training on different tasks, we plot the testing results during whole lifelong learning stages with the order of WOZ (1-9 epoch) → SQL (10-18 epoch) → CNN (19-27 epoch) in Figure 3. In Figure 3a, the performance of WOZ for all methods is illustrated. The finetune baseline (purple line) significantly degrades when moving to the next task (SQL) in the second training stage, while other methods can keep the performance. We observe that applying soft-target Word-KD (blue) or Seq-KD$_{\text{soft}}$ (red) can increase the scores faster than hard-target Seq-KD (yellow) and LAMOL baseline (green) at the initial epochs, indicating the effectiveness of the proposed L2KD. In terms of other two tasks, all distillation methods (Word-KD, Seq-KD$_{\text{soft}}$, Seq-KD) are capable of maintaining the performance of WOZ slightly better than LAMOL, and finally converge to better points in the third training stage. A similar trend can be observed in Figure 3b, where soft-target Word-KD and Seq-KD$_{\text{soft}}$ rise faster in the second training stage and finally drop less than original LAMOL in the third training stage, demonstrating the great property of our proposed methods as LLL models.

In Figure 3c, in the third stage, the yellow line (Seq-KD) converges to a better point than all other methods, because it reduces the complexity of the noisy summarization dataset. However, although Seq-KD$_{\text{soft}}$ also reduces the complexity, it does not achieve the same performance as Seq-KD. The probable reason is that the teacher decoding sentences may be easy enough for the LLL model to learn from, and the soft target here makes the model not completely converge on these easy sentences.

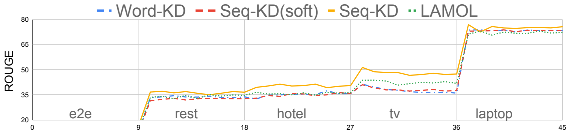
(d) Learning curve of RNNLG (tv).



(e) Learning curve of RNNLG (laptop).

Figure 4: The learning curves on NLG tasks with the hardest-to-easiest (left-to-right) order.

4.2 Same Task in Different Domains

We perform L2KD on the same NLG task with five different domains: *restaurant* from E2ENLG, *restaurant/hotel/tv/laptop* from RNNLG. Note that although both E2ENLG and RNNLG has the *restaurant* domain, their input formats and label types are totally different. The results are shown in Table 4, where we only show two orders in the experiments: from the hardest task to the easiest one (left-to-right) and its reverse order (right-to-left)[3]. The results show that L2KD outperforms original LAMOL for most cases and improves the averaged ROUGE score by nearly 2 points.

We find that different training orders bring slightly different results. In the right-to-left order, the baseline LAMOL can easily outperform multi-task models due to its easiest-to-hardest order, which helps the model to better transfer the knowledge gradually in these NLG tasks, similar to curriculum learning (Bengio et al., 2009). There-

---

[3] The shown results are representative among all others.

fore, it does not mean that lifelong learning can beat multi-task model in all the experiment.

We plot the learning curves of these five tasks in left-to-right order in Figure 4 for further analysis. Except for E2ENLG, the Seq-KD in yellow lines usually gain more performance at the end of the training stream. Also, we observe that when forward transfer exists, Seq-KD usually benefits more. For example, in Figure. 4c, when training on RNNLG (restaurant) in 10-18th epochs, the ROUGE score on RNNLG (hotel) has risen even before the model first sees RNNLG (hotel) data at the 19th epoch, indicating that the forward transfer exists in this order. The rising trend is more obvious in Seq-KD (yellow), and the same trend can also be obversed in Figure 4d and 4e.

4.3 Text Classification Tasks

Although our method is mainly designed for sequence generation tasks, we investigate whether this idea also benefits text classification (TC) tasks. Thus we perform L2KD on five TC tasks, where the answers are always very short sequences representing the class labels of the given documents, such as `World, Sports, Business, or Sci/Tech` in the AGNews dataset. Hence, generating such short answers is not complex for the proposed model, and the performance mainly reflects the text understanding performance instead of the generating capability.

We also conduct the experiments from the hardest task to the easiest task, and its reverse order shown in Table 5. To our surprise, L2KD also improves LAMOL to get better results on TC tasks. The results of these two orders are only 0.1% worse than the multi-task upper bounds. The Word-KD improves the most on these TC tasks in most cases, and the improvements are more obvious especially for the earlier learned tasks. The details of the learning curves in TC tasks are also shown in Appendix B for reference.

Because the answers in TC tasks are not as complex as other sequence generation tasks, we investigate where the improvement mainly comes from during the distillation process. Therefore, we split each testing set into two groups: (A) *questions correctly answered by the teacher model*; (B) *questions incorrectly answered by the teacher model*. We suspect that the LLL model trained by L2KD may totally copy the behavior from the teacher models and get improvement mainly from the group (A), while it fails to answer the questions in the group (B). To figure it out, we compute the accuracy of each LLL model (in left-to-right experiment) for the groups (A) and (B) respectively, and the difference between original LAMOL and three distillation strategies on five tasks. The averaged results are shown in Table 6, and the more detailed results for each task can be found in Appendix C. Surprisingly, applying L2KD does not largely degrade the accuracy in the group (B) comparing to the original LAMOL, and even improves for Word-KD, showing that the LLL model does not fully copy the behavior from its teacher models. On the other hand, the total improvement indeed mainly comes from the group (A), and Word-KD also can improve the most. The double improvement both on group (A) and (B) for Word-KD indicates that on these TC tasks, the LLL model trained by Word-KD can better reach the balance between the *teacher knowledge* and the *transfer ability*. Therefore, it can get the advantages from the teacher knowledge while avoid some false knowledge taught from its teacher by integrating the knowledge from other tasks.

5 Related Work

Knowledge distillation has been introduced to the field of lifelong learning; for example, Learning without Forgetting (LwF) (Li and Hoiem, 2017), Generative Replay with Distillation (DGR+distill), Replay-through-Feedback (RtF) (van de Ven and Tolias, 2018), and Lifelong GAN (Zhai et al., 2019), a lot of prior studies have also used knowledge distillation in lifelong learning, but all in computer vision tasks. Different from the prior work, this paper is the first attempt that adopts knowledge distillation for NLP tasks in the lifelong learning framework. Moreover, the prior work used the old model as a teacher to help the current model retain the knowledge about previous tasks. In contrast, our method trains a new teacher model on the incoming new task. Thus, these two directions of applying knowledge distillation are complementary to each other, showing the potential of applying the proposed method to the fields other than NLP.

6 Conclusion

This paper presents Lifelong Language Knowledge Distillation (L2KD), a simple method that effectively help lifelong language learning models to maintain good performance comparable to its multitask upper bounds. The experiments show the consistent improvement achieved by L2KD for three different settings, indicating the effectiveness of the proposed method to train robust LLL models. In addition, the proposed approach only requires a little extra time for training the teacher without extra memory or capacity needed, showing the potential of being applied to the practical scenarios.

A Training Details

We use a single NVIDIA TESLA V100 (32G) for each experiment. The average runtime of experiments in Section 4.1 and 4.2 are 3-8 hours. The experiments in Section 4.3 need about 3 days for a single experiment.

We did not conduct hyperparameter search, but follow all best settings in the official implementation of LAMOL [4] to keep the results comparable. The main hyperparameters are listed in Table 7. More details can be found in our released code.

Sparse Parallel Training of Hierarchical Dirichlet Process Topic Models

Alexander Terenin

Leif Jonsson
Ericsson AB
and Linköping University

Abstract

To scale non-parametric extensions of probabilistic topic models such as Latent Dirichlet allocation to larger data sets, practitioners rely increasingly on parallel and distributed systems. In this work, we study data-parallel training for the hierarchical Dirichlet process (HDP) topic model. Based upon a representation of certain conditional distributions within an HDP, we propose a doubly sparse data-parallel sampler for the HDP topic model. This sampler utilizes all available sources of sparsity found in natural language—an important way to make computation efficient. We benchmark our method on a well-known corpus (PubMed) with 8m documents and 768m tokens, using a single multi-core machine in under four days.

1 Introduction

Topic models are a widely-used class of methods that allow practitioners to identify latent semantic themes in large bodies of text in an unsupervised manner. They are particularly attractive in areas such as history (Yang et al., 2011; Wang et al., 2012), sociology (DiMaggio et al., 2013), and political science (Roberts et al., 2014), where a desire for careful control of structure and prior information incorporated into the model motivates one to adopt a Bayesian approach to learning. In these areas, large corpora such as newspaper archives are becoming increasingly available (Ehrmann et al., 2020), and models such as latent Dirichlet allocation (LDA) (Blei et al., 2003) and its nonparametric extensions (Teh et al., 2006; Teh, 2006; Hu and Boyd-Graber, 2012; Paisley et al., 2015) are widely used by practitioners. Moreover, these models are emerging as a component of data-efficient language models (Guo et al., 2020). Training topic models efficiently entails two requirements.

1. Expose sufficient parallelism that can be taken advantage of by the hardware.
2. Utilize sparsity found in natural language to control memory requirements and computational complexity.

In this work, we focus on the *hierarchical Dirichlet process* (HDP) topic model of Teh et al. (2006), which we review in Section 2. This model is a simple non-trivial extension of LDA to the nonparametric setting. This parallel implementation provides a blueprint for designing massively parallel training algorithms in more complicated settings, such as nonparametric dynamic topic models (Ahmed and Xing, 2010) and tree-based extensions (Hu and Boyd-Graber, 2012).

Parallel approaches to training HDPs have been previously introduced by a number of authors, including Newman et al. (2009), Wang et al. (2011), Williamson et al. (2013), Chang and Fisher (2014) and Ge et al. (2015). These techniques suit various settings: some are designed to explicitly incorporate sparsity present in natural language and other discrete spaces, while others are intended for HDP-based continuous mixture models. Gal and Ghahramani (2014) have pointed out that some methods can suffer from load-balancing issues, which limit their parallelism and scalability. The largest benchmark of parallel HDP training performed to our awareness is by Chang and Fisher (2014) on the 100m-token NYTimes corpora. Throughout this work, we focus on Markov chain Monte Carlo (MCMC) methods—empirically, their scalability is comparable to variational methods (Magnusson et al., 2018; Hoffman and Ma, 2019), and, subject to convergence, they yield the correct posterior.

Our contributions are as follows. We propose an augmented representation of the HDP for which the topic indicators can be sampled in parallel over documents. We prove that, under this representation, the global topic distribution $\boldsymbol{\Psi}$ is conditionally conjugate given an auxiliary parameter $\boldsymbol{l}$. We develop

K^*	Index for implicitly-represented topics	$\alpha, \boldsymbol{\beta}, \gamma$	Prior concentration for $\boldsymbol{\theta}_d$, $\boldsymbol{\phi}_k$, $\boldsymbol{\Psi}$

Table 1: Notation for the HDP topic model. Sufficient statistics are conditional on the algorithm's current iteration. Bold symbols refer to matrices, bold italics refer to vectors, possibly countably infinite.

fast sampling schemes for $\boldsymbol{\Psi}$ and $\boldsymbol{l}$, and propose a training algorithm with a per-iteration complexity that depends on the minima of two sparsity terms—it takes advantage of both document-topic and topic-word sparsity simultaneously.

2 Partially collapsed Gibbs sampling for hierarchical Dirichlet processes

The hierarchical Dirichlet process topic model (Teh et al., 2006) begins with a global distribution $\boldsymbol{\Psi}$ over topics. Documents are assumed exchangeable—for each document d, the associated topic distribution $\boldsymbol{\theta}_d$ follows a Dirichlet process centered at $\boldsymbol{\Psi}$. Each topic is associated with a distribution of tokens $\boldsymbol{\phi}_k$. Within each document, tokens are assumed exchangeable (bag of words) and assigned to topic indicators $z_{i,d}$. For given data, we observe the tokens $w_{i,d}$.

We thus arrive at the GEM representation of a HDP, given by equation (19) of Teh et al. (2006) as

$$\begin{aligned} \boldsymbol{\Psi} &\sim \mathrm{GEM}(\gamma) && (1)\\ \boldsymbol{\theta}_d \mid \boldsymbol{\Psi} &\sim \mathrm{DP}(\alpha, \boldsymbol{\Psi}) && (2)\\ \boldsymbol{\phi}_k &\sim \mathrm{Dir}(\boldsymbol{\beta}) && (3)\\ z_{i,d} \mid \boldsymbol{\theta}_d &\sim \mathrm{Discrete}(\boldsymbol{\theta}_d) && (4)\\ w_{i,d} \mid z_{i,d}, \boldsymbol{\Phi} &\sim \mathrm{Discrete}(\boldsymbol{\phi}_{z_{i,d}}) && (5) \end{aligned}$$

where $\alpha, \boldsymbol{\beta}, \gamma$ are prior hyperparameters.

2.1 Intuition and augmented representation

At a high level, our strategy for constructing a scalable sampler is as follows. Conditional on $\boldsymbol{\Psi}$, the likelihood in equations (1)–(5) is the same as that of LDA. Using this observation, the Gibbs step for $\boldsymbol{z}$, which is the largest component of the model, can be handled efficiently by leveraging insights on sparse parallel sampling from the well-studied LDA literature (Yao et al., 2009; Li et al., 2014; Magnusson et al., 2018; Terenin et al., 2019). For this strategy to succeed, we need to ensure that all Gibbs steps involved in the HDP under this representation are analytically tractable and can be computed efficiently. For this, the representation needs to be modified.

To begin, we integrate each $\boldsymbol{\theta}_d$ out of the model, which by conjugacy (Blackwell and MacQueen, 1973) yields a Pólya sequence for each $\boldsymbol{z}_d$. By definition, given in Appendix A, this sequence is a mixture distribution with respect to a set of Bernoulli random variables $\boldsymbol{b}_d$, each representing whether $z_{i,d}$ was drawn from $\boldsymbol{\Psi}$ or from a repeated draw in the Pólya urn. Thus, the HDP can be written

$$\begin{aligned} \boldsymbol{\Psi} &\sim \mathrm{GEM}(\gamma) && (6)\\ b_{i,d} &\sim \mathrm{Ber}\left(\tfrac{\alpha}{i-1+\alpha}\right) && (7)\\ \boldsymbol{\phi}_k &\sim \mathrm{Dir}(\boldsymbol{\beta}) && (8)\\ \boldsymbol{z}_d \mid \boldsymbol{b}_d, \boldsymbol{\Psi} &\sim \mathrm{PS}(\boldsymbol{\Psi}, \boldsymbol{b}_d) && (9)\\ w_{i,d} \mid z_{i,d} &\sim \mathrm{Discrete}(\boldsymbol{\phi}_{z_{i,d}}) && (10) \end{aligned}$$

where $\mathrm{PS}(\boldsymbol{\Psi}, \boldsymbol{b}_d)$ is a Pólya sequence, defined in Appendix A. This representation defines a posterior distribution over $\boldsymbol{z}, \boldsymbol{\Phi}, \boldsymbol{\Psi}, \boldsymbol{b}$ for the HDP. To derive a Gibbs sampler, we calculate its full conditionals.

2.2 Full conditionals for $\boldsymbol{z}$, $\boldsymbol{\Phi}$, and $\boldsymbol{b}$

The full conditionals $\boldsymbol{z} \mid \boldsymbol{\Phi}, \boldsymbol{\Psi}$ and $\boldsymbol{\Phi} \mid \boldsymbol{z}, \boldsymbol{\Psi}$, with $\boldsymbol{b}$ marginalized out, are essentially those in partially collapsed LDA (Magnusson et al., 2018; Terenin et al., 2019). They are

$$\begin{aligned} &\mathbb{P}(z_{i,d} = k \mid \boldsymbol{z}_{-i,d}, \boldsymbol{\Phi}, \boldsymbol{\Psi}) && (11)\\ &\qquad \propto \phi_{k,v(i)} \left[\alpha \Psi_k + m^{-i}_{d,k}\right] && (12) \end{aligned}$$

where $v(i)$ is the word type for word token i, and

$$\boldsymbol{\phi}_k \mid \boldsymbol{z} \sim \mathrm{Dir}(\boldsymbol{\beta} + \boldsymbol{n}_k) \qquad (13)$$

where $m_{d,k}^{-i}$ denotes the document-topic sufficient statistic with index i removed, and $\boldsymbol{n}_k$ is the topic-word sufficient statistic. Note the number of possible topics and full conditionals $\boldsymbol{\phi}_k \mid \boldsymbol{z}$ here is countably infinite. The full conditional for each $b_{i,d}$ is

$$\mathbb{P}(b_{i,d} = 1 \mid \boldsymbol{z}_d, \boldsymbol{\Psi}, \boldsymbol{b}_{-i,d}) \tag{14}$$

$$= \frac{\alpha \Psi_{z_{i,d}}}{\alpha \Psi_{z_{i,d}} + \sum_{j=1}^{i} \mathbb{1}_{z_{j,d}}(z_{i,d})}. \tag{15}$$

The derivation, based on a direct application of Bayes' Rule with respect to the probability mass function of the Pólya sequence, is in Appendix A.

2.3 The full conditional for $\boldsymbol{\Psi}$

To derive the full conditional for $\boldsymbol{\Psi}$, we examine the prior and likelihood components of the model. It is shown in Appendix A that the likelihood term $\boldsymbol{z}_d \mid \boldsymbol{b}_d, \boldsymbol{\Psi}$ may be written

$$p(\boldsymbol{z}_d \mid \boldsymbol{b}_d, \boldsymbol{\Psi}) \tag{16}$$

$$= \underbrace{\prod_{\substack{i=1 \\ b_{i,d} \neq 1}}^{N_d} \sum_{j=1}^{i-1} \frac{1}{i-1} \mathbb{1}_{z_{j,d}}(z_{i,d})}_{\text{doesn't enter posterior}} \prod_{\substack{i=1 \\ b_{i,d}=1}}^{N_d} \prod_{k=1}^{\infty} \Psi_k^{\mathbb{1}_k(z_{i,d})}.$$

The first term is a multiplicative constant independent of $\boldsymbol{\Psi}$ and vanishes via normalization. Thus, the full conditional $\boldsymbol{\Psi} \mid \boldsymbol{z}, \boldsymbol{b}$ depends on $\boldsymbol{z}$ and $\boldsymbol{b}$ only through the sufficient statistic $\boldsymbol{l}$ defined by

$$l_k = \sum_{d=1}^{D} \sum_{\substack{i=1 \\ b_{i,d}=1}}^{N_d} \mathbb{1}_{z_{i,d}=k} \tag{17}$$

and so we may suppose without loss of generality that the likelihood term is categorical. Under these conditions, we prove the full conditional for $\boldsymbol{\Psi}$ admits a stick-breaking representation.

Proposition 1. *Without loss of generality, suppose*

$$\boldsymbol{\Psi} \sim \operatorname{GEM}(\gamma) \quad \boldsymbol{x} \mid \boldsymbol{\Psi} \sim \operatorname{Discrete}(\boldsymbol{\Psi}). \tag{18}$$

Then $\boldsymbol{\Psi} \mid \boldsymbol{x}$ *is given by*

$$\Psi_k = \varsigma_k \prod_{i=1}^{k-1} (1 - \varsigma_i) \quad \varsigma_k \sim \operatorname{Beta}(a_k^{(\boldsymbol{\Psi})}, b_k^{(\boldsymbol{\Psi})}) \tag{19}$$

$$a_k^{(\boldsymbol{\Psi})} = 1 + l_k \qquad b_k^{(\boldsymbol{\Psi})} = \gamma + \sum_{i=k+1}^{\infty} l_i \tag{20}$$

where $\boldsymbol{l}$ *are the empirical counts of* $\boldsymbol{x}$.

Proof. Appendix B. □

This expression is similar to the stick-breaking representation of a Dirichlet process $\operatorname{DP}(\cdot, F)$—however, it has different weights and does not include random atoms drawn from F as part of its definition—see Appendix B for more details. Putting these ideas together, we define an infinite-dimensional parallel Gibbs sampler.

Algorithm 1. *Repeat until convergence.*

- *Sample* $\boldsymbol{\phi}_k \sim \operatorname{Dir}(\boldsymbol{n}_k + \boldsymbol{\beta})$ *in parallel over topics for* $k = 1, .., \infty$.
- *Sample* $z_{i,d} \propto \phi_{k,v(i)}\, \alpha\, \Psi_k + \phi_{k,v(i)}\, m_{d,k}^{-i}$ *in parallel over documents for* $d = 1, .., D$.
- *Sample* $b_{i,d}$ *according to equation* (14) *in parallel over documents for* $d = 1, .., D$.
- *Sample* $\boldsymbol{\Psi}$ *according to equations* (19)–(20).

Algorithm 1 is completely parallel, but cannot be implemented as stated due to the infinite number of full conditionals for $\boldsymbol{\Phi}$, as well as the infinite product used in sampling $\boldsymbol{\Psi}$. We now bypass these issues by introducing an approximate finite-dimensional sampling scheme.

2.4 Finite-dimensional sampling of $\boldsymbol{\Psi}$ and $\boldsymbol{\Phi}$

By way of assuming $\boldsymbol{\Psi} \sim \operatorname{GEM}(\gamma)$, an HDP assumes an infinite number of topics are present a priori, with the number of tokens per topic decreasing rapidly with the topic's index in a manner controlled by γ. Thus, under the model, a topic with a sufficiently large index should contain no tokens with high probability.

We thus propose to approximate $\boldsymbol{\Psi}$ by projecting its tail onto a single flag topic K^*, which stands for all topics not explicitly represented as part of the computation. This can be done by by deterministically setting $\varsigma_{K^*} = 1$ in equation (19). The resulting finite-dimensional $\boldsymbol{\Psi}$ will be the correct posterior full conditional for the finite-dimensional generalized Dirichlet prior considered previously in Section 2.3. Hence, this finite-dimensional truncation forms a Bayesian model in its own right, which suggests it should perform reasonably well. From an asymptotic perspective, Ishwaran and James (2001) have shown that the approximation is almost surely convergent and, therefore, well-posed.

Once this is done, $\boldsymbol{\Psi}$ becomes a finite vector of length K^*, and only K^* rows of $\boldsymbol{\Phi}$ need to be explicitly instantiated as part of the computation. This instantiation allows the algorithm to be defined on a fixed finite state space, simplifying bookkeeping and implementation.

From a computational efficiency perspective, the resulting value K^* takes the place of K in partially collapsed LDA. However, it *cannot* be interpreted as the number of topics in the sense of LDA. Indeed, LDA implicitly assumes that $\boldsymbol{\Psi} = \mathrm{Unif}(1,..,K)$ deterministically—i.e., that every topic is assumed a priori to contain the same number of tokens. In contrast, the HDP model learns this distribution from the data by letting $\boldsymbol{\Psi} \sim \mathrm{GEM}(\gamma)$.

If we allow the state space to be resized when topic K^* is sampled, then following Papaspiliopoulos and Roberts (2008), it is possible to develop truncation schemes which introduce no error. Since this results in more complicated bookkeeping which reduces performance, we instead fix K^* and defer such considerations to future work. We recommend setting K^* to be sufficiently large that it does not significantly affect the model's behavior, which can be checked by tracking the number of tokens assigned to the topic K^*.

2.5 Sparse sampling of $\boldsymbol{\Phi}$ and $\boldsymbol{z}$

To be efficient, a topic model needs to utilize the sparsity found in natural language as much as possible. In our case, the two main sources of sparsity are as follows.

1. *Document-topic sparsity*: most documents will only contain a handful of topics.
2. *Topic-word sparsity*: most word types will not be present in most topics.

We thus expect the document-topic sufficient statistic $\mathbf{m}$ and topic-word sufficient statistic $\mathbf{n}$ to contain many zeros. We seek to use this to reduce sampling complexity. Our starting point is the Poisson Pólya Urn sampler of Terenin et al. (2019), which presents a Gibbs sampler for LDA with computational complexity that depends on the minima of two sparsity coefficients representing document-topic and topic-word sparsity—such algorithms are termed *doubly sparse*. The key idea is to approximate the Dirichlet full conditional for $\boldsymbol{\phi}_k$ with a Poisson Pólya Urn (PPU) distribution defined by

$$\phi_{k,v} = \frac{\varphi_{k,v}}{\sum_{v=1}^{V} \varphi_{k,v}} \qquad \varphi_{k,v} \sim \mathrm{Pois}(\beta_{k,v} + n_{k,v}) \quad (21)$$

for $v = 1,..,V$. This distribution is discrete, so $\boldsymbol{\Phi}$ becomes a sparse matrix. The approximation is accurate even for small values of $n_{k,v}$, and Terenin et al. (2019) proves that the approximation error will vanish for large data sets in the sense of convergence in distribution.

If $\boldsymbol{\beta}$ is uniform, we can further use sparsity to accelerate sampling $\varphi_{k,v}$. Since a sum of Poisson random variables is Poisson, we can split $\varphi_{k,v} = \varphi_{k,v}^{(\beta)} + \varphi_{k,v}^{(\mathbf{n})}$. We then sample $\varphi_{k,v}^{(\beta)}$ sparsely by introducing a Poisson process and sampling its points uniformly, and sample $\varphi_{k,v}^{(\mathbf{n})}$ sparsely by iterating over nonzero entries of $\mathbf{n}$.

For $\boldsymbol{z}$, the full conditional

$$\begin{aligned} &\mathbb{P}(z_{i,d} = k \mid \boldsymbol{z}_{-i,d}, \boldsymbol{\Phi}, \boldsymbol{\Psi}) && (22) \\ &\quad \propto \phi_{k,v(i)} \left[\alpha \Psi_k + m_{d,k}^{-i} \right] && (23) \\ &\quad \propto \underbrace{\phi_{k,v(i)} \alpha \Psi_k}_{(a)} + \underbrace{\phi_{k,v(i)} m_{d,k}^{-i}}_{(b)} && (24) \end{aligned}$$

is similar to to the one in partially collapsed LDA (Magnusson et al., 2018)—the difference is the presence of Ψ_k. As Ψ_k only enters the expression through component (a) and is identical for all $z_{i,d}$, it can be absorbed at each iteration directly into an alias table (Walker, 1977; Li et al., 2014). Component (b) can be computed efficiently by utilizing sparsity of $\boldsymbol{\Phi}$ and $\mathbf{m}$ and iterating over whichever has fewer non-zero entries.

