of *catastrophic-forgetting* while transferring BERT in high-resource settings, with a sophisticated fine-tuning approach. In concurrent work, Chen et al. (2019) propose knowledge-distillation using BERT for various text generation tasks, including NMT, by incentivizing the sequence-to-sequence models to "look into the future". However, in our work we address a different problem (low-resource NMT) and have different motivation. Also, we consider auto-regressive LMs as priors, which have clear interpretation, unlike BERT that is not strictly a LM and requires bidirectional context. Note that, large pretrained LMs, such as BERT or GPT-2, have not yet achieved the transformative results in NMT that we observe in natural language understanding tasks (e.g., GLUE benchmark (Wang et al., 2019)).

There are also other approaches that have used posterior regularization to incorporate prior knowledge into NMT. Zhang et al. (2017) exploit linguistic real-valued features, such as dictionaries or length ratios, to construct the distribution for regularizing the TM's posteriors. Recently, Ren et al. (2019) used posterior regularization for unsupervised NMT, by employing an SMT model, which is robust to noisy data, as a prior over a neural TM to guide it in the iterative back-translation process. Finally, LMs have been used in a similar fashion as priors over latent text sequences in discrete latent variable models (Miao and Blunsom, 2016; Havrylov and Titov, 2017; Baziotis et al., 2019).

7 Conclusions

In this work, we present a simple approach for incorporating knowledge from monolingual data to NMT. Specifically, we use a LM trained on target-side monolingual data, to regularize the output distributions of a TM. This method is more efficient than alternative approaches that used pretrained LMs, because it is not required during inference. Also, we avoid the translation errors introduced by LM-fusion, because the TM is able to deviate from the prior when needed.

We empirically show that while this method works by simply changing the training objective, it achieves better results than alternative LM-fusion techniques. Also, it yields consistent performance gains even with modest monolingual data (3M sentences) across all translation directions. This makes it useful for low-resource languages, where not only parallel but also monolingual data are scarce.

In future work, we intend to experiment with the LM-prior under more challenging conditions, such as when there is domain discrepancy between the parallel and monolingual data. Also, we would like to explore how to overcome the obstacles that prevent us from fully exploiting large pretrained LMs (e.g., GPT-2) in low-resource settings.

A Appendix

Our preliminary experiments were conducted with recurrent neural networks (RNN), because we faced stability problems with the Transformer-based TMs. We include those results here for completeness. The experiments were conducted with the 3M monolingual data in all translation directions, therefore they match the top section of the main results reported in the paper (Table 4). We observe the same relative performance as with the Transformer-based models, which verifies that the proposed approach transfers across architectures. However, the differences are smaller, because the RNN-based models achieved overall worse BLEU scores and perplexities, for the translation and language modeling tasks, respectively.

Model Configuration We employ the attentional encoder-decoder (Bahdanau et al., 2015) architecture, using the "global" attention mechanism (Luong et al., 2015). The recurrent cells are implemented using Long short-term memory (LSTM; Hochreiter and Schmidhuber (1997)) units. We use a bidirectional LSTM encoder and a unidirectional LSTM decoder. We also tie the embedding and the output (projection) layers of the decoders (Press and Wolf, 2017; Inan et al., 2017). and apply layer normalization (Ba et al., 2016) to the last decoder representation, before the softmax.

We did not do any hyperparameter tuning, but selected the hyper-parameter values based on Sennrich and Zhang (2019), while also trying to keep approximately the same number of parameters as their Transformer-based counterparts. Table 5 lists all the model hyperparameters. All models were optimized with the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.0002 and with mini-batches with 2000 tokens per batch.

Language Models For the LMs we used an identical architecture as the decoder of the TM, but with larger size. We also followed the same optimization process. Table 5 lists all the RNN-LM hyperparameters.

A.1 Language Models

For completeness, we include here some additional information about the training of the LMs. In all experiments we paired the TM with LMs with the same architecture, in order to evaluate how the proposed approach generalizes across architectures. We train one LM for each language, on its respective monolingual corpus. For the Transformer-based LMs we also used a larger corpus for the high resource languages, as a part of our comparison shown in the main body of the paper. To evaluate the performance of the LMs and to perform early stopping we used a small held-out development set with 10K sentences. Specifically, we stopped training when the perplexity on the development was not improved on for more than 10 epochs. In Table 6 we report the perplexities achieved by the LMs on each monolingual corpus.

Abstract

Word sense disambiguation is a well-known source of translation errors in NMT. We posit that some of the incorrect disambiguation choices are due to models' over-reliance on dataset artifacts found in training data, specifically superficial word co-occurrences, rather than a deeper understanding of the source text. We introduce a method for the prediction of disambiguation errors based on statistical data properties, demonstrating its effectiveness across several domains and model types. Moreover, we develop a simple adversarial attack strategy that minimally perturbs sentences in order to elicit disambiguation errors to further probe the robustness of translation models. Our findings indicate that disambiguation robustness varies substantially between domains and that different models trained on the same data are vulnerable to different attacks.[1]

1 Introduction

Consider the sentence *John met his wife in the hot spring of 1988*. In this context, the polysemous term *spring* unambiguously refers to the season of a specific year. Its appropriate translation into German would therefore be *Frühling* (the season), rather than one of its alternative senses, such as *Quelle* (the source of a stream). To contemporary machine translation systems, however, this sentence presents a non-trivial challenge, with Google Translate (GT) producing the following translation: *John traf seine Frau in der heißen Quelle von 1988.*

Prior studies have indicated that neural machine translation (NMT) models rely heavily on source sentence information when resolving lexical ambiguity (Tang et al., 2019). This suggests that the combined source contexts in which a specific sense of an ambiguous term occurs in the training data greatly inform the models' disambiguation decisions. Thus, a stronger correlation between the English collocation *hot spring* and the German translation *Quelle*, as opposed to *Frühling*, in the training corpus may explain this disambiguation error. Indeed, *John met his wife in the spring of 1988* is translated correctly by GT.

We propose that our motivating example is representative of a systematic pathology NMT systems have yet to overcome when performing word sense disambiguation (WSD). Specifically, we hypothesize that translation models learn to disproportionately rely on lexical correlations observed in the training data when resolving word sense ambiguity. As a result, disambiguation errors are likely to arise when an ambiguous word co-occurs with words that are strongly correlated in the training corpus with a sense that differs from the reference.

To test our hypothesis, we evaluate whether dataset artifacts are predictive of disambiguation decisions made in NMT. First, given an ambiguous term, we define a strategy for quantifying how much its context biases NMT models towards its different target senses, based on statistical patterns in the training data. We validate our approach by examining correlations between this bias measure and WSD errors made by baseline models. Furthermore, we investigate whether such biases can be exploited for the generation of minimally-perturbed adversarial samples that trigger disambiguation errors. Our method does not require access to gradient information nor the score distribution of the decoder, generates samples that do not significantly diverge from the training domain, and comes with a clearly-defined notion of attack success and failure.

The main contributions of this study are:

1. We present evidence for the over-reliance of NMT systems on inappropriate lexical correlations when translating polysemous words.

---

[1] Experimental codebase available at `http://github.com/demelin/detecting_wsd_biases_for_nmt`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7635–7653,
November 16–20, 2020.

2. We propose a method for quantifying WSD biases that can predict disambiguation errors.
3. We leverage data artifacts for the creation of adversarial samples that facilitate WSD errors.

2 Can WSD errors be predicted?

To evaluate whether WSD errors can be effectively predicted, we first propose a method for measuring the bias of sentence contexts towards different senses of polysemous words, based on lexical co-occurrence statistics of the training distribution. We restrict our investigation to English→German, although the presented findings can be assumed to be language-agnostic. To bolster the robustness of our results, we conduct experiments in two domains - movie subtitles characterized by casual language use, and the more formal news domain. For the former, we use the OpenSubtitles2018 (OS18) (Lison et al., 2019) corpus[2], whereas the latter is represented by data made available for the news translation task of the Fourth Conference on Machine Translation (WMT19)[3] (Barrault et al., 2019). Appendix A.1 reports detailed corpus statistics.

2.1 Quantifying disambiguation biases

An evaluation of cross-lingual WSD errors presupposes the availability of certain resources, including a list of ambiguous words, a lexicon containing their possible translations, and a set of parallel sentences serving as a disambiguation benchmark.

Resource collection

Since lexical ambiguity is a pervasive feature of natural language, we limit our study to homographs - polysemous words that share their written form but have multiple, unrelated meanings. We further restrict the set of English homographs to nouns that are translated as distinct German nouns, so as to confidently identify disambiguation errors, while minimizing the models' ability to disambiguate based on syntactic cues. English homographs are collected from web resources[4], excluding those that do not satisfy the above criteria. Refer to appendix A.2 for the full homograph list.

We next compile a parallel lexicon of homograph translations, prioritizing a high coverage of all possible senses. Similar to (Raganato et al., 2019), we obtain sense-specific translations from cross-lingual BabelNet (Navigli and Ponzetto, 2010) synsets. Since BabelNet entries vary in their granularity, we iteratively merge related synsets as long as they have at least three German translations in common or share at least one definition.[5] This leaves us with multiple sense clusters of semantically related German translations per homograph. To further improve the quality of the lexicon, we manually clean and extend each homograph entry to address the noise inherent in BabelNet and its incomplete coverage.[6] Appendix A.7 provides examples of the final sense clusters.

In order to identify sentence contexts specific to each homograph sense, parallel sentences containing known homographs are extracted from the training corpora in both domains. We lemmatize homographs, their senses, and all sentence pairs using spaCy (Honnibal and Montani, 2017) to improve the extraction recall. Homographs are further required to be aligned with their target senses according to alignments learned with fast_align (Dyer et al., 2013). Each extracted pair is assigned to one homograph sense cluster based on its reference homograph translation. Pairs containing homograph senses assigned to multiple clusters are ignored, as disambiguation errors are impossible to detect in such cases.

Bias measures

It can be reasonably assumed that context words co-occurring with homographs in a corpus of natural text are more strongly associated with some of their senses than others. Words that are strongly correlated with a specific sense may therefore bias models towards the corresponding translation at test time. We refer to any source word that co-occurs with a homograph as an *attractor* associated with the sense cluster of the homograph's translation. Similarly, we denote the degree of an attractor's association with a sense cluster as its *disambiguation bias* towards that cluster. Table 1 lists the most frequent attractors identified for the different senses of the homograph *spring* in the OS18 training set.

Intuitively, if an NMT model disproportionately relies on simple surface-level correlations when resolving lexical ambiguity, it is more likely to make WSD errors when translating sentences that contain

season	*water source*	*device*
summer	hot	like
winter	water	back
come	find	thing

Table 1: Examples of attractors for *spring*.

strong attractors towards a wrong sense. To test this, we collect attractors from the extracted parallel sentences, quantifying their disambiguation bias (DB) using two metrics: Raw co-occurrence frequency (FREQ) and positive point-wise mutual information (PPMI) between attractors and homograph senses. FREQ is defined in Eqn.1, while Eqn.2 describes PPMI, with $w \in V$ denoting an attractor term in the source vocabulary[7], and $sc \in SC$ denoting a sense cluster in the set of sense clusters assigned to a homograph. For PPMI, $P(w_i, sc_j)$, $P(w_i)$, and $P(sc_j)$ are estimated via relative frequencies of (co-)occurrences in training pairs.

$$FREQ(w_i, sc_j) = Count(w_i, sc_j) \tag{1}$$

$$PPMI(w_i, sc_j) = max(\frac{P(w_i, sc_j)}{P(w_i)P(sc_j)}, 0) \tag{2}$$

The disambiguation bias associated with the entire context of a homograph is obtained by averaging sense-specific bias values $DB(w_i, sc_j)$ of all attractors in the source sentence $S = \{w_1, w_2, ..., w_{|S|}\}$, as formalized in Eqn.3. Context words that are not known attractors of sc_j are assigned a disambiguation bias value of 0.

$$DB(S, sc_j) = \frac{1}{|S|}\sum_{i=1}^{|S|} DB(w_i, sc_j) \tag{3}$$

As a result, sentences containing a greater number of strong attractors are assigned a higher bias score.

2.2 Probing NMT models

To evaluate the extent to which sentence-level disambiguation bias is predictive of WSD errors made by NMT systems, we train baseline translation models for both domains. The baselines include Transformer (Vaswani et al., 2017), LSTM (Luong et al., 2015), and convolutional Seq-to-Seq (ConvS2S) (Gehring et al., 2017) models of comparable size. Appendix A.4 details the training regime and hyper-parameter choices. SacreBLEU (Post, 2018) scores reported in Table 2 indicate that all models are reasonably competent.

		WMT	
Architecture	**OS18 test**	**test 2014**	**test 2019**
Transformer	29.7	27.5	38.2
LSTM	27.7	24.1	34.3
ConvS2S	27.7	23.5	32.5

Table 2: EN-DE translation performance (BLEU).

Test sets for WSD error prediction are constructed by extracting parallel sentences from held-out, development, and test data (see appendix A.1 for details). The process is identical to that described in section 2.1, with the added exclusion of source sentences shorter than 10 tokens, as they may not provide enough context. For each source sentence, disambiguation bias values are computed according to equation 3, with sc_j corresponding to either the correct sense cluster (DB$_{\checkmark}$) or the incorrect sense cluster with the strongest bias (DB$_{\text{✗}}$). Additionally, we consider the difference DB$_{\text{DIFF}}$ between DB$_{\text{✗}}$ and DB$_{\checkmark}$ which can be interpreted as the overall statistical bias in a source sentence towards an incorrect homograph translation. All bias scores are computed either using FREQ or PPMI.

We examine correlations between the proposed bias measures and WSD errors produced by the in-domain baseline models. Translations are considered to contain WSD errors if the target homograph sense does not belong to the same sense cluster as its reference translation. We check this by looking up target words aligned with source homographs according to fast_align. To estimate correlation strength we employ the ranked biserial correlation (RBC) metric[8] (Cureton, 1956) and measure statistical significance using the Mann-Whitney U (MWU) test (Mann and Whitney, 1947).

In order to compute the RBC values, test sentences are divided into two groups - one containing correctly translated source sentences and another comprised of source sentences with incorrect homograph translations. Next, all possible pairs are constructed between the two groups, pairing together each source sentence from one group with all source sentences from the other. Finally, the

---

[7] We consider any word that co-occurs with a homograph in the training corpus as an attractor of the homograph's specific sense cluster, except for the homograph itself which is not regarded as an attractor for any of its known sense clusters.

[8] We additionally used the non-parametric generalization of the Common Language Effect Size (Ruscio, 2008) for correlation size estimation, but couldn't detect any advantages over RBC in our experimental setting.

Table 3: Rank biserial correlation between disambiguation bias measures and lexical disambiguation errors.

proportion of pairs f where the DB score of the incorrectly translated sentence is greater than that of the correctly translated sentence is computed, as well as the proportion of pairs u where the opposite relation holds. The RBC value is then obtained according to Eqn.4.

$$RBC = f - u \tag{4}$$

Statistical significance, on the other hand, is estimated by ranking all sentences in the test set according to their DB score in ascending order while resolving ties, and computing the U-value according to Eqn.5-7, where R_1 denotes to the sum of ranks of sentences with incorrectly translated homographs and n_1 their total count, while R_2 denotes the sum of ranks of correctly translated sentences and n_2 their respective total count.

$$U = min(U_1, U_2) \tag{5}$$

$$U_1 = R_1 - \frac{n_1(n_1 + 1)}{2} \tag{6}$$

$$U_2 = R_2 - \frac{n_2(n_2 + 1)}{2} \tag{7}$$

To obtain the p-values, U-values are subjected to tie correction and normal approximation.[9]

Table 3 summarizes the results[10], including correlation estimates between WSD errors and source sentence length, as a proxy for disambiguation context size. Statistically significant correlations are discovered for all bias estimates based on attractors ($p <$ 1e-5, two-sided). Moreover, the observed correlations exhibit a strong effect size (McGrath and Meyer, 2006). See appendix A.5 for the model-specific effect size interpretation thresholds. For all models and domains the strongest correlations are observed for DB$_{\text{DIFF}}$ derived from simple co-occurrence counts.

Challenge set evaluation

To establish the predictive power of the uncovered correlations, a challenge set of 3000 test pairs with the highest FREQ$_{\text{DIFF}}$ score is subsampled from the full WSD test pair pool in both domains. In addition, we create secondary sets of equal size by randomly selecting pairs from each pool. As Figure 1 illustrates, our translation models exhibit a significantly higher WSD error rate - by a factor of up to **6.1** - on the challenge sets as compared to the randomly chosen pairs. While WSD performance is up to 96% on randomly chosen sentences, performance drops to 77–82% for the best-performing model (Transformer). This suggests that lexical association artifacts, from which the proposed disambiguation bias measure is derived, can be an effective predictor of lexical ambiguity resolution errors across model architectures and domains.

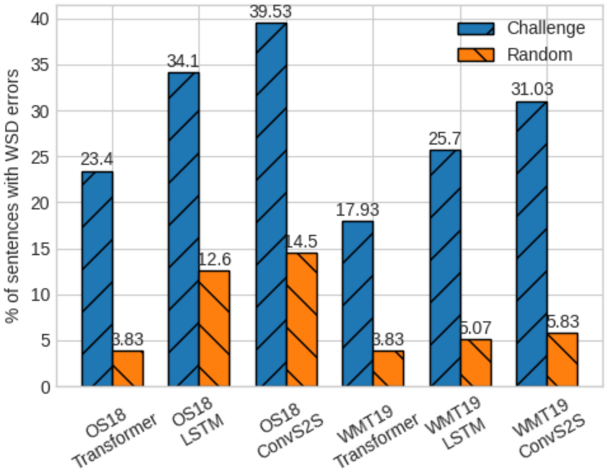

Figure 1: WSD errors in subsampled challenge sets.

---

[9] We use Python implementations of RBC and MWU provided by the pingouin library (Vallat, 2018).

[10] Positive values denote a positive correlation between bias measures and the presence of disambiguation errors in model translations, whereas negative values denote negative correlations. The magnitude of the values, meanwhile, indicates the correlations' effect size.

The observed efficacy of attractor co-occurrence counts for WSD error prediction may be partially due to sense frequency effects, since more frequent senses occur in more sentence pairs, yielding more frequent attractors. NMT models are known to underperform on low-frequency senses of ambiguous terms (Rios et al., 2017), prompting us to investigate if disambiguation biases capture the same information. For this purpose, another challenge set of 3000 pairs is constructed by prioritizing pairs assigned to the rarest among each homograph's sense sets. We find that the new challenge set has a 72.63% overlap with the disambiguation bias challenge set in the OS18 domain and 64.4% overlap in the WMT19 domain. Thus, disambiguation biases appear to indeed capture some sense frequency effects, which themselves represent a dataset artifact, but also introduce novel information.

Our experimental findings indicate that translation models leverage undesirable surface-level correlations when resolving lexical ambiguity and are prone to disambiguation errors in cases where learned statistical patterns are violated. Next, we use these insights for the construction of adversarial samples that cause disambiguation errors by minimally perturbing source sentences.

3 Adversarial WSD attacks on NMT

Adversarial attacks probe model robustness by attempting to elicit incorrect predictions with perturbed inputs (Zhang et al., 2020). By crafting adversarial samples that explicitly target WSD capabilities of NMT models, we seek to provide further evidence for their susceptibility to dataset artifacts.

3.1 Generating adversarial WSD samples

Our proposed attack strategy is based on the assumption that introducing an attractor into a sentence can flip its inherent disambiguation bias towards the attractor's sense cluster. Thus, translations of the so perturbed sentence will be more likely to contain WSD errors. The corresponding sample generation strategy consists of four stages:

1. Select *seed* sentences containing homographs to be adversarially perturbed.
2. Identify attractors that are likely to yield fluent and natural samples.
3. Apply perturbations by introducing attractors into seed sentences.
4. Predict effective adversarial samples based on attractor properties.

The targeted attack is deemed successful if a victim model accurately translates the homograph in the seed sentence, but fails to correctly disambiguate it in the adversarially perturbed sample, instead translating it as one of the senses belonging to the attractor's sense cluster. This is a significantly more challenging attack success criterion than the general reduction in test BLEU typically employed for evaluating adversarial attacks on NMT systems (Cheng et al., 2019). Samples are generated using homographs and attractors collected in section 2.1, while all test sentence pairs extracted in section 2.2 form the domain-specific seed sentence pools. Attack success is evaluated on the same baseline translation models as used throughout section 2.

Seed sentence selection

In order to generate informative and interesting adversarial samples, we focus on seed sentences that are likely to be unambiguous. We thus apply three filtering heuristics to seed sentence pairs:

- Sentences have to be at least 10 tokens long.
- We mask out the correct homograph sense in the reference translation and use a pre-trained German BERT model (Devlin et al., 2019)[11] to predict it. Pairs are rejected if the most probable sense does not belong to the correct sense cluster which suggests that the sentence context may be insufficient for correctly disambiguating the homograph. As a result, WSD errors observed in model-generated translations of the constructed adversarial samples are more likely to be due to the applied adversarial perturbations.
- 10% of pairs with the highest disambiguation bias towards incorrect sense clusters are removed from the seed pool.

Setting the rejection threshold above 10% can further reduce WSD errors in seed sentences. At the same time, it would likely render minimal perturbations ineffective, due to the sentences' strong bias towards the correct homograph sense. Thus, we aim for a working compromise.

---

[11] We use the implementation provided by the Hugging Face Transformers library (Wolf et al., 2019). We do not fine-tune BERT, as our use case corresponds to its original masked language modeling objective.

IH	During this **first** **spring**, he planted another tree that looked the same.
RH	A **hot** ~~new~~ **spring** will conquer the dark nights of winter.
InH	Come the **spring**, I will be invading the **whole** country called Frankia.
RnH	After a long, **eternal** ~~fallow~~ winter, **spring** has come again to Fredericks Manor.

Table 4: Perturbation examples; seed sense: *season*, adversarial sense: *water source*. Insertion/replacement in red.

Perturbation types

Naively introducing new words into sentences is expected to yield disfluent, unnatural samples. To counteract this, we constrain candidate attractors to adjectives, since they can usually be placed in front of English nouns without violating grammatical constraints. We consider four perturbation types:

- Insertion of the attractor adjective in front of the homograph (IH)
- Replacement of a seed adjective modifying the homograph (RH)
- Insertion of the attractor adjective in front of a non-homograph noun (InH)
- Replacement of a seed adjective modifying a non-homograph noun (RnH)

Replacement strategies require seed sentences to contain adjectives, but can potentially have a greater impact on the sentence's disambiguation bias by replacing attractors belonging to the correct sense cluster. Examples for each generation strategy are given in Table 4, with homographs highlighted in blue and added attractors in red.

Attractor selection

Since adjectives are subject to selectional preferences of homograph senses, not every attractor will yield a semantically coherent adversarial sample. For instance, inserting the attractor *flying* in front of the homograph *bat* in a sentence about baseball will likely produce a nonsensical expression, whereas an attractor like *huge* would be more acceptable. We attempt to control for this type of disfluency by only considering attractors that had been previously observed to modify the homograph in its seed sentence sense. For non-homograph perturbations, attractors must have been observed modifying the non-homograph noun. This is ensured by obtaining a dependency parse for each sentence in the English half of the training data and maintaining a list of modifier adjectives for each known target homograph sense set and source noun.[12]

Lastly, to facilitate the fluency and naturalness of adversarial samples, the generation process incorporates a series of constraints:

- Comparative and superlative adjective forms are excluded from the attractor pool.
- Attractors may not modify compound nouns due to less transparent selectional preferences.
- Attractors are not allowed next to other adjectives modifying the noun, to avoid violating the canonical English adjective order.

As all heuristics rely on POS taggers or dependency parsers,[13] they are not free of noise, occasionally yielding disfluent or unnatural samples.

We restrict the number of insertions or replacements to one, so as to maintain a high degree of semantic similarity between adversarial samples and seed sentences. A single seed sentence usually yields several samples, even after applying the aforementioned constraints. Importantly, we generate samples using all retained attractors at this stage, without selecting for expected attack success.

Post-generation filtering

To further ensure the naturalness of generated samples, sentence-level perplexity is computed for each seed sentence and adversarial sample using a pre-trained English GPT2 (Radford et al., 2019) language model.[14] Samples are rejected if their perplexity exceeds that of their corresponding seed sentence by more than 20%. In total, we obtain a pool of ~500K samples for the OS18 domain and ~3.9M samples for the WMT19 domain. Each sample is translated by all in-domain models.

3.2 Identifying effective attractors

The success of the proposed attack strategy relies on the selection of attractors that are highly likely

---

[12] This assumes correctness of homograph reference translations, which is unfortunately not always guaranteed.

[13] We use spaCy in all cases.

[14] As implemented in the Transformers library.

Model	**FREQ$_{\text{✗}}$**	**PPMI$_{\text{✗}}$**	**FREQ$_{\text{DIFF}}$**	**PPMI$_{\text{DIFF}}$**

Table 5: Rank biserial correlation between attractors' disambiguation bias and attack success.

to flip the homograph translation from the correct *seed* sense towards an *adversarial* sense belonging to the attractors' own sense set. To identify such attractors, we examine correlations between attractors' disambiguation biases and the effectiveness of adversarial samples containing them. The attractors' bias values are based either on co-occurrence frequencies (Eqn.1) or PPMI scores (Eqn.2) with the homographs' sense clusters. In particular, we examine the predictive power of an attractor's bias towards the adversarial sense cluster (DB$_{\text{✗}}$) as well as the difference between its adversarial and seed bias values (DB$_{\text{DIFF}}$). As before, RBC and MWU measures are used to estimate correlation strength, with Table 5 summarizing the results.

Similarly to the findings reported in section 2.2, all uncovered correlations are strong and statistically significant with $p < 1e\text{-}5$ (see appendix A.5 for effect size thresholds). Importantly, FREQ$_{\text{DIFF}}$ exhibits the strongest correlation in all cases.

We are furthermore interested in establishing which of the proposed perturbation methods yields most effective attacks. For this purpose, we examine the percentage of attack successes per perturbation strategy in Figure 2, finding perturbations proximate to the homograph to be most effective.

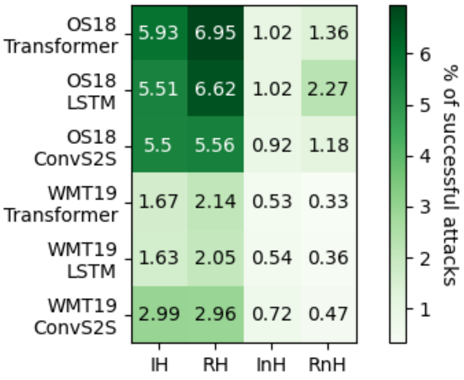

Figure 2: Successful attacks per perturbation.

Challenge set evaluation

Having thus identified a strategy for selecting attractors that are likely to yield successful attacks, we construct a challenge set of 10000 adversarial samples with the highest attractor FREQ$_{\text{DIFF}}$ scores that had been obtained via the IH or RH perturbations. To enforce sample diversity, we limit the number of samples to at most 1000 per homograph. Additionally, we create equally-sized, secondary challenge sets by drawing samples at random from each domain's sample pool. Figure 3 illustrates the attack success rate for both categories, while Table 6 shows some of the successful attacks on the OS18 transformer. Further successful samples are reported in Appendix A.7.

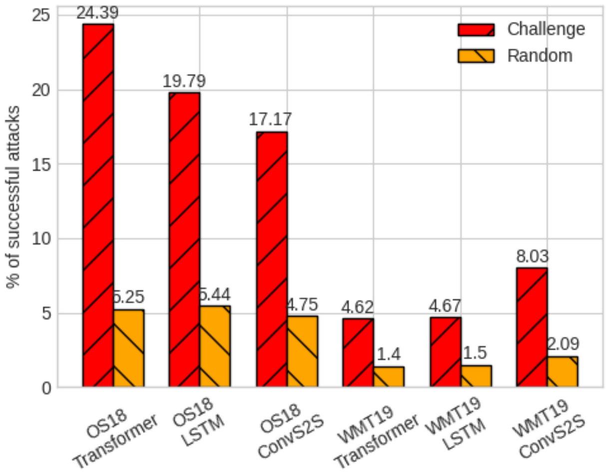

Figure 3: Successful challenge sets attacks.

The success rates are modest, ranging from 4.62% to 24.39%, but nonetheless showcase the capacity of targeted, minimal perturbations for flipping correct homograph translations towards a specific sense set. Since our attacks do not require access to model gradients or predictive score distributions, fall within the same domain as the models' training data, and have a strict notion of success,

Source input / Original output / Perturbed output	Seed sense	Adv. sense

Table 6: Examples of successful attacks on the OS18 transformer. Homographs are blue, attractors are red.

direct comparisons with previous work are difficult. Crucially, compared with a random sample selection strategy, subsampling informed by attractors' disambiguation bias is up to **4.25** times more successful at identifying effective adversarial samples.

While the relative improvement in attack success rate over the random baseline is comparable in both domains, the OS18 models are more susceptible to attacks in absolute terms. This may be due to their lower quality, or the properties of the training data, which can suffer from noisiness (Lison et al., 2019). Interestingly, the relative robustness of individual model architectures to WSD attacks also differs between domains, despite similar quality in terms of BLEU (see Table 2). A more thorough investigation of architecture-specific WSD vulnerabilities is left for future work.

3.3 Sample quality analysis

To examine whether our adversarial samples would appear trivial and innocuous to human translators, automatic and human evaluation of samples included in the challenge set is conducted. Following (Morris et al., 2020), we use a grammar checker[15] to evaluate the number of cases in which adversarial perturbations introduce grammatical errors. In the OS18 domain, only 1.04% of samples are less grammatical than their respective seed sentences, whereas this is the case for 2.04% of WMT19 samples, indicating a minimal degradation.

We additionally present two bilingual judges with 1000 samples picked at random from adversarial challenge sets in both domains and 1000 regular sentences from challenge sets constructed in section 2.2. For each adversarial source sentence, annotators were asked to choose whether the homograph's translation belongs to the correct or adversarial seed cluster. For each regular sentence, the choice was between the correct and randomly selected clusters. Across both domains, annotator error rate was 11.23% in the adversarial setting and 11.45% for regular sentences. As such, the generated samples display a similar degree of ambiguity to natural sentences that are likely to elicit WSD errors in NMT models. Annotator agreement was substantial (Cohen's kappa = 0.7).

The same judges were also asked to rate the naturalness of each sentence on a Likert scale from 1 to 5. Perturbed sentences were assigned a mean score of 3.94, whereas regular sentences scored higher at 4.18. However, annotator agreement was low (weighted Kappa = 0.17). The observed drop in naturalness is likely due to the selection of attractors that are not fully consistent with the selectional preferences of homograph senses during sample generation. We attribute this to WSD errors in reference translations. For instance, we find that the attractor *vampire* is occasionally applied to seed sentences containing the homograph *bat* in its *sporting equipment* sense, which can only occur if the attractor has been observed to modify this sense cluster in the training data (see 3.1). Appendix A.6 replicates annotator instructions for both tasks.

4 Transferability of adversarial samples

An interesting question to consider is whether translation models trained on the same data are vulnerable to the same adversarial samples. We evaluate this by computing the Jaccard similarity index between successful attacks on each baseline model from the entire pool of adversarial samples

---

[15] `http://languagetool.org`

described in section 3.2. We find the similarity to be low, raging between 10.1% and 18.2% for OS18 and between 5.7% and 9.1% for WMT19 samples, which suggests that different model architectures appear to be sensitive to different corpus artifacts, possibly due to differences in their inductive biases.

Considering the observed discrepancy in vulnerabilities between architectures, a natural follow-up question is whether two different instances of the same architecture are susceptible to the same set of attacks. We investigate this by training a second transformer model for each domain, keeping all settings constant with the initial models, but choosing a different seed for the random initialization. While the similarity between sets of successful adversarial samples is greater for two models of the same type, with 25.2% in the OS18 and 12.4% in WMT19 domain, is it still remarkably low.

5 Literature review

Polysemous terms represent a long-standing challenge for NMT. Past investigations sought to quantify the WSD capacity of translation models through challenge sets (Rios et al., 2017; Raganato et al., 2019), to understand the disambiguation process by analysing their internal representations (Marvin and Koehn, 2018; Tang et al., 2019), or to improve ambiguity resolution capabilities of translation models (Rios et al., 2017; Liu et al., 2018). To our knowledge, no study so far has examined the interaction between training data artifacts and WSD performance in detail.

Dataset artifacts, on the other hand, have previously been shown to enable models to make correct predictions based on incorrect or insufficient information (McCoy et al., 2019; Gururangan et al., 2018) by over-relying on spurious correlations present in the training data. Within NMT, models were found to exhibit gender-bias, reinforcing harmful stereotypes (Vanmassenhove et al., 2018; Stanovsky et al., 2019). As a response, strategies have been proposed for de-biasing the training data (Li and Vasconcelos, 2019; Le Bras et al., 2020), as well as for making models more robust to data biases through adversarial training (Belinkov et al., 2019).

Adversarial attacks have recently been extended as an effective model analysis tool from vision to language tasks (Samanta and Mehta, 2017; Alzantot et al., 2018; Glockner et al., 2018; Zhang et al., 2019), including NMT (Cheng et al., 2018, 2019), where the focus so far has been on strategies requiring direct access to the victim model's loss gradient or output distribution. Recent surveys suggested that state-of-the-art attacks often yield ungrammatical and meaning-destroying samples, thus diminishing their usefulness for the evaluation of model robustness (Michel et al., 2019; Morris et al., 2020). Targeted attacks on WSD abilities of translation models have so far remained unexplored.

6 Conclusion

We conducted an initial investigation into leveraging data artifacts for the prediction of WSD errors in machine translation and proposed a simple adversarial attack strategy based on the presented insights. Our results show that WSD is not yet a solved problem in NMT, and while the general performance of popular model architectures is high, we can identify or create sentences where models are more likely to fail due to data biases.

The effectiveness of our methods owes to neural models struggling to accurately distinguish between meaningful lexical correlations and superficial ones. As such, the presented approach is expected to be transferable to other language pairs and translation directions, assuming that the employed translation models share this underlying weakness. Given the model-agnostic nature of our findings, this is likely to be the case.

As a continuation to this work, we intend to evaluate whether multilingual translation models are more resilient to lexical disambiguation biases and, as a consequence, are less susceptible to adversarial attacks that exploit source-side homography. Extending model-agnostic attack strategies to incorporate other types of dataset biases and to target natural language processing tasks other than machine translation is likewise a promising avenue for future research. Lastly, the targeted development of models that are resistant to dataset artifacts is a promising direction that is likely to aid generalization across linguistically diverse domains.

A Supplementary material

A.1 Data properties

The WMT19 data is obtained by concatenating the Europarl v9, Common Crawl, and News Commentary v14 parallel corpora. Basic data cleaning is performed for both domains, which includes removal of pairs containing sentences classified by langid[16] as neither German or English and pairs with a source-to-target sentence length ratio exceeding 2. We create development and training splits for the OS18 domain by removing 10K sentence pairs from the full, shuffled corpus in each case. For each domain, we additionally hold-out 20% of pairs to be used for the extraction of test pairs containing homographs, as described in section 2.2. Final statistics for the OS18 domain are reported in table 9 and in 10 for the WMT19 domain.

Each dataset is subsequently tokenized and truecased using Moses (Koehn et al., 2007) scripts[17]. For model training and evaluation, we additionally learn and apply BPE codes (Sennrich et al., 2016) to the data using the subword-NMT implementation[18], with 32k merge operations and the vocabulary threshold set to 50.

A.2 Homograph list

The full list of homographs used in our experiments is as follows: anchor, arm, band, bank, balance, bar, barrel, bark, bass, bat, battery, beam, board, bolt, boot, bow, brace, break, bug, butt, cabinet, capital, case, cast, chair, change, charge, chest, chip, clip, club, cock, counter, crane, cycle, date, deck, drill, drop, fall, fan, file, film, flat, fly, gum, hoe, hood, jam, jumper, lap, lead, letter, lock, mail, match, mine, mint, mold, mole, mortar, move, nail, note, offense, organ, pack, palm, pick, pitch, pitcher, plaster, plate, plot, pot, present, punch, quarter, race, racket, record, ruler, seal, sewer, scale, snare, spirit, spot, spring, staff, stock, subject, tank, tear, term, tie, toast, trunk, tube, vacuum, watch.

A.3 Sense cluster examples

Table 11 lists some of the identified sense clusters for several homographs. All homographs used in our experiments have at least two sense clusters associated with them.

A.4 Baseline models

Table 12 provides implementation and training details for each architecture. Same settings are used for training identical models types in different domains. We use standard fairseq[19] (Ott et al., 2019) implementations for all model types and train them on NVIDIA 1080ti or NVIDIA 2080ti GPUs. Model translations are obtained by averaging the final 5 model checkpoints and decoding using beam search with beam size 5.

A.5 Base-rate adjusted effect size thresholds

Whether the effect size of correlations between dichotomous and quantitative variables can be considered strong depends on the size ratio between the two groups denoted by the dichotomous variable, i.e. its base rate. As the standard formulation of RBC is sensitive to the base rate, the estimated effect size decreases as the base rate becomes more extreme (see (McGrath and Meyer, 2006) for details). Applied to our experimental setting, this means that the observed correlation values are sensitive to the number of sentences containing disambiguation errors relative to the amount of those that do not. This is an undesirable property, as we are only interested in the predictive power of our quantitative variables, regardless of how often disambiguation errors are observed. Thus, we adjust the thresholds for the interpretation of correlation strength to account for WSD errors being less frequent than WSD successes overall, in analogy to (McGrath and Meyer, 2006). Doing so enables the direct comparison of correlation strength between domains and model types, as each combination of the two factors exhibits a different disambiguation success base rate.

A common practice for interpreting effect size strength that does not account for base rate inequalities is the adoption of Cohen's benchmark (Cohen, 2013), which posits that the effect size d is large if $d >= 0.8$, medium if $d >= 0.5$, and small if $d >= 0.2$. To adjust these threshold values for the observed base rates, they are converted according to Eqn. 8, where $p1$ and $p2$ represent the proportions of groups described by the dichotomous variable, with $p_2 = 1 - p_1$:

$$threshold = \frac{d}{\sqrt{d^2 + \frac{1}{p_1, p_2}}} \tag{8}$$

[17] http://github.com/moses-smt/mosesdecoder

[18] http://github.com/rsennrich/subword-nmt

[19] http://github.com/pytorch/fairseq

The adjusted effect size interpretation thresholds for WSD error correlation values as given in Table 3 are provided in Table 7. Adjusted thresholds for attack success correlations as given in Table 5 are summarized in Table 8.

A.6 Annotator instructions

The judges were presented with the following instructions for the described annotation tasks:

Your first task is to judge whether the meaning of the homograph as used in the given sentence is best described by the terms in the SENSE 1 cell or by those in the SENSE 2 cell. Please use the drop-down menu in the WHICH SENSE IS CORRECT? column to make your choice. If you think that neither sens captures the homograph's meaning, please select NONE from the options in the drop-down menu. If you think that the homograph as used in the given sentence can be equally interpreted both as SENSE 1 or SENSE 2, please select BOTH.

We're also asking you to give us your subjective judgment whether the sentence you've been evaluating makes sense to you, i.e. whether it's grammatical, whether it can be easily understood, and whether it sounds acceptable to you as a whole. Typos and spelling mistakes, on the other hand, can be ignored. Specifically, we would like you to assign each sentence a naturalness score, ranging from 1 to 5, according to the following scale:

- *1 = Completely unnatural (i.e. sentence is clearly ungrammatical, highly implausible, or meaningless / incoherent)*
- *2 = Somewhat unnatural (i.e. sentence is not outright incoherent, but sounds very strange)*
- *3 = Unsure (i.e. sentence is difficult to judge either way)*
- *4 = Mostly natural (i.e. sentence sounds good for the most part)*
- *5 = Completely natural (i.e. a well-formed English sentence)*

For instance a sentence like "John ate ten pancakes for breakfast." may get a ranking between 4 and 5, as it satisfies all of the above criteria. A sentence like "John ate green pancakes for breakfast." is grammatical but somewhat unusual and may therefore get a score between 3 and 4. "John ate late pancakes for breakfast.", on the other hand, does not sound very natural since pancakes cannot be "late" and may therefore be rated as 1 or 2. For this judgment we ask you to pay special attention to words in the neighborhood of the homograph. To submit your judgment please select the appropriate score from the drop-down menu in the DOES THE SENTENCE MAKE SENSE? column.

A.7 Examples of successful adversarial samples

Tables 13 - 18 list examples of successful adversarial attacks across the examined model architectures and dataset domains. As done throughout the paper, homographs are highlighted in blue, whereas the introduced attractors are emphasized in red.

MAD-X: An Adapter-Based Framework for Multi-Task Cross-Lingual Transfer

Abstract

The main goal behind state-of-the-art pretrained multilingual models such as multilingual BERT and XLM-R is enabling and bootstrapping NLP applications in *low-resource languages* through zero-shot or few-shot cross-lingual transfer. However, due to limited model capacity, their transfer performance is the weakest exactly on such low-resource languages and languages *unseen* during pretraining. We propose **MAD-X**, an adapter-based framework that enables high portability and parameter-efficient transfer to arbitrary tasks and languages by learning modular language and task representations. In addition, we introduce a novel invertible adapter architecture and a strong baseline method for adapting a pretrained multilingual model to a new language. MAD-X outperforms the state of the art in cross-lingual transfer across a representative set of typologically diverse languages on named entity recognition and causal commonsense reasoning, and achieves competitive results on question answering. Our code and adapters are available at AdapterHub.ml.

1 Introduction

Current deep pretrained multilingual models (Devlin et al., 2019; Conneau and Lample, 2019) achieve state-of-the-art results on cross-lingual transfer, but do not have enough capacity to represent all languages. Evidence for this is the importance of the vocabulary size (Artetxe et al., 2020) and *the curse of multilinguality* (Conneau et al., 2020), a trade-off between language coverage and model capacity. Scaling up a model to cover all of the world's 7,000+ languages is prohibitive. At the same time, limited capacity is an issue even for high-resource languages where state-of-the-art multilingual models underperform their monolingual variants (Eisenschlos et al., 2019; Virtanen et al., 2019; Nozza et al., 2020), and performance decreases further with lower-resource languages covered by the pretrained models. Moreover, the model capacity issue is arguably most severe for languages that were not included in the training data at all, and pretrained models perform poorly on those languages (Ponti et al., 2020b).

In this paper, we propose Multiple ADapters for Cross-lingual transfer (**MAD-X**), a modular framework that leverages a small number of extra parameters to address the fundamental capacity issue that limits pretrained multilingual models. Using a state-of-the-art multilingual model as the foundation, we adapt the model to arbitrary tasks and languages by learning modular language- and task-specific representations *via adapters* (Rebuffi et al., 2017; Houlsby et al., 2019), small bottleneck layers inserted between a model's weights.

In particular, using a recent efficient adapter variant (Pfeiffer et al., 2020a; Rücklé et al., 2020), we train **1)** *language-specific adapter modules* via masked language modelling (MLM) on unlabelled target language data, and **2)** *task-specific adapter modules* via optimising a target task on labelled data in any source language. Task and language adapters are stacked as in Figure 1, allowing us to adapt the pretrained multilingual model also to languages that are not covered in the model's (pre)training data by substituting the target language adapter at inference.

In order to deal with a mismatch between the shared multilingual vocabulary and target language vocabulary, we propose *invertible adapters*, a new type of adapter that is well suited to performing MLM in another language. Our framework goes beyond prior work on using adapters for cross-lingual transfer (Bapna and Firat, 2019; Artetxe et al., 2020) by enabling adaptation to languages *unseen* during pretraining and without learning expensive language-specific token-level embeddings.

We compare MAD-X against state-of-the-art

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7654–7673,
November 16–20, 2020.

cross-lingual transfer methods on the standard WikiANN NER dataset (Pan et al., 2017; Rahimi et al., 2019) and the XCOPA dataset (Ponti et al., 2020a) for causal commonsense reasoning, relying on a representative set of typologically diverse languages which includes high-resource, low-resource, as well as languages unseen by the pretrained model. MAD-X outperforms the baselines on seen and unseen high-resource and low-resource languages. On the high-resource languages of the challenging XQuAD QA dataset (Artetxe et al., 2020), our framework achieves competitive performance while being more parameter-efficient.

Another contribution of our work is a simple method of adapting a pretrained multilingual model to a new language, which outperforms the standard setting of transferring a model only from labelled source language data.

In sum, our contributions are as follows. **1)** We propose MAD-X, a modular framework that mitigates the curse of multilinguality and adapts a multilingual model to arbitrary tasks and languages. Both code and adapter weights are integrated into the AdapterHub.ml repository (Pfeiffer et al., 2020b).[1] **2)** We propose invertible adapters, a new adapter variant for cross-lingual MLM. **3)** We demonstrate strong performance and robustness of MAD-X across diverse languages and tasks. **4)** We propose a simple and more effective baseline method for adapting a pretrained multilingual model to target languages. **5)** We shed light on the behaviour of current methods on languages that are unseen during multilingual pretraining.

2 Related Work

Cross-lingual Representations Research in modern cross-lingual NLP is increasingly focused on learning general-purpose cross-lingual representations that can be applied to many tasks, first on the word level (Mikolov et al., 2013; Gouws et al., 2015; Glavaš et al., 2019; Ruder et al., 2019; Wang et al., 2020) and later on the full-sentence level (Devlin et al., 2019; Conneau and Lample, 2019; Cao et al., 2020). More recent models such as multilingual BERT (Devlin et al., 2019)—large Transformer (Vaswani et al., 2017) models pretrained on large amounts of multilingual data—have been observed to perform surprisingly well when transferring to other languages (Pires et al., 2019; Wu and Dredze, 2019; Wu et al., 2020) and the current state-of-the-art model, XLM-R is competitive with the performance of monolingual models on the GLUE benchmark (Conneau et al., 2020). Recent studies (Hu et al., 2020), however, indicate that state-of-the-art models such as XLM-R still perform poorly on cross-lingual transfer across many language pairs. The main reason behind such poor performance is the current lack of capacity in the model to represent all languages equally in the vocabulary and representation space (Bapna and Firat, 2019; Artetxe et al., 2020; Conneau et al., 2020).

Adapters Adapter modules have been originally studied in computer vision tasks where they have been restricted to convolutions and used to adapt a model for multiple domains (Rebuffi et al., 2017, 2018). In NLP, adapters have been mainly used for parameter-efficient and quick fine-tuning of a base pretrained Transformer model to new tasks (Houlsby et al., 2019; Stickland and Murray, 2019) and new domains (Bapna and Firat, 2019), avoiding catastrophic forgetting (McCloskey and Cohen, 1989; Santoro et al., 2016). Bapna and Firat (2019) also use adapters to fine-tune and recover performance of a multilingual NMT model on high-resource languages, but their approach cannot be applied to languages that were not seen during pretraining. Artetxe et al. (2020) employ adapters to transfer a pretrained monolingual model to an unseen language but rely on learning new token-level embeddings, which do not scale to a large number of languages. Pfeiffer et al. (2020a) combine the information stored in multiple adapters for more robust transfer learning between monolingual tasks. In their contemporaneous work, Üstün et al. (2020) generate adapter parameters from language embeddings for multilingual dependency parsing.

3 Multilingual Model Adaptation for Cross-lingual Transfer

Standard Transfer Setup The standard way of performing cross-lingual transfer with a state-of-the-art large multilingual model such as multilingual BERT or XLM-R is 1) to fine-tune it on labelled data of a downstream task in a source language and then 2) apply it directly to perform inference in a target language (Hu et al., 2020). A downside of this setting is that the multilingual initialisation balances *many* languages. It is thus not suited to excel at a specific language at inference time. We propose a simple method to ameliorate this issue by allowing the model to additionally

---

[1] https://github.com/Adapter-Hub/adapter-transformers

adapt to the particular target language.

Target Language Adaptation Similar to fine-tuning monolingual models on the task domain (Howard and Ruder, 2018), we propose to fine-tune a pretrained multilingual model via MLM on unlabelled data of the target language prior to task-specific fine-tuning in the source language. A disadvantage of this approach is that it no longer allows us to evaluate the same model on multiple target languages as it biases the model to a specific target language. However, this approach might be preferable if we only care about performance in a specific (i.e., fixed) target language. We find that target language adaptation results in improved cross-lingual transfer performance over the standard setting (§6). In other words, it does not result in catastrophic forgetting of the multilingual knowledge already available in the pretrained model that enables the model to transfer to other languages. In fact, experimenting with methods that explicitly try to prevent catastrophic forgetting (Wiese et al., 2017) led to worse performance in our experiments.

Nevertheless, the proposed simple adaptation method inherits the fundamental limitation of the pretrained multilingual model and the standard transfer setup: the model's limited capacity hinders effective adaptation to low-resource and unseen languages. In addition, fine-tuning the full model does not scale well to many tasks or languages.

4 Adapters for Cross-lingual Transfer

Our MAD-X framework addresses these deficiencies and can be used to effectively adapt an existing pretrained multilingual model to other languages. The framework comprises three types of adapters: language, task, and invertible adapters. As in previous work (Rebuffi et al., 2017; Houlsby et al., 2019), adapters are trained while keeping the parameters of the pretrained multilingual model fixed. Our framework thus enables learning language and task-specific transformations in a modular and parameter-efficient way. We show the full framework as part of a standard Transformer model in Figure 1 and describe the three adapter types.

4.1 Language Adapters

For learning language-specific transformations, we employ a recent efficient adapter architecture proposed by Pfeiffer et al. (2020a). Following Houlsby et al. (2019) they define the interior of the adapter to be a simple down- and up-projection combined with a residual connection.[2] The language adapter LA_l at layer l consists of a down-projection $\mathbf{D} \in \mathbb{R}^{h \times d}$ where h is the hidden size of the Transformer model and d is the dimension of the adapter, followed by a ReLU activation and an up-projection $\mathbf{U} \in \mathbb{R}^{d \times h}$ at every layer l:

$$\mathsf{LA}_l(\mathbf{h}_l, \mathbf{r}_l) = \mathbf{U}_l(\mathsf{ReLU}(\mathbf{D}_l(\mathbf{h}_l))) + \mathbf{r}_l \qquad (1)$$

where $\mathbf{h}_l$ and $\mathbf{r}_l$ are the Transformer hidden state and the residual at layer l, respectively. The residual connection $\mathbf{r}_l$ is the output of the Transformer's feed-forward layer whereas $\mathbf{h}_l$ is the output of the subsequent layer normalisation (see Figure 1).

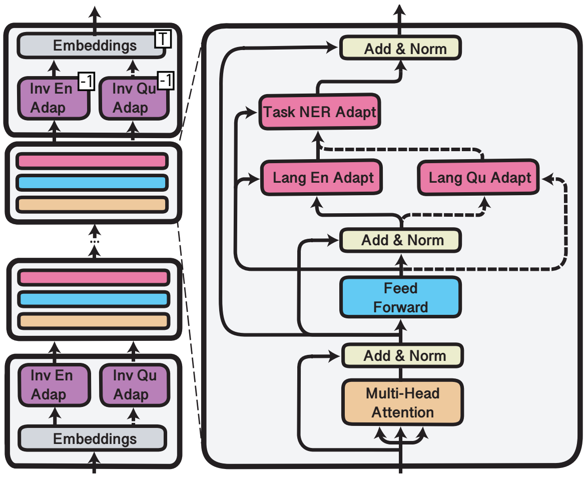

Figure 1: The MAD-X framework inside a Transformer model. Input embeddings are fed into the invertible adapter whose inverse is fed into the tied output embeddings. Language and task adapters are added to each Transformer layer. Language adapters and invertible adapters are trained via masked language modelling (MLM) while the pretrained multilingual model is kept frozen. Task-specific adapters are stacked on top of source language adapters when training on a downstream task such as NER (full lines). During zero-shot cross-lingual transfer, source language adapters are replaced with target language adapters (dashed lines).

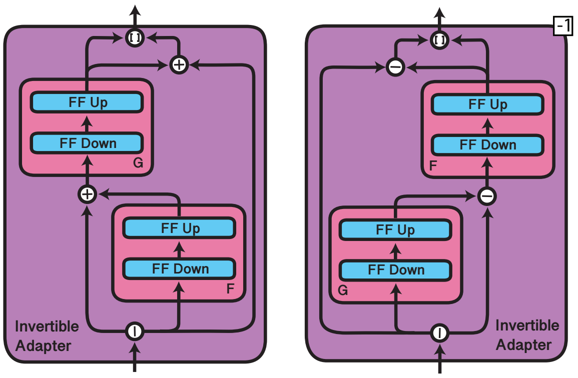
We train language adapters on unlabelled data of a language using MLM, which encourages them to learn transformations that make the pretrained multilingual model more suitable for a specific language. During task-specific training with labelled data, we use the language adapter of the corresponding source language, which is kept fixed. In order to perform zero-shot transfer to another language, we

---

[2] Pfeiffer et al. (2020a) perform an extensive hyperparameter search over adapter positions, activation functions, and residual connections within each Transformer layer. They arrive at an architecture variant that performs on par with that of Houlsby et al. (2019), while being more efficient.



(a) The invertible adapter (b) The inversed adapter

Figure 2: The invertible adapter (a) and its inverse (b). The input is split and transformed by projections F and G, which are coupled in an alternating fashion. | indicates the splitting of the input vector, and [ ] indicates the concatenation of two vectors. $+$ and $-$ indicate element-wise addition and subtraction, respectively.

simply replace the source language adapter with its target language component. For instance, as illustrated in Figure 1, we can simply replace a language-specific adapter trained for English with a language-specific adapter trained for Quechua at inference time. This, however, requires that the underlying multilingual model does not change during fine-tuning on the downstream task. In order to ensure this, we additionally introduce task adapters that capture task-specific knowledge.

4.2 Task Adapters

Task adapters TA_l at layer l have the same architecture as language adapters. They similarly consist of a down-projection $\mathbf{D} \in \mathbb{R}^{h \times d}$, a ReLU activation, followed by an up-projection. They are stacked on top of the language adapters and thus receive the output of the language adapter LA_l as input, together with the residual $\mathbf{r}_l$ of the Transformer's feed-forward layer[3]:

$$\mathsf{TA}_l(\mathbf{h}_l, \mathbf{r}_l) = \mathbf{U}_l(\mathsf{ReLU}(\mathbf{D}_l(\mathsf{LA}_l))) + \mathbf{r}_l \tag{2}$$

The output of the task adapter is then passed to another layer normalisation component. Task adapters are the only parameters that are updated when training on a downstream task (e.g., NER) and aim to capture knowledge that is task-specific but generalises across languages.