2.6 Direct sampling of $\boldsymbol{l}$

Rather than sampling $\boldsymbol{b}$, whose size will grow linearly with the number of documents, we introduce a scheme for sampling the sufficient statistic $\boldsymbol{l}$ directly. Observe that

$$l_k = \sum_{d=1}^{D} \sum_{\substack{i=1 \\ b_{i,d}=1}}^{N_d} \mathbb{1}_{z_{n,d}=k} = \sum_{d=1}^{D} \sum_{\substack{i=1 \\ z_{i,d}=k}}^{N_d} \mathbb{1}_{b_{i,d}=1} \quad (25)$$

where the domain of summation and the value of the indicators have been switched. By definition of $b_{i,d}$, we have

$$\sum_{\substack{i=1 \\ z_{i,d}=k}}^{N_d} \mathbb{1}_{b_{i,d}=1} = \sum_{j=1}^{m_{d,k}} b_{j,d,k} \quad (26)$$

where

$$b_{j,d,k} \sim \mathrm{Ber}\left(\frac{\Psi_k \alpha}{\Psi_k \alpha + j - 1} \right). \quad (27)$$

Summing this expression over documents, we obtain the expression

$$l_k = \sum_{j=1}^{\max_d m_{d,k}} c_{j,k} \qquad c_{j,k} \sim \mathrm{Bin}\left(D_{k,j}, \frac{\Psi_k \alpha}{\Psi_k \alpha + j - 1} \right) \quad (28)$$

where $D_{k,j}$ is the total number of documents with $m_{d,k} \geq j$. Since $m_{d,k} = 0$ for all topics k without any tokens assigned, we only need to sample $\boldsymbol{l}$ for topics that have tokens assigned to them. This idea can also be straightforwardly applied to other HDP samplers (Chang and Fisher, 2014; Ge et al., 2015), by allowing one to derive alternative full conditionals in lieu of the *Stirling distribution* (Antoniak, 1974). The complexity of sampling $\boldsymbol{l}$ directly is constant with respect to the number of documents, and depends instead on the maximum number of tokens per document.

To handle the bookkeeping necessary for computing $D_{k,j}$, we introduce a sparse matrix $\mathbf{d}$ of size $K \times \max_d N_d$ whose entries $d_{k,p}$ are the number of documents for topic k that have a total of p topic indicators assigned to them. We increment $\mathbf{d}$ once $\boldsymbol{z}_d$ been sampled by iterating over non-zero elements in $\boldsymbol{m}_d$. We then compute $D_{k,j}$ as the reverse cumulative sum of the rows of $\mathbf{d}$.

2.7 Poisson Pólya urn partially collapsed Gibbs sampling

Putting all of these ideas together, we obtain the following algorithm.

Algorithm 2. *Repeat until convergence.*

- *Sample* $\phi_k \sim \mathrm{PPU}(\boldsymbol{n}_k + \boldsymbol{\beta})$ *in parallel over topics for* $k = 1, .., K^*$.
- *Sample* $z_{i,d} \propto \phi_{k,v(i)}\, \alpha\, \Psi_k + \phi_{k,v(i)}\, m^{-i}_{d,k}$ *in parallel over documents for* $d = 1, .., D$.
- *Sample* l_k *according to equation* (28) *in parallel over topics for* $k = 1, .., K^*$.
- *Sample* $\boldsymbol{\Psi}$ *according to equations* (19)–(20), *except with* $\varsigma_{K^*} = 1$.

Algorithm 2 is sparse, massively parallel, defined on a fixed finite state space, and contains no infinite computations in any of its steps. The Gibbs step for $\boldsymbol{\Phi}$ converges in distribution (Terenin et al., 2019) to the true Gibbs steps as $N \to \infty$, and the Gibbs step for $\boldsymbol{\Psi}$ converges almost surely (Ishwaran and James, 2001) to the true Gibbs step as $K^* \to \infty$.

2.8 Computational complexity

We now examine the per-iteration computational complexity of Algorithm 2. To proceed, we fix K^* and maximum document size $\max_d N_d$, and relate the vocabulary size V with the number N of total words as follows.

Assumption (Heaps' Law)**.** *The number of unique words in a corpus follows Heaps' law (Heaps, 1978)* $V = \xi N^{\zeta}$ *with constants* $\xi > 0$ *and* $\zeta < 1$.

The per-iteration complexity of Algorithm 2 is equal to the sum of the per-iteration complexity of sampling its components. The sampling complexities of $\boldsymbol{\Psi}$ and $\boldsymbol{l}$ are constant with respect to the number of tokens, and the sampling complexity of $\boldsymbol{\Phi}$ has been shown by Magnusson et al. (2018) to be negligible under the given assumptions. Thus, it suffices to consider $\boldsymbol{z}$.

At a given iteration, let $K^{(\mathbf{m})}_{d(i)}$ be the number of existing topics in document d associated with word token i, and let $K^{(\boldsymbol{\Phi})}_{v(i)}$ be the number of nonzero topics in the row of $\boldsymbol{\Phi}$ corresponding to word token i. It follows immediately from the argument given by Terenin et al. (2019) that the per-iteration complexity of sampling each topic indicator z_i is

$$\mathcal{O}\left[\min\left(K^{(\mathbf{m})}_{d(i)}, K^{(\boldsymbol{\Phi})}_{v(i)}\right)\right]. \qquad (29)$$

Algorithm 2 is thus a doubly sparse algorithm.

3 Performance results

To study performance of the *partially collapsed* sampler—Algorithm 2—we implemented it in Java using the open-source MALLET[1] (McCallum, 2002) topic modeling framework. We ran it on the AP, CGCBIB, NEURIPS, and PUBMED corpora,[1] which are summarized in Table 2. Prior hyperparameters controlling the degree of sparsity were set to $\alpha = 0.1, \beta = 0.01, \gamma = 1$. We set $K^* = 1000$ and observed no tokens ever allocated to the topic K^*. Data were preprocessed with default Mallet (McCallum, 2002) stop-word removal, minimum document size of 10, and a rare word limit of 10. Following Teh et al. (2006), the algorithm was initialized with one topic. All experiments were repeated five times to assess variability. Total runtime for each experiment is given in Table 2.

To assess Algorithm 2 in a small-scale setting, we compare it to the widely-studied sparse fully collapsed *direct assignment* sampler of Teh et al. (2006), which is not parallel. We ran 100 000

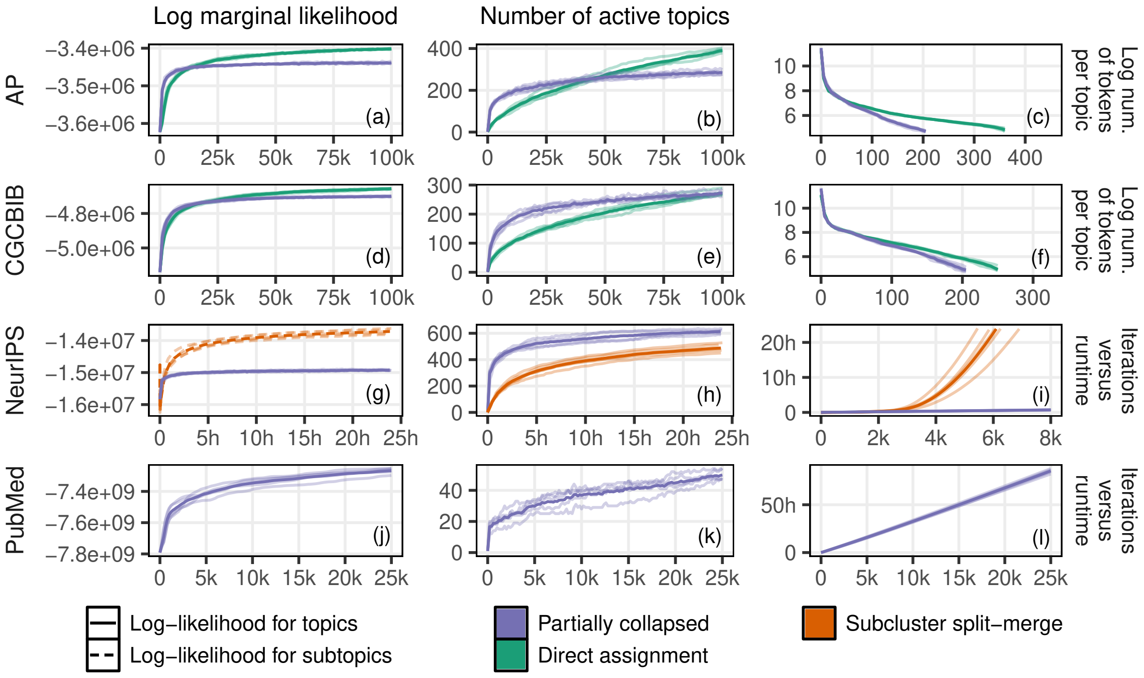

Figure 1: Trace plots for log-likelihood, number of active topics, and additional metrics for CGCBIB, NeurIPS, and PubMed. On the x axis, per-iteration scale is used for AP, CGCBIB and PubMed, and real-time scale is used for NeurIPS. Algorithms used are partially collapsed HDP for all corpora, direct assignment HDP for AP and CGCBIB, and subcluster split-merge HDP for NeurIPS. Individual traces are partially transparent, and their mean is opaque.

iterations of both methods on AP and CGCBIB. We selected these corpora because they were among the larger corpora on which it was feasible to run our direct assignment reference implementation within one week.

Trace plots for the log marginal likelihood for $\boldsymbol{z}$ given $\boldsymbol{\Psi}$ and the number of active topics, i.e., those topics assigned at least one token, can be seen in Figure 1(a,d) and Figure 1(b,e), respectively. The direct assignment algorithm converges slower, but achieves a slightly better local optimum in terms of marginal log-likelihood, compared to our method. This fact indicates that the direct assignment method may stabilize around a different local optimum, and may represent a potential limitation of the partially collapsed sampler in settings where non-parallel methods are practical.

To better understand the distributional differences between the algorithms, we examined the number of tokens per topic, which can be seen in Figure 1(c,f). The partially collapsed sampler is seen to assign more tokens to smaller topics, indicating that it stabilizes around a local optimum with slightly broader semantic themes.

To visualize the effect this has on the topics, we examined the most common words for each topic. Since the algorithms generate too many topics to make full examination practical, we instead compute a quantile summary with five topics per quantile. The quantile is computed by ranking all topics by the number of tokens, choosing the five closest topics to the 100%, 75%, 50%, 25%, and 5% quantiles in the ranking, and computing their top words. This approach gives a representative view of the algorithm's output for large, medium, and small topics. Results may be seen in Appendix D and Appendix C—we find the direct assignment and partially collapsed samplers to be mostly com-

Corpus	V	D	N	Iterations	Threads	Runtime
AP	7 074	2 206	393 567	100 000	8	3.8 hours
CGCBIB	6 079	5 940	570 370	100 000	12	2.7 hours
NeurIPS	12 419	1 499	1 894 051	255 500	8	24 hours
PubMed	89 987	8 199 999	768 434 972	25 000	20	82.4 hours

Table 2: Corpora used in experiments, together with compute configuration.

parable, with substantial overlap in top words for common topics.

Next, we assess Algorithm 2 in a more demanding setting and compare against previous parallel state-of-the-art. There are various scalable samplers available for the HDP. For a fair comparison, we restrict ourselves to those samplers designed for topic models and explicitly incorporate sparsity of natural language in their construction. Among these, we selected the parallel *subcluster split-merge* algorithm of Chang and Fisher (2014) as our baseline because it was used in the largest-scale benchmark of the HDP topic model performed to date to our awareness, and shows comparable performance to other methods (Ge et al., 2015). The subcluster split-merge algorithm is designed to converge with fewer iterations, but is more costly to run per iteration. Thus, we used a fixed computational budget of 24 hours of wall-clock time for both algorithms. Computation was performed on a system with a 4-core 8-thread CPU and 8GB RAM.

Results can be seen in Figure 1(g)—note that the subcluster split-merge algorithm is parametrized using *sub-topic indicators* and *sub-topic probabilities*, so its numerical log-likelihood values are not directly comparable to ours and should be *interpreted purely to assess convergence*. Algorithm 2 stabilizes much faster with respect to both the number of active topics in Figure 1(g), and marginal log-likelihood in Figure 1(h). The subcluster split-merge algorithm adds new topics one-at-a-time, whereas our algorithm can create multiple new topics per iteration—we hypothesize this difference leads to faster convergence for Algorithm 2.

In Figure 1(i), we observe that the amount of computing time per iteration increases substantially for the subcluster split-merge method as it adds more topics. For Algorithm 2, this stays approximately constant for its entire runtime.

To evaluate the topics produced by the algorithms, we again examined the most common words for each topic via a quantile summary, given in Appendix E. We find the subcluster split-merge algorithm appears to generate topics with slightly more semantic overlap compared to Algorithm 2, but otherwise produces comparable output.

Finally, to assess scalability, we ran 25 000 iterations of Algorithm 2 on PubMed, which contains 768m tokens. To our knowledge, this dataset is an order of magnitude larger than any datasets used in previous MCMC-based approaches for the HDP. Computation was performed on a compute node with 2x10-core CPUs with 20 threads and 64GB of RAM. The marginal likelihood and number of active topics are given in Figure 1(j) and Figure 1(k).

To evaluate the topics discovered by the algorithm, we examined their most common words—these may be seen in full in Appendix F. We observe that the semantic themes present in the topics vary according to how many tokens they have: topics with more tokens appear to be broader, whereas topics with fewer tokens appear to be more specific. This behavior illustrates a key difference between the HDP and methods like LDA, which do not contain a learned global topic distribution $\mathbf{\Psi}$ in their formulation. We suspect the effect is particularly pronounced on PubMed compared to CGCBIB and NeurIPS due to its large number of tokens.

4 Discussion

In this work, we introduce the parallel partially collapsed Gibbs sampler—Algorithm 1—for the HDP topic model, which converges to the correct target distribution. We propose a doubly sparse approximate sampler—Algorithm 2—which allows the HDP to be implemented with per-token sampling complexity of $\mathcal{O}\big[\min\big(K^{(\mathbf{m})}_{d(i)}, K^{(\mathbf{\Phi})}_{v(i)}\big)\big]$ which is the same as that of Pólya Urn LDA (Terenin et al., 2019). Compared to other approaches for the HDP, it offers the following improvements.

1. The algorithm is fully parallel in all steps.
2. The topic indicators $\boldsymbol{z}$ utilize all available sources of sparsity to accelerate sampling.
3. All steps not involving $\boldsymbol{z}$ have constant complexity with respect to data size.
4. The proposed sparse approximate algorithm becomes exact as $N \to \infty$ and $K^* \to \infty$.

These improvements allow us to train the HDP on larger corpora. The data-parallel nature of our approach means that the amount of available parallelism increases with data size. This parallelism avoids load-balancing-related scalability limitations pointed out by Gal and Ghahramani (2014).

Nonparametric topic models are less straightforward to evaluate empirically than ordinary topic models. In particular, we found topic coherence scores (Mimno et al., 2011) to be strongly affected by the number of active topics K, which causes preference for models with fewer topics and more

k	Topic 1	Topic 5	Topic 9	Topic 13	Topic 17

Figure 2: Top 8 words for topics obtained by Algorithm 2 on PubMed, together with topic index k and total number of words $n_{k,\bullet}$ present in the topic. We observe that the topics range from broad to specific: this is a consequence of the hierarchical Dirichlet process prior via the inclusion of the global topic proportions $\mathbf{\Psi}$. Topics obtained by Algorithm 2 on all corpora may be seen in Appendix C, Appendix D, Appendix E, and Appendix F.

semantic overlap per topic. We view the development of summary statistics that are K-agnostic and those measuring other aspects of topic quality such as overlap, to be an important direction for future work. We are particularly interested in techniques that can be used to compare algorithms for sampling from the same model defined over fully disjoint state spaces, such as Algorithm 2 and the subcluster split-merge algorithm in Section 3.

Partially collapsed HDP can stabilize around a different local mode than fully collapsed HDP as proposed by Teh et al. (2006). There have been attempts to improve mixing in that sampler (Chang and Fisher, 2014), including the use of Metropolis-Hastings steps for jumping between modes (Jain and Neal, 2004). These techniques are largely complementary to ours and can be explored in combination with the ideas presented here.

The HDP posterior is a heavily multimodal target for which full posterior exploration is known to be difficult (Chang and Fisher, 2014; Gal and Ghahramani, 2014; Buntine and Mishra, 2014), and sampling schemes are generally used more in the spirit of optimization than traditional MCMC. These issues are mirrored in other approaches, such as variational inference. There, restrictive mean-field factorization assumptions are often required, which reduces the quality of discovered topics. We view MAP-based analogs of ideas presented here as a promising direction, since these may allow additional flexibility that may enable faster training.

Many of the ideas in this work, such as the binomial trick, are generic and apply to any topic model structurally similar to the HDP's GEM representation (Teh et al., 2006) given in Section 2. For example, one could consider an informative prior for $\mathbf{\Psi}$ in lieu of GEM(γ), potentially improving convergence and topic quality, or developing parallel schemes for other nonparametric topic models such as Pitman-Yor models (Teh, 2006), tree-based models (Hu and Boyd-Graber, 2012; Paisley et al., 2015), embedded topic models (Dieng et al., 2020), as well as nonparametric topic models used within data-efficient language models (Guo et al., 2020) in future work.

Conclusion

We introduce the doubly sparse partially collapsed Gibbs sampler for the hierarchical Dirichlet process topic model. By formulating this algorithm using a representation of the HDP which connects it with the well-studied Latent Dirichlet Allocation model, we obtain a parallel algorithm whose per-token sampling complexity is the minima of two sparsity terms. The ideas used apply to a large array of topic models which possess the same full conditional for the topic indicators $\boldsymbol{z}$. Our algorithm for the HDP scales to a 768m-token corpus (PubMed) on a single multicore machine in under four days.

The proposed techniques leverage parallelism and sparsity to scale nonparametric topic models to larger datasets than previously considered feasible for MCMC or other methods possessing similar convergence properties. We hope these contributions enable wider use of Bayesian nonparametrics for large collections of text.

Abstract

Few/Zero-shot learning is a big challenge of many classifications tasks, where a classifier is required to recognise instances of classes that have very few or even no training samples. It becomes more difficult in multi-label classification, where each instance is labelled with more than one class. In this paper, we present a simple multi-graph aggregation model that fuses knowledge from multiple label graphs encoding different semantic label relationships in order to study how the aggregated knowledge can benefit multi-label zero/few-shot document classification. The model utilises three kinds of semantic information, i.e., the pre-trained word embeddings, label description, and pre-defined label relations. Experimental results derived on two large clinical datasets (i.e., MIMIC-II and MIMIC-III) and the EU legislation dataset show that methods equipped with the multi-graph knowledge aggregation achieve significant performance improvement across almost all the measures on few/zero-shot labels.

1 Introduction

Multi-label learning is a fundamental and practical problem in computer vision and natural language processing. Many tasks, such as automated medical coding (Yan et al., 2010; Rios and Kavuluru, 2018; Du et al., 2019), recommender systems (Halder et al., 2018), image classification (Chen et al., 2019; Wang et al., 2020), law study (Parikh et al., 2019; Chalkidis et al., 2019), and stance detection (Ferreira and Vlachos, 2019) can be formulated as a multi-label learning problem. Different from multi-class classification, an instance in multi-label learning is often associated with more than one class label, which makes the task even more challenging due to the combinatorial nature of the label space. i.e., the number of possible label combinations is exponential with the total number of labels.

In real-world applications, there are often insufficient or even unavailable training data of ever emerging classes (Vinyals et al., 2016; Xian et al., 2019). For instance, more than half of the International Classification of Diseases (ICD) codes are not associated with a discharge summary in the MIMIC-III dataset (Johnson et al., 2016; Rios and Kavuluru, 2018). As a solution, zero-shot learning (Xian et al., 2019; Wang et al., 2019) aims to generalize classifiers to unseen classes by leveraging various label semantics. Those classifiers are required to recognise instances of classes that have never been seen in the training set, which becomes more difficult in multi-label learning.

Moreover, the number of classes can reach hundreds of thousands. The ICD-9-CM taxonomy contains 17K diagnosis/procedure codes[1], where the majority occurs less than 10 times in MIMIC-III; the EU legislation corpus (EURLEX57X) (Chalkidis et al., 2019) contains about 7K labels, 70%of which have been assigned to less than 10 documents. The power-law distribution of labels (Liu et al., 2017; Xie et al., 2019; Song et al., 2019) leads to the few-shot learning challenge, where each label has a few training instances.

Classes come naturally with structures, which capture different relationships between individual classes. For example, codes in the ICD-9-CM taxonomy are organised in a rooted tree with edges representing is-a relationships between parents and children (Perotte et al., 2014). We can compute a code similarity graph using the code description and a code co-occurrence graph using the annotated discharge summaries in MIMIC-II/III. These two graphs can capture label relationships that are missing in the taxonomy. For example, the sim-

ilarity graph can reveal the relationship between "hypertensive chronic kidney disease" and "acute kidney failure"; the co-occurrence graph can give us information about that "coronary atherosclerosis of native coronary artery" frequently co-occurs with "coronary arteriography using two catheters". It has been shown that ignoring this structured information and assuming all classes to be mutually exclusive are insufficient (Zhao et al., 2018; Gaure and Rai, 2017; Kavuluru et al., 2015).

In this paper, we present a simple but effective multi-graph knowledge aggregation model that can transform and fuse the structural information from multiple label graphs while utilising three kinds of semantics: the pre-trained word embeddings, label description, and the label relations. To demonstrate its efficacy, we adapt the model as a sub-module to several existing neural architectures (Rios and Kavuluru, 2018; Chalkidis et al., 2019) for multi-label few/zero-shot learning. However, this model can work as a self-contained module and be flexibly adapted to most existing multi-label learning models (Xie et al., 2019; Li and Yu, 2020) that use GCNs to leverage the label structures. Experiments on three real-world datasets show that neural classifiers equipped with our multi-graph knowledge aggregation model can significantly improve the few/zero-shot classification performance.

2 Related Work

Leveraging structural label information via GCNs (Kipf and Welling, 2017) has become a promising approach of tackling the few/zero-shot problem, attracting increasing attention in recent years. Wang et al. (2018); Kampffmeyer et al. (2019), and Chen et al. (2017) have used GCNs to learn visual classifiers for multi-class image classification. These ideas can be generalised to multi-label learning (Lee et al., 2018; Chen et al., 2019; Do et al., 2019; Wang et al., 2020; You et al., 2020). However, none of these methods can be directly adapted to multi-label few/zero-shot text classification. Using the label-wise attention mechanism (Mullenbach et al., 2018; Xiao et al., 2019), Rios and Kavuluru (2018) introduced an attention-based CNN to convert each document into a feature matrix, each row of which is a label-specific document feature vector. The multi-label document classifiers were learned from a GCN over the label hierarchy. While considering only the efficiency of the document encoder, Chalkidis et al. (2019); Li and Yu (2020); Xie et al. (2019) further proposed to replace the simple CNN with BIGRU, multi-filter residual CNN and densely-connected CNN respectively. In contrast, our work focuses on the learning of the classifiers from multiple label graphs. Existing work on multiple graphs learning often proposed to either fuse multiple graphs before fed into a GCN (Khan and Blumenstock, 2019; Wang et al., 2020) or consider the multi-dimensionality of graphs (Ma et al., 2019; Wu et al., 2019) for only note classification/link prediction.

3 Learning with Knowledge Aggregation

Problem Formulation Let $\mathcal{C}_S$ and $\mathcal{C}_U$ be disjoint sets of seen and unseen labels. $\mathcal{C}_S$ is further divided into frequent labels $\mathcal{C}_S^R$ and few-shot labels $\mathcal{C}_S^F$ such that $\mathcal{C}_S = \mathcal{C}_S^R \cup \mathcal{C}_S^F$. Given a training set $\{(\mathbf{x}_1, \mathbf{y}_1), \ldots, (\mathbf{x}_N, \mathbf{y}_N)\}$, where $\mathbf{x}_i$ indicates the i-th document and $\mathbf{y}_i \subset \mathcal{C}_S$ is the subset of labels assigned to $\mathbf{x}_i$, the goal is to predict $\hat{\mathbf{y}}_i$ for each test document in generalised zero-shot settings (Xian et al., 2019), where $\hat{\mathbf{y}}_i$ is a subset of $\mathcal{C}_S \cup \mathcal{C}_U$. Note that: *i)* every label has a description; *ii)* the label relationships encoded in graphs can be computed from various resources; *iii)* documents associated with any label from $\mathcal{C}_U$ are excluded from training.

Document Encoder with Label-wise Attention According to the characteristic of different datasets, different document encoders ϕ can be used to generate the document representation, i.e., $\mathbf{F}_i = \phi(\mathbf{x}_i)$. For a corpus, like EURLEX57X, where the average document length is in hundreds, one can consider Bi-GRU/LSTM, HAN (Yang et al., 2016), BERT (Devlin et al., 2019), etc. For a corpus, like MIMIC-II/III, where the discharge summaries contain multiple long and heterogeneous medical narratives, the CNN-based encoders have shown prominet performance, like those discussed in Section 2. The size of $\mathbf{F}_i \in \mathbb{R}^{n \times u}$ varies, depending on the encoder. For BERT, n is the number of words and u is the size of the output layer of BERT; for CNNs, n is the number of s-grams generated by CNNs with a filter size s and u the number of filters.

In addition, we create label embeddings $\mathbf{v}_l$ by TF-IDF weighted average of pre-trained word embeddings (Chen et al., 2017) according to the label description, and use those label embeddings to compute the label-wise attention (Mullenbach et al., 2018; Rios and Kavuluru, 2018) for each

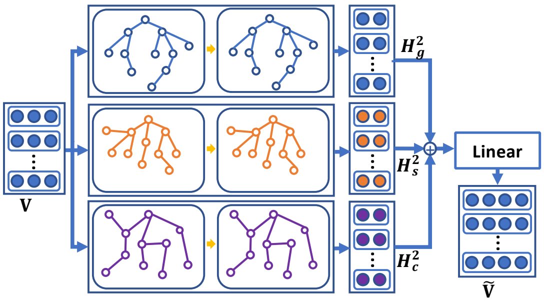

Figure 1: Multi-graph knowledge aggregation

document $\mathbf{x}_i$ as follows:

$$\begin{aligned} \mathbf{a}_{i,l} &= \mathrm{softmax}(\tanh(\mathbf{F}_i\mathbf{W}_0 + \mathbf{b}_0)\mathbf{v}_l) \quad (1) \\ \mathbf{z}_{i,l} &= \mathbf{a}_{i,l}^T\mathbf{F}_i, \quad (2) \end{aligned}$$

where $\mathbf{W}_0 \in \mathbb{R}^{u\times d}$, $\mathbf{b}_0 \in \mathbb{R}^d$. The attention is to capture how different parts of texts are relevant to different classes.

Knowledge Aggregation from Multi-Graphs (KAMG) We consider the label hierarchy ($\mathbf{A}_g$) given by the class taxonomy, the semantic similarity graph ($\mathbf{A}_s$) computed from their descriptions, and the label co-occurrence graph ($\mathbf{A}_c$) extracted for $\mathcal{C}_S$ from the training data, although our method can be generated to more label graphs. Let $\mathbf{A} \in \mathbb{R}^{|\mathcal{C}_S|\times|\mathcal{C}_S|}$ be any of the three label graphs, $\mathbf{V} \in \mathbb{R}^{L\times d}$ be the label embedding matrix, a two-layer GCN is applied to each graph as follows:

$$\begin{aligned} \mathbf{H}^1 &= \sigma(\mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}\mathbf{V}\mathbf{W}_1) \quad (3) \\ \mathbf{H}^2 &= \sigma(\mathbf{D}^{-1/2}\mathbf{A}\mathbf{D}^{-1/2}\mathbf{H}^1\mathbf{W}_2) \quad (4) \end{aligned}$$

where $\mathbf{D}_{i,i} = \sum_j A_{i,j}$ is a degree matrix of $\mathbf{A}$, $\mathbf{W}^1 \in \mathbb{R}^{d\times q}$ and $\mathbf{W}^2 \in \mathbb{R}^{q\times p}$ are two weight matrices, $\mathbf{H}^1$ and $\mathbf{H}^2$ indicate the hidden states and outputs respectively, σ is the non-linear activation function, a rectified linear unit (ReLU) in our case.

Different from Rios and Kavuluru (2018); Xie et al. (2019), we feed a two-layer GCN to each of the three graphs and generate three sets of label embeddings: $\mathbf{H}_g^2$, $\mathbf{H}_s^2$ and $\mathbf{H}_c^2$, which are supposed to capture different semantic relations between labels. A linear layer is then used to fuse the three types of label embeddings:

$$\tilde{\mathbf{v}}_l = f([\mathbf{h}_{g,l}^2, \mathbf{h}_{s,l}^2, \mathbf{h}_{c,l}^2], \mathbf{W}_3) \quad (5)$$

where $\mathbf{W}_3 \in \mathbb{R}^{3p\times\tilde{q}}$, and $\tilde{\mathbf{v}}_l \in \mathbb{R}^{\tilde{q}}$. We acknowledge that it is also worth trying the techniques used in multi-model learning (Kiela et al., 2018), which is subject to future work. Figure 1 visualises the multi-graph knowledge aggregation process.

We concatenate both $\mathbf{v}_l$ with $\tilde{\mathbf{v}}_l$ to form the final text classifiers as $\bar{\mathbf{v}}_l = [\mathbf{v}_l, \tilde{\mathbf{v}}_l]$, $\bar{\mathbf{v}}_l \in \mathbb{R}^{d+\tilde{q}}$. The label-wise document embeddings ($\mathbf{z}_{i,l}$) are projected onto the same space as $\bar{\mathbf{v}}_l$ via a simple non-linear transformation as

$$\bar{\mathbf{z}}_{i,l} = \mathrm{ReLU}(\mathbf{W}_4\mathbf{z}_{i,l} + \mathbf{b}_4) \quad (6)$$

where $\mathbf{W}_4 \in \mathbb{R}^{(d+\tilde{q})\times u}$ and $\mathbf{b}_4 \in \mathbb{R}^{(d+\tilde{q})}$. The prediction for each label l is generated with $\hat{y}_{i,l} = \mathrm{sigmoid}(\bar{\mathbf{z}}_{i,l}^T\bar{\mathbf{v}}_l)$. The model is optimised via a multi-label binary cross-entropy loss. Although we used three label graphs (label hierarchy, similarity and co-occurrence) to demonstrate the advantage of aggregating knowledge from multi-graphs, the model itself is general enough to be applied to other datasets where there exist multiple label graphs.

Zero-Shot Classification For zero-shot prediction, we extend $\mathbf{A} \in \mathbb{R}^{|\mathcal{C}_S|\times|\mathcal{C}_S|}$ to $\tilde{\mathbf{A}} \in \mathbb{R}^{(|\mathcal{C}_S|+|\mathcal{C}_U|)\times(|\mathcal{C}_S|+|\mathcal{C}_U|)}$, so that the new graph can encode the relationship between unseen and seen classes. All labels will be optimized simultaneously during the training stage as in (Rios and Kavuluru, 2018). Note that $\mathbf{A}_c$ counts only the co-occurrence of seen classes.

4 Experiments

In this section, several experiments were conducted to evaluate the efficacy of KAMG in classifying discharge summaries and legislative documents. We compared our methods with several state-of-the-art multi-label classifiers in a few/zero-shot setting, and studied how KAMG behaves by varying label graphs in a set of ablation experiments.

Datasets We used two benchmark medical datasets (MIMIC II and III) and the EU legislation dataset (EURLEX57K) to evaluate our method in the few/zero-shot settings. Statistics of these datasets are shown in Table 1. Following Rios and Kavuluru (2018); Chalkidis et al. (2019), we split the datasets in such a way that 1) zero-shot labels (i.e., unseen) do not have any instances in training; 2) few-shot labels (i.e., less frequent labels) were defined as those whose frequencies in the training set are less than or equal to 5 for MIMIC-II and MIMI-III and 50 for EURLEX57K. The 200-dimensional word embeddings pre-trained on PubMed and MIMIC-III (Zhang et al., 2019; Chen et al., 2019) were used for MIMIC-II/III, and 200-dimensional word embeddings pre-trained on law corpra provided by Chalkidis et al. (2019) were used for EURLEX57k.

Experiment settings and metrics For MIMIC-II/III, we used the NeuralClassifier (Liu et al., 2019) as a base framework to implement our methods. We used 200 filters with kernel size 10 to setup

Table 3: Multi-label classification results on EURLEX57K. Bold figures indicate the best results for each score among the three models designed specifically for zero-shot learning. Italics indicate the best results overall.

the CNNs by following Rios and Kavuluru (2018) and the GCNs' hidden layer size was set to 200. For EURLEX57K, we leveraged Chalkidis et al. (2019)'s code, and used the one-layer BiGRU with hidden dimension 100 as reported in their paper. The size of the GCNs' hidden states was set to 200. Moreover, the dropout rate was set to 0.2, 0.1 for MIMIC-II/III and EURLEX57K respectively and applied after the embedding layer. Adam optimizer (i.e., learning rate: 0.001 for CNN and 0.0003 for BIGRU) was used to train all the models. All experiments were run with one NVIDIA GPU V100.

We report a variety of ranking metrics, including Recall@K and nDCG@K. We argue that the ranking metrics are more preferable for few/zero-shot label without introducing significant bias towards frequent labels; they are more inline with the human annotation process, like the ICD coding, where clinicians often review a limited number of candidate codes. K was set to 10 for MiMIC-II/III and 5 for URLEX57K.

Results on MIMIC-II/III We compared KAMG, which uses all three label graphs ($\mathbf{H}_g$, $\mathbf{H}_s$ and $\mathbf{H}_c$), with the following baselines: CNN, RCNN (the best model in Liu et al. (2019)), CAML, DR-CAML, ZACNN and ZAGCNN. Table-2 shows the performance of all those models. KAMG outperforms the other models in all the metrics across almost all the settings on both datasets with a notable margin, due to our multi-graph knowledge aggregation model. Specifically, while classifying zero-shot labels, ACNN-KAMG outperforms ZAGCNN, which uses only the label hierarchy (i.e., $\mathbf{H}_g$), by 8% in R@10 and 6.5% in nDCG@10 on MIMIC-II and 4.1% in R@10 and 10.5% in nDCG@10 on MIMIC-III. Similarly, ACNN-KAMG gains 4% in R@10 and 2.7% in nDCG@10 on MIMIC-II and 3.7% in R@10 and 6.5% in nDCG@10 on MIMIC-III over ZAGCNN on few-shot labels.

Results on EURLEX57K We further compared AGRU-KAMG with with BIGRU-LAWN, ZERO-CNN-LAWN, and ZERO-BIGRU-LAWN, which are the best performing models using label-wise attention on few/zero-shot labels in (Chalkidis et al., 2019). We implemented AGRU-KAMG by directly modifying ZERO-BIGRU-LAWN's published code. Results in Table 3 show AGRU-KAMG performs significantly better than ZERO-BIGRU-LAWN on zero-shot labels by gaining 9.0% improvement in R@5 and 6.9% in nDCG@5, and comparably with ZERO-BIGRU-LAWN on few-shot labels. BIGRU-LAWN exhibits strong performance on frequent/few-shot labels, which

is inline with Chalkidis et al. (2019)'s finding. This could be attributed to the fine-tuning of label embeddings in the learning process. In contrast, AGRU-KAMG has label embeddings fixed to those computed from pretrained embedding in order to leverage label description in the zero-shot setting.

Results on pre/post-GCN fusion Table 4 shows the performance difference between the following two graph fusion methods: 1) merging two label graphs into one graph, and then feeding it into one GCN (Ma et al., 2019; Wang et al., 2020), and 2) our method, where two graphs were fed into two GCNs and then fused together. The results showed that our method performs much better than the pre-GCN fusion method.

Results on using different combinations of label graphs We further conducted a set of ablation experiments based on the use of different combinations of label graphs to study how the performance of KAMG varies while using different graphs in both few and zero-shot settings. The results in Tables 5 and 6 show that i) KAMG performs better with multiple graphs than with a single graph overall, which demonstrates it is beneficial to aggregate information from multiple graphs; ii) graphs contribute differently to the classification performance, the ICD taxonomy plays an important role while being used in conjunction with the other graphs, and the three graphs work complementary to each other on EURLEX57K.

5 Conclusion

We have proposed a multi-graph aggregation method that can effectively fuse knowledge from multiple label graphs. Experiments on MIMIC-II/III and EURLEX57K have shown that the classifiers derived from the multi-graph aggregation have achieved substantial performance improvements particularly on few/zero-shot labels. As future work, we will further study our method's ability of extreme multi-label learning (Bhatia et al., 2016) and different document encoders.

Acknowledgments

We thank anonymous reviewers for their valuable comments.

Abstract

One key principle for assessing textual similarity is measuring the degree of semantic overlap between two texts by considering the word alignment. Such alignment-based approaches are both intuitive and interpretable; however, they are empirically inferior to the simple cosine similarity between general-purpose sentence vectors. We focus on the fact that the *norm* of word vectors is a good proxy for word importance, and the *angle* of them is a good proxy for word similarity. Alignment-based approaches do not distinguish the norm and direction, whereas sentence-vector approaches automatically use the norm as the word importance. Accordingly, we propose decoupling word vectors into their norm and direction then computing the alignment-based similarity with the help of earth mover's distance (optimal transport), which we refer to as *word rotator's distance*. Furthermore, we demonstrate how to "grow" the norm and direction of word vectors (*vector converter*); this is a new systematic approach derived from the sentence-vector estimation methods, which can significantly improve the performance of the proposed method. On several STS benchmarks, the proposed methods outperform not only alignment-based approaches but also strong baselines. [1]

1 Introduction

This paper addresses the task of semantic textual similarity (STS), the goal of which is to measure the degree of semantic equivalence between two sentences (Agirre et al., 2012). STS methods can be used to upgrade loss functions and automatic evaluation metrics of text generation tasks because one of the requirements of these functions is precisely the calculation of STS (Wieting et al., 2019; Zhao et al., 2019; Zhang et al., 2019).

There are two major approaches to tackling STS. One is to measure the degree of semantic overlap between the texts by considering the word alignment, which we refer to as *alignment-based approaches* (Sultan et al., 2014; Kusner et al., 2015; Zhao et al., 2019). The other is to generate general-purpose sentence vectors from two texts (typically using word vectors) and then calculate their similarity, which we refer to as *sentence vector approaches* (Arora et al., 2017; Ethayarajh, 2018). Alignment-based approaches are consistent with human intuitions concerning textual similarity, and their predictions are interpretable; however, the performance of such methods is lower than that of sentence-vector approaches.

We hypothesize that one reason for the inferiority of alignment-based methods is that alignment-based approaches do not separate the *norm* and *direction* of the word vectors. Conversely, sentence-vector approaches automatically exploit the norm of word vectors as the relative importance of words.

Accordingly, we propose a new alignment-based STS method that separates the norm and direction of word vectors with the help of earth mover's distance (EMD). The key idea is to map the *norm* and *angle* of word vectors to the EMD parameters *mass* and *transportation cost*, respectively. The proposed method is mathematically natural, preserves the features of alignment-based methods, and can directly incorporate the sentence-vector estimation methods, leading to fairly high performance.

Our main contributions are as follows.

- We demonstrate that the norm of a word vector implicitly encodes the weight of a word and that the angle between word vectors is a good proxy for the dissimilarity of the words.
- We propose a new textual similarity measure, word rotator's distance, which can separately utilize the norm and direction of word vectors.
- To enhance the method, we further propose a new

word vector conversion mechanism with the help of recent sentence encoders.

- We demonstrate that the proposed methods achieve high performance compared to strong baseline methods on several STS tasks.

2 Task and Notation

Semantic textual similarity (STS) is the task of measuring the degree of semantic equivalence between two sentences (Agirre et al., 2012). For example, the sentences "*Two boys on a couch are playing video games.*" and "*Two boys are playing a video game.*" are mostly equivalent (the similarity score of 4 out of 5) while the sentences "*The woman is playing the violin.*" and "*The young lady enjoys listening to the guitar.*" are not equivalent but on the same topic (score of 1) (Agirre et al., 2013). System predictions are customarily evaluated by Pearson correlation with the gold scores. Hence, systems are only required to predict relative similarity rather than absolute scores.

We focus on *unsupervised* STS, following Arora et al. (2017) and Ethayarajh (2018). That is, we utilize only pre-trained word vectors, and do not use any supervision including training data for related tasks (e.g., natural language inference) and external resources (e.g., paraphrase database). *Semi-supervised* methods that utilize such external corpora have been successful in English STS. However, the need for external corpora is a major obstacle when applying STS, a fundamental technology, to low-resource languages.

Formally, given sentences s and s' consisting of n and n' words from the vocabulary $\mathcal{V}$

$$s = (w_1, \ldots, w_n), \; s' = (w'_1, \ldots, w'_{n'}), \qquad (1)$$

the goal is to predict the similarity $\mathrm{sim}(s, s') \in \mathbb{R}$. Bold face $\boldsymbol{w}_i \in \mathbb{R}^d$ denotes the word vector corresponding to word w_i. Let $\langle \cdot, \cdot \rangle$ and $\|\cdot\|$ denote the dot product and the Euclidean norm, respectively

$$\langle \boldsymbol{w}, \boldsymbol{w}' \rangle := \boldsymbol{w}^\top \boldsymbol{w}', \quad \|\boldsymbol{w}\| := \sqrt{\langle \boldsymbol{w}, \boldsymbol{w} \rangle}. \qquad (2)$$

3 Related Work

We briefly review the methods that are directly related to unsupervised STS.

Alignment-based Approach. One major approach for unsupervised STS is to compute the degree of semantic overlap between two texts (Sultan et al., 2014, 2015). Recently, determining the soft alignment between word vector sets has become a mainstream method. Tools used for alignment include attention mechanism (Zhang et al., 2019), fuzzy set (Zhelezniak et al., 2019), and earth mover's distance (EMD) (Kusner et al., 2015; Clark et al., 2019; Zhao et al., 2019).

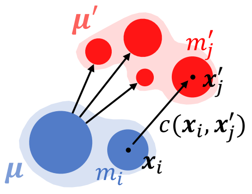

Figure 1:
Earth Mover's Distance.

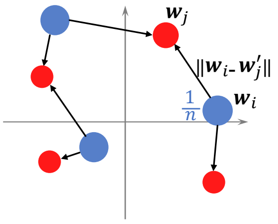

Figure 2:
Word Mover's Distance.

Of those, EMD has several unique advantages. First, it has a rich theoretical foundation for measuring the differences between probability distributions in a metric space (Villani, 2009; Peyré and Cuturi, 2019). Second, EMD can incorporate structural information such as syntax trees (Alvarez-Melis et al., 2018; Titouan et al., 2019). Finally, with a simple modification, EMD can be differentiable and can be incorporated into larger neural networks (Cuturi, 2013). Despite these advantages, EMD-based methods have underperformed sentence-vector-based methods on STS tasks. The goal of this study is to identify and resolve the obstacles faced by EMD-based methods (Section 5).

Sentence-vector Approach. Another popular approach is to employ general-purpose sentence vectors of given texts and to compute the cosine similarity between such vectors. A variety of methods to compute sentence vectors have been proposed, ranging from deep sentence encoders (Kiros et al., 2015; Conneau et al., 2017; Cer et al., 2018), learning and using word vectors optimized for summation (Khodak et al., 2018; Pagliardini et al., 2018; Wieting and Gimpel, 2018), to estimating latent sentence vectors from pre-trained word vectors (Arora et al., 2017; Ethayarajh, 2018; Liu et al., 2019b). This paper demonstrates that some recently proposed sentence vectors can be reformulated as a sum of the converted pre-trained word vectors. By applying this conversion, our method can achieve similar or better performance compared to sentence-vector approaches (Section 6).

4 Word Mover's Distance and its Issue

4.1 Earth Mover's Distance

Intuitively, *earth mover's distance (EMD)*[2] (Villani, 2009; Santambrogio, 2015; Peyré and Cuturi, 2019) is the minimum cost required to turn one pile of dirt into the another pile of dirt (Figure 1). Formally, EMD takes the following inputs.

1. Two **probability distributions**, $\boldsymbol{\mu}$ (initial arrangement) and $\boldsymbol{\mu}'$ (final arrangement)[3]:

$$\boldsymbol{\mu} = \Big\{(\boldsymbol{x}_i,\, m_i)\Big\}_{i=1}^{n},\ \boldsymbol{\mu}' = \Big\{(\boldsymbol{x}'_j,\, m'_j)\Big\}_{j=1}^{n'}. \tag{3}$$

   Here, $\boldsymbol{\mu}$ denotes a probability distribution, in which each point $\boldsymbol{x}_i \in \mathbb{R}^d$ has a probability mass $m_i \in [0, 1]$ ($\sum_i m_i = 1$). In Figure 1, each circle represents a pair $(\boldsymbol{x}_i, m_i)$, where the location and size of the circle represent a vector $\boldsymbol{x}_i$ and its probability m_i, respectively.
2. The **transportation cost function**, c:

$$c\colon \mathbb{R}^d \times \mathbb{R}^d \to \mathbb{R}. \tag{4}$$

   Here, $c(\boldsymbol{x}_i, \boldsymbol{x}'_j)$ determines the transportation cost per unit amount (distance) between two points $\boldsymbol{x}_i$ and $\boldsymbol{x}'_j$.

The EMD between $\boldsymbol{\mu}$ and $\boldsymbol{\mu}'$ is then defined via the following optimization problem:

$$\mathrm{EMD}(\boldsymbol{\mu}, \boldsymbol{\mu}'; c) := \min_{\boldsymbol{T}\in\mathbb{R}_{\geq 0}^{n\times n'}} \sum_{i,j} \boldsymbol{T}_{ij}\, c(\boldsymbol{x}_i, \boldsymbol{x}'_j), \tag{5}$$

$$\text{s.t.} \quad \begin{cases} \boldsymbol{T}\mathbb{1}_n = \boldsymbol{m} := (m_1, \ldots, m_n)^\top, \\ \boldsymbol{T}^\top\mathbb{1}_{n'} = \boldsymbol{m}' := (m'_1, \ldots, m'_{n'})^\top. \end{cases} \tag{6}$$

A solution $\boldsymbol{T} \in \mathbb{R}_{\geq 0}^{n\times n'}$ denotes a transportation plan, in which each element $\boldsymbol{T}_{ij}$ represents the mass transported from $\boldsymbol{x}_i$ to $\boldsymbol{x}'_j$. To summarize, $\mathrm{EMD}(\boldsymbol{\mu}, \boldsymbol{\mu}'; c)$ is the cost of the best transportation plan between two distributions $\boldsymbol{\mu}$ and $\boldsymbol{\mu}'$.

Side Benefit: Alignment. Under the above optimization, if the locations $\boldsymbol{x}_i$ in $\boldsymbol{\mu}$ and $\boldsymbol{x}'_j$ in $\boldsymbol{\mu}'$ are *close* (i.e., the transportation cost $c(\boldsymbol{x}_i, \boldsymbol{x}'_j)$ is small), they are likely to be *aligned* (i.e., $\boldsymbol{T}_{ij}$ might be assigned a large value). In this way, EMD can be seen as aligning the points of two discrete distributions. This is one of the reasons why we adopt EMD as a key technology for the STS problem.

4.2 Word Mover's Distance

Word mover's distance (WMD) (Kusner et al., 2015) is a dissimilarity measure between two texts, a pioneering work that introduced EMD into the natural language processing (NLP) community. Our study is strongly inspired by this work. We introduce WMD in preparation for our proposed method.

WMD is the cost of transporting a set of word vectors in the embedding space (Euclidean space) (Figure 2). Formally, after removing stopwords, Kusner et al. (2015) regard each sentence s as a uniformly weighted distribution $\boldsymbol{\mu}_s$ consisting of word vectors (bag-of-word-vectors distribution):

$$\boldsymbol{\mu}_s := \Big\{(\boldsymbol{w}_i,\, \frac{1}{n})\Big\}_{i=1}^{n},\ \boldsymbol{\mu}_{s'} := \Big\{(\boldsymbol{w}'_j,\, \frac{1}{n'})\Big\}_{j=1}^{n'}. \tag{7}$$

In Figure 2, each circle represents each word, where the location and size of the circle represent the vector $\boldsymbol{w}_i$ and its weight $\frac{1}{n}$, resp. Next, they use Euclidean distance as the transportation cost between the word vectors

$$c_{\mathrm{E}}(\boldsymbol{w}_i, \boldsymbol{w}'_j) := \|\boldsymbol{w}_i - \boldsymbol{w}'_j\|. \tag{8}$$

Then, WMD is defined as the EMD between two such distributions using the cost function c_{E}

$$\mathrm{WMD}(s, s') := \mathrm{EMD}(\boldsymbol{\mu}_s, \boldsymbol{\mu}_{s'}; c_{\mathrm{E}}). \tag{9}$$

4.3 Issues with Word Mover's Distance

Despite its intuitive formulation, WMD would often misalign words with each other, and the STS performance of WMD is lower than that of methods that simply add up word vectors and the compute cosine similarity. For example, "noodle" and "snack" might be aligned instead of "noodle" and "pho" (a type of Vietnamese noodle).

5 Word Rotator's Distance

In this section, we first discuss the role of the norm and direction of word vectors. Then, we describe the issues with WMD from the perspective of the role of the norm and direction. Finally, we propose our new method, word rotator's distance, which is able to resolve these issues.

5.1 Role of Norm and Direction

We hypothesis that the norm and direction of word vectors have the following different roles.

---

[2] In this paper, following convention, we use the term earth mover's distance in the sense of optimal transport cost according to the Kantrovich formulation. If the cost is a distance, it can also be called the 1-Wasserstein distance.

[3] Strictly speaking, Equation 3 is $\boldsymbol{\mu} = \sum_{i=1}^{n} m_i \delta[\boldsymbol{x}_i]$, where the Dirac delta function describes a discrete probability measure. In this paper, we omit delta for notational simplicity.

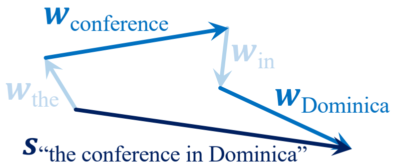

Figure 3: The operation of addition implicitly uses the norm of the vectors as the weighting factor.

- **Norm of a word vector as weighting factor**: The norm of a word vector indicates the extent to which the word contributes to the overall meaning of a sentence.
- **Angle between word vectors as dissimilarity**: The angle between two word vectors (the difference between the direction of these vectors) indicates the (dis)similarity of the two words.

We elaborate on the validity of this hypothesis in this section. Henceforth, λ_i and $\boldsymbol{u}_i$ denote the norm and the direction vector of word vector $\boldsymbol{w}_i$, resp.:

$$\lambda_i := \|\boldsymbol{w}_i\|, \;\; \boldsymbol{u}_i := \boldsymbol{w}_i/\lambda_i \;\; \big(\boldsymbol{w}_i = \lambda_i\boldsymbol{u}_i\big). \quad (10)$$

Note that any $\boldsymbol{u}_i$ is a unit vector $\big(\|\boldsymbol{u}_i\| = 1\big)$.

Additive Compositionality. As a starting point, we review the well-known nature of additive compositionality. The NLP community has confirmed that a simple sentence vector, i.e., the average of the vectors of the words in a sentence, can achieve remarkable results when assessing STS tasks, as well as many downstream tasks (Mitchell and Lapata, 2010; Mikolov et al., 2013; Wieting et al., 2016; Perone et al., 2018; Ma et al., 2019).

$$\boldsymbol{s}_{\text{ADD}} = \frac{1}{n}\sum_{w_i \in s} \boldsymbol{w}_i, \quad \boldsymbol{s}'_{\text{ADD}} = \frac{1}{n'}\sum_{w'_j \in s'} \boldsymbol{w}'_j, \quad (11)$$

$$\text{sim}(s, s') = \cos(\boldsymbol{s}_{\text{ADD}}, \boldsymbol{s}'_{\text{ADD}}). \quad (12)$$

Norm as Weighting Factor. At first glance, Equation 11 may appear to treat each word vector equally. However, several studies have confirmed that the norm of word vectors has a large dispersion (Schakel and Wilson, 2015; Arefyev et al., 2018). In other words, a sentence vector would contain word vectors of various sizes. In such a situation, a word vector having a large norm will dominate in the resulting sentence vector, and vice versa (Figure 3). Here, the usefulness of additive composition (implicit weighting by the norm) suggests that *the norm of each word vector functions as the weighting factor of the word when generating a sentence representation*. In our experiments, we provide data-driven evidence to support this claim.

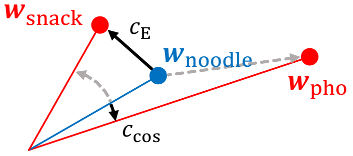

Figure 4: Euclidean distance "mixes up" the norm (a weighting factor for each word) and direction vectors (for word dissimilarity).

Moreover, regarding the relationship between the word vector norm and the word importance, the followings are known: (1) content words tend to have larger norms than function words (Schakel and Wilson, 2015); and (2) fine-tuned word vectors have larger norms for medium-frequency words, which is consistent with the traditional weighting guideline by Luhn in information retrieval (Khodak et al., 2018; Pagliardini et al., 2018). Both suggest that the norm serves as a weighting factor in situations where additive composition works.