4.3 Invertible Adapters

The majority of the "parameter budget" of pretrained multilingual models is spent on token embeddings of the shared multilingual vocabulary. Despite this, they underperform on low-resource languages (Artetxe et al., 2020; Conneau et al., 2020), and are bound to fare even worse for languages not covered by the model's training data.

In order to mitigate this mismatch between multilingual and target language vocabulary, we propose invertible adapters. They are stacked on top of the embedding layer while their respective inverses precede the output embedding layer (see Figure 1). As input and output embeddings are tied in multilingual pretrained models, invertibility allows us to leverage the same set of parameters for adapting both input and output representations. This is crucial as the output embeddings, which get discarded during task-specific fine-tuning might otherwise overfit to the pretraining task.

To ensure this invertibility, we employ Non-linear Independent Component Estimation (NICE; Dinh et al., 2015). NICE enables the invertibility of arbitrary non-linear functions through a set of coupling operations (Dinh et al., 2015). For the invertible adapter, we split the input embedding vector $\mathbf{e}_i$ of the i-th token into two vectors of equal dimensionality $\mathbf{e}_{1,i}, \mathbf{e}_{2,i} \in \mathbb{R}^{h/2}$.[4] For two arbitrary non-linear function F and G, the forward pass through our invertible adapter $A_{inv}()$ is:

$$\begin{aligned} &\mathbf{o}_1 = F(\mathbf{e}_2) + \mathbf{e}_1; \;\; \mathbf{o}_2 = G(\mathbf{o}_1) + \mathbf{e}_2 \\ &\mathbf{o} = [\mathbf{o}_1, \mathbf{o}_2] \end{aligned} \tag{3}$$

where $\mathbf{o}$ is the output of the invertible adapter A_{inv} and $[\cdot, \cdot]$ indicates concatenation of two vectors.

Correspondingly, the inverted pass through the adapter, thus A^{-1}_{inv}, is computed as follows:

$$\begin{aligned} &\mathbf{e}_2 = \mathbf{o}_2 - G(\mathbf{o}_1); \;\; \mathbf{e}_1 = \mathbf{o}_1 - F(\mathbf{e}_2) \\ &\mathbf{e} = [\mathbf{e}_1, \mathbf{e}_2]. \end{aligned} \tag{4}$$

$\mathbf{e}$ is the output of $A^{-1}_{Inv}()$. For the non-linear transformations F and G, we use similar down- and up-projections as for the language and task adapters:

$$\begin{aligned} F(\mathbf{x}) &= \mathbf{U}_F(\mathsf{ReLU}(\mathbf{D}_F(\mathbf{x}))) \\ G(\mathbf{x}) &= \mathbf{U}_G(\mathsf{ReLU}(\mathbf{D}_G(\mathbf{x}))). \end{aligned} \tag{5}$$

where $\mathbf{D}_F, \mathbf{D}_G \in \mathbb{R}^{\frac{h}{4} \times \frac{h}{2}}$ and $\mathbf{U}_F, \mathbf{U}_G \in \mathbb{R}^{\frac{h}{2} \times \frac{h}{4}}$ and $\mathbf{x}$ is a placeholder for $\mathbf{e}_1, \mathbf{e}_2, \mathbf{o}_1$ and $\mathbf{o}_2$. We

---

[3] Initial experiments showed that this residual connection performs better than one to the output of the language adapter.

[4] For brevity, we further leave out the dependency on i.

illustrate the complete architecture of the invertible adapter and its inverse in Figure 2.

The invertible adapter has a similar function to the language adapter, but aims to capture token-level language-specific transformations. As such, it is trained together with the language adapters using MLM on unlabelled data of a specific language. During task-specific training we use the fixed invertible adapter of the source language, and replace it with the target-language invertible during zero-shot transfer. Importantly, our invertible adapters are much more parameter-efficient compared to the approach of Artetxe et al. (2020), which learns separate token embeddings for every new language.

An Illustrative Example We provide a brief walk-through example from Figure 1. Assuming English (*En*) as the source language and Quechua (*Qu*) as the target language, we first pretrain invertible adapters A_{Inv}^{En} and A_{Inv}^{Qu}, and language adapters A_{Lang}^{En} and A_{Lang}^{Qu} with MLM for which the output of the last layer is passed through $A_{Inv}^{En\ -1}$. We then train a task adapter for the NER task A_{Task}^{NER} on the English NER training set. During training, embeddings are passed through A_{Inv}^{En}. At every layer of the model the data is first passed through the fixed A_{Lang}^{En} and then into the NER adapter A_{Task}^{NER}. For zero-shot inference, the English invertible and language adapters A_{Inv}^{En} and A_{Lang}^{En} are replaced with their Quechua counterparts A_{Inv}^{Qu} and A_{Lang}^{Qu} while the data is still passed through the NER task adapter A_{Task}^{NER}.

5 Experiments

Data We conduct experiments on three tasks: Named entity recognition (NER), question answering (QA), and causal commonsense reasoning (CCR). For NER, we use the WikiANN (Pan et al., 2017) dataset, which was partitioned into train, development, and test portions by Rahimi et al. (2019). For QA, we employ the XQuAD dataset (Artetxe et al., 2020), a cross-lingual version of SQuAD (Rajpurkar et al., 2016). For CCR, we rely on XCOPA (Ponti et al., 2020a), a cross-lingual version of COPA (Roemmele et al., 2011).

Languages The partitioned version of WikiANN covers 176 languages. In order to obtain a comprehensive comparison to state-of-the-art cross-lingual methods under different evaluation conditions, we select languages based on: **a)** variance in data availability (by selecting languages with a range of respective Wikipedia sizes); **b)** their presence in pretrained multilingual models; more precisely, whether data in the particular language was included in the pretraining data of both multilingual BERT and XLM-R or not; and **c)** typological diversity to ensure that different language types and families are covered. In total, we can discern four categories in our language set: **1)** high-resource languages and **2)** low-resource languages covered by the pretrained SOTA multilingual models (i.e., by mBERT and XLM-R); as well as **3)** low-resource languages and **4)** truly low-resource languages not covered by the multilingual models. We select four languages from different language families for each category. We highlight characteristics of the 16 languages from 11 language families in Table 1.

Language	ISO code	Language family	# of Wiki articles	Covered by SOTA?

Table 1: Languages in our NER evaluation.

We evaluate on all possible language pairs (i.e., on the Cartesian product), using each language as a source language with every other language (including itself) as a target language. This subsumes both the standard *zero-shot cross-lingual transfer setting* (Hu et al., 2020) as well as the standard *monolingual in-language* setting.

For CCR and QA, we evaluate on the 12 and 11 languages provided in XCOPA and XQuAD respectively, with English as source language. XCOPA contains a typologically diverse selection of languages including two languages (Haitian Creole and Quechua) that are unseen by our main model. XQuAD comprises slightly less typologically diverse languages that are mainly high-resource.

Table 2: NER F1 scores averaged over all 16 target languages when transferring from each source language (i.e. the columns are source languages). The vertical dashed line distinguishes between languages seen in multilingual pretraining and the unseen ones (see also Table 1).

5.1 Baselines

The baseline models are based on different approaches to multilingual model adaptation for cross-lingual transfer, discussed previously in §3.

XLM-R The main model we compare against is XLM-R (Conneau et al., 2020), the current state-of-the-art model for cross-lingual transfer (Hu et al., 2020). It is a Transformer-based model pretrained for 100 languages on large cleaned Common Crawl corpora (Wenzek et al., 2020). For efficiency, we use the XLM-R Base configuration as the basis for most of our experiments. However, we note that the main idea behind the MAD-X framework is not tied to any particular pretrained model, and the framework can be easily adapted to other pretrained multilingual models as we show later in §6 (e.g., multilingual BERT). First, we compare against XLM-R in the standard setting where the entire model is fine-tuned on labelled data of the task in the source language.

XLM-R^{Base} MLM-SRC; XLM-R^{Base} MLM-TRG In §3, we have proposed target language adaptation as a simple method to adapt pretrained multilingual models for better cross-lingual generalisation on the downstream task. As a sanity check, we also compare against adapting to the source language data; we expect it to improve in-language performance but not to help with transfer. In particular, we fine-tune XLM-R with MLM on unlabelled source language (XLM-R^{Base} MLM-SRC) and target language data (XLM-R^{Base} MLM-TRG) prior to task-specific fine-tuning.

5.2 MAD-X: Experimental Setup

For the **MAD-X** framework, unless noted otherwise, we rely on the XLM-R Base architecture; we evaluate the full MAD-X, MAD-X without invertible adapters (–INV), and also MAD-X without language and invertible adapters (– LAD – INV). We use the Transformers library (Wolf et al., 2020) for all our experiments. For fine-tuning via MLM on unlabelled data, we train on the Wikipedia data of the corresponding language for 250,000 steps, with a batch size of 64 and a learning rate of $5e-5$ and $1e-4$ for XLM-R (also for the -SRC and -TRG variants) and adapters, respectively. We train models on NER data for 100 epochs with a batch size of 16 and 8 for high-resource and low-resource languages, respectively, and a learning rate of $5e-5$ and $1e-4$ for XLM-R and adapters, respectively. We choose the best checkpoint for evaluation based on validation performance. Following Pfeiffer et al. (2020a), we learn language adapters, invertible adapters, and task adapters with dimensionalities of 384, 192 (384 for both directions), and 48, respectively. XLM-R Base has a hidden layer size of 768, so these adapter sizes correspond to reductions of 2, 2, and 16.

For NER, we conduct five runs of fine-tuning on the WikiAnn training set of the source language—except for XLM-R^{Base} MLM-TRG for which we conduct one run for efficiency purposes for every source language–target language combination. For QA, we conduct three runs of fine-tuning on the English SQuAD training set, evaluate on all XQuAD target languages, and report mean F_1 and exact match (EM) scores. For CCR, we conduct three runs of fine-tuning on the respective English training set, evaluate on all XCOPA target languages, and report accuracy scores.

6 Results and Discussion

Named Entity Recognition As our main summary of results, we average the cross-lingual transfer results of each method for each source language across all 16 target languages on the NER dataset. We show the aggregated results in Table 2. Moreover, in the appendix we report the detailed results for all methods across each single language pair, as well as a comparison of methods on the most common setting with English as source language.

In general, we observe that XLM-R performance is indeed lowest for unseen languages (the right half of the table after the vertical dashed line). XLM-R^{Base} MLM-SRC performs worse than XLM-R, which indicates that source-language fine-tuning is not useful for cross-lingual transfer in general.[5] On the other hand, XLM-R^{Base} MLM-TRG is a stronger transfer method than XLM-R on average, yielding gains in 9/16 target languages. However, its gains seem to vanish for low-resource languages. Further, there is another disadvantage, outlined in §3: XLM-R^{Base} MLM-TRG requires fine-tuning the full large pretrained model separately for each target language in consideration, which can be prohibitively expensive.

MAD-X without language and invertible adapters performs on par with XLM-R for almost all languages present in the pretraining data (left half of the table). This mirrors findings in the monolingual setting where task adapters have been observed to achieve performance similar to regular fine-tuning while being more parameter-efficient (Houlsby et al., 2019). However, looking at unseen languages, the performance of MAD-X that only uses task adapters deteriorates significantly compared to XLM-R. This shows that task adapters alone are not expressive enough to bridge the discrepancy when adapting to an unseen language.

Adding language adapters to MAD-X improves its performance across the board, and their usefulness is especially pronounced for low-resource languages. Language adapters help capture the characteristics of the target language and consequently provide boosts for unseen languages. Even for high-resource languages, the addition of language-specific parameters yields substantial improvements. Finally, invertible adapters provide further gains and generally outperform only using task and language adapters: for instance, we observe gains with MAD-X over MAD-X –INV on 13/16 target languages. Overall, the full MAD-X framework improves upon XLM-R by more than 5 F_1 points on average.

Figure 3: Relative F_1 improvement of MAD-X^{Base} over XLM-R^{Base} in cross-lingual NER transfer.

To demonstrate that our framework is model-agnostic, we also employ two other strong multilingual models, XLM-R^{Large} and mBERT as foundation for MAD-X and show the results in Table 2. MAD-X shows consistent improvements even over stronger base pretrained models.

For a more fine-grained impression of the performance of MAD-X in different languages, we show its relative performance against XLM-R in the standard setting in Figure 3. We observe the largest differences in performance when transferring from high-resource to low-resource and unseen languages (top-right quadrant of Figure 3), which is arguably the most natural setup for cross-lingual transfer. In particular, we observe strong gains when transferring from Arabic, whose script might not be well represented in XLM-R's vocabulary. We also detect strong performance in the in-language monolingual setting (diagonal) for the subset of low-resource languages. This indicates that MAD-X may help bridge the perceived weakness of multilingual versus monolingual models. Finally, MAD-X performs competitively even when the target language is high-resource.[6]

Causal Commonsense Reasoning We show results on transferring from English to each target language on XCOPA in Table 3. For brevity, we only show the results of the best fine-tuning set-

---

[5] However, there are some examples (e.g., JA, TK) where it does yield slight gains over the standard XLM-R transfer.

[6] In the appendix, we also plot relative performance of the full MAD-X method (with all three adapter types) versus XLM-R^{Base} MLM-TRG across all language pairs. The scores lead to similar conclusions as before: the largest benefits of MAD-X are observed for the set of low-resource target languages (i.e., the right half of the heatmap). The scores also again confirm that the proposed XLM-R^{Base} MLM-TRG transfer baseline is more competitive than the standard XLM-R transfer across a substantial number of language pairs.

Table 4: F_1 / EM scores on XQuAD with English as the source language for each target language.

ting from Ponti et al. (2020a)—fine-tuning first on SIQA (Sap et al., 2019) and on the English COPA training set—and report other possible settings in the appendix. Target language adaptation outperforms XLM-R^{Base} while MAD-X^{Base} achieves the best scores. It shows gains in particular for the two unseen languages, Haitian Creole (ht) and Quechua (qu). Performance on the other languages is also generally competitive or better.

Question Answering The results on XQuAD when transferring from English to each target language are provided in Table 4. The main finding is that MAD-X achieves similar performance to the XLM-R baseline. As before, invertible adapters generally improve performance and target language adaptation improves upon the baseline setting. We note that all languages included in XQuAD can be considered high-resource, with more than 100k Wikipedia articles each (cf. Wikipedia sizes of NER languages in Table 1). The corresponding setting can be found in the top-left quadrant in Figure 3 where relative differences are comparable.

These and XCOPA results demonstrate that, while MAD-X excels at transfer to unseen and low-resource languages, it achieves competitive performance even for high-resource languages and on more challenging tasks. These evaluations also hint at the modularity of the adapter-based MAD-X approach, which holds promise of quick adaptation to more tasks: we use exactly the same language-specific adapters in NER, CCR, and QA for languages such as English and Mandarin Chinese that appear in all three evaluation language samples.

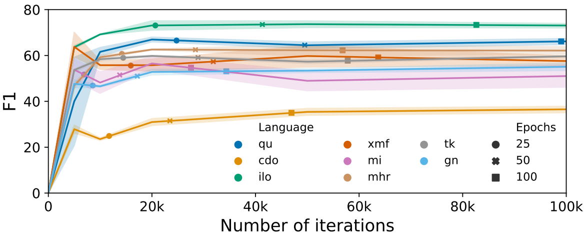

Figure 4: Cross-lingual NER performance of MAD-X transferring from English to the target languages with invertible and language adapters trained on target language data for different numbers of iterations. Shaded regions denote variance in F_1 scores across 5 runs.

Model		+ Params	% Model
MAD-X^{Base}		8.25M	3.05
MAD-X^{Base}	– INV	7.96M	2.94
MAD-X^{Base}	– LAD – INV	0.88M	0.32

Table 5: Number of parameters added to XLM-R Base, and as a fraction of its parameter budget (270M).

7 Further Analysis

Impact of Invertible Adapters We also analyse the relative performance difference of MAD-X with and without invertible adapters for each source language–target language pair on the NER data set (see Section D in the appendix). Invertible adapters improve performance for many transfer pairs, and particularly when transferring to low-resource languages. Performance is only consistently lower with a single low-resource language as source (Maori), likely due to variation in the data.

Sample Efficiency The main adaptation bottleneck of MAD-X is training language adapters and invertible adapters. However, due to the modularity of MAD-X, once trained, these adapters have an advantage of being directly reusable (i.e., "plug-and-playable") across different tasks (see the discussion in §6). To estimate the sample efficiency of adapter training, we measure NER performance on several low-resource target languages (when transferring from English as the source) conditioned on the number of training iterations. The results are given in Figure 4. They reveal that we can achieve strong performance for the low-resource languages already at 20k training iterations, and longer training offers modest increase in performance.

Moreover, in Table 5 we present the number of parameters added to the original XLM-R Base model per language for each MAD-X variant. The full MAD-X model for NER receives an additional set of 8.25M adapter parameters for every language, which makes up only 3.05% of the original model.

8 Conclusion

We have proposed MAD-X, a general modular framework for transfer across tasks and languages. It leverages a small number of additional parameters to mitigate the capacity issue which fundamentally hinders current multilingual models. MAD-X is model-agnostic and can be adapted to any current pre-trained multilingual model as foundation. We have shown that it is particularly useful for adapting to languages not covered by the multilingual model's training model, while also achieving competitive performance on high-resource languages.

In future work, we will apply MAD-X to other pre-trained models, and employ adapters that are particularly suited for languages with certain properties (e.g. with different scripts). We will also evaluate on additional tasks, and investigate leveraging pre-trained language adapters from related languages for improved transfer to truly low-resource languages with limited monolingual data.

LAD – INV), 9 (MAD-X^{Base} – INV), 10 (MAD-X^{Base}), 11 (mBERT), 12 (MAD-X^{mBERT}) , 13 (XLM-R^{Large}), and 14 (MAD-X^{mBERT}). Each score is averaged over five runs.

D Relative improvement of MAD-X over baselines in cross-lingual NER transfer

We show the heatmaps which depict relative F1 improvements of the full MAD-X^{Base} framework in the cross-lingual NER transfer task over: (a) the baseline model XLM-R^{Base} MLM-TRG (Figure 15) and (b) the MAD-X^{Base} variant without invertible adapters: MAD-X^{Base} –INV (Figure 16).

The heatmap which depicts relative F1 improvements of the full MAD-X^{mBERT} framework over mBERT can be found in Figure 17.

Finally, the heatmap which depicts relative F1 improvements of the full MAD-X^{Large} framework over XLM-R^{Large} can be found in Figure 18.

E XCOPA results for all settings

We show the results on XCOPA for all fine-tuning settings in Table 7.

Translation Artifacts in Cross-lingual Transfer Learning

Mikel Artetxe, Gorka Labaka, Eneko Agirre

Abstract

Both human and machine translation play a central role in cross-lingual transfer learning: many multilingual datasets have been created through professional translation services, and using machine translation to translate either the test set or the training set is a widely used transfer technique. In this paper, we show that such translation process can introduce subtle artifacts that have a notable impact in existing cross-lingual models. For instance, in natural language inference, translating the premise and the hypothesis independently can reduce the lexical overlap between them, which current models are highly sensitive to. We show that some previous findings in cross-lingual transfer learning need to be reconsidered in the light of this phenomenon. Based on the gained insights, we also improve the state-of-the-art in XNLI for the *translate-test* and *zero-shot* approaches by 4.3 and 2.8 points, respectively.

1 Introduction

While most NLP resources are English-specific, there have been several recent efforts to build **multilingual benchmarks**. One possibility is to collect and annotate data in multiple languages separately (Clark et al., 2020), but most existing datasets have been created through translation (Conneau et al., 2018; Artetxe et al., 2020). This approach has two desirable properties: it relies on existing professional translation services rather than requiring expertise in multiple languages, and it results in parallel evaluation sets that offer a meaningful measure of the cross-lingual transfer gap of different models. The resulting multilingual datasets are generally used for evaluation only, relying on existing English datasets for training.

Closely related to that, **cross-lingual transfer learning** aims to leverage large datasets available in one language—typically English—to build multilingual models that can generalize to other languages. Previous work has explored 3 main approaches to that end: machine translating the test set into English and using a monolingual English model (TRANSLATE-TEST), machine translating the training set into each target language and training the models on their respective languages (TRANSLATE-TRAIN), or using English data to finetune a multilingual model that is then transferred to the rest of languages (ZERO-SHOT).

The dataset creation and transfer procedures described above result in a **mixture of original,**[1] **human translated and machine translated data** when dealing with cross-lingual models. In fact, the type of text a system is trained on does not typically match the type of text it is exposed to at test time: TRANSLATE-TEST systems are trained on original data and evaluated on machine translated test sets, ZERO-SHOT systems are trained on original data and evaluated on human translated test sets, and TRANSLATE-TRAIN systems are trained on machine translated data and evaluated on human translated test sets.

Despite overlooked to date, we show that **such mismatch has a notable impact** in the performance of existing cross-lingual models. By using back-translation (Sennrich et al., 2016) to paraphrase each training instance, we obtain another English version of the training set that better resembles the test set, obtaining substantial improvements for the TRANSLATE-TEST and ZERO-SHOT approaches in cross-lingual Natural Language Inference (NLI). While improvements brought by machine translation have previously been attributed to data augmentation (Singh et al., 2019), we reject this hypothesis and show that the phenomenon is only present in translated test sets, but not in original ones. Instead, our analysis reveals that

---

[1] We use the term *original* to refer to non-translated text.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7674–7684,
November 16–20, 2020.

this behavior is caused by subtle **artifacts arising from the translation** process itself. In particular, we show that translating different parts of each instance separately (e.g., the premise and the hypothesis in NLI) can alter superficial patterns in the data (e.g., the degree of lexical overlap between them), which severely affects the generalization ability of current models. Based on the gained insights, we improve the state-of-the-art in XNLI, and show that some previous findings need to be reconsidered in the light of this phenomenon.

2 Related work

Cross-lingual transfer learning. Current cross-lingual models work by pre-training multilingual representations using some form of language modeling, which are then fine-tuned on the relevant task and transferred to different languages. Some authors leverage parallel data to that end (Conneau and Lample, 2019; Huang et al., 2019), but training a model akin to BERT (Devlin et al., 2019) on the combination of monolingual corpora in multiple languages is also effective (Conneau et al., 2020). Closely related to our work, Singh et al. (2019) showed that replacing segments of the training data with their translation during fine-tuning is helpful. However, they attribute this behavior to a data augmentation effect, which we believe should be reconsidered given the new evidence we provide.

Multilingual benchmarks. Most benchmarks covering a wide set of languages have been created through translation, as it is the case of XNLI (Conneau et al., 2018) for NLI, PAWS-X (Yang et al., 2019) for adversarial paraphrase identification, and XQuAD (Artetxe et al., 2020) and MLQA (Lewis et al., 2020) for Question Answering (QA). A notable exception is TyDi QA (Clark et al., 2020), a contemporaneous QA dataset that was separately annotated in 11 languages. Other cross-lingual datasets leverage existing multilingual resources, as it is the case of MLDoc (Schwenk and Li, 2018) for document classification and Wikiann (Pan et al., 2017) for named entity recognition. Concurrent to our work, Hu et al. (2020) combine some of these datasets into a single multilingual benchmark, and evaluate some well-known methods on it.

Annotation artifacts. Several studies have shown that NLI datasets like SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018) contain spurious patterns that can be exploited to obtain strong results without making real inferential decisions. For instance, Gururangan et al. (2018) and Poliak et al. (2018) showed that a hypothesis-only baseline performs better than chance due to cues on their lexical choice and sentence length. Similarly, McCoy et al. (2019) showed that NLI models tend to predict *entailment* for sentence pairs with a high lexical overlap. Several authors have worked on adversarial datasets to diagnose these issues and provide a more challenging benchmark (Naik et al., 2018; Glockner et al., 2018; Nie et al., 2020). Besides NLI, other tasks like QA have also been found to be susceptible to annotation artifacts (Jia and Liang, 2017; Kaushik and Lipton, 2018). While previous work has focused on the monolingual scenario, we show that translation can interfere with these artifacts in multilingual settings.

Translationese. Translated texts are known to have unique features like simplification, explicitation, normalization and interference, which are refer to as *translationese* (Volansky et al., 2013). This phenomenon has been reported to have a notable impact in machine translation evaluation (Zhang and Toral, 2019; Graham et al., 2019). For instance, back-translation brings large BLEU gains for reversed test sets (i.e., when translationese is on the source side and original text is used as reference), but its effect diminishes in the natural direction (Edunov et al., 2020). While connected, the phenomenon we analyze is different in that it arises from translation inconsistencies due to the lack of context, and affects cross-lingual transfer learning rather than machine translation.

3 Experimental design

Our goal is to analyze the effect of both human and machine translation in cross-lingual models. For that purpose, the core idea of our work is to (i) use machine translation to either translate the training set into other languages, or generate English paraphrases of it through back-translation, and (ii) evaluate the resulting systems on original, human translated and machine translated test sets in comparison with systems trained on original data. We next describe the models used in our experiments (§3.1), the specific training variants explored (§3.2), and the evaluation procedure followed (§3.3).

3.1 Models and transfer methods

We experiment with two models that are representative of the state-of-the-art in monolingual and cross-lingual pre-training: (i) ROBERTA (Liu et al., 2019), which is an improved version of BERT that uses masked language modeling to pre-train an English Transformer model, and (ii) XLM-R (Conneau et al., 2020), which is a multilingual extension of the former pre-trained on 100 languages. In both cases, we use the large models released by the authors under the fairseq repository.[2] As discussed next, we explore different variants of the training set to fine-tune each model on different tasks. At test time, we try both machine translating the test set into English (TRANSLATE-TEST) and, in the case of XLM-R, using the actual test set in the target language (ZERO-SHOT).

3.2 Training variants

We try 3 variants of each training set to fine-tune our models: (i) the original one in English (ORIG), (ii) an English paraphrase of it generated through back-translation using Spanish or Finnish as pivot (BT-ES and BT-FI), and (iii) a machine translated version in Spanish or Finnish (MT-ES and MT-FI). For sentences occurring multiple times in the training set (e.g., premises repeated for multiple hypotheses), we use the exact same translation for all occurrences, as our goal is to understand the inherent effect of translation rather than its potential application as a data augmentation method.

In order to train the machine translation systems for MT-XX and BT-XX, we use the big Transformer model (Vaswani et al., 2017) with the same settings as Ott et al. (2018) and SentencePiece tokenization (Kudo and Richardson, 2018) with a joint vocabulary of 32k subwords. For English-Spanish, we train for 10 epochs on all parallel data from WMT 2013 (Bojar et al., 2013) and ParaCrawl v5.0 (Esplà et al., 2019). For English-Finnish, we train for 40 epochs on Europarl and Wiki Titles from WMT 2019 (Barrault et al., 2019), ParaCrawl v5.0, and DGT, EUbookshop and TildeMODEL from OPUS (Tiedemann, 2012). In both cases, we remove sentences longer than 250 tokens, with a source/target ratio exceeding 1.5, or for which `langid.py` (Lui and Baldwin, 2012) predicts a different language, resulting in a final corpus size of 48M and 7M sentence pairs, respectively. We use sampling decoding with a temperature of 0.5 for inference, which produces more diverse translations than beam search (Edunov et al., 2018) and performed better in our preliminary experiments.

3.3 Tasks and evaluation procedure

We use the following tasks for our experiments:

Natural Language Inference (NLI). Given a premise and a hypothesis, the task is to determine whether there is an *entailment*, *neutral* or *contradiction* relation between them. We fine-tune our models on MultiNLI (Williams et al., 2018) for 10 epochs using the same settings as Liu et al. (2019). In most of our experiments, we evaluate on XNLI (Conneau et al., 2018), which comprises 2490 development and 5010 test instances in 15 languages. These were originally annotated in English, and the resulting premises and hypotheses were independently translated into the rest of the languages by professional translators. For the TRANSLATE-TEST approach, we use the machine translated versions from the authors. Following Conneau et al. (2020), we select the best epoch checkpoint according to the average accuracy in the development set.

Question Answering (QA). Given a context paragraph and a question, the task is to identify the span answering the question in the context. We fine-tune our models on SQuAD v1.1 (Rajpurkar et al., 2016) for 2 epochs using the same settings as Liu et al. (2019), and report test results for the last epoch. We use two datasets for evaluation: XQuAD (Artetxe et al., 2020), a subset of the SQuAD development set translated into 10 other languages, and MLQA (Lewis et al., 2020) a dataset consisting of parallel context paragraphs plus the corresponding questions annotated in English and translated into 6 other languages. In both cases, the translation was done by professional translators at the document level (i.e., when translating a question, the text answering it was also shown). For our BT-XX and MT-XX variants, we translate the context paragraph and the questions independently, and map the answer spans using the same procedure as Carrino et al. (2020).[3] For the TRANSLATE-TEST approach, we use the official machine translated versions of MLQA, run inference over them, and map the predicted answer spans back to the target language.[4]

---

[2] https://github.com/pytorch/fairseq

[3] We use FastAlign (Dyer et al., 2013) for word alignment, and discard the few questions for which the mapping method fails (when none of the tokens in the answer span are aligned).

[4] We use the same procedure as for the training set except that (i) given the small size of the test set, we combine it with WikiMatrix (Schwenk et al., 2019) to aid word alignment, (ii) we use Jieba for Chinese segmentation instead of the Moses tokenizer, and (iii) for the few unaligned spans, we return the English answer.

Table 1: **XNLI dev results (acc).** BT-XX and MT-XX consistently outperform Orig in all cases.

Both for NLI and QA, we run each system 5 times with different random seeds and report the average results. Space permitting, we also report the standard deviation across the 5 runs. In our result tables, we use an underline to highlight the best result within each block, and boldface to highlight the best overall result.

4 NLI experiments

We next discuss our main results in the XNLI development set (§4.1, §4.2), run additional experiments to better understand the behavior of our different variants (§4.3, §4.4, §4.5), and compare our results to previous work in the XNLI test set (§4.6).

4.1 Translate-Test results

We start by analyzing XNLI development results for Translate-Test. Recall that, in this approach, the test set is machine translated into English, but training is typically done on original English data. Our BT-ES and BT-FI variants close this gap by training on a machine translated English version of the training set generated through back-translation. As shown in Table 1, this brings substantial gains for both Roberta and XLM-R, with an average improvement of 4.6 points in the best case. Quite remarkably, MT-ES and MT-FI also outperform Orig by a substantial margin, and are only 0.8 points below their BT-ES and BT-FI counterparts. Recall that, for these two systems, training is done in machine translated Spanish or Finnish, while inference is done in machine translated English. This shows that the loss of performance when generalizing from original data to machine translated data is substantially larger than the loss of performance when generalizing from one language to another.

4.2 Zero-Shot results

We next analyze the results for the Zero-Shot approach. In this case, inference is done in the test set in each target language which, in the case of XNLI, was human translated from English. As such, different from the Translate-Test approach, neither training on original data (Orig) nor training on machine translated data (BT-XX and MT-XX) makes use of the exact same type of text that the system is exposed to at test time. However, as shown in Table 1, both BT-XX and MT-XX outperform Orig by approximately 2 points, which suggests that our (back-)translated versions of the training set are more similar to the human translated test sets than the original one. This also provides a new perspective on the Translate-Train approach, which was reported to outperform Orig in previous work (Conneau and Lample, 2019): while the original motivation was to train the model on the same language that it is tested on, our results show that machine translating the training set is beneficial even when the target language is different.

4.3 Original vs. translated test sets

So as to understand whether the improvements observed so far are limited to translated test sets or apply more generally, we conduct additional experiments comparing translated test sets to original ones. However, to the best of our knowledge, all

		XNLI dev		Our dataset

	BT-FI	89.7	86.5	80.8	78.8	79.2
	MT-ES	90.2	**87.5**	81.3	78.4	78.9
	MT-FI	90.4	87.1	81.1	78.3	78.9

Table 2: **NLI results on original (OR), human translated (HT) and machine translated (MT) sets (acc).** BT-XX and MT-XX outperform Orig in translated sets, but do not get any clear improvement in original ones.

existing non-English NLI benchmarks were created through translation. For that reason, we build a new test set that mimics XNLI, but is annotated in Spanish rather than English. We first collect the premises from a filtered version of CommonCrawl (Buck et al., 2014), taking a subset of 5 websites that represent a diverse set of genres: a newspaper, an economy forum, a celebrity magazine, a literature blog, and a consumer magazine. We then ask native Spanish annotators to generate an *entailment*, a *neutral* and a *contradiction* hypothesis for each premise.[5] We collect a total of 2490 examples using this procedure, which is the same size as the XNLI development set. Finally, we create a human translated and a machine translated English version of the dataset using professional translators from Gengo and our machine translation system described in §3.2,[6] respectively. We report results for the best epoch checkpoint on each set.

As shown in Table 2, both BT-XX and MT-XX clearly outperform Orig in all test sets created through translation, which is consistent with our previous results. In contrast, the best results on the original English set are obtained by Orig, and neither BT-XX nor MT-XX obtain any clear improvement on the one in Spanish either.[7] This confirms that the underlying phenomenon is limited to translated test sets. In addition, it is worth mentioning that the results for the machine translated test set in English are slightly better than those for the human translated one, which suggests that the difficulty of the task does not only depend on the translation quality. Finally, it is also interesting that MT-ES is only marginally better than MT-FI in both Spanish test sets, even if it corresponds to the Translate-Train approach, whereas MT-FI needs to Zero-Shot transfer from Finnish into Spanish. This reinforces the idea that it is training on translated data rather than training on the target language that is key in Translate-Train.

		Competence		Distraction			Noise
Model	Train	AT	NR	WO	NG	LN	SE
RoBERTa	Orig	72.9	**65.7**	64.9	59.1	**88.4**	86.5
	BT-FI	56.6	57.2	**80.6**	67.8	87.7	**86.6**
XLM-R	Orig	**78.4**	56.8	67.3	61.2	86.8	85.3
	BT-FI	60.6	51.7	76.7	64.6	86.2	85.4
	MT-FI	64.3	50.3	77.8	**68.5**	86.4	85.3

Table 3: **NLI Stress Test results (combined matched & mismatched acc).** AT = antonymy, NR = numerical reasoning, WO = word overlap, NG = negation, LN = length mismatch, SE = spelling error. BT-FI and MT-FI are considerably weaker than Orig in the competence test, but substantially stronger in the distraction test.

4.4 Stress tests

In order to better understand how systems trained on original and translated data differ, we run additional experiments on the NLI Stress Tests (Naik et al., 2018), which were designed to test the robustness of NLI models to specific linguistic phenomena in English. The benchmark consists of a competence test, which evaluates the ability to understand antonymy relation and perform numerical reasoning, a distraction test, which evaluates the robustness to shallow patterns like lexical overlap and the presence of negation words, and a noise test, which evaluates robustness to spelling errors. Just as with previous experiments, we report results for the best epoch checkpoint in each test set.

As shown in Table 3, Orig outperforms BT-FI and MT-FI on the competence test by a large margin, but the opposite is true on the distraction test.[8] In particular, our results show that BT-FI and MT-FI are less reliant on lexical overlap and the presence of negative words. This feels intuitive, as translating the premise and hypothesis independently—as BT-FI and MT-FI do—is likely to reduce the lexical overlap between them. More generally, the trans-

---

[5] Unlike XNLI, we do not collect 4 additional labels for each example. Note, however, that XNLI kept the original label as the gold standard, so the additional labels are irrelevant for the actual evaluation. This is not entirely clear in Conneau et al. (2018), but can be verified by inspecting the dataset.

[6] We use beam search instead of sampling decoding.

[7] Note that the standard deviations are around 0.3.

[8] We observe similar trends for BT-ES and MT-ES, but omit these results for conciseness.

lation process can alter similar superficial patterns in the data, which NLI models are sensitive to (§2). This would explain why the resulting models have a different behavior on different stress tests.

4.5 Output class distribution

With the aim to understand the effect of the previous phenomenon in cross-lingual settings, we look at the output class distribution of our different models in the XNLI development set. As shown in Table 4, the predictions of all systems are close to the true class distribution in the case of English. Nevertheless, Orig is strongly biased for the rest of languages, and tends to underpredict *entailment* and overpredict *neutral*. This can again be attributed to the fact that the English test set is original, whereas the rest are human translated. In particular, it is well-known that NLI models tend to predict *entailment* when there is a high lexical overlap between the premise and the hypothesis (§2). However, the degree of overlap will be smaller in the human translated test sets given that the premise and the hypothesis were translated independently, which explains why *entailment* is underpredicted. In contrast, BT-FI and MT-FI are exposed to the exact same phenomenon during training, which explains why they are not that heavily affected.

So as to measure the impact of this phenomenon, we explore a simple approach to correct this bias: having fine-tuned each model, we adjust the bias term added to the logit of each class so the model predictions match the true class distribution for each language.[9] As shown in Table 5, this brings large improvements for Orig, but is less effective for BT-FI and MT-FI.[10] This shows that the performance of Orig was considerably hindered by this bias, which BT-FI and MT-FI effectively mitigate.

4.6 Comparison with the state-of-the-art

So as to put our results into perspective, we compare our best variant to previous work on the XNLI test set. As shown in Table 6, our method improves the state-of-the-art for both the Translate-Test and the Zero-Shot approaches by 4.3 and 2.8 points, respectively. It also obtains the best overall results published to date, with the additional advantage that the previous state-of-the-art required a machine translation system between English and each of the 14 target languages, whereas our method uses a single machine translation system between English and Finnish (which is not one of the target languages). While the main goal of our work is not to design better cross-lingual models, but to analyze their behavior in connection to translation, this shows that the phenomenon under study is highly relevant, to the extent that it can be exploited to improve the state-of-the-art.

		EN			EN → XX (avg)		
Model	Train	ent	neu	con	ent	neu	con
RoBERTa (*translate-test*)	Orig	33.4	32.8	33.8	23.2	40.7	36.1
	BT-FI	34.5	31.9	33.6	30.2	35.7	34.1
XLM-R (*zero-shot*)	Orig	32.4	33.2	34.4	27.0	37.8	35.2
	BT-FI	34.3	31.6	34.1	33.1	32.9	34.0
	MT-FI	33.6	32.6	33.9	30.8	35.3	33.9
Gold Standard		33.3	33.3	33.3	33.3	33.3	33.3

Table 4: **Output class distribution on XNLI dev.** All systems are close to the true distribution in English, but Orig is biased toward *neu* and *con* in the transfer languages. BT-FI and MT-FI alleviate this issue.

Model	Train	Base	Unbias	+Δ
RoBERTa (*translate-test*)	Orig	77.7 ±0.6	80.6 ±0.2	2.9 ±0.5
	BT-FI	82.3 ±0.2	82.8 ±0.1	0.4 ±0.2
XLM-R (*zero-shot*)	Orig	81.0 ±0.2	82.4 ±0.2	1.4 ±0.3
	BT-FI	83.2 ±0.1	83.3 ±0.1	0.1 ±0.1
	MT-FI	83.4 ±0.2	83.8 ±0.1	0.4 ±0.2

Table 5: **XNLI dev results with class distribution unbiasing (average acc across all languages).** Adjusting the bias term of the classifier to match the true class distribution brings large improvements for Orig, but is less effective for BT-FI and MT-FI.

5 QA experiments

So as to understand whether our previous findings apply to other tasks besides NLI, we run additional experiments on QA. As shown in Table 7, BT-FI and BT-ES do indeed outperform Orig for the Translate-Test approach on MLQA. The improvement is modest, but very consistent across different languages, models and runs. The results for MT-ES and MT-FI are less conclusive, presumably because mapping the answer spans across languages might introduce some noise. In contrast, we do not ob-

---

[9] We achieve this using an iterative procedure where, at each step, we select one class and set its bias term so the class is selected for the right percentage of examples.

[10] Note that we are adjusting the bias term in the evaluation set itself, which requires knowing its class distribution and is thus a form of cheating. While useful for analysis, a fair comparison would require adjusting the bias term in a separate validation set. This is what we do for our final results in §4.6, where we adjust the bias term in the XNLI development set and report results on the XNLI test set.

serve any clear improvement for the ZERO-SHOT approach on this dataset. Our XQuAD results in Table 8 are more positive, but still inconclusive.

These results can partly be explained by the translation procedure used to create the different benchmarks: the premises and hypotheses of XNLI were translated independently, whereas the questions and context paragraphs of XQuAD were translated together. Similarly, MLQA made use of parallel contexts, and translators were shown the sentence containing each answer when translating the corresponding question. As a result, one can expect both QA benchmarks to have more consistent translations than XNLI, which would in turn diminish this phenomenon. In contrast, the questions and context paragraphs are independently translated when using machine translation, which explains why BT-ES and BT-FI outperform ORIG for the TRANSLATE-TEST approach. We conclude that the translation artifacts revealed by our analysis are not exclusive to NLI, as they also show up on QA for the TRANSLATE-TEST approach, but their actual impact can be highly dependent on the translation procedure used and the nature of the task.

6 Discussion

Our analysis prompts to reconsider previous findings in cross-lingual transfer learning as follows:

The cross-lingual transfer gap on XNLI was overestimated. Given the parallel nature of XNLI, accuracy differences across languages are commonly interpreted as the loss of performance when generalizing from English to the rest of languages. However, our work shows that there is another factor that can have a much larger impact: the loss of performance when generalizing from original to translated data. Our results suggest that the real cross-lingual generalization ability of XLM-R is considerably better than what the accuracy numbers in XNLI reflect.

Overcoming the cross-lingual gap is not what makes TRANSLATE-TRAIN work. The original motivation for TRANSLATE-TRAIN was to train the model on the same language it is tested on. However, we show that it is training on translated data, rather than training on the target language, that is key for this approach to outperform ZERO-SHOT as reported by previous authors.

Improvements previously attributed to data augmentation should be reconsidered. The method by Singh et al. (2019) combines machine translated premises and hypotheses in different languages (§2), resulting in an effect similar to BT-XX and MT-XX. As such, we believe that this method should be analyzed from the point of view of dataset artifacts rather than data augmentation, as the authors do.[11] From this perspective, having the premise and the hypotheses in different languages can reduce the superficial patterns between them, which would explain why this approach is better than using examples in a single language.

---

[11] Recall that our experimental design prevents a data augmentation effect, in that the number of unique sentences and examples used for training is always the same (§3.2).

The potential of Translate-Test was underestimated. The previous best results for Translate-Test on XNLI lagged behind the state-of-the-art by 4.6 points. Our work reduces this gap to only 0.8 points by addressing the underlying translation artifacts. The reason why Translate-Test is more severely affected by this phenomenon is twofold: (i) the effect is doubled by first using human translation to create the test set and then machine translation to translate it back to English, and (ii) Translate-Train was inadvertently mitigating this issue (see above), but equivalent techniques were never applied to Translate-Test.

Future evaluation should better account for translation artifacts. The evaluation issues raised by our analysis do not have a simple solution. In fact, while we use the term *translation artifacts* to highlight that they are an unintended effect of translation that impacts final evaluation, one could also argue that it is the original datasets that contain the artifacts, which translation simply alters or even mitigates.[12] In any case, this is a more general issue that falls beyond the scope of cross-lingual transfer learning, so we argue that it should be carefully controlled when evaluating cross-lingual models. In the absence of more robust datasets, we recommend that future multilingual benchmarks should at least provide consistent test sets for English and the rest of languages. This can be achieved by (i) using original annotations in all languages, (ii) using original annotations in a non-English language and translating them into English and other languages, or (iii) if translating from English, doing so at the document level to minimize translation inconsistencies.

7 Conclusions

In this paper, we have shown that both human and machine translation can alter superficial patterns in data, which requires reconsidering previous findings in cross-lingual transfer learning. Based on the gained insights, we have improved the state-of-the-art in XNLI for the Translate-Test and Zero-Shot approaches by a substantial margin. Finally, we have shown that the phenomenon is not specific to NLI but also affects QA, although it is less pronounced there thanks to the translation procedure used in the corresponding benchmarks. So as to facilitate similar studies in the future, we release

---

[12] For instance, the high lexical overlap observed for the *entailment* class is usually regarded a spurious pattern, so reducing it could be considered a positive effect of translation.

our NLI dataset,[13] which, unlike previous benchmarks, was annotated in a non-English language and human translated into English.

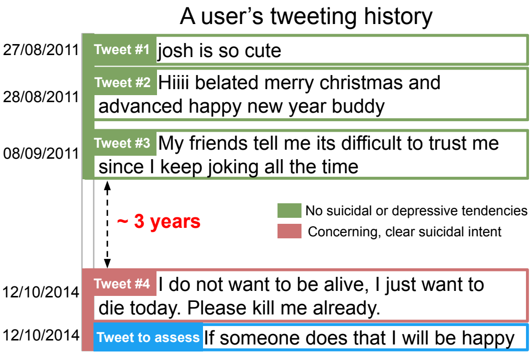
Abstract

Social media's ubiquity fosters a space for users to exhibit suicidal thoughts outside of traditional clinical settings. Understanding the build-up of such ideation is critical for the identification of at-risk users and suicide prevention. Suicide ideation is often linked to a history of mental depression. The emotional spectrum of a user's historical activity on social media can be indicative of their mental state over time. In this work, we focus on identifying suicidal intent in English tweets by augmenting linguistic models with historical context. We propose STATENet, a time-aware transformer based model for preliminary screening of suicidal risk on social media. STATENet outperforms competitive methods, demonstrating the utility of emotional and temporal contextual cues for suicide risk assessment. We discuss the empirical, qualitative, practical, and ethical aspects of STATENet for suicide ideation detection.[1]

1 Introduction



josh is so cute

Hiiii belated merry christmas and advanced happy new year buddy

My friends tell me its difficult to trust me since I keep joking all the time

I do not want to be alive, I just want to die today. Please kill me already.

If someone does that I will be happy

Figure 1: We study a user whose latest tweet is not indicative of suicidal intent. Without seeing the user's recent historic tweet, which shows self-harm tendencies, it is difficult to accurately assess suicidal risk. However, analyzing a user's tweeting history sequentially without factoring in time irregularities between tweets may lead to an inaccurate representation of a user's mental state. Time-aware modeling of the temporal dependency between historic tweets reduces the impact of tweets from 3 years ago, providing a more realistic risk assessment. *All examples in this paper have been paraphrased for user privacy (Chancellor et al., 2019).*

Globally, close to 800,000 people die by suicide each year, and 20 times more people attempt suicide. Suicide is the second leading cause of death in the 15 to 29 year age group (WHO, 2014) with a rising suicide rate of 35% in the US since 1999 (Hedegaard et al., 2020). Extending clinical and psychological care to people showing suicidal ideation relies heavily on identifying those at risk. Tragically, 80% of patients do not undergo psychiatric treatment, and about 60% of those who died of suicide denied having suicidal thoughts to mental health practitioners (McHugh et al., 2019). Recent studies (Coppersmith et al., 2018) also show that people exhibiting suicidal ideation make frequent use of social media, e.g., Twitter, to share their mental state, with eight out of ten disclosing their suicidal thoughts and plans (Golden et al., 2009).

While recent advances in computational social science (Coppersmith et al., 2018; Ji et al., 2019) have made progress in assessing suicidal risk on social media, analyzing the linguistic traits of tweets is often not sufficient for accurate suicidal intent detection. Additional user-level contexts such as tweeting history can be instrumental in identifying a build-up of negative emotions that are often linked to suicide ideation (Oliffe et al., 2012; Robins et al., 1959). Such a build-up can occur weeks, months, or even years before the onset of suicidal ideation (Overholser, 2003) and suicidal activity can also be influenced by past ideation or suicide attempts (Van Heeringen and Marušic,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7685–7697,
November 16–20, 2020. ©2020 Association for Computational Linguistics

2003). Analyzing the user history and emotion spectrum, as shown in Figure 1 can provide crucial context to estimate suicidal risk in a tweet authored by that user. Such an **Emotional Historic Context (EHC)** of a user over time can be characteristic of their mental health (Coppersmith et al., 2014).

Modeling temporal user context, either as a bag-of-tweets (Gaur et al., 2019), or sequentially (Cao et al., 2019; Matero et al., 2019) helps in identifying suicidal intent. However, in Figure 1, we show that the impact of varying time intervals between tweets is crucial for an accurate assessment. It is critical to model the large gap between the user's recent tweets that are collectively indicative of suicidal intent and those three years apart. Such uneven **Temporal Tweeting Irregularities (TTI)** ranging from seconds to years (Wojcik and Hughes, 2019) between successive tweets influence the assessment of a user's tweet differently. Sequential models such as Long Short Term Memory (LSTMs) networks assume that posting intervals are uniform, hindering the learning ability of a user's emotion spectrum over varying time intervals.

Contributions: Taking into account a user's emotional historic context and temporal tweeting irregularities, we propose STATENet: **S**uicidality assessment **T**ime-**A**ware **TE**mporal **Net**work, a neural framework that evaluates the presence of suicidal intent on social media **(Sec. 3.1)**. Building on transfer learning's success in Natural Language Processing, STATENet uses a dual transformer-based architecture to learn the linguistic and emotional cues in tweets. STATENet jointly learns from the language of the tweet **(Sec. 3.2)** to be assessed, and the historic Plutchik-based (Plutchik, 1980) emotional spectrum of a user in a time-sensitive manner **(Sec. 3.3)**. Through a series of experiments **(Sec. 4)** on real-world data **(Sec. 4.1)**, we show that STATENet significantly outperforms competitive methods **(Sec. 5)**, with the F1 Score of 80%. We demonstrate practical applicability through a qualitative analysis **(Sec. 5.4)**, and discuss the ethical implications of this study **(Sec. 6)**.

At a minimum, we establish validity for time-aware emotional temporal context for identifying suicide ideation on social media. We focus on the intersection of NLP and suicidal risk assessment by taking a step towards improving risk assessment in a **non-intrusive manner**. Our work could be considered as a preliminary screening tool that optimistically forms a component in a larger infrastructure involving psychologists, health care providers, and social media enterprises.[2] In practice, STATENet would flag tweets as *"at-risk"* for suicidality as part of a human-in-the-loop system to support decisions about potential intervention.

2 Related Work

Traditional Methods: Researchers have developed various psychoclinical methods to measure suicidal risk (Pestian et al., 2016), such as the Suicide Probability Scale (Bagge and Osman, 1998), Depression Anxiety Stress Scales-21 (Crawford and Henry, 2003), Adult Suicide Ideation Questionnaire (wa Fu et al., 2007), Suicidal Affect-Behavior-Cognition Scale (Harris et al., 2015), etc. While these methods are professional and effective, they require participants to either answer questionnaires (Venek et al., 2017) or engage in interviews (Scherer et al., 2013), hence not reaching suicidal people who are either unable to access these resources or have a low motivation to seek professional help (Zachrisson et al., 2006; Essau, 2005). Studies suggest that taking a suicide assessment can negatively impact individuals showing depressive symptoms (Harris and Goh, 2016).

NLP Methods: In recent years, social media has shown promise in providing insights into the psychological state of individuals (Paul and Dredze, 2011). Jashinsky et al. (2014) reported that Twitter is a viable tool for real-time monitoring (Braithwaite et al., 2016) of suicide risk. Early efforts in utilizing social media include the use of user features (Masuda et al., 2013) and online suicide notes (Pestian et al., 2010; Huang et al., 2007). Since then, the focus has been on using psycholinguistic lexicons such as LIWC (De Choudhury et al., 2016; Sawhney et al., 2018b) and textual features such as POS, tense, etc. for classification (Ji et al., 2018; Huang et al., 2014). Shared tasks such as CLPsych (Zirikly et al., 2019) and CLEF eRISK (Losada et al., 2019) have seen a rise in the use of deep learning for suicidality prediction. CNN based architectures (Du et al., 2018; Sawhney et al., 2018a; Shing et al., 2018; Naderi et al., 2019) and LSTM based architectures (Ji et al., 2018; Tadesse et al., 2020) utilize pre-trained word embeddings to predict suicide risk. Although these text-based methods capture the semantic nature of posts in isolation, no user associated context is provided

---

[2] Similar to the type of algorithmic model deployed for post level screening on Facebook (Card, 2018).

that can give insight into the user's mental state to improve predictive power (Venek et al., 2017). A user-dependent, personalized context can truly process the "natural" language of a user and understand the semantic context from the perspective of that specific user (Flek, 2020). User context may include the user's emotion spectrum (Ren et al., 2016), social graph methods (Mishra et al., 2019) and temporal context (Mathur et al., 2020). Suicide risk assessment for preliminary screening has been done at both binary (suicidal intent present, suicidal intent absent) (Cao et al., 2019; De Choudhury et al., 2016; Mathur et al., 2020; Losada et al., 2019), and multiple (Zirikly et al., 2019; Vioules et al., 2018; Gaur et al., 2019) levels of risk ranging from no risk to severe risk.

Contextual Methods: The best performing model, the dual context BERT (Matero et al., 2019), at the CLPsych 2019 shared task (Zirikly et al., 2019) for suicidal estimation on Reddit exemplifies the utility of temporal context. The Dual Context BERT utilizes post level BERT embeddings passed sequentially through an attention-based RNN. Similarly, Cao et al. (2019) employ a LSTM and fastText-based architecture for modeling temporal context. These RNN and LSTM based approaches assume that users' historical posts are equally spaced in time, hindering the suicide ideation detection model's ability to learn their relative importance in a time-aware manner. Time-aware sequential models have shown improvements in other clinical tasks (Baytas et al., 2017), such as patient subtyping, and in other domains like user activity modeling (Zhu et al.). More recently, Mathur et al. (2020) and Sinha et al. (2019) have modeled a user's historic emotion spectrum using latent representations of GloVe embeddings of historic tweets. These latent features are then aggregated based on specific functions such as exponential decay and sinusoids as opposed to learning them as sequences. These approaches assume that suicidal ideation conforms to specific trajectories, which may not generalize well across users (Giletta et al., 2015) and lose the context of individual historic tweets by aggregating them. Approaches besides deep learning have also been explored, such as the work done by Vioules et al. (2018), which uses the martingale framework (Ho, 2005) with sentiment scores and tweet level features such as likes to study two users on Twitter.