Angle as Dissimilarity. What does a direction vector (i.e., the rest of the word vector "minus" its norm) represent?[4] Obviously, the most common calculation using the direction vectors of words is to measure their angles, i.e., their cosine similarity

$$\cos(\boldsymbol{w}, \boldsymbol{w}') = \frac{\langle \boldsymbol{w}, \boldsymbol{w}' \rangle}{\lambda\lambda'} = \langle \boldsymbol{u}, \boldsymbol{u}' \rangle. \quad (13)$$

It is widely known that the cosine similarity of word vectors trained on the basis of the distributional hypothesis approximates the similarity of words well (Pennington et al., 2014; Mikolov et al., 2013; Bojanowski et al., 2017). Naturally, *the difference in direction vectors represents the dissimilarity of words.* In our experiments, we confirm that cosine similarity is an empirically better proxy for word similarity compared to other measures.

5.2 Why doesn't WMD Work?

According to the above discussion, WMD has the following limitations.

- **Weighting of words:** While EMD can consider the weights of each point via their probability mass (Eq. 3) and the weighting factor of each word is encoded in the norm, WMD ignores the norm and weights each word vector uniformly (Eq. 7).

---

[4] Analogous to the polar coordinate system, Equation 10 decouples each word vector into a one-dimensional norm and a $(d-1)$-dimensional direction vector.

	noodle	*pho*	*snack*	*Pringles*
noodle	-	**0.43**	0.58	0.83
pho	**0.43**	-	0.73	0.94
snack	0.58	0.73	-	**0.56**
Pringles	0.83	0.94	**0.56**	-

(a) Cosine distance.

	noodle	*pho*	*snack*	*Pringles*
noodle	-	3.52	**3.39**	4.62
pho	**3.52**	-	4.52	5.60
snack	**3.39**	4.52	-	3.84
Pringles	4.62	5.60	**3.84**	-

(b) Euclidean distance.

Table 1: Differences in behavior between cosine and Euclidean distance. For each row, the lowest value (the closest word) is shown in **bold**. Inappropriate alignments are further **underlined**. We used pre-trained word2vec (Mikolov et al., 2013) as the word vectors.

- **Dissimilarity between words:** While EMD can consider the distance between points via a transportation cost (Eq. 4) and the dissimilarity between words can be measured by angle, WMD uses Euclidean distance, which *mixes* the weighting factor and the dissimilarity (Eq. 8).

This leads to estimates of low similarity for word pairs$_{\langle A\rangle}$ whose meanings are close$_{\langle B\rangle}$ but whose concreteness or importance is very different$_{\langle C\rangle}$, for example, "noodle" and "pho". This is clear from the relationship between the Euclidean distance (Eq. 8) and the cosine distance (Eq. 14).

$$c_{\cos}(\boldsymbol{w}, \boldsymbol{w}') := 1 - \cos(\boldsymbol{w}, \boldsymbol{w}') \tag{14}$$

$$c_{\mathrm{E}}(\boldsymbol{w}, \boldsymbol{w}') = \sqrt{(\lambda\boldsymbol{u} - \lambda'\boldsymbol{u}')^\top(\lambda\boldsymbol{u} - \lambda'\boldsymbol{u}')} \tag{15}$$

$$= \sqrt{\lambda\lambda'\,(2c_{\cos}(\boldsymbol{w}, \boldsymbol{w}') + (\lambda - \lambda')^2)}. \tag{16}$$

From Eq. 16, $c_{\mathrm{E}}(\boldsymbol{w}, \boldsymbol{w}')$ would be estimated as being large$_{\langle A\rangle}$ even if $c_{\cos}(\boldsymbol{w}, \boldsymbol{w}')$ is small$_{\langle B\rangle}$, as long as $|\lambda - \lambda'|$ is large$_{\langle C\rangle}$.

This undesirable property of Euclidean distance is also confirmed when using real data. Table 1 and Figure 4 show the cosine and Euclidean distances between the vectors of "noodle," "pho," "snack," and "Pringles" (the name of a snack). By using Euclidean distance, "noodle" and "snack" are judged to be similar (more likely to be aligned) than "noodle" and "pho".

5.3 Word Rotator's Distance

Given the above considerations, we propose a simple yet powerful sentence similarity measure using EMD. Our method regards each sentence as a discrete distribution on the unit hypersphere and calculates EMD on this hypersphere (Figure 5). Because the alignment of the direction vectors corresponds to a rotation on the unit hypersphere, we refer to the method as *word rotator's distance (WRD)*.

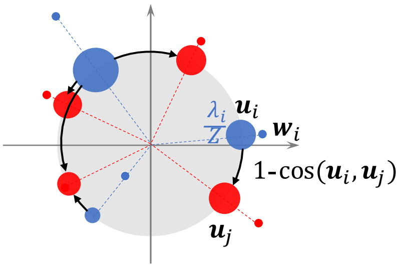

Figure 5: Word Rotator's Distance.

Formally, we regard each sentence s as a discrete distribution $\boldsymbol{\nu}_s$ consisting of direction vectors weighted by their norm (bag-of-direction-vectors distribution)

$$\boldsymbol{\nu}_s := \left\{\left(\boldsymbol{u}_i,\ \frac{\lambda_i}{Z}\right)\right\}_{i=1}^{n},\ \boldsymbol{\nu}_{s'} := \left\{\left(\boldsymbol{u}'_j,\ \frac{\lambda_j}{Z'}\right)\right\}_{j=1}^{n'}, \tag{17}$$

where Z and Z' are normalizing constants ($Z := \sum_i \lambda_i$, so as Z'). In Figure 5, each circle represents a word, where the location and size of the circle represent the direction vector $\boldsymbol{u}_i$, $\boldsymbol{u}'_j$, and its weight λ_i/Z, λ'_j/Z'. For the cost function, we use the cosine distance.

$$c_{\cos}(\boldsymbol{u}_i, \boldsymbol{u}'_j) = 1 - \cos(\boldsymbol{u}_i, \boldsymbol{u}'_j) \geq 0 \tag{18}$$

That is, to align words, it takes a cost of rotation. Then, the WRD between two sentences is:

$$\mathrm{WRD}(s, s') := \mathrm{EMD}(\boldsymbol{\nu}_s, \boldsymbol{\nu}_{s'}; c_{\cos}). \tag{19}$$

Unlike WMD, the above procedure allows our WRD to make the following appropriate correspondences between EMD and the word vectors.

- Probability mass (**weight** of each point) ↔ Norm (**weight** of each word)
- Transportation cost (**distance** between points) ↔ Angle (**dissimilarity** between words)

Algorithm. To ensure reproducibility, the specific (and quite simple) algorithm and implementation guidelines for WRD are shown in Appendix C.

6 Vector Converter-enhanced WRD

To further improve the performance of WRD, we attempted to integrate methods for estimating latent sentence vectors, the most powerful sentence encoders for STS, into WRD. However, determining a method to combine sentence-vector estimation methods with WRD is not a straightforward task. This is because WRD takes *word vectors* as input, whereas sentence-vector estimation methods require the processing of *sentence vectors*.

6.1 From Sentence Vector to Word Vector

Sentence-vector Estimation. Based on Arora's pioneering random-walk language model (LM) (Arora et al., 2016, 2017), a number of sentence-vector estimation methods have been proposed (Arora et al., 2017; Mu and Viswanath, 2018; Ethayarajh, 2018; Liu et al., 2019a,b) and achieved great success in many NLP applications, including STS. Given pre-trained vectors of the words that compose a sentence, these methods allow us to estimate the latent sentence vectors that generated the word vectors.

Such sentence-encoder methods can be summarized in the following form

$$\operatorname{Encode}(s) = f_3\left(\frac{1}{n}\sum_{w\in s}\alpha_2(w)f_1(\boldsymbol{w})\right), \tag{20}$$

where

- $f_1\colon \mathbb{R}^D \to \mathbb{R}^D$ "denoises" each word vector,
- $\alpha_2\colon \mathcal{V} \to \mathbb{R}$ scales each word vector, and
- $f_3\colon \mathbb{R}^D \to \mathbb{R}^D$ "denoises" each sentence vector.

Here, we focus only on the form of the equation for sentence-vector estimation. For specific algorithms, see the experimental section and Appendix D.

Word Vector Converter. By noticing that all the proposed denoising function f_3 is linear, Equation 20 can be rewritten as

$$\operatorname{Encode}(s) = \frac{1}{n}\sum_{w\in s}\widetilde{\boldsymbol{w}} \tag{21}$$

$$\widetilde{\boldsymbol{w}} = f_{\mathrm{VC}}(\boldsymbol{w}) := f_3\left(\alpha_2(w)\cdot f_1(\boldsymbol{w})\right). \tag{22}$$

That is, the encoders first perform a transformation f_{VC} on each word vector independently and then simply sum them up (additive composition!). We refer to the f_{VC} as *(word) vector converter (VC).*

6.2 Norm and Direction

We believe that the vector converter $f_{\mathrm{VC}}\colon \boldsymbol{w} \mapsto \widetilde{\boldsymbol{w}}$ improves the norm and direction of pre-trained word vectors for the reasons discussed in the following sections. We will conduct our experiments to support this hypothesis.

Norm as Weighting Factor. In Section 5, in light of the success of additive composition, we proposed the use of norms to weight words. In Section 6.1, we confirmed that the sentence-vector estimation methods, which have achieved greater success in STS than standard additive composition, simply add up the transformed word vectors (improved additive composition). Therefore, we expect that the importance of a word w is "better" encoded in the norm of a converted word vector $\widetilde{\boldsymbol{w}}$ than in that of the original word vector $\boldsymbol{w}$.

Angle as Dissimilarity. The denoising function f_1, based on the random-walk LM, makes the word vector space isotropic (i.e., uniform in the sense of angle); as a result, the angle of word vectors becomes a better proxy for the word dissimilarity (Mu and Viswanath, 2018; Liu et al., 2019b). Further, the conversion by α_2 and f_3 allows a more realistic generative model to be assumed (i.e., the unigram probability is taken into account). This would improve the isotropy of the vector space, making the angle of the word vectors would be a better proxy for the dissimilarity of words.

6.3 Vector Converter-enahanced WRD

As we have shown so far, converted word vectors $\{\widetilde{\boldsymbol{w}}\}$ may have preferred properties in terms of their norm and direction. In addition, because they remain word vectors, $\{\widetilde{\boldsymbol{w}}\}$ can be used as is for the input of WRD. Let $\widetilde{\lambda}$ and $\widetilde{\boldsymbol{u}}$ denote the norm and direction vector of $\widetilde{\boldsymbol{w}}$, respectively, a variant of WRD using $\{\widetilde{\boldsymbol{w}}\}$ is

$$\widetilde{\boldsymbol{\nu}}_s := \left\{\left(\widetilde{\boldsymbol{u}}_i, \frac{\widetilde{\lambda}_i}{Z}\right)\right\}_{i=1}^{n}, \widetilde{\boldsymbol{\nu}}_{s'} := \left\{\left(\widetilde{\boldsymbol{u}}'_j, \frac{\widetilde{\lambda}_j}{Z'}\right)\right\}_{j=1}^{n'}, \tag{23}$$

$$\mathrm{WRD}_{\text{with VC}}(s, s') := \mathrm{EMD}(\widetilde{\boldsymbol{\nu}}_s, \widetilde{\boldsymbol{\nu}}_{s'}; c_{\cos}), \tag{24}$$

where Z and Z' are normalizing constants. We believe that using $\{\widetilde{\boldsymbol{w}}\}$ will improve the performance of WRD because WRD depends on the weights and dissimilarities encoded in the norm and angle.

7 Experiments

As pre-trained word embeddings, we mainly used the most standard **GloVe** (Pennington et al., 2014), **word2vec** (Mikolov et al., 2013), and **fastText** (Bojanowski et al., 2017). As of now, BERT (Devlin et al., 2019) and its variants have not been effective in unsupervised STS tasks. We discuss this topic in Appendix B. As STS datasets, we mainly used **STS'15** (Agirre et al., 2015) for comparison with Zhelezniak et al. (2019); Kiros et al. (2015); Peters et al. (2018); **STS-B** (Cer et al., 2017), one of the most actively used datasets, and **Twitter'15** (Xu et al., 2015) to validate methods against casual writing. See Appendix A for the complete list. For VC, we used the followings algorithms.

	ADD	W/O NORM
GloVe	**54.16**	46.25
word2vec	**72.43**	63.20
fastText	**70.40**	56.31
ELMo	**63.22**	57.96
BERT-large	**65.76**	64.04

SCWS	62.96	**67.09**	65.83
SimLex999	40.84	46.74	**49.83**
WS353-REL	68.75	70.73	**72.35**
WS353-SIM	79.57	**80.97**	79.32

(b) VC gradually "grow" the direction of word vectors.

Table 3: Spearman's $\rho \times 100$ between the predicted scores and the gold scores is reported. In each row, the best result and the results where the difference from the best result is < 0.5 are indicated in **bold**. "+ AW" is omitted from Table 3b because W (scaling function) alone does not change the angle.

- f_1: **A**ll-but-the-top (Mu and Viswanath, 2018), conceptor **N**egation (Liu et al., 2019a), norm-based feature **S**caling (Ethayarajh, 2018)[5].
- α_2: SIF **W**eighting (Arora et al., 2017), **U**nsupervised SIF weighting (Ethayarajh, 2018).
- f_3: common component **R**emoval (Arora et al., 2017), **P**iecewise common component removal (Ethayarajh, 2018), **C**onceptor removal (Liu et al., 2019b).

Henceforth, a bold character denotes each method. In addition, **VC**(AWR), for example, denotes the **V**ector **C**onverter induced by **A**, **W**, and **R**. Note that we did not tune the hyperparameters; instead, we used the values acquired from previous studies. See Appendix D for detailed settings. All experiments were performed on a laptop computer with 2.2 GHz 6-core Intel Core i7 and 32 GB of RAM.

7.1 Workings of Norm

We hypothesized that the norm functioned as a weighting factor because additive composition implicitly uses the norm to weight words (Eq. 11).

Pre-trained Word Vectors. Let us consider another additive composition that excludes the effect of weighting by the norm

$$\boldsymbol{s}_{\text{ADD W/O NORM}} = \sum_{w_i \in s} \boldsymbol{w}_i / \lambda_i = \sum_{w_i \in s} \boldsymbol{u}_i. \qquad (25)$$

Table 2a shows the experimental results on the STS-benchmark dataset using two types of sentence vectors (Eqs. 11 and 25). According to these results, ignoring the norm of the word vectors leads to consistently poor performances. This demonstrates that the norm of a word vector plays the role of the weighting factor of the word.

Converted Word Vectors. In addition, to verify our hypothesis that the word vector converter f_{VC} improves the norm, we also performed the above experiment on the transformed word vector. Table 2b shows that ignoring the norm of a word vector results in consistently worse predictive performances. Note that, even when the norm is ignored, the performance is improved by the transformation sequence of the word vectors. The reason for this might be the improvement in the direction vector (for the word dissimilarity).

7.2 Workings of Angle

We assumed that the angle between two word vectors is a good proxy for the dissimilarity of two words. Presently, the cosine similarity between word vectors is one of the most widely used metrics to compute word dissimilarity. However, several alignment-based STS methods employ Euclidean distance (Kusner et al., 2015) or dot product (Zhelezniak et al., 2019) to compute the word dissimilarity. Therefore, the question arises as to which is the most suitable method for computing word dissimilarity. Here, we experimentally confirm the superiority of cosine similarity via nine word-similarity tasks. See Appendix A for the details of the datasets.

---

[5] Ethayarajh (2018) proposed three methods: S, U, and P. For the sake of correctness, we abbreviate the series of methods as SUP, while abbreviated as UP in the original paper.

Removing Stopwords	WMD	**WRD**	WMD ✓	**WRD** ✓
GloVe	62.56	**64.66**	**71.34**	**71.13**
GloVe + A	65.74	**68.83**	**75.19**	**75.19**
GloVe + AW	63.34	**77.21**	74.41	**76.44**
GloVe + A + SIF weights	76.81	-	76.56	-
GloVe + **VC**(AWR)	61.42	**79.20**	72.81	**78.60**

Table 4: **Pearson's r × 100** between the predicted scores and the gold scores for each word vector (each row) and each method (each column). The STS-B dataset (dev) is used. The best result and results where the difference from the best < 0.5 in each row are in **bold**, and the best result are further **underlined**.

Pre-trained Word Vectors. Table 3a shows that using cosine similarity (i.e., ignoring the norm of the word vectors) yields consistently higher correlation with human evaluations as opposed to using dot product or Euclidean distance (i.e., using the norm). This indicates that the angle of word vectors encodes the dissimilarity of words relatively well; on the other hand, the norm does not matter.

Converted Word Vectors. In light of the discussion in Section 6, we expect that the word dissimilarity of w and w' is "better" encoded in the angle between the converted word vectors $\langle \widetilde{\boldsymbol{u}}, \widetilde{\boldsymbol{u}}' \rangle$ than in that between the pre-trained word vectors $\langle \boldsymbol{u}, \boldsymbol{u}' \rangle$. Table 3b demonstrates that the dissimilarity of words becomes increasingly accurately encoded by the angle of the word vectors as the conversion proceeds. This suggests that VC improves the word vectors in terms of the meaning of the words encoded in the direction vectors.

7.3 Ablation Study

We experimentally confirmed the effectiveness of the two proposed methods, WRD and VC, via the degree of performance improvement over the baseline, WMD. Table 4 shows the results. Following Kusner et al. (2015), we further experimented with stopword removal. In nearly all cases, WRD shows a higher predictive performance than WMD. We summarize some major findings as follows.

- As the word vectors are transformed by VC, the performance of WRD improves steadily. This is because WRD can directly utilize the weight and dissimilarity encoded in the norm and angle, whose quality is enhanced by VC. Conversely, WMD does not benefit from VC.
- WRD *without* stopwords removal achieves the best results. This is likely because WRD can softly compare differences in importance between stopwords using their norm.
- One might think that W (SIF weighting) can be directly used as the probability mass for the WMD computation because it is just a scaling factor for each word. "+ SIF weights" in Table 4 denotes such a computation. Howver, even when WMD removes stopwords and uses SIF directly, it does not reach the performance of WRD.

We obtained similar results for the other word vectors (see Appendix E for more details).

7.4 Benchmark Tasks

Finally, we compare the performance of the proposed methods (WRD and VC) with various base-

---

[6] http://ixa2.si.ehu.es/stswiki/index.php/STSbenchmark

line methods, including recent alignment-based methods such as **WMD** (Kusner et al., 2015), **BERTScore** (Zhang et al., 2019), and **DynaMax** (Zhelezniak et al., 2019). The results are shown in Table 5. We summarize some of our major findings as follows.

- Of the methods that consider word alignment, WRD + VC achieved the best performance. This is likely because other methods use Euclidean distance (Kusner et al., 2015) or dot product (Zhelezniak et al., 2019) as word similarity measures. These metrics cannot distinguish the two types of information (weight and dissimilarity) that each word vector holds separately by dividing it into a norm and a direction.
- BERTScore uses cosine similarity like WRD, but their scores were inferior to WRD on average. This can be attributed to the fact that BERTScore is completely disregarding the norm.
- Compared with strong baselines (WR, SUP), WRD using the same word vectors (**VC**(WR), **VC**(WR)) performed equally or better. This result is unexpected given that WR and SUP were originally proposed to create sentence vectors, and WRD simply uses them without tuning. Thus, we assume that considering word alignment is an inherently good hypothesis for STS.

See Appendix F for the comprehensive results using additional datasets and methods, including results semi-supervised and supervised approaches.

8 Connection to Other Methods

In this section, we present the relation between ADD (the cosine similarity of additive sentence vectors; (11)(12)), WMD, and WRD from the perspective of sentence representation.

Connection to Additive Composition. *ADD is a special case of WRD.* Indeed, given a discrete-distribution representation containing only one sentence vector, $\boldsymbol{\mu}_s^{\text{point}} = \{(\boldsymbol{s}, 1)\}$, the obvious EMD cost between them is equivalent to ADD.

$$\mathrm{EMD}(\boldsymbol{\mu}_s^{\text{point}}, \boldsymbol{\mu}_{s'}^{\text{point}}; c_{\cos}) = 1 - \cos(\boldsymbol{s}, \boldsymbol{s}') \quad (26)$$

The relationship between ADD and WRD becomes clearer when examining their sentence representations:

$$\boldsymbol{s} = \frac{1}{n}\sum_i \lambda_i \boldsymbol{u}_i, \quad \boldsymbol{\nu}_s = \frac{1}{Z}\sum_i \lambda_i \delta[\boldsymbol{u}_i], \quad (27\text{ a,b})$$

where $\delta[\cdot]$ is the Dirac delta function. As for the formulae, they are still quite similar. The key difference lies in the fact that ADD treats a sentence as a single vector (the barycenter of direction vectors), whereas WRD treats a sentence as a set of direction vectors. Thus, it is natural that WRD had a positive effect on STS tasks, given that STS tasks require the word alignment (i.e., they assume that words are treated disjointedly). On the other hand ADD demonstrated higher performance on the topic similarity task[7]. For a task where it is sufficient to know the trend of the meaning of the whole sentence, it might be preferable to aggregate the meaning of the entire sentence into a single vector.

Connection to WMD. Why do WMD and WRD differ in performance on STS tasks even though both of them represent sentences as "bag-of-word-vectors" representations? Sentence representations for ADD and WMD are as follows:

$$\boldsymbol{s} = \frac{1}{n}\sum_i 1 \cdot \boldsymbol{w}_i, \quad \boldsymbol{\mu}_s = \frac{1}{n}\sum_i 1 \cdot \delta[\boldsymbol{w}_i]. \quad (28\text{ a,b})$$

Note that, barycenters (27a) and (28a) for ADD are identical since $\lambda_i \boldsymbol{u}_i = \boldsymbol{w}_i$ holds by definition (10); on the other hand, the discrete distributions (27b) for WRD and (28b) for WMD are quite different. WRD treats the norm λ as a weighting factor, as ADD implicitly does; in contrast, WMD assigns uniform weights to both long and short vectors. This is one reason why the most natural representation (28b) does not work well.

9 Conclusion

To solve the performance problem remaining for alignment-based STS methods, we proposed word rotator's distance (WRD), a new unsupervised, EMD-based STS metric. We first indicated that (1) the norm and angle of word vectors are good proxies for the importance of a word and the dissimilarity between words, respectively, and (2) some previous methods "mix up" the norm and direction vectors. Based on this finding, WRD was designed so that the norm and angle of word vectors correspond to the probability mass and transportation cost in EMD, respectively. Moreover, we found that the latest powerful methods for sentence-vector estimation improve the norm and angle of word vectors (via vector converter; VC). In experiments on multiple STS benchmarks, the proposed methods outperformed not only alignment-based methods such as WMD but also powerful sentence vectors.

A Resources Used in Experiments

A.1 Pre-trained Word Embeddings.

We used the following pre-trained word embeddings in our experiments.

- **GloVe** trained with Common Crawl (Pennington et al., 2014)[8]
- **word2vec** trained with Google News (Mikolov et al., 2013)[9]
- **fastText** trained with Common Crawl (Bojanowski et al., 2017)[10]
- **PSL**, the ParagramSL-999 embeddings, trained with the PPDB paraphrase database (Wieting et al., 2015)[11]
- **ParaNMT** trained with ParaNMT-50, a large scale English-English paraphrase database (Wieting and Gimpel, 2018)[12]
- **ELMo** pre-trained with 1 Billion Word Benchmark, a corpus with approximately 30 million sentences (Chelba et al., 2014) (BiLSTM hidden size of 4096, output size of 512, and 2 highway layers) (Peters et al., 2018)[13]
- **BERT-Large** pre-trained with the BooksCorpus (800M words) and English Wikipedia (2500M words) (uncased, 24 layers, hidden size of 1024, 16 self-attention heads, and 340M parameters) (Devlin et al., 2019)[14]. We use the PyTorch implementation of BERT (Wolf et al., 2019)[15].

A.2 Word Similarity Datasets

We used the following nine different datasets for the word similarity task.

- **MEN** (Bruni et al., 2012)
- **MTurk287** (Radinsky et al., 2011)
- **MC30** (Miller and Charles, 1991)
- **RW** (Luong et al., 2013)
- **RG65** (Rubenstein and Goodenough, 1965)
- **SCWS** (Huang et al., 2012)
- **SimLex999** (Hill et al., 2015)
- **WS353** (Finkelstein et al., 2002)

A.3 STS Datasets Used in Experiments

We used the following STS datasets in our experiments.

- **STS'12** (Agirre et al., 2012), **STS'13** (Agirre et al., 2013), **STS'14** (Agirre et al., 2014), and **STS'15** (Agirre et al., 2015): semantic textual similarity shared tasks in SemEval
- **STS-B**: semantic textual similarity benchmark (Cer et al., 2017), which is the collection from SemEval STS tasks 2012–2017 (Agirre et al., 2012, 2013, 2014, 2015, 2016; Cer et al., 2017)
- **Twitter**: paraphrase and semantic similarity in twitter (PIT) task in SemEval 2015 (Xu et al., 2015)
- **SICK-R**: SemEval 2014 semantic relatedness task (Marelli et al., 2014)

Tokenization. In every experiment, we first tokenized all the STS datasets other than the Twitter dataset with a modified NLTK (Bird and Loper, 2004; Ethayarajh, 2018)[16]. The Twitter dataset has already been tokenized by the organizer. We then lowercased all corpora to conduct experiments under the same conditions with cased embeddings and non-cased embeddings.

B BERT and Variants on Unsupervised STS

BERT and its variants have not yet shown good results on *unsupervised* STS (note that, in a supervised or semi-supervised setting where there exists training data or external resources, BERT-based models show the current, best results). One particularly promising usage of BERT-based models for unsupervised STS is BERTScore (Zhang et al., 2019), which was originally proposed as an automatic evaluation metric. However, our preliminary experiments[17] show that BERTScore performs poorly on unsupervised STS. Since BERTScore is definitely promising as a method, we reported the results using non-contextualized vectors, e.g., GloVe, where we confirmed a higher performance compared to BERT. Needless to say, the application of BERT-based models to unsupervised STS is a very important future research topic.

C Algorithm of Word Rotator's Distance

The algorithm used in the actual computation of WRD is shown in Algorithm 1.

[14] https://github.com/google-research/bert

[15] https://github.com/huggingface/transformers

[16] https://github.com/kawine/usif

[17] We used BERT-large and RoBERTa-large. For the embedding, we used either the last layer or the concatenation of all the layers. In the original paper, which allows the use of teacher data, the development set was used to select the layer.