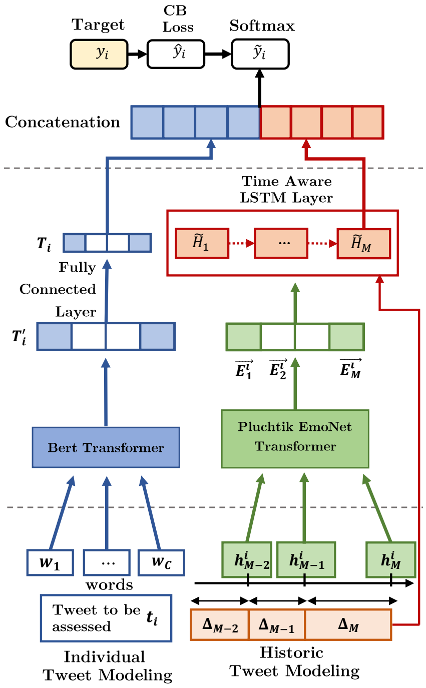

Figure 2: STATENet: Model Architecture

3 Methodology

3.1 Notations and Problem Formulation

We acknowledge that modeling suicidal intent as a binary classification task is a strong simplification and in this work, we focus on identifying the presence of suicide ideation within a tweet using a user-level temporal context. We denote a tweet to be assessed for suicidal risk as $t_i \in T = \{t_1, t_2, \cdots, t_N\}$ authored by a user $u_j \in U = \{u_1, u_2, \cdots, u_M\}$ made at time τ^i_{curr}. Each tweet t_i is associated with history $H_{i,j} = [(h^i_1, \tau^i_1), (h^i_2, \tau^i_2), \cdots, (h^i_L, \tau^i_L)]$ where h^i_k is a historic tweet by the user u_j posted at time τ^i_k with $\tau^i_1 < \tau^i_2 < \cdots < \tau^i_L < \tau^i_{curr}$. We formulate the problem as a classification task to predict a label y_i for the tweet t_i, where, $y_i \in$ {suicidal intent present, suicidal intent absent}.

3.2 Encoding the Tweet to be Assessed

Studies have shown that the linguistic styles of social media users can aid in understanding their mental state (De Choudhury et al., 2013) and that their suicidal behaviour is correlated with suicidal tweets (Sueki, 2015). Static word embeddings such as GloVe (Pennington et al., 2014) have been used to encode tweets for detecting suicide ideation (Sinha et al., 2019) in the past. However, recent studies have shown that pre-trained transformer models yield more comprehensive representations of linguistic features in a tweet (Salminen et al., 2020). We found that SentenceBERT (Reimers and Gurevych, 2019) empirically outperforms embeddings used in previous works such as FastText (Cao et al., 2019), ELMo (Mohammadi et al., 2019), etc. We use the 768-dimensional encoding obtained from SentenceBERT.[3] Formally,

$$T_i^{'} = \text{SentenceBERT}(t_i) \tag{1}$$

where $T_i' \in \mathbb{R}^{768}$ is linearly transformed using a dense layer to $T_i \in \mathbb{R}^d$ with dimension d.

3.3 User Historical Emotion Spectrum

Individual Historic Tweet Encoding: Amplification of emotional factors such as emotional reactivity (Tarrier et al., 2007), intensity (Links et al., 2008) and instability (Palmier-Claus et al., 2012) can increase suicide risk. Building on this, we extract the emotion spectrum of each historic tweet h_k^i. Although proficient in semantic modeling of text, general text encoders fail to capture the fine-grained emotions expressed in social media posts. To capture fine-grained emotions, we utilize Plutchik's wheel of emotions (Plutchik, 1980). This taxonomy suggests three hierarchical sets of eight emotions arranged as four pairs of opposing dualities. The primary set of emotions described by the wheel are: Joy - Sadness, Surprise - Anticipation, Anger - Fear, and Trust - Disgust. We obtain an encoding that models the emotional spectrum of a historical tweet, and thus that of a user at a historic time. Based on empirical comparisons and the success of transfer learning in NLP, we fine-tune pre-trained BERT embeddings on the Emonet dataset (Abdul-Mageed and Ungar, 2017). The dataset consists of a total of 1,608,233 tweets labeled across 24 emotions as per Plutchik's wheel of emotions. The presence of the primary emotions in the dataset is skewed towards joy, sadness, and fear, with their representation being 20.57%,8.85%, and 6.13%, respectively, with other emotions having fewer samples. These are labeled using distant supervision using a total of 665 emotion hashtags.

We call this transformer the PlutchikTransformer. This transformer tokenizes each historical post and adds the `[CLS]` token at the beginning of each post. We use the final hidden state corresponding to this `[CLS]` token (768-dimensional encoding) as the aggregate representation of the emotional spectrum. We define the emotion vector ($E_k^i \in \mathbb{R}^{768}$) of each historic tweet h_k^i as:

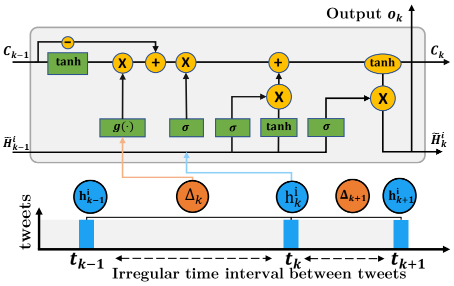

Figure 3: Architecture of a Time-aware LSTM cell. Figure is adapted from Baytas et al. (2017).

$$E_k^i = \text{PlutchikTransformer}(h_k^i) \tag{2}$$

Modeling Historical Tweets Sequentially: The emotional historic context of tweets can be used to model progressive emotional states of the author of those tweets (Abdul-Mageed and Ungar, 2017; De Choudhury et al., 2013). This makes recurrent neural networks (RNN), and particularly LSTMs (Hochreiter and Schmidhuber, 1997), the most natural methods for encoding and learning from a sequence of a user's historical tweets.

However, the time interval between the posting of historic tweets can vary widely, from a few seconds to a few years (Wojcik and Hughes, 2019). Such variations can be an important factor in analyzing the emotional states of a user over time (Sueki, 2015). LSTM cells assume the input to be equally spaced sequences and thus are unable to model irregularities in posting times of historical tweets. Using this relative time difference between the user's historical tweets can progressively model the user's emotions more accurately over time. Hence, we propose the use of a Time-aware LSTM (T-LSTM) (Baytas et al., 2017) where time lapse between successive tweets is fed to the T-LSTM cell, as shown in Figure 3. The T-LSTM cell thus incorporates the actual time differences between tweets, along with each historical tweet's emotional context E_k^i.

T-LSTM applies time decay to the memory according to the elapsed time between successive elements and weights the short-term memory cell C_k^S. Intuitively, the greater the time elapsed be-

---

[3] SentenceBERT computes the mean of output vectors for all tokens to derive a fixed size sentence embedding.

tween two tweets, the less impact they should have on each other. To achieve this, T-LSTM uses a monotonically decreasing function of elapsed time, which transforms time into appropriate weights. Time lapses are incorporated in the T-LSTM as:

$$C^S_{k-1} = \tanh(W_d C_{k-1} + b_d) \quad \text{(Short-term memory)}$$
$$\hat{C}^S_{k-1} = C^S_{k-1} * g(\Delta_k) \quad \text{(Discounted short-term memory)}$$
$$C^{LT}_{k-1} = C_{k-1} + C^S_{k-1} \quad \text{(Long-term memory)}$$
$$C^{*}_{k-1} = C^{LT}_{k-1} + \hat{C}^S_{k-1} \quad \text{(Adjusted previous memory)}$$

where C_{k-1} and C_k are previous and current cell memories, and $\{W_d, b_d\}$ are network parameters. Δ_k is the elapsed time between historic tweets h_{k-1} and h_k, and $g(\cdot)$ is a heuristic decaying function that reduces the effect of short-term memory as Δ_k increases. We select $g(\Delta_k) = 1/\Delta_k$ empirically and as suggested in Baytas et al. (2017). For each historic tweet h^i_k, the T-LSTM cell modifies LSTM gate operations to compute the current hidden state ($\tilde{H}^i_k \in \mathbb{R}^d$) by feeding C^*_{k-1} instead of C_{k-1}.

3.4 Joint Network Optimization

To identify the presence of suicidal intent in a tweet, STATENet jointly learns from the language of the tweet to be assessed and the emotional historic spectrum in a time-aware manner. For this we apply the concatenation operation $\oplus$ to T_i and $\tilde{H}^i_k$ respectively, followed by a dense layer with Rectified Linear Unit ($ReLU$) (Hahnloser et al., 2000) to form a prediction vector. Finally, a softmax function (Goodfellow et al., 2016) is used to output the probabilities of suicidal intent present.

$$\begin{aligned} \tilde{y}_i &= ReLU(W_y(T_i \oplus \tilde{H}^i_k) + b_y) \\ \hat{y}_i &= softmax(\tilde{y}_i) \end{aligned} \tag{3}$$

where $\hat{y}_i$ is the final suicide risk assessment and $\{W_y, b_y\}$ are network parameters.

Tweet indicating suicidal intent form a very small proportion of the data (Ji et al., 2019). To address this problem of class imbalance *(in practice, the imbalance is much greater in the real world)*, we train STATENet using Class-Balanced loss proposed by Cui et al. (2019) along with Focal Loss (Lin et al., 2017). This loss function applies a class-wise re-weighting scheme by introducing a weighting factor that is inversely proportional to the number of samples. The loss function $\mathcal{L}$ is:

$$\mathcal{L} = \text{CB}_{focal}(\hat{y}_i, y_i; \beta, \gamma) \tag{4}$$

where CB_{focal} is class-balanced focal loss, $\hat{y}_i$ is the predicted label and y_i is the label of the current tweet. β and γ are hyperparameters.

4 Experiments

4.1 Dataset

We use the Twitter timeline data of users from the dataset introduced by Sinha et al. (2019). Sinha et al. (2019) began with a collection of Twitter posts based on a lexicon of 143 suicidal phrases. After manual inspection of the dataset for trivially non-suicidal tweets, their final dataset contained 34,306 tweets. Some of these tweets were authored by the same user; thus, the total number of unique users for which tweets were to be classified was 32,558. We summarize the annotation instructions (Sawhney et al., 2018b) that were followed by two annotators, both students of Clinical Psychology, for annotating the collected 34,306 tweets:

- **Suicidal Intent (SI) Present**: Posts where suicide ideation or previous attempts are discussed in a somber and non-flippant tone.
- **Suicidal Intent (SI) Absent**: Tweets with no evidence for risk of suicide, including song lyrics, condolence message, awareness, news.

It is important to note that this process produced suicide risk labels at the level of individual tweets and not for individual user histories. An acceptable inter-annotator agreement was achieved with a Cohen's Kappa score (Cantor, 1996) of 0.72, under the supervision of a professional clinical psychologist. The resulting dataset contains 3984 suicidal tweets. The Twitter timeline was collected for each user. These timelines span over ten years from 2009 to 2019. The mean number of tweets in user history is 748 *(max 3,200)* with a standard deviation of 789 tweets. We trim the user history to the 100 most recent tweets for users with a large number of historical tweets.[4] The mean time difference between two consecutive tweets for a user is two days with a standard deviation of almost 24 days between two tweets, indicative of large variations across users. 4070 users were found to have no historical tweets.

Data Preprocessing: We deidentified the dataset by performing named entity recognition and removing any identifiable information such as email

---

[4] This was done due to memory and computation constraints faced during the training of STATENet.

addresses, URLs, and names. Next, we follow standard procedures of converting the text to lowercase, removing punctuation and accents, striping whitespaces, and removing stopwords. We split the tweets in the dataset on the basis of users such that there is no overlap between users in the train, validation, and test set. We perform a stratified 70:10:20 split across the three sets, such that the train, validation, and test sets consist of 24014, 3431, and 6861 tweets, respectively. Although there may be multiple tweets to be assessed by the same user, their associated history differs according to the tweets' posting timestamps. We ensure that for each tweet to be classified, only the historical tweets having timestamps older than that of the tweet to be assessed are used for historic modeling.

4.2 Experimental Settings

Baseline Methods: We evaluate STATENet using the macro F1 and recall for *suicidal intent present* (recall^{s}), against two types of baseline methods; tweet level (TL) and user-level (UL). UL baselines were adapted for tweet level assessment by concatenating embeddings of the tweet to be assessed with the user level features.

Random Forest + Tweet features (Sawhney et al., 2018b): A non contextual TL approach that applies Random Forests (RF) with tweet level features including statistical, LIWC (Pennebaker et al., 2001) features, n-grams and POS counts.

C-LSTM (Sawhney et al., 2018a): We replicate the TL deep Neural Network that uses CNN to capture local features and LSTMs for tweet encoding.

Suicide Detection Model (SDM) (Cao et al., 2019): UL model that encodes tweets using fine-tuned FastText embeddings. Historic tweets were passed sequentially through LSTM + attention and concatenated with the tweet to be assessed.

Contextual CNN (Gaur et al., 2019): Non-sequential UL model using GloVe embeddings for encoding tweets. Bag of tweets were concatenated and fed to a contextual CNN (Shin et al., 2018).

Exponential Decay (Sinha et al., 2019): TL model that weighs GloVe embeddings of historic tweets through an exponential decay function and ensembles it with the GloVe embedding trained on a BiLSTM + Attention for the tweet to be assessed.

Surprise and Episodic Modeling (Mathur et al., 2020): Decision level ensemble TL model similar to Exponential Decay, but factors in sinusoidal and white Gaussian noise for historic tweet modeling.

DualContextBert (Matero et al., 2019): Best performing UL model at CLPsych 2019. DualContextBert uses BERT for encoding Reddit posts fed to an attention-based RNN layer. In our implementation, we use all the user's historic tweets.

Experimental Setup: We select hyperparameters based on the highest Macro F1 obtained on the validation set for all models. We use grid search to explore: number of features in hidden state $\tilde{H}^{D} \in \{8, 64, 128, 256, 512\}$, number of LSTM layers $n \in \{1, 2, 5\}$, dropout $\delta \in \{0.0, 0.1, \cdots, 0.5\}$, $\beta \in \{0.99, 0.999, 0.9999\}$ and $\gamma \in \{1.0, 1.5, 2.0\}$ in class-balanced focal loss, initial learning rate $I_{lr} \in \{0.01, 0.001, 0.0005, 0.0001\}$, warm-up steps $S_{ws} \in \{3, 5, 7\}$. The optimal hyperparameters were found to be: $\tilde{H}^{D} = 512$, $n = 1$, $\delta = 0.5$, $\beta = 0.9999$, $\gamma = 2.0$, $I_{lr} = 0.0001$, $S_{ws} = 5$. We implement all methods with PyTorch 1.5 (Paszke et al., 2019) and optimize using mini-batch AdamW with a batch size of 256 and $I_{lr} = 0.0001$. We use the cosine scheduler with a warmup step of 5 (Gotmare et al., 2018). We train the model for 20 epochs and apply early stopping with a patience of 5 epochs. The model takes 4,361s to train on an Nvidia Tesla K80 GPU.

5 Results and Analysis

5.1 Comparative Performance

We note from Table 1 that STATENet significantly ($p < 0.005$) outperforms competitive baselines. We compare against both text only, and temporal contextual models for suicidal risk assessment.

STATENet and other contextual models perform better than the non-contextual RF + tweet features and C-LSTM models. We believe this is because temporal contextual models offer greater insight into the author's historical mental state, thereby increasing predictive power. STATENet and sequential models outperform the Contextual CNN, likely due to their ability to better learn representations from the temporal dependence in historical tweets, as opposed to Contextual CNN's bag of tweets approach. We also observe that STATENet significantly outperforms competitive sequential models. We postulate this to the ability of the time-aware LSTM in STATENet to capture irregularities in tweeting intervals of users. Such time-aware modeling likely learns more accurate latent representations of users' emotional historic context. While exponential decay and episodic modeling

Type of Contextual Modeling	Model	Macro F1 ↑	Recall^s ↑	Accuracy ↑
None	Random Forest + Tweet features	0.536	0.513	0.548
	C-LSTM	0.588	0.597	0.602
Non Sequential	Contextual CNN	0.729	0.587	0.803
Sequential	Suicide Detection Model (SDM)	0.743	0.755	0.819
	DualContextBert	0.767	0.786	0.823
Specific Temporal Functions	Exponential Decay	0.737	0.759	0.828
	Surprise and Episodic Modeling	0.741	0.762	0.831
Timeaware Sequential	**STATENet**	**0.799***	**0.810***	**0.851***

Table 1: Mean of results obtained over 10 different runs. * indicates that the result is significantly better than DualContextBert ($p < 0.005$) under Wilcoxon's Signed Rank test). **Bold** denotes best performance.

Model Component	Macro F1↑	Recall^s↑
Current tweet only	0.731	0.551
Current + Random History *(Plutchik)*	0.730	0.608*
Current + Sequential History *(BERT)*	0.767*	0.786*
Current + Sequential History *(Plutchik)*	0.778*	0.795*
Current + TA History *(Plutchik)*	**0.799***	**0.810***

Table 2: Ablation study over STATENet. We report the mean of results obtained over ten different runs. * shows significant compared to the current tweet ($p < 0.005$) under Wilcoxon's Signed Rank test. Current: encoding of the tweet to be assessed. History: encoding of historical tweets. TA: Time-Aware. **Bold** denotes the best performance.

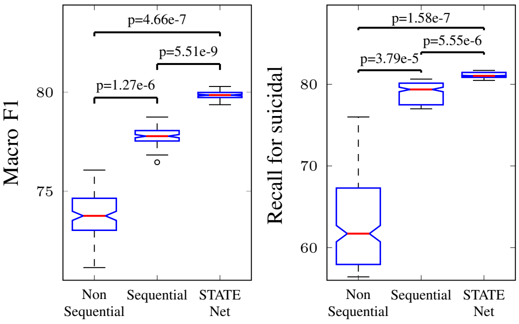

Figure 4: Confidence intervals for evaluation metrics of temporal variants over 10 different runs and data splits.

perform well, we note that STATENet does better, in terms of all metrics, particularly recall for the suicidal intent present class. We believe this is because not every user's emotional historic context may conform to fixed trajectories that these approaches aggregate historic tweets on.

5.2 Ablation Study

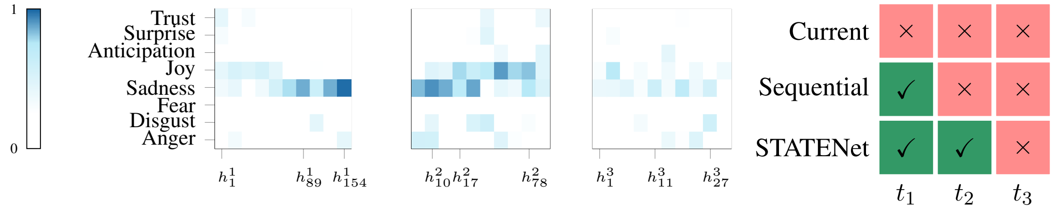
To assess EHC and TTI, we perform an ablation study (Table 2) with different configurations. Without considering historic tweets, the performance of the model drops drastically. We believe that adding historic tweets, even in a random order, adds additional contextual cues about the user, resulting in improved performance. We observe that the *PlutchikTransformer* variant of Current + Sequential History outperforms its *BERT* counterpart. This can be attributed to the ability of the *PlutchikTransformer* to capture the EHC of a user. STATENet jointly models the Current Tweet and EHC in a time-aware manner, overcoming the limitation of previous models that assume equal time intervals between posts. On inspecting the results for the 647 users without any historic tweets, we find that STATENet performs well with a recall of 0.74 and macro F1 of 0.75. This reiterates the ability of linguistic only non-contextual models in suicidal intent identification. This is particularly interesting, as, for users with no available history, assessment can still be performed to some degree.

5.3 Temporal Analysis

The tweet's language should be studied with historical context to better understand the user's emotional state over time, based on the EHC. To analyze the importance of the order and temporal dependency of historic tweets, we first try a non-sequential, bag of tweets like variant. We feed the Plutchik transformer-based encodings to a Contextual CNN. We observe that the bag of tweets approach is slightly better than the Contextual CNN baseline, likely because of the transformer-based encoding as opposed to static GloVe embeddings used by the baseline. The non-sequential approach drastically underperforms over ten runs in comparison to temporal variants. Further investigating EHC and TTI, we first feed historic tweets in sequential order (Sequential Model) to a regular LSTM, and then we factor in TTI through T-LSTM in STATENet. Figure 4 shows that STATENet is

	User 1	User 2	User 3
t_i	**[14/07/2017]**: i dont want to be here anymore again *(SI Present)*	[08/03/2016]: been a year since i lost the most important woman the loss has never sunk *(SI Absent)*	[05/01/2019]: Nobody be shocked when I snap and take a life either my own or theirs *(SI Present)*
$h^i_{k_3}$	**[13/07/2017]**: yes i almost tried to kill myself again tonight yes it is only been ten minutes and im now retweeting tweets	**[16/11/2015]**: i wrote this a year ago today and one year on i am boxing things up and moving into my own house it is crazy	**[29/12/2018]** when you said your last goodbye, i die a little bit inside, i lay in tears in bed all night, alone without you by my side
$h^i_{k_2}$	**[27/05/2017]**: i do not know if its seasonal depression or just me avoiding christmas by staying in all day	**[19/11/2014]**: I don't think i will see the end of today, there is nothing left for me to do	**[21/12/2018]**: Do you collect anything. If so what is it? Memories hahhahahhaa
$h^i_{k_1}$	**[02/06/2016]**: i love my mother she is great life is amazing	**[16/11/2014]**: i deserve death, dear 16 old me it will never get better	**[16/12/2018]**: I am alive and I am happy about it dammit why even

Table 3: Tweet to be assessed (t_i) and historic tweets ($h^i_{k_1}$, $h^i_{k_2}$ and $h^i_{k_3}$ are chronologically ordered) of three users along with tweet timestamp information. We also show visualized self-attention (averaged over all 12 Sentence-BERT attention heads) per token. Darker intensity of the red color denotes higher attention weights.



(a) User 1 (b) User 2 (c) User 3 (d) Model predictions for tweets

Figure 5: (a), (b) and (c) are emotion intensity across 8 primary emotions based on the Plutchik Wheel for User 1, 2, 3 over time respectively, from White to Blue. h^i_k represents k^{th} historic tweet associated with the current tweet t_i. In (d) Green and Red represent correct and incorrect assessment of suicidal risk respectively for different tweets. We display only the 8 primary emotions of the Plutchik wheel for brevity.

significantly ($p < 0.005$) better than the sequential but non-time-aware variant, and shows the least variation in performance over 10 different runs. For the difference in performance between the Sequential Model and STATENet, we believe that is due to the temporal dependency of historic tweets on the elapsed time between successive tweets.

5.4 Qualitative Analysis

For a detailed insight and aiding interpretability, we analyze some cases where STATENet performs well. We also highlight the limitations of STATENet through error analysis. We qualitatively analyze three interesting cases in Table 3 and Figure 5. We see that the tweet to be assessed for User 1 does not show any explicit suicidal intent and alone may not be sufficient to assess suicidal risk. However, temporal models correctly classify the tweet as they learn the build-up of sadness in the historic tweets, which we observe from the Pluchtik emotional intensity in Figure 5a.

When the current tweet of the user is non-indicative, temporal models can get additional context by learning historic activity of the user. Often, temporal patterns are variable, and posting frequencies vary drastically. These TTI present challenges in only relying on the sequence of historic tweets rather than the actual time lapses. For instance, initial tweets of User 2 showed sadness and suicidal intent, whereas the recent historic tweet ($h^2_{k_3}$) of the user represents joy (Figure 5b). LSTM-based models aggregate sadness and hence assume the history to be suicidal. Contrarily, STATENet is able to learn from the variable time-lapses and their relative importance in the context of suicide ideation. However, we found some cases where all models failed. For User 3, the current tweet does not contain strong semantic indicators of suicidal intent. Moreover, historic tweets do not show any recognizable emotional pattern (Figure 5c). Such a case presents the complexities associated with suicide risk assessment.Another interesting observation from Figure 5 is that the learned Plutchik emotion intensity distribution for users is skewed towards joy (positive) and sadness (negative). Although the highly granular emotional context captured by the PlutchikTransformer improves STATENet's performance (**Sec.** 5.2), over the more generic language features captured by BERT. We leave further exploring the impact of emotion granularity to our future research directions.

6 Discussion

Ethical Considerations: The preponderance of the work presented in our discussion presents heightened ethical challenges. As explored in Coppersmith et al. (2018), we address the trade-off between privacy and effectiveness. While data is essential in making models like STATENet effective, we must work within the purview of acceptable privacy practices to avoid coercion and intrusive treatment. To that end, we utilize publicly available Twitter data in a purely observational (Norval and Henderson, 2017; Broer, 2020), and non-intrusive manner. Although informed consent of each user was not sought as it may be deemed coercive, automated de-identification of the dataset was performed to reduce the risk of including any identifying data in the raw data. All tweets shown as examples in Figure 1 and Section 5.4 have been paraphrased as per the *moderate disguise* scheme suggested in Bruckman (2002) to protect the privacy of individuals (Fiesler and Proferes, 2018). The annotation of user data has been kept separately from raw user data on protected servers linked only through anonymous IDs (Benton et al., 2017). Assessments made by STATENet are sensitive and should be shared selectively to avoid misuse, such as Samaritan's Radar (Hsin et al., 2016). Our work does not make any diagnostic claims related to suicide. We study the social media posts in a purely observational capacity (Norval and Henderson, 2017) and do not intervene with the user experience in any way.

Limitations: We acknowledge that studying suicidality is subjective in nature (Keilp et al., 2012) and that the interpretation of the analysis presented may vary across individuals. Due to the situatedness of language, the studied data may be susceptible to demographic, annotator, and medium-specific biases (Hovy and Spruit, 2016). We recognize that suicide risk exists on a diverse spectrum, and the simplification of binary labels could lead to artificial notions of risk (Bryan and Rudd, 2006).

Practical Implications: Through STATENet, we suggest a neural architecture for preliminary screening of at-risk users on social media to aid the prioritization of clinical resources. Our work observes Twitter in a non-intrusive manner and does not intervene with the user experience in any way. STATENet should form part of a distributed human-in-the-loop (de Andrade et al., 2018) system for finer interpretation of risk. Focusing on STATENet's practical applicability, we work with tweet level annotations rather than the more subjective and difficult to scale user-level annotations. We emphasize on tweet-level prediction; however, STATENet can also be applied for user-level suicide risk assessment given its dual text and historic modeling components.

7 Conclusion

Motivated by the rising use of social media for exhibiting suicide ideation as opposed to standard clinical practice (McHugh et al., 2019), we present STATENet. Building on psychological studies on analyzing a user's temporal emotional spectrum, STATENet models the time aware emotional context of users through historical tweets for more accurate suicide risk estimation on social media. We plan to explore the impact of varying amounts of historical context for a user in our future work. We show STATENet's applicability as a preliminary tool in assessing suicidality in tweets. We present a qualitative analysis for a deeper understanding of STATENet. Through this work, we aim to form a component in a larger human-in-the-loop infrastructure for analyzing potentially concerning suicide-related social media posts. Priority-based suicide risk assessment for ranking tweets for suicidal risk, rather than classifying them forms our future direction. Additionally, in the future, we would also want to quantify the impact of varying degrees of granularity of learning emotional features from tweets on STATENet's performance.

Weakly Supervised Learning of Nuanced Frames for Analyzing Polarization in News Media

Shamik Roy

Dan Goldwasser
Purdue University
`dgoldwas@purdue.edu`

Abstract

In this paper, we suggest a minimally-supervised approach for identifying nuanced frames in news article coverage of politically divisive topics. We suggest to break the broad policy frames suggested by Boydstun et al., 2014 into fine-grained subframes which can capture differences in political ideology in a better way. We evaluate the suggested subframes and their embedding, learned using minimal supervision, over three topics, namely, immigration, gun-control, and abortion. We demonstrate the ability of the subframes to capture ideological differences and analyze political discourse in news media.

1 Introduction

As the political climate and the news media in the United States become increasingly polarized (Prior, 2013; Pew Research Center, 2018), it is important to understand the perspectives underlying the political divisions and analyze their differences. Political framing, studied by political scientists (Entman, 1993; Chong and Druckman, 2007), provides the means to study these perspectives. It is a nuanced political strategy, used to bias the discussion on an issue towards a specific stance by emphasizing specific aspects that prime the reader to accept that stance. To help clarify this definition, consider two articles on the highly polarized immigration issue.

Example 1: *Different Perspectives on Immigration*

Adapted from **Alternet** (*Left*)

Employees-many of whom are undocumented immigrants from Mexico, Ecuador and elsewhere-toil seven days a week for less than minimum wage, with no overtime pay.

Adapted from **Breitbart** (*Right*)

Mass immigration has come at the expense of America's working and middle class, which suffered from poor job growth, stagnant wages, and increased public costs.

The two articles capture opposite political perspectives, liberal (top) and conservative (bottom). They do not directly contradict each other, instead they focus the discussion on different aspects helping them argue their case. The first emphasizing the deprivation of minimum wage for immigrants, and the second emphasizing implication on wages for U.S. workers. This process is known as *framing*. Our goal is to define, and automatically identify, relevant framing dimensions in politically-motivated coverage of news events *to the extent they can capture and explain the differences in perspectives* across the conservative-liberal ideological divide (Ellis and Stimson, 2012; Preoţiuc-Pietro et al., 2017). We focus on three divisive topics – immigration, gun-control and abortion.

Previous work by Boydstun et al. (2014) studied policy issue framing on news media and suggested 15 broad frames to analyze how issues are framed, which include *economic, morality* and *security*, among others. These framing dimensions can help capture ideological splits (Johnson and Goldwasser, 2016; Johnson et al., 2017b). For example, by framing the immigration issue using the morality frame or using the security frame, the reader is primed to accept the liberal or conservative perspectives, respectively. However, as shown in Example 1, in some cases this analysis is too coarse grained, as both articles frame the issue using the economic frame, suggesting that a finer grained analysis is needed to capture the differences in perspective. To help resolve this issue, we suggest a data-driven refinement, trained with minimal supervision effort.

Our approach works in three steps. First, we construct topic-specific lexicons capturing the way the frames are instantiated in each topic. In the second step, we identify repeating expressions used in the context of the different frames, and group them to form *subframes* which separate between different

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7698–7716,
November 16–20, 2020.

usages of the same frame to express different political perspectives. In Example 1, *Minimum Wage Economy* and *Salary Stagnation* are both subframes of the Economy frame, which capture the ideological differences in the two articles. We use external knowledge sources to identify relevant subframes for each topic and rely on human judgements to match the repeating expressions with these subframes. Finally, we exploit this resource to train an embedding model, which represents in the same space the subframes labels, the lexicon containing subframes indicator expressions and paragraphs extracted from news articles containing these expressions. The embedding model captures the context in which subframe appear, and as a result can generalize and capture subframe usage in new texts.

Our approach can be viewed as a middle ground between event-specific frames, emerging from the data and capturing properties unique to the given topic (Tsur et al., 2015; Demszky et al., 2019), and general issue frames (Boydstun et al., 2014; Card et al., 2015b; Johnson et al., 2017a; Field et al., 2018; Hartmann et al., 2019) that use the same set of framing dimensions for all topics. On the one hand, it can capture nuanced, topic-specific subframes, while on the other, it maps these subframes into general framing dimensions. In the above example, it allows us to identify that the economy frame is important for both the liberal and conservative perspectives on immigration, despite the fact that it is instantiated using a different subframe.

We evaluate the quality of the learned model in several ways, by applying it politically-motivated news article coverage of divisive topics. First, we show that the lexicon we developed and the induced sub-frames can effectively separate between ideological standpoints expressed in the articles. Second, we evaluate the quality of the learned model, showing that subframe labels assigned to new paragraphs correlate well with human judgements. Finally, we use the model to analyze the different perspectives in left and right leaning news coverage, and their change over time.

2 Related Work

Understanding and analyzing political perspectives in news coverage has gathered significant interest in recent years (Lin et al., 2006; Greene and Resnik, 2009; Iyyer et al., 2014; Li and Goldwasser, 2019; Fan et al., 2019; Jiang et al., 2019; Hanawa et al., 2019), broadly related to analysis of bias or partisanship and expressions of implicit sentiment (Recasens et al., 2013; Baumer et al., 2015; Field et al., 2018; Gentzkow et al., 2016; Monroe et al., 2008; An et al., 2019; Menini et al., 2017). In addition to predicting the underlying perspective, our work focuses on explaining the perspectives underlying the ideological coverage of news events. We build specifically on issue-frames (Boydstun et al., 2014), however our work is related to framing and agenda setting analysis work more broadly (Tsur et al., 2015; Baumer et al., 2015; Fulgoni et al., 2016; Field et al., 2018; Demszky et al., 2019).

3 Data Collection

We collected $21,645$ news articles on three politically polarized topics, *abortion, immigration* and *gun control*. We used the hyper-partisan news dataset (Kiesel et al., 2019) and we crawled additional news articles on the topics from sources with known political bias provided by `mediabiasfactcheck.com`, where the articles are categorized based on their topics on the websites of the sources. All the news articles are U.S. politics based and written in English. We identify the topic of news articles in the hyper-partisan news dataset by looking at presence of certain keywords in the titles and urls of news articles. For example, 'abortion' for topic *abortion*; 'migrant', 'migration' for topic *immigration*; 'gun' for topic *gun control*. In case of absence of any of the keywords in the title or url, we annotate the article with the corresponding topic if the keywords appear at least 3 times in the article text. The hyper-partisan news dataset provides bias-labels of the news articles and we labeled our crawled news articles based on their source bias according to `mediabiasfactcheck.com`. We consider only the left and right biased news articles. The dataset is summarized in Table 1.

	Abortion	**Immigration**	**Gun Control**
# of News Articles	6,476	8,516	6,653
# of Left Articles	3,437	3,496	3,198
# of Right Articles	3,039	5,020	3,455
# of Paragraphs	106,931	135,479	95,872
Span of Year	1984-2019	2000-2019	1996-2019
>80%-Articles Since	2010	2016	2011

Table 1: Dataset Summary. (Articles are split into paragraphs by newline character.)

4 Modeling Political Framing

Our goal in this paper is to identify framing dimensions that can be used to capture difference between the two ideological polarities. The frames used for this analysis could be issue specific, or as suggested by Boydstun et al. (2014), generalize over several policy issues, using a fixed set of framing dimensions. In many cases, as we show in this paper, the general policy frames do not capture the nuanced aspects of the issue highlighted by each side to bias the discussion. In Example 1, **both** sides use the *economy* frame, however it is instantiated in different ways, to promote opposite views. To help combat this issue, we suggest a middle ground between generalized policy frames and event-specific frames, by constructing a hierarchy of frames and sub-frames, the first derived from the definitions and data of media frames corpus (Card et al., 2015a), and the second emerging from the data directly, by tracking the differences in the vocabulary used when these frames are instantiated in different topics, and grouping them to sub-frames.

This process takes place in three steps. First, we create a lexicon of topic specific phrases capturing how the frame is invoked in each policy issue. Second, we manually group these phrases into subframes. Finally, we embed the sub-frames using weak-supervision, allowing us to associate subframes with new text, beyond the extracted phrases. The following subsections explain each step.

4.1 Extending Frame Lexicon

Step 1: Annotate News Article Paragraphs with Policy Frames. We follow the procedure suggested and validated by Field et al. (2018), and use the media frame corpus to derive a unigram lexicon for each of the 15 policy frames (Boydstun et al., 2014) based on their Pointwise Mutual Information (PMI) (Church and Hanks, 1990). We use the 250 top-PMI words for each of the frames. We discard unigrams which occur in less than 0.5% of the documents and more than 98% of the documents, the same thresholds used by Field et al. (2018). We define these unigrams as ***frame indicators***, and use them to annotate our data. We break the articles in our dataset into paragraphs, and annotate them by ranking frames using the number of lexicon matches. We use the top 2 frames per paragraph. Since news articles can cover a topic from multiple angles, we identify frames in paragraph level instead of article level.

Step 2: Building Topic-specific Lexicons. We hypothesize that the frame-level analysis cannot capture nuanced talking points. In Example 1, both texts use the *Economic* frame using same unigram indicator ('wage'). However, other words in the text can help identify the nuanced talking points (e.g., 'minimum wage' in case of left and 'stagnant wages' in case of right). We follow this intuition, and extend the frame-level dictionary to topic-specific frame lexicon, using bi-gram and tri-gram phrases extracted from the annotated paragraphs with frames in Step 1. For an n-gram g we calculate the PMI with frame f, $I(g, f)$, as follows:

$$I(g, f) = \log \frac{P(g|f)}{P(g)}$$

Where $P(g|f)$ is computed by taking all paragraphs annotated with frame f and computing $\frac{count(g)}{count(allngrams)}$ and similarly, $P(g)$ is computed by counting n-gram g over the whole corpus. We assign each n-gram to the frame with highest PMI score and build an n-gram lexicon for each frame. We did not consider bi-grams or tri-grams appearing in more than 50% of the paragraphs and less than 0.02% of the paragraphs. The process is topic-specific, resulting in three lexicons, one for each topic we study in this paper. Following this procedure we found $4,116$ bigrams and $1,787$ trigrams for the topic *abortion*, $3,293$ bigrams and $1,451$ trigrams for the topic *gun control*, $3,743$ bigrams and $1,385$ trigrams for the topic *immigration*. We define these n-grams as ***subframe indicators***.

Step 3: Lexicon Validation. We hypothesize that the topic-specific subframe indicators capture political perspective better than the frame indicators. To validate this claim we compare the correlation between the usage of frame and subframe indicators in left and right biased news articles. We break the dataset into left and right biased documents. Each group is associated with a ranked list of frames and sub-frames indicators, based on their averaged tf-idf scores in all documents with the same political bias. Then we compare the ranks using Spearman's Rank Correlation Coefficient (Zar, 2005) where coefficient 1 means perfect correlation. Table 2 validates our claim. It shows that the frame indicator lists have a much higher correlation compared to subframe indicators, indicating their usage by both sides with similar importance.

We investigate the expressivity of the two indicator groups by using them as one-hot features when classifying the political bias of documents

TOPICS	FRAME INDICATORS RANK CORR. COEF.	SUBFRAME INDICATORS RANK CORR. COEF.
Abortion	0.94 (0.017)	0.35 (0.128)
Immigration	0.91 (0.018)	0.25 (0.142)
Gun Control	0.94 (0.011)	0.40 (0.112)

Table 2: Average rank correlation coefficient of frame and subframe indicators' ranks between left and right over 15 policy frames with standard deviations in the brackets. Correlations in individual frames can be found in Appendix A.

MODELS	ABORT.	IMM.	GUN
LR (Frame Indicators)	74.57 (0.6)	82.36 (0.6)	70.62 (0.8)
LR (Subframe Indicators)	81.47 (0.2)	85.31 (0.2)	72.34 (0.5)
BERT	81.58 (1.8)	79.72 (3.7)	73.21 (0.7)
HLSTM	81.12 (0.4)	84.69 (1.7)	71.08 (2.8)

Table 3: Test F1 scores (standard deviation) of article classification task (left/right) using 3-fold CV. LR is for Logistic Regression with type of feature in the bracket.

using a simple logistic regression classifier. The results in Table 3 shows that the subframe indicators are better in all of the three topics. We also included two strong contextualized feature representation: BERT (base-uncased) (Devlin et al., 2018) and hierarchical-LSTM (HLSTM) (Hochreiter and Schmidhuber, 1997). BERT used the first 512 tokens of each article. In HLSTM, we run a biLSTM over the $300d$ GLOVE (Pennington et al., 2014) words embeddings in each paragraph, and average their hidden states to represent the paragraph, a second bidirectional LSTM was used to create the final representation for the news article in $300d$. The subframe indicator feature outperforms HLSTM in all three topics and BERT in case of immigration.

4.2 Identification of Subframes

Our next step is to identify the nuanced subframes captured by the subframe indicators lexicon we extracted. We use human knowledge to guide this process, such that each general frame can be decomposed into multiple sub-frames, by grouping repeating subframe indicators (i.e. n-grams associated with each frame) to known political talking points. For example, in case of *abortion*, the phrases 'Hobby Lobby', 'freedom restoration act' discuss a similar issue and can be grouped together to form a subframe (which we denoted as 'Hobby Lobby'). We extracted the talking points from Wikipedia and `ontheissues.com`, which maintains political perspectives on these issues. We did not consider the frames 'Political' and 'Others' categories, as all of the three topics are political. We only focused on frames relevant for our three topics. For example, 'Security and Defense' is not related to the topic *abortion*. Table 4, shows all the identified subframes, their parent frames. The subframes' associated n-grams and full definition can be found in Appendix B and C respectively.

ABORTION	IMMIGRATION	GUN CONTROL
Economic: - Health Care - Abort. Provider Economy - Abortion Funding **Fairness & Equality:** - Reproduction Right - Right of Human Life **Legality, Constitutionality, Jurisdiction:** - Hobby Lobby - Late Term Abortion - Roe V. Wade **Crime & Punishment:** - Stem Cell Research - Sale of Fetal Tissue - Sexual Assault Victims **Health & Safety:** - Birth Control **Morality:** - Sanctity of Life - Women Freedom **Quality of Life:** - Planned Parenthood - Pregnancy Centers - Life protection **Public Sentiment:** - Pro-Life - Anti-Abortion - Pro-Choice	**Economic:** - Minimum Wage - Salary Stagnation - Wealth Gap - Cheap labor availability - Taxpayer Money **Crime & Punishment** - Deportation: Illegal Immigrants - Deportation: In General - Detention **Security & Defense** - Terrorism - Border Protection **Legality, Const., Juri** - Asylum - Refugee - Birth citizenship & 14th Amendment **Policy Pres. & Eval.** - Amnesty - Dream Act - Family Separation Policy - DACA **Fairness & Equality** - Racism & Xenophobia - Merit Based Immigration - Human Right **Cultural Identity** - Racial Identity - Born identity	**Economic** - Gun Buyback Program - Gun Business **Capacity & Resource** - School Safety **Cultural Identity** - White Identity - Person of Color Identity **Legality, Constitutionality, Jurisdiction:** - Ban on Handgun - Second Amendment - Concealed Carry Reciprocity Act - Gun Control to Restrain Violence **Crime & Punishment** - Illegal Gun - Gun Show Loophole **Security & Defense** - Background Check - Terrorist Attack **Health & Safety** - Gun Research - Mental Health - Gun Homicide **Policy Pres. & Eval.** - Assault Weapon **Morality** - Right to Self-Defense - Stop Gun Crime

Table 4: Subframes with corresponding frames.

4.3 Weakly Supervised Categorization of Subframes

In the previous steps we identified relevant subframes for each issue and mapped them to the appropriate topic-specific indicators. The indicators can be used for annotating the text directly, as suggested by Field et al. (2018), however we note that they only cover 16.03%, 11.51% and 11.22% of the paragraphs in the topics abortion, immigration and gun control respectively. Instead we use the indicators as a seed set for a weakly-supervised learning process, which intends to generalize the subframe analysis to new text that does not contain the seed subframe indicators, by capturing the relevant context in which these indicators appear.

To identify subframes in paragraphs that do not contain a subframe indicator, we embed the news articles, broken into paragraphs, the complete subframe indicator lexicon and the subframe labels in a common embedding space. The embedding space is shaped by following two objectives: (1) the similarity between the embedding of a paragraph and a subframe indicator is maximized if it appears in the paragraph, (2) the similarity between the embedding of a subframe indicator and its corresponding subframe is maximized.

We briefly describe the embedding learning objective as follows. Given an instance o, a positive example m^p and a negative example m^n, where o is needed to be closer to m^p and far from m^n in the embedding space, the embedding loss is defined:

$$E_r(o, m^p, m^n) = l(\text{sim}(o, m^p), \text{sim}(o, m^n))$$

Here, E_r defines the embedding loss for objective type r (paragraph to subframe indicator or subframe indicator to subframe label). Our goal is to maximize the similarity of a node embedding with a positive example and minimize the similarity with a negative example. We call a subframe indicator a positive example for a paragraph, if the paragraph contains the subframe indicator. Similarly, a subframe label is a positive example for a subframe indicator, if it is an indicator of the subframe. We randomly sample 5 negative examples for each positive example from the subset of subframe indicator not present in a paragraph and do the same in case of the subframe indicator to subframe label objective. As, a similarity function ($sim()$) we use dot product and $l()$ is cross-entropy loss which is defined as follow.

$$l(p, n) = -\log\left(\frac{e^{\text{sim}(o,m^p)}}{e^{\text{sim}(o,m^p)} + e^{\text{sim}(o,m^n)}}\right)$$

Now, for all kind of objectives we can minimize the summed loss $\sum_{r\in R} \lambda_r E_r$, where R is the set of all kind of objective functions and λ_r is the weight of loss for objective function of type r. We initialized $\lambda_r = 1$, for both objectives.

We initialize the embeddings of subframe indicators and subframe labels randomly and the paragraph embeddings are obtained by running a bidirectional-LSTM (Hochreiter and Schmidhuber, 1997) over the Glove (Pennington et al., 2014) word embeddings of the words of the paragraph. We concatenated the hidden states of the two opposite directional LSTMs to get representation over one time-stamp and average the representations of all time-stamps to get a single representation of the paragraph. All the embeddings are initialized in a $300d$ space. We train this bidirectional-LSTM jointly with the embedding learning. We stop learning if the embeddings learning loss does not decrease for 10 epochs or reach at 100 epochs. Dataset and codes can be found at `https://github.com/ShamikRoy/Subframe-Prediction`.

After the embeddings learning we can get a distribution over all of the subframe labels for each paragraph which is based on the cosine similarity between the embeddings of the paragraph and subframe labels. Thus our model combined with the labeled n-grams have the ability to expand the subframe labels to unlabeled text from other domains of the same topics without any human evaluation.

Evaluating the Embedding Space. We evaluate the resulting embedding in two ways. First, we interpret the correctness of the *subframe representation* in the embedding space by evaluating whether the paragraphs most similar to it, actually express that subframe based on human judgement. In the second evaluation, we randomly sample articles and use the embedding space similarity to predict relevant subframes. In both cases we intentionally use instances that **do not** include explicit subframe indicators, in order to evaluate the model's ability to generalize beyond the lexicon. We compare our embedding space to topic-model baseline, using the same subframe indicators as a seed set.

Topic Model Baseline. We compare our model with guided LDA (Jagarlamudi et al., 2012), a variant of LDA (Blei et al., 2003) where topics can be guided based on world knowledge. Traditional LDA assigns uniform Dirichlet prior to each word over all topics. Guided LDA assigns more bias to the seed words of a topic which are believed to be true representatives of the topic. Considering each subframe as a topic, we used the annotated indicators as the seed phrases. We learn the guided LDA model over stemmed unigrams, bigrams and trigrams. To omit out stop words and rarely used words we discarded phrases occurring in less than 0.005% and more than 80% of the paragraphs. Now, we compare our model with guided LDA in the following two ways.

(1) Subframe Prediction Evaluation. We evaluate our model's performance when identifying subframes in new paragraphs compared to guided LDA. We take top 20 most similar paragraphs under each subframe identified by each model and ask human annotators to evaluate if the content of the paragraphs match with the subframe label. We chose the paragraphs which did not have the seed n-grams in their content, so we take the paragraphs that are newly identified. For abortion, immigration and gun control, it resulted in 400, 440 and 380 such examples respectively. We shuffled the paragraphs identified by the two models while presenting to the annotators. We asked 2 graduate students individually to perform the task by providing them with the subframe descriptions (in Appendix C). We found the Cohen's kappa (Cohen, 1960) score between the annotators to be 0.83 implying almost perfect agreement. In case of a disagreement, we asked a 3rd annotator to break the tie who is a researcher in Computational Social Science. Based on the majority voting our model outperforms guided LDA (Table 5).

Models	Abort.	Imm.	Gun
Guided LDA	42.00%	39.77%	42.63%
Our Model	95.25%	87.01%	90.53%

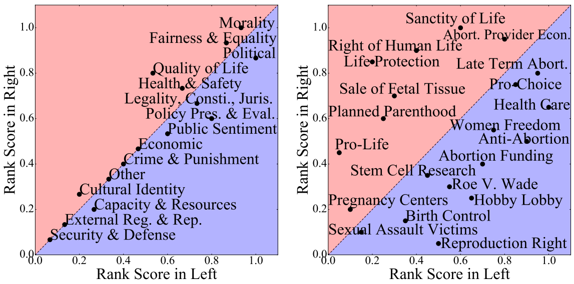
Table 5: % of paragraphs with matching subframe out of 400, 440 and 380 examples per model for the topics Abortion, Immigration and Gun Control respectively.

(2) Identifying Talking Points in News Articles. We can identify the main talking points of a news article based on the distribution of subframes for each paragraph in the news article. We take the average distribution of all the paragraphs and output top-k most probable subframes as summary of the news article. To reduce noise, we restrict the value of k to 3. Similarly, we get the top-3 subframes for each news article using the guided LDA model. We randomly sampled 10 articles from each side (left, right) for each topic resulting in 60 articles, and identified their top-3 subframes using our model and guided LDA. We asked 2 graduate students to annotate individually which set of subframes best describe the talking point of the news article. We found the Cohen's kappa score of 0.63 which implies substantial agreement. In case of a tie, we break the tie by the 3rd annotator. While selecting the news articles, we considered news articles not having any of the seed indicators and having at least 300 and at most 500 words. Based on majority voting, In case of abortion, immigration and gun control respectively 16, 18 and 15 news articles are better described using our model than guided LDA out of 20 in each topic. In case of Immigration, 1 news article had the same top 3 subframes by both of the models.

Topics	Frame Rank Corr.	Subframe Rank Corr.
Abortion	0.86 (0.07)	0.25 (0.2)
Immigration	0.81 (0.09)	0.54 (0.2)
Gun Control	0.87 (0.08)	0.55 (0.3)

Topics	Left		Right	
	Frame Rank Corr.	Subframe Rank Corr.	Frame Rank Corr.	Subframe Rank Corr.
Abortion	0.92 (0.02)	0.62 (0.2)	0.92 (0.05)	0.69 (0.08)
Immigration	0.90 (0.05)	0.78 (0.1)	0.85 (0.08)	0.61 (0.2)
Gun Control	0.92 (0.03)	0.76 (0.06)	0.90 (0.04)	0.73 (0.15)

Table 6: Average Frame and Subframe rank correlation *between* (top table) and *within* (bottom table) ideologies calculated over years 2014-2019. Standard deviations are in the brackets.



(a) Frame Usage (b) Subframe Usage

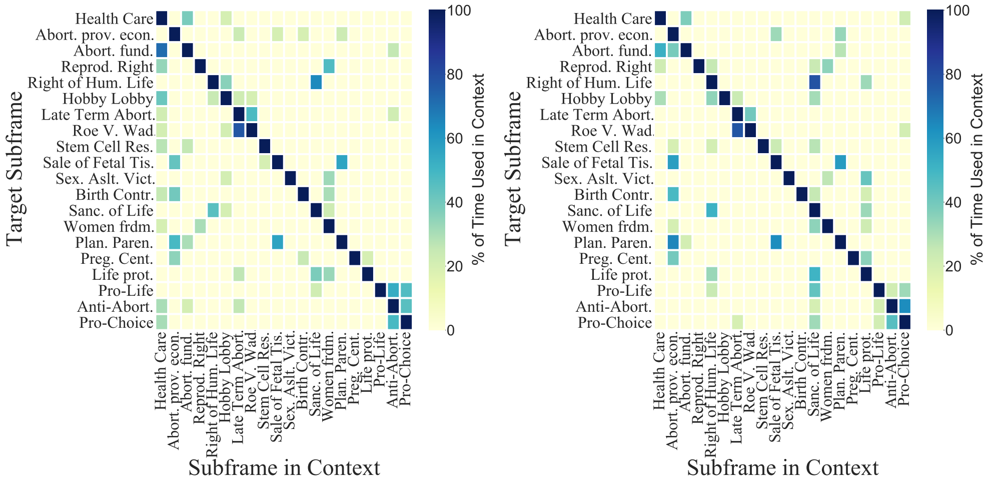
Figure 1: Polarization in usage of frames and subframes. The ranking scores are obtained by taking the normalized rank of the frames and subframes where the highest ranked instance get a score of 1. The rankings are over all news articles in the topic Abortion.

5 Analyzing Polarization on News Media

In this section we show how our model can be used to analyze polarization on news media. We focus on comparing several different qualitative results, contrasting the analysis obtained by policy frames and our subframe approach. Similar to the previous section, we identify the top 3 subframes in a news article using the embedding model. To compare with frame usage, we identify the top 3 frames for each news article by following the same process used by Field et al. (2018), counting the number of word occurrences in an article from a frame lexicon and taking the most frequent 3 as predicted frames.

5.1 Overall Frame and Subframe Usage

To compare frame and subframe usage *between* and *within* ideologies, we create a ranked list of frames and subframes based on their occurrence frequency in articles identified with each ideology. We create ranked list for each year, and calculate the average correlation between the lists each year, *between* ideologies to capture how similar are the framing



(a) Left Articles

(b) Right Articles

Figure 2: Heatmaps showing subframes used in the context of a subframe on the topic Abortion. Subframes used less than 20% of the time in context are rounded down to zero for a cleaner representation purpose.

dimensions, and *within* ideologies by calculating the correlation between pairs of consecutive years within the same ideology, measuring the change in perspectives over time in each ideological camp. We use Spearman's Rank Correlation Coefficient to measure the agreement between rankings. Table 6 show the correlations averaged over years 2014-2019. We take this time-frame as it accounts for the majority of news articles in all 3 topics (Table 1). Less agreement *between* ideologies in subframe usage than frame usage shows that subframe analysis can better capture the polarization. Figure 1 shows this polarity for the topic *abortion*, generated by considering articles from all time-frames. Subframes related to the fetus life is more used by the right while reproduction rights related subframes (Roe V. Wade, Women Freedom) are more focused by the left. In frame usage the parties are almost identical. This figure also shows that frames like 'Security and Defense' are least used by each ideology which supports our claim in the subframe creation step that some frames are irrelevant to certain topics. Polarization graph for other two topics are shown in Appendix G. Less agreement in subframe usage than frame usage *within parties* over years (in Table 6) implies that parties use different subframes at different times, possibly in response to events occurred at that time. This hypothesis is further qualitatively analyzed in Section 5.3.