Algorithm 1 Word Rotator's Distance (WRD)

```
Input: a pair of sentences $s = (\boldsymbol{w}_1, \ldots, \boldsymbol{w}_n)$, $s' = (\boldsymbol{w}'_1, \ldots, \boldsymbol{w}'_{n'})$
1:  $Z \leftarrow \sum_{i=1}^{n} \|\boldsymbol{w}_i\| \in \mathbb{R}$
2:  $Z' \leftarrow \sum_{j=1}^{n'} \|\boldsymbol{w}'_j\| \in \mathbb{R}$
3:  $\boldsymbol{m}_s \leftarrow \frac{1}{Z}(\|\boldsymbol{w}_1\|, \ldots, \|\boldsymbol{w}_n\|) \in \mathbb{R}^n$
4:  $\boldsymbol{m}_{s'} \leftarrow \frac{1}{Z'}(\|\boldsymbol{w}'_1\|, \ldots, \|\boldsymbol{w}'_{n'}\|) \in \mathbb{R}^{n'}$
5:  for $i \leftarrow 1$ to $n$ do
6:      for $j \leftarrow 1$ to $n'$ do
7:          $\boldsymbol{C}_{ij} \leftarrow 1 - \cos(\boldsymbol{w}_i, \boldsymbol{w}'_j)$
8:      end for
9:  end for
10: $\mathrm{WRD}(s, s') \leftarrow \mathrm{EMD}(\boldsymbol{m}_s, \boldsymbol{m}_{s'}; \boldsymbol{C})$
Output: $\mathrm{WRD}(s, s') \in \mathbb{R}$
```

For EMD computation, off-the-shelf libraries can be used[18]. Note that most EMD (optimal transport) libraries take two probabilities (mass) $\boldsymbol{m} \in \mathbb{R}^n$, $\boldsymbol{m}' \in \mathbb{R}^{n'}$ and a cost matrix $\boldsymbol{C} \in \mathbb{R}^{n \times n'}$ with $\boldsymbol{C}_{ij} = d(\boldsymbol{x}_i, \boldsymbol{x}'_j)$ as inputs. Parameters ($\boldsymbol{m}$, $\boldsymbol{m}'$, $\boldsymbol{C}$) have the same information as ($\boldsymbol{\mu}$, $\boldsymbol{\mu}'$, d), introduced in Section 4.3. The notation of Algorithm 1 follows this style.

The cosine distance $1 - \cos(\boldsymbol{w}_i, \boldsymbol{w}'_j)$ in line 7 of Algorithm 1 is equivalent to $1 - \cos(\boldsymbol{u}_i, \boldsymbol{u}'_j)$ in Equation 18. We adopted the former simply to reduce the computation steps.

D Algorithms of Vector Converter

Algorithm 2 summarizes the overall procedure of word vector converter f_{VC} (Eq. 22).

When computing Algorithm 2, we set hyperparameters as $D_{\mathrm{A}} = 3$, $\alpha_{\mathrm{N}} = 2$, and $a_{\mathrm{W}} = 10^{-3}$, following Mu and Viswanath (2018), Liu et al. (2019a), and Arora et al. (2017), respectively, without tuning. We used the unigram probability $\mathbb{P}$ of English words estimated based on the enwiki dataset, preprocessed by Arora et al. (2017)[19].

See Table 6 for an overview of the existing methods. There are many possible combinations of f_1, f_2, and f_3, and exploring them is a good direction for future work.

E Full Results of Ablation Study

See Table 7 for full results.

Algorithm 2 Word Vector Converter (VC), induced from **A**ll-but-the-top (Mu and Viswanath, 2018) or conceptor **N**egation (Liu et al., 2019a), SIF **W**eighting (Arora et al., 2017), and common component **R**emoval (Arora et al., 2017).

```
Input: pre-trained word vectors $\{\boldsymbol{w}_1, \ldots, \boldsymbol{w}_{|\mathcal{V}|}\} \subseteq \mathbb{R}^d$, sentences in interest $\mathcal{S} = \{s_1, \ldots, s_{|\mathcal{S}|}\}$, word unigram probability $\mathbb{P}\colon \mathcal{V} \to [0, 1]$, and constants $D_{\mathrm{A}}$ (or $\alpha_{\mathrm{N}}$), $a_{\mathrm{W}}$
Compute parameters of $f_1$:
··· if using All-but-the-top:
$\overline{\boldsymbol{w}} \leftarrow \frac{1}{|\mathcal{V}|} \sum_{i=1}^{|\mathcal{V}|} \boldsymbol{w}_i \in \mathbb{R}^D$
for $i \leftarrow 1$ to $|\mathcal{V}|$ do
    $\overline{\boldsymbol{w}}_i \leftarrow \boldsymbol{w}_i - \overline{\boldsymbol{w}}$
end for
$\boldsymbol{u}_1, \ldots, \boldsymbol{u}_{D_{\mathrm{A}}} \leftarrow \mathrm{PCA}(\{\overline{\boldsymbol{w}}_1, \ldots, \overline{\boldsymbol{w}}_{|\mathcal{V}|}\})$
                                        ▷ top $D_{\mathrm{A}}$ singular vectors
$\boldsymbol{A}_1 \leftarrow \boldsymbol{I} - \sum_{j=1}^{D_{\mathrm{A}}} \boldsymbol{u}_j \boldsymbol{u}_j^\top \in \mathbb{R}^{D \times D}$
$\boldsymbol{b}_1 \leftarrow \overline{\boldsymbol{w}} \in \mathbb{R}^D$
··· else if using conceptor Negation:
$\boldsymbol{R} \leftarrow \frac{1}{|\mathcal{V}|} \sum_{i=1}^{|\mathcal{V}|} \boldsymbol{w}_i \boldsymbol{w}_i^\top \in \mathbb{R}^{D \times D}$
$\boldsymbol{C} \leftarrow \boldsymbol{R}(\boldsymbol{R} + {\alpha_{\mathrm{N}}}^{-2} \boldsymbol{I})^{-1} \in \mathbb{R}^{D \times D}$
$\boldsymbol{A}_1 \leftarrow \boldsymbol{I} - \boldsymbol{C} \in \mathbb{R}^{D \times D}$
$\boldsymbol{b}_1 \leftarrow \boldsymbol{0} \in \mathbb{R}^D$
Compute parameters of $f_3$:
for $i \leftarrow 1$ to $|\mathcal{S}|$ do
    $\boldsymbol{s}_i \leftarrow \frac{1}{|s_i|} \sum_{w \in s_i} \alpha_2(w) \boldsymbol{A}_1(\boldsymbol{w} - \boldsymbol{b}_1)$
end for
$\boldsymbol{v} \leftarrow \mathrm{PCA}(\{\boldsymbol{s}, \ldots, \boldsymbol{s}_{|\mathcal{S}|}\})$
                                        ▷ first singular vector
$\boldsymbol{A}_3 \leftarrow \boldsymbol{I} - \boldsymbol{v}\boldsymbol{v}^\top \in \mathbb{R}^{d \times d}$
Convert word vectors:
for $i \leftarrow 1$ to $|\mathcal{V}|$ do
    $\alpha_2(w) \leftarrow a_{\mathrm{W}} / (\mathbb{P}(w) + a_{\mathrm{W}})$
    $\widetilde{\boldsymbol{w}}_i \leftarrow \boldsymbol{A}_3(\alpha_2(w) \boldsymbol{A}_1(\boldsymbol{w}_i - \boldsymbol{b}_1))$
end for
Output: Converted word vectors $\{\widetilde{\boldsymbol{w}}_1, \cdots, \widetilde{\boldsymbol{w}}_{|\mathcal{V}|}\}$
```

F Full Results of Comparative Experiments

See Table 8 for full results in an unsupervised settings. See Table 9 for full results in an semisupervised and supervised settings.

---

[18] In our experiments, we used the well-developed python optimal transport (POT) library: `https://github.com/rflamary/POT/`. In particular, `ot.emd2()` was used.

Abstract

Graph embedding (GE) methods embed nodes (and/or edges) in graph into a low-dimensional semantic space, and have shown its effectiveness in modeling multi-relational data. However, existing GE models are not practical in real-world applications since it overlooked the streaming nature of incoming data. To address this issue, we study the problem of *continual graph representation learning* which aims to continually train a GE model on new data to learn incessantly emerging multi-relational data while avoiding catastrophically forgetting old learned knowledge. Moreover, we propose a disentangle-based continual graph representation learning (DiCGRL) framework inspired by the human's ability to learn procedural knowledge. The experimental results show that DiCGRL could effectively alleviate the catastrophic forgetting problem and outperform state-of-the-art continual learning models. The code and datasets are released on `https://github.com/KXY-PUBLIC/DiCGRL`.

1 Introduction

Multi-relational data represents relationships between entities in the world, which is usually denoted as a multi-relational graph with nodes and edges connecting them. It is widely used in real-world NLP applications such as *knowledge graphs* (KGs) (e.g., Freebase (Bollacker et al., 2008) and DBpedia (Lehmann et al., 2015)) and *information networks* (e.g., social network and citation network). Therefore, modeling multi-relational graph with graph embeddings (Bordes et al., 2013; Tang et al., 2015a; Sun et al., 2019; Bruna et al., 2014) has been attracting intensive attentions in both academia and industry. Graph embedding (GE), aiming to embed nodes and/or edges in the graph into a low-dimensional semantic space to enable neural models to effectively and efficiently utilize multi-relational data, has demonstrated remarkable effectiveness in various downstream NLP tasks such as question answering (Bordes et al., 2014) and dialogue system (Moon et al., 2019).

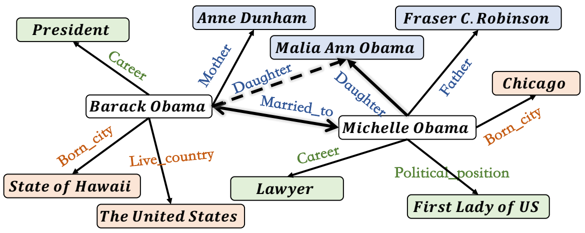

Figure 1: An example of edges that compressed into multiple components, which represented in different colors. The dotted line represents the inferred procedural knowledge from two **bold** edges.

Nevertheless, most existing graph embedding works overlook the streaming nature of the incoming data in real-world scenarios. In consequence, these models have to be retrained from scratch to reflect the data change, which is computationally expensive. To tackle this issue, we propose to study the problem of *continual graph representation learning* (CGRL) in this work.

The goal of continual learning is to alleviate catastrophically forgetting old data while learning new data. There are two mainstream continual learning methods in NLP: (1) consolidation-based methods (Kirkpatrick et al., 2017; Zenke et al., 2017; Liu et al., 2018; Ritter et al., 2018) which consolidate the important model parameters of old data when learning new data; and (2) memory-based methods (Lopez-Paz and Ranzato, 2017; Shin et al., 2017; Chaudhry et al., 2019) which remember a few old examples and learn them with new data jointly. Despite the promising results these methods have achieved on classification tasks, their effectiveness has not been validated on graph representation learning. Unlike the classification

problem where instances are generally independent and can be operated individually, nodes and edges in multi-relational data are correlated, making it sub-optimal to directly deploy existing continuous learning methods on the multi-relational data.

In cognitive psychology (Solso et al., 2005), procedural knowledge refers to a set of operational steps. Its smallest unit is production, where multiple productions can complete a series of cognitive activities. When learning new procedural knowledge, humans would update cognitive results by only updating a few related productions and leave the rest intact. Intuitively, such a process can be mimicked to learn constantly growing multi-relational data by regarding each new data as a new procedural knowledge. For example, as illustrated in Figure 1, the relational triplets of *Barack Obama* and *Michelle Obama* are related to three concepts: "family", "occupation" and "location". When a new relational triplet (*Michelle Obama*, `Daughter`, *Malia Ann Obama*) appears, we only need to update the "family"-related information in *Barack Obama*. Consequently, we can further infer that the triplet (*Barack Obama*, `Daughter`, *Malia Ann Obama*) also holds.

Inspired by procedural knowledge learning, we propose a disentangle-based continual graph representation learning framework DiCGRL in this work. Our proposed DiCGRL consists of two modules: (1) **Disentangle module.** It decouples the relational triplets in the graph into multiple independent components according to their semantic aspects, and leverages two typical GE methods including Knowledge Graph Embedding (KGE) and Network Embedding (NE) to learn disentangled graph embeddings; (2) **Updating module.** When new relational triplets arrive, it selects the relevant old relational triplets and only updates the corresponding components of their graph embeddings. Compared with memory-based continual learning methods which save a fixed set of old data, DiCGRL could dynamically select important old data according to new data to fine-tune the model, which makes DiCGRL better model the complex multi-relational data stream.

We conduct extensive experiments on both KGE and NE settings based on the real-world scenarios, and the experimental results show that DiCGRL effectively alleviates the catastrophic forgetting problem and significantly outperforms existing continual learning models while remaining efficient.

2 Related Work

2.1 Graph Embedding

Graph embedding (GE) methods are critical techniques to obtain a good representation of multi-relational data. There are mainly two categories of typical multi-relational data in the real-world, *knowledge graphs* (KGs) and *information networks*. GE handles them via Knowledge Graph Embedding (KGE) and Network Embedding (NE) respectively, and our DiCGRL framework can adapt to the above two typical GE methods, which demonstrates the generalization ability of our model.

KGE is an active research area recently, which can be mainly divided into two categories to tackle link prediction task (Ji et al., 2020). One line of work is reconstruction-based models, which reconstruct the head/tail entity's embedding of a triplet using the relation and tail/head embeddings, such as TransE (Bordes et al., 2013), RotatE (Sun et al., 2019), and ConvE (Dettmers et al., 2018). Another line of work is bilinear-based models, which consider link prediction as a semantic matching problem. They take head, tail and relation's embeddings as inputs, and measure a semantic matching score for each triplet using bi-linear transformation (e.g., DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016), ConvKB (Nguyen et al., 2018)). Besides KGE, NE is also widely explored in both academia and industry. Early works (Perozzi et al., 2014; Tu et al., 2016; Tang et al., 2015b) focus on learning static node embeddings on information graphs. More recently, graph neural networks (Bruna et al., 2014; Henaff et al., 2015; Veličković et al., 2018) have been attracting considerable attention and achieved remarkable success in learning network embeddings. However, most existing GE models assume the training data is static, i.e., do not change over time, which makes them impractical in real-world applications.

2.2 Continual Learning

Continual learning, also known as life-long learning, helps alleviate catastrophic forgetting and enables incremental training for stream data. Methods for continual learning in natural language processing (NLP) field can mainly be divided into two categories: (1) consolidation-based methods (Kirkpatrick et al., 2017; Zenke et al., 2017), which slow down parameter updating to preserve old knowledge, and (2) memory-based methods (Lopez-Paz and Ranzato, 2017; Shin et al., 2017; Chaudhry et al., 2019; Wang et al., 2019), which retain examples from old data for re-play upon learning the new data. Although continual learning has been widely studied in NLP (Sun et al., 2020) and computer vision (Kirkpatrick et al., 2017), its exploration on graph embedding is relatively rare. Sankar et al. (2018) seek to train graph embedding on constantly evolving data. However, it assumes the timestamp information is known beforehand, which hinders its application to other tasks. Song and Park (2018) extend the idea of regulation-based methods to continually learn graph embeddings which straightforwardly limits parameter updating on only the embedding layer. It is therefore hard to generalize to more complex multi-relational data. Our proposed DiCGRL model is distinct from previous works in two aspects: (1) Our method does not require pre-annotated timestamps, which make it more feasible in various types of multi-relational data; (2) Inspired by procedural knowledge learning, we exploit disentanglement to conduct continual learning and achieve promising results.

3 Methodology

3.1 Task Formulation and Overall Framework

We represent multi-relational data as a multi-relational graph $G = (V, E)$, where V, E denote the node set and the edge set within a graph G, and G can be formalized as a set of relational triplets $\{(u, r, v)\} \subseteq V \times E \times V$. Given a relational triplet $(u, r, v) \in G$, we denote the embeddings of them as $\boldsymbol{u}$, $\boldsymbol{v} \in \mathbb{R}^d$ and $\boldsymbol{r} \in \mathbb{R}^l$, where d and l indicate the vector dimension.

Continual graph representation learning trains graph embedding (GE) models on constantly growing multi-relational data, where the i-th part of multi-relational data has its own training set $\mathcal{T}_i$, validation set $\mathcal{V}_i$, and query set $\mathcal{Q}_i$. The i-th training set is defined as a set of relational triplets, i.e., $\mathcal{T}_i = \{(u_1^{\mathcal{T}_i}, r_1^{\mathcal{T}_i}, v_1^{\mathcal{T}_i}), \dots, (u_N^{\mathcal{T}_i}, r_N^{\mathcal{T}_i}, v_N^{\mathcal{T}_i})\}$, where N is the instance number of $\mathcal{T}_i$. The i-th validation and query sets are defined similarly. As new relational triplets emerges, continual graph representation learning requires GE models to achieve good results on all previous query sets. Therefore, after training on the i-th training set $\mathcal{T}_i$, GE models will be evaluated on $\tilde{\mathcal{Q}}_i = \bigcup_{j=1}^{i} \mathcal{Q}_j$ to measure whether they could well model both new and old multi-relational data. The evaluation protocol indicates that it will be more and more difficult for the model to achieve high performance as the emerging of new relational triplets.

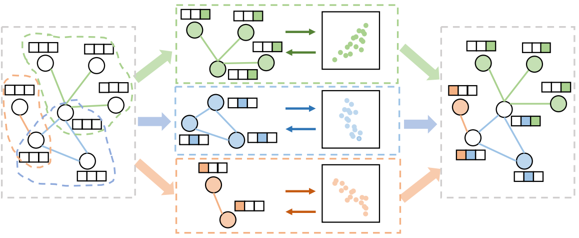

Figure 2: The disentangle module of our model. Different colors indicate different semantic aspects of nodes.

In general, our model continually learns on the streaming data. Whenever there comes a new part of multi-relational data, DiCGRL will learn the new graph embeddings and meanwhile prevent catastrophically forgetting old learned knowledge through two procedures: (1) **Disentangle module**. It decouples the relational triplets in the graph into multiple components according to their semantic aspects, and learns disentangled graph embeddings that divide node embeddings into multiple independent components where each component describes a semantic aspect of node; (2) **Updating module**. When new relational triplets arrive, DiCGRL first activates the old relational triplets from previous graphs which have relevant semantic aspects with the new ones, and only updates the corresponding components of their graph embeddings.

3.2 Disentangle Module

When the i-th training set $\mathcal{T}_i$ becomes available, DiCGRL needs to update the graph embeddings according to these new relational triplets. To this end, for each node $u \in V$, we want to learn a disentangled node embedding $\boldsymbol{u}$, which is composed of K independent components, i.e., $\boldsymbol{u} = [\boldsymbol{u}^1, \boldsymbol{u}^2, ..., \boldsymbol{u}^k, ..., \boldsymbol{u}^K]$, where $(0 \leq k \leq K)$ and $\boldsymbol{u}^k \in \mathbb{R}^d$. The component $\boldsymbol{u}^k$ is used to represent the k-th semantic aspect of node u. As shown in Figure 2, the key challenge of the disentangle module is how to decouple the relational triplets into multiple components according to their semantic aspects, and learn the disentangled graph embeddings in different components independently.

Formally, given a relational triplet $(u, r, v) \in \mathcal{T}_i$, we aim to extract the most related semantic components of u and v with respective to the relation r. Specifically, we model this process with an attention mechanism, where (u, r, v) is associated with K attention weight $(\alpha_r^1, \alpha_r^2, \dots, \alpha_r^K)$, which respectively represent the probability being assigned to the k-th semantic component. After that, we select the top-n related components of $\boldsymbol{u}$ and $\boldsymbol{v}$ with the highest attention weight. Then we leverage exiting GE methods to extract different features in the selected top-n related components, and we denote the feature extraction operation as $\boldsymbol{f}$. Here, $\boldsymbol{f}$ could be any graph embedding operation that can incorporate the features of node u and v in the selected top-n related components. In this work, we adapt our DiCGRL model in two typical graph embeddings including:

Knowledge Graph Embeddings (KGEs) Intuitively, the most related semantic components of a relational triplet in KG are related to their relation r. Therefore, we can directly set K attention values for each explicit relation r, and the k-th attention value a_r^k $(0 \leq k \leq K)$ is a trainable parameter which indicates how related this edge is to the k-th component. The normalized attention weight α_r^k is computed as:

$$\alpha_r^k = \frac{\exp(a_r^k)}{\sum_{j=1}^{K} \exp(a_r^j)}. \quad (1)$$

As described in related work, KGE models can mainly be divided into two categories: reconstruction-based and bilinear-based models. We explore the effectiveness of both two lines of works to extract features in our framework. Specifically, we leverage two classic KGE models as $\boldsymbol{f}$ to extract latent features in our experiment including TransE (reconstruction-based):

$$\boldsymbol{f} = ||\hat{\boldsymbol{u}} + \boldsymbol{r} - \hat{\boldsymbol{v}}||_p, \quad (2)$$

and ConvKB (bilinear-based):

$$\boldsymbol{f} = \boldsymbol{W}_1 \left(\text{ReLU}\big(\text{Conv}([\hat{\boldsymbol{u}}; \boldsymbol{r}; \hat{\boldsymbol{v}}])\big)\right), \quad (3)$$

where $\hat{\boldsymbol{u}}, \hat{\boldsymbol{v}}$ are the concatenation of top-n component embeddings of node u and node v respectively; $||\cdot||_p$ denotes the p-norm operation; $[\cdot;\cdot]$ denotes the concatenate operation; $\text{Conv}(\cdot)$ indicates the convolutional layer with M filters, and $\boldsymbol{W}_1 \in \mathbb{R}^{1 \times \frac{Mdn}{K}}$ is a trainable matrix. In total, $\boldsymbol{f}$ is expected to give higher scores for valid triplets than invalid ones.

Network Embeddings (NEs) We first determine α_r^k according to the representations of node u and node v since NE usually does not provide explicit relations. Hence, α_r^k is calculated by performing a non-linearity transformation over the concatenation of $\boldsymbol{u}$ and $\boldsymbol{v}$:

$$\alpha_r^k = \frac{\exp\left(\text{ReLU}(\boldsymbol{W}_2[\boldsymbol{u}^k; \boldsymbol{v}^k])\right)}{\sum_{j=1}^{K} \exp\left(\text{ReLU}(\boldsymbol{W}_2[\boldsymbol{u}^j; \boldsymbol{v}^j])\right)}, \quad (4)$$

where $\boldsymbol{W}_2 \in \mathbb{R}^{1 \times 2d}$ is a trainable matrix[1].

Graph attention networks (GATs) (Veličković et al., 2018) gather information from the node's neighborhood and assign varying levels of importance to neighborhoods, which is a widely used and powerful way to learn embeddings for information networks. Thus we leverage GATs as $\boldsymbol{f}$ to extract latent features for NE. Given a target node u and its neighbors $\{v | v \in N_u\}$, we first determine the top-n related components for each pair of nodes (u, v) according to the attention weights α_r^k. When updating the k-th component of u, a neighbor v is considered if and only if the k-th component is in the the top-n related components for the node pair (u, v). In this way, we can thoroughly disentangle the neighbors of the target node into different components to play their roles separately. GATs are used to update each component as follows:

$$\boldsymbol{u}^k = \sum_{v \in N_u} \sigma(\boldsymbol{W}_3 \boldsymbol{v}^k) \boldsymbol{W}_4^k \boldsymbol{v}^k, \quad (5)$$

where $\boldsymbol{W}_3 \in \mathbb{R}^{1 \times d}$ and $\boldsymbol{W}_4 \in \mathbb{R}^{h \times d}$ are two trainable matrices, h is hidden size within GATs, and σ is the softmax function which is used to calculate the neighbor's relative attention value in the k-th component.

3.3 Updating Module

Now, the remaining problem is how to update the disentangled graph embedding when new relation triplets appear while preventing catastrophic forgetting. As shown in Figure 3, this process mainly includes two steps:

(1) **Neighbor activation**: DiCGRL needs to identify which relational triplets from $\mathcal{T}_1, ..., \mathcal{T}_{i-1}$ need to be updated. Since in the multi-relational data, nodes are not independent, and therefore a new relational triplet may have influence on the embeddings of nodes that not directly connect to it. Inspired by that, for each relational triplet (u, r, v), we activate both their direct and indirect neighbor triplets[2]. Specifically, neighbors of triplet

---

[1] Note that we also evaluate this definition on KG data, and the experimental results are presented in Appendix A.

[2] 1-order and 2-order neighbors are both considered in our experiments.

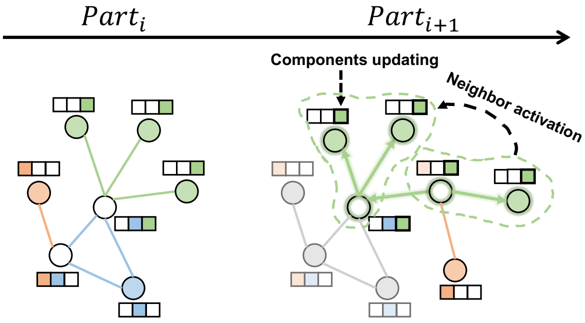

Figure 3: The updating module of DiCGRL, where different colors indicate disentangled components, and a node (white) may contain multiple components.

$(u, r, v) \in \mathcal{T}_i$ refers to all triplets which contain node u or node v on the previous multi-relational graph $(\mathcal{T}_1, ..., \mathcal{T}_{i-1})$. In practice, adding all neighbors to $\mathcal{T}_i$ is computationally expensive occasionally since some nodes have very high degrees[3], i.e., they have a huge amount of neighbors. Therefore, we leverage a selection mechanism inspired by human's ability to learn procedural knowledge introduced in Section 1 and only update a few related neighbors: for each (u, r, v), we only activate the neighbors with related semantic components (i.e., they share at least one component in their top-n semantic components).

(2) **Components updating**: It is not necessary to update all semantic components of activated neighbors. For example, if a relational triplet $(u', r', t') \in (\mathcal{T}_1, \cdots, \mathcal{T}_{i-1})$ is activated by $(u, r, t) \in \mathcal{T}_i$, we only need to update *the common components*, i.e., top-n components, since the semantics of other components does not change. We use existing GE embedding method to update their features, as explained in our disentangle module. Generally speaking, in each epoch, we iteratively train new relational triplets and relevant semantic aspects of activated neighbor relational triplets. Through this training process, our model can not only effectively prevent catastrophic forgetting, but also learn the embeddings of new data.

3.4 Training Objective

As mentioned before, for newly arrived multi-relational data $\mathcal{T}_i$, we iteratively train our model on $\mathcal{T}_i$ and its activated neighbor relational triplets. We denote loss functions of these two parts as $\mathcal{L}_{new}$ and $\mathcal{L}_{old}$ respectively. For KGE, we utilize soft-margin loss to train DiCGRL on link prediction task. The loss function $\mathcal{L}_{new}$ can be defined as:

$$\mathcal{L}_{new} = -\sum_{(u,r,v)\in\mathcal{T}_i\cup\mathcal{T}_i^*} \log\left(1+\exp\left(y\cdot \boldsymbol{f}(u,r,v)\right)\right), \tag{6}$$

where $\mathcal{T}_i^*$ represents a set of relational invalid triplets for $\mathcal{T}_i$; $y = 1$ if $(u, r, t) \in \mathcal{T}_i$, otherwise, $y = -1$. For NE, we leverage a standard cross entropy loss according to GATs and train our model on node classification task. $\mathcal{L}_{new}$ can be formulated as follows:

$$\mathcal{L}_{new} = -\sum_{u\in N(\mathcal{T}_i)} \frac{1}{|C|}\sum_{c=1}^{|C|} y(c)\cdot\log\left(\sigma(\boldsymbol{W_5 u})\right), \tag{7}$$

where c is node's class and $y(c) = 1$ if the node label is c, otherwise $y(c) = 0$; $N(\mathcal{T}_i)$ is the node set of $\mathcal{T}_i$, $|C|$ indicates the number of class, and $\boldsymbol{W_5} \in \mathbb{R}^{|C|\times d}$ is a trainable matrix. For KGE and NE, $\mathcal{L}_{old}$ can be defined in the same way with $\mathcal{L}_{new}$ on the selected old relational triplets set.

Intuitively, *the less components a relation focuses on, the better the disentanglement is*. Therefore, we add a constraint loss terms $\mathcal{L}_{norm}$ for $\mathcal{T}_i$ [4] to encourage the sum of the attention weights of the top-n selected components to reach 1, i.e.,

$$\mathcal{L}_{norm} = \sum_{(u,r,v)\in\mathcal{T}_i} (1-\sum_{k}^{n}\alpha_r^k), \tag{8}$$

where n indicates the number of selected components.

The overall loss function $\mathcal{L}$ of our proposed model is defined as follows:

$$\mathcal{L} = \mathcal{L}_{old} + \mathcal{L}_{new} + \beta\cdot\mathcal{L}_{norm}, \tag{9}$$

where β is a hyper-parameter.

4 Experiments

In this section, we evaluate our model on two popular tasks: *link prediction* for knowledge graph and *node classification* for information network.

4.1 Datasets

We conduct experiments on several continual learning datasets adapted from existing graph embedding benchmarks:

KGE datasets. We considered two link prediction benchmark datasets, namely FB15K-237 (Toutanova and Chen, 2015) and

---

[3] The highest degree of FB15k-237 dataset is 7,614.

[4] The attention weights for the activated neighbor relational triplets are computed using the last checkpoint of the model and not updated during training $\mathcal{T}_i$.

WN18RR (Dettmers et al., 2018). We randomly split each benchmark dataset into five parts to simulate the real world scenarios, with each part having the ratio of $0.8 : 0.05 : 0.05 : 0.05 : 0.05$ respectively [5]. We further divide each part into training set, validation set and query set. The statistics of FB15k-237 and WN18RR datasets are presented in Appendix C.

NE datasets. We conduct our experiments on three real-world information networks for node classification task: Cora, CiteSeer and PubMed (Sen et al., 2008). The nodes, edges and labels in these three citation datasets represent articles, citations and research areas respectively, and their nodes are provided with rich features. Like KGE datasets, we split each dataset into four parts and the partition ratio is $0.7 : 0.1 : 0.1 : 0.1$. We further split train/validation/query set for each part. The statistics of Cora, CiteSeer and PubMed are presented in Appendix C.

4.2 Experimental Settings

We use Adam (Kingma and Ba, 2015) as the optimizer and fine-tune the hyper-parameters on the validation set for each task. We perform a grid search for the hyper-parameters specified as follows: the number of components $K \in \{2, 4, 6, 8, 10\}$, the number of top components $n \in \{2, 4\}$, node embedding dimension $d \in \{100, 200\}$ (note that relation embedding dimension in KG is $l = \frac{d \times n}{K}$, and d is fixed to feature length in information network), initial learning rate $lr \in \{0.001, 0.005\}$, and the weight of regulation loss L_{norm} $\beta \in \{0.1, 0.3\}$. The optimal hyper-parameters on FB15k-237 dataset are: $K = 8$, $n = 4$, $d = 200$, $lr = 0.001$, $\beta = 0.3$; and those on WN18RR dataset are: $K = 4$, $n = 2$, $d = 200$, $lr = 0.001$, $\beta = 0.1$. For the NE datasets, the optimal hyper-parameters are: $K = 8$, $n = 4$, $lr = 0.005$, $\beta = 0.1$. For a fair comparison, we implement the baseline models (TransE, ConvKB, and GATs) by ourselves based on released codes, and use the same hyper-parameters as DiCGRL. For example, the embedding dimension for TransE and ConvKB are both 200; the number of heads in GATs is 8.

As the continual learning on the multi-relational data is not task dependent as previous works, we implement the baseline models by ourselves based on the toolkit [6] released by Han et al. (2020). For fair comparison, we use the same embedding dimension (i.e., $d = K{*}n$) and same replay instances number for both our model and baselines. For other hyper-parameters, we follow the settings in Han et al. (2020).

Following existing works (Bordes et al., 2013), the evaluation metrics of link prediction task include mean reciprocal rank (MRR) and proportion of valid test triplets in top-10 ranks (H@10). For node classification task, we use accuracy as our evaluation metric. We use two settings to evaluate the overall performance of our DiCGRL after learning on all graphs: (1) **whole performance** calculates the evaluation metrics on the whole test set of all data; (2) **average performance** averages the evaluation metrics on all test sets. As average performance highlights the performance of handling catastrophic forgetting problem, thus it is the main metric to evaluate models.

4.3 Baselines

We compare our model with several baselines including two theoretical models to measure the lower and upper bounds of continual learning:

(1) **Lower Bound**, which continually fine-tunes models on the new multi-relational dataset without memorizing any historical instances;

(2) **Upper Bound**, which continually re-train models with all historical and new incoming instances. In fact, this model serves as the ideal upper bound for the performance of continual learning; and several typical continual learning models:

(3) **EWC** (Kirkpatrick et al., 2017), which adopts elastic weight consolidation to add regularization on parameter changes. It uses Fisher information to measure the parameter importance relative to old data, and slows down the update of those important parameters when learning new data;

(4) **EMR** (Parisi et al., 2019), a basic memory-based method, which memorizes a few historical instances and conducts memory replay. Each time when new data comes in, EMR mixes memorized instances with new instances to fine-tune models;

(5) **GEM** (Lopez-Paz and Ranzato, 2017), which memorizes a few historical instances and adds a constraint on directions of new gradients to make sure that there is no conflict of optimization directions with gradients on old data.

---

[5] The characteristics of multi-relational graphs in real world scenarios are: 1) large-scale 2) the new multi-relational data is coming every day and small in scale proportional to the original size of these graphs.

4.4 Overall Results

Table 1 and Table 2 show the overall performance on both KGE and NE benchmarks under two evaluation settings. From the tables, we can see that:

(1) Our proposed DiCGRL model significantly outperforms other baselines and achieves state-of-the-art performance almost in all settings and datasets. It verifies the effectiveness of our disentangled approach in continual learning, which decouples the node embeddings into multiple components with respect to the semantic aspects, and only updates the corresponding components of graph embedding for new relational triplets.

(2) There is still a huge gap between our model and the upper bound. It indicates although we have proposed an effective approach for continual graph representation learning, it still remains an open problem deserving further exploration.

(3) Although DiCGRL outperforms other baselines in almost all settings in three information network benchmarks, the performance gain is not as high as it is on the KG datasets. The reason is that these three citation benchmarks are provided with rich node features, which would reduce the impact of topology changes. As can be seen, even the weakest Lower Bound achieves relatively high results close to Upper Bound.

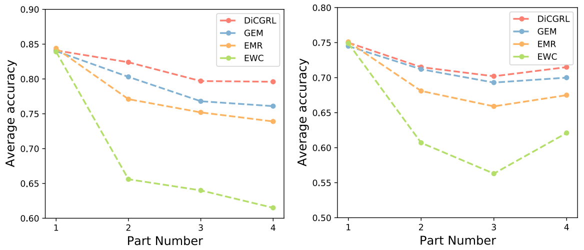
Figure 4: Changes in H@10 and MRR with increasing knowledge graph data through the continual learning process, and the feature extraction method used in DiCGRL is ConvKB.



(a) Cora (b) CiteSeer

Figure 5: Changes in accuracy with increasing information network data through the continual learning process. The result of PubMed dataset is presented in Appendix B.

To further investigate how evaluation metrics change while learning new relational triplets, we show the average performance on the KG and NE datasets at each part in Figure 4 and Figure 5. From the figures, we observe that:

(1) With increasing numbers of new relational triplets, the performance of all the models in almost all the datasets decreases to some degree (CiteSeer may introduce some instability in random data splitting since this dataset is small). This indicates that catastrophically forgetting old data is inevitable, and it is indeed one of the major difficulties for continual graph representation learning.

(2) The memory-based method GEM outperforms the consolidation-based methods, which demonstrates the memory-based methods may be more suitable for alleviating catastrophic forgetting

in multi-relational data to some extent.

(3) Our proposed DiCGRL model achieves significantly better results compared to other baseline models. It indicates that disentangling relational triplets and updating dynamically selected components of relational triplets are more useful and reasonable than rote memorization of static examples from old multi-relational data.

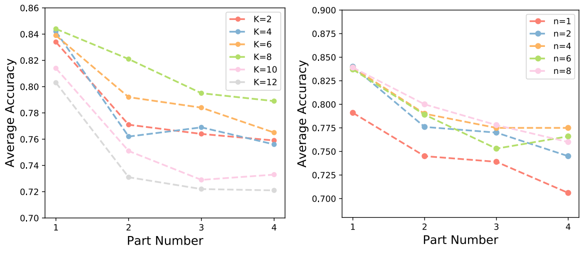
In addition, we evaluate our model under non-continual learning settings to illustrate the superiority of our disentangled approach, and the results are presented in Appendix A.

4.5 Hyper-Parameter Sensitivity

In this section, we investigate the effect of the number of components K and the top selected component number n, which are important hyper-parameters of our DiCGRL. These experiments are only performed on NE datasets, since the node embedding dimension d can be affected by K and n in KG as introduced in Section 4.2, which would make it difficult to make a fair comparison.

Component Number K: We use $n = 2, \beta = 0.1$ to run DiCGRL on the Cora dataset with five different K settings. The results are illustrated in Figure 6(a). From the figure, we find that overall the average accuracy raises when K increases from 2 to 8, which suggests the importance of disentangling components. However, when K grows larger than 8, the performance starts to decline. One possible reason is that the number of components is already larger than that of semantics aspects, making it harder to achieve a good disentanglement. Therefore, we select the component number K for each dataset on the development set, and for most dataset, we select $K = 4$ or $K = 8$.

Top Selected Component Number n: For a fair comparison, we set $K = 8, \beta = 0.1$ and vary n on the Cora dataset. As shown in Figure 6(b), except for the case of $n = 1$, the other settings have comparable performance. However, it can be seen that when $n = 4$, the average accuracy on the last task is the highest, which indicates that the model has the strongest ability to avoid catastrophic forgetting problem when $n = 4$.



(a) Effect of K (b) Effect of n

Figure 6: Hyper-parameter sensitivity of K and n.

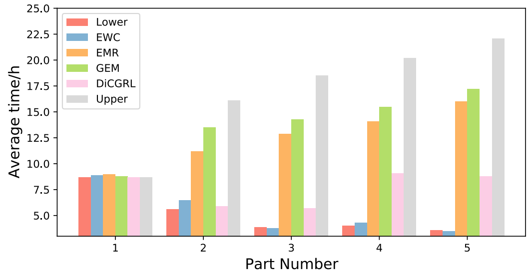


Figure 7: Training time (hour) on FB15k-237 datasets through the continual learning process.

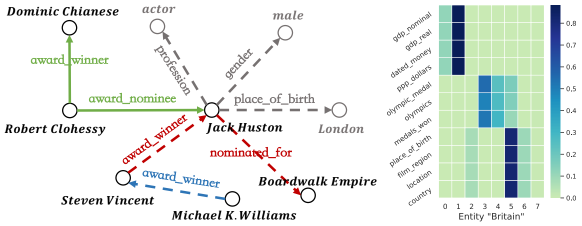

(a) Example (b) Visualization

Figure 8: Figure(a) is an example of DiCGRL on the second part of FB15k-237 dataset, where solid line and dotted line represent newly arrived and previous relational triplets respectively. Red and blue color represents the activated 1-order and 2-order neighbors respectively. Figure(b) is the visualization of attention values on the entity *Britain*

4.6 Efficiency Analysis

We show the training time of different continual learning methods on the biggest benchmark FB15k-237, so as to highlight the efficiency gap in different methods. For a fair comparison, all algorithms use the same KGE method TransE. As shown in Figure 7, GEM takes much longer training time compared with other baselines, which is pretty close to Upper Bound. Although our model also requires some previous data, it is much less in time consumption than GEM and EMR, which verifies the efficiency of our disentangled approach in continual learning.

4.7 Case Study

In this section, we visualize an example case from FB15k-237 dataset (more readable than other datasets) to show that the activated neighbors in our updating module are in line with human commonsense. For example, as shown in Figure 8(a) newly arrived relational triplets such as (*Robert Clohessy*, `award_nominee`, *Jack Huston*) and (*Robert Clohessy*, `award_winner`, *Dominic Chianese*), both related to "award" semantic aspects. Therefore, only "award"-related neighbors of new triplets are updated, like (*Jack Huston*, `nominated_for`, *Boardwalk Empire*). since *Robert Clohessy* is also very likely to be related to the movie of *Boardwalk Empire*. Meanwhile, relational triples of `place_of_birth` and `gender`, which are not related to "award", will not be updated.

Moreover, to verify the learned representation satisfies the intuition that different relations focus on different components of entities, we plot the attention values on the components of the entity *Britain* in Figure 8(b), where the y-coordinate is sampled relations that appear in the same triplets with "*Britain*". We observe that semantically similar relations have similar attention value distributions. For example, relations "`gdp_nominal`", "`gdp_real`", "`dated_money`", "`ppp_dollars`", are all related to economics, relations "`olympic_medal`", "`olympics`", "`medal_won`" are all related to Olympics competitions. These results demonstrate that the disentangled representations learned by our DiCGRL are semantically meaningful.

5 Conclusion and Future Work

In this paper, we propose to study the problem of continual graph representation learning, aiming to handle the streaming nature of the emerging multi-relational data. To this end, we propose a disentangled-based continual graph representation learning (DiCGRL) framework, inspired by human's ability to learn procedural knowledge. Extensive experiments on several typical KGE and NE datasets show that DiCGRL achieves consistent and significant improvement compared to existing continual learning models, which verifies the effectiveness of our model on alleviating the catastrophic forgetting problem. In the future, we will explore to extend the idea of disentanglement in the continual learning of other NLP tasks.

A Results under Non-Continual Learning Settings

Results under non-continual learning settings, i.e., using the entire training sets to train the models, are presented in Table 3 and Table 4. For a fair comparison, we also reproduce the results of baselines, and using the same optimal hyper-parameters as in Section Experimental Settings in the main paper. DiCGRL (T) and DiCGRL (C) indicate using ConvKB and TransE as feature extraction method for DiCGRL respectively. DiCGRL (·)_α1 represents that α^k is calculated by performing a non-linearity transformation over the concatenation of $\boldsymbol{u}$ and $\boldsymbol{v}$ as doing in Network Embedding, and DiCGRL (·)_α2 represents that α^k is calculated by performing a non-linearity transformation over the concatenation of $\boldsymbol{u}$, $\boldsymbol{r}$ and $\boldsymbol{v}$, since relations are an integral part of KGs.

From the tables, we can see that:

(1) DiCGRL is comparable with our reproduced baselines, especially on the FB15k-237 and Cora datasets, our DiCGRL performs better than vanilla GE methods. This phenomenon shows the effectiveness of our disentangled approach by decoupling the relational triplets in the graph into multiple independent components according to their semantic aspects.

(2) As shown in Table 3, the performance of DiCGRL (·)_α1 and DiCGRL (·)_α2 are worse than DiCGRL, even worse than original baseline in some settings. This indicates that assigning global attention values for each relation as done in DiCGRL is an optimal option for KG datasets.

Model	**WN18RR**		**FB15k-237**

Abstract

Semi-supervision is a promising paradigm for Bilingual Lexicon Induction (BLI) with limited annotations. However, previous semi-supervised methods do not fully utilize the knowledge hidden in annotated and non-annotated data, which hinders further improvement of their performance. In this paper, we propose a new semi-supervised BLI framework to encourage the interaction between the supervised signal and unsupervised alignment. We design two message-passing mechanisms to transfer knowledge between annotated and non-annotated data, named prior optimal transport and bi-directional lexicon update respectively. Then, we perform semi-supervised learning based on a cyclic or a parallel parameter feeding routine to update our models. Our framework is a general framework that can incorporate any supervised and unsupervised BLI methods based on optimal transport. Experimental results on MUSE and VecMap datasets show significant improvement of our models. Ablation study also proves that the two-way interaction between the supervised signal and unsupervised alignment accounts for the gain of the overall performance. Results on distant language pairs further illustrate the advantage and robustness of our proposed method.

1 Introduction

Bilingual Lexicon Induction (BLI) is of huge interest to the research frontier. BLI methods learn cross-lingual word embeddings from separately trained monolingual embeddings. BLI is believed to be a promising way to transfer semantic information between different languages, and spawns lots of NLP applications like machine translation (Lample et al., 2018b; Artetxe et al., 2018b), Part Of Speech (POS) tagging (Gaddy et al., 2016), parsing (Xiao and Guo, 2014), and document classification (Klementiev et al., 2012).

The key step of BLI is to learn a transformation between monolingual word embedding spaces (Ruder et al., 2019), which could be further used for translation retrieval or cross-lingual analogy tasks. However, it is hard to obtain the high quality transformation with low supervision signals, i.e. with limited annotated lexicon. Thus, some semi-supervised BLI methods (Artetxe et al., 2017; Patra et al., 2019) are proposed to make use of annotated and non-annotated data. Artetxe et al. (2017) bootstrapped the supervised lexicon to enhance the supervision but ignored the knowledge in non-annotated data. Meanwhile, Patra et al. (2019) combined the unsupervised BLI loss that captured the structural similarity in word embeddings (Lample et al., 2018a) with the supervised loss (Joulin et al., 2018). However, this loss combination still performed poorly since the bad supervised optimization under limited annotations, see the Experiment part for details. As a result, existing semi-supervised BLI methods suffer from low effectiveness (Artetxe et al., 2017) or low robustness (Patra et al., 2019).

In this work, we focus on designing a new semi-supervised BLI method to make full use of both annotated and non-annotated data. We propose a novel framework with two different strategies, which exceeds the previous separate (Artetxe et al., 2017; Patra et al., 2019) semi-supervised methods by emphasizing the two-way interaction between the supervised signal and unsupervised alignment. In this framework, supervised training tries to align the parallel lexicon and unsupervised training can exploit the structure similarity between monolingual embedding spaces. The foundation of two-way interaction is in two carefully designed *message passing mechanisms*, see Section 3.1 and 3.2. Two-way interaction enables semi-supervised BLI

November 16–20, 2020.

to guide the exploitation of structural similarity by *unsupervised procedure* (Grave et al., 2019) and extend insufficient lexicon for *supervised procedure* (Joulin et al., 2018) simultaneously, see Figure 1. In this paper, we only consider the unsupervised BLI methods based on Optimal Transport (OT) (Grave et al., 2019; Alaux et al., 2019; Huang et al., 2019; Alvarez-Melis et al., 2018), which have achieved impressive results on BLI task.

More specifically, the contributions of this paper are listed below.

- We propose the two-way interaction between the supervised signal and unsupervised alignment. It consists of two message passing mechanisms, Prior Optimal Transport (POT) and Bidirectional Lexicon Update (BLU). POT enables the OT-based unsupervised BLI approach to be guided by any prior BLI transformation, i.e. transfers what is learned by supervised BLI method to the unsupervised BLI method. BLU employs the alignment results in bi-directional retrieval to enlarge the annotated data, and thus enhances the supervised training by unsupervised BLI transformation.
- We propose two strategies of semi-supervised BLI framework based on POT and BLU, named by Cyclic Semi-Supervision (CSS) and Parallel Semi-Supervision (PSS). They are recognized by the cyclic and parallel parameter feeding routines, respectively, see Figure 1. Notably, CSS and PSS are universal to admit any supervised BLI methods and OT-based unsupervised BLI methods.
- Extensive experiments on two popular datasets show that CSS and PSS exceed all previous supervised, unsupervised, and semi-supervised approaches and are suitable to different scenarios. Ablation study of CSS and PSS demonstrates that the two-way interaction (POT and BLU) is the key to improve the performance. Results on distant language pairs show the advantage and robustness of our method.

2 Background

In this section, we describe the basic formulation of related supervised and unsupervised BLI methods. We define two embedding matrices $X, Y \in \mathbb{R}^{n\times d}$, where n is the number of words and d is the dimension of the word embedding.

The key to supervised BLI is the parallel lexicon between two languages, say word x_i in X is translated to word y_i in Y. Mikolov et al. (2013) suggested regarding supervised BLI as a regression problem aligning word embeddings by a linear transformation $Q^\star$.

$$Q^\star = \arg\min_{Q\in\mathbb{R}^{d\times d}} \sum_i \|X_iQ - Y_i\|_2^2 \tag{1}$$

Artetxe et al. (2016) introduced the orthogonal constraint on Q. Therefore, Problem (1) has a closed-form solution $Q^\star = UV^\top$, where U, V are defined by the SVD decomposition $Y^\top X = USV^\top$. Joulin et al. (2018) proposed to replace the 2-norm in Problem (1) by Relaxed Cross-domain Similarity Local Scaling (RCSLS) loss to mitigate the hubness problem, which is formulated in Equation (2).

$$\begin{aligned}\texttt{RCSLS}(x_iQ, y_i) = & -2Q^\top x_i^\top y_i \\ & + \frac{1}{k}\sum_{y\in\mathcal{N}_Y(x_iQ)} Q^\top x_i^\top y \\ & + \frac{1}{k}\sum_{xQ\in\mathcal{N}_X(y_j)} Q^\top x^\top y_j\end{aligned} \tag{2}$$

where $\mathcal{N}_X(y)$ represents the set which consists of the k nearest neighbors of y in the point cloud X, so as $\mathcal{N}_Y(x_iQ)$.

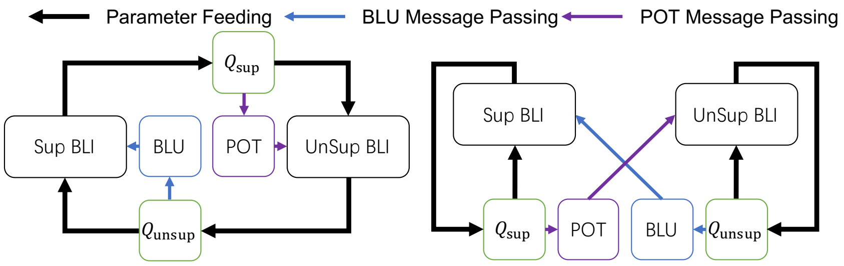
For unsupervised BLI, embeddings in X and Y are totally out of order. As a result, unsupervised BLI methods need to model an unknown permutation matrix $P \in \mathcal{P}_n = \{0,1\}^{n\times n}$

$$\min_{Q\in\mathcal{O}_d, P\in\mathcal{P}_n} \|XQ - PY\|_F^2 \tag{3}$$

where $\mathcal{O}_d$ is the set of orthogonal matrices. Problem (3) could be solved by iteratively minimizing Q and P. More specifically, Grave et al. (2019) considered random samples $\bar{X}, \bar{Y} \in \mathbb{R}^{m\times d}$ from X, Y in a stochastic optimization scheme. Minimizing P directly is hard. The key to unsupervised methods is how to solve P approximately, see Section 6. OT based methods solve P by optimal transport (Zhang et al., 2017; Grave et al., 2019; Alaux et al., 2019; Huang et al., 2019). Grave et al. (2019) and Zhang et al. (2017) proposed to solve the Wasserstein problem between the two distributions supported on $\bar{X}Q$ and $\bar{Y}$, respectively.

$$W_2^2(\bar{X}Q, \bar{Y}) = \min_{P\in\Pi} \sum_{i,j} P_{ij}D_{ij} \tag{4}$$

where D_{ij} is the cost between x_iQ and y_j, such as 2-norm, RCSLS loss, or other costs. $P \in \Pi =$



(a) Cyclic Semi-Supervision (b) Parallel Semi-Supervision

Figure 1: Illustration for Cyclic Semi-Supervision and Parallel Semi-Supervision

$\{P \in \mathbb{R}_+^{m\times m} | \sum_i P_{ij} = \sum_j P_{ij} = 1\}$ is the transport plan (Peyré et al., 2019). OT related metrics can be solved by the entropy regularized Sinkhorn algorithm (Cuturi, 2013).

$$W_2^2(\bar{X}Q, \bar{Y}) = \min_{P\in\Pi} \sum_{i,j} P_{ij}D_{ij} + \epsilon H(P) \quad (5)$$

To summarize, the foundation of supervised BLI is the annotated parallel lexicon for training, and the critical step of OT-based unsupervised BLI is the solution of transport plan P.

3 Message Passing in BLI

In this section, we present two message passing mechanisms for semi-supervised framework, including POT and BLU. POT is proposed to enhance the unsupervised BLI by the knowledge passed from the supervised BLI. Meanwhile BLU enhances the supervised BLI by the additional lexicon based on the unsupervised retrieval results. Therefore, POT and BLU form the two-way interaction between the supervised signal and unsupervised alignment.

3.1 Prior Optimal Transport

We present POT to strengthen the stochastic optimization in unsupervised BLI with prior information from supervised BLI. More specifically, POT is designed to guide the original OT solution of P, see Problem (4). POT can replace the original OT problems in unsupervised BLI models such as (Grave et al., 2019). In this way, we enable the transformation Q_{sup} trained in supervised BLI to enhance the unsupervised BLI.

Given Q_{sup} learned from any supervised BLI and random word embedding samples $\{x_i\}$ and $\{y_j\}$, we compute the cost matrix C between transformed source embeddings and target embeddings. In this work, we choose RCSLS as the specific formulation of C_{ij}

$$C_{ij} = RCSLS(x_i Q_{sup}, y_j). \quad (6)$$

Based on this cost function, we propose to use the Boltzmann Distribution, i.e. softmax function with temperature to construct a prior transport plan Γ:

$$\Gamma_{ij} = \frac{e^{-C_{ij}/T}}{\sum_{1\leq k\leq n} e^{-C_{ik}/T}}. \quad (7)$$

Γ_{ij} represents the probability that the i-th word in X is a translation of the j-th word in Y. Temperature T controls the significance of translation in Γ. Γ, induced from Q_{sup}, assigns each pair of words with a smaller cost in C a higher probability of forming a lexicon.