5.2 Subframes Instantiation Differences

To help get a better understanding of how subframes are used by each side, we analyze their co-occurrence. We represent this information using heatmaps. Each row in the heatmap captures the association strength between a given subframe (y-axis) and all the other subframes. The heatmap cell colors represents the percentage of times the two subframes appear in the same context.

The heatmaps for *abortion* are shown in Figure 2 for both of the sides, and demonstrates how subframes are used differently by each side. For example, when the left talks about 'Women Freedom', it is used in the context of 'Reproduction Right' and 'Health Care', implying the association between concepts. On the other hand, the right uses 'Sanctity of Life', 'Life Protection' in the context of 'Women Freedom', implying they counter the issue of women freedom with the necessity of protecting lives of the unborn babies. In case of discussing 'Hobby Lobby', the left relates it with 'Roe V. Wade', possibly their conflicts, while the right relates 'Hobby Lobby' with life protection issues more. Heatmaps for other two topics are shown in Appendix F.

5.3 Differences in Event News Coverage

To investigate how event news coverage differs across ideological lines, we pick 3 defining events, one in each topic, and investigate the usage of frames and subframes by either side around the time of those events. The events are as follows[1]

- **Abortion Event:** Undercover videos released on July 14, 2015 showing an official at

---

[1] The Wikipedia links to the events are in Appendix D.

EVENTS	FRAME USAGE		SUBFRAME USAGE		WORDS USAGE IN CONTEXT OF COMMON SUBFRAMES	
	LEFT	RIGHT	LEFT	RIGHT	LEFT	RIGHT
Abortion Event: Leaked video of Planned Parenthood (Jul 14, 2015), Shooting at Planned Parenthood, CO (Nov 27, 2015)	- Political - Fairness & Equality - Health & Safety - Morality - Legal., Cons., Juri.	- Quality of Life - Morality - Fairness & Equality - Health & Safety - Political	- Planned Parenthood - Sale of Fetal Tissue - Abort. prov. econ. - Abortion funding - Women freedom	- Sale of Fetal Tissue - Abort. prov. econ. - Planned Parenthood - Sanctity of Life - Right of Hum. Life	- Sale of Fetal Tissue: *sting, donation, deceptively, state, health* - Planned Parenthood: *called, shooting, smear, campaign, spring* - Abortion Providers economy: *first, patient, state, go, take*	- Sale of Fetal Tissue: *story, organ, harvesting, human, money* - Planned Parenthood: *report, made, service, affiliate, year* - Abortion Providers economy: *government, industry, profit, affiliate, claim*
Imm. Event: Midterm Election (Nov 6, 2018) Govt. Shutdown (Dec 22, 2018 - Jan 25, 2019)	- Political - Crime & Punish. - Ext. Reg. & Rep. - Capacity & Resour. - Fairness & Equality	- Crime & Punish. - Security & Defense - Capacity & Resour. - Political - Ext. Reg. & Rep.	- Racism & Xenophobia - Border Protection - Racial Identity - Family Sep. Policy - Detention	- Refugee - Border Protection - Deportation: Illegal Immigrants - Asylum - Detention	- Border Protection: *work, crisis, agent, also, part* - Detention: *mother, administration, separated, woman, report*	- Border Protection: *week, migrant, congress, illegal, secure* - Detention: *release, county, bed, officer, migrant*
Gun Event: Stoneman Douglas High School shooting (Feb 14, 2018)	- Political - Crime & Punish. - Fairness & Equality - Quality of Life - Policy Pres., Eval.	- Political - Crime & Punish. - Policy Pres., Eval. - Fairness & Equality - Quality of Life	- School Safety - Gun Show Loophole - Gun Control to Restrain Violence - White Identity - Stop Gun Crime	- School Safety - Gun Show Loophole - Gun Control to Restrain Violence - Mental Health - Background Check	- School Safety: *officer, elementary, arming, classroom, time* - Gun Con. to Rest. Vio.: *shot, style, health, petition, expansion* - Gun Show Loophole: *universal, minimum, anyway, still, style*	- School Safety: *massacre, president, staff, rifle, person* - Gun Con. to Rest. Vio.: *said, empower, extreme, danger, stop* - Gun Show Loophole: *south, limit, allowed, student, close*

Table 7: In response to real life events usage of frames, subframes and words by ideologies; all appearing in order of their rank by frequency of usage. Articles on topic Abortion are taken from 6 months period from the planned parenthood video leaking; on topic Immigration from Jul 1, 2018 to Jan 31, 2018; on topic Gun Control 1 month period from the shooting date. In case of Abortion, we don't consider the subframes 'pro-life', 'anti-abortion' and 'pro-choice' while ranking as they capture addressing framing.

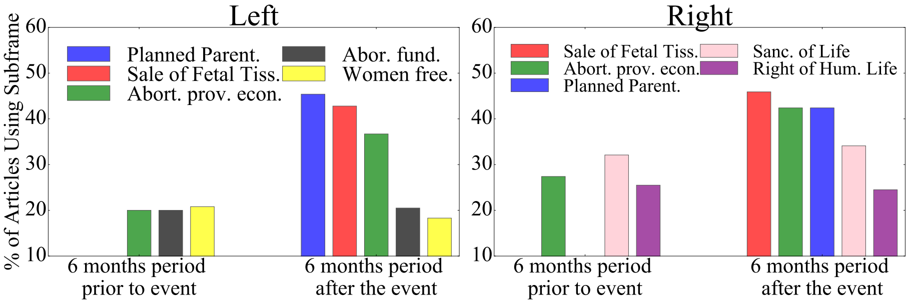
Planned Parenthood discussing how to abort a fetus and preserve the organs and the costs associated with sharing that tissue with scientists. These videos and the defunding of Planned Parenthood came in presidential candidates' debates. Following this event, on Nov 27, 2015, three people were murdered at a Planned Parenthood health center in Colorado by a shooter.

- **Immigration Event:** In the 2018 US midterm elections (Nov 6, 2018), 40 seats flipped from Republican to Democratic control. The election had a huge anti-immigration rhetoric. Following the election the longest government shutdown in US history occurred (Dec 22, 2018 - Jan 25, 2019), caused by a dispute over the funding amount for an expansion of the US-Mexico border barrier.
- **Gun Control Event:** On February 14, 2018, a gunman opened fire with a semi-automatic rifle at Marjory Stoneman Douglas High School in Parkland, Florida, killing 17 people and injuring 17 others. The shooter was a former student of the same school who is ethnically white.

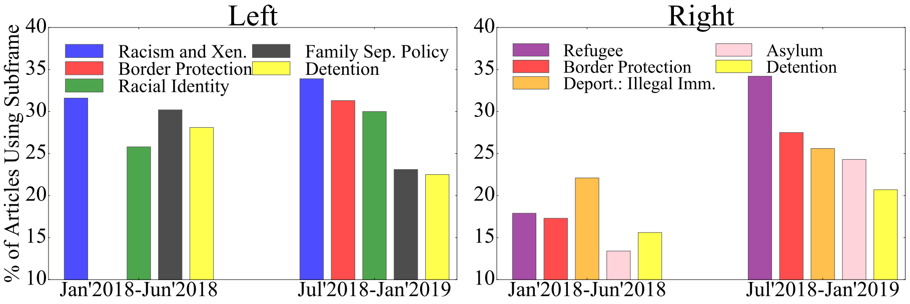
The usage of frames and subframes in response to these events are summarized in Table 7. It shows that frames usage by both parties overlaps, although with varying importance, and as a result offers limited insight. Analyzing subframes usage shows that some subframes are unique to each side in the context of the analyzed event. For example, the Abortion event analysis shows that 'Sale of Fetal Tissue', 'Planned Parenthood' and 'Abortion Providers Economy' are used by both sides, as they are very relevant to the event. However, 'Women freedom', and 'Sanctity of human life' are unique to each side.

Figure 3 captures the change in framing behavior as a response to the event by comparing subframe usage before and after the event. It shows a spike in event related subframes by both sides, showing they respond to the specifics of the event. That supports our claim in Section 5.1 that the left and right react to events by using event related subframes. In topic Abortion, apart from the event related subframes, the left used 'Abortion Funding' and 'Women Freedom', and the right used subframes related to saving the life of the unborn. In the case of immigration, the left responded to the debates related to 'Border Protection' by framing it as 'Family Separation Policy', 'Racism and Xenophobia', while the right framed it as a 'Refugee' issue. Around the school shooting event, the left talked about the 'White Identity' of the shooter, while the right framed it as a 'Mental Health' issue, a finding consistent with the claim by Demszky et al. (2019) that the shooter's race plays a role in frame usage after a mass shooting event.

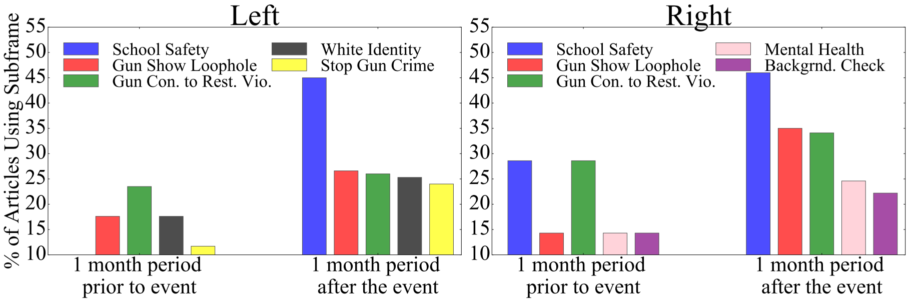
We take a closer look at the difference between the usage of the same subframe by both sides by comparing the words used by each side. We look at the top 5 high PMI words in the context of those



(a) Abortion



(b) Immigration



(c) Gun Control

Figure 3: Each party's use of the top-5 subframes before and after the events in Table 7.

subframes for each party[2] shown in the right-most two columns of Table 7. Interestingly, in context of 'Sale of Fetal Tissue', the left used words like *sting, donation, deceptively*; suggesting they framed it as a propaganda ploy, while the right used words like *organ, harvesting, human, money*; indicating a different interpretation. In case of 'Border Protection', the left used words like *crisis*, while the right used *illegal, secure*. This analysis indicates again that even when the sides use similar event-specific subframes, their intent is different.

6 Summary

We study the news media coverage of 3 politically polarized topics - *abortion, immigration*, and *gun control*; by breaking the high level policy frames into more fine grained, and topic-specific, subframes. We demonstrate that the subframes can account better for the way issues are framed in the news by both sides to influence their readers. We propose a novel embedding-based model extending our subframe lexicon to new text, allowing us to perform analysis more broadly. Our study serves as a starting point for additional work on hierarchical framing classification that can combine issue-specific or event-specific framing analysis with generalized framing dimensions that are comparable across different events and issues. To assist this effort, and improve reproducibility we provide additional details in Appendix H.

A Polarity in Frame Indicators and Subframe Indicators

The rank correlation coefficient of frame indicator ranks and subframe indicator ranks between left and right for each issue frame are shown in Table 8.

B Subframe Seeds

The stemmed version of the following seeds were used for the corresponding subframes.

B.1 Abortion

Health Care care act, affordable care act, affordable care

Abortion Provider Economy abortion giant, abortion vendor, abortion business, abortion industry, largest abortion provider, sell abortion, human capital

Abortion Funding fund abortion, abortion fund, funding of planned, fund family planning, title x funding, funding to planned, taxpayer funded abortion, parenthood's funding, family planning fund, funding of abortion, fund planned parenthood, fund for planned, funding for abortion, fund from planned, subsidizing abortion, cut planned parenthood, strip planned parenthood

Reproduction Right reproductive justice, reproductive freedom, reproductive decision, reproductive choice, reproductive justice advocacy

Right of Human Life life liberty, unborn life, life matter movement, respect for life, human life begin, right to life

Hobby Lobby hobby lobby, hobby lobby case, freedom restoration, freedom restoration act, restoration act, exercise of religion

Late Term Abortion partial birth, ban on partial, called partial birth, partial birth abortion

Roe V. Wade revisit roe, landmark roe, decision roe, challenge roe, overturn roe, overrule roe, roe v, uphold roe, roe decision, see roe, decision in roe, court overturn roe, challenge to roe, ruling in roe, court's roe, roe is overturned, roe v wade, wade ruling, wade supreme, wade decision, v wade, wade supreme court, wade the landmark, wade the supreme

Stem Cell Research cell research, tissue research, stem cell research, fetal tissue research

Sale of Fetal Tissue sell fetal, sell baby, parenthood sell, sell fetal tissue, sell baby part, planned parenthood sell, procurement company, tissue procurement company

Sexual Assault Victims rape victim, statutory rape, forced rape, victim of rape, sex crime, child sex, sex trafficking, sexual abuse, sexually offend, sexual assault, sexual misconduct, sex predator, child sex abuse, accused of sexual, victim of sexual, trafficking victim, sex trafficker', human trafficking

Birth Control birth control, birth control pill, cover birth control, use birth control, birth control mandate, birth control access, unwanted pregnancy, prevent unwanted, prevent unwanted pregnancy, prevent unintended, prevent pregnancy, drug induced, abortion inducing drug, drug induced abortion

Sanctity of Life sanctity of life, life is sacred, believe life, life catholicism, priest for life, evil of abortion, abortion is murdering, abortion is wrong

Women Freedom punish woman, hurt woman, control woman, force woman, woman's movement

Planned Parenthood parenthood support, planned parenthood clinic, planned parenthood abortion, planned parenthood sting, local planned parenthood, planned parenthood support

Pregnancy Centers pregnancy help center, pregnancy resource center, resource center, pregnancy center, pregnancy help, pregnancy resource

Life Protection child protection, protect life, baby's life, child's life, take a life, baby's life, end a life, take the life, pro life pregnancy, end the life, end of life, kill the baby, abort the baby, rip the baby, child killing, kill the child

Pro-life pro life vote, pro life message, pro life group, pro life campaign, pro life advocate, pro life organization, pro life candidate, strong pro life, life rally, life protest, life voter, life group, life campaign, life organization, life candidate, life message, life advocate, life supporter, public life, life commission, coalition for life, march for life

Anti-abortion anti abortion protest, anti abortion, anti abortion march, anti abortion right, anti abortion vote, anti abortion organization, anti abortion protest, anti abortion group, anti abortion democrat, anti abortion candidate, anti abortion

FRAMES	ABORTION		IMMIGRATION		GUN CONTROL	
	FRAME INDICATOR	SUBFRAME INDICATOR	FRAME INDICATOR	SUBFRAME INDICATOR	FRAME INDICATOR	SUBFRAME INDICATOR
Economic	0.95	0.44	0.92	0.28	0.94	0.29
Capacity and Resources	0.95	0.24	0.89	0.38	0.92	0.38
Morality	0.91	0.30	0.89	0.16	0.93	0.16
Fairness and Equality	0.93	0.37	0.92	0.30	0.93	0.41
Legality, Constitutionality, Jurisdiction	0.96	0.54	0.92	0.46	0.95	0.39
Policy Prescription and Evaluation	0.97	0.58	0.92	0.07	0.95	0.48
Crime and Punishment	0.94	0.36	0.90	0.32	0.94	0.61
Security and Defense	0.95	0.17	0.91	0.28	0.93	0.41
Health and Safety	0.96	0.43	0.94	0.13	0.95	0.48
Quality of Life	0.94	0.34	0.92	0.37	0.93	0.19
Cultural Identity	0.93	0.22	0.88	0.03	0.93	0.41
Public Sentiment	0.91	0.33	0.90	0.05	0.94	0.42
Political	0.94	0.53	0.93	0.51	0.96	0.46
External Regulation and Reputation	0.93	0.22	0.88	0.18	0.93	0.51
Other	0.94	0.18	0.92	0.21	0.93	0.38
Overall	0.94 (0.017)	0.35 (0.128)	0.91 (0.018)	0.25 (0.142)	0.94 (0.011)	0.40 (0.112)

Table 8: After ranking frames and sub-frame lexical indicators based on their usage in left and right biased documents, we measured and compared the correlation between the two ranks. Overall, frame indicators are not indicative of the label, as opposed to subframe indicators.

advocate, anti abortion position, anti abortion lawmaker, opposed to abortion, oppose abortion right, oppose abortion, oppose abortion right, opponent of abortion

Pro-choice pro choice vote, pro abortion right, pro choice organizing, pro choice position, pro choice woman, pro choice group, pro abortion group, pro choice candidate, pro choice advocate, supported abortion right, defend abortion right, support of abortion, favor abortion right, abortion right supporter

B.2 Immigration

Minimum Wage income inequality, raise the minimum, minimum wage

Salary stagnation cut salary, wage cut, stagnant wage, wage stagnation, lowering wage, wage lowering, driven down wage

Wealth Gap widen wealth, shift wealth, wealth gap, wealth from young, widen wealth gap, immigration shift wealth, price widen wealth, wealth gap reduce

Cheap labor availability cheap labor, cheap labor economy, low wage work, cheap foreign worker, cheap foreign labor, cheap labor migration, cheap foreigner, massive cheap labor, cheap labor strategy, successful cheap labor, cheap worker, inflow of cheap, cheap labor policy

Taxpayer Money pay tax, taxpayer money, taxpayer dollar

Deportation: Illegal Immigrants deport illegal, deport illegal immigrant, deport illegal alien, deportation of illegal, previously deported illegal, deport undocumented

Deportation: In General face deportation, deport immigrant, deport back, deport person, mas deportation, deport million, deportation policy, arrest and deportation, detain and deport, stop the deportation

Detention federal detention, immigrant detention, ice detention, detention facility, detention center, immigrant detention facility, release from detention, immigrant detention center

Terrorism foreign terrorist, potential terrorist, terrorism related, terrorist suspect, terrorist problem, terrorist threat, suspected terrorist, terrorist group, terrorist organization, terrorist activity, domestic terrorism, war on terrorism

Border Protection porous border, border fencing, border barrier, border enforcement, build the border, united state border, illegal border crossing, cross my border, border wall construction, wall prototype, build wall, build the wall, secure fencing, mile of fence

Asylum grant asylum, asylum case, asylum application, asylum applicant, legitimate asylum, deny asylum, asylum claim, asylum rule, asylum officer, political asylum, asylum process, asylum seeking, seek asylum, asylum request, asylum system, asylum law, asylum hearing, claim asylum,

asylum policy, qualified for asylum, claim for asylum, eligibility for asylum, apply for asylum, person seek asylum, refuge and asylum, number of asylum, immigration and asylum, ask for asylum

Refugee refugee status, seek refugee, refugee and asylum

Birthright citizenship and 14th Amendment birthright citizenship, end birthright, end birthright citizenship, fourteenth amendment, 14th amendment, automatically citizen

Amnesty grant amnesty, executive amnesty, temporary amnesty, expand amnesty, amnesty program, given amnesty, amnesty bill, offer amnesty, amnesty proposal, amnesty plan, act amnesty, amnesty legislation, temporary amnesty program, amnesty to illegal

Dream Act dreamer illegal, dream act, dream act amnesty

Family Separation Policy separation policy, separate family, family separation policy, policy of separation, separation of child, end family separation, practice of separating, separation of family

DACA deferred action, created deferred action, era deferred action, childhood arrival, action for childhood, illegally as child, country as child, childhood arrival program

Racism and Xenophobia race bait, racial discrimination, racist attack, racist profiling, racism and xenophobia

Merit Based Immigration merit based, based on merit, merit based system, merit based immigration

Human Right human right, human right abuse, human right advocate, human right violation, civil right, civil disobedience, civil liberty, civil right activist, civil right movement

Racial Identity white national, white supremacist, white supremacy, class white, white male, white race, white person, white identity, white woman, white man, white worker, new black, black community, younger black, black man, black woman, black voter, black person, first black, black president, black and brown, black and white, person of color, non white

Born Identity born outside, foreign born, international migrant, eastern refugee, foreign student, foreign refugee, foreign born population, number of foreigner, family based chain, based chain migration, illegal alien population

B.3 Gun Control

Gun Buyback Program buyback second, higher buyback, buyback rate, lower buyback, buyback program, gun buyback, buyback second firearm, lower buyback rate, higher buyback rate, gun buyback program

Gun Business Industry firearm industry, gun business, gun company, gun market, firearm manufacturer, gun manufacturer, gun industry, firearm dealer, gun shop, gun dealer, licensed dealer, gun shop owner, gun store owner, licensed firearm dealer

School Safety arming school, school security, school safety, student safety, protect student, arming teacher

White Identity white guy, white male, white person, white supremacy

Person of Color Identity black male, black neighborhood, black person, black man, person of color

Ban on Handgun transfer ban, handgun transfer, handgun transfer ban, handgun ban, ban on handgun

Second Amendment heller decision, second amendment protected, second amendment guarantee, second amendment right, 2nd amendment right, amendment right, second amendment right, amendment protected, protection the second

Concealed Carry Reciprocity Act reciprocity act, carry reciprocity, carry reciprocity act, concealed carry, carry concealed firearm, conceal carry law, concealed carry permit, concealed carry license

Gun Control to Restrain Violence violence restraining, gun violence restraining, violence restraining order, domestic violence restraining, prevent gun violence

Illegal Gun illegal possession, gun illegally, illegal gun, illegal firearm, criminal possession

Gun Show Loophole loophole that allow, show loophole, close loophole, gun show

Background Check instant criminal background, criminal background check, background check system, gun background check, strengthen background check, passing background check, stronger background check, new background check, conduct background check, background check requirement, strengthening background check, universal background check, comprehensive background check

Terrorist Attack terrorist threat, international terrorism, terrorist watch, terrorist attack, terrorist suspect, terrorist group, terrorist activity, suspected terrorist, domestic terror, foreign terror, terrorist organization, anti terrorism, terror gap, terrorist watch list, war on terrorism, act of terrorism

Gun Research gun violence research, gun death researcher, gun research, death researcher, violence researcher

Mental Health seriously mentally, severe mental, mental state, mental illness, address mental, mental health care, person with mental, mentally ill person

Gun Homicide firearm death, gun death, shooting death, gun death domestic, gun death, gun death rate, gun death researcher, reduce gun death, gun public health

Assault Weapon new assault, ban assault, semiautomatic assault, new assault weapon, ban assault weapon, automatic firearm, automatic gun, fully automatic, automatic rifle, semiautomatic rifle, semi automatic, automatic fire, automatic machine, semiautomatic assault, semiautomatic weapon, allow semi automatic, fully automatic rifle, ban semi automatic, fully automatic firearm, full automatic weapon, semi automatic gun, semi automatic rifle, fully automatic machine, rifle and shotgun, rifle to fire, rifle ban

Right to Self-Defense religious right, given right, god given right, right to protect, right of gun, god given, exercised their second, bill of right

Stop Gun Crime commit violence, mas violence, history of violent, culture of violence, stop gun violence, risk of violence, curb gun violence, victim of violence, end gun violence, thought and prayer, victim of domestic

C Subframe Description

Subframes with corresponding description are summarized in Table 9

D Event References

- **Topic: Abortion**
  Event: Undercover videos released on July 14, 2015 showing an official at Planned Parenthood discussing how to abort a fetus and preserve the organs and the costs associated with sharing that tissue with scientists[3]. These videos and defunding of Planned Parenthood came in presidential candidates' debates. Following this event, on Nov 27, 2015, three people were murdered at a Planned Parenthood health center in Colorado by a shooter[4].

- **Topic: Immigration**
  Event: In the 2018 US midterm elections (Nov 6, 2018), 40 seats flipped from Republican to Democratic control[5]. The election had a huge anti-immigration rhetoric. Following the election the longest government shutdown in US history occurred (Dec 22, 2018 - Jan 25, 2019)[6], caused by a dispute over the funding amount for an expansion of the US-Mexico border barrier.

- **Topic: Gun Control**
  Event: On February 14, 2018, a gunman opened fire with a semi-automatic rifle at Marjory Stoneman Douglas High School in Parkland, Florida, killing 17 people and injuring 17 others. The shooter was a former student of the same school who is ethnically white[7].

E Detection of Top-5 Highest PMI Words in the Context of Subframes by for Each Party

To detect the top PMI words for each party label (left, right) in the context of a subframe, s, we

---

[3] `https://en.wikipedia.org/wiki/Planned_Parenthood_2015_undercover_videos_controversy`

[4] `https://en.wikipedia.org/wiki/Colorado_Springs_Planned_Parenthood_shooting`

[5] `https://en.wikipedia.org/wiki/2018_United_States_elections`

[6] `https://en.wikipedia.org/wiki/2018%E2%80%9319_United_States_federal_government_shutdown`

[7] `https://en.wikipedia.org/wiki/Stoneman_Douglas_High_School_shooting`

follow the following procedure. If a news article is detected to have a subframe, s, in its top 3 subframes, we take only the paragraphs from that news article which have the highest probability as having the subframe, s, over all the subframes and also belongs to the top-500 nearest paragraphs of the subframe, s, in the embeddings space. This top-500 list is created based on cosine similarity between the embedding of the subframe, s, and the embedding of all paragraphs on the topic. Now we tokenize the subset of paragraphs having subframe, s. To remove stopwords and very rarely occurring words we consider only the words appearing in less than 5% of the paragraphs and more than 60% of the paragraphs. For a word w we calculate the pointwise mutual information (PMI) with label l, $I(w, l)$ using the following formula.

$$I(w, l) = \log \frac{P(w|l)}{P(w)}$$

Where $P(w|l)$ is computed by taking all paragraphs with label l and computing $\frac{count(w)}{count(allwords)}$ and similarly, $P(w)$ is computed by counting word w over the set of paragraphs combining both left and right biased ones. Now, we rank words for each label (left, right) based on their PMI scores.

F Usage of Subframes in Context of Other Subframes

The heatmaps showing usage of a subframe in the context of other subframes for the topics immigration and gun control are showed in Figure 4.

G Polarization in Frame and Subframe Usage

Figure 5 and 6 shows the polarization in usage of frames and subframes by each party for the topics Immigration and Gun Control respectively.

H Reproducibility

Machine Used We used a Nvidia GeForce GTX 1080 Ti, 12 GB memory GPU in a machine with Intel(R) 12 Core(TM) i7-8700 CPU @ 3.20GHz and a RAM of 64GB to run all the experiments.

Libraries Used For implementation of HLSTM, BERT and the embedding learning we used PyTorch. To implement the guided LDA we used Python guidedlda library.

Guided LDA Hyper-parameters We ran the guided LDA models for 100 iterations with a random state of 7. This threshold was set by looking at the log-likelihood of the model. For all of the topics at 100th iteration the log-likelihood became stable. We used seed confidence of 1 each time which means the seed n-grams had 100% prior probability of being in the corresponding topics i.e. subframes.

Text Classification Baseline For the text classification baseline, HLSTM, we used validation accuracy as a stopping criteria. If the validation accuracy didn't increase for 10 epochs we stopped training. 10% of the news articles from the training set was used as validation set. This training took on average 10 minutes for each fold for all of the topics. In BERT training using a batch size of 4 and learning rate of $5e^{-5}$ yielded the best performance.

Joint learning of paragraphs and subframe label embeddings While initializing the embeddings randomly we used a random seed of 1234. Each learning epoch took on average 67 seconds for Abortion and Gun Control and 122 seconds for $Immigration$. We trained the model for at most 100 epochs or stopped learning if the embedding learning loss didn't decrease for 10 consecutive epochs.

ABORTION

FRAME	SUBFRAME	SHORT DESCRIPTION
Economic	Health Care	Affordable Care Act, healthcare facilities, health insurance, their coverage etc.
	Abort. Provider Economy	Statistics, services, profits of abortion providers like Planned Parenthood.
	Abortion Funding	Source of funding; granting or cutting funding for abortion providers like Planned Parenthood.
Fairness & Equality	Reproduction Right	Reproduction rights and women's access to reproduction healthcare.
	Right of Human Life	Fetus in the womb has the same right of life as a grown human.
Legality, Consti., Jurisdiction	Hobby Lobby	Supreme Court's exemption for corporations to provide contraceptives if it conflicts with their religious belief.
	Late Term Abortion	Discuss ban and regulation on abortion after later stages of pregnancy.
	Roe V. Wade	Implications of the 1973 landmark decision of the U.S. Supreme Court that ensures the right to choose.
Crime & Punishment	Stem Cell Research	Research and its implications using stem cell, embryonic cell and fetal tissue.
	Sale of Fetal Tissue	Abortion providers donation or selling of the fetal tissue and baby body parts from aborted babies.
	Sexual Assault Victims	Any kind of sexual offense against women and pregnancies resulted from that.
Health, Saf.	Birth Control	Birth control measures and access to those.
Morality	Sanctity of Life	The holiness of life from a religious and moral perspective and the evil of abortion.
	Women Freedom	Advocating women freedom or talking about suppression on women, from a moral perspective.
Quality of Life	Planned Parenthood	Abortion services provided by Planned Parenthood.
	Pregnancy Centers	Pregnancy services provided by pregnancy care centers, pregnancy crisis center etc.
	Life Protection	Abortion kills human being and they should be protected.
Public Sentiment	Pro-life	Addressing of any personality, movement or legislation as supporting life.
	Anti-abortion	Addressing of any personality, movement or legislation as opposing abortion instead of addressing as pro-life.
	Pro-choice	Addressing of any personality, movement or legislation as supporting abortion and the right to choose.

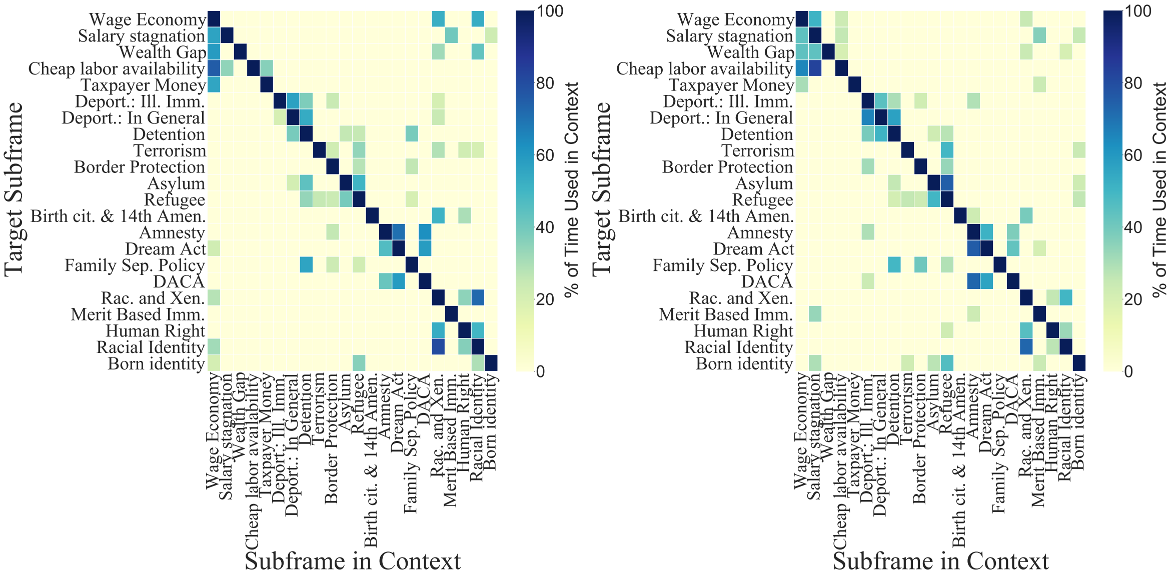
IMMIGRATION

FRAME	SUBFRAME	SHORT DESCRIPTION
Economic	Minimum Wage	Wage inequality and discussion on raising the minimum wage.
	Salary Stagnation	Reasons of salary stagnation and how to overcome those.
	Wealth Gap	Wealth gap among the classes in the society; profits by large organizations etc.
	Cheap Labor Availability	Cheap labor availability and its effects.
	Taxpayer Money	Taxpayer money and the facilities they get or are deprived of, such as social security.
Fairness & Equality	Racism and Xenophobia	Addressing of someone/something racist and xenophobic in a discussion.
	Merit Based Immigration	Discussion on merit based immigration system.
	Human Right	Necessity of protecting human and civil rights; their violations.
Legality, Consti., Jurisdiction	Asylum	Implications of granting asylum to the asylum seeking migrants.
	Refugee	Political refugees from various countries.
	Birth citizenship & 14th Amen.	Birthright citizenship; 14th Amendment; citizenship granting procedure.
Crime & Punishment	Deportation: Illegal Immigrants	Necessity of deportation of the illegal immigrants.
	Deportation: In General	Procedure, policy and way to deport the undocumented immigrants.
	Detention	Detention facilities; detention procedure and the state of the detainees.
Security & defense	Terrorism	Threats of terrorism by foreign nationals.
	Border Protection	Border wall; border patrol and other measures to secure the border.
Policy Prescription, Evaluation	Amnesty	Implications and procedure of granting amnesty to the undocumented immigrants.
	DREAM Act	2001, DREAM Act, its implications; DREAMers and procedure of their path to citizenship.
	Family Separation Policy	Family separation policy and its effects; separation of children from their families in the border.
	DACA	DACA policy that protects the individuals from deportation who came to the USA as children.
Cultural Identity	Racial Identity	Discussion on a topic by focusing on the race.
	Born Identity	Discussion on a topic by addressing the born identity, such as, 'foreign born'.

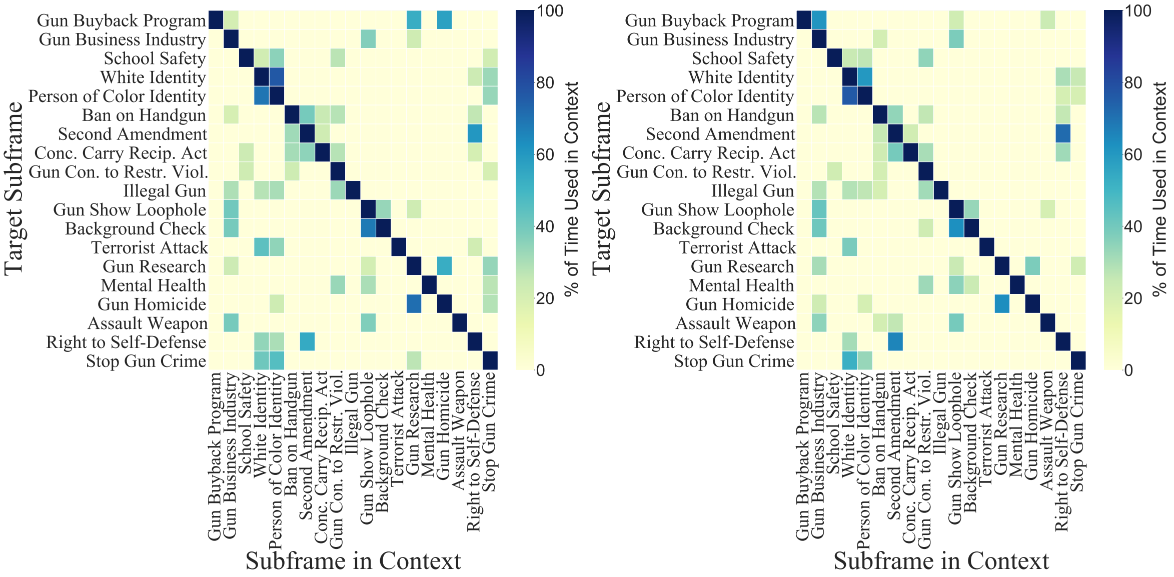
GUN CONTROL

FRAME	SUBFRAME	SHORT DESCRIPTION
Economic	Gun Buyback Program	Gun buyback program and its effects.
	Gun Business	Licensed gun store owners; gun business industry.
Health & Safety	Gun Research	Research on gun violence and how to control it; funding on gun research.
	Mental Health	Mental illness; importance of providing mental health care.
	Gun Homicide	Statistics on deaths due to gun violence.
Legality, Consti., Jurisdiction	Ban on Handgun	Banning handgun and its effects.
	Second Amendment	2nd Amendment which ensures right to self-defense and allows law abiding citizens to carry guns.
	Concealed Carry Reciprocity Act	Concealed carry reciprocity act and its effects and implications.
	Gun Control to Restrain Violence	Violence-restraining gun control measures.
Crime & Punishment	Illegal Gun	Illegal possession of gun; gun trafficking etc.
	Gun Show Loophole	Loophole in the gun shows that allows criminals to get gun.
Security & defense	Background Check	Necessity of background check and ways to ensure it while selling guns.
	Terrorist Attack	Threats of terrorist attack.
Policy Pres., Eval.	Assault Weapon	Debate over the definition of assault weapon and which ones are needed to be banned.
Cultural Identity	White Identity	Focusing on white racial identity of a person; white supremacy etc.
	Person of Color Identity	Focusing on person of color racial identity.
Capacity, Resource	School Safety	Measures to ensure school safety; arming teachers; control gun to reduce violence in schools etc.
Morality	Right to Self-Defense	God given right to self defense; necessity of carrying guns for self-defense etc.
	Stop Gun Crime	Urge to stop gun violence; expression of solidarity with mass shooting victims etc.

Table 9: Subframe Description

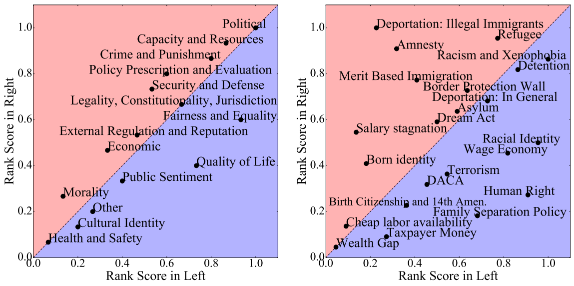


(a) Immigration



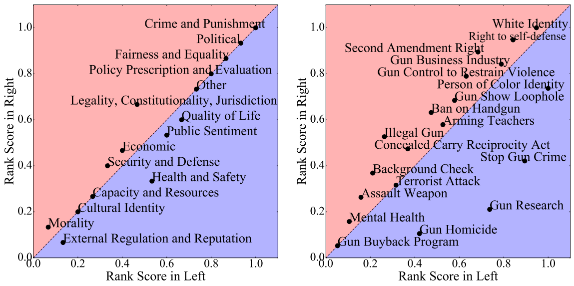
(b) Gun Control

Figure 4: Heatmaps showing subframes used in the context of a subframe on the topics Immigration and Gun Control. The left images are for left biased news articles and the right ones are for right biased ones. Subframes used less than 20% of the time in context are rounded down to zero for a cleaner representation purpose.



(a) Frame (b) Subframe

Figure 5: Polarization in usage of frames and subframes. The ranking scores are obtained by taking the normalized rank of the frames and subframes where the highest ranked instance get a score of 1. The rankings are over all news articles in the topic Immigration.



(a) Frame (b) Subframe

Figure 6: Polarization in usage of frames and subframes. The ranking scores are obtained by taking the normalized rank of the frames and subframes where the highest ranked instance get a score of 1. The rankings are over all news articles in the topic Gun Control.

Where Are the Facts? Searching for Fact-checked Information to Alleviate the Spread of Fake News

Nguyen Vo and **Kyumin Lee**
Computer Science Department, Worcester Polytechnic Institute
Worcester, Massachusetts, 01609, USA
`{nkvo,kmlee}@wpi.edu`

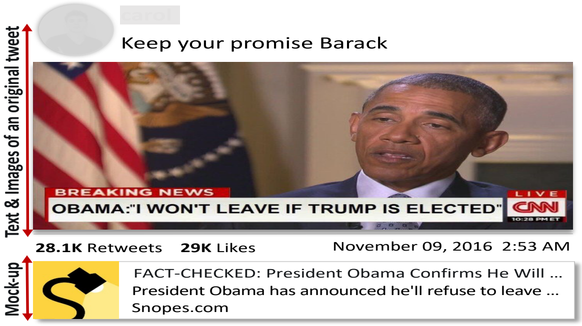
Abstract

Although many fact-checking systems have been developed in academia and industry, fake news is still proliferating on social media. These systems mostly focus on fact-checking but usually neglect *online users* who are the main drivers of the spread of misinformation. How can we use fact-checked information to improve users' consciousness of fake news to which they are exposed? How can we stop users from spreading fake news? To tackle these questions, we propose a novel framework to search for fact-checking articles, which address the content of an original tweet (that may contain misinformation) posted by online users. The search can directly warn fake news posters and online users (e.g. the posters' followers) about misinformation, discourage them from spreading fake news, and scale up verified content on social media. Our framework uses both text and images to search for fact-checking articles, and achieves promising results on real-world datasets. Our code and datasets are released at `https://github.com/nguyenvo09/EMNLP2020`.

1 Introduction

The rampant spread of biased news, partisan stories, false claims and misleading information has raised heightened societal concerns in recent years. Many reports pointed out that fabricated stories possibly caused citizens' misperception about political candidates (Allcott and Gentzkow, 2017), manipulated stock prices (Kogan et al., 2019) and threatened public health (Ashoka, 2020; Alluri, 2019).

The proliferation of misinformation has provoked the rise of fact-checking systems worldwide. Since 2014, the number of fact-checking outlets has totally increased 400% in 60 countries (Stencel, 2019). However, fabricated stories and hoaxes are still pervading our cyberspace. Fig. 1 shows an example of a fake quote related to Barack Obama.



Keep your promise Barack

OBAMA:"I WON'T LEAVE IF TRUMP IS ELECTED"

28.1K Retweets 29K Likes November 09, 2016 2:53 AM

FACT-CHECKED: President Obama Confirms He Will ...
President Obama has announced he'll refuse to leave ...
Snopes.com

Figure 1: An original tweet and a mock-up of how a correctly retrieved fact-checking article is presented.

The quote had been debunked by Snopes (Emery, 2016) on September 08, 2016 but two months later, it appeared again inside an original tweet posted by a Twitter user (called an original poster) and was retweeted over 28 thousand times. Perhaps, the original poster and people who shared the original tweet did not know if it was fact-checked or they might share it simply because it was suitable for their personal preferences or ideologies (Lewandowsky et al., 2012). In other words, existing fact-checking systems mainly focus on detection but neglect online users who play the critical role in spreading fake news. After detecting fake news, what are the next steps to discourage people from sharing it? Recent studies (Vo and Lee, 2018, 2019) tried to curb the above weakness. However, these approaches are not proactive since they rely on fact-checkers who may be unreliable.

Recent works showed that when seeing fact-checked information, users' likelihood to delete fake news's shares went up 400% (Friggeri et al., 2014) and 95% of the time users did not further consume or go through fake news (CNN, 2020). Observing the downside of existing methods and impacts of broadcasting verified news, our goal is to search for *fact-checking articles* (FC-articles) which address the content of original tweets (i.e. confirming, supporting, debunking or refuting). We

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7717–7731,
November 16–20, 2020.

show a mock-up of how a relevant FC-article is linked/displayed given an original tweet in Fig. 1. By searching for FC-articles and incorporating fact-checked information into social media posts, we can warn users (e.g. followers of original posters) about fake news to which they are exposed. The search also proactively scales up volume of verified content on social media. However, achieving the goal is challenging since we need to solve two problems: **(P1)** what information in original tweets should we use to find correct FC-articles? and **(P2)** how can we design a framework to retrieve and rank FC-articles?

With the first problem **(P1)**, we can use original tweets' text to find FC-articles. However, this approach is suboptimal since fake news can appear in many forms (e.g. text, images, videos) (Friggeri et al., 2014; O'Brien, 2018) as shown in Fig. 1. Thus, we propose to use both text and images of original tweets to search for FC-articles. Regarding the second problem **(P2)**, we propose a framework consisting of two key steps: (1) using a basic retrieval (i.e. BM25) to find initial lists of candidate FC-articles and then (2) re-ranking the initial lists by using advanced models for ranking refinement. In the first step, since original tweets' text may be insufficient to find correct articles as shown in Fig. 1 where there is no meaningful information in the text but in the image, we propose to expand original tweets' text by using text inside original tweets' images. For the second step, we propose an attention mechanism to focus on key textual matching signals and jointly integrate them with visual information to boost ranking quality. By tackling these issues, our contributions are as follows:

- To the best of our knowledge, our study is the first one that searches for fact-checking articles to increase users' awareness of fact-checked information when they are exposed to fake news.
- We propose a novel neural ranking model which jointly utilizes textual and visual matching signals. The model is also integrated with a novel attention mechanism.
- Experiments on two datasets demonstrate effectiveness and generality of our model over state-of-the-art retrieval techniques.

2 Related Work

Fake News and Fact-checking. Fake news detection methods mainly use linguistics and textual content (Zellers et al., 2019; Zhao et al., 2015; Wang, 2017; Shu et al., 2019), temporal spreading patterns (Liu and Wu, 2018; Ma et al., 2018), network structures (Wu and Liu, 2018; Liu et al., 2020) and users' feedbacks (Vo and Lee, 2019, 2020; Shu et al., 2019). Studies about multimodal fake news detection (Gupta et al., 2013; Wang et al., 2018b) are different from ours since their inputs are text and images of tweets while our inputs are pairs of a multimodal tweet and a FC-article.

Our work is closely related to evidence-aware fact-checking. Thorne et al. (2018); Nie et al. (2019) built a pipeline to find documents and sentences to fact-check mutated claims generated from Wikipedia pages, Wang et al. (2018a) aimed to find webpages related to given FC-articles and predict their stances on claims in the FC-articles. Popat et al. (2018) only focused on fact-checking and (Shaar et al., 2020) detected previously fact-checked claims. Our paper deviates from these work since we aim to find FC-articles given multimodal fake news in social media posts. As our goal is to increase users' awareness of verified news, studies about fact-checkers (Vo and Lee, 2018, 2019; You et al., 2019) are close to ours.

Neural Ranking Models for Text Search. Neural ranking models for text search mainly fall into two groups: semantic matching and relevance matching models. The former one seeks to learn representations of a query and a document, and measure their similarity (Huang et al., 2013; Shen et al., 2014; Severyn and Moschitti, 2015; Nie et al., 2019; Zhu et al., 2019), while the later one (Chen et al., 2018; Hui et al., 2017; Pang et al., 2016; Guo et al., 2016; Xiong et al., 2017; Hui et al., 2018; Dai et al., 2018) aims to capture relevant matching signals between a query and a document based on word interactions. There are methods unifying two categories such as Mitra et al. (2017); Rao et al. (2019a). Our model can be viewed as a relevance matching method in which a novel attention mechanism is designed to focus on crucial word interactions.

Neural Models for Multimodal Retrieval. Multimodal data (e.g. text and images) are used in cross-modal retrieval (Cao et al., 2016; Wang et al., 2017; Balaneshin-kordan and Kotov, 2018; Chen et al., 2016), visual Q&A task (Kim et al., 2018), product search (Laenen et al., 2018; Guo et al., 2018) and so on. Our work is the first using multimodal data in social media posts to search for verified information.

3 Our framework

Given an original tweet q and a FC-article d, where every original tweet q contains text and images and the article d contains text and/or images, we aim to derive function $f(q, d)$ which determines their relevancy[1]. We use $f(q, d)$ to rank all FC-articles.

Following (Thorne et al., 2018), we adopt the re-ranking methodology as follows: (1) quickly retrieving candidate FC-articles/documents[2] for each original tweet/query[3] by a basic retrieval and (2) re-ranking the candidates by our MAN (Multimodal Attention Network) as shown in Fig. 2. We describe our input representations, basic retrieval and MAN in following subsections.

3.1 Input Representations

We denote text and images of an original tweet q as (q_{text}, q_{images}) where q_{text} is a sequence of N words $\{w_i^q\}_{i=1}^N$ and q_{images} is a list of X images $\{v_i^q\}_{i=1}^X$. Similarly, text and images of a fact-checking article d are denoted as (d_{text}, d_{images}) where d_{text} is a sequence of M words $\{w_j^d\}_{j=1}^M$ and d_{images} is a list of Y images $\{v_j^d\}_{j=1}^Y$.

3.2 Basic Retrieval

We use BM25 as a basic retrieval due to its good performance compared with several ranking models (McDonald et al., 2018; Pang et al., 2017). Since using tweets' text may be insufficient to find relevant articles, we expand queries' text by using text extracted from images. For example, in Fig. 1, text extracted from the image is *Breaking News: Obama: "I won't leave if Trump is elected"*. Following (Vosoughi et al., 2018), we use a tool (OCR Space, 2020) to extract text in images. To our knowledge, our work is the first one using text in images to find verified information.

3.3 Multimodal Attention Network (MAN)

MAN has four components: (1) projection layers, (2) textual matching layer (3) visual matching layer and (4) unifying textual and visual information.

3.3.1 Projection Layers

We use two projection layers: one for Glove embeddings and the other one for contextual word embeddings.

Projection layer for Glove embeddings. Each word w, which can be w_i^q or w_j^d, is mapped into a vector $\mathbf{t} \in \mathbb{R}^{300}$ by a fixed word embedding layer initialized by Glove embeddings (Pennington et al., 2014). Then, the vector $\mathbf{t}$ is projected into $\mathbf{g} \in \mathbb{R}^P$ by a trainable linear layer shown in Eq. 1.

$$\mathbf{g} = tanh(\mathbf{W}_1 \cdot \mathbf{t} + \mathbf{b}_1) \quad (1)$$

where $\mathbf{W}_1 \in \mathbb{R}^{P\times300}$, $\mathbf{b}_1 \in \mathbb{R}^P$. P is projection dimensions. After going through the linear layer, we denote $\mathbf{g}_i^q \in \mathbb{R}^P$ and $\mathbf{g}_j^d \in \mathbb{R}^P$ as representations of word w_i^q and word w_j^d, respectively.

Projection layer for contextual word embeddings. Since Glove embeddings do not reflect context of words in queries and articles, we integrate ELMo (Peters et al., 2018) as a static encoder to generate contextual word embeddings. ELMo maps each word w, which can be w_i^q or w_j^d, into a vector $\boldsymbol{\ell} \in \mathbb{R}^{1024}$ which is then projected into $\mathbf{h} \in \mathbb{R}^P$ by a trainable linear layer shown in Eq. 2.

$$\mathbf{h} = tanh(\mathbf{W}_2 \cdot \boldsymbol{\ell} + \mathbf{b}_2) \quad (2)$$

where $\mathbf{W}_2 \in \mathbb{R}^{P\times1024}$, $\mathbf{b}_2 \in \mathbb{R}^P$. P is projection dimensions. After going through the linear layer, we denote $\mathbf{h}_i^q \in \mathbb{R}^P$ and $\mathbf{h}_j^d \in \mathbb{R}^P$ as contextual representations of words w_i^q and w_j^d, respectively.

3.3.2 Textual Matching Layer

We derive (1) Glove embeddings interactions, (2) attended interaction matrix and (3) contextual word embedding interactions, and input them to convolution neural networks (CNNs) for feature extraction.

Glove Embeddings Interactions. An article may be relevant to an original tweet if they have overlapping words or similar words. To capture such signals, we use cosine similarity to derive matrix $\mathbf{S} \in \mathbb{R}^{N\times M}$ as shown in Eq. 3.

$$\mathbf{S}_{ij} = \frac{\mathbf{g}_i^{qT} \cdot \mathbf{g}_j^d}{||\mathbf{g}_i^q|| \times ||\mathbf{g}_j^d||}, \text{i = 1..N, j = 1..M} \quad (3)$$

Let's look at an example of matrix $\mathbf{S}$ in Fig. 4(a) where x-axis is an article and y-axis is a query. Roughly speaking, matrix $\mathbf{S}$ looks like a *gray-scale image* in which the overlapping phrase 'at a costume party' is like a *segment* at the bottom of the image, suggesting the article is relevant to the query. To capture such patterns, CNNs are widely used.

Attended Interaction Matrix. Matrix $\mathbf{S}$ captures overlapping words between a query and an article. However, when word w_i^q is same as word w_j^d, sometime they may not have the same meaning. Thus, we need an attention mechanism to avoid over-reliance on raw similarities in matrix $\mathbf{S}$. Inspired by Tay et al. (2019), we measure how dissimilar w_i^q

---

[1] Relevance means that the fact-checking article fact-checks the query

[2] We use fact-checking articles, articles and documents interchangeably

[3] We use original tweets and queries interchangeably

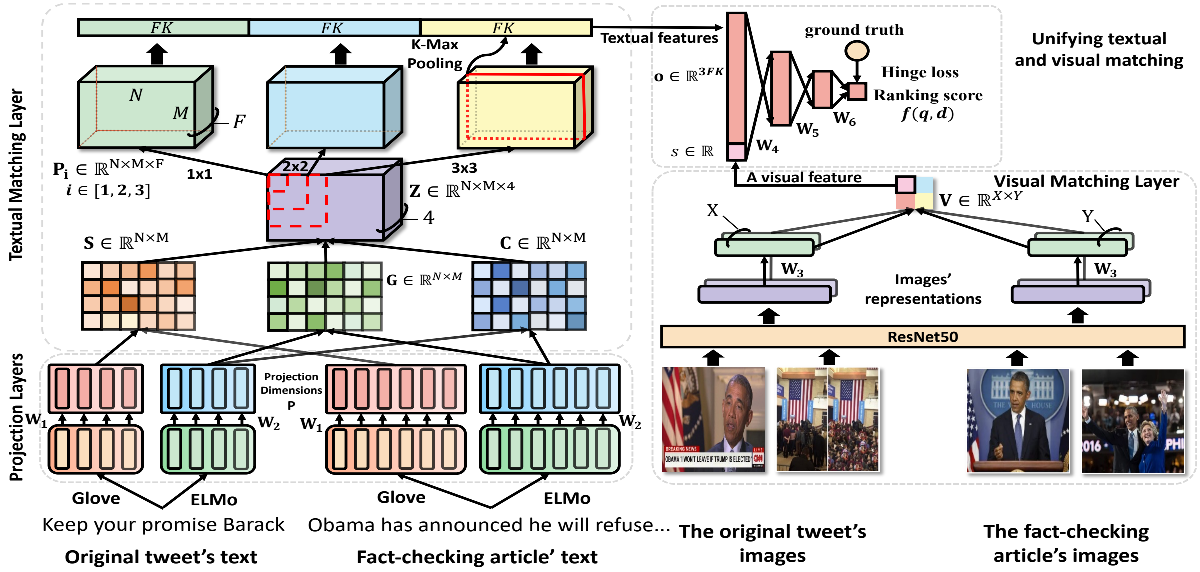


Figure 2: Our proposed model MAN

and w_j^d are based on Euclidean distance between their contextual representations as follows:

$$\mathbf{G}_{ij} = 2 \times \boldsymbol{\sigma}(-||\mathbf{h}_i^q - \mathbf{h}_j^d||), \text{i = 1..N, j = 1..M} \quad (4)$$

where $\boldsymbol{\sigma}(.)$ is a sigmoid function. Since Euclidean distance is non negative, $\boldsymbol{\sigma}(-||\mathbf{h}_i^q - \mathbf{h}_j^d||)$ will be in $(0, 0.5]$ and $\mathbf{G}_{ij}$ will be in $(0, 1]$. Therefore, we can use $\mathbf{G}_{ij}$ to attend to $\mathbf{S}_{ij}$ as follows:

$$\mathbf{A}_{ij} = \mathbf{S}_{ij} \times \mathbf{G}_{ij}, \text{i = 1..N, j = 1..M} \quad (5)$$

It is clear to see that when the distance between $\mathbf{h}_i^q$ and $\mathbf{h}_j^d$ is large, $\mathbf{G}_{ij}$ will be closer to 0 which helps downgrade impact of $\mathbf{S}_{ij}$. From Eq. 5, we can form attended interaction matrix $\mathbf{A} \in \mathbb{R}^{N \times M}$.

To our knowledge, our work is the first one using dissimilarity between contextual word embeddings to attend to interactions of Glove embeddings.

Contextual Word Embeddings Interactions. In our case studies in Section 6.5, we find that contextual word embeddings are able to capture high similarity between a typo and a normal word (e.g. hillar vs. hillary) while Glove embeddings fail to do so. To further exploit contextual embeddings, we derive matrix $\mathbf{C} \in \mathbb{R}^{N \times M}$ as follows:

$$\mathbf{C}_{ij} = \frac{\mathbf{h}_i^{qT} \cdot \mathbf{h}_j^d}{||\mathbf{h}_i^q|| \times ||\mathbf{h}_j^d||}, \text{i = 1..N, j = 1..M} \quad (6)$$

Again, we can view matrix $\mathbf{C}$ as a greyscale image as shown in Fig. 4(d). In addition to cosine similarities, we found that using bilinear function (Rao et al., 2019a) works pretty well as well.

Textual Feature Extraction. We stack matrices $\mathbf{S}$ (Eq. 3), $\mathbf{A}$ (Eq. 5) and $\mathbf{C}$ (Eq. 6) and $\mathbf{S} - \mathbf{C}$ to generate a tensor $\mathbf{Z} \in \mathbb{R}^{N \times M \times 4}$ shown in Eq. 7. The matrix $\mathbf{S} - \mathbf{C}$ is used to make our model aware of differences between interaction matrices.

$$\mathbf{Z} = [\mathbf{S} \oplus \mathbf{A} \oplus \mathbf{C} \oplus (\mathbf{S} - \mathbf{C})] \quad (7)$$

'$\oplus$' denotes matrix stacking. We apply n CNNs on tensor $\mathbf{Z}$ to extract features. The i^{th} CNN is performed with kernel size, stride and the number of filters equal to $i \times i \times 4$, 1 and F, respectively. The output feature map of the i^{th} CNN layer is $\mathbf{P}_i \in \mathbb{R}^{N \times M \times F}$, $i \in \{1..n\}$. Note, padding zeros are used to ensure $\mathbf{P}_i$ has size of $N \times M \times F$.

Next, we apply k-max pooling on each j^{th} output channel of $\mathbf{P}_i$ denoted as $\mathbf{P}_i[:,:,j] \in \mathbb{R}^{N \times M}$ to generate vector $\mathbf{o}_{i,j} \in \mathbb{R}^K$ as shown in Eq. 8.

$$\mathbf{o}_{i,j} = \text{kmax}(\mathbf{P}_i[:,:,j]), \text{ i = 1..n, j = 1..F} \quad (8)$$

Finally, nF vectors $\mathbf{o}_{i,j}$ are concatenated to create textual features vector $\mathbf{o} \in \mathbb{R}^{nFK}$ shown in Eq. 9.

$$\mathbf{o} = [\mathbf{o}_{1,1}; ...; \mathbf{o}_{i,j}; ...; \mathbf{o}_{n,F}] \in \mathbb{R}^{nFK} \quad (9)$$

3.4 Visual Matching Layer

A fixed pretrained ResNet50 (He et al., 2016) maps an image v, which is either an image of an original tweet v_i^q or an image of a FC-article v_j^d, into vector $\mathbf{v} \in \mathbb{R}^H$ which is then projected into vector $\mathbf{m} \in \mathbb{R}^T$ by a trainable linear layer: $\mathbf{m} = \mathbf{W}_3 \cdot \mathbf{v} + \mathbf{b}_3$, where $\mathbf{W}_3 \in \mathbb{R}^{T \times H}$ and $\mathbf{b}_3 \in \mathbb{R}^T$. H and T are set to 2048 and 300, respectively. After the linear layer, we denote $\mathbf{m}_i^q \in \mathbb{R}^T$ and $\mathbf{m}_j^d \in \mathbb{R}^T$ as representations of v_i^q and v_j^d, respectively.

Intuitively, an article is relevant to a query if the article has images similar to the query's images. Thus, we derive matrix $\mathbf{V} \in \mathbb{R}^{X \times Y}$ of pairwise similarities of images in Eq. 10.

$$\mathbf{V}_{ij} = \frac{\mathbf{m}_i^{qT} \cdot \mathbf{m}_j^d}{||\mathbf{m}_i^q|| \times ||\mathbf{m}_j^d||}, \text{i = 1..X, j = 1..Y} \quad (10)$$

Similar to (Rao et al., 2019a,b), we pool the largest pairwise similarity s as a visual feature as follows:

$$s = max(\mathbf{V}), \text{where } s \in \mathbb{R} \quad (11)$$

When the article has no images, s is set to -1.

3.5 Unifying Textual and Visual Information

We unify textual and visual information by appending scalar s (Eq. 11) to vector **o** (Eq. 9), denoted as $[\mathbf{o}; s]$, and derive $f(q, d)$ as shown in Eq. 12.

$$f(q, d) = \mathbf{W}_6 \cdot relu(\mathbf{W}_5 \cdot relu(\mathbf{W}_4 \cdot [\mathbf{o}; s])) \quad (12)$$

where $\mathbf{W}_4 \in \mathbb{R}^{128\times(nFK+1)}$, $\mathbf{W}_5 \in \mathbb{R}^{64\times128}$ and $\mathbf{W}_6 \in \mathbb{R}^{1\times64}$. We remove biases to avoid clutter. Our model is trained on triples consisting of a query q, relevant document d^+ and non-relevant document d^-, minimizing hinge loss in Eq. 13.

$$\mathcal{L}(q, d^+, d^-) = max(0, 1 - f(q, d^+) + f(q, d^-)) \quad (13)$$

4 Data Collection

Finding FC-articles, which address an original tweet, is laborious since we have to read many FC-articles even when using search engines (Popat et al., 2017, 2018). To reduce labeling efforts, we looked at existing datasets (Jiang and Wilson, 2018; Vosoughi et al., 2018; Vo and Lee, 2019) and found that a dataset in Vo and Lee (2019) met our need. The dataset provides non-anonymized pairs of an original tweet and its reply in which FC-articles, from two major fact-checking sites *snopes.com* and *politifact.com*, are embedded. *Fact-checkers* in Vo and Lee (2019) replied to the original tweet posters with FC-articles as evidence. From the original tweets' replies, we generate pairs of an original tweet q and a FC-article d. We also only kept original tweets where text and images are both available.

After preprocessing, we have 19,341 original tweet in English and FC-article pairs (q, d) in which there are 18,961 unique original tweets and 2,845 FC-articles. Following Vosoughi et al. (2018), a labeling step is conducted to ensure that in each pair, the article fact-checks the original tweet. We hired native U.S. English speakers since they were more likely to be familiar with topics in the tweets and FC-articles. The labelers labeled each pair (q, d) as 1 if the article d fact checked the tweet q. Otherwise, they labeled it as 0. They were trained directly by the authors and were asked to label several examples as exercises to ensure that they fully understood the task. We required labelers to read the original tweet's text, the article's text and images, and developed a labeling UI to help labelers to quickly explore the linked FC-articles shown in Fig. 5 in our appendix. For each pair, three different labelers labeled it. The final label is based on the majority vote. The Kappa value is 0.56, suggesting moderate agreement among the labelers (Viera et al., 2005).

The moderate agreement between labelers was because there were many pairs of an original tweet and a FC-article where the tweet and the article are topically similar but the article does not fact-check the tweet. For example, the tweet is about Hillary Clinton's mishandled classified emails while the article fact-checks if she gave uranium to Russia. Both the tweet and the article were about Hillary Clinton but the article did not precisely fact-check the tweet's content. As we utilized the dataset in (Vo and Lee, 2019) which was collected during the 2016 U.S. presidential election, many tweets and FC-articles were about misinformation related to Hillary Clinton and Donald Trump, leading to topically similar pairs which might confuse labelers. After labeling, we have a full dataset of 13,239 positive pairs made by 13,091 original tweets and 2,170 FC-articles.

We observe that there may be *false negatives* in the full dataset, meaning that a FC-article actually fact-checks an original tweet but the article is viewed as an irrelevant one (i.e., 100% precision but less than 100% recall) because the FC-article was not embedded in a fact-checker's reply. For example, an original tweet is fact-checked by both a Snopes article and a Politifact one but only the Snopes article was embedded in the fact-checker's reply to the original tweet while the Politifact one was not included in the reply. If we build a model on the full dataset, the false negatives may mislead our model. To mitigate impact of this problem, we split the full dataset into two sub datasets called Snopes and Politifact datasets. The former one contains pairs where FC-articles are from *snopes.com* and the later one contains pairs where FC-articles are from *politifact.com*. Note, there still may be false negatives in each sub dataset since an original tweet may have multiple fake news stories fact-checked by different articles from the same fact-checking website but a fact-checker did not embed all of the articles in the reply. But the number of false negatives under this case would be smaller than those in the full dataset. In Snopes dataset, we have 11,202 positive pairs made by 11,167 tweets and 1,703 FC-articles. In PolitiFact dataset, we have 2,037 positive pairs made by 2,026 tweets and 467 FC-articles. There are 102 overlapping tweets between the two datasets. The number of unique original posters is 8,277 and 1,482 in Snopes and Politifact respectively. On average, each original poster posted ∼1.35 tweets in our datasets.

5 Data Analysis

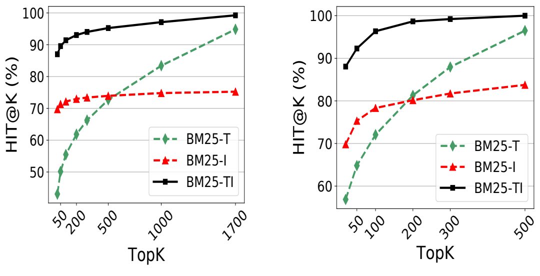
Topics of original tweets/queries. Since the topic of an original tweet is related to the topic of a corresponding FC-article, we extracted topics of relevant FC-articles to understand the topical distribution of tweets. By analyzing each FC-article, top 5 topics of tweets in Snopes are as follows: Politics (42.3%), Fauxtography (22.7%), Junk News (8.1%), Uncategorized (6.8%), Quotes (4.8%). For Politifact, tweets' topics are mostly about politics due to its political mission. In conclusion, our datasets captured various topics.

Similarity of text in tweets and text in images. As we utilize text in images to enhance ranking performance, we seek to understand how similar text in tweets and text in images. For each query/tweet having text in its images, we transformed its text in tweet and its text in images into two vectors of TF-IDF values, and computed their cosine similarity. From all queries of a dataset, we computed mean cosine similarity. The mean similarity is 0.083 and 0.102 for Snopes and Politifact respectively, indicating that text in tweets is less similar to text in images. The number of tweets/queries containing text in images is 8,494 (76%) and 1,742 (86%) for Snopes and Politifact respectively.

6 Experiments

6.1 Neural Ranking Baselines

We compare with 9 state-of-the-art neural ranking baselines, divided into 3 groups as follows: (1) multimodal retrieval methods including DVSH (Cao et al., 2016) and TranSearch (Guo et al., 2018), (2) semantic matching models including ESIM (Chen et al., 2017) and NSMN (Nie et al., 2019), and (3) relevance matching methods including Match-Pyramid (Pang et al., 2016), KNRM (Xiong et al., 2017), ConvKNRM (Dai et al., 2018), CoPACRR (Hui et al., 2018) and DUET (Mitra et al., 2017). Please see the appendix for details of the baselines.



(a) Snopes (b) Politifact

Figure 3: Performance of basic retrieval methods

6.2 Experimental Design

Evaluation Metrics. We adopt NDCG@K (Xiong et al., 2017) and HIT@K (He et al., 2017) as evaluation metrics. We report mean HIT@K and NDCG@K where K $\in [1, 3, 5]$ based on all queries. Since over 99.5% queries have only one relevant document, HIT@K is almost equal to Recall@K. Note, HIT@1 is equal to NDCG@1.

Performance of the Basic Retrieval. We test BM25 in three cases shown in Fig. 3: (1) queries are tweets' text (BM25-T), (2) queries are text in tweets' images (BM25-I) and (3) queries are tweets' text + text in tweets' images (BM25-TI).

In Fig. 3(a), HIT@50 of BM25-T is only 50% while BM25-I's HIT@50 is 70%, suggesting that a lot of fake news appear in images. This is because tweets' text has at most 280 characters. Images are more attractive to online users and easier to convey fake news to them. When K is larger, BM25-I's HIT@K saturates quickly since only 76% queries have text inside their images. Finally, BM25-TI is the best. Its HIT@50 is 89.6%. Similar patterns appear in Politifact in Fig. 3(b). With BM25-TI, HIT@50 is 94%. From these results, we choose BM25-TI as the basic retrieval of our framework.

Split Datasets. We need to choose value of K - the number of initial candidates for each query. If K is too small, initial candidates may not have relevant articles, leading to a meaningless re-ranking step. If K is too large, rerankers' running time may be high for online apps. We set K to 50 for both datasets. The number of queries, each of which has at least one relevant article in top 50 candidates, is 10,003 out of 11,167 for Snopes and 1,870 out of 2,026 for Politifact. Similar to Thorne et al. (2018), from these queries of each dataset, we randomly split them into train, validation and testing sets with ratio 80%/10%/10% as shown in Table 1. There are 1,164 and 156 leftover queries in Snopes and Politifact, respectively. Note, having leftover queries is a common issue for re-ranking based systems

Table 1: Split datasets

Datasets	Snopes			Politifact		
Items	Train	Valid	Test	Train	Valid	Test
|Original Tweets|	8,002	1,000	1,001	1,496	187	187
|FC-Articles|	1,703	1,697	1,697	467	467	467

(Thorne et al., 2018). Initial candidates output by BM25-TI are used by all neural ranking models.

Testing Scenarios. All models are tested in the re-ranking step with 2 scenarios (**SC1** and **SC2**). The main difference between them is whether to extract text from images of original tweets and FC-articles, and to incorporate the text with the other information (i.e., text and images of both the tweets and FC-articles). **SC1** and **SC2** are without text from images and with text from images, respectively.

Experimental Settings. For all baselines and our model, we use Adam optimizer (Kingma and Ba, 2014) with learning rate set to 0.001, and early stop training based on HIT@3 and NDCG@3 on a validation set with patience set to 10 epochs. Weight decay of L2-norm is 0.001. Batch size is 16. The number of negative documents sampled for each positive document during training is 3. Maxinum |words| in queries is 50 for **SC1** and 100 for **SC2** respectively. Maximum |words| in documents is 1,000. Vocab size V in Snopes dataset is 25,932 in **SC1** and 40,670 in **SC2** respectively. Vocab size V in Politifact dataset is 10,957 in **SC1** and 15,747 in **SC2** respectively. Maxinum |images| in queries is 4. Maxinum |images| in docs is 17. Images' shape is (224, 224, 3).

For our model, the number of projection dimensions P is chosen from $\{64, 128, 256, 512\}$. The number of output channels F is chosen from $\{16, 24\}$. The value of k in kmax pooling is chosen from $\{16, 32, 48\}$. The number of CNNs n is chosen from $\{1, 2, 3\}$. Our model performs best on Snopes with P, F, k and n equal to 256, 16, 32 and 2, respectively. It performs best on PolitiFact with P, F, k and n equal to 256, 16, 48 and 3, respectively. We implement our model with PyTorch 0.4.1 and test it on a NVIDIA 1080 GTX GPU.

6.3 Performance of Multimodal Attention Network and Variants

We also show results of MAN's variants as follows: (1) only using text (Eq. 9) and (2) only using images (Eq. 11). We call the former *Contextual Text Matching* (CTM) and the later *Visual Matching Network* (VMN). We show MAN's improvements wrt. the best result of baselines in each metric.

SC1: Re-ranking using images and text in tweets. In Table 2, our CTM outperforms the best baselines, achieving maximum improvements of 4.7% on NDCG@1. Our VMN amazingly outperforms text-based ranking baselines in Snopes perhaps because fauxtography is one of the most popular categories on Snopes (Friggeri et al., 2014) while Politifact mainly fact-checks political claims. By using both text and images, our MAN shows an average increase of 17.2% over the best baselines with the maximum improvement of 39.6%.

SC2: Re-ranking using images, tweets' text and images' text. We omit VMN from Table 3 since its results are same as Table 2. In Table 3, both our MAN and CTM outperform baselines on two datasets. Interestingly, MAN has lower performance than CTM on Snopes while it has higher performance than CTM on Politifact. We suspect that the abundance of textual signals between original tweets and FC-articles in **SC2** unintentionally makes MAN tend to favor textual signals and neglect visual signals. To remedy this issue, we propose to augment training data in **SC2** with training data in **SC1** while keeping the same validation and testing set from **SC2**. Intuitively, the augmented training data may regularize MAN better (Yu et al., 2018) by letting it observe both rich textual overlapping pairs in **SC2** and pairs with sparse textual signals in **SC1**. We name our model trained under the augmented training data as MAN-A. In Table 3, MAN-A mitigates the above issue with an average increase of 4.8% over the best baselines with the maximum improvement of 11.2%. Text in images has a high impact on performance of CTM and MAN. In Table 3, when using text in images to expand textual content of queries, performance of CTM and MAN increased by 17∼34% compared with their performances in Table 2.

From Tables 2 and 3, semantic matching models and multimodal baselines perform worse than relevance matching methods because the first two groups' goal is to compress whole queries and articles into dense vectors and measure their similarities. However, when compressing textual contents, some irrelevant information may be captured, leading to poor representations (Rao et al., 2019a).

In conclusion, our model MAN outperforms all baselines in both two testing scenarios .

Experiments on the leftover original tweets (i.e., 1,164 tweets in Snopes and 156 tweets in Politifact). We further test benefits of using text and images on each leftover query where we rank its x

Table 2: Performance of our models and baselines when using images and text in tweets

relevant articles against $50 - x$ negative documents randomly sampled by following Wan et al. (2016); Wu et al. (2017). It means there are 50 FC-articles per query/tweet. Table 4 shows results of our best model MAN-A and best baselines in each group. As expected, MAN-A outperforms all the baselines due to sparse textual content in leftover queries.

6.4 Effect of Contextual Word Embeddings

To understand effects of word embeddings on our model, we remove visual information and study re-ranking results of our model when (1) using only Glove embeddings, (2) using only contextual word embeddings from ELMo and (3) Glove+ELMo. In Table 5, when combining Glove and ELMo, we consistently achieve best NDCG in both datasets.

6.5 Case Studies

Qualitative comparison with the best baseline. An example tweet is 'You won't have to wait long [4]' embedded with a picture of an Antifa member beating a police officer. Clearly, the tweet's text does not have any meaningful information while the image contains useful information. Given the tweet, the best baseline CoPACRR failed to find relevant FC-articles, whereas MAN ranked the correct FC-article (Evon, 2017) in top-3 results.

Visualization of interaction matrices and attended matrix Fig. 4 visualizes matrices **S**, **G**, **A** and **C** in Eq. 3, 4, 5, 6 respectively of an original tweet and its FC-article from a testing set. Note, these matrices are learned by our model. In Fig. 4(a), Glove embeddings help reveal overlapping phrases (e.g. *at a costume party*, *clinton*) but closeness of *hillar* and *hillary* is not well captured (i.e. sim(*hillar*, *hillary*) = 0.3). In contrast, sim(*hillar*, *hillary*) is 0.86 in Fig. 4(d), indicating quality of contextual word embeddings. The matrix **G** in Fig. 4(b) has high values for key interactions (e.g. a list of values for *at a costume party* is [0.56,

Figure 4: Visualization of matrix **S**, matrix **G**, attended matrix **A** and matrix **C** (Best viewed in color)

0.66, 0.68, 0.69]) in lieu of uniform values [1.0, 1.0, 1.0, 1.0] in matrix **S**). When combing matrix **S** and **G**, we have a sparse matrix **A** in Fig. 4(c) which pays more attention to key interactions (e.g. *costume* and *party*). In conclusion, the attention mechanism helps us capture key matching signals.

Impact of Searching for FC-Articles. We measure how much impact we can make on online users when correct FC-articles are retrieved (i.e. HIT@1 = 1). Totally, our best model, MAN-A, accurately finds FC-articles for 910 original tweets in test set of Snopes dataset. From these tweets, the total number of their retweets is 527,299 and total number of followers of the original posters who posted 910 original tweets is 233M. Roughly speaking, we can inform fact-checked information to millions of users. Security systems can prevent half million shares of fake news in those original tweets.

7 Discussion

Since Snopes and Politifact are the most popular fact-checking sites, building two models for them is an acceptable cost. When facing a real-life social media post, we run two trained models sequentially. If there is no found FC-article, we can inform users that the post is unverified and suggest related pages from verified sites (e.g. governments' sites). When tweets do not have any images, we can use CTM which may find less relevant articles compared with MAN. However, CTM still performed better than the baselines as shown in Tables 2 and 3. We also built our best model (MAN-A) on the full dataset but observed some reduction in NDCG@1 and NDCG@3, but not HIT@3 compared with results of **SC2** on separate datasets maybe because of the *false negatives* described in Section 4. However, our model still outperformed the baselines.

There are a few things our work could be improved. First, our basic retrieval BM25-TI does not consider images' similarities. To improve BM25-TI, we may combine images' similarities and BM25's score. We leave it as future work. Second, we create train/test data based on unique original tweets. Though there are no retweets and quotes, it is hard to completely ensure all queries's content are unique. However, our settings are applied to all models for fair comparisons. In addition, as shown in Fig. 1, online users tend to re-post fake news. Therefore, it may be reasonable to have similar original tweets' content. Third, we tried to fine tune BERT but did not achieve good results perhaps because we did not have enough data. Interestingly, prior work (Shaar et al., 2020) also had a similar observation when fine-tuning BERT.

8 Conclusions

In this paper, we propose a novel method to alleviate the spread of fake news. By searching for FC-articles and incorporating fact-checked information into social media posts, we can warn users about fake news and discourage them from spreading misinformation. Our framework uses text and images to search for FC-articles, achieving an average increase of 4.8% over best baselines with the maximum improvement of 11.2%. Complementary to fake news detection methods, our method proactively scales up verified content on social media.

Our framework can be used for other multimodal retrieval tasks (e.g. searching for verified sites as we suggested in the previous section).

A Appendix for the Reproducibility

A.1 Labeling UI

We developed a labeling UI as shown in Fig. 5 to support labelers to quickly explore linked articles. It includes text and images of original tweets as well as text and images of a FC-article.

A.2 Descriptions and Hyperparameters of the Baselines

Multimodal Retrieval Models. DVSH (Cao et al., 2016) accepts a pair of a multimodal query and a multimodal article, and outputs similarity score. It uses cosine max-margin loss. We also tried to compare with DVSH by using hashcode of queries' text to match articles' images and vice versa. However, DVSH did not perform well perhaps because queries' text and documents' images may be not semantically similar. We implemented DVSH by ourselves because there is no publicly downloadable code. We set its hidden size to 300 and used AlexNet to extract visual features by following (Cao et al., 2016).

TranSearch (Guo et al., 2018) learns representations of queries by using queries' text and representations of documents by using text and images of the documents. For TranSearch, we omitted the pretraining step because our datasets do not have *also_viewed* or *buy_after_viewing* information. VGG19 was used to extract visual features by following (Guo et al., 2018). We used the publicly accessible TranSearch implementation.

Semantic Matching Models. We compare with ESIM (Chen et al., 2017) and NSMN (Nie et al., 2019). Both models utilize BiLSTM encoders to learn contextual representations and measure similarity between queries and documents. NSMN also uses contextual word embeddings from ELMo with skip connections for better performance. The pre-trained ELMo[5] with 93.6M parameters was used for NSMN and our proposed models. Its hidden size was 4,096, and output size was 512 with using 2 highway layers.

In ESIM, a hidden size was set to 300. In NSMN, we set its hidden size to 100 to all BiLSTM layers. We also tried to set its hidden size to $\{200, 300\}$ but we got out-of-memory error on our GPU because NSMN is memory-intensive due to concatenation of word embeddings, contextual embeddings from ELMo and multiple BiLSTM layers on our documents with 1,000 tokens.

Relevance Matching Models. We compare with several state-of-the-art models in this category. MatchPyramid (Pang et al., 2016) uses CNN to capture spatial patterns. KNRM (Xiong et al., 2017) and ConvKNRM (Dai et al., 2018) use RBF kernel to pool n-gram matching signals. CoPACRR (Hui et al., 2018) uses similarities between queries' representations and context-aware representations of words in documents to attend to matching signals. DUET (Mitra et al., 2017) unifies semantic and relevance matching signals into one model.

Implementation of MatchPyramid, KNRM, ConvKNRM, and DUET was obtained from MatchZoo (Guo et al., 2019). In MatchPyramid, we used default setting of MatchZoo. The number of kernels of KNRM and ConvKNRM was chosen from $\{7, 9, 11\}$. In ConvKNRM, we set |filters| to 300 like the word embeddings' dimension size. n-gram was chosen from $\{1, 2, 3\}$. In DUET, we followed the same architecture proposed in (Mitra et al., 2017).

In CoPACRR, the number of CNN layers was chosen from $\{2, 3, 4\}$, the number of filters was chosen from $\{5, 10, 15\}$, top k largest matching signals ns was chosen from {5, 10, 15}. The number of segments to conduct k-max pooling $cpos$ was chosen from {4, 5, 6} and context windows were chosen from $\{5, 9, 11\}$. We used the publicly accessible CoPACRR implementation.

Fortifying Toxic Speech Detectors Against Veiled Toxicity

ytsvetko@cs.cmu.edu

Abstract

Modern toxic speech detectors are incompetent in recognizing disguised offensive language, such as adversarial attacks that deliberately avoid known toxic lexicons, or manifestations of implicit bias. Building a large annotated dataset for such veiled toxicity can be very expensive. In this work, we propose a framework aimed at fortifying existing toxic speech detectors without a large labeled corpus of veiled toxicity. Just a handful of probing examples are used to surface orders of magnitude more disguised offenses. We augment the toxic speech detector's training data with these discovered offensive examples, thereby making it more robust to veiled toxicity while preserving its utility in detecting overt toxicity.[1]

Warning: this paper contains examples that may be offensive or upsetting.

1 Toxic Language in Disguise

Toxic language has been recognized as a severe problem in the online social communities. While great efforts have been made to detect and prevent the spread of overt trolling, hate speech, abusive language, and toxic comments (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018), they often build upon lexicon-based approaches (Waseem and Hovy, 2016; Davidson et al., 2017) and thus are ineffective at detecting forms of veiled toxicity; e.g., codewords (Taylor et al., 2017), novel forms of offense (Jain et al., 2018), and subtle and often unintentional manifestations of social bias such as microaggressions and condescension (Breitfeller et al., 2019; Wang and Potts, 2019).

In this work, we focus on disguised toxic language that is often undetected by existing tools.[2] It can be innocuous on the surface lexicon-level, but as offensive as hate speech and lastingly harmful (Sue et al., 2007; Sue, 2010; Nadal et al., 2014; Jurgens et al., 2019).[3]

Detecting veiled toxicity is hard: deep semantic analysis and large datasets are needed. But veiled offenses are not represented in existing toxicity datasets (Waseem and Hovy, 2016; Davidson et al., 2017; Founta et al., 2018) and building a new dataset is expensive: candidates for annotation cannot be filtered through lexicons and random sampling of social media posts will surface only a tiny fraction of relevant examples (Breitfeller et al., 2019). Moreover, since biased text is often unconscious and subjective, untrained annotators might mislabel it due to their own biases (Breitfeller et al., 2019; Field and Tsvetkov, 2020).

We propose a framework to surface veiled offenses and improve toxicity classifiers that are compromised in detecting them. It requires a small set of labeled probing examples to surface orders of magnitude more disguised offenses missed by the classifier, through interpretable ML techniques tracking the *influence* of training examples on classifier's predictions (Koh and Liang, 2017; Pruthi et al., 2020). From an original classifier that detects veiled toxicity with an accuracy of 1%, we achieve up-to 51% accuracy in detecting veiled offenses while preserving the utility of the classifier in detecting overt offenses. To the best of our knowledge, our work is the first in making toxic speech detectors robust against veiled toxicity with almost no annotated data.

---

[1] Our code is available at `https://github.com/xhan77/veiled-toxicity-detection`.

[2] We use the terms *veiled* and *disguised* toxicity interchangeably in this work.

[3] To demonstrate, an offensive example from the Social Bias Inference Corpus (Sap et al., 2020) *"What is the difference between a bench and an African? A bench can support a family."* is determined as non-toxic by a popular toxic speech detector Perspective API, `https://perspectiveapi.com/`; the example gets a toxicity score of 0.1 out of 1. It is originally from Reddit's r/darkJokes.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7732–7739,
November 16–20, 2020.

2 Identifying Veiled Toxicity

A typical toxicity classifier C might fail to identify veiled offenses because they are not well represented among toxic examples in its training data $\mathcal{D}$. Moreover, the non-toxic portion of $\mathcal{D}$ might be polluted with (mislabeled) disguised offenses. At inference time, C might thus mislabel, for example, microaggressions as well as adversarial attacks deliberately avoiding known toxic lexicons.

To make such compromised classifier C more robust, we propose a framework that does not require access to $\mathcal{D}$.[4] We start with a dataset $\mathcal{D}'$ comprising examples that can be labeled as offensive or non-offensive.[5] We build a student model C' on $\mathcal{D}'$ that approximates the behavior of C: $C' = \text{argmin}_\theta \mathcal{L}(\theta, x, C(x))$, where x are instances from $\mathcal{D}'$.

An effective C' would mimic the behavior of C, including mislabeling disguised toxic examples x_{veiled} as non-offensive. To address this issue, we surface the unknown x_{veiled} out of the training set by probing the C' with a small labeled held-out set of veiled offenses $\mathcal{P}$,[6] and tracing the model's decisions back to training examples in $\mathcal{D}'$. We hypothesize the 'influential' training examples that lead to C''s predictions on $\mathcal{P}$ are likely to be x_{veiled}. One probing example can surface multiple influential examples in the training data. These influential examples can then be re-annotated, making the model more robust to future veiled toxicity.

The key observation is that sampling on random a subset of non-offensive data to annotate it for disguised offensiveness is prohibitively expensive, as only a tiny fraction of annotated examples will be indeed offensive. Our proposed approach increases the likelihood to identify disguised offensiveness by surfacing training examples that influence the decisions of C' when tested on $\mathcal{P}$. The key challenge is to devise a method to track examples influential to classifier's predictions; we discuss candidate approaches in the rest of this section.

2.1 Probing for veiled toxicity

We explore several methods to define the influence $\mathcal{I}(x_{trn}, x_{prb})$ of a training example $x_{trn} \in \mathcal{D}'$ over a probing example $x_{prb} \in \mathcal{P}$.

Embedding product Modern neural classifiers often consist of two parts: an encoding module $f_{enc}(\cdot)$ that transforms the input to some hidden representation, and a projection layer $f_{proj}(\cdot)$ that projects the output of the encoding module to the label space. Our first influence measure is based on the intuition that the training example with the closest embedding to the probing example in the hidden encoding space could be the most influential:

$$\mathcal{I}(x_{trn}, x_{prb}) = f_{enc}(x_{trn}) \cdot f_{enc}(x_{prb}).$$

Influence functions Koh and Liang (2017) propose influence functions for ML models, following the vision from robust statistics. It first approximates how upweighting a particular training example (x_{trn}, y_{trn}) in the training set $\{(x_1, y_1), \ldots, (x_n, y_n)\}$ by an infinitesimal ϵ_{trn} would change the learned model parameters θ:

$$\frac{d\theta}{d\epsilon_{trn}} = -H_\theta^{-1} \nabla_\theta \mathcal{L}(\theta, x_{trn}, y_{trn}),$$

where $H_\theta = \frac{1}{n} \sum_{i=1}^{n} \nabla_\theta^2 \mathcal{L}(\theta, x_i, y_i)$ is the Hessian of the model. We can then use the chain rule to measure how this change in the model parameters would in turn affect the loss of the probing input:

$$\frac{d\mathcal{L}(\theta, x_{prb}, \hat{y}_{prb})}{d\epsilon_{trn}} = \nabla_\theta \mathcal{L}(\theta, x_{prb}, \hat{y}_{prb}) \cdot \frac{d\theta}{d\epsilon_{trn}},$$

where $\hat{y}_{prb}$ is the *wrong* label for the probing example, since we want to know which training examples lead to a *wrong* prediction of the probing disguised offense. The final influence of a train example to a probing example is defined as: $\mathcal{I}(x_{trn}, x_{prb}) = -\frac{d\mathcal{L}(\theta, x_{prb}, \hat{y}_{prb})}{d\epsilon_{trn}}$. More details of influence functions and their applications in NLP can be found in Koh and Liang (2017) and Han et al. (2020).[7]

Gradient product Computing the inverse Hessian H_θ^{-1} in the influence functions is expensive and requires approximations if the model is non-convex. If we ignore the inverse Hessian term, the calculation reduces to the dot product between the gradient of the training loss $\mathcal{L}(\theta, x_{trn}, y_{trn})$ and the gradient of the probing loss $\mathcal{L}(\theta, x_{prb}, \hat{y}_{prb})$.

---

[4] Since hate speech training data is often proprietary and platform-specific (MacAvaney et al., 2019).

[5] Here we assume a binary classifier for simplicity, but our setup is applicable to multi-class settings.

[6] Although it could be very expensive to create large-scale datasets for disguised offenses, it is feasible to collect a very small number (e.g., less than 100) of exemplars, using methods like user reporting, e.g., `https://www.microaggressions.com/`.

[7] Implementation details can be found in the Appendix.

This method is discussed in Pruthi et al. (2020). Specifically, we adopt the *TrackIn* method, which defines the influence as:

$$\mathcal{I}(x_{trn}, x_{prb}) = \sum_{i=1}^{k} \nabla_\theta \mathcal{L}(\theta_i, x_{trn}, y_{trn}) \cdot \nabla_\theta \mathcal{L}(\theta_i, x_{prb}, \hat{y}_{prb}),$$

where θ_i is the checkpoint of the model at each training epoch. The intuition behind this method is to approximate the total reduction in the probing loss $\mathcal{L}(\theta, x_{prb}, \hat{y}_{prb})$ during the training process when the training example x_{trn} is used. More details on *TrackIn* can be found in Pruthi et al. (2020).[8]

Training loss Our last method to define the influence of training examples can be considered as a baseline which is often used in active learning as 'uncertainty-based sampling' (Lewis and Gale, 1994; Zhu et al., 2008). The intuition is that a training example with a high loss (low confidence) could indicate that the model struggles to predict that example correctly. This alone can show that the outlier training example has a dubious label, regardless of its relationship to the probing example. For consistency, we define the influence of a training example to the mis-prediction of disguised offenses as: $\mathcal{I}(x_{trn}) = \mathcal{L}(\theta, x_{trn}, y_{trn})$.[9]

3 Experiments

3.1 Setup

We use a popular toxic language detection tool, Perspective API by Jigsaw and Google, as the compromised classifier C. It builds upon a convolutional neural network with pretrained word embeddings and proprietary large labeled data. For the student model C', we use a BERT-based model (Devlin et al., 2019), initialized with the pretrained weights and fine-tuned on our training set. Below we instantiate our training set $\mathcal{D}'$ and a probing set $\mathcal{P}$ of veiled offenses.

SBIC – Social Bias Inference Corpus (Sap et al., 2020) is a dataset containing 45K social media posts with crowdsourced annotations of offensiveness, intention, and targeted group from a variety of origins, including hate speech, offensive language, and microaggressions, and selected dangerous threads on Reddit (e.g., r/darkJokes) and hate sites. We use SBIC as our base dataset. We consider three attributes in SBIC posts: offensive, target some marginalized groups, while subtly expressed. Each post's offensiveness scores can be 0 (harmless), 0.5 (maybe offensive), or 1 (offensive). We select the posts with an average offensiveness > 0.5 (i.e., more than half of the annotators thought it was offensive). SBIC also asks annotators to identify the potential groups of people that might be offended by the post. We keep the posts with at least one identified target group.

We first extract **veiled toxicity set**. We randomly sample 10K general reddits from no specific domains and measure their average Perspective API toxicity score $tox_{general} \approx 0.17$ on a scale [0,1]. We then measure the Perspective API toxicity scores of the posts in SBIC that are offensive to at least one minority group. We sort these scores from low to high in $x_1, x_{(2)}, \cdots, x_{(n)}$. We pick the least toxic m posts as our veiled offensive language set so that $\frac{1}{m}\sum_{i=1}^{m} tox(x_{(i)}) = tox_{general}$. The extracted veiled offenses are equally non-toxic as some random general-domain reddits according to Perspective API.[10] There are about 3K resulting posts. We use 2K in our training set $\mathcal{D}'$ (as discussed in §2.1 they are (mis)labeled as non-toxic), 1K for the test set, and reserve 100 for the probing set $\mathcal{P}$.

It is worth noting that Perspective API can misclassify toxic inputs for several reasons. First, although it was trained on comments from online forums such as discussions of Wikipedia and New York Times, it could misclassify SBIC examples due to a domain mismatch leading to different manifestations of overt toxicity. In addition, as we discuss above, misclassifications can be attributed to novel lexicons of toxicity, to (intentional or unintentional) spelling variations, or to more subtly expressed implicit offenses. Our set of veiled offenses covers any of these forms, as they are hidden from the original toxicity detection model.[11]

We extract all SBIC posts annotated as non-offensive and also sort their Perspective API toxicity scores from low to high in $x_1, x_{(2)}, \cdots, x_{(n')}$. We pick the least toxic m' posts as our **non-offensive clean set** so that $\frac{1}{m'}\sum_{i=1}^{m'} tox(x_{(i)}) =$

---

[8] More influence metrics can be found in Yeh et al. (2018), Khanna et al. (2019), and Barshan et al. (2020). We leave the exploration of them in our framework to future work.

[9] Note that this method does not require probing examples.

[10] All toxicity scores are under 0.5, i.e., Perspective API labels none of them as offensive. 12.6% of instances with more than one annotation do not have a full annotator agreement that the instance is offensive.

[11] In practice, we observe the extracted veiled offenses to be indeed *covertly* toxic, as shown in a list of randomly selected examples in the Appendix, and not a mere domain mismatch.

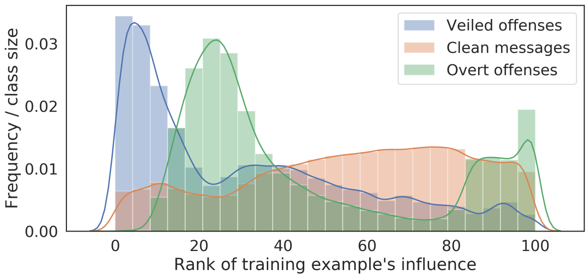

Figure 1: Distribution of each training example's influence rank to each probing veiled offense by the *gradient product* method. An influence rank towards 0(%) means a high influence.

$tox_{general}$. The intuition is to create a control set for the veiled offenses: these clean data are from the same domain as the veiled offenses, have the same Perspective API score as the veiled offenses on average, while being annotated in SBIC as non-offensive. There are about 10K posts in this category. We use 8K in $\mathcal{D}'$ and 1K for testing.

For the SBIC posts that are identified as offensive, we extract those with Perspective API toxicity score $>$ 0.8 (a recommended threshold by Perspective API for determining bad language) and consider them as our **overtly offensive set**. From 3K such posts, we use 2K in $\mathcal{D}'$ and 1K for testing.

3.2 Student model evaluation

Would a vanilla toxicity classifier recognize veiled offenses? We apply our student model C' on the three sets in §3.1. The model attains a class recall of 99.6% and 97.2% on the non-offensive and overtly offensive test sets, respectively. However, it fails to recognize test veiled offenses as offensive, yielding an 1.2% class recall. In sum, it mimics Perspective API's predictions accurately.

3.3 Evaluating probing and re-annotation

We hypothesized that the more influential a training example is to a wrongly predicted example from $\mathcal{P}$, the more probable that this training example is x_{veiled} – an undetected veiled offense by the original compromised classifier C. If this is indeed true, we may surface multiple x_{veiled} instances in the top influential training examples, and enable training data corrections with a high efficiency.

In Figure 1, we show a distribution of the training examples' influence rank derived by the gradient product method (§2.1).[12] The influence ranks of the veiled offenses are highly skewed towards the left of the spectrum (more influential) compared to others, confirming our hypothesis. In Table 1, we show the number of veiled offensive training examples surfaced among the most influential examples under different influence definitions. A random set of examples labeled as non-offensive would contain ≈20% veiled offenses.[13] All probing methods attain 1.5–3x better results than random, with influence function and gradient product methods outperforming the training loss baseline that is often used in the active learning scenario.[14]

Method	@ 500	1000	1500	2000
Random	100	200	300	400
Training loss	267	464	634	775
Embedding product	162	303	445	570
Influence function	259	472	647	806
Gradient product	**290**	**563**	**777**	**961**

Table 1: Number of veiled offenses found in the highest averagely ranked (most influential) training examples over all probing veiled offenses by different methods.

Does the detection and re-annotation of veiled offenses improve the model? We retrain the original student classifier and for each influence metric we: (1) simulate the active learning scenario, fixing the labels for veiled offenses within the top k examples (following gold SBIC annotations), and (2) flipping the labels for all of the top k examples, including the non-offensive clean data. The former mimics a scenario where extra human annotation is available; the latter requires no extra human labor, and is motivated by the observation that crowdsourced annotations of veiled toxicity are expensive and not always trustworthy. But this setup might compromise the model performance on non-toxic data, since we will also flip innocuous influential training instances.

Table 2 shows the performance of the models improved by each method. The *gradient product* method achieves the best performance in recognizing the veiled offenses. Flipping the labels for all top influential training examples helps this performance on veiled offenses more than only correcting

---

[12] Recall that each training example x_{trn} has an influence score over each probing example x_{prb}. For each x_{prb}, we rank the influence of all x_{trn}, creating an *influence rank* for each x_{trn} in $\mathcal{D}'$ w.r.t. x_{prb}.

[13] Since there are 2K veiled offenses and 8K non-offensive instances in the training set.

[14] We show in the Appendix that this result holds consistently even when probing with only 20 examples (instead of 100).

Model	Operation	VO	NO	OO
Original		1.2	99.6	97.2
Training loss	fix top 500	8.9	99.5	97.0
	fix top 2000	26.7	98.2	98.2
	flip top 500	13.0	97.9	98.2
	flip top 2000	41.5	85.2	99.4
Embedding product	fix top 500	3.4	99.7	95.6
	fix top 2000	16.9	98.7	98.6
	flip top 500	7.3	97.1	96.3
	flip top 2000	29.9	85.4	98.3
Influence function	fix top 500	9.5	99.5	97.3
	fix top 2000	28.0	98.7	98.0
	flip top 500	12.7	98.5	98.1

	fix top 2000	37.5	97.6	98.0
	flip top 500	14.6	97.6	98.4
	flip top 2000	51.1	87.6	99.5
Gold		76.0	94.8	98.2

Table 2: Class recall of the original model and the retrained models by different influence tracking methods on the veiled offensive (VO) test set, non-offensive (NO) test set, and overtly offensive (OO) test set.

the labels, but also compromises the performance on non-offensive clean data. All of the updated models still preserve the utility in recognizing the overt toxicity. However, there remains a significant gap between our improved models and the benchmark model, which has the correct information of all veiled offenses, clean data and overtly offensive language in the training set.

Examples Table 3 shows a probing example and top influential training examples identified by each influence metric. Using the training loss metric, we get exactly the same influential examples for every probing instance since the metric does not depend on the probing examples. It surfaces a racist comment, although Perspective API classified the whole sentence as not toxic. For the influence function metric, although the surfaced misogynistic example is overtly offensive, it was not recognized as toxic by Perspective API as well. The embedding product metric surfaces a post related to the topic of sexual harassment as the probing example, but the post is actually non-offensive, which underscores the need for further validation of surfaced comments using manual annotations or more sophisticated toxicity detection methods. Finally, the gradient product metric surfaces a homophobic microaggression. Overall, although these influence metrics can help finding candidates for veiled offensiveness, the discovered messages might not necessarily target the same social groups as the probing examples and also might not be toxic. Future work should focus on incorporating knowledge about social groups to the classifiers, and on a deeper analysis of presuppositions encoded in the surfaced messages to analyze toxicity in conversational and social contexts.

Probing example	Literally the only thing that matters for choosing a wife - The woman's chastity.
Training loss	What does Nike and KKK have in common? They both make the nigga's run.
Embedding product	Question: Can misandry be classified as sexual harassment and be subject to the same grounds for a lawsuit as misogyny?
Influence function	I would pay money to hatefuck some of the female users on this sub.
Gradient product	Of course I love you, I just prefer the straight part of you to the gay part.

Table 3: Top influential training examples to a probing veiled offense by different influence metrics.

4 Conclusion

We propose a framework to robustify toxicity classifiers against veiled toxicity. Through a few labeled probing examples, we can accurately surface orders of magnitude more disguised toxic messages missed by a compromised classifier, using interpretable ML techniques that track the influence of training examples on the probing examples. Our framework, however, is not limited to toxicity detection. Future work can explore how to enhance a sub-optimal model using the teacher-student setup for tasks that change across domains or over time, or in scenarios where the original model and data are restricted for privacy reasons.

A Implementation Details

The student classifier we used for experiments is a BERT-Base model (Devlin et al., 2019), adapted from Wolf et al. (2019). The model has 110 million parameters. We used the default BERT optimizer with default hyperparameters: a learning rate of 5e-5, a total of 3 epochs, a max sequence length of 200, and a training batch size of 24. The training (finetuning) of the student classifier would take approximately 10 minutes on one NVIDIA GeForce RTX 2080 Ti GPU.

For influence functions, we followed Han et al. (2020) which adapted code from Koh and Liang (2017) to PyTorch and used the same stochastic estimation trick, LiSSA (Agarwal et al., 2017). Since our model is not convex, we used a "damping" term of 3e-3. This value was picked so that the recursive approximation to the inverse Hessian-vector product can be finished (converged) in a reasonable time.[15] More specifically, we chose the recursion depth to be 3000 (with a total of 12k training examples), the number of recursions to be 1, and a scaling factor to be 1e8. In each step estimating the Hessian-vector product, we took a batch of 8 training examples for stability. We empirically checked that the inverse Hessian-vector product converges after the recursive estimation for all probing examples on which we performed the analysis.

For the gradient product method, we adopted *TrackInCP (Equally Weighted)* from Pruthi et al. (2020). We used 3 checkpoints of the BERT model (i.e., $k = 3$; one checkpoint after each epoch) since we finetuned the classifier with 3 epochs.

B Sample Veiled Offenses

Table 4 shows 20 random veiled offensive examples as extracted in §3.1. They got low toxicity scores from Perspective API, but were annotated as offensive to at least one social group according to the SBIC dataset. Most of them are *covert* but no less offensive to human readers.

C Robustness Check

In the main paper, we used 100 labeled veiled offensive examples as our probing set to discover more veiled offenses in the training set. As a robustness check, we show in Table 5 that the result is consistent when using only 20 probing examples.

---

[15] 15 minutes for each training and probing example pair on one NVIDIA GeForce RTX 2080 Ti GPU.

Explainable Automated Fact-Checking for Public Health Claims

Neema Kotonya and **Francesca Toni**
Department of Computing
Imperial College London, United Kingdom
`{nk2418,ft}@ic.ac.uk`

Abstract

Fact-checking is the task of verifying the veracity of claims by assessing their assertions against credible evidence. The vast majority of fact-checking studies focus exclusively on political claims. Very little research explores fact-checking for other topics, specifically subject matters for which expertise is required. We present the first study of explainable fact-checking for claims which require specific expertise. For our case study we choose the setting of public health. To support this case study we construct a new dataset PUBHEALTH of 11.8K claims accompanied by journalist crafted, gold standard explanations (i.e., judgments) to support the fact-check labels for claims[1]. We explore two tasks: veracity prediction and explanation generation. We also define and evaluate, with humans and computationally, three *coherence* properties of explanation quality. Our results indicate that, by training on in-domain data, gains can be made in explainable, automated fact-checking for claims which require specific expertise.

1 Introduction

A great amount of progress has been made in the area of automated fact-checking. This includes more accurate machine learning models for veracity prediction and datasets of both naturally occurring (Wang, 2017; Augenstein et al., 2019; Hanselowski et al., 2019) and human-crafted (Thorne et al., 2018) fact-checking claims, against which the models can be evaluated. However, a few blind spots exist in the state-of-the-art. In this work we address specifically two shortcomings: the narrow focus on political claims, and the paucity of explainable systems.

One subject area which we believe could benefit from expertise-based fact-checking is public health – including the study of epidemiology, disease prevention in a population, and the formulation of public policies (Turnock, 2012). Recent events, including the COVID-19 pandemic, demonstrate the significant potential harm of misinformation in the public health setting, and the importance in accurately fact-checking claims. Unlike political and general misinformation, specific expertise is required in order to fact check claims in this domain. Oftentimes this expertise may be limited, and thus claims which surround public health may be inaccessible (e.g., because of the use of jargon and biomedical terminology) in a way political claims are not. Nonetheless, like political misinformation, the public health variety is also potentially very dangerous, because it can put people in imminent danger and risk lives.

Typically, statements which are candidates for fact-checking originate in the political domain (Vlachos and Riedel, 2014; Ferreira and Vlachos, 2016; Wang, 2017), and tend to surround more general topics or be non-subject specific (Thorne et al., 2018). This follows the trend of the rising interest in political fact-checking in the last decade (Graves, 2018). There are on-going efforts with respect to fact-checking scientific claims (Grabitz et al., 2017). Fact-checking in domains where specific subject expertise is required presents an interesting challenge because general purpose fact-checking systems will not necessarily adapt well to these domains.

The second shortcoming we look to address is the paucity of explainable models for fact-checking (of any kind). Explanations have a particularly important role to play in the task of automated fact-checking. The efficacy of journalistic fact-checking hinges on the credibility and reliability of the fact-check, and explanations (e.g., provided by model agnostic tools such as LIME (Ribeiro et al., 2016)) can strengthen this by communicating fidelity in

predictive models. Explainable models can also aid the end users' understanding as they further elucidate claims and their context.

In this study we explore the novel case of explainable automated fact-checking for claims for which specialised expertise or in-domain knowledge is essential. For our case study we examine the the public health (biomedical) context.

The system for veracity prediction we aim to produce must fulfil two requirements: (1) it should provide a human-understandable explanation (i.e., judgment) for the fact-checking prediction, and (2) that judgement should be understandable for people who do not have expertise in the subject domain. We list the following as our **three main contributions** in this paper:

1. We present a novel dataset for explainable fact-checking with gold standard fact-checking explanations by journalists. To the best of our knowledge, this is the first dataset specifically for fact-checking in the public health setting.

2. We introduce a framework for generating explanations and veracity prediction specific to public health fact-checking. We show that gains can be made through the use of in-domain data.

3. In order to evaluate the quality of our fact-checking explanations, we define three coherence properties. These can be evaluated by humans as well as computationally, as approximations for human evaluations of fact-checking explanations.

The explanation model trained on in-domain data outperforms the general purpose model on summarization evaluation and also when evaluated for explanation quality.

2 Related Work

A number of recent works in automated fact-checking look at various formulations of fact-checking and its analogous tasks (Ferreira and Vlachos, 2016; Hassan et al., 2017; Zlatkova et al., 2019). In this paper, we choose to focus on the two specific aspects of concern to us, which have not been thoroughly explored in the literature. These are domain-specific and expertise-based claim verification and explainability for automated fact-checking predictions.

2.1 Language Representations for Health

Fewer language resources exist for medical and scientific applications of NLP compared with other NLP application settings, e.g., social media analysis, NLP for law, and computational journalism and fact-checking. We consider the former below.

There are a number of open source pre-trained language models for NLP applications in the scientific and biomedical domains. The most recent of these pre-trained models are based on the BERT language model (Devlin et al., 2019). One example is BIOBERT, which is fine-tuned for the biomedical setting (Lee et al., 2020). BIOBERT is trained on abstracts from PubMed and full article texts from PubMed Central. BIOBERT demonstrates higher accuracies when compared to BERT for named entity recognition, relation extraction and question answering in the biomedical domain.

SCIBERT is another BERT-based pre-trained model (Beltagy et al., 2019). SCIBERT is trained on 1.14M Semantic Scholar articles relating to computer science and biomedical sciences. Similar to BIOBERT, SCIBERT also shows improvements on original BERT for in-domain tasks. SCIBERT outperforms BERT in five NLP tasks including named entity recognition and text classification.

Given that models for applications of NLP tasks in the biomedical domain, e.g., question answering, show marked improvement when domain-specific, we hypothesize that public health fact-checking could also benefit from the language representations suited for that specific domain. We will make use of both SCIBERT and BIOBERT in our framework.

2.2 Explainable Fact-Checking.

A number of in-roads have been made in developing models to extract explanations from automated fact-checking systems. To our knowledge, the current state of the art in explainable fact-checking mostly looks to produce extractive explanations, i.e., explanations for veracity predictions in relation to inputs to the system. Instead, our focus in this paper is on abstractive explanations. We choose this approach, which aims to distill the explanation into the most salient components which form it, as more amenable to users with limited domain expertise, as we discuss below.