Instead of considering Problem (4), we consider the POT regularized by the Kullback-Leibler (KL) divergence between Γ and P.

$$\texttt{POT}(\bar{X}Q, \bar{Y}) = \min_{P\in\Pi} \langle D, P\rangle + \varepsilon KL(P\|\Gamma), \quad (8)$$

where $\langle D, P\rangle = \sum_{i,j} P_{ij}D_{ij}$ is the matrix inner product. We note that KL regularization in POT problem is totally different from the aforementioned entropic regularization (5). For entropy regularized OT, the regularization coefficient ϵ is expected to be as small as possible to approximate the original OT solution. However, for POT discussed in (8), the regularization coefficient ε controls the interpolation of OT transport plan that minimizes Problem (4) and prior transport plan Γ. Therefore, ε does not need to be as small as possible. Instead, it is a proper number to coordinate the effect from prior supervised transformation Q_{sup}.

The key to solving Problem (8) is to decompose the KL divergence into entropic term and linear term. Therefore, Problem (8) is reduced to

$$\min_{P\in\Pi} \langle D - \varepsilon \log \Gamma, P\rangle + \varepsilon H(P). \quad (9)$$

By treating $D - \varepsilon \log \Gamma$ as the Γ-prior cost matrix $D(\varepsilon, \Gamma)$, Problem (8) could also be solved by Sinkhorn algorithm. Again, since POT does not require ε to be closed to zero, the solution of POT Problem (8) will not suffer from numerical instability problems (Peyré et al., 2019).

3.2 Bi-directional Lexicon Update

As stated in Section 2, the key to supervised BLI is its parallel lexicon for training. Therefore, to enhance the supervised BLI, we propose BLU to extend the parallel lexicon by the structural similarity of word embeddings exploited in unsupervised BLI. To distinguish from unsupervised notations in Section 3.1, let $S, T \in \mathbb{R}^{n\times d}$ be the parallel word embedding matrices for source and target languages respectively. The i-th row s_i of S and t_i of T form a translation pair in the annotated lexicon. BLU selects the additional lexicon $S', T' \in \mathbb{R}^{l\times d}$ with high credit scores to extend S and T. Let $S^* = S \oplus S'$ and $T^* = T \oplus T'$ be the extended lexicon, where $\oplus$ denotes the concatenation operation along columns between two matrices.

Given the forward and backward transformations $\overrightarrow{Q}_{unsup}$ and $\overleftarrow{Q}_{unsup}$ between source language and target language from unsupervised BLI. BLU defines the S' and T' by Q_{unsup} and $Q_{unsup}^{\top}$ respectively in four steps:

(1) Compute the forward and backward distance matrices. Forward distance matrix $\overrightarrow{D}$ is defined between transformed source embeddings and target embeddings, while backward distance matrix $\overleftarrow{D}$ is defined between source embeddings and backward transformed target embeddings.

(2) Generate forward and backward translation pairs. Let $\overrightarrow{B} = \{(i,j)|j = \arg\min_k \overleftarrow{D}_{ik}\}$ and $\overleftarrow{B} = \{(i,j)|i = \arg\min_k \overleftarrow{D}_{kj}\}$ be the translation pair sets. Then take the intersection $B = \overrightarrow{B} \cap \overleftarrow{B}$ as the candidate additional lexicon.

(3) Compute the credit score CS for each translation pair. Firstly, we define the forward and backward credit scores for a pair $(i,j) \in B$. Let $\overrightarrow{C}(i)$ be the set of target word indices k, $\overrightarrow{C}(i)$ $=\{k|$ $k \neq j$ and k is among top $K+1$ elements of $-\overrightarrow{D}_{i*}\}$, so as $\overleftarrow{C}(j)$. The forward credit score is defined by $\overrightarrow{CS}_{ij} = \sum_{k\in\overrightarrow{C}(i)} \overrightarrow{D_{ik}}/K - \overrightarrow{D}_{ij}$, and $\overleftarrow{CS}_{ij}$ is similarly defined. Then we define credit score CS_{ij} for $(i,j) \in B$ by $CS_{ij} = \overrightarrow{CS}_{ij} + \overleftarrow{CS}_{ij}$.

(4) Select additional lexicon by credit score. The additional lexicon is selected in descending order of the CS for each translation pair (i,j).

Based on the steps mentioned above, we append the *annotated lexicon* with the *additional lexicon* that contains high credit translation pairs.

This message passing mechanism is related to the bootstrap routine in (Artetxe et al., 2018a). However, we select the credible translation pairs from the intersection, rather than union, of the forward and backward set of translation pairs. In this way, we guarantee the high quality of the additional lexicon.

4 Semi-Supervision with Two-way Interaction

In the previous section, we have presented two message passing mechanisms to enhance supervised BLI and OT-based unsupervised BLI by prior transformation Q_{unsup} and Q_{sup}, respectively. Moreover, recent state-of-the-art (SOTA) supervised(Sup) and unsupervised($UnSup$) approaches are all based on stochastic optimization rather than the closed-form solution. This means that all SOTA Sup and $UnSup$ approaches can be considered as a module that operates on the feed-in parameter Q. Therefore, we propose two different strategies for semi-supervision that emphasize the two-way interaction between the supervised signal and unsupervised alignment based on the message passing mechanisms, see Figure 1. All SOTA Sup and OT-based $UnSup$ methods can be plugged into the proposed framework seamlessly.

4.1 Cyclic Semi-Supervision

The first proposed semi-supervised BLI strategy is CSS, see Figure 1 (a). CSS feeds the parameter Q into Sup and $UnSup$ iteratively in a cyclic parameter feeding routine. Cyclic parameter feeding is a "hard" way to share the parameters and is no more than Patra et al. (2019) itself. Besides parameter feeding, we propose to use the message passing mechanisms BLU and POT to strengthen the Sup and $UnSup$. However, there is no convergence guarantee for this optimization scheme. As a result, it may suffer from limited performance when the BLI task is hard, as will be detailed in Section 5.

4.2 Parallel Semi-Supervision

The second strategy is PSS, see Figure 1 (b), where Sup and $UnSup$ are performed in parallel. The information between Sup and $UnSup$ is only passed by the proposed message passing mechanisms. In this point of view, Artetxe et al. (2017) only had the Sup part with lexicon update and ignored the UnSup part. Compared to CSS, PSS indirectly shares the information in a "soft" way and may be suitable for some hard BLI tasks. We use the metric formulated in Equation 4 to evaluate Q_{sup} and Q_{unsup} on the word embedding spaces and choose the better one as the final output of PSS.

5 Experiment

In this section, we conduct extensive experiments to evaluate the performance of CSS and PSS. We open the source code on Github[*].

5.1 Setup

Baselines We take several methods proposed in recent five years as baselines, including supervised (Artetxe et al., 2016; Joulin et al., 2018; Jawanpuria et al., 2019), unsupervised (Artetxe et al., 2016; Lample et al., 2018a; Mohiuddin and Joty, 2019; Grave et al., 2019; Alaux et al., 2019) and semi-supervised (Artetxe et al., 2017; Patra et al., 2019; Mohiuddin et al., 2020) approaches. Brief introductions could be found in Section 6. The scores of baselines are retrieved from their papers or by running the publicly available codes if necessary. For Mohiuddin et al. (2020), we don't find the released source code.

Datasets We evaluate CSS and PSS against baselines on two popularly used datasets: the MUSE[†] dataset (Lample et al., 2018a) and the VecMap[‡] dataset (Dinu and Baroni, 2015). The MUSE dataset consists of FASTTEXT word embeddings (Bojanowski et al., 2017) trained on Wikipedia corpora and more than 100 bilingual dictionaries of different languages. The FASTTEXT embeddings used in MUSE are trained on very large and highly semantically similar language corpora (Wikipedia), which means the results on MUSE are biased (Artetxe et al., 2018a) and easier to obtain. On the contrary, the VecMap dataset is less biased and harder using CBOW embeddings trained on the WacKy scrawled corpora and bilingual dictionaries obtained from the Europarl word alignments (Dinu and Baroni, 2015). We use the default training and test splits for both datasets.

Evaluation Setting Similar to Mohiuddin et al. (2020), we compare CSS and PSS against baselines on three annotated lexicons with different sizes, including one-to-one and one-to-many mappings: "100 unique" and "5K unique" contain one-to-one mappings of 100 and 5000 source-target pairs respectively, while "5K all" contains one-to-many mappings of all 5000 source and target words, that is, for each source word there may be multiple target words. Moreover, we present the experiment results of five totally unsupervised baselines and three supervised ones. All the accuracies reported in this section are the average of four repetitions. For detailed experimental data, such as the standard deviation, please refer to the tables in appendix.

Hyperparameter Setting We train our models using Stochastic Gradient Descent with a batch size of 400 and a learning rate 1.0 for Sup, a batch size of 8K and a learning rate 500 for UnSup. The temperature T in Equation (7) is 0.1 and the coefficient ε in Equation (8) is 1. The additional lexicon size is set 10000. Each epoch contains 2K supervised iterations and 50 unsupervised iterations. Each case runs 5 epochs. The aforementioned parameters work sufficiently good and we didn't search the best hyperparameters in this work. All the experiments are conducted by 32-core CPU and one NVIDIA Tesla V100 core. Our framework finished in 30 minutes, while the running time for Mohiuddin and Joty (2019) was 3 hours.

5.2 Results on MUSE Dataset

In Table 1, we show the word translation results for five language pairs from the MUSE dataset, including 10 BLI tasks considering bidirectional translation.

With "100 unique" annotated lexicon, CSS outperforms all other semi-supervised methods on every task. The accuracy score of Patra et al. (2019) is less than 3% on all tasks because the limited annotated lexicon is insufficient for effective learning, while Artetxe et al. (2017) avoided this problem by lexicon bootstrap. Both CSS and PSS keep strong performance with insufficient annotated lexicon by the proposed message passing mechanisms, and achieve 2.8% and 0.9% improvement over Artetxe et al. (2017), respectively. Compared to the iterative CSS that feeds parameters by UnSup directly into Sup, the parallel PSS has fewer connections between Sup and UnSup. Thus, CSS performance is better than PSS under low supervision.

We notice that semi-supervised approaches with "100 unique" annotated lexicon are even worse than

Table 1: Word translation accuracy(@1) of CSS and PSS on the MUSE dataset with RCSLS as their supervised loss. ('EN': English, 'ES': Spanish, 'FR': French, 'DE': German, 'RU': Russian, 'IT': Italian. Underline: the highest accuracy among the group. In bold: the best among all methods).

the unsupervised methods. This indicates that 100 annotation lexicon is too weak for supervised approach to learn meaningful transformation. It does not mean our approach has marginal contribution. On the contrary, these empirical results reveal that bad supervised BLI won't hurt the overall performance of our semi-supervised framework and this is what previous work cannot achieve.

As the annotated lexicon size increases, the dominance of CSS and PSS is still observed. Moreover, the gap between CSS and PSS disappears as the size of annotated lexicon gets larger. With "5K unique" annotated lexicon, CSS and PSS outperform other semi-supervised methods on all tasks. With "5K all" annotated lexicon, CSS and PSS outperform other semi-supervised baselines on 9 of 10 tasks. On average, CSS exceeds Artetxe et al. (2017), Patra et al. (2019) and Mohiuddin et al. (2020) by $4.2\%, 0.8\%, 5.8\%$, respectively.

Taking all methods into consideration, including supervised, semi-supervised and unsupervised, CSS and PSS achieve the highest accuracy on 8 of 10 tasks and the best results on average.

5.3 Results on VecMap Dataset

In Table 2, we show the word translation accuracy for three language pairs, including 6 translation tasks on the harder VecMap dataset (Dinu and Baroni, 2015).

Notably, a couple of unsupervised approaches (Lample et al., 2018a; Mohiuddin and Joty, 2019; Grave et al., 2019; Alaux et al., 2019) are evaluated to have a zero accuracy on some of the language pairs. On the one hand, their valotile results demonstrate the toughness of the VecMap dataset where the structural similarity for unsupervised BLI is very low. On the other hand, unstable performance may be explained by the high dependence of those methods on the initialization. Though the performance of those methods are highest in some cases,

Table 2: Word translation accuracy(@1) of CSS and PSS on the VecMap dataset with RCSLS as their supervised loss. ('EN': English, 'ES': Spanish, 'DE': German, 'IT': Italian. Underline: the highest accuracy among the group. In bold: the best among all methods. In bold and marked by †: the second-highest among all methods).

e.g. Alaux et al. (2019), due to the unstable nature. We also mark the second-highest score by bold font and † if necessary.

At all supervision levels, CSS and PSS outperform all other semi-supervised approaches. Taking all unsupervised, semi-supervised and supervised methods into account, CSS and PSS achieve SOTA accuracy on average. Notably, PSS gets the highest or the second-highest (except the unstable unsupervised baseline (Alaux et al., 2019)) scores for 5 of 6 language pairs.

The results for "100 unique" annotated lexicon support our finding on the MUSE dataset that CSS learns better at low supervision level. Interestingly, with "5K unique" and "5K all" annotated lexicons, PSS outperforms CSS on almost every task, which is different from the MUSE dataset. Given that the structural similarity of embeddings between different languages in VecMap is very low, UnSup procedure is very unstable. In this case, CSS has lower performance due to the unstable Q_{unsup} is directly fed into Sup, while the parallel strategy of PSS does not suffer from this problem.

5.4 Ablation Study

In the ablation study, we disassemble CSS and PSS into the basic components to analyze the contribution of each component. Specifically, we consider the proposed two message passing mechanisms POT and BLU. For CSS, we also include the effect of Sup or UnSup module in the cyclic parameter feeding. However, if Sup or UnSup in PSS is removed, the framework falls back to the unsupervised or supervised BLI, whose results are already in Table 1 and 2.

We conduct ablation experiments with two annotated lexicons with different sizes, "5K all" and "1K unique" to compare the behavior of CSS and PSS under different annotation level. The experimental setting is the same as the main experiments. The ablation results are presented in Table 3 on four language pairs (2 from MUSE dataset and 2 from VecMap dataset).

Effectiveness of POT and BLU:

Regardless of the annotated lexicon size, removing POT, BLU and both of them from CSS brings 2.4%, 0.9% and 13.0% decline of accuracy respectively on average. Notably, the cyclic parameter feeding does not bring further benefits. Only when combined with at least one message passing mechanism, POT or BLU, the accuracy is improved significantly. For PSS, removal of POT or BLU brings 1.6% and 1.0% decline on the average score respectively.

Moreover, we consider different annotated lexicon sizes. On average, removal of POT, BLU or both from CSS brings 1.2%, 0.7% and 4.2% decline respectively with "5K all" annotated lexicon size, 3.4%, 0.9% and 21.6% decline with "1K unique" annotated lexicon size. The message passing mechanisms contribute drastically with a smaller annotated lexicon size since Sup receives significantly larger additional lexicons from UnSup to strengthen its performance. As for PSS, removal of POT and BLU brings 0.9% and 1.5% decline respectively with "5K all" annotated lexicon size, 2.3% and 0.7% decline with "1K unique" annotated lexicon size. No significant effect of annotation level for PSS is observed in ablation study. For both CSS and PSS, the contribution of POT is slightly larger than that of BLU and the combination of them could bring impressive improvement in general.

Analysis of Sup and UnSup in CSS:

In this step, we remove Sup or UnSup from CSS

Table 3: Ablation Study with ”5K all” and ”1K unique” annotated lexicon. (⊖: remove specific component from the CSS or PSS. &: remove both components.)

and monitor the performance change. Note that if we remove UnSup from CSS, POT also needs to be removed as we do not need any prior transport plan for UnSup anymore. Removing Sup also means the removal of BLU for a similar reason. After removing UnSup and POT, CSS feeds Q_{sup} exactly to BLU for additional lexicon and then to Sup again, just like Artetxe et al. (2017, 2018a). After removing Sup and BLU, UnSup takes the transformation learned by itself in previous steps to generate the prior transport plan. The average accuracy drops by 1.5% and 4.5% with ”5K all” and ”1K unique” annotated lexicon respectively after removing UnSup, by 1.7% and 0.8% after removing Sup.

Given the comparison above, Sup contributes less than UnSup with ”1K unique” annotated lexicon. Whereas Sup and UnSup contribute comparably with ”5K all” annotated lexicon. In other words, at low annotation level, i.e. ”1K unique”, where Sup BLI does not work well, the participation of UnSup extends the valuable additional lexicon.

5.5 Results on distant language pairs

In this section, We report the tranlation accuracy of our method on five distant language pairs with 5000 lexicon. We choose three methods as baselines: Patra et al. (2019) proposed semi-supervised SOTA method. Jawanpuria et al. (2019) is the supervised SOTA method. Zhou et al. (2019) designed an unsupervised matching procedure with density matching technologies, which achieved significant improvement on distant language pairs. As we need to compare supervised, unsupervised and semi-supervised method simultaneously, we conduct evaluation only on the ”5K unique” supervision level.

As shown in Table 4, our method also retains a distinct advantage on these distant language pairs. In the cases between ”EN” and ”JA”, Patra et al. (2019) and Jawanpuria et al. (2019) are completely inefficient. While our method obtains stable results on these cases, which proves the robustness of CSS and PSS. Moreover, our method outperforms Zhou et al. (2019) on most cases. In short, CSS and PSS could obtain stable and better results on various language pairs.

6 Related Work

This paper is mainly related to the following three lines of work.

Supervised methods. Mikolov et al. (2013) pointed out that it was a feasible way to BLI by learning a linear transformation based on the Euclidean distance. Artetxe et al. (2016) applied normalization to word embeddings and imposed an orthogonal constraint on the linear transformation which led to a closed-form solution. Joulin et al. (2018) replaced Euclidean distance with the RCSLS distance to relieve the hubness phenomenon and achieved SOTA results for many languages. Jawanpuria et al. (2019) optimized a Mahalanobis metric along with the transformation to refine the similarity between word embeddings.

Unsupervised methods. Artetxe et al. (2018a) proposed an unsupervised method to generate an initial lexicon by exploiting the similarity in cross-lingual space and applied a robust self-learning to improve it iteratively. Lample et al. (2018a) did the first work for unsupervised BLI which learned a linear transformation by adversarial training and improved it by a refinement procedure. Mohiuddin and Joty (2019) revisited adversarial autoencoder for unsupervised word translation and proposed two novel extensions to it. Moreover, OT-based

unsupervised BLI is the central part in this paper. Alvarez-Melis and Jaakkola (2018) exploited the structure similarity of embedding space by minimizing the Gromov-Wasserstein metric between source and target word embedding distributions. Grave et al. (2019) viewed unsupervised BLI task as the minimization of Wasserstein distance between the source and target distributions of word embeddings. They optimized this problem by using Sinkhorn and Procrustes alternatively. Alaux et al. (2019) furthered the work of Grave et al. (2019) by using the RCSLS as the distance metric, which addresses hubness phenomenon better than Euclidean distance. Zhao et al. (2020) proposed an relaxed matching procedure derived from unbalanced OT algorithms and solved the polysemy problem to a certain extent. Xu et al. (2018) used a neural network implementation to calculate the Sinkhorn distance, a well-defined OT-based distributional similarity measure, and optimized the objective through back-propagation.

Semi-supervised methods. Artetxe et al. (2017) proposed a simple self-learning approach that can be combined with any dictionary-based mapping technique and started with almost no lexicon. Patra et al. (2019) proposed a semi-supervised approach that relaxes the isometric assumption and optimizes a supervised loss and an unsupervised loss together.

Notably, comparing with the self-learning method like (Artetxe et al., 2018a) or (Vulic et al., 2019), our framework with two message passing mechanisms is quite different from theirs. Although the lexicon updating procedures in their papers are similar with the BLU that we proposed, there are two main differences: (1) Their approaches use the lexicon from current step to extract the lexicon for next step. Meanwhile, BLU uses unsupervised output to extract lexicon for the supervised part. Our models will degenerate to their situation after removing the unsupervised part and POT. This situation has been discussed in the ablation study in Section 5.4. (2) BLU extracts lexicon according to bidirectional matching information while they only consider one direction. This trick improves the lexicon quality.

Moreover, alignment of word embeddings in latent spaces by Auto-Encoders or other projections is another trend of BLI research. Latent space alignment includes unsupervised variants (Dou et al., 2018; Bai et al., 2019; Mohiuddin and Joty, 2019) and semi-supervised variants (Mohiuddin et al., 2020). We emphasize that the latent space alignment is orthogonal to our proposed framework. Our entire framework can be transferred to any given latent space.

7 Conclusions

In this paper, we introduce the two-way interaction between the supervised signal and unsupervised alignment by proposed POT and BLU message passing mechanisms. POT guides the OT-based unsupervised BLI by prior BLI transformation. BLU employs a bidirectional retrieval to enlarge the annotated data and stabilize the training of supervised BLI approaches. Ablation study shows that the two-way interaction by POT and BLU is the key to significant improvement.

Based on the message passing mechanisms, we design two strategies of semi-supervised BLI to integrate supervised and unsupervised approaches, CSS and PSS, which are constructed on cyclic and parallel strategies respectively. The results show that CSS and PSS achieve SOTA results over two popular datasets. As CSS and PSS are compatible with any supervised BLI and OT-based unsupervised BLI approaches, they can also be applied to the latent space optimization.

Abstract

One approach to matching texts from asymmetrical domains is projecting the input sequences into a common semantic space as feature vectors upon which the matching function can be readily defined and learned. In real-world matching practices, it is often observed that with the training goes on, the feature vectors projected from different domains tend to be indistinguishable. The phenomenon, however, is often overlooked in existing matching models. As a result, the feature vectors are constructed without any regularization, which inevitably increases the difficulty of learning the downstream matching functions. In this paper, we propose a novel match method tailored for text matching in asymmetrical domains, called WD-Match. In WD-Match, a Wasserstein distance-based regularizer is defined to regularize the features vectors projected from different domains. As a result, the method enforces the feature projection function to generate vectors such that those correspond to different domains cannot be easily discriminated. The training process of WD-Match amounts to a game that minimizes the matching loss regularized by the Wasserstein distance. WD-Match can be used to improve different text matching methods, by using the method as its underlying matching model. Four popular text matching methods have been exploited in the paper. Experimental results based on four publicly available benchmarks showed that WD-Match consistently outperformed the underlying methods and the baselines.

1 Introduction

Asymmetrical text matching, which predicts the relationship (e.g., category, similarity) of two text sequences from different domains, is a fundamental problem in both information retrieval (IR) and natural language processing (NLP). For example, in natural language inference (NLI), text matching has been used to determine whether a hypothesis is entailment, contradiction, or neutral given a premise (Bowman et al., 2015). In question answering (QA), text matching has been used to determine whether a answer can answer the given question (Wang et al., 2007; Yang et al., 2015). In IR, text matching has been widely used to measure the relevance of a document to a query (Li and Xu, 2014; Xu et al., 2020).

One approach to asymmetrical text matching is projecting the text sequences from different domains into a common latent space as feature vectors. Since these feature vectors have identical dimensions and in the same space, matching functions can be readily defined and learned. This type of approach includes a number of popular methods, such as DSSM (Huang et al., 2013), DecAtt (Parikh et al., 2016), CAFE (Tay et al., 2018a), and RE2 (Yang et al., 2019). In real-world matching practices, it is often observed that learning of the matching models is a process of moving the projected feature vectors together in the semantic space. For example, Figure 1 shows the distribution of the feature vectors generated by RE2. During the training of RE2 (Yang et al., 2019) on SciTail dataset (Khot et al., 2018), it is observed that at the early stage of the training, the feature vectors corresponding to different domains are often separately distributed (according to the visualization by tNSE (Maaten and Hinton, 2008)) (Figure 1(a)). With the training went on, these separated feature vectors gradually moved closer and finally mixed together (Figure 1(b) and (c)).

The phenomenon can be explained as follows. Given two text sequences from two asymmetrical domains (e.g., NLI), the first sequence (e.g., premise) and the second sequence (e.g., hypothesis) are heterogeneous and there exists a lexical gap that needs to be bridged between them (Tay

et al., 2018c), similar to that of learning cross-modal matching model (Wang et al., 2017a). Existing studies (Wang et al., 2017a; Kamath et al., 2019) have shown that it is essentially critical that the projection network should generate domain- or modal-invariant features. That is, the global distributions of feature vectors should be similar in a common subspace such that their origins cannot be discriminated. The phenomenon is not unique but recurs in the experiments based on other matching models and other datasets.

Existing text matching models, however, are still lack of constraints or regularizations to ensure that the projected vectors are well distributed for matching. One natural question is, can we design a mechanism that can explicitly guide the mix of the feature vectors and better distribute them. To answer the question, this paper presents a novel learning to match method in which the Wasserstein distance (between the two distributions respectively corresponding to the two asymmetrical domains) is introduced as a regularizer, called WD-Match. WD-Match consists of three components: (1) a feature projection component which jointly projects each pair of text sequences into a latent semantic space, as a pair of feature vectors; (2) a regularizer component which estimates the Wasserstein distance with a feed-forward neural network on the basis of the projected features; (3) a matching component which conducts the matching, also on the same set of projected features.

The training of WD-Match amounts to repeatedly interplays between two branches under the adversarial learning framework: a regularizer branch that learns a neural network for estimating the upper bound on the dual form Wasserstein distance, and a matching branch that minimizes a Wasserstein distance regularized matching loss. In this way, the minimization of the loss function leads to a learning method not only to minimize the matching loss, but also to well distribute the feature vectors in the semantic space for better matching.

To summarize, this paper makes the following main contributions:

- We highlight the critical importance of the global distribution of the projected feature vectors in matching texts between asymmetrical domains, which has not yet been seriously studied in existing models.
- We propose a new learning to match method under the adversarial framework, in which the text matching model is learned by minimizing a Wasserstein distance-regularized matching loss.
- We conducted empirical studies on four large scale benchmarks, and demonstrated that WD-Match achieved better performance than the baselines and the underlying models. Extensive analysis showed the effects of Wasserstein distance-based regularizer in terms of guiding the distributions of feature vectors and improving the matching accuracy.

The source code of WD-Match is available at `https://github.com/RUC-WSM/WD-Match`

2 Related Work

In this section, we first review the sequence representation used in text matching, then introduce the Wasserstein distance and its applications.

2.1 Sequence Representation in Text Matching

Sequence representation lies in the core of text matching (Xu et al., 2020). Early works inspired by Siamese architecture assign respective neural networks to encode two input sequences into high-level representations. For example, DSSM (Huang et al., 2013) is one of the classic representation-based matching approaches to text matching which uses feed-forward neural networks to project a text sequence. CDSSM (Shen et al., 2014), ARC-I (Hu et al., 2014) and CNTN (Qiu and Huang, 2015) change sequence encoder to a convolutional neural network which shares parameters in a fixed size sliding window. To further capture the long-term dependence of a text sequence, a group of recurrent neural network based methods were proposed, including RNN-LSTM (Palangi et al., 2016) and MV-LSTM (Wan et al., 2015).