Various methods have been applied to the explainable fact-checking task. These methods span the gamut form logic-based approaches such as probabilistic answer set programming (Ahmadi et al., 2019) and reasoning with Horn rules (Ahmadi et al., 2019; Gad-Elrab et al., 2019) to deep learning and attention-based approaches, e.g., leveraging co-attention networks and human annotations in the form of news article comments (Shu et al., 2019a). The outputs of these systems also take a number of forms including Horn rules (Ahmadi et al., 2019), saliency maps (Shu et al., 2019a; Popat et al., 2018), and natural language generation (Atanasova et al., 2020).

All approaches produce explanations which are a distillation of the most relevant portion of the system input. In this paper we expand on the work by Atanasova et al. as we formulate explanation generation as a summarization exercise. However, our work differs from the existing literature as we construct a framework for joint extractive and *abstractive* explanation generation, as opposed to a purely extractive model. We choose an abstractive approach as we hypothesize that particularly in the case of public health claims, where specific expertise is required to understand the context, abstractive explanations can make the explanation more accessible, particularly for those with little knowledge of the subject matter. In this way we take into account the nature of the claims, something other explainable fact-checking systems do not consider.

2.3 Evaluation of Explanation Quality

Only a few explainable fact-checking systems employ thorough evaluation in order to assess the quality of explanations produced. In the cases where evaluations are provided, these primarily take the form of human evaluation, e.g., enlisting annotators to score the quality of explanations with respect to some properties (Atanasova et al., 2020; Gad-Elrab et al., 2019) or through the use of an established evaluation metric in the case where explanation generation is modelled as another task (Atanasova et al., 2020).

There is also work on the evaluation of explanation quality more broadly, independently of the task for which explanations are sought. Notably, Sokol and Flach (2019) present explainability factsheets for evaluating (machine learning) explanations along five axes, including usability. One of the usability criteria discussed by Sokol and Flach is *coherence*, which we use to develop our three explanation quality properties (see Section 5.3). Whereas Sokol and Flach discuss coherence in general, we provide concrete definitions and use them for evaluating our methods for explaining veracity predictions for public health claims.

3 The PUBHEALTH dataset

We constructed a dataset of 11,832 claims for fact-checking, which are related a range of health topics including biomedical subjects (e.g., infectious diseases, stem cell research), government healthcare policy (e.g., abortion, mental health, women's health), and other public health-related stories (see *unproven*, *false* and *mixture* examples in Table 1), along with explanations offered by journalists to support veracity labelling of these claims. The claims were collected from two sources: fact-checking websites and news/news review websites. An example dataset entry is shown in Table 1.

To the best of our knowledge, this is the first fact-checking dataset to explicitly include gold standard texts provided by journalists specifically as explanation of the fact-checking judgment. We describe below how the data was collected and processed to obtain the final PUBHEALTH dataset, and provide an analysis of the dataset.

3.1 Data collection

Initially, we scraped 39,301 claims, amounting to: 27,578 fact-checked claims from five fact-checking websites (Snopes[2], Politifact[3], TruthorFiction[4], FactCheck[5], and FullFact[6]); 9,023 news headline claims from the health section and health tags of Associated Press[7] and Reuters News[8] websites; and 2,700 claims from the news review site Health News Review (HNR)[9].

We scraped data for two text fields which are essential for fact-checking: 1) the full text of the fact-checking or news article discussing the veracity of the claim, and 2) the fact-checking justification or news summary as explanation for the veracity label of the claim. We also collected the URLs of sources cited by the journalists in the fact-checking and news articles. For each URL, in the case where the referenced sources could be accessed and read, we also scraped the source texts.

Claim	Label	Explanation
Blue Buffalo pet food contains unsafe and higher-than-average levels of lead.	UNPROVEN	Aside from a single claimant's lawsuit against Blue Buffalo and an unrelated recall on one variety of Blue Buffalo product in March 2017, we found no credible information suggesting that Blue Buffalo dog food was tested and found to have abnormally high levels of lead.
Children who watch at least 30 minutes of "Peppa Pig" per day have a 56 percent higher probability of developing **autism**.	FALSE	Talk of a Harvard study linking the popular British children's show "Peppa Pig" to **autism** went viral, but neither the study nor the scientist who allegedly published it exists.
Expired boxes of cake and pancake mix are dangerously toxic.	MIXTURE	What's true: Pancake and cake mixes that contain mold can cause **life-threatening allergic reactions**. What's false: Pancake and cake mixes that have passed their expiration dates are not inherently dangerous to ordinarily **healthy** people, and the yeast in packaged baking products does not "over time develops spores."
Families tell U.S. lawmakers of **heparin** deaths.	TRUE	A man who said he lost his wife and a son to reactions from tainted **heparin** made with ingredients from China urged U.S. lawmakers on Tuesday to protect **patients** from other unsafe **drugs**.

Table 1: Example of claims and explanations for PubHealth dataset entries. Vocabulary from the public health glossary which are contained in the claims and explanations are highlighted in **bold**.

All claims make reference to articles published between October 19 1995 and May 14 2020. In addition to the claim, article texts, explanation texts, and the date on which the fact-check or news article was published, we scraped meta-data related to each claim. These meta-data include the tags (single or multiple tokens) which may, for example, categorize the topics of the claim or indicate the source of the claim (see Appendix A.1), and the names of the fact-checkers and news reporters who contributed to the article.

3.2 Data processing and analysis

The data processing involved three tasks: standardizing the veracity labels, filtering out non-biomedical claims from the dataset, and finally removing claims with incomplete and brief explanations.

Labels for news headline claims did not require standardization, as we assumed all news headline claims (coming from reputable sources as they were) to be verified and thus labelled these *true*, but filtered out from the dataset news entries with the headline prefixes "AP EXCLUSIVE", "Correction", "AP Interview", and "AP FACT CHECK". Indeed, it would be difficult to label the veracity of the claim in this type of entries. On the other hand, fact-check and news claims, which were associated with 141 different veracity labels, did require compression. We standardized the original labels for 4-way classification (see Appendix A.1). The chosen 4 labels are *true*, *false*, *mixture*, and *unproven*. We discounted claims with labels that cannot be reduced to one of these 4 labels. The distribution of labels in the final PubHealth is shown in Table 2. The dataset consists of a majority false claims. Unproven claims are the least common in the dataset.

Website	tru.	fal.	mix.	unp.	total
AP News	2,132	0	0	0	2,132
FactCheck	0	50	29	8	87
FullFact	65	39	16	48	168
HNR	819	839	745	0	2,433
Politifact	671	1,339	423	0	2,433
Reuters	1,971	0	0	0	1,971
Snopes	386	1,131	405	220	2,142
TruthOrFict.	132	172	120	72	496
Total	6,176	3,570	1,526	299	11,832

Table 2: Summary of the distribution of true (**tru.**), false (**fal.**), mixture (**mix.**) and unproven (**unp.**) veracity labels in PubHealth, across the original sources from which data originated.

The second step in processing the data was to remove claims with no biomedical context. This step was especially crucial for the claims which originated from fact-checking websites where the bulk of fact-checks concern political and economic claims. Health claims are easier to acquire from news websites, such as Reuters, as they can be quickly identified by the section of the website in which they were located during the data collection process. Although we mentioned that a sizeable number of claims from fact-checking sources are related to political events, some are connected to both political and health events or other mixed health context, and we collected claims whose subject matter intersects other topics in order to obtain a subject-rich dataset (see Appendix A.1).

Claims in the larger dataset were filtered according to a lexicon of 7,000 unique public health and health policy terms scraped from five health information websites (See Appendix A.1).

Furthermore, we manually added 65 more public health terms that were not retrieved during the initial scraping, but which we determined would positively contribute to the lexicon because of their relevance to the COVID-19 pandemic (see Appendix A.1). These claims were identified through exploratory data analysis of bigram and trigram collocations in PUBHEALTH.

In order to filter out the entries which are not health-related, we kept only claims with main article texts that mentioned more than three unique terms in our lexicon. Specifically, let L be our lexicon, and A_c and T_c, respectively, be the article text and claim text accompanying a candidate dataset entry c. Then, we included in PUBHEALTH only the following set C of claim entries, with accompanying information:

$$C_A = \{c \mid \{l_1, ..., l_n\} = A_c \cap L, n > 3\}$$
$$C_T = \{c \mid \{l_1, ..., l_n\} = T_c \cap L, n > 3\}$$
$$C = C_A \cup C_T \qquad (1)$$

As we already knew that all Reuters health news claims qualify for our dataset, we used the lower bound frequency of words from our lexicon present in these article texts to determine our lower bound of three unique terms. We acknowledge that there might be disparities in the amount of medical information present in entries. However, analysis of the dataset shows, quite promisingly, that on average claims' accompanying article texts have 8.92 ± 5.54 unique health lexicon terms and claim texts carry 4.45 ± 0.88 unique terms from the health lexicon.

Claims and explanations in the entries in the dataset were also cleaned. Specifically, we also ensured all claims are between 25 and 400 characters in length. We removed explanations less than 25 characters long as we determined that very few claims shorter than this length contained fully formed claims; we removed claims longer than 400 characters to avoid the complexities of dealing with texts containing multiple claims. We also omitted claims and explanations ending in a question mark to ensure that all claims are statements, i.e., clearly defined.

Note that one aspect of the explanations' quality which we chose not to control, was the intended purpose of the text we labelled as the explanation: as shown in Table 7 in Appendix A.1, there was a wide variation across the websites we crawled.

Table 3 shows the Flesch-Kincaid (Kincaid et al., 1975) and Dale-Chall (Chall and Dale, 1995) readability evaluations of claims from our fact-checking dataset when compared to four other fact-checking datasets. The results show that PUBHEALTH claims are, on average, the most challenging to read. Claims from our dataset have a mean Flesch-Kincaid reading ease score of 59.1, which corresponds to a 10th-12th grade reading level and fairly difficult to read. The other fact-checking datasets have reading levels which fit into the 6th, 7th and 8th grade categories. Similarly for the Dale-Chall readability metric, on average our claims are more difficult to understand. Our claims have a mean score of 9.5 which is equivalent to the reading age of college student, whereas all other datasets' claims have an average score which indicates that they are readable by 10th to 12th grade students. Both these results support our earlier assertion about the complexity of public health claims relative to political and more general claims.

Dataset	**Flesch-Kincaid**		**Dale-Chall**	
	μ	σ	μ	σ
Wang (2017)	61.9	20.2	8.4	2.2
Shu et al. (2019b)	67.1	24.3	8.9	3.0
Thorne et al. (2018)	71.7	24.9	8.2	3.3
Augenstein et al. (2019)	60.8	22.1	8.9	2.5
Our dataset	59.1	23.3	9.5	2.6

Table 3: Comparison of readability of claims presented in large fact-checking datasets (i.e., those with > 10K claims). We compute the mean and standard deviation for Flesch-Kincaid and Dale-Chall scores of claims for LIAR (Wang, 2017), FEVER (Thorne et al., 2018), MultiFC (Augenstein et al., 2019), FAKENEWSNET (Shu et al., 2019b), and also our own fact-checking dataset. The sample sizes used for evaluation for each dataset are as follows, LIAR: 12,791, MultiFC: 34,842, FAKENEWSNET: 23,196, FEVER: 145,449, and 11,832 for our dataset.

.

4 Methods

In this section we describe in detail the methods we employed for devising automated fact-checking models. We trained two fact-checking models: a classifier for veracity prediction, and a second summarization model for generating fact-checking explanations. The former returns the probability of an input claim text belonging to one of four classes: true, false, unproven, mixture. The latter uses a form of joint extractive and abstractive summarization to generate explanations for the veracity of claims from article text about the claims. Full details of hyperparameters chosen and computer infrastructure which was employed can be found in Appendix A.2.

4.1 Veracity Prediction

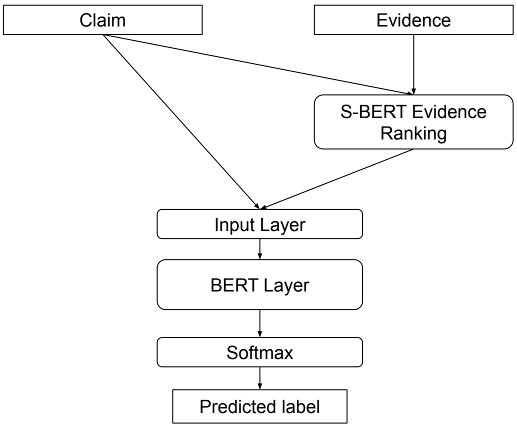

Figure 1: Architecture of veracity prediction.

Veracity prediction is composed of two parts: evidence selection and label prediction (see Figure 1).

For evidence selection, within fact-checking and news articles, we employ Sentence-BERT (S-BERT) (Reimers and Gurevych, 2019). SBERT is a model for sentence-pair regression tasks which is based on the BERT language model (Devlin et al., 2019), to encode contextualized representations for each of the evidence sentences and then rank these sentences according to their cosine similarity with respect to the contextualized representation of the claim sentence. We then select the top k sentences for veracity prediction. As with sentence selection approaches from the fact-checking literature (Nie et al., 2019; Zhong et al., 2019), we choose $k = 5$.

The claim and selected evidence sentences form the inputs for the label prediction part of our model (see Figure 1). We fine-tuned, on the PUBHEALTH dataset, pre-trained models for the downstream task of fact-checking label prediction. We employed four pre-trained models: original BERT uncased, SCIBERT, BIOBERT v1.0, and also BIOBERT v1.1. The two versions of BIOBERT differ slightly in that the earlier version is trained for 470K steps on PubMed abstracts and PubMed Central (PMC) full article texts, whereas BIOBERT v1.1 is trained for 1M steps on PubMed abstracts.

4.2 Explanation Generation as Abstractive Summarization

We make use of extractive-abstractive summarization (Liu and Lapata, 2019) in developing the explanation model. We choose this architecture because explanations for claims which concern a specific topic area having a highly complex lexicon can benefit from the ability to articulate judgment in simpler terms. In order to deploy the model proposed by (Liu and Lapata, 2019) we also implemented an explanation generation model.

Just as is the case for the predictor model, the explanation model is fine-tuned for the task on evidence sentences ranked by S-BERT. However, for the explanation model we use all article sentences as well as the claim sentence to fine-tune a BERT-based summarization model pre-trained on the Dailymail/CNN news article and summaries dataset (Hermann et al., 2015). One of our models, EXPLAINERFC, is fine-tuned using non-public health data, which we extract from the portion of the 39.3K originally crawled fact-checks, news reviews, and news articles not included in PUBHEALTH. For fairness, we ensure these data have the same proportion of claims from each website and the number of examples is the same as PUBHEALTH. The second model, EXPLAINERFC-EXPERT, is fine-tuned on PUBHEALTH. Also, we evaluate both models on PUBHEALTH test data. Table 2 shows an example of the explanations generated by the two methods.

5 Results

We conducted experiments to evaluate the performance of both predictor(s) and explainer(s). The performance of the (various incarnations of the) prediction model is evaluated using an automatic approach, whereas the performance of the (two incarnations of the) explainer is assessed using both automatic and human evaluation.

Claim **Label: FALSE**

Under Obamacare, patients 76 and older must be admitted to the hospital by their primary care physicians in order to be covered by Medicare.

Gold explanation

Obamacare does not require that patients 76 and older must be admitted to the hospital by their primary care physicians in order to be covered by Medicare.

EXPLAINERFC explanation

What's true: nothing in the Affordable Care Act requires that a primary care physician admit patients 76 or older to a hospital in order for their hospital care to be treated under Medicare. What's false: none of the provisions or rules put an upper age limit on medicare coverage.

EXPLAINERFC-EXPERT explanation

The Affordable Care Act does not require Medicare to admit patients to a hospital after paying the Part B deductible. It's not the same age limit on medicare coverage. But the evidence doesn't specifically set an upper age limit.

Figure 2: Example of model-generated explanations as compared to the gold standard from our fact-checking dataset.

5.1 Prediction

We split the PubHealth dataset as follows: 9,466 training examples, 1,183 examples for validation and 1,183 examples for testing.

We evaluated veracity prediction using macro-F1, precision, recall and accuracy metrics as shown in Table 4. We employ two baselines: a randomized sentence selection approach with BERT (bert-base-uncased) classifier, and lastly a BERT model, also using pre-trained uncased BERT, which does not make use of sentence selection and instead makes use of the entire article text to fine-tune for the fact-checking task.

Out of the four BERT-derived models, SciBERT achieves the highest macro F1, precision and accuracy scores on the test set. BioBERT v1.1 achieves the second highest scores for F1, precision and accuracy. As expected, BioBERT v1.1 outperforms BioBERT v1.0 on all four metrics. The standard BERT model achieves the highest precision score of the four models, however it also achieves the lowest recall and F1 scores. This supports the argument we presented in Section 1 that subject-specific fact-checking can benefit from training on in-domain models.

Model	**Pr.**	**Rc.**	**F1**	**Acc.**
BERT (rand. sents.)	38.97	39.38	39.16	20.99
BERT (all sents.)	56.50	56.50	56.50	55.40
BERT (top k sents.)	**77.39**	54.77	63.93	66.02
SciBERT	75.69	**66.20**	**70.52**	**69.73**
BioBERT 1.0	73.93	57.57	64.57	65.18
BioBERT 1.1	75.04	61.68	67.48	68.89

Table 4: Veracity prediction results for the two baselines and four BERT-based models on the test set. Model performance is assessed against precision (Pr.), recall (Rc.), macro F1, and accuracy (Acc.) metrics.

5.2 Explanations

We use two methods for evaluating the quality of explanations generated by our methods: automated evaluation and qualitative evaluation, in turn amounting to human and computational evaluation of explanation properties.

5.2.1 Automated Evaluation

We make use of ROUGE summarization evaluation metrics (Lin, 2004). Specifically we use the F1 values for ROUGE-1, ROUGE-2, and ROUGE-L, to evaluate the explanations generated by the ExplainerFC and ExplainerFC-Expert models.

As in the setup employed by Liu and Lapata (2019), we compare our explanation models to two other methods: a Lead-3 baseline, which constructs a summary out of the first three sentences of an article, and an extractive summarization-based Oracle upper bound. The results of this evaluation are shown in Table 5. The ExplainerFC-Expert explanation model outperforms ExplainerFC. ExplainerFC-Expert achieves higher scores than ExplainerFC for R1, R2, and RL metrics.

Model	ROUGE-F R1	 R2	 RL
Oracle	39.24	14.89	32.78
Lead-3	29.01	10.24	24.18
ExplainerFC	31.42	12.38	26.27
ExplainerFC-Expert	**32.30**	**13.46**	**26.99**

Table 5: ROUGE-1 (R1), ROUGE-2 (R2) and ROUGE-L (RL) F1 scores for explanations generated via our two explanation models.

5.3 Evaluation of Explanation Quality

As the explanations we generate are from heterogeneous sources (and therefore not directly comparable), evaluation using ROUGE does not present us with a complete picture of the usefulness or quality of these explanations. For this reason, we adapt to the task of explainable fact-checking three of the desirable usability properties for machine learning explanations offered by Sokol and Flach (2019). We define these properties formally and evaluate the quality of the generated explanations against them. These same properties are also used for our human evaluations and for a comparison between human and computational evaluation of the quality of our explanations. To the best of our knowledge, ours is the first systematic evaluation of the quality of explanations for fact-checking in terms of formal properties. We define the three explanation properties as (two forms of) global coherence and (a form of) local coherence, as follows.

Global Coherence refers to the suitability of fact-checking explanations with respect to both the claim and label to which it is associated. We consider two incarnations of global coherence:

- *Strong global coherence.* Let E be an explanation of the veracity label l for claim C, where $e_1, \ldots, e_N$ are all the individual sentences which make up E. Then, E satisfies strong global coherence iff $\forall e_i \in E$, $e_i \models C$. Put simply, for this property to hold for a generated fact-checking explanation, every sentence in the explanatory text must entail ($\models$) the claim.

- *Weak global coherence.* Let E be an explanation of the veracity label l for claim C, where $e_1, \ldots, e_N$ are all the individual sentences which make up E. Then, E satisfies weak global coherence iff $\forall e_i \in E$, $e_i \not\models \neg C$. For this property to hold for a generated fact-checking explanation, no sentence in the explanatory text should contradict the claim (by entailing its negation); from a natural language inference (NLI) perspective, for weak global coherence to hold all explanatory sentences should entail or have a neutral relation with respect to the claim.

When measuring coherence, we treat as *neutral* claims originally labelled as *false* if their claim is *contradicted* by its explanation. Note that if the *false* claim is *entailed* by its explanation we do not reassign the label, because doing so would impose too strong an assumption that the entailment is related to the veracity which we cannot verify.

Local Coherence. Let E be an explanation of the veracity label l for claim C, where $e_1, \ldots, e_N$ are all the individual sentences which make up E. Then, E satisfies local coherence iff $\forall e_i, e_j \in E$, $e_i \not\models \neg e_j$.

Local coherence is a measure of how cohesive sentences in an explanation are. For local coherence to hold any two sentences in an explanation must not contradict each other, i.e., there is no pairwise disagreement between sentences which make up the explanation.

Note that all three coherence properties relate to the usability property of coherence discussed by Sokol and Flach (2019). Local coherence draws specifically on the idea of avoiding internal inconsistencies in explanations. Figure 3 shows an example of evaluation of the three properties, for a specific claim-explanation pair. Schematic examples of explanations and evidence sentence relations which satisfy these coherence properties are shown in Appendix A.4.

5.3.1 Human & Computational Evaluations

We employ human evaluation in order to assess the quality of the gold and generated explanations with respect to these properties. Also, we conduct a computational evaluation of the three coherence properties using NLI.

For human evaluation, we randomly sampled 25 entries from the test set of PUBHEALTH, and enlisted 5 annotators to evaluate the quality of the gold explanations and explanations generated by EXPLAINERFC and EXPLAINERFC-EXPERT for these entries. We asked participants to annotate explanations according to the following criteria: 1) the agreement and disagreement between sentences in the explanation, and 2) relevance of the explanation to the claim. Further information, including an example from the questionnaire, can be found in Appendix A.3.

We conducted the computational evaluation on three pretrained NLI models: 1) a decomposable attention model (Parikh et al., 2016) using ELMo embeddings (Peters et al., 2018) trained on the Stanford Natural Language Inference (SNLI) corpus (Bowman et al., 2015), 2) RoBERTa (Liu et al., 2019) trained on SNLI, and 3) RoBERTa trained on the Multi-Genre Natural Language Inference (MNLI) corpus (Williams et al., 2018). We implemented these evaluation methods using the AllenNLP platform (Gardner et al., 2018).

For the human evaluation we computed Randolph's free-marginal κ (Randolph, 2005) and overall agreement (O.A.) for all multiple choice questions. For the gold explanations, we computed κ (and O.A.) of 0.24 (62%), 0.48 (65.6%), and 0.39 (54.4%) for 2-, 3-, and 4-nary questions respectively. For ExplainerFC, 0.06 (53.2%), 0.17 (44.8%), and 0.12 (34%) for 2-, 3-, and 4-nary questions respectively. Lastly for ExplainerFC-Expert, we computed κ and O.A. of 0.36 (68%), 0.44 (62.73%), and 0.20 (40%) for 2-, 3-, and 4-nary questions. The computational evaluation was conducted on all examples from the test set. The results of both the human and computational evaluation of the three coherence measures are shown in Table 6. Our results suggest that the NLI approximation is a reliable approximation for weak global coherence and local coherence properties. However, entailment appears to be a poor approximation for strong global coherence. Further, a larger human evaluation study would be required in order to verify these results.

Evaluation Method	SGC	WGC	LC
	Gold explanations		
Human	76.80	98.40	65.60
DA+ELMo; SNLI	8.72	87.61	55.20
RoBERTa; SNLI	1.28	75.87	52.12
RoBERTa; MNLI	2.66	87.52	54.84
ExplainerFC generated explanations			
Human	53.60	88.80	58.10
DA+ELMo; SNLI	8.26	89.45	51.32
RoBERTa; SNLI	0.46	76.42	48.01
RoBERTa; MNLI	0.73	84.59	50.20
ExplainerFC-Expert generated explanations			
Human	60.4	76.80	59.30
DA+ELMo; SNLI	7.61	89.72	64.60
RoBERTa; SNLI	0.64	76.15	60.07
RoBERTa; MNLI	2.48	84.04	62.43

Table 6: % of explanations which satisfy strong global coherence (SGC), weak global coherence (WGC) and local coherence (LC) properties.

Claim
A list of chemicals, written as if they were ingredients on a food label, accurately depicts the chemical composition of a banana.
Label: **TRUE**
Explanation
In sum, this graphic accurately depicts the chemicals that comprise a banana, using a variety of tactics to make that completely natural food appear to be full of "chemicals" — something originally created by a high school chemistry teacher as part of a lesson on chemophobia.

Figure 3: Example of explanation which satisfies all three coherence properties.

6 Conclusion and Future work

In this paper, we explored fact-checking for claims for which specific expertise is required to produce a veracity prediction and explanations (i.e., judgments used for awarding the label/veracity prediction). To support this exploration we constructed PubHealth, a sizeable dataset for public health fact-checking and the first fact-checking dataset to include explanations as annotations. Our results show that training veracity prediction and explanation generation models on in-domain data improves the accuracy of veracity prediction and the quality of generated explanations compared to training on generic language models without explanation.

We hope to explore the topics of explainable fact-checking and specialist fact-checking further. In order to do this, we hope to explore other subjects, in addition to public health, for which fact-checking requires a level of expertise in the subject area. Furthermore, we hope to explore the quality of fact-checking explanations with respect to properties other than coherence, e.g., actionability and impartiality. lastly, we plan to explore congruity between veracity prediction and explanation generation tasks, i.e., generating explanations which are compatible with the predicted label and vice versa.

Acknowledgements

We would like to thank all those who participated in the explanation evaluation study for their valuable contributions. The first author is supported by a doctoral training grant from the UK Engineering and Physical Sciences Research Council (EPSRC).

A Supplementary Material

A.1 Dataset

Here we expand on the dataset analysis presented in Section 3. Figure 4 shows the most commonly occuring public health terms in the PUBHEALTH dataset entry texts. Figure 5 illustrates the distribution of claim and explanation lengths. Note that the nature and format of the explanations for each of the scraped websites differed slightly.

Table 7 shows the origin fact-checking explanations included in the PUBHEALTH dataset. In Table 8 we show examples of the subject-rich tags scraped alone with the claims. Table 9 shows the mapping between the standardized and original veracity labels.

Building the public health lexicon. In order to compile the lexicon we scraped health related terms from the following website sources. In total we scraped vocabulary from a number of pages across six websites. These websites are NHS Health A-Z,[10] Everyday Health, [11] Medline Plus,[12] Think Local, Act Personal,[13] National Careers Healthcare Job,[14] and the Mayo Clinic.[15]

Additional words added the health lexicon. The following are the extra words added to lexicon which we did not scraped. ‘Centers for Disease Control and Prevention’, ‘abscess’, ‘adolescence’, ‘airborne’, ‘alimentation’, ‘alopecia’, ‘aneurysm’, ‘anorexia’, ‘anti-vaxxer’, ‘arrhythmia’, ‘bacteria’, ‘bacterium’, ‘biohazard’, ‘bioterrorism’, ‘bleeding’, ‘blood pressure’, ‘chickenpox’, ‘chloroquine’, ‘contagious’, ‘death’, ‘disease’, ‘embolism’, ‘endemic’, ‘environment’, ‘epidemiology’, ‘first aid’, ‘flatten the curve’, ‘flu’, ‘gallbladder’, ‘gangrene’, ‘heart attack’, ‘heparin’, ‘hospital’, ‘hydroxychloroquine’, ‘hygiene’, ‘hypertension’, ‘illness’, ‘immune’, ‘infant mortality rate’, ‘infect’, ‘influenza’, ‘lactose intolerance’, ‘liver’, ‘medicine’, ‘menstruation’, ‘mental health’, ‘nurse’, ‘organs’, outbreak, pacemaker, ‘pandemic’, ‘pathogen’, ‘patients’, ‘period poverty’, ‘public health’, ‘quarantine’, ‘sickness’, ‘smoking’, ‘stroke’, ‘surgical’, ‘tumour’, ‘vaccine’, ‘ventilator’, ‘virus’, ‘x-ray’.

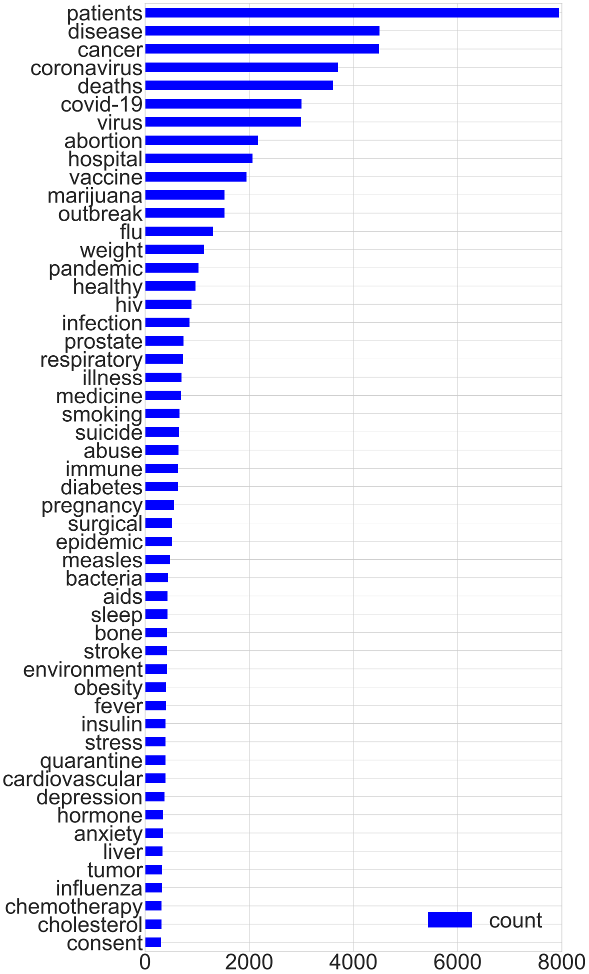

Figure 4: Vocabulary from the health lexicon which features > 300 times in PUBHEALTH article texts.

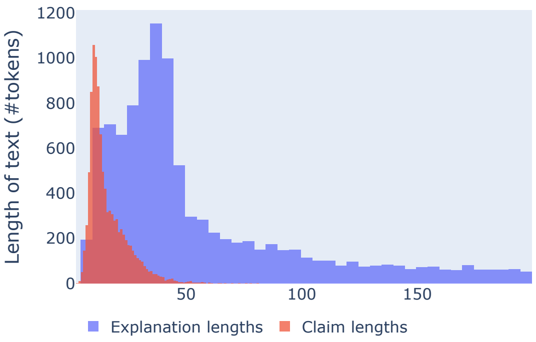

Figure 5: Histograms showing the distribution of lengths, measured by the number of tokens, for claims and explanations in the PUBHEALTH dataset.

A.2 Reproducibility

Here we provide further information about the experiments described in Section 4.

Prediction models hyperparameters. We perform hyper-parameter grid search as part of validation for batch sizes from {8, 16, 32}, learning rates from {1e-5, 5e-6, 1e-6}, and epochs {2, 3, 4}. We optimize our veracity prediction model on cross entropy loss. The hyper-parameters we selected from this grid search are a batch size of 16, learning rate 1e-6 and 4 epochs for model training.

Computing Infrastructure. All experiments were run on a machine with a dual Intel(R) Core(TM) i9-9900X 3.50GHz CPU. The GPU used for experiments is the Nvidia GeForce RTX 2080 Ti model. Additional information about the software packages used in the development of the explanation generation and veracity prediction models can be found in the GitHub repository, the link to which is given in Footnote 1.

A.3 Human Evaluation Questionnaire

The following are example question and response pairs typical of those presented to participants in the human evaluation questionnaire (see Section 5.3). Question and response pairs are related to the claim and explanation presented below.

1. **Question**: Are there any sentences or phrases in the explanation which disagree with each other?

   Response options: {Yes, No}.

2. **Question**: Which veracity label would you give to the claim taking into account the entire explanation?

   Response options: {Mixture, false, true, unproven}.

Claim

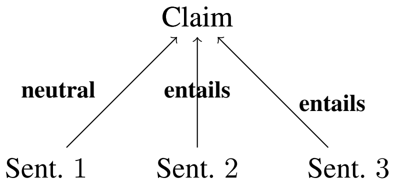
State reports new findings of mosquito-borne illnesses.

Explanation

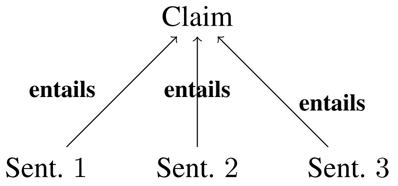
Rhode Island health officials say a second mosquito case tested positive for eastern equine encephalitis has been confirmed in the state, marking the first human case of the equine encephalitis in Rhode Island in more than two years.

A.4 Coherence properties

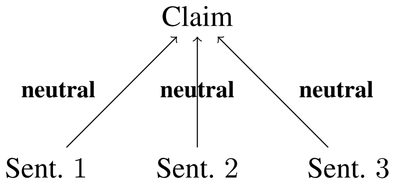
Figure 6 shows examples of the three coherence properties mentioned in Section 5.3, shown schematically in graphical form.



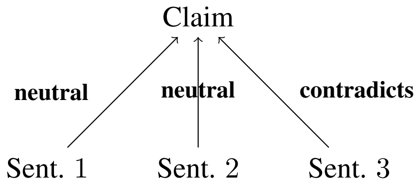
(a) Strong Global Coherence not satisfied



(b) Strong Global Coherence satisfied.



(c) Weak Global Coherence satisfied.



(d) Weak Global Coherence not satisfied.

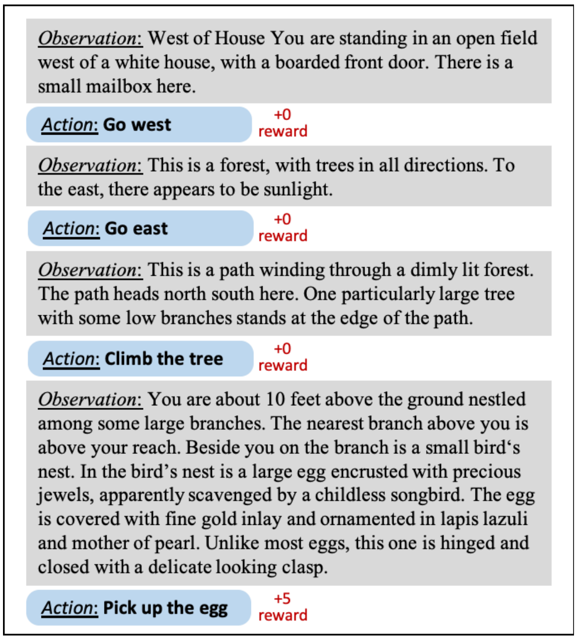
Abstract

Interactive Fiction (IF) games with real human-written natural language texts provide a new natural evaluation for language understanding techniques. In contrast to previous text games with mostly synthetic texts, IF games pose language understanding challenges on the human-written textual descriptions of diverse and sophisticated game worlds and language generation challenges on the action command generation from less restricted combinatorial space. We take a novel perspective of IF game solving and re-formulate it as Multi-Passage Reading Comprehension (MPRC) tasks. Our approaches utilize the context-query attention mechanisms and the structured prediction in MPRC to efficiently generate and evaluate action outputs and apply an object-centric historical observation retrieval strategy to mitigate the partial observability of the textual observations. Extensive experiments on the recent IF benchmark (*Jericho*) demonstrate clear advantages of our approaches achieving high winning rates and low data requirements compared to all previous approaches.[1]



Observation: West of House You are standing in an open field west of a white house, with a boarded front door. There is a small mailbox here.

Action: **Go west** +0 reward

Observation: This is a forest, with trees in all directions. To the east, there appears to be sunlight.

Action: **Go east** +0 reward

Observation: This is a path winding through a dimly lit forest. The path heads north south here. One particularly large tree with some low branches stands at the edge of the path.

Action: **Climb the tree** +0 reward

Observation: You are about 10 feet above the ground nestled among some large branches. The nearest branch above you is above your reach. Beside you on the branch is a small bird's nest. In the bird's nest is a large egg encrusted with precious jewels, apparently scavenged by a childless songbird. The egg is covered with fine gold inlay and ornamented in lapis lazuli and mother of pearl. Unlike most eggs, this one is hinged and closed with a delicate looking clasp.

Action: **Pick up the egg** +5 reward

Figure 1: Sample gameplay for the classic dungeon game *Zork1*. The objective is to solve various puzzles and collect the 19 treasures to install the trophy case. The player receives textual observations describing the current game state and additional reward scalars encoding the game designers' objective of game progress. The player sends textual action commands to control the protagonist.

1 Introduction

Interactive systems capable of understanding natural language and responding in the form of natural language text have high potentials in various applications. In pursuit of building and evaluating such systems, we study learning agents for Interactive Fiction (IF) games. IF games are world-simulating software in which players use text commands to control the protagonist and influence the world, as illustrated in Figure 1. IF gameplay agents need to simultaneously understand the game's information from a text display (**observation**) and generate natural language command (**action**) via a text input interface. Without providing an explicit game strategy, the agents need to identify behaviors that maximize objective-encoded cumulative rewards.

IF games composed of human-written texts (distinct from previous text games with synthetic texts) create superb new opportunities for studying and evaluating natural language understanding (NLU) techniques due to their unique characteristics. (1) Game designers elaborately craft on the literariness of the narrative texts to attract players when creating IF games. The resulted texts in IF games are more linguistically diverse and sophisticated than the template-generated ones in synthetic text games. (2) The language contexts of IF games

(a) Multi-Passage Retrieval for Partial Observability

(b) Multi-Passage RC for Action Value Learning

Figure 2: Overview of our approach to solving the IF games as Multi-Paragraph Reading Comprehension (MPRC) tasks.

are more versatile because various designers contribute to enormous domains and genres, such as adventure, fantasy, horror, and sci-fi. (3) The text commands to control characters are less restricted, having sizes over six orders of magnitude larger than previous text games. The recently introduced *Jericho* benchmark provides a collection of such IF games (Hausknecht et al., 2019a).

The complexity of IF games demands more sophisticated NLU techniques than those used in synthetic text games. Moreover, the task of designing IF game-play agents, intersecting NLU and reinforcement learning (RL), poses several unique challenges on the NLU techniques. The first challenge is the difficulty of exploration in ***the huge natural language action space***. To make RL agents learn efficiently without prohibitive exhaustive trials, the action estimation must generalize learned knowledge from tried actions to others. To this end, previous approaches, starting with a single embedding vector of the observation, either predict the elements of actions independently (Narasimhan et al., 2015; Hausknecht et al., 2019a); or embed each valid action as another vector and predict action value based on the vector-space similarities (He et al., 2016). These methods do not consider the compositionality or role-differences of the action elements, or the interactions among them and the observation. Therefore, their modeling of the action values is less accurate and less data-efficient.

The second challenge is ***partial observability***. At each game-playing step, the agent receives a textual observation describing the locations, objects, and characters of the game world. But the latest observation is often not a sufficient summary of the interaction history and may not provide enough information to determine the long-term effects of actions. Previous approaches address this problem by building a representation over past observations (e.g., building a graph of objects, positions, and spatial relations) (Ammanabrolu and Riedl, 2019; Ammanabrolu and Hausknecht, 2020). These methods treat the historical observations equally and summarize the information into a single vector without focusing on important contexts related to the action prediction for the current observation. Therefore, their usages of history also bring noise, and the improvement is not always significant.

We propose a novel formulation of IF game playing as Multi-Passage Reading Comprehension (MPRC) and harness MPRC techniques to solve the *huge action space* and *partial observability* challenges. The graphical illustration is shown in Figure 2. First, the action value prediction (i.e., predicting the long-term rewards of selecting an action) is essentially *generating and scoring a compositional action structure by finding supporting evidence from the observation*. We base on the fact that each action is an instantiation of a **template**, i.e., a verb phrase with a few placeholders of object arguments it takes (Figure 2b). Then the action generation process can be viewed as extracting objects for a template's placeholders from the textual observation, based on the interaction between the template verb phrase and the relevant context of the objects in the observation. Our approach addresses the structured prediction and interaction problems with the idea of context-question attention mechanism in RC models. Specifically, we treat the observation as a passage and each template verb phrase as a question. The filling of object placeholders in the template thus becomes an extractive QA problem that selects objects from the observation given the template. Simultaneously each action (i.e., a template with all placeholder replaced) gets its evaluation value predicted by the RC model. Our formulation and approach better capture the fine-grained interactions between observation texts and structural actions, in contrast to previous approaches that represent the observation as a single vector and ignore the fine-grained dependency among action elements.

Second, alleviating partial observability is essentially *enhancing the current observation with potentially relevant history* and *predicting actions over the enhanced observation*. Our approach retrieves potentially relevant historical observations with an object-centric approach (Figure 2a), so that the retrieved ones are more likely to be connected to the current observation as they describe at least one shared interactable object. Our attention mechanisms are then applied across the retrieved multiple observation texts to focus on informative contexts for action value prediction.

We evaluated our approach on the suite of *Jericho* IF games, compared to all previous approaches. Our approaches achieved or outperformed the state-of-the-art performance on **25** out of 33 games, trained with less than **one-tenth** of game interaction data used by prior art. We also provided ablation studies on our models and retrieval strategies.

2 Related Work

IF Game Agents. Previous work mainly studies the text understanding and generation in parser-based or rule-based text game tasks, such as TextWorld platform (Côté et al., 2018) or custom domains (Narasimhan et al., 2015; He et al., 2016; Adhikari et al., 2020). The recent platform *Jericho* (Hausknecht et al., 2019a) supports over thirty human-written IF games. Earlier successes in real IF games mainly rely on heuristics without learning. NAIL (Hausknecht et al., 2019b) is the state-of-the-art among these "no-learning" agents, employing a series of reliable heuristics for exploring the game, interacting with objects, and building an internal representation of the game world. With the development of learning environments like *Jericho*, the RL-based agents have started to achieve dominating performance.

A critical challenge for learning-based agents is how to handle the **combinatorial action space** in IF games. LSTM-DQN (Narasimhan et al., 2015) was proposed to generate verb-object action with pre-defined sets of possible verbs and objects, but treat the selection and learning of verbs and objects independently. Template-DQN (Hausknecht et al., 2019a) extended LSTM-DQN for template-based action generation, introducing one additional but still independent prediction output for the second object in the template. Deep Reinforcement Relevance Network (DRRN) (He et al., 2016) was introduced for choice-based games. Given a set of valid actions at every game state, DRRN projects each action into a hidden space that matches the current state representation vector for action selection. Action-Elimination Deep Q-Network (AE-DQN) (Zahavy et al., 2018) learns to predict invalid actions in the adventure game *Zork*. It eliminates invalid action for efficient policy learning via utilizing expert demonstration data.

Other techniques focus on addressing the **partial observability** in text games. Knowledge Graph DQN (KG-DQN) (Ammanabrolu and Riedl, 2019) was proposed to deal with synthetic games. The method constructs and represents the game states as knowledge graphs with objects as nodes and uses pre-trained general purposed OpenIE tool and human-written rules to extract relations between objects. KG-DQN handles the action representation following DRRN. KG-A2C (Ammanabrolu and Hausknecht, 2020) later extends the work for IF games, by adding information extraction heuristics to fit the complexity of the object relations in IF games and utilizing a GRU-based action generator to handle the action space.

Reading Comprehension Models for Question Answering. Given a question, reading comprehension (RC) aims to find the answer to the question based on a paragraph that may contain supporting evidence. One of the standard RC settings is extractive QA (Rajpurkar et al., 2016; Joshi et al., 2017; Kwiatkowski et al., 2019), which extracts a span from the paragraph as an answer. Our formulation of IF game playing resembles this setting.

Many neural *reader* models have been designed for RC. Specifically, for the extractive QA task, the reader models usually build question-aware passage representations via attention mechanisms (Seo et al., 2016; Yu et al., 2018), and employ a pointer network to predict the start and end positions of the answer span (Wang and Jiang, 2016). Powerful pre-trained language models (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019) have been recently applied to enhance the encoding and attention mechanisms of the aforementioned reader models. They give performance boost but are more resource-demanding and do not suit the IF game playing task very well.

Reading Comprehension over Multiple Paragraphs. Multi-paragraph reading comprehension (MPRC) deals with the more general task of answering a question from multiple related paragraphs, where each paragraph may not necessarily support the correct answer. Our formulation becomes an MPRC setting when we enhance the state representation with historical observations and predict actions from multiple observation paragraphs.

A fundamental research problem in MPRC, which is also critical to our formulation, is to select relevant paragraphs from all the input paragraphs for the reader to focus on. Previous approaches mainly apply traditional IR approaches like BM25 (Chen et al., 2017; Joshi et al., 2017), or neural ranking models trained with distant supervision (Wang et al., 2018; Min et al., 2019a), for paragraph selection. Our formulation also relates to the work of evidence aggregation in MPRC (Wang et al., 2017; Lin et al., 2018), which aims to infer the answers based on the joint of evidence pieces from multiple paragraphs. Finally, recently some works propose the entity-centric paragraph retrieval approaches (Ding et al., 2019; Godbole et al., 2019; Min et al., 2019b; Asai et al., 2019), where paragraphs are connected if they share the same-named entities. The paragraph retrieval then becomes a traversal over such graphs via entity links. These entity-centric paragraph retrieval approaches share a similar high-level idea to our object-based history retrieval approach. The techniques above have been applied to deal with evidence from Wikipedia, news collections, and, recently, books (Mou et al., 2020). We are the first to extend these ideas to IF games.

3 Multi-Paragraph RC for IF Games

3.1 Problem Formulation

Each IF game can be defined as a Partially Observable Markov Decision Process (POMDP), namely a 7-tuple of $\langle\ S,\ A,\ T,\ O,\ \Omega,\ R,\ \gamma\ \rangle$, representing the hidden game state set, the action set, the state transition function, the set of textual observations composed from vocabulary words, the textual observation function, the reward function, and the discount factor respectively. The game playing agent interacts with the game engine in multiple turns until the game is over or the maximum number of steps is reached. At the t-th turn, the agent receives a textual observation describing the current game state $o_t \in O$ and sends a textual action command $a_t \in A$ back. The agent receives additional reward scalar r_t which encodes the game designers' objective of game progress. Thus the task of the game playing can be formulated to generate a textual action command per step as to maximize the expected cumulative discounted rewards $\mathbf{E}\left[\sum_{t=0}^{\infty} \gamma^t r_t\right]$. Value-based RL approaches learn to approximate an observation-action value function $Q(o_t, a_t; \boldsymbol{\theta})$ which measures the expected cumulative rewards of taking action a_t when observing o_t. The agent selects action based on the action value prediction of $Q(o, a; \boldsymbol{\theta})$.

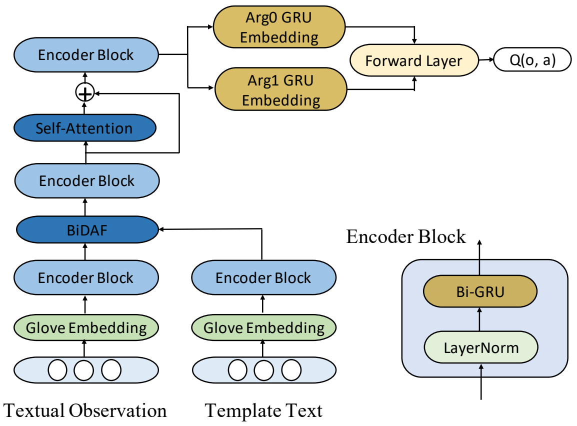

Figure 3: Our RC-based action prediction model architecture. The template text is a verb phrase with placeholders for objects, such as [pick up OBJ] and [break OBJ with OBJ].

Template Action Space. Template action space considers actions satisfying decomposition in the form of $\langle \mathit{verb}, \mathit{arg}_0, \mathit{arg}_1 \rangle$. *verb* is an interchangeable verb phrase template with placeholders for objects and arg_0 and arg_1 are optional objects. For example, the action command [east], [pick up eggs] and [break window with stone] can be represented as template actions $\langle \mathit{east}, \mathit{none}, \mathit{none} \rangle$, $\langle \mathit{pick\ up\ OBJ}, \mathit{eggs}, \mathit{none}$ and $\langle \mathit{break\ OBJ\ with\ OBJ}, \mathit{window}, \mathit{stone} \rangle$. We reuse the template library and object list from *Jericho*. The verb phrases usually consist of several vocabulary words and each object is usually a single word.

3.2 RC Model for Template Actions

We parameterize the observation-action value function $Q(o, a{=}\langle \textit{verb}, \textit{arg}_0, \textit{arg}_1\rangle; \boldsymbol{\theta})$ by utilizing the decomposition of the template actions and context-query contextualized representation in RC. Our model treats the observation o as a context in RC and the $\textit{verb}{=}(v_1, v_2, ..., v_k)$ component of the template actions as a query. Then a *verb*-aware observation representation is derived via a RC reader model with Bidirectional Attention Flow (BiDAF) (Seo et al., 2016) and self-attention. The observation representation responding to the $\textit{arg}_0$ and $\textit{arg}_1$ words are pooled and projected to a scalar value estimate for $Q(o, a{=}\langle \textit{verb}, \textit{arg}_0, \textit{arg}_1\rangle; \boldsymbol{\theta})$. A high-level model architecture of our model is illustrated in Figure 3.

Observation and *verb* Representation. We tokenize the observation and the *verb* phrase into words, then embed these words using pre-trained GloVe embeddings (Pennington et al., 2014). A shared encoder block that consists of LayerNorm (Ba et al., 2016) and Bidirectional GRU (Cho et al., 2014) processes the observation and *verb* word embeddings to obtain the separate observation and *verb* representation.

Observation-*verb* Interaction Layers. Given the separate observation and *verb* representation, we apply two attention mechanisms to compute a *verb*-contextualized observation representation. We first apply BiDAF with observation as the context input and *verb* as the query input. Specifically, we denote the processed embeddings for observation word i and template word j as $\boldsymbol{o_i}$ and $\boldsymbol{t}_j$. The attention between the two words is then $a_{ij}{=}\boldsymbol{w_1}{\cdot}\boldsymbol{o_i}{+}\boldsymbol{w_2}{\cdot}\boldsymbol{t_j}{+}\boldsymbol{w_3}{\cdot}(\boldsymbol{o_i}{\otimes}\boldsymbol{t_j})$, where $\boldsymbol{w_1}$, $\boldsymbol{w_2}$, $\boldsymbol{w_3}$ are learnable vectors and $\otimes$ is element-wise product. We then compute the "*verb*2observation" attention vector for the i-th observation word as $\boldsymbol{c_i}{=}\sum_j p_{ij}\boldsymbol{t_j}$ with $p_{ij}{=}\exp(a_{ij})/\sum_j \exp(a_{ij})$. Similarly, we compute the "observation2*verb*" attention vector as $\boldsymbol{q}{=}\sum_i p_i\boldsymbol{o_i}$ with $p_i = \exp(\max_j a_{ij})/\sum_i \exp(\max_j a_{ij})$. We concatenate and project the output vectors as $\boldsymbol{w_4} \cdot [\boldsymbol{o_i}, \boldsymbol{c_i}, \boldsymbol{o_i} \otimes \boldsymbol{c_i}, \boldsymbol{q} \otimes \boldsymbol{c_i}]$, followed by a linear layer with leaky ReLU activation units (Maas et al., 2013). The output vectors are processed by an encoder block. We then apply a residual self-attention on the outputs of the encoder block. The self-attention is the same as BiDAF, but only between the observation and itself.

Observation-Action Value Prediction. We generate an action by replacing the placeholders ($\textit{arg}_0$ and $\textit{arg}_1$) in a template with objects appearing in the observation. The observation-action value $Q(o, a{=}\langle \textit{verb}, \textit{arg}_0{=}\textit{obj}_m, \textit{arg}_1{=}\textit{obj}_n\rangle; \theta)$ is achieved by processing each object's corresponding *verb*-contextualized observation representation. Specifically, we get the indices of an *obj* in the observation texts $I(\textit{obj}, o)$. When the object is a noun phrase, we take the index of its headword.[2] Because the same object has different meanings when it replaces different placeholders, we apply two GRU-based embedding functions for the two placeholders, to get the object's *verb*-placeholder dependent embeddings. We derive a single vector representation $\boldsymbol{h}_{\textit{arg}_{\boldsymbol{0}}=\textit{obj}_{\boldsymbol{m}}}$ for the case that the placeholder $\textit{arg}_0$ is replaced by $\textit{obj}_m$ by mean-pooling over the *verb*-placeholder dependent embeddings indexed by $I(\textit{obj}_m, o)$ for the corresponding placeholder $\textit{arg}_0$. We apply a linear transformation on the concatenated embeddings of the two placeholders to obtain the observation action value $Q(o, a){=}\boldsymbol{w}_5 \cdot [\boldsymbol{h}_{\textit{arg}_{\boldsymbol{0}}=\textit{obj}_{\boldsymbol{m}}}, \boldsymbol{h}_{\textit{arg}_{\boldsymbol{1}}=\textit{obj}_{\boldsymbol{n}}}]$ for $a{=}\langle \textit{verb}, \textit{arg}_0{=}\textit{obj}_m, \textit{arg}_1{=}\textit{obj}_n\rangle$. Our formulation avoids the repeated computation overhead among different actions with a shared template verb phrase.

3.3 Multi-Paragraph Retrieval Method for Partial Observability

The observation at the current step sometimes does not have full-textual evidence to support action selection and value estimation, due to the inherent partial observability of IF games. For example, when repeatedly attacking a troll with a sword, the player needs to know the effect or feedback of the last attack to determine if an extra attack is necessary. It is thus important for an agent to efficiently utilize historical observations to better support action value prediction. In our RC-based action prediction model, the historical observation utilization can be formulated as selecting evidential observation paragraphs in history, and predicting the action values from multiple selected observations, namely a Multiple-Paragraph Reading Comprehension (MPRC) problem. We propose to retrieve past observations with an object-centric approach.

Past Observation Retrieval. Multiple past observations may share objects with the current obser-

---

[2] Some templates may take zero or one object. We denote the unrequired objects as `none` so that all templates take two objects. The index of the *none* object is for a special token. We set to the index of split token of the observation contents.

Agents	Action strategy	State strategy	Interaction data
TDQN	Independent selection of template and the two objects	*None*	1M
DRRN	Action as a word sequence without distinguishing the roles of verbs and objects	*None*	1M
KG-A2C	Recurrent neural decoder that selects the template and objects in a fixed order	Object graph from historical observations based on OpenIE and human-written rules	1.6M
Ours	Observation-template representation for object-centric value prediction	Object-based history observation retrieval	0.1M

Table 1: Summary of the main technical differences between our agent and the baselines. All agents use DQN to update the model parameters except KG-A2C uses A2C. All agents use the same handicaps.

vation, and it is computationally expensive and unnecessary to retrieve all of such observations. The utility of past observations associated with each object is often time-sensitive in that new observations may entirely or partially invalidate old observations. We thus propose a time-sensitive strategy for retrieving past observations. Specifically, given the detected objects from the current observation, we retrieve the most recent K observations with at least one shared object. The K retrieved observations are sorted by time steps and concatenated to the current observation. The observations from different time steps are separated by a special token. Our RC-based action prediction model treats the concatenated observations as the observation inputs, and no other parts are changed. We use the notation o_t to represent the current observation and the extended current observation interchangeably.

3.4 Training Loss

We apply the Deep Q-Network (DQN) (Mnih et al., 2015) to update the parameters $\boldsymbol{\theta}$ of our RC-based action prediction model. The loss function is:

$$\mathcal{L}(\theta) = \mathbf{E}_{(o_t,a_t,r_t,o_{t+1})\sim\rho(\mathcal{D})}\Big[||Q(o_t,a_t;\theta) - (r_t + \gamma \max_b Q(o_{t+1},b;\theta^-))||\Big]$$

where $\mathcal{D}$ is the experience replay consisting of recent gameplay transition records and ρ is a distribution over the transitions defined by a sampling strategy.

Prioritized Trajectories. The distribution ρ has a decent impact on DQN performance. Previous work samples transition tuples with immediate positive rewards more frequently to speed up learning (Narasimhan et al., 2015; Hausknecht et al., 2019a). We observe that this heuristic is often insufficient. Some transitions with zero immediate rewards or even negative rewards are also indispensable in recovering well-performed trajectories. We thus extend the strategy from transition level to trajectory level. We prioritize transitions from trajectories that outperform the exponential moving average score of recent trajectories.

4 Experiments

We evaluate our proposed methods on the suite of Jericho supported games. We compared to all previous baselines that include recent methods addressing the huge action space and partial observability challenges.

4.1 Setup

***Jericho* Handicaps and Configuration.** The handicaps used by our methods are the same as other baselines. First, we use the Jericho API to check if an action is valid with game-specific templates. Second, we augmented the observation with the textual feedback returned by the command [*inventory*] and [*look*]. Previous work also included the last action or game score as additional inputs. Our model discarded these two types of inputs as we did not observe a significant difference by our model. The maximum game step number is set to 100 following baselines.

Implementation Details. We apply spaCy[3] to tokenize the observations and detect the objects in the observations. We use the 100-dimensional GloVe embeddings as fixed word embeddings. The out-of-vocabulary words are mapped to a randomly initialized embedding. The dimension of Bi-GRU hidden states is 128. We set the observation representation dimension to be 128 throughout the model. The history retrieval window K is 2. For DQN configuration, we use the ϵ-greedy strategy

Table 2: Average game scores on Jericho benchmark games. The best performing agent score per game is **in bold**. The *Winning percentage / counts* row computes the percentage / counts of games that the corresponding agent is best. The scores of baselines are from their papers. The missing scores are represented as "–", for which games KG-A2C skipped. We also added the 100-step results from a human-written game-playing walkthrough, as a reference of human-level scores. We denote the difficulty levels of the games defined in the original Jericho paper with colors in their names – possible (i.e., easy or normal) games in green color, difficult games in tan and extreme games in red. Best seen in color.
[a] *Zork3* walkthrough does not maximize the score in the first 100 steps but explores more. [b] Our agent discovers some unbounded reward loops in the game *Ztuu*.

for exploration, annealing ϵ from 1.0 to 0.05. γ is 0.98. We use Adam to update the weights with 10^{-4} learning rate. Other parameters are set to their default values. More details of the Reproducibility Checklist is in Appendix A.

Baselines. We compare with all the public results on the Jericho suite, namely TDQN (Hausknecht et al., 2019a), DRRN (He et al., 2016), and KG-A2C (Ammanabrolu and Hausknecht, 2020). As discussed, our approaches differ from them mainly in the strategies of handling the large action space and partial observability of IF games. We summarize these main technical differences in Table 1. In summary, all previous agents predict actions conditioned on a single vector representation of the whole observation texts. Thus they do not exploit the fine-grained interplay among the template components and the observations. Our approach addresses this problem by formulating action prediction as an RC task, better utilizing the rich textual observations with deeper language understanding.

Training Sample Efficiency. We update our models for 100,000 times. Our agents interact with the environment one step per update, resulting in a total of 0.1M environment interaction data. Compared to the other agents, such as KG-A2C (1.6M), TDQN (1M), and DRRN (1M), our environment interaction data is significantly smaller.

Game	Template Action Space ($\times 10^6$)	Avg. Steps Per Reward	Dialog Actions	Darkness Limit	Nonstandard	Inventory
advent	107	7		✓	✓	✓
detective	19	2				
karn	63	17	✓	✓		
ludicorp	45	4			✓	✓
pentari	32	5			✓	
spirit	195	21	✓	✓	✓	✓
zork3	67	39	✓	✓		✓

Table 3: Difficulty levels and characteristics of games on which our approach achieves the most considerable improvement. *Dialog* indicates that it is necessary to speak with another character. *Darkness* indicates that accessing some dark areas requires a light source. *Nonstandard Actions* refers to actions with words not in an English dictionary. *Inventory Limit* restricts the number of items carried by the player. Please refer to (Hausknecht et al., 2019a) for more comprehensive definitions.

4.2 Overall Performance

We summarize the performance of our Multi-Paragraph Reading Comprehension DQN (MPRC-DQN) agent and baselines in Table 2. Of the 33 IF games, our MPRC-DQN achieved or improved the state of the art performance on 21 games (i.e., a winning rate of 64%). The best performing baseline (DRRN) achieved the state-of-the-art performance on only ten games, corresponding to the winning rate of 30%, lower than half of ours. Note that all the methods achieved the same initial scores on five games, namely *905*, *anchor*, *awaken*, *deephome*, and *moonlit*. Apart from these five games, our MPRC-DQN achieved more than three times wins. Our MPRC-DQN achieved significant improvement on some games, such as *adventureland*, *afflicted*, *detective*, etc. Appendix C shows some game playing trajectories.

We include the performance of an RC-DQN agent, which implements our RC-based action prediction model but only takes the current observations as inputs. It also outperformed the baselines by a large margin. After we consider the RC-DQN agent, our MPRC-DQN still has the highest winning percentage, indicating that our RC-based action prediction model has a significant impact on the performance improvement of our MPRC-DQN and the improvement from the multi-passage retrieval is also unneglectable. Moreover, compared to RC-DQN, our MPRC-DQN has another advantage of faster convergence. The learning curves of our MPRC-DQN and RC-DQN agents on various games are in Appendix B.

Finally, our approaches, overall, achieve the new state-of-the-art on 25 games (i.e., a winning rate of 76%), giving a significant advance in the field of IF game playing.

Competitors	Win	Draw	Lose
MPRC-DQN v.s. TDQN	23	6	4
MPRC-DQN v.s. DRRN	18	13	2
MPRC-DQN v.s. KG-A2C	18	7	3

Table 4: Pairwise comparison between our MPRC-DQN versus each baseline.

Pairwise Competition. To better understand the performance difference between our approach and each of the baselines, we adopt a direct one-to-one comparison metric based on the results from Table 2. Our approach has a high winning rate when competing with any of the baselines, summarized in Table 4. All the baselines have a rare chance to beat us on games. DRRN gives a higher chance of draw-games when competing with ours.

Human-Machine Gap. We additionally compare IF gameplay agents to human players to better understand the improvement significance and the potential improvement upper-bound. We measure each agent's game progress as the macro-average of the normalized agent-to-human game score ratios, capped at 100%. The progress of our MPRC-DQN is 28.5%, while the best performing baseline DRRN is 17.8%, showing that our agent's improvement is significant even in the realm of human players. Nevertheless, there is a vast gap between the learning agents and human players. The gap indicates IF games can be a good benchmark for the development of natural language understanding techniques.

Difficulty Levels of Games. Jericho categorizes the supported games into three difficulty levels, namely possible games, difficult games, and extreme games, based on the characteristics of the game dynamics, such as the action space size, the length of the game, and the average number of

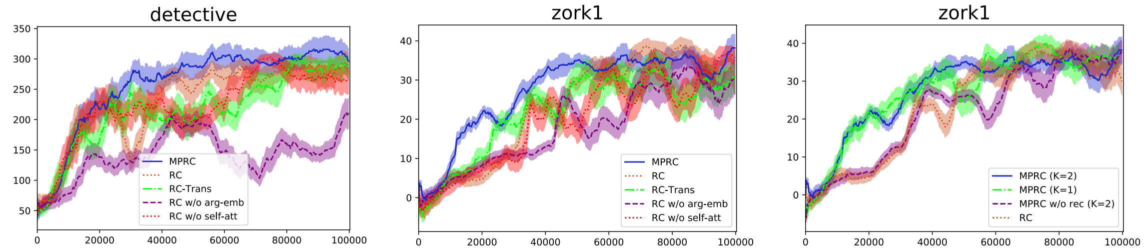

Figure 4: Learning curves for ablative studies. **(left)** Model ablative studies on the game *Detective*. **(middle)** Model ablative studies on *Zork1*. **(right)** Retrieval strategy study on *Zork1*. Best seen in color.

steps to receive a non-zero reward. Our approach improves over prior art on seven of the sixteen possible games, seven of the eleven difficult games, and three of the six extreme games in Table 2. It shows that the strategies of our method are generally beneficial for any difficulty levels of game dynamics. Table 3 summarizes the characteristics of the seven games in which our method improves the most, i.e., larger than 15% of the game progress in the first 100 steps.[4] First, these mostly improved games have medium action space sizes, and it is an advantageous setting for our methods where modeling the template-object-observation interactions is effective. Second, our approach improves most on games with a reasonably high degree of reward sparsity, such as *karn*, *spirit*, and *zork3*, indicating that our RC-based value function formulation helps in optimization and mitigates the reward sparsity. Finally, we remark that these game difficulty levels are not directly categorized based on natural language-related characteristics, such as text comprehension and puzzle-solving difficulties. Future studies on additional game categories based on those natural language-related characteristics would shed light on related improvements.

4.3 Ablative Studies

RC-model Design. The overall results show that our RC-model plays a critical role in performance improvement. We compare our RC-model to some alternative models as ablative studies. We consider three alternatives, namely (1) our RC-model without the self-attention component (`w/o self-att`), (2) without the argument-specific embedding (`w/o arg-emb`) and (3) our RC-model with Transformer-based block encoder (`RC-Trans`) following QANet (Yu et al., 2018). Detailed architecture is in Appendix A.

The learning curves for different RC-models are in Figure 4 (left/middle). The RC-models without either self-attention or argument-specific embedding degenerate, and the argument-specific embedding has a greater impact. The Transformer-based encoder block sometimes learns faster than Bi-GRU at the early learning stage. It achieved a comparable final performance, even with much greater computational resource requirements.

Retrieval Strategy. We compare with history retrieval strategies with different history sizes (K) and pure recency-based strategies (i.e., taking the latest K observations as history, denoted as `w/o rec`). The learning curves of different strategies are in Figure 4 (right). In general, the impact of history window size is highly game-dependent, but the pure recency based ones do not differ significantly from RC-DQN at the beginning of learning. The issues of pure recency based strategy are: (1) limited additional information about objects provided by successive observations; and (2) higher variance of retrieved observations due to policy changes.

5 Conclusion

We formulate the general IF game playing as MPRC tasks, enabling an MPRC-style solution to efficiently address the key IF game challenges on the huge combinatorial action space and the partial observability in a unified framework. Our approaches achieved significant improvement over the previous state-of-the-art on both game scores and training data efficiency. Our formulation also bridges broader NLU/RC techniques to address other critical challenges in IF games for future work, e.g., common-sense reasoning, novelty-driven exploration, and multi-hop inference.

Acknowledgments

We would like to thank Matthew Hausknecht for helpful discussions on the Jericho environments.

DORB: Dynamically Optimizing Multiple Rewards with Bandits

Ramakanth Pasunuru **Han Guo** **Mohit Bansal**
UNC Chapel Hill
{ram, hanguo, mbansal}@cs.unc.edu

Abstract

Policy gradients-based reinforcement learning has proven to be a promising approach for directly optimizing non-differentiable evaluation metrics for language generation tasks. However, optimizing for a specific metric reward leads to improvements in mostly that metric only, suggesting that the model is gaming the formulation of that metric in a particular way without often achieving real qualitative improvements. Hence, it is more beneficial to make the model optimize multiple diverse metric rewards jointly. While appealing, this is challenging because one needs to manually decide the importance and scaling weights of these metric rewards. Further, it is important to consider using a dynamic combination and curriculum of metric rewards that flexibly changes over time. Considering the above aspects, in our work, we automate the optimization of multiple metric rewards simultaneously via a multi-armed bandit approach (DORB), where at each round, the bandit chooses which metric reward to optimize next, based on expected arm gains. We use the Exp3 algorithm for bandits and formulate two approaches for bandit rewards: (1) Single Multi-reward Bandit (SM-Bandit); (2) Hierarchical Multi-reward Bandit (HM-Bandit). We empirically show the effectiveness of our approaches via various automatic metrics and human evaluation on two important NLG tasks: question generation and data-to-text generation. Finally, we present interpretable analyses of the learned bandit curriculum over the optimized rewards.

1 Introduction

Recent advancements in end-to-end neural networks-based approaches have shown wide success in various sequence generation tasks: machine translation (Sutskever et al., 2014; Luong et al., 2015), dialogue systems (Vinyals and Le, 2015; Serban et al., 2016), textual summarization (Rush et al., 2015; Nallapati et al., 2016; See et al., 2017), image/video captioning (Bahdanau et al., 2015; Venugopalan et al., 2015; Pasunuru and Bansal, 2017a), question generation (Du et al., 2017; Du and Cardie, 2018; Zhang and Bansal, 2019), etc. In all of these tasks, cross-entropy loss optimization has been widely used as a standard optimization approach (Sutskever et al., 2014), but this approach suffers from exposure-bias issue (Ranzato et al., 2016) and does not optimize for the non-differentiable automatic evaluation metrics that measure the quality of the generated sequence. Recent introduction of policy gradient-based reinforcement learning approaches address these issues for sequence generation tasks by directly optimizing the non-differentiable evaluation metrics (Zaremba and Sutskever, 2015; Ranzato et al., 2016; Rennie et al., 2017).

However, optimizing for a particular metric/reward via policy gradient-based approaches often leads to improvement in mostly that specific metric, suggesting that this approach is gaming the metrics (Paulus et al., 2018). The weighted average of multiple metrics or surrogate rewards have been explored (Liu et al., 2017), but these approaches have to deal with finding the optimal scale balance across different metrics. One can alternatively optimize multiple metrics via a mixing ratio (Pasunuru and Bansal, 2018), but this still needs careful tuning of the mixing ratio. Moreover, all these reward approaches are fixed and do not change over training, and all the metrics may not be important over every stage of the training. Thus, it might be useful to consider using a dynamic combination of metrics, which rewards to use early vs. later, or which rewards might be useful to come back later in training, and consider the context of the full history of rewards, as well as the models current state and the nature of the metric.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7766–7780,
November 16–20, 2020.

To this end, we present a multi-armed bandit approach (which we name the DORB framework) where the arms of the bandit are the choices of the metrics that we want to optimize as rewards. At every round, the bandit chooses the next possible metric to optimize based on its previous performance history over these metrics, hence allowing the automatic learning of an optimal curriculum of rewards. We explore this approach in the context of exploration vs. exploitation via Exp3 algorithm (Auer et al., 2002b) with two novel approaches for bandit rewards: (1) Single Multi-reward Bandit (SM-Bandit); (2) Hierarchical Multi-reward Bandit (HM-Bandit). First, we present a reward scaling approach to maintain the metric rewards range in $[0, 1]$. Next, we present our SM-Bandit, where at each round, the bandit's reward is based on the performance improvement from multiple sources. Here, we use the average of all the scaled metric rewards from multiple sources as the final reward to the bandit. Finally, we present our HM-Bandit, which consists of a single first-level controller, as well as K second-level multi-armed bandits. The first-level controller's goal is to find the under-performing reward metric, while the second-level bandits' goal is to trigger the specific metric optimizer that will lead to a promising improvement in this specific metric.

We validate the effectiveness of our approaches on two important generation tasks: question generation and data-to-text generation, via both automatic evaluation metrics and human evaluation. For question generation, we present results on the SQuAD QG dataset (Du et al., 2017), and for data-to-text NLG, we choose the WebNLG dataset (Gardent et al., 2017). We show that our bandit-based approaches perform statistically significantly better (based on human evaluation) than strong single-reward based RL models as well as non-bandits based multi-reward methods such as the multi-task approach of Pasunuru and Bansal (2018). We further present various interpretable analyses of our bandit progress and learned rewards curriculum over different bandit approaches.

2 Related Works

Policy Gradient and Generative Models: Neural sequence to sequence models with cross-entropy optimization, potentially with attention mechanism (Bahdanau et al., 2015) and pointer-copy mechanism (See et al., 2017; Gulcehre et al., 2016; Vinyals et al., 2015a; Merity et al., 2018), are widely used in language generation tasks such as machine translation (Sutskever et al., 2014; Luong et al., 2015), abstractive summarization (Chopra et al., 2016; Nallapati et al., 2016), question generation (Du et al., 2017; Zhang and Bansal, 2019), video/image captioning (Xu et al., 2015; Vinyals et al., 2015b; Pasunuru and Bansal, 2017a; Zhou et al., 2018), as well as sentence simplification (Zhang and Lapata, 2017; Guo et al., 2018). However, often the final metrics of interest are not differentiable, and thus not compatible with the standard maximum-likelihood based training. Motivated by this, recently there has been a surge in applications of reinforcement learning techniques to language generation (Ranzato et al., 2016), in which the gradients of non-differentiable metrics are approximated using the scoring function (REINFORCE (Williams, 1992)). A few successful examples include image captioning (Rennie et al., 2017; Ren et al., 2017), abstractive summarization (Paulus et al., 2018; Chen and Bansal, 2018; Pasunuru and Bansal, 2018; Celikyilmaz et al., 2018), machine translation (Wu et al., 2016; Gu et al., 2017), sentence simplification (Zhang and Lapata, 2017), as well as video captioning (Pasunuru and Bansal, 2017b; Wang et al., 2018). Previous works have explored the problem of optimizing multiple rewards in the context of machine translation (Neubig and Watanabe, 2016). For example, the works of Duh et al. (2012) and Sankaran et al. (2013) are based on the theory of Pareto Optimality. Our approach, instead, dynamically decides the trade-off among metrics, rather than exploring the set of static Pareto-optimal hypotheses. The most related work on this line is Pasunuru and Bansal (2018), which simultaneously optimizes multiple rewards in alternate fashion for abstractive summarization. In our work, we use a multi-armed bandit framework to dynamically switch among multiple diverse reward optimizations in the context of policy-gradient-based generative models.[1]

Multi-Armed Bandit: Many control problems can be cast as multi-armed bandit problems, where the goal is to select a sequence of arms/actions in order to optimize certain objective (e.g., expected fu-

---

[1] When we say dynamic switching, we mean using one metric at a time (i.e., no explicit weighted combination of loss metrics' optimization for a single mini-batch), but to learn an implicit ratio/proportion of metrics' importance over the overall training trajectory (e.g., BLEU metric might be sampled three times more than ROUGE on average).

ture payoff) (Bubeck et al., 2012). One widely studied problem in the multi-armed bandit literature is finding the optimal trade-off between exploration and exploitation (Audibert et al., 2009; Macready and Wolpert, 1998; Auer et al., 2002a; Kveton et al., 2019; Bubeck et al., 2012). Some widely used bandit algorithms include ϵ-greedy (Sutton and Barto, 2018), Boltzmann exploration (Kaelbling et al., 1996), UCB (Auer et al., 2002a), Thompson sampling (Chapelle and Li, 2011), contextual bandit (Sharaf and Daumé III, 2019), as well as Exp3 adversarial bandit (Auer et al., 2002b). In this work, we use Exp3, and the hierarchical version of it, for the problem of optimizing multiple rewards.[2]

Multi-armed bandit algorithms have been used in a wide range of applications, such as online advertising (Chen et al., 2013), recommendation (Li et al., 2010), multi-task task selection (Guo et al., 2019a), and hyper-parameter optimization (Li et al., 2018; Merentitis et al., 2018). Recently, Graves et al. (2017) apply a non-stationary multi-armed bandit (in particular, the Exp3.S algorithm) to select an adaptive policy (curriculum) that a neural network follows to maximize the learning efficiency. Sharma and Ravindran (2017) use multi-armed bandit sampling to choose which domain data (harder vs. easier) to feed as input to a single model (using different Atari games). To our knowledge, we are the first ones to apply a multi-armed bandit to optimize multiple rewards in the context of text generation.

3 Multi-Reward Optimization

In this section, we first describe the policy gradients-based reinforcement learning (RL) approach for text generation tasks, and then discuss the need for a better multi-reward optimization approach for RL in the context of generation tasks. Lastly, we introduce our novel methods for multi-reward optimization via multi-armed bandits.

Glossary: Agent: RL policy gradients; Bandit: multi-armed bandit; Controller: controller in HM-Bandit (see Fig. 2).

Policy Gradient Background. Cross-entropy loss based optimization is traditionally used for the sequence generation tasks. However, recent policy gradient-based reinforcement learning approach has shown two advantages over the cross-entropy loss optimization approach: (1) avoiding *exposure bias* issue which is about the mismatch in the output distributions created by different train and test time decoding approaches in cross-entropy loss optimization; (2) able to directly optimize the non-differentiable evaluation metrics.

To this end, REINFORCE algorithm (Williams, 1992; Zaremba and Sutskever, 2015) is used to learn a policy p_θ defined by the model parameters θ to predict the next action (tokens in our setup). Specifically, instead of minimizing the negative log-likelihood, we minimize the following loss:

$$L_{\text{RL}} = -\mathbb{E}_{w^s \sim p_\theta}[r(w^s)] \tag{1}$$

where w^s is the sequence of sampled tokens and $r(\cdot)$ is the reward function that measures the quality of w^s. The derivative of this loss function can then be approximated using a single sample along with a bias estimator $\hat{b}$ to reduce variance:

$$\nabla_\theta L_{\text{RL}} = -(r(w^s) - \hat{b})\nabla_\theta \log p_\theta(w^s) \tag{2}$$

There are several ways to calculate the baseline estimator, and in this work we use the SCST mechanism (Rennie et al., 2017).

Need for a better multi-reward optimization. Often, an RL agent can improve the policy p_θ via multiple reward sources. However, efficient ways of optimizing multiple rewards in a policy gradient-based reinforcement learning setup have been less explored. Previous works have either explored using a weighted combination of multiple rewards (Zhang and Lapata, 2017; Li et al., 2016) or alternate fashion of optimizing multiple rewards inspired via multi-task learning setup (Pasunuru and Bansal, 2018). However, these approaches have a disadvantage of tuning the weights of the rewards combination or using a static tunable mixing ratio while optimizing in an alternate fashion. To this end, we explore multi-reward optimization via a multi-armed bandit approach (Bubeck et al., 2012; Lattimore and Szepesvári, 2019; Burtini et al., 2015). During the training, the bandit explores/exploits the choice of reward functions in order to improve the overall performance of the model. In the remaining part of this section, we discuss various multi-armed bandit-based models for multi-reward optimization (Sec. 3.1), and reward settings (Sec. 3.2). Then, we present

---

[2] In our initial experiments, we experimented with a few other bandit approaches (UCB, contextual bandit, variants of Exp3, e.g., Exp3-S), but we ended up with our current Exp3 setting due to its performance and stability reasons within the scope of our methods and tasks.

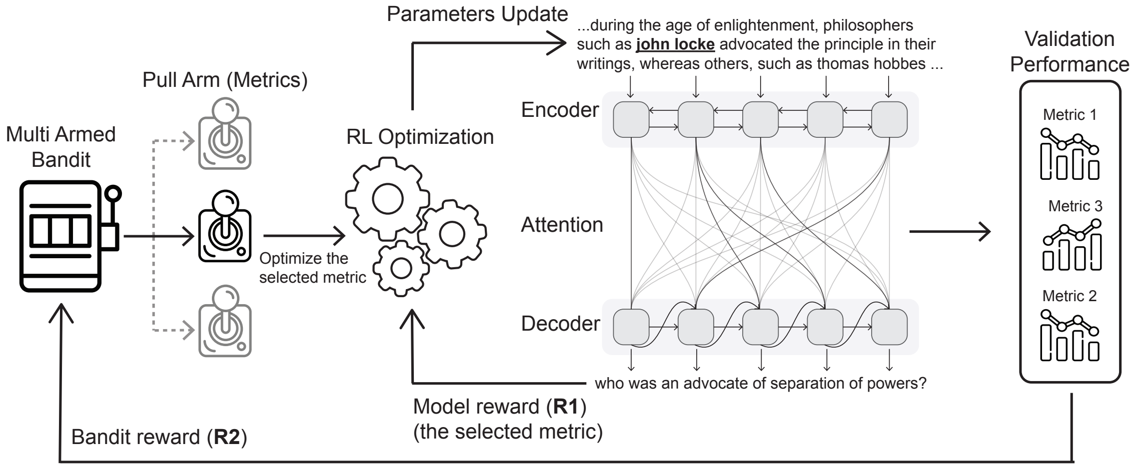

Figure 1: Overview of our multi-armed bandit reward selection framework DORB. At each step, the model outputs are scored based on a reward function (metric), where the choice of the reward function is dynamically controlled by the multi-armed bandit. Then the corresponding optimization is executed based on the chosen reward function. Finally, the observed validation performance metrics are given as feedback to the bandit.

the two novel approaches, namely Single Multi-reward Bandit (SM-Bandit, Sec. 3.3) and Hierarchical Multi-reward Bandit (HM-Bandit, Sec. 3.4).

3.1 Multi-Armed Bandit for Multi-Reward Optimization

Given a set of K candidate actions (arms) $\{a_1, a_2, ..., a_K\}$, the objective of a multi-armed bandit problem is to maximize rewards earned through a sequence of lever pulls (actions). We call this reward as bandit reward. We view the problem of optimizing multiple rewards as a sequential design of experiments (Robbins, 1952), where the bandit's goal is to decide the next arm (loss function) to pull after each round in order to maximize the rewards it earns.

Let $\{R_1, R_2, .., R_K\}$ be a set of different rewards from K sources which can measure the model/policy's performance. To directly maximize the performance of these K rewards, we need to use K different reinforcement learning-based loss functions. Let the loss function for R_i be:

$$L_{\mathrm{RL}_i} = -\mathbb{E}_{w^s \sim p_\theta}[R_i(w^s)] \tag{3}$$

Each of these K loss functions is considered as an arm of the multi-armed bandit (i.e., the arms/joysticks in Fig. 1), where pulling the i^{th} arm will result in optimizing for reinforcement based loss function L_{RL_i} (i.e., in Fig. 1, main model parameters get updated). The goal of the bandit is to explore and exploit different loss functions and maximize its reward (the validation performance of the model, see Fig. 1). One widely studied problem is the trade-off between "exploitation" of the arm with the highest estimated payoff and "exploration" of less known arms. For this, we use the popular Exp3 bandit algorithm (Auer et al., 2002b) (see Appendix A for more details on Exp3).

3.2 Bandit Reward Settings

Note that in this work, we have two sets of rewards: rewards used for optimizing the sequence generation model via policy gradients-based reinforcement learning (R1 in Fig. 1, Sec. 3), and rewards used for the bandit (R2 in Fig. 1). The rewards for the generation model are used to optimize the model w.r.t. the metric of interest, while the rewards for the bandit help the bandit decide which "metric of interest" the generation model should optimize.

In order to maintain consistent magnitude/scale across metric rewards while using them for bandits, we use scaled rewards via the quantiles of rewards history following Graves et al. (2017). Let $\mathbf{R}^t = \{R^i\}_{i=1}^{t-1}$ be the history of unscaled rewards up to time step t. Let q_t^{lo} and q_t^{hi} be the lower and upper quantiles of $\mathbf{R}^t$, respectively.[3] Then, the scaled reward, $\hat{r}^t$ is defined as follows:

$$\hat{r}^t = \begin{cases} 0 & \text{if } R^t < q_t^{lo} \\ 1 & \text{if } R^t > q_t^{hi} \\ \frac{R^t - q_t^{lo}}{q_t^{hi} - q_t^{lo}}, & \text{otherwise} \end{cases} \tag{4}$$

Instead of keeping the entire history of rewards, we use past n rewards from the history.

---

[3] We set q_t^{lo} and q_t^{hi} to be 20^{th} and 80^{th} quantiles.

Algorithm 1 SM-Bandit Training

```
Inputs: #rewards: $K$, #train steps: $n_{\text{train}}$, #steps in bandit round: $n_{\text{bandit}}$
Initialize the Exp3 bandit $B$ with $K$ arms
$a \leftarrow$ chooseArm($B$)                          ▷ Based on Eqn. 5
$i \leftarrow 0$
while $i < n_{\text{train}}$ do
    Sample word sequence $w^s$ from model
    Calculate rewards $R^{\text{train}}$ based on $w^s$
    Optimize model's $L_{\text{RL}_a}$ loss using $R_a^{\text{train}}$
    if $i \mod n_{\text{bandit}} == 0$ then
        Evaluate model to get $R^{\text{val}}$
        $r \leftarrow \frac{1}{K}\sum_{k=1}^{K}$ scaled($R_k^{\text{val}}$)    ▷ Based on Eqn. 4
        updateBandit($B, a, r$)                        ▷ Based on Eqn. 7
        $a \leftarrow$ chooseArm($B$)
    end if
    $i \leftarrow i + 1$
end while
```

3.3 Single Bandit with Multi-Reward

Often, we want to optimize multiple metrics in our RL approach. For this, we have to give a joint reward coming from multiple sources (metrics in our case) to the bandit as a bandit reward. One can easily give the weighted combination of these rewards coming from multiple sources as a reward to the bandit. However, tuning these weights is intractable if the number of reward sources is large. Here, we introduce a new approach called Single Multi-reward Bandit (SM-Bandit), which avoids tuning and uses rewards from multiple sources as feedback to the bandit. Let L_{RL_1}, L_{RL_2}, and L_{RL_3} be the reinforcement learning-based loss functions corresponding to three arms of the bandit: arm_1, arm_2, and arm_3, respectively. If arm_2 is selected at round t, then we optimize for L_{RL_2} and measure the performance of all the unscaled metric scores on the validation set and then calculate the corresponding scaled rewards for each metric. We average over these scaled rewards and give that as a reward to the bandit. The generalization of this reward for K-armed bandit is: $r^t = \frac{1}{K}\sum_{i=1}^{K}\hat{r}_i^t$, where r^t is the bandit reward at round t and $\hat{r}_i^t$ is the scaled reward (Eq. 4) for the metric corresponding to arm_i at round t. This approach allows us to avoid tuning the balancing weights across the metrics that we optimize, and ensure that the bandit is improving all metrics, as the bandit goal is to maximize the average of all metrics. A detailed procedure of SM-Bandit is described in Algorithm 1.

3.4 Hierarchical Bandit with Multi-Reward

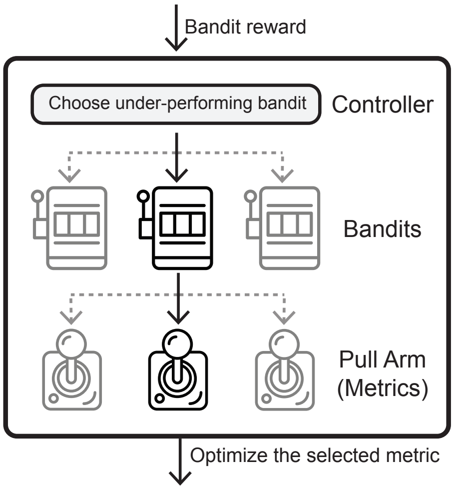

Figure 2: Overview of the hierarchical multi-armed bandit. The first-level has a controller and the second-level has bandits. The controller decides which bandit of the second-level will be pulled. The second-level bandits then decide which metric to use as the reward function during RL optimization.

The SM-bandit's goal in the previous approach described in Sec. 3.3 is to improve all metrics using a single bandit. In this section, we introduce another bandit-based variant to improve all metrics but by using multiple bandits which are controlled by a controller, called Hierarchical Multi-reward Bandits (HM-Bandit, Fig. 2). The HM-Bandit consists of a single first-level controller (not a bandit, top row in Fig. 2), and K second-level multi-armed bandits (middle row in Fig. 2). The first-level controller's goal is to find the under-performing reward metric, while the second-level bandits' goal is to trigger a specific metric optimizer that will lead to a promising improvement in this specific metric. More intuitively, the first-level controller sets the objective (e.g., ROUGE needs to be improved), while the second-level bandit decides which specific reward function can help accomplish the objective. A detailed procedure of our HM-bandit is described in Algorithm 2. This concept is also loosely related to Bayesian model selection, where it's common to use a hierarchical specification of models (Rasmussen and Williams, 2005).

4 Tasks and Setup

We use question generation and data-to-text generation tasks in our experiments. In this section, we discuss the details on these two tasks along with the experimental setup.

4.1 Question Generation

The goal of the question generation (QG) task is to generate a natural question that can be answered by the given answer span in a context. Recent works have applied seq2seq neural models for QG, e.g.,

Algorithm 2 HM-Bandit Training

```
Inputs: #rewards: $K$, #train steps: $n_{\text{train}}$, #steps in bandit round: $n_{\text{bandit}}$, #steps in controller round: $n_{\text{controller}}$
Create the controller $C$ with $K$ bandits
Initialize all bandits, and set $j \leftarrow 0$
$B \leftarrow \text{chooseBandit}(C, j)$        ▷ choose bandit at index $j$
$a \leftarrow \text{chooseArm}(B)$        ▷ Based on Eqn. 5
$i \leftarrow 0$
while $i < n_{\text{train}}$ do
    Sample word sequence $w^s$ from model
    Calculate rewards $R^{\text{train}}$ based on $w^s$
    Optimize model's $L_{\text{RL}_a}$ loss using $R_a^{\text{train}}$
    if $i \mod n_{\text{bandit}} == 0$ then
        Evaluate model to get $R^{\text{val}}$
        $r \leftarrow \text{scaled}(R_j^{\text{val}})$
        $\text{updateBandit}(B, a, r)$        ▷ Based on Eqn. 7
        $a \leftarrow \text{chooseArm}(B)$
    end if
    if $i \mod n_{\text{controller}} == 0$ then
        Evaluate model to get $R^{\text{val}}$
        $j \leftarrow \text{argmin}_k \{\text{scale}(R_k^{\text{val}})\}_{k=1}^{K}$
        $B \leftarrow \text{chooseBandit}(C, j)$
        $a \leftarrow \text{chooseArm}(B)$
    end if
    $i \leftarrow i + 1$
end while
```

generating the question given answer sentence (Du et al., 2017; Zhou et al., 2017), or the whole paragraph (Du and Cardie, 2018; Song et al., 2018b; Liu et al., 2019a; Zhao et al., 2018; Kim et al., 2019; Sun et al., 2018). Many works also used RL to optimize specific metrics (Song et al., 2018a; Kumar et al., 2019; Yuan et al., 2017). Recently, Zhang and Bansal (2019) proposed semantics-enhanced rewards to improve the QG model, and also used the multi-reward approach proposed by Pasunuru and Bansal (2018) in their RL models.

Baseline. Given a paragraph p, and an answer span a, the goal of the QG model is to generate a question q answering a. We follow the encoder-attention-decoder style architecture (see Fig. 1). The encoder is a bi-directional LSTM-RNN (Hochreiter and Schmidhuber, 1997) with self-attention (Wang et al., 2017), and the decoder is a uni-directional LSTM-RNN with attention (Luong et al., 2015) and pointer (Gu et al., 2016) mechanism, similar to Zhang and Bansal (2019). The input to the model is a concatenation of contextualized word representations (BERT (Devlin et al., 2019)), answer tag embedding (BIO tagging scheme), Part-of-Speech (POS) tag embedding, and Named-Entity (NER) tag embedding.

Rewards. We use ROUGE-L, QPP, and QAP (Zhang and Bansal, 2019) as rewards for this task. QPP is calculated as the probability of the generated question being the paraphrase of the ground-truth question via a classifier trained on Quora Question Pairs. QAP is calculated as the probability of a pre-trained QA model to correctly answer the given generated question as input.

Dataset & Evaluation. We use the SQuAD QG English dataset from Du et al. (2017) for the QG task, derived from SQuAD v1.1 (Rajpurkar et al., 2016), and the test set consists of 10% sampled examples from the training set, as the SQuAD test set is not open. For pre-processing, we do standard tokenization. We report on evaluation metrics including BLEU-4, METEOR, ROUGE-L, Q-BLEU1 (Nema and Khapra, 2018), as well as QPP and QAP (Zhang and Bansal, 2019).

4.2 Data-to-Text Generation

Data-to-text is the task of expressing the components (attributes and values) of meaning representation (MR) as human-readable natural sentences. Previous work in this area include templates (Reiter, 1995), rules (Reiter et al., 2005), pipelines (Reiter, 2007; Reiter and Dale, 1997), probabilistic models (Liang et al., 2009) and more recently end-to-end as well as neural-based methods (Wen et al., 2015; Mei et al., 2016; Dušek and Jurcicek, 2016; Lampouras and Vlachos, 2016; Dušek et al., 2020; Wiseman et al., 2017; Gong, 2018; Chen and Mooney, 2008; Reiter, 2017; Lebret et al., 2016; Distiawan et al., 2018; Gehrmann et al., 2018; Marcheggiani and Perez-Beltrachini, 2018; Guo et al., 2019b; Zhao et al., 2020). In our work, we use the state-of-the-art model from Zhao et al. (2020) as our baseline.

Baseline. Given a set of Resource Description Framework (RDF) triples,[4] the task is to generate a natural language text describing the facts in the RDF data. Following Zhao et al. (2020), we serialize and reorder the RDF data as an intermediate planning setup, and feed the plan into a seq2seq model with attention and copy mechanism.

Rewards. We use BLEU, ROUGE-L, and Entailment-Score (Pasunuru and Bansal, 2018) as rewards. Entailment-Score is calculated based on the probability that the generated sentence is classified as an entailment w.r.t. the ground truth.[5]

---

[4] Each triple contains a subject, a predicate, and an object.

[5] We use a RoBERTa classifier (Liu et al., 2019b) trained on MultiNLI (Williams et al., 2018) as entailment scorer.

Models	BLEU-4	METEOR	ROUGE-L	Q-BLEU1	QPP	QAP

Table 1: Performance of our baselines and multi-armed bandit-based models on question generation task. † denotes that these models use ROUGE-L, QPP, and QAP rewards during the optimization.

Dataset & Evaluation. We use the WebNLG dataset (Gardent et al., 2017) - a widely used English benchmark for data-to-text generation which focuses on micro-planning involving several subtasks like referring expression generation, aggregation, lexicalization, sentence segmentation, and surface realization. It contains 9,674 unique RDF triple-sets and 25,298 text references, which is divided into train, dev, and test sets.[6] We report all our results on the 'seen' part of the test set. For each sample, the input is a set of up to 7 RDF triples from DBPedia, and the output is their text descriptions. The standard evaluation metrics for this dataset include METEOR[7] (Denkowski and Lavie, 2014), BLEU (Papineni et al., 2002), and TER[8] (Snover et al., 2006). We also report ROUGE-L (Lin, 2004) and Entailment-Score (Pasunuru and Bansal, 2018).

4.3 Training Details

All the hyperparameters are tuned on the validation set for both question generation and data-to-text tasks. We use TITAN X and GeForce GTX 1080 GPUs for all our experiments. For the question generation task, we use two layers for both encoder and decoder. We set the hidden size of LSTM-RNN to 600 and use BERT-based contextual embeddings as input. We use a batch size of 32, encoder maximum length of 512 and decoder maximum length of 50, and maximum gradient clipping of 5. We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 1e-3 and 1e-6 for the cross-entropy and RL models, respectively. For data-to-text task, we use the same hyperparameters as discussed in Zhao et al. (2020) for the cross-entropy model, e.g., we use Adam with a batch size of 64 and an initial learning rate of 0.001. All RL models are initialized with the best cross-entropy model checkpoint, and use Adam with a learning rate of 1e-6. We refer to Appendix B for full training details.

5 Results and Analysis

In this section, we present the performance of previous work, our cross-entropy baselines, our RL-based baselines, and finally our multi-arm bandit-based models. We start with results on automatic evaluation (Sec. 5.1-5.2). Next, we present results on human evaluation (Sec. 5.3). Finally, we present an interpretable analysis on the bandits (Sec. 5.4).

5.1 Results on Question Generation

Baselines. Table 1 presents results on the question generation dataset for our baselines. We use the previous state-of-the-art work (Zhang and Bansal, 2019) as our cross-entropy baseline. Next, we apply policy gradients-based reinforcement learning (RL) approach, and observe that all these models are better than the baseline in all metrics. Next, we will discuss the multi-reward RL models.

Multi-Armed Bandit Approaches. Finally, we evaluate our two bandit approaches: SM-Bandit and HM-Bandit as described in Sec. 3.3 and Sec. 3.4, respectively. Further, for a fair comparison of our multi-arm bandit-based models, we further implemented multi-reward alternate optimization approach introduced by Pasunuru and Bansal (2018) and considered it as baseline for our multi-reward models.[9],[10] This model is slightly better

Our HM-Bandit†	63.38	45.34	**33.58**	**74.39**	**100.21**

Table 2: Performance of our baselines and multi-arm bandit-based models on the 'seen' test set of WebNLG data-to-text task. † denotes that these models use ROUGE-L, BLEU, and Entailment rewards during the optimization. For TER metric, lower (↓) is better. For all other metrics, higher (↑) is better.

than single reward-based RL baselines. Table 1 presents the performance of the proposed two bandit models (SM-Bandit and HM-Bandit) on various automatic evaluation metrics, and we observe that on average these models perform much better than the cross-entropy and single reward RL baseline models. Further, our bandit models also perform better than the multi-reward approach proposed by Pasunuru and Bansal (2018), suggesting that our bandit-based models are able to dynamically select the reward to optimize for overall improvement in all the metrics that we want to optimize. Also see discussion of significant improvements in human evaluation in Sec 5.3.

5.2 Results on Data-to-Text Generation

Baselines. Table 2 presents our baselines on the WebNLG data-to-text task. Our cross-entropy model is comparable to the very recent state-of-the-art model (Zhao et al., 2020). Further, we present single reward based RL models with ROUGE-L, BLEU, and Entailment score as rewards, which again perform better than our cross-entropy model. Next, we will discuss multi-reward models.

Multi-Armed Bandit Approaches. Table 2 also presents our multi-armed bandit models (SM-Bandit and HM-Bandit) which simultaneously use ROUGE-L, BLEU, and Entailment score as rewards. Again, we consider the model proposed by Pasunuru and Bansal (2018) as a baseline for multi-reward models. On average, our bandit-based models perform better than all our baselines that are discussed in the above paragraph and also the model based on Pasunuru and Bansal (2018). Also see discussion of significant improvements in human evaluation in Sec 5.3.

Model	ROUGE	PB (2018)	SMB	HMB
QUESTION GENERATION TASK				
Relevance	4.28	4.40	4.56	4.55
Coherence	4.42	4.48	4.49	4.47
WEBNLG DATA-TO-TEXT TASK				
Relevance	4.61	4.68	4.79	4.81
Coherence	4.75	4.79	4.78	4.80

Table 3: Human evaluation results on QG and WebNLG tasks. ROUGE: ROUGE-L single-reward RL; PB (2018): Pasunuru and Bansal (2018). Our SM-Bandit and HM-Bandit are statistically significantly better than ROUGE and PB models (see Sec. 5.3).

5.3 Human Evaluation

It is shown that RL models can game the metric that we use as the objective function (Paulus et al., 2018). This motivated us to optimize the RL models on multiple metrics simultaneously, thus trying to improve all the metrics and making the RL model hard to game any particular metric. In this section, we validate the superiority of our bandit models via human evaluation studies.

We performed anonymous human evaluation studies using Amazon Mechanical Turk (MTurk). We chose human annotators such that they are located in the USA, have at least 10,000 approved HITs, and have an approval rate of greater than 98%. For both question generation and WebNLG data-to-text, we considered 200 samples for each, and compared ROUGE-L RL, Pasunuru and Bansal (2018), SM-Bandit, and HM-Bandit models by asking the annotators to rate the quality of the generated outputs based on relevance and coherence on 5-

---

task are very close to the baseline model (Pasunuru and Bansal, 2018): 18.31(BLEU), 22.50 (METEOR), 46.75 (ROUGE-L), 49.65 (Q-BLEU1), 30.04 (QPP), 56.56 (QAP). This is expected as the random choice baseline is same as uniform sampling of metrics, which is closer to alternate optimization.

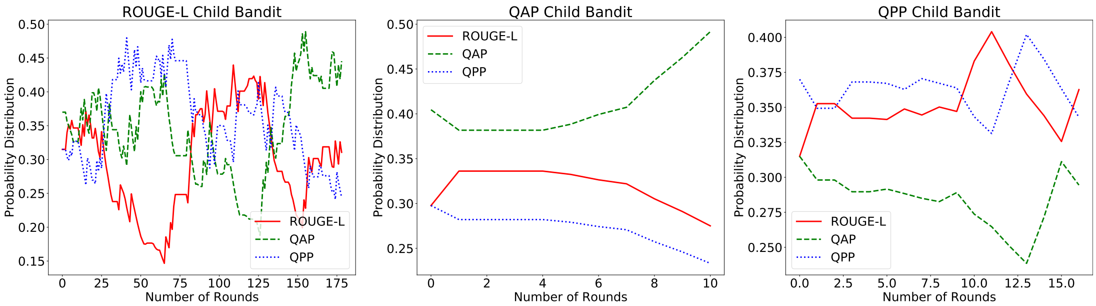

Figure 3: Plots showing the probability distribution of each child bandit of the HM-Bandit model on the QG task.

point Likert scale.[11] Table 3 presents these human evaluation studies. In terms of relevance, our SM-Bandit and HM-Bandit models are significantly better than Pasunuru and Bansal (2018) ($p<0.01$) and ROUGE-L RL models ($p<0.01$) on question generation.[12] On data-to-text, in terms of relevance, our SM-Bandit and HM-Bandit models are significantly better than Pasunuru and Bansal (2017a) with $p<0.03$ and $p<0.02$, respectively. Also, both bandit models are significantly better than ROUGE-L RL model with $p<0.01$.

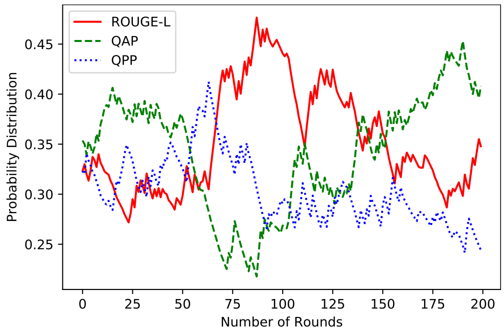

Figure 4: Plot showing the probability distribution of each arm of the SM-Bandit on question generation task.

5.4 Interpretable Bandit Analysis

Figure 4 presents the interpretable visualization of the probability distribution of each arm of the SM-Bandit as the training progresses. We observe that each metric has played an important role (as high probability arm) for at least a few rounds over the training trajectory. Also, there are multiple switchings of these metrics over the training trajectory, suggesting that this kind of automatic dynamic switching is important to improve the overall performance of RL models with multiple rewards.

Figure 3 presents the progress of child bandits of HM-Bandit during the training for question generation. As discussed in Sec. 3.4, these child bandits are controlled by a controller that selects the under-performing bandit. We observe that our HM-Bandit mostly used ROUGE-L child bandit for overall improvement in all metrics (as it is the under-performing metric). Further, each child bandit gave more importance to the metric that it wants to improve, e.g., the QAP child bandit gave more importance to the QAP arm. However, there is an exception for the ROUGE-L child bandit, where ROUGE-L arm is not the most important, suggesting that to improve the ROUGE-L metric other RL loss functions (QAP and QPP) are also useful.

6 Conclusion

We presented novel approaches for dynamically optimizing multiple reward metrics simultaneously via multi-armed bandit approach in the context of language generation. We described two such mechanisms, namely single bandit and hierarchical bandit with multiple rewards. We conducted experiments on two challenging language generation tasks: question generation and data-to-text generation, and our method achieved strong improvements based on human evaluation over previous approaches. We further presented interpretable analysis on our bandit methods.

---

[11] For question generation, relevance is defined as how clearly the generated question will be able to point to the right answer, given an input paragraph as context. For WebNLG data-to-text, relevance is defined as how related is the generated description w.r.t. the given RDF data such as mentioning the facts. For both tasks, coherence is based on the logic, readability, and fluency of the generated question or description.

[12] We use bootstrap test (Efron and Tibshirani, 1994; Noreen, 1989) for calculating the statistical significance score.

A Exp3 Bandit Algorithm

A stochastic bandit is completely determined by the distribution of rewards of respective actions. However, it will be hard to argue that rewards are truly randomly generated, and even if they are randomly generated, the rewards could be correlated over time (e.g., the validation performance at the next step will be correlated with validation performance at this time step). Taking all these factors into account makes the algorithm overly complicated, and thus an alternative is to assume nothing about the underlying mechanism that generates the rewards while still trying to achieve the lowest possible regret. This is called the adversarial bandit problem, where the goal is to design an algorithm that keeps the regret small regardless of what rewards are assigned to actions.

Exponential-weight algorithm for Exploration and Exploitation, or Exp3 (Auer et al., 2002b), was created to handle the non-stochastic adversarial bandit problem. We use this algorithm in our DORB framework. Exp3 works by maintaining a set of weights for each candidate action, and the weights are used to decide randomly which action to take next. The empirical observation is fed back to the bandit to either increase or decrease the relevant weights. The algorithm also has a hyperparameter $\gamma \in [0,1]$ that decides the probability to take action uniformly at random. Specifically, at round t, the bandit picks action (arm) i among K arms based on the arm selection probability which is defined as follows:

$$p_t(i) = (1-\gamma)\frac{w_{t,i}}{\sum_{j=1}^{K} w_{t,j}} + \frac{\gamma}{K} \tag{5}$$

where the weights $w_{t,i}$ are updated based on the observed bandit reward r_t^B:

$$\hat{r}_{t,j}^B = \begin{cases} r_t^B / p_t(i) & \text{if } j = i \\ 0 & \text{otherwise} \end{cases} \tag{6}$$

$$w_{t+1,i} = w_{t,i} \exp(\gamma \hat{r}_{t,i}^B / K) \tag{7}$$

B Training Details

All the hyperparameters are tuned on the validation set for both question generation and data-to-text tasks. We use TITAN X and GeForce GTX 1080

GPUs for all our experiments, where all our RL models roughly take 1 day to train on a single GPU.

For the question generation task, we use two layers for both bi-directional encoder and uni-directional decoder. We set the hidden size of LSTM-RNN to 600 and use BERT-based contextual embeddings as input instead of word embeddings. The number of parameters in our model is 33.3 million. We use a batch size of 32, encoder maximum length of 512 and decoder maximum length of 50, and maximum gradient clipping of 5. We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 1e-3 and 1e-6 for cross-entropy model and RL models, respectively. We use a dropout of 0.3 for the cross-entropy model and no dropout for RL models. For multi-reward bandit models, we set the bandit coefficient (γ) to 0.1, and each round of the bandit consists of optimization of 100 mini-batches of training data. For HM-Bandit, we set the controller round size to 300 mini-batches. We consider the following short hyperparameters ranges and manually tune on: learning rate in the range [1e-5, 1e-7]; bandit coefficient in the range [0.01, 0.5]; bandit round - $\{10, 100\}$; and controller round size - $\{30, 300\}$.

For WebNLG data-to-text task, we first serialize and reorder the RDF data as an intermediate planning setup, and then feed the plan into an encoder-attention-decoder style architecture with copy mechanism, to generate the text describing the RDF data. We use same hyperparameters as discussed in Zhao et al. (2020) for the cross-entropy model, e.g., we use Adam with a batch size of 64, initial learning rate of 0.001, and a dropout of 0.3. All RL models are initialized with the best cross-entropy model checkpoint, and use Adam with a learning rate of 1e-6. We do not use dropout for RL models. The number of parameters in our model is 5.9 million. For multi-reward bandit models, we set the bandit coefficient (γ) to 0.15, and each round of the bandit consists of optimization of 10 mini-batches of training data. For HM-Bandit, we set the controller round size to 30 mini-batches. We consider the following short hyperparameters ranges and manually tune on: learning rate in the range [1e-5, 1e-7]; bandit coefficient in the range [0.01, 0.5]; bandit round - $\{10, 100\}$; and controller round size - $\{30, 300\}$.

MEDFILTER: Improving Extraction of Task-relevant Utterances through Integration of Discourse Structure and Ontological Knowledge

Abstract

Information extraction from conversational data is particularly challenging because the task-centric nature of conversation allows for effective communication of implicit information by humans, but is challenging for machines. The challenges may differ between utterances depending on the role of the speaker within the conversation, especially when relevant expertise is distributed asymmetrically across roles. Further, the challenges may also increase over the conversation as more shared context is built up through information communicated implicitly earlier in the dialogue. In this paper, we propose the novel modeling approach MEDFILTER, which addresses these insights in order to increase performance at identifying and categorizing task-relevant utterances, and in so doing, positively impacts performance at a downstream information extraction task. We evaluate this approach on a corpus of nearly 7,000 doctor-patient conversations where MEDFILTER is used to identify medically relevant contributions to the discussion (achieving a 10% improvement over SOTA baselines in terms of area under the PR curve). Identifying task-relevant utterances benefits downstream medical processing, achieving improvements of 15%, 105%, and 23% respectively for the extraction of symptoms, medications, and complaints.

1 Introduction

In this paper, we propose a novel modeling approach that embodies insights regarding the organization of task-oriented conversations in order to improve performance at utterance classification over SOTA baseline approaches. Task-oriented conversations involve sharing task-relevant information that may be useful as the task ensues (Liu et al., 2019a; Kazi and Kahanda, 2019). Unfortunately, human-to-human conversations are less well structured than expository text, which is more often the source material for information extraction and summarization. Expository text is typically structured top-down and organized around information flow. Task-oriented conversations, on the other hand, are typically organized around the task and knowledge of task structure provides an implicit scaffold for understanding. Thus speakers feel free to elide or imply important information rather than making it explicit. The challenges have been well documented (Waitzkin, 1989; Lacson et al., 2006). Prior work in utterance classification is a source of SOTA modeling approaches that perform relatively well despite these challenges while leaving much room for improvement.

Our evaluation in this paper specifically focuses on doctor-patient interactions. Doctor-patient interactions are task-oriented, expert-layperson interactions in which the concerns voiced by the layperson (e.g., symptoms), the underlying issue identified by the expert (e.g., complaint) and the prescribed solutions (e.g., medications) play a crucial part. Customer-service chats are another example of such dialogue. As in the general case, topic switching abounds: the doctor may jump from a question about a symptom to a statement providing initial assessment then back again, with or without waiting for a reply from the patient (which may, itself, be responsive or introduce a new concern). In addition, the participants make unequal contributions to different parts of the schema due to the inherent asymmetry between their roles in terms of knowledge and authority. Despite these challenges, humans are able to communicate very effectively in this way. Because of that, the issues increase as the conversation progresses and more shared context is built up, in part because of a certain amount of shared domain knowledge, despite differences in the extent and phrasing of it. In response to these insights, our proposed model, which we refer to as MEDFILTER, integrates elements of dis-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 7781–7797,
November 16–20, 2020.

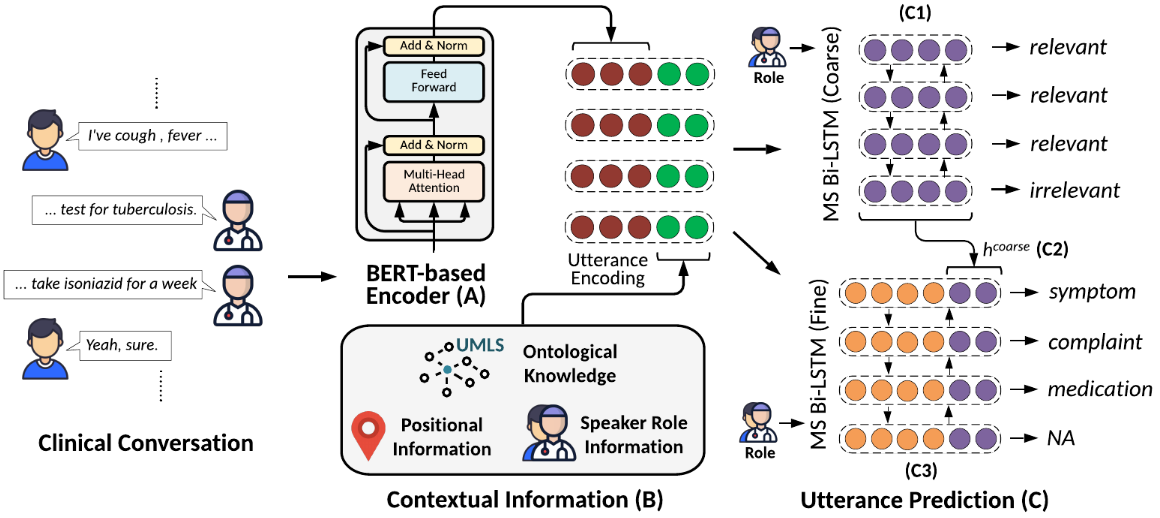

Figure 1: Overview of MEDFILTER. MEDFILTER first encodes each utterance of the given conversation using a BERT-based encoder (A). The obtained utterance embedding is concatenated with contextual information like speaker role, position of utterance in the conversation, and ontological knowledge (B). This is then fed to a MS-BiLSTM (C1) for medical relevance identification. MS-BiLSTM leverages speaker role information to learn speaker-specific context for each utterance. This contextual representation is concatenated with the utterance embedding (C2) and passed through another MS-BiLSTM (C3) which focuses on fine-grained categorization. Both tasks are jointly learned. Refer to Section 3 for more details.

course structure and ontological knowledge to improve utterance classification, the impact of which is also observed in a downstream extraction task. We evaluate the approach on a corpus of nearly 7,000 doctor-patient interactions as a case study.

Our proposed method, MEDFILTER[1], is illustrated in Figure 1 and described in detail in Section 3. Its architecture specifically reflects an awareness of the challenges above and begins to address them. In particular, the speaker's role (i.e., doctor, patient, and other) and position within the interaction are both introduced as structuring variables. Insights from ontological knowledge are also made available through a domain ontology: specifically, the Unified Medical Language System (UMLS) (Bodenreider, 2004). From a more technical perspective, the architecture introduces a novel Multi-Speaker BiLSTM to learn role-specific context representations. MEDFILTER also benefits from the incorporation of a hierarchical loss that jointly learns the coarse-grained task of predicting medical relevance to improve fine-grained topic-based utterance classification. The ability to extract medically relevant utterances from doctor-patient conversations and categorize them into the medical topics/categories has a substantial practical impact in medical practice (Finley et al., 2018; Quiroz et al., 2019).

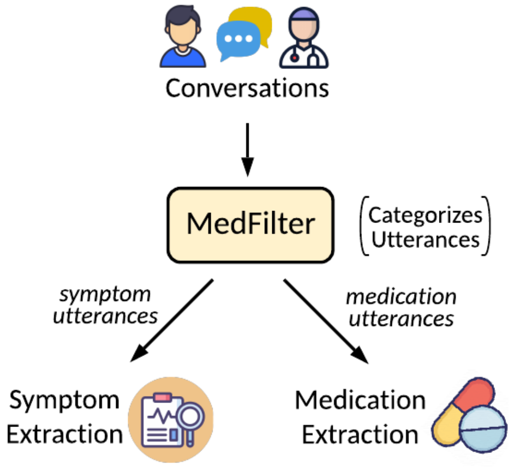

Figure 2: MEDFILTER as a part of extraction pipeline.

2 Related Work

Dialogue Summarization: In addition to the challenges noted earlier in the paper, other linguistic phenomena such as backchannels, false starts, and topic diffusion are prominent in human-to-human conversations. They add noise, which challenges the capabilities of otherwise effective sumarization approaches such as pointer-generator networks (See et al., 2017; Liu et al., 2019b).

Some prior work has relied on an Information Extraction (IE) based approach to extract details about individual medical entities such as symptoms or medications (Du et al., 2019; Selvaraj

---

[1] `https://github.com/sopankhosla/MedFilter`

and Konam, 2019). However, recently, multiple studies (Lacson et al., 2006; Kocaballi et al., 2019; Liu et al., 2019a,b; Park et al., 2019) have shown the benefits of using the topical structure in goal-oriented dialogues to improve summarization. Within that scope, Liu et al. (2019a) introduce *key-point sequences* that describe the logical topic flow of the summary of customer-service chats. They propose a hierarchical transformer to predict these topics (key-points) for each utterance and use them as auxiliary labels to guide the summarization.

This past work inspires our work in which we extend the approach and then apply it in the more challenging domain of doctor-patient interactions. We consider it more challenging both in terms of the number of utterances per conversation (avg. 225 vs 20) and topic switches (Kocaballi et al., 2019). To improve the key-point sequence utterance-level topic classification approach (Liu et al., 2019a), we propose MedFilter that models speaker-specific context augmented with ontological knowledge and a hierarchical loss function.

Intent Classification: The problem of classifying utterances into medical topics/categories has many similarities with the task of utterance-level intent classification (Zhang et al., 2019; Budzianowski et al., 2018b; Qu et al., 2019). In our case, medical categories act as coarse-grained intents that drive the content of the discussion. Much of the previous work in intent classification caters to creating better dialog agents that condition their responses on the intent of the previous utterance (Budzianowski et al., 2018a; Bocklisch et al., 2017). For instance, Chen et al. (2019); Kim et al. (2017) propose intent classification as a text classification task where each utterance is considered a complete, independent command. However, this is not true in our case as the discussion about a medical category might range over multiple utterances, each dependent on context. Hence, we tackle the classification problem as a sequence-labeling task.

Sequence Labeling in Dialogue: Most prior work that employs sequence labeling for utterance classification in dialogues (Raheja and Tetreault, 2019; Liu et al., 2017; Jiao et al., 2019a) evaluates their systems on dialogue-act classification (Shriberg et al., 2004, 1998) or emotion recognition datasets (Poria et al., 2019). In this paper, we adopt state-of-the-art modeling approaches from the emotion recognition task (Jiao et al., 2019a,b) to serve as baselines in our evaluation since our task has not previously been benchmarked.

3 Proposed Method: MedFilter

The overall architecture of MedFilter is shown in Figure 1. The input to MedFilter is a transcribed clinical conversation $\mathcal{C}$ of form $\{u_1, u_2, ..., u_n\}$, where each u_i represents an utterance. Each utterance in the conversation is passed through a BERT-based encoder (Fig. 1A and Sec. 3.1) to get a fixed-dimensional representation. Contextual information such as speaker role, the utterance's position in the conversation, and ontological knowledge (Fig. 1B and Sec. 3.2) is then appended to the BERT representation. The encoding is input to the coarse Multi-Speaker BiLSTM (MS-BiLSTM) model (Fig. 1C1) followed by a fully-connected layer to classify the relevance of utterances for topical classification. The representation created by MS-BiSLTM (Coarse) is then concatenated with the utterance encoding (Fig. 1C2) and the resulting vector is fed to the fine-grained MS-BiLSTM (Fig. 1C3) to classify utterances into different medical categories (Sec. 3.3). MedFilter is jointly optimized on both classification tasks.

3.1 BERT-based Encoder

Given the superior modeling capabilities of long-range dependencies in Transformer-based models (Vaswani et al., 2017), we use pre-trained BERT (Devlin et al., 2019) for encoding each utterance u_i. We first encode each token in the utterance using BERT, i.e., $[\boldsymbol{h}_{i1}^{\texttt{BERT}}, \boldsymbol{h}_{i2}^{\texttt{BERT}}, ..., \boldsymbol{h}_{im}^{\texttt{BERT}}]$, where $\boldsymbol{h}_{ij}$ represents BERT-encoding of j^{th} token of u_i. Now, following Reimers and Gurevych (2019), we use `MEAN` pooling for obtaining a representation for the entire utterance ($\boldsymbol{h}_i^{\texttt{Text}}$). Since the original pre-trained BERT model is trained on a general web corpus such as Wikipedia, it might not generalize well to our corpus. Therefore, we further fine tune the BERT model in a supervised manner for the task of predicting the utterance type.

3.2 Contextual Information

In addition to encoding the text of an utterance, we also make use of the following types of contextual information.

1. Speaker Role Info: In conversations in general, speaker identity helps ground co-references like *I, You*. In doctor-patient conversations, each of the speakers play a specific role in the goals of the interaction. For example, the doctor is more likely to discuss medications than the patient. To allow the representation to be sensitive to speaker information, we map the speaker roles, namely, doctor, patient, and other, to a d-dimensional embedding ($\boldsymbol{h}_i^{\texttt{speaker}}$) which is learned during training and given to the model along with the text-based representation.

2. Positional Info: Clinical conversations often follow a pattern where topics like symptoms and complaints are discussed earlier in the dialog and prescribed medications are narrated in the middle or toward the end. To include this signal in MEDFILTER, we partition all the utterances in a conversation into k equal parts based on their position. For instance, if the conversation has 40 utterances and $k = 4$ then the initial 10 belong to 1^{st} partition and the next 10 belong to 2^{nd} and so on. Similar to speaker role information, a trainable embedding is associated with each partition ($\boldsymbol{h}_i^{\texttt{position}}$).

3. Ontological Knowledge: UMLS (Unified Medical Language System) (Bodenreider, 2004) is a combination of a semantic network and a meta-thesaurus. The semantic network consists of a set of 127 broad subject categories, or semantic types, which provide a consistent categorization of all concepts represented in the meta-thesaurus. In MEDFILTER, we use Quick-UMLS (Soldaini and Goharian, 2016), which identifies clinical mentions in an utterance and retrieves the associated UMLS Concept Unique Identifers (CUIs) and semantic type, to inform our model about the type of medical phrases present in the input. We believe that types such as *Pharmacologic Substance*, *Symptoms*, and *Diseases* can be helpful in correctly classifying the utterances. We assign a trainable embedding to each semantic type. However, since each utterance can contain multiple clinical mentions of varied semantic types, we average the semantic-type embeddings for each mention present in the utterance and pass it to the model ($\boldsymbol{h}_i^{\texttt{semantic}}$).

3.3 Utterance Prediction

The classifier takes in the extended representation for each utterance u_i in the conversation given as

$$\boldsymbol{h}_i = [\boldsymbol{h}_i^{\texttt{Text}}; \boldsymbol{h}_i^{\texttt{speaker}}; \boldsymbol{h}_i^{\texttt{position}}; \boldsymbol{h}_i^{\texttt{semantic}}].$$

To explicitly model the separate roles performed by each speaker (as discussed in Section 1), we propose a novel module **Multi-Speaker BiLSTM (MS-BiLSTM)** that includes speaker-level BiLSTMs to learn the context for each speaker type separately. We note, for example, that when the doctor is prescribing medications to the patient, she is more likely to expand on her previous utterance in order to discuss different details about the medicine, whereas the patient is most likely to give simple acknowledgments or ask questions in her turn. Having separate speaker-level BiLSTMs allows MS-BiLSTM to model this difference in the use of context.

MS-BiLSTM takes in $\boldsymbol{h}_i$ and s_i (utterance's speaker) as input. $\boldsymbol{h}_i$ is passed through a background BiLSTM ($\texttt{BiLSTM}_{\texttt{bg}}$) and different speaker-level BiLSTMs ($\texttt{BiLSTM}_{\texttt{s}}$). Thus, if there are 3 speaker roles in the conversation, then the extended representation for each utterance ($\boldsymbol{h}_i$) would be input to 4 BiLSTMs (1 background BiLSTM + 3 speaker BiLSTMs). The hidden representations from $\texttt{BiLSTM}_{\texttt{bg}}$ and $\texttt{BiLSTM}_{\texttt{s}_\texttt{i}}$ are combined using a sigmoid gate that is learned during training:

$$\begin{aligned}
\hat{\boldsymbol{h}}_i^{\texttt{bg}} &= \texttt{BiLSTM}_{\texttt{bg}}(\boldsymbol{h}_i) \\
\hat{\boldsymbol{h}}_i^{\texttt{s}_\texttt{j}} &= \texttt{BiLSTM}_{\texttt{s}_\texttt{j}}(\boldsymbol{h}_i), \; \forall j \in \text{speakers} \\
g^s &= \sigma(w_g) \\
\boldsymbol{h}_i' &= g^{s_i} * \hat{\boldsymbol{h}}_i^{\texttt{s}_\texttt{i}} + (1 - g^{s_i}) * \hat{\boldsymbol{h}}_i^{\texttt{bg}}, \\
\boldsymbol{h}_i' &= \texttt{MS-BiLSTM}(\boldsymbol{h}_i, s_i).
\end{aligned}$$

Each speaker-level BiLSTM ($\texttt{BiLSTM}_{\texttt{s}_\texttt{i}}$) only receives gradients for that speaker's utterance (u_i) thus focusing on role-specific context. The gate between $\hat{\boldsymbol{h}}_i^{\texttt{s}_\texttt{i}}$ and $\hat{\boldsymbol{h}}_i^{\texttt{bg}}$ controls the relative importance of the role-specific and general-context representation learned by speaker-level and background BiLSTMs respectively.

In this paper, we focus on classifying an utterance into one or more out of three categories, namely *symptoms*, *complaints*, and *medications*. However, these categories can be combined together to create a coarse-grained task of predicting if the utterances are *medically relevant*. We leverage this coarse-grained supervision to create a hierarchical model with a joint-learning loss.

Hierarchical Modeling: In this architecture, the extended representation ($\boldsymbol{h}_i$) and the corresponding speaker role (s_i) are first passed through a coarse-grained MS-BiLSTM and a fully-connected layer followed by softmax to be classified into one of the two categories {*Medically Relevant*, *Irrelevant*}. The representation $\boldsymbol{h}_i^{\texttt{coarse}}$ learned by this MS-BiLSTM would model the differences between medically relevant and irrelevant text which can also benefit fine-grained classification. Hence, $\boldsymbol{h}_i^{\texttt{coarse}}$ is concatenated with $\boldsymbol{h}_i$ and sent to the fine-grained MS-BiLSTM which focuses on the multi-label classification into the three categories discussed earlier:

$$\begin{aligned}
\boldsymbol{h}_i^{\texttt{coarse}} &= \texttt{MS-BiLSTM}_{\texttt{coarse}}(\boldsymbol{h}_i, s_i),\\
\boldsymbol{h}_i'' &= [\boldsymbol{h}_i; \boldsymbol{h}_i^{\texttt{coarse}}],\\
\boldsymbol{h}_i^{\texttt{fine}} &= \texttt{MS-BiLSTM}_{\texttt{fine}}(\boldsymbol{h}_i'', s_i),\\
\boldsymbol{p}_{\texttt{coarse}} &= softmax(\boldsymbol{W}_c \boldsymbol{h}_i^{\texttt{coarse}} + \boldsymbol{b}),\\
\boldsymbol{p}_{\texttt{fine}} &= \sigma(\boldsymbol{W}_f \boldsymbol{h}_i^{\texttt{fine}} + \boldsymbol{b}).
\end{aligned}$$

Both tasks are jointly optimized and the hyperparameter β controls the relative strength of the medical-relevance classification loss ($\boldsymbol{L}_{\texttt{coarse}}$):

$$\boldsymbol{L} = \boldsymbol{L}_{\texttt{fine}} + \beta \boldsymbol{L}_{\texttt{coarse}}.$$

Such a loss function could also be used in other utterance classification tasks where classes follow a hierarchical structure. For instance, in emotion classification (Poria et al., 2019), the fine-grained categories (e,g, happiness, anger, etc.) can be combined to create an *emotive* class, and a coarse-grained classifier could be used to learn features that differentiate between *emotive* and *neutral* utterances.

4 Experimental Setup

4.1 Corpus Description

Our data set comprises 6,862 annotated transcripts of real and de-identified doctor-patient conversations with an average of 225 utterances per conversation, primarily from the doctor and patient but occasionally including contributions from nurses, caregivers, and other attendees as well. The annotation guidelines were developed by a team of professional medical scribes and NLP experts. Annotators were trained to identify the medically-relevant utterances in a given conversation and assign one or more (out of 15 possible) tags to each utterance. Each of these tags represents a medical category like *symptom*, *previous medical history*, *diagnosis* etc. Most conversations contain some informal, social interactions with utterances that are irrelevant to the downstream clinical tasks.[2]

In this work, we leverage the labels to train MEDFILTER on the task of utterance classification and focus on three categories, namely, *symptoms*, *complaints*, and *medications*, where *medications* include past/current medications taken by the patient and prescriptions given by the doctor.[3] We choose the above-mentioned categories as they are found in every office visit, and most closely generalize to other domains like customer-service chats. However, our approach can be easily generalized for capturing other aspects such as *previous medical history*, *diagnosis*, and *assessments* as well. We set aside a random sample of 627 and 592 conversations for validation and testing respectively.

4.2 Baselines

Since sequence-labelling models haven't been applied to utterance classification in doctor-patient conversations previously, we compare our proposed method, MEDFILTER, against baseline methods that give SOTA results on utterance-level emotion recognition data sets. **HiGRU-sf** (Jiao et al., 2019b) is a hierarchical gated recurrent unit (HiGRU) framework with an utterance-level GRU and a conversation-level GRU. **BiF-AGRU** (Jiao et al., 2019a) denotes a two-level BiGRU fusion model with uni-directional AGRU for attentive context representation. **UniF-BiAGRU** is similar to BiF-AGRU, but uses a uni-directional GRU for contextual utterance representation and a bi-directional AGRU for attentive context. For implementation, we use the official code provided by the authors.[4][5]

Evaluation Metric: We use the mean area under the PR curve (AUC), a widely used metric in multi-label classification setting (Riedel et al., 2013; Mintz et al., 2009), as our evaluation metric. It is also used for early stopping and hyperparameter tuning.[6]

5 Utterance Classification Results

MEDFILTER performs better than any of the baseline approaches in assigning utterances in doctor-patient conversations to medically relevant categories. Table 1 presents the AUC scores for different utterance-labeling models on our test set. Each result is the mean of 5 independent runs with different seeds.

A BERT-based classifier that passes the mean of token-level embeddings through an FC layer

BERT variants	BERT	33.5 (0.08)
	Clinical BioBERT-FT	36.1 (0.11)
	BERT-FT	36.2 (0.08)
With Context	BERT BiLSTM FT	44.5 (0.22)
	BERT-FT BiLSTM	45.8 (0.16)
Our Method	MEDFILTER	**47.2** (0.26)

Table 1: Utterance classification results on the test-set (**Avg. (std. dev.)**). Results on valid-set are shown in the Appendix. The improvements are statistically significant (p < 0.01).

gives a low score of 33.5 AUC. When the BERT encoder is fine-tuned along with the classification layer (BERT-FT), the performance jumps to 36.2 underlining the benefits of fine-tuning BERT (Devlin et al., 2019). We also find that using Clinical BioBERT-FT (fine-tuned) does not beat BERT-FT. This is partly because the former is further pre-trained on MIMIC notes (Alsentzer et al., 2019) which are much more formal than medical conversations and thus the additional knowledge does not transfer well to our corpus.

Adding context to BERT-based models , using, e.g. BiLSTM, gives substantial boosts. End-to-end fine-tuned BERT BiLSTM (BERT BiLSTM FT) performs worse than BERT-FT BiLSTM that passes fine-tuned BERT embeddings through a BiLSTM as non-learnable features. MEDFILTER, which further includes contextual information, uses MS-BiLSTM in place of BiLSTM, and optimizes a hierarchical loss, significantly outperforms all baselines and obtains 1.4 absolute AUC points over BERT-FT BiLSTM (2^{nd} best). It also surpasses emotion recognition SOTA methods like HiGRU-sf by 4.1 AUC points.

Ablation Results: To understand the importance of each module in MEDFILTER, we perform a cumulative ablation study (Figure 3). We find that removing individual modules results in notably reduced performance. The model that does not incorporate hierarchical modeling, shows a dip of 0.4 AUC points. This suggests that the information learned in the medical-relevance prediction layer aids the final classification task. Further, replacing MS-BiLSTM with a simple BiLSTM leads to a drop of an additional 0.6 AUC points, revealing the importance of modeling speaker-specific context. Without contextual information, we see a reduction of 0.4 AUC points. This shows that features like speaker role, position, and semantic types are essential for our task.

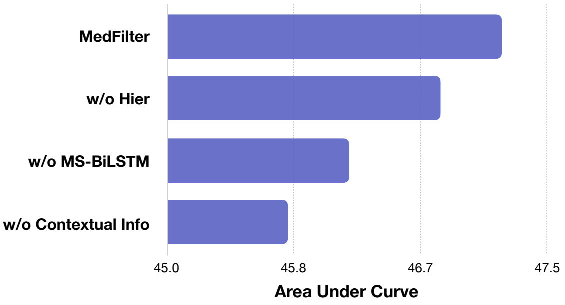

Figure 3: Cumulative Ablation Results

6 Impact of Utterance Classification on Downstream Medical Extraction

The results in the previous section portray the effectiveness of MEDFILTER at sorting important utterances in clinical conversations into medically relevant categories. Such filtering, when included in the pipeline (for example, as a pre-processing step), can assist downstream medical processing methods to focus on utterances that contain information pertinent for their tasks (Figure 2), by improving the signal-to-noise ratio in the input. In this section, we evaluate whether the use of MEDFILTER to prune irrelevant utterances is advantageous for symptom, medication, and complaint extraction.

6.1 Task Setup

The extractor takes the conversation as input and outputs the discussed symptoms/medications/complaints within.

Conversation-level labels for all three extraction tasks are taken from a predefined set provided by the corpus annotators. For **symptoms**, they include 14 coarse-grained classes to represent different body systems (e.g., cardiovascular) and 178 fine-grained ones for the corresponding issues (e.g., palpitations). Given the small size of the training data, we use the coarse-grained body-systems for symptom extraction. We then manually curate a list of different symptoms corresponding to each body-system using UMLS and use their UMLS CUIs as labels.[7]

For **medications**, we manually link medication labels to their corresponding UMLS (Bodenreider, 2004) concepts and group them using hierarchies

---

QuickUMLS (SU BERT-FT BiLSTM)	35.9	49.2
QuickUMLS (MR MEDFILTER)	35.2	47.4
QuickUMLS (SU MEDFILTER)	36.1	**49.3**

Table 3: Results(%) for Symptom Extraction. **MR**=Medically Relevant, **SU**=Symptom Utterances.

from NCI Thesaurus (Sioutos et al., 2007). [8] We pass each medication name through QuickUMLS to get a list of possible CUIs for the term in UMLS. We take the candidate CUI with a similarity of 1 and find its NCI hierarchy in the UMLS metatheasurus. The four topmost nodes in the hierarchy are extracted, which act as the pseudo-label for that CUI. In order to reduce the class-imbalance, some of these hierarchies are combined to form a coarser label. This reduces the number of labels to 31. Finally, *Others* label is added, which inhabits medicine names (in the test-set) that do not correspond to any of the previous 31 labels. This reduces the label count to 32 for medications.[9]

Complaints in our corpus range from follow-up visits to disease names to vaccine requests. Similar to medication extraction, we leverage SNOMED-CT hierarchies[10] to constraint the tag list to 11, where the first 10 represent diseases of different body systems and *Others* encompasses complaints like follow-up, vaccine requests, medication refill requests, etc. (Table A11).

We use the same train/val/test split as defined for the utterance classification experiments in Section 4.1. The performance of the extraction pipeline is evaluated on Micro and Macro-F1 scores.

6.2 Extractor Details

All three extraction tasks are modeled as multi-label classification. We leverage a state-of-the-art medical entity-linking tool, QuickUMLS (Soldaini and Goharian, 2016)[11], that takes in a conversation and outputs UMLS CUIs corresponding to all identified candidate concepts. Concepts with a similarity measure of 1 are chosen as predictions. For symptom extraction, the predictions are compared against a manually created list of CUIs (presented in Appendix Table A12) for symptoms associated with each of the 14 Body Systems. The presence of a symptom of body-system b is determined by the presence of the predicted CUIs in the target list for that body system. We compare the NCI and the SNOMED-CT hierarchies of the predicted concepts against the label hierarchies for medications and complaints, respectively. Concepts that do not fit into one of the specific categories are grouped under the label *Others*. In the next section, we report the results for the best performing filtering thresholds.[12]

6.3 Results

We find that the performance of the baseline medication and symptom extractor QuickUMLS (All Text) is substantially boosted by filtering out irrelevant utterances (Tables 2 and 3). Pruning medically irrelevant utterances using MEDFILTER (MR MEDFILTER) improves Micro F1 by 29.3 and 4.7 points for medication and symptom extraction, respectively. If only the medication/symptomatic utterances (MU/SU) are input to the extractors, the results improve further.

Results for complaint extraction are shown in Table 4. We find that the QuickUMLS extractor does not perform well on complaint extraction. However, consistent with the other two categories' trends, pruning irrelevant utterances before sending the conversation through the extractor improves performance. Micro-F1 score increases from 35.6 for All Text to 43.7 for CU MEDFILTER.

Pruning done using MEDFILTER seems to be more beneficial than BERT-FT BiLSTM (2^{nd} best utterance classifier in Table 1) for medication and complaint extraction, however they perform equally well for symptom extraction. This suggests that the benefits from the inclusion of discourse structure, domain knowledge, and a hierarchical loss function, do not transfer well to symptom ex-

traction. In Section 7, we investigate the kinds of utterance classification errors MedFilter makes, that need to be addressed to further improve the symptom extraction pipeline.

7 Discussion

Why does contextual information help? Ablation results (Figure 3) show that incorporating speaker role information and UMLS semantic-type information provides significant improvements in AUC scores for utterance classification. In Figure 4a, we plot the proportion of utterances from different medical categories against their speakers. While both parties contribute equally to symptom discussions, there is a clear asymmetry in the number of *medication* and *complaint* utterances spoken by the doctor and the patient, explaining the contribution of speaker role information in differentiating *medication/complaint* utterances from others.

We also plot the distribution of the four most frequent UMLS semantic types present in the utterances of different medical categories (Figure 4b). For medications, we find that UMLS entities with semantic type *Pharmacologic Substance* are present in more than 55% of the medication utterances indicating that its detection is a knowledge-dependent task. Similarly, and supporting our hypothesis, *Disease/Syndrome* and *Sign/Symptom* are the most frequent semantic types in complaint and symptom utterances, respectively.

Error Analysis: In this section, we present a deeper analysis of some of the systematic knowledge-extraction errors made by MedFilter that limit its performance in recognizing medically-relevant utterances.

1. Informal Language: The model sometimes overlooks informal references to symptoms. For instance, utterances such as *PT: I feel something unusual in my leg* or *PT: My heart beats funny!* discuss musculoskeletal and cardiovascular symptoms but do not use medical terms to refer to them. These patterns seem to be more frequent in patient utterances, likely because they are less familiar with medical terminology. Off-the-shelf entity-linkers, like QuickUMLS (Soldaini and Goharian, 2016), do not transfer well to spoken medical conversations. They are unable to recognise the correct UMLS concepts (and semantic types) corresponding to the colloquial symptomatic phrases which reduces their effectiveness as features.[13] For instance, for the utterance *PT: My heart is racing.*, QuickUMLS outputs 1A rather than 1B:

Input: PT: My heart is racing
(A): PT: My $[\textbf{heart}]_{\texttt{body\_part}}$ is racing. (1)
(B): PT: My $[[\textbf{heart}]_{\texttt{body\_part}}\ \textbf{is racing}]_{\texttt{symptom}}$.

2. Physical Manifestations of Symptoms: Internal symptoms often manifest themselves physically as a digression from the natural ability to

---

[13] *Sign/Symptom* entities are identified in less than 30% of total symptomatic utterances (Figure 4b).

perform typical activities. For instance, when the patient says *I can't do anything after I'm back from office* or *I can only walk up one flight of stairs*, she might be implicitly mentioning a cardiovascular symptom. A sizeable subset of such examples includes usage of duration or frequency to convey the implicit deviation, like

Duration: PT: I only sleep for **4 hours**,
Frequency: PT: I go to the bathroom **10 times** at night,
Quantity: DR: I see you are up to **300 pounds** now.

8 Future Work

For a system to correctly classify the samples of the above two categories, it needs both to generalize to patient-generated language, and to have a semantic understanding of whether the description strays from normal. Incorporating data from online self-disclosure sites like medical subreddits and discussion forums (Basaldella and Collier, 2019) during training might prove beneficial for learning better representations for such vocabulary. Concept normalization data sets (Miftahutdinov and Tutubalina, 2019; Lee et al., 2017) could also be leveraged in this regard. Our approach of training the BERT encoder separately from the context encoder would allow MEDFILTER to learn from such non-dialogue resources.

Extraction tasks (Section 6) mostly evaluate the ability of MEDFILTER to recognize utterances that contain the most information about the name or type of the medication, symptom, or complaint. However, to quantify the context-level benefits of MEDFILTER, especially the speaker-specific context modeling (MS-BiLSTM), on downstream processing, we need to evaluate the system on problems like regimen extraction (Selvaraj and Konam, 2019) or symptom summarization (Liu et al., 2019b). Such tasks require utterance classification models to correctly identify utterances that discuss fine-grained details about the topic and would therefore evaluate a model's ability to solve multiple challenges like coreference resolution, speaker-specific context detection, thread identification, etc. Such an evaluation is a part of future work.

9 Conclusion

In this paper, we have proposed a novel text classification approach that specifically leverages insights into the organization of task-oriented conversations in order to improve performance at topic-based utterance classification over SOTA baseline approaches. In particular, we have demonstrated that our utterance classification model, MEDFILTER, benefits from discourse information, domain knowledge, speaker-specific context modeling, and a hierarchical loss to reach a new state-of-the-art performance on a doctor-patient interactions dataset. We find that using topic-based utterance classification in general, and MEDFILTER in particular, as a pre-processing step before medical extraction tasks, significantly improves the extraction scores. We believe that the contributions made in this work would also generalize to other kinds of expert-lay dialogue like customer-service chats.

Acknowledgements

We thank the anonymous EMNLP reviewers for their insightful comments. We are also grateful to the members of the TELEDIA group at LTI, CMU for the invaluable feedback. This work was funded in part by Dow Chemical, University of Pittsburgh Medical Center, and Microsoft.

Appendix

A Dataset Details

A.1 Dataset Statistics

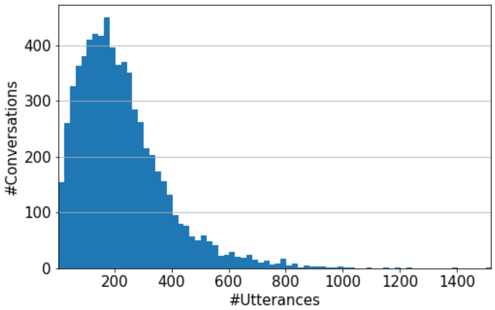

Figure A1: Distribution of the number of utterances in each conversation for the entire dataset.

The de-identified doctor-patient dialogue corpus used in this work was made available by University of Pittsburgh Medical Center (UPMC) and Abridge AI Inc.. Most of the conversations in this corpus are follow-up encounters between cardiovascular/general medicine doctors and patients. Figure A1 shows the distribution of the number of utterances in each conversation. The number ranges from as low as 3 to as high as 1521 with a mean of 225. The proportion of medically relevant utterances in a conversation is quite low (Table A1). As shown, utterances that belong to the three categories combined make up less than 10% of the conversation portraying the amount of noise present in doctor-patient conversations with regards to further medical processing.

Category	**#MR-Utt**	**#MR-Utt/#Utt** (%)
Complaints	6.17 (3.40)	4.34 (6.06)
Symptoms	3.56 (4.00)	1.98 (2.37)
Medications	4.79 (3.70)	3.10 (5.49)

Table A1: Avg. (std. dev.) medically relevant utterances (MR-Utt) in each medically relevant category.

In Table A2, we show the average position in the doctor-patient conversation where the speakers start discussing different medical topics. Several of the the encounters are follow-up discussions about a pre-existing complaint. Therefore, patient's current condition with respect to the complaint is often discussed earlier in the conversation. This is generally followed by a discussion about different body systems and associated symptoms that may be bothering the patient, which allows the doctor to prescribe suitable medications.

Category	**Relative Position**
Complaints	0.133 (0.043)
Symptoms	0.321 (0.057)
Medications	0.524 (0.069)

Table A2: Avg. (std. dev.) relative position in the conversation where speakers start discussing different medical topics.

The above-mentioned flow is merely an ideal depiction of the logical path that could be followed in the dialogue. However, real conversations in the corpus contain multiple topic-switches. For example, discussion of a symptom could be followed by medication which could then lead into a discourse about another symptom and so on.

	Utterance	**Labels**
1 1	Check if conversation can be added **DR:** Good Morning.	
2	**PT:** Good Morning.	
3	**DR:** I'm here with, [PATIENT NAME].	
4	**DR:** Last time I saw you, you were getting pains in your left leg. Is it still the case?	C,S
5	**PT:** Yes, I do.	S
6	**DR:** Okay, and generally, what are you doing when you get the pains?	
7	**PT:** Um, usually just a heating pad or, you know, ice.	
8	**DR:** Right, but what causes the pains, is what I was getting at?	S
9	**PT:** Uh, I think just the strain of, like, walking, or, or exercise.	S
10	**DR:** All right.	
11	**DR:** I think I am going to ask you to try some Baclofen.	M
12	**DR:** This is a patch you put on the foot when it's bothering you.	M
13	**DR:** Try one patch.	M
14	**DR:** It'll last up to 6 hours.	
15	**PT:** Okay.	
16	**DR:** If you like it, let me know.	
17	**DR:** We'll get you a prescription.	
18	**PT:** Okay.	
19	**DR:** The difference is, you can put this exactly where you need it on the foot and since it's going through the skin, it's not rough on your stomach like, let's say, Ibuprofen or Aspirin or any of the over the counter stuff would be.	
20	**PT:** Okay.	

Table A3: A constructed example conversation (**S** = Symptoms, **C** = Complaints, and **M** = Medications). Because conversations in the corpus cannot be published or distributed without agreement, the example here is based on a corpus conversation but with the details changed.

A.2 Example Conversation

An example conversation (details modified) from our corpus is shown in Table A3. Utterances 4,5,8,9 in the conversation discuss a symptom, with the Patient's reply (A3:5) acting as an important information about confirmation of the presence of that symptom. Furthermore, A3:8 and A3:9 provide additional details about the physical activities that cause the symptom. Although, the symptom name is discussed only in A3:4, information presented in the other utterances plays an important role in the clinical note. Similarly, utterances A3:11,12,13 discuss the medication *Baclofen*. Doctor prescribes the medication in A3:11. She provides further information like frequency of usage in A3:12, and dosage in A3:13, all of which is extremely important for regimen extraction. A3:19 contains names of two medications however it is not a medication utterance. This is case because the utterance does not discuss any medication that the patient is currently taking or being prescribed. The doctor is merely comparing the benefits of her prescribed medication against two popular pain pills.

A.3 Symptom and Medication Extraction Labels

In addition to identifying the type of each utterance, corpus annotators also provide a class label to the symptoms and medications from a predefined set. For symptoms, guidelines include 178 classes of the form <*Body System*>*:* <*symptom*> (e.g. Cardiovascular: Palpitations). Given the small size of the training data, instead of predicting given symptom classes, we predict the body system with which a symptom is associated (Table A10). Table A12 contains the list of target UMLS CUIs for each body system that are used as labels for Symptom Extraction. Please note that the list is manually curated and therefore is not exhaustive. For medications, we manually link each medication label in our training-set to its corresponding UMLS (Bodenreider, 2004) concept and group them using hierarchies from NCI Thesaurus (Sioutos et al., 2007) (Table A13).

B Hyperparameters

All our experiments are performed on a single Nvidia GeForce GTX 1080 Ti GPU. For MEDFILTER and other BERT-based baselines, we divide the conversations into windows of 128 utterances to ensure fair comparison against BERT-BiLSTM FT, which cannot process more than 128 utterances at a time due to GPU constraints. Other hyperparameters are presented in Table A4. We perform manual tuning on the entire range of hyper-parameters. AUC under the PR curve metric was chosen to select the best configuration. Results were not very sensitive to different non-zero values of β.

Hyper-parameter	**Search Range**	**Best**
GRU hidden size in baselines	$[100, 300, 512]$	300
Max. utterance length	$[64]$	64
BERT embedding size	$[768]$	768
#Speakers	$[3]$	3
Speaker embedding size	$[3, 4, 8, 16]$	8
Number of bins (k)	$[4]$	4
Position embedding size	$[4]$	4
Semantic Type embedding size	$[8, 16]$	8
BiLSTM hidden size	$[512, 1024, 2048]$	1024
Weight of $L_{\texttt{coarse}}$ (β)	$[0, 0.25, 0.5, 1, 5]$	1
Learning-rate	$[0.0005, 0.001, 0.01]$	0.0005
Batch-size	$[8, 16, 32]$	16

Table A4: Hyper-parameters. We search over the entire Cartesian product of the different hyper-parameters mentioned here. Best values are chosen using mean AUC of PR curve metric.

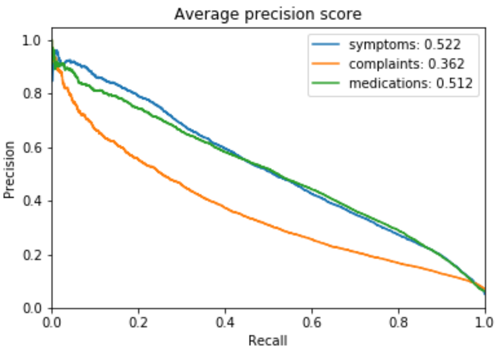

Figure A2: Category-wise PR curves for BERT-FT BiLSTM

C Utterance Classification

C.1 PR Curves

Figures A2 and A3 show the precision-recall curves for each category separately. MEDFILTER improves utterance classification for all three categories. For symptom classification, the AUC scores improve from 52.2 to 53.5. However, symptom extraction results (Section 6 in the main paper) suggest that most of this improvement is on identifying utterances that discuss fine-grained details about symptom discussion and not on recognizing the utterance that contains the actual symptom name.

C.2 Performance on Validation Set

Table A5 shows the performance of different utterance classification models on the validation set.

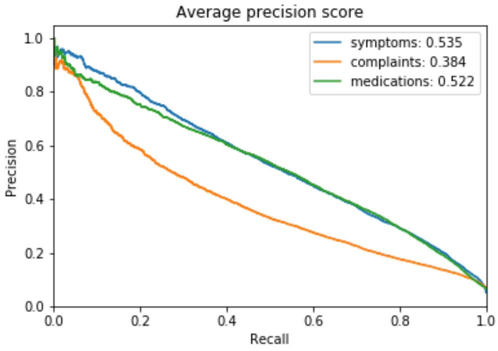

Figure A3: Category-wise PR curves for MEDFILTER

Similar to the trend shown on test-set, MEDFILTER beats all of the baselines reaching a score of 50.5 AUC points.

Methods	Val AUC	#Param	Time (hrs)
UniF-BiAGRU	42.7	1.3M	1
BiF-AGRU	42.9	1.3M	1
HiGRU-sf	45.0	2.6M	0.45
BERT	35.9	110M	-
Clinical BioBERT-FT	38.5	110M	10
BERT-FT	38.5	110M	10
BERT BiLSTM FT	47.9	125M	12
BERT-FT BiLSTM	49.6	125M	10 + 0.1
MEDFILTER	50.5	169M	10 + 1

Table A5: Results on val-set and the number of trainable parameters corresponding to each utterance classification model. The time taken by models that use BERT-FT is shown as a sum of two numbers as fine-tuning BERT is only done once, which is then used for both BERT-FT BiLSTM and MEDFILTER.

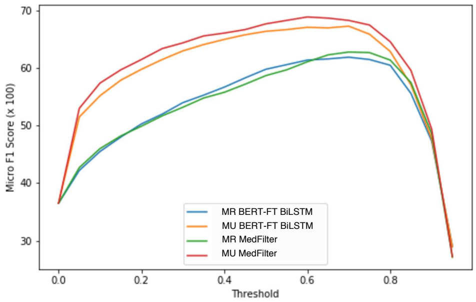

Figure A4: Medication Extraction: Micro-F1 vs Threshold

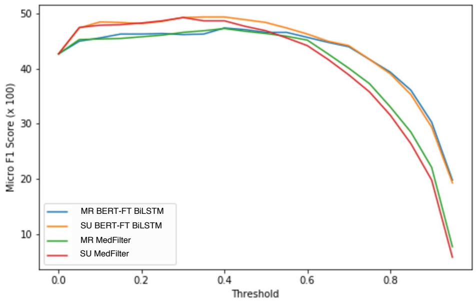

Figure A5: Symptom Extraction: Micro-F1 vs Threshold

D Downstream Medical Extraction

D.1 Micro-F1 vs Threshold

Figure A4 and A5 show how the performance of medication (ME) and symptom extraction (SE) varies against different utterance topic prediction probability thresholds. We plot the results for BERT-FT BiLSTM and MEDFILTER for brevity. Micro F1 scores for ME increase monotonically when the threshold is increased from 0 to ∼ 0.75 (Figure A4). This suggests that QuickUMLS medication extractor has low precision that is substantially improved when we prune irrelevant utterances. However, the graph for SE (Figure A5) shows that the extractor's performance is dominated by its recall. Pruning helps with improving the precision however does not help with the low recall. This explains the lower gains as compared to ME when using topic-based utterance classification in the SE pipeline (Table 3 in the main paper).

D.2 Oracle Results

Table A6 contains results for medication extraction when medically relevant (MR) or medication (MU) utterances are chosen using an oracle (MR/MU Oracle). Similarly, oracle results for symptom and complaint extraction are shown in Tables A7 and A8, respectively.

We find that there is still a substantial room for improvement in the symptom extraction pipeline. By just improving the topic-based utterance classifier, one can observe a potential jump of 5 Micro-F1 points in symptom extraction. However, we do not observe this trend for medication extraction where the topic-classification done by MEDFILTER performs much better than the Oracle.

D.2.1 Why does MEDFILTER perform better than Oracle on Medication Extraction?

Extraction experiments (like medication extraction or symptom extraction) evaluate the performance at the conversation-level. So, where the medication

Medication Extraction	**Macro F1**	**Micro F1**
QuickUMLS (All Text)	25.4	33.5
QuickUMLS (MR Oracle)	30.0	41.3
QuickUMLS (MU Oracle)	37.6	58.3
QuickUMLS (MR MedFilter)	34.2	62.8
QuickUMLS (MU MedFilter)	**35.9**	**68.9**

Table A6: Results(%) for Medication Extraction (ME). **MR**=Medically Relevant (Symptom + Complaints + Medications) Utterances, **MU**=Medication Utterances.

Symptom Extraction	**Macro F1**	**Micro F1**
QuickUMLS (All Text)	33.9	42.7
QuickUMLS (MR Oracle)	36.9	47.2
QuickUMLS (SU Oracle)	41.9	54.5
QuickUMLS (MR MedFilter)	35.2	47.4
QuickUMLS (SU MedFilter)	**36.1**	**49.3**

Table A7: Results(%) for Symptom Extraction (SE). **MR**=Medically Relevant, **SU**=Symptom Utterances.

name gets extracted from within the conversation is irrelevant to the task.

Oracle picks utterances that would be sufficient for a human to identify the medications discussed in the dialogue. However, they might not be adequate for an automatic string-matching based extractor like QuickUMLS. Since QuickUMLS uses non-contextual surface-level features to identify medication names, it would look for phrases (in the input given to it) that match the surface requirements. So, it is possible for the Oracle utterances not to contain the proper surface-level forms that QuickUMLS could leverage for extracting medications. Furthermore, the utterances categorized as medication utterances by MedFilter on the other hand, even though incorrect, might contain the medication names in the form QuickUMLS expects, thus improving the score over the Oracle. One should note, however, that a perfect downstream extractor would not suffer from these side-effects.

Complaint Extraction	**Macro F1**	**Micro F1**
QuickUMLS (All Text)	10.0	35.6
QuickUMLS (MR Oracle)	10.6	38.8
QuickUMLS (SU Oracle)	13.4	44.3
QuickUMLS (MR MedFilter)	11.1	40.7
QuickUMLS (CU MedFilter)	**11.1**	**43.7**

Table A8: Results(%) for Complaint Extraction (CE). **MR**=Medically Relevant, **CU**=Complaint Utterances.

D.3 Supervised Extractor

For symptom extraction (SE), we also show the benefits of using topic-based utterance classification on a supervised-classification based SE approach that leverages a BiLSTM with attention (BiLSTM-Attn) for the problem of predicting the symptoms present in a conversation.

D.3.1 BiLSTM-Attn

Each utterance in the conversation is passed through the embedding layer and a BiLSTM layer to obtain a contextualized representation.

$$\begin{aligned} h_i &= \texttt{BiLSTM}(e(s_i), h_{i-1}) \\ \mathbf{H_i} &= \{h_1, h_2, ..., h_n\} \end{aligned}$$

where $e(.)$ is the embedding function. The final state of the BiLSTM is re-weighted using attention calculated as shown in Equation A1.

$$\begin{aligned} h_{final} &= [\overleftarrow{h}_0; \overrightarrow{h}_{n-1}] \\ \mathbf{S} &= \mathbf{H_i} h_{final} \\ \mathbf{A} &= softmax(\mathbf{S}) \\ h'_{final} &= \mathbf{H_i^T A} \end{aligned} \qquad (2)$$

This allows our model to pay attention to important utterances in the conversation to extract symptom information. We pass h'_{final} through a linear classifier and a sigmoid layer to get logits for each possible symptom label (Table A10).

D.3.2 Experimental Setup

Similar to the QuickUMLS based extractor, we use Micro and Macro F1 scores to evaluate the performance of the supervised extraction pipeline. BiLSTM-Attn (All Text) model takes in the entire conversation as input, whereas the other variants are given only a subset of utterances. MR Oracle/MedFilter models are trained on the medically relevant utterances as output by the oracle. Similarly, SU Oracle/MedFilter models are trained on the Oracle symptom utterances in each conversation in the training-set. Therefore, topic-based classification is used as a pre-processing step in the pipeline.

D.3.3 Results

We present the results for symptom extraction (SE) using a BiLSTM-Attn model in Table A9. We find that using topic-based utterance classification to remove irrelevant utterances before passing the conversation through the BiLSTM-Attn improves the SE performance of the pipeline (4 point jump in Micro F1). The results are further improved when the Oracle symptom utterances (SU Oracle) are input to the BiLSTM-Attn.

Symptom Extraction	Macro F1	Micro F1
BiLSTM-Attn (All Text)	28.1	57.7
BiLSTM-Attn (MR Oracle)	29.3	59.4
BiLSTM-Attn (SU Oracle)	31.5	66.6
BiLSTM-Attn (MR MedFilter)	28.7	58.4
BiLSTM-Attn (SU MedFilter)	**29.8**	**61.7**

Table A9: BiLSTM-Attn results(%) for Symptom Extraction (SE). **MR**=Medically Relevant, **SU**=Symptom Utterances.

Hierarchical Evidence Set Modeling for Automated Fact Extraction and Verification

Shyam Subramanian and **Kyumin Lee**

Abstract

Automated fact extraction and verification is a challenging task that involves *finding relevant evidence sentences* from a reliable corpus to *verify the truthfulness of a claim*. Existing models either (i) concatenate all the evidence sentences, leading to the inclusion of redundant and noisy information; or (ii) process each claim-evidence sentence pair separately and aggregate all of them later, missing the early combination of related sentences for more accurate claim verification. Unlike the prior works, in this paper, we propose Hierarchical Evidence Set Modeling (HESM), a framework to extract evidence sets (each of which may contain multiple evidence sentences), and verify a claim to be supported, refuted or not enough info, by encoding and attending the claim and evidence sets at different levels of hierarchy. Our experimental results show that HESM outperforms 7 state-of-the-art methods for fact extraction and claim verification. Our source code is available at `https://github.com/ShyamSubramanian/HESM`.

1 Introduction

A study by Gabielkov et al. (2016) has revealed that 60% of people on social media share the news after reading just the title, without reading the actual content of the news. Unfortunately, the rise of social media has further accelerated the communication and propagation of unverified information. To solve the problem, our work focuses on automated fact extraction and verification task, which requires retrieving the evidence related to a claim as well as verifying the claim based on the evidence. The task is challenging since it requires semantic understanding and reasoning to learn the subtleties that differ between evidence that supports and evidence that refutes a claim. The task's difficulty is further amplified for claims that require aggregating information from multiple evidence sentences in different documents.

Previous works, in fact verification, either operate by combining all the evidence sentences (Nie et al., 2019) or they operate at each evidence sentence-level and aggregate them later (Yoneda et al., 2018; Hanselowski et al., 2018a). Combining all the sentences together may lead to the combination of redundant, noisy, and irrelevant information with the relevant information. This makes claim verification more complicated in terms of identifying and learning the context of only the relevant sentences. On the other hand, processing each evidence sentence separately, delays the combination of relevant sentences that belong to the same evidence set, for claims that require aggregating information from multiple sentences. It also makes claim verification harder since it summarizes information without complete context. Figure 1 depicts an example of an ideal verification system, which extracts evidence sets, processes them individually, and then aggregates them later. In the example, four evidence sentences are retrieved. Sentences which are relevant and hyperlinked, are combined to form evidence sets (called Evidence Set [1] and Evidence Set [2] in the figure). Each evidence set verifies the claim individually, and then they are aggregated for the final verification.

Like Figure 1, our proposed framework also retrieves and combines evidence sentences into evidence sets in an iterative fashion. Then, it processes each evidence set individually to form a representation of the evidence set using word-level attention. Then, it combines information from all the evidence set representations using contextual and non-contextual aggregation methods, which use evidence set-level attention. The word-level attention, along with evidence set-level attention, forms a hierarchical attention mechanism. Finally, our

framework learns to verify the claim at different levels of hierarchy (i.e., at each evidence set-level and the aggregated evidence level).

Our main contributions are as follows:

- We propose Hierarchical Evidence Set Modeling, which consists of document retriever, multi-hop evidence retriever, and claim verification.
- Our multi-hop evidence retriever retrieves evidence sentences and combines them as evidence sets. Our claim verification component conducts the hierarchical verification based on each evidence set individually and then based on all the evidence sets.
- Our experimental results show that our model outperforms 7 state-of-the-art baselines in both the evidence retrieval and claim verification.

2 Related Work

Several works exist in fact verification based on different forms of claim and evidence. Thorne and Vlachos (2017); Vlachos and Riedel (2015) verify numerical claims using subject-predicate-object triples from knowledge graph as evidence. Nakashole and Mitchell (2014); Bast et al. (2017) verify subject-predicate-object triple based claims. Chen et al. (2020) verifies textual claims based on evidences in a tabular format. Fact verification is studied in different natural language settings namely Recognizing Textual Entailment (Dagan et al., 2005), Natural Language Inference (Bowman et al., 2015) and Claim verification (Thorne et al., 2018a). A differently motivated but closely related problem is fact checking in journalism, also known as fake news detection (Ferreira and Vlachos, 2016; Wang, 2017). In this work, we focus on Claim verification using the FEVER dataset (Thorne et al., 2018a) with textual claims and evidence.

Previous works on the fact extraction and claim verification task follow a three-stage pipeline that includes *document retrieval, evidence sentence retrieval and claim verification*. Most previous works reuse the document retrieval component of top-performing systems (Hanselowski et al., 2018b; Yoneda et al., 2018; Nie et al., 2019) in the FEVER Shared Task 1.0 challenge (Thorne et al., 2018b).