Recently, with the help of attention mechanism (Parikh et al., 2016), the sequence representation is obtained by aligning the sequence itself and the other sequence in the input pairs. For example, CSRAN (Tay et al., 2018b) performs multi-level attention refinement with dense connections among multiple levels. DRCN (Kim et al., 2019) stacks encoding layers and attention layers, then concatenates all previously aligned results. RE2 (Yang et al., 2019) introduces a consecutive architecture based on augmented residual connection between convolutional layers and attention layers. These models yield strong performance on several benchmarks.

2.2 Wasserstein Distance

Wasserstein distance (Chen et al., 2018) is a metric based on the theory of optimal transport. It gives a natural measure of the distance between two probability distributions.

Wasserstein distance has been successfully used in the Generative Adversarial Networks (GAN) (Goodfellow et al., 2014) framework of deep learning. Arjovsky et al. (2017) propose WGAN which uses the Wasserstein-1 metric as a way to improve the original framework of GAN, to alleviate the vanishing gradient and the mode collapse issues in the original GAN. The Wasserstein distance has also been explored to learn the domain-invariant features in domain adaptation tasks. For example, Chen et al. (2018) propose to minimize the Wasserstein distance between the feature distributions of the source and the target domains, yielding better performance and smoother training than the standard training method with a Gradient Reversal Layer (Ganin et al., 2016). Shen et al. (2017b) propose to learn domain-invariant features with the guidance of Wasserstein distance.

Inspired by its success in variant applications, this paper introduces Wasserstien distance to text matching in asymmetrical domains, as a regularizer to improve the sequence representations.

3 Our Approach: WD-Match

In this section, we describe our proposed method WD-Match.

3.1 Model Architecture

Suppose that we are given a collection of N instances of sequence-sequence-label triples: $\mathcal{D} = \{(X_i, Y_i, \mathbf{z}_i)\}_{i=1}^{N}$ where $X_i \in \mathcal{X}$, $Y_i \in \mathcal{Y}$, and $\mathbf{z}_i \in \mathcal{Z}$ respectively denote the first sequence, the second sequence, and the label indicating the relationship of X_i and Y_i. As shown in Figure 2, WD-Match consists of three components:

The feature projection component: Given a sequence pair (X, Y), it is first processed by the feature projection component F,

$$[\mathbf{h}^X, \mathbf{h}^Y] = F(X, Y),$$

where the feature projection function F outputs a pair of K-dimensional feature vectors $\mathbf{h}^X, \mathbf{h}^Y$ in the semantic space. We suppose that F is a neural network with a set of parameters θ_F and all the parameters in θ_F are sharing for X and Y.

The matching component: The output vectors from the feature projection component are then fed to the matching component M,

$$\hat{\mathbf{z}} = M([\mathbf{h}^X, \mathbf{h}^Y]),$$

M outputs the predicted label $\hat{\mathbf{z}}$. We suppose that M is a neural network with a set of parameters θ_M.

The regularizer component: Given two sets of the projected feature vectors $\mathbf{h}^X$ and $\mathbf{h}^Y$, the regularizer component estimates the Wasserstein distance between $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$, we denote $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ are two distributions defined over the two groups of feature vectors $\mathbf{h}^X$ and $\mathbf{h}^Y$ respectively.

$$\begin{aligned}\mathbb{P}_F^X &\triangleq P\left(\mathbf{h}^X | [\mathbf{h}^X, \mathbf{h}^Y] = F(X,Y) \wedge (X,Y) \sim \mathcal{X} \times \mathcal{Y}\right),\\ \mathbb{P}_F^Y &\triangleq P\left(\mathbf{h}^Y | [\mathbf{h}^X, \mathbf{h}^Y] = F(X,Y) \wedge (X,Y) \sim \mathcal{X} \times \mathcal{Y}\right),\end{aligned} \tag{1}$$

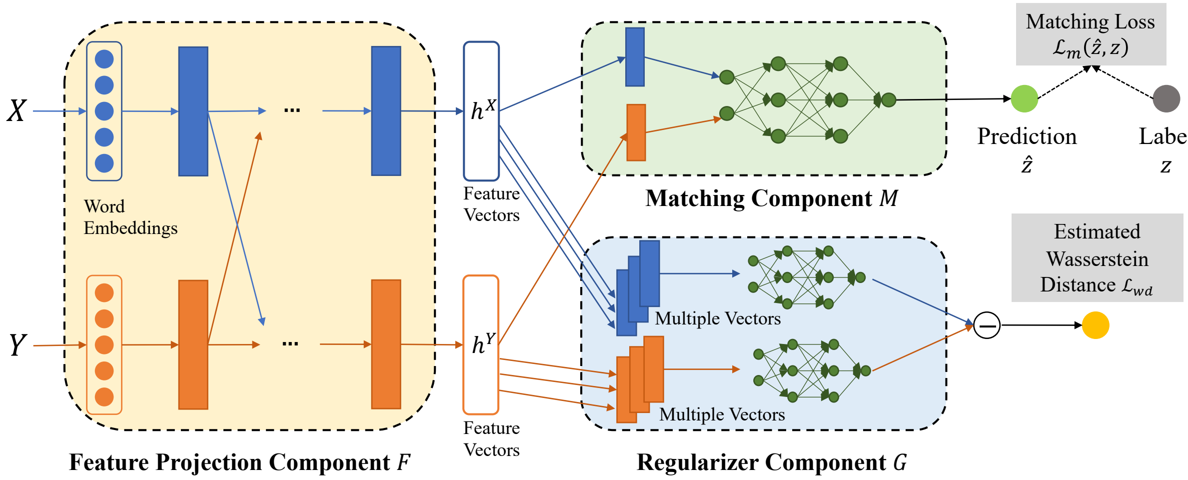

Figure 2: WD-Match architecture. Note that the multiple parallel arrow lines to the regularizer component G means that G takes a set of feature vectors (based on a batch of sequence pairs), rather than one feature vector, as its inputs.

where '$\sim$' means that the pairs (X,Y) are sampled from the joint space $\mathcal{X} \times \mathcal{Y}$. Specifically, the Wasserstein distance between two probabilistic distributions $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ is defined as:

$$W(\mathbb{P}_F^X, \mathbb{P}_F^Y) = \inf_{\gamma \in \mathcal{J}(\mathbb{P}_F^X, \mathbb{P}_F^Y)} \int \|X - Y\| d\gamma(X,Y),$$

where $\mathcal{J}(\mathbb{P}_F^X, \mathbb{P}_F^Y)$ denotes all joint distributions, γ stands for (X,Y) that have marginal distributions $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$. It can be shown that W has the dual form (Villani, 2003):

$$W(\mathbb{P}_F^X, \mathbb{P}_F^Y) = \sup_{|G|_L \leq 1} E_{\mathbb{P}_F^X}[G(\mathbf{h}^X)] - E_{\mathbb{P}_F^Y}[G(\mathbf{h}^Y)], \tag{2}$$

where '$|G|_L \leq 1$' denotes that the 'sup' is taken over the set of all 1-Lipschitz[1] function G; and function $G : \mathcal{R}^K \rightarrow \mathcal{R}$ maps each K-dimensional feature vector in the semantic space to a real number. In this paper, G is set as a two-layer feed-forward neural network with a set of parameters θ_G clipped to $[-c, c]$, where $c > 0$ is a hyper-parameter.

Please note that different configurations of the feature projection component F, matching component M, and matching loss $\mathcal{L}_m$ leads to different matching models. Therefore, WD-Match can improve a matching model by setting the matching method as its underlying model.

3.2 Adversarial Training

To learn the model parameters $\{\theta_F, \theta_M, \theta_G\}$, WD-Match sets up two training goals: minimizing the Wasserstein distance between $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$, and minimizing the loss in prediction in terms of the mistakenly predicted matching labels. The training process can be implemented under the adversarial learning framework and amounts to repeatedly interplays between two learning branches: the regularizer branch and the matching branch.

In the regularizer branch, the objective term in the dual form Wasserstein distance (Equation (2)) is approximately written as:

$$\mathcal{O}_G(\theta_F, \theta_G) = \sum_{(X,Y)} \left[G(\mathbf{h}^X) - G(\mathbf{h}^Y)\right],$$

where $[\mathbf{h}^X, \mathbf{h}^Y] = F(X,Y)$ are the projected feature vectors for (X,Y). Maximizing $\mathcal{O}_G$ w.r.t. the parameters θ_G can achieve an approximation of the Wasserstein distance between $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ in the semantic space defined by F:

$$\mathcal{L}_{wd}(\theta_F) = \max_{\theta_G} \mathcal{O}_G(\theta_F, \theta_G). \tag{3}$$

To make G a Lipschitz function (up to a constant) and following the practices in (Arjovsky et al., 2017), all of the parameters in θ_G are always clipped to a fixed range $[-c, c]$. In practice, the sequence pairs for training G are randomly sampled from the training set $\mathcal{D}$. Note that $\mathcal{L}_{wd}$ still takes θ_F as parameters because it is calculated on the basis of features generated by F.

---

[1] G is 1-Lipschitz $\Leftrightarrow |G(\mathbf{h}) - G(\mathbf{h}')| \leq |\mathbf{h} - \mathbf{h}'|$ for all $\mathbf{h}$ and $\mathbf{h}'$

The matching branch simultaneously updates the matching network M and feature projection network F by seeking the minimization of the Wasserstein distance-regularized matching loss:

$$\min_{\theta_F,\theta_M} \mathcal{L}_{reg} = \mathcal{L}_m(\theta_F,\theta_M) + \lambda \cdot \mathcal{L}_{wd}(\theta_F), \tag{4}$$

where $\lambda \in [0,1]$ is a trade-off coefficient to balance the matching loss and regularizer, and $\mathcal{L}_m(\theta_F,\theta_M)$ is defined as

$$\mathcal{L}_m(\theta_F,\theta_M) = \sum_{(X,Y,z)\in\mathcal{D}} \ell_m(M(F(X,Y)),\mathbf{z}),$$

where $\ell_m(\cdot,\cdot)$ is the matching loss function defined over each sequence-sequence-label triple in the training data. It can be, for example, the cross-entropy loss that measure the goodness of the predicted label $\hat{\mathbf{z}} = M(F(X,Y))$ by the matching network, compared to the ground truth label $\mathbf{z}$.

Algorithm 1 shows the general procedure of WD-Match. WD-Match takes training set $\mathcal{D} = (X_i,Y_i,z_i)_{i=1}^{N}$ and a number of hyper-parameters as inputs, and outputs the learned parameters θ_F and θ_M. WD-Match run multiple rounds until convergence, and at each round it estimates the Wasserstein distance of the projected features and then update the projection component F and matching component M. At each round, WD-Match alternatively maintains two branches. The regularizer branch updates the parameters θ_G, with the θ_F fixed[2]. It contains a sub-iteration in which the parameters are optimized in an iterative manner: First, objective $\mathcal{O}_G$ is constructed based on the sampled sequence pairs (line 4 - line 6); Then θ_G is updated with gradient ascent (line 7); Finally, each parameter in θ_G is clipped to $[-c,c]$ for satisfying the 1-Lipschitz constraint (line 8). The matching branch updates θ_F and θ_M, with θ_G fixed. It first samples another mini-batch data from the training data and estimates the regularized loss $\mathcal{L}_{adv}$ using the fixed G (line 11 - line 13). Then, the gradients of the parameters is estimated and used to update the parameters (line 14).

4 Experiments

We conducted experiments to test the performances of WD-Match, and analyzed the results.

WikiQA	question-answer	R	20k

4.1 Datasets and Metrics

We use four large scale publicly matching benchmarks: SNLI (Stanford Natural Langauge Inference) (Bowman et al., 2015), SciTail (Khot et al., 2018), TrecQA (Wang et al., 2007), WikiQA (Yang et al., 2015). Table 1 provides a summary of the datasets used in our experiments.

SNLI [3] is a benchmark for natural language inference. In SNLI, each data record is a premise-hypothesis-label triple. The premise and hypothesis are two sentences and the label could be "entailment", "neutral", "contradiction", or "-". In our

---

[2] Note that the regularizer does not depend on M, given F.

[3] `https://nlp.stanford.edu/projects/snli`

experiments, following the practices in (Bowman et al., 2015), the data with label "-" are ignored. We follow the original dataset partition. Accuracy is used as the evaluation metric for this dataset.

SciTail [4] is an entailment dataset based on multiple-choice science exams and web sentences. Each record is a premise-hypothesis-label triple. The label is "entailment" or "neutral", because scientific factors cannot contradict. We follow the original dataset partition. Accuracy are used as the evaluation metric for this dataset.

TrecQA [5] is a answer sentence selection dataset designed for the open-domain question answering setting. We use the raw version TrecQA, questions with no answers or with only positive/negative answers are included. The raw version has 82 questions in the development set and 100 questions in the test set. Mean average precision (MAP) and mean reciprocal rank (MRR) are used as the evaluation metrics for this task.

WikiQA [6] is a retrieval-based question answering dataset based on Wikipedia. We follow the data split of original paper. This dataset consists of 20.4k training pairs, 2.7k development pairs, and 6.2k testing pairs. We use MAP and MRR as the evaluation metrics for this task.

4.2 Experimental Setup

In WD-Match, different configurations of the feature projection component F and matching component M lead to different matching models. In the experiments, RE2 (Yang et al., 2019), DecATT (Parikh et al., 2016), CAFE (Tay et al., 2018a) and BERT (Devlin et al., 2018) were set as the underlying models, achieving new models respectively denoted as "WD-Match (RE2)", "WD-Match (DecAtt)", "WD-Match (CAFE)", and "WD-Match (BERT)".

Specifically, in WD-Match(RE2), F is a stacked blocks which consist of multiple convolution layers and multiple attention layers, and M is an MLP; in WD-Match(DecAtt), F is an attention layer and a aggregation layer, M is an MLP. Please note that we did not implement the Intra-Sentence Attention in our experiments; in WD-Match(CAFE), F is a highway encoder with a alignment layer and a factorization layer and M is another highway network. Please note that we remove the character embedding and position embedding in our experiments; in WD-Match(BERT), F is a pre-trained BERT-base[7] model, M is an MLP. Please note that for easing of combining with WD-Match, BERT was only used to extract the sentence features separately in our experiments. The G module for four models are identical: a non-linear projection layer and a linear projection layer.

For all models, the parameters of F and M were directly set as its original settings. In the training, all models were trained using the Adam optimizer with learning rate η_2 tuned amongst $\{0.0001, 0.0005, 0.001\}$. Batch size n_2 was tuned amongst $\{256, 512, 1024\}$. The trade-off coefficient λ was tuned from [0.0001, 0.01]. Clipping threshold was tuned from [0.1, 0.5]. Word embeddings were initialized with GloVe (Pennington et al., 2014) and fixed during training. We implemented WD-Match models in Tensorflow.

4.3 Experimental Results

Table 2 reports the results of WD-Match and the popular baselines on the SNLI test set. The baselines results are reported from their original papers. From the results, we found that WD-Match (RE2) outperformed all of the baselines, including the underlying model RE2. The results indicate the effectiveness of WD-Match and its Wasserstein distance-based regularizer in the asymmetric matching tasks of natural language inference. We further tested the performances of WD-Match (DecAtt) and WD-Match(BERT) which used DecAtt and BERT as the underlying matching models, respectively, to show whehter WD-Match can improve a matching method by using the method as its underlying model. From the results shown in Table 2, we can see that on SNLI, WD-Match (DecAtt) ourperform DecAtt in terms of accuracy. Similarly, WD-Match (BERT) improved BERT about 0.4 points in terms of accuracy.

Table 3 reports the results of WD-Match and the baselines on the SciTail test set. The baselines results are reported from the original papers. We found that WD-Match (RE2) outperformed all of the baselines. The result further confirm WD-match's effectiveness in the asymmetric matching task of scientific entailment. We also tested the performances of WD-Match (DecAtt) and WD-

Match(BERT) on Scitail dataset. From the results shown in Table 3, we can see that WD-Match (DecAtt) improved DecAtt 1.2 points in terms of accuracy. Similarly, WD-Match (BERT) improved BERT about 2.7 points in terms of accuracy. The results verified that WD-Match's ability in improving its underlying model.

Table 4 reports the results of WD-Match and the baselines on the WikiQA test set. The baselines result are reported from the original papers. Following RE2, point-wise binary classification loss rather than pairwise ranking loss was used to train the model. The best hyperparameters including early stopping were tuned on WikiQA development set. From the results we can see that WD-Match (RE2) obtained a better result in terms of MAP and MRR on WikiQA. To further verify the effectiveness of WD-Match on QA task, we incorporated DecAtt and CAFE (Tay et al., 2018a) into WD-Match, then compare their performance to the respective underlying models on WikiQA and TrecQA datasets. Table 4 and Table 5 report the experimental results on WikiQA test set and TrecQA test set respectively. Similarly, WD-Match outperformed its underlying model on both datasets.

Table 4: Performance comparison on WikiQA test set.

WD-Match (CAFE)	**67.49**	**73.05**

We list the number of parameters of different text matching models in Table 2. Compared to the underlying model, the additional parameters of WD-Match come from the regularizer component G. We can see that the parameters of the regularizer component G are far less than the underlying model. G module is implemented as a two-layer MLP (the number of neurons in the second layer is set as one). Therefore, the additional computing cost comes from the training of the two-layer MLP, which is of $O(T * N * K * 1)$, where T is the number of training iterations, N number of training examples, K number of neurons in the first layer of MLP (without considering the compute cost of the activation function). We can see that the additional computing overhead is much lower than that of the underlying methods which usually learn much more complex neural networks for the feature projection and the matching.

Summarizing the results above and the results reported in Section 4.3, we can conclude that WD-

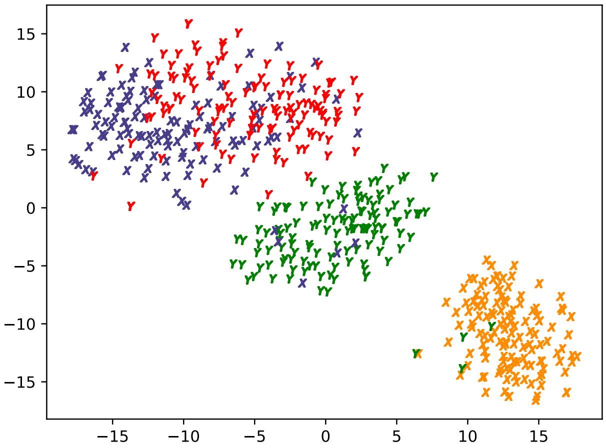

Figure 3: t-SNE visualization of the projected feature vectors, based on the RE2 and WD-Match (RE2) models trained on SciTail dataset. This figure illustrates the vector distributions after 5 training steps. The orange 'X' and green 'Y' correspond to $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ of RE2, The dark blue 'X' and red 'Y' correspond to $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ of WD-Match (RE2), respectively.

Match is a general while strong framework that can improve different matching models by using them as its underlying matching model.

4.4 Visualization of the Distributions of Feature Vectors

Figure 1(a) shows that there exists a gap between two feature vectors, due to the heterogenous nature of the texts from two asymmetrical domains. We conducted experiments to analyze how the feature vectors (i.e., $\mathbf{h}^X$ and $\mathbf{h}^Y$) generated by WD-Match distributed in the common semantic space, using WD-Match(RE2) as an example. Specifically, we trained a RE2 model and a WD-Match (RE2) model based on SciTail dataset. Note that in this experiment, the adversarial training step k is set as 5, that is, WD-Match (RE2) repeats regularizer branch for 5 times before matching branch. We recorded all of the training feature vectors (i.e., $\mathbf{h}^X$ and $\mathbf{h}^Y$) and illustrated them in the Figure 3 by t-SNE . The orange 'X' and green 'Y' correspond to $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ of RE2, The dark blue 'X' and red 'Y' correspond to $\mathbb{P}_F^X$ and $\mathbb{P}_F^Y$ of WD-Match (RE2), respectively. As we can see from Figure 3, the feature vectors from RE2 are separately distributed while the feature vectors from WD-Match (RE2) are indistinguishable. It demonstrates that compared to the underlying model RE2, WD-Match (RE2) distributes the feature vectors in semantic space better and faster.

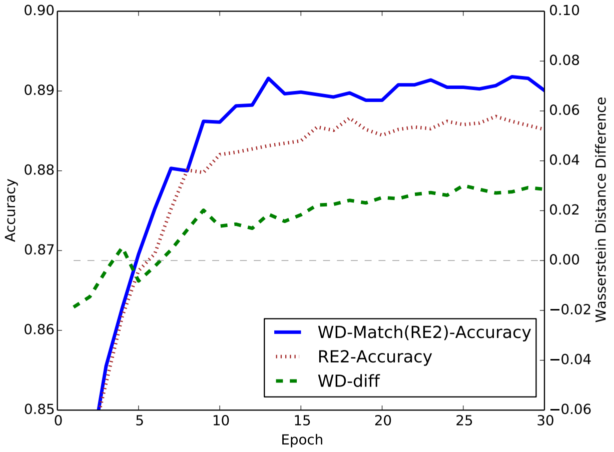

Figure 4: Accuracy curves and Wasserstein distance difference curve w.r.t. training epochs for RE2 and WD-Match (RE2).

4.5 Convergence and Effects of Wasserstein Distance-based Regularizer

We conducted experiments to test how the Wasserstein distance-based regularizer guides the training of matching models.

Specifically, we tested the WD-Match (RE2) and RE2 models generated at each training epochs. The accuracy curve on the basis of development set of SNLI was illustrated in Figure 4 (denoted as "WD-Match (RE2)-Accuracy" and "RE2-Accuracy"). Comparing these two training curves, we can see that WD-Match (RE2) outperformed RE2 when the training closing to converge (after about 15 epochs). We can conclude that WD-Match (RE2) obtained higher accuracy than RE2.

To investigate how the Wasserstein distance guides the training of matching models, we recorded the estimated Wasserstein distances at all of the training epochs of RE2 and WD-Match (RE2) based on the converged G network. The curve "WD-Diff" shows the differences between the Wasserstein distances by RE2 and that of by WD-Match (RE2) at each of the training epoch (i.e., $\mathcal{L}_{wd}(\theta_F)$ of RE2 minus $\mathcal{L}_{wd}(\theta_F)$ of WD-Match (RE2)). From the curve we can see that at the beginning of the training (i.e., epoch 1 to 5), the "WD-Diff" was near to zero. With the training went on (i.e., epoch 5 to 30), the Wasserstein distance by WD-Math(RE2) became smaller than that of by RE2 (the WD-Diff curve is above the zero line), which means that WD-Match (RE2)'s feature projection module F was guided to move feature vectors together more thoroughly and faster, which are more suitable for matching. The results indicate

WD-Match achieved its design goal of guiding the distributions of the projected feature vectors.

It is interesting to note that, comparing all of the three curves in Figure 4, we found the WD-Diff curve is close to zero at the beginning of the training, and the accuracy curves of WD-Match (RE2)-Accuracy and RE2-Accuracy are similar at the beginning. With the training went on (after epoch 10), the Wasserstein distance differences became larger. At the same time, the accuracy gaps (between WD-Match (RE2)-Accuracy and RE2-Accuracy) also become larger. The results clearly reflect the effects of Wasserstein distance-based regularizer: minimizing the regularizer leads to better distribution of feature vectors in terms of matching.

5 Conclusion and Future Work

In this paper, we proposed a novel Wasserstein distance-based regularizer to improve the sequence representations, for text matching in asymmetrical domains. The method, called WD-Match, amounts to adversarial interplay of two branches: estimating the Wasserstein distance given the projected features, and minimizing the Wasserstein distance regularized matching loss. We show that the regularizer helps WD-Match to well distribute the generated feature vectors in the semantic space, and therefore more suitable for matching. Experimental results on four benchmarks showed that WD-Match can outperform the baselines including its underlying models. Empirical analysis showed the effectiveness of the Wasserstein distance-based regularizer in text matching.

In the future, we plan to study different regularizers in the asymmetrical text matching task, for further exploring their effectiveness in bridging the gap between asymmetrical domains.

A Simple Approach to Learning Unsupervised Multilingual Embeddings

Pratik Jawanpuria, Mayank Meghwanshi, Bamdev Mishra
Microsoft, India
{pratik.jawanpuria,mamegh,bamdevm}@microsoft.com

Abstract

Recent progress on unsupervised cross-lingual embeddings in the bilingual setting has given the impetus to learning a shared embedding space for several languages. A popular framework to solve the latter problem is to solve the following two sub-problems jointly: 1) learning unsupervised word alignment between several language pairs, and 2) learning how to map the monolingual embeddings of every language to shared multilingual space. In contrast, we propose a simple approach by decoupling the above two sub-problems and solving them separately, one after another, using existing techniques. We show that this proposed approach obtains surprisingly good performance in tasks such as bilingual lexicon induction, cross-lingual word similarity, multilingual document classification, and multilingual dependency parsing. When distant languages are involved, the proposed approach shows robust behavior and outperforms existing unsupervised multilingual word embedding approaches.

1 Introduction

Learning cross-lingual word representations has been the focus of many recent works (Mikolov et al., 2013; Faruqui and Dyer, 2014; Artetxe et al., 2016). It aims at learning a shared embedding space for words across two (bilingual word embedding) or more languages (multilingual word embedding or MWE), by mapping similar words (or concepts) across different languages close to each other in a shared embedding space. Such a representation is useful in various applications such as cross-lingual text classification (Klementiev et al., 2012), building bilingual lexicons (Mikolov et al., 2013), cross-lingual information retrieval (Vulić and Moens, 2015), and machine translation (Gu et al., 2018), to name a few.

Mikolov et al. (2013) showed that the geometric arrangement of word embeddings could be (approximately) preserved by linearly transforming the word embeddings from one language space to another. Subsequently, several works have explored learning bilingual word embeddings in both supervised (Xing et al., 2015; Artetxe et al., 2016, 2018a; Smith et al., 2017; Jawanpuria et al., 2019) and unsupervised (Zhang et al., 2017a,b; Conneau et al., 2018; Artetxe et al., 2018b; Alvarez-Melis and Jaakkola, 2018; Hoshen and Wolf, 2018; Grave et al., 2019; Jawanpuria et al., 2020a) settings.

Representing word embeddings of many languages in a common shared space is desirable to allow knowledge transfer between different languages. Chen and Cardie (2018) are among the first to propose unsupervised learning of MWEs. They extend the GAN-based iterative refinement procedure for learning bilingual word embeddings (Conneau et al., 2018) to the multilingual setting. However, adversarial training has known concerns of optimization stability with distant language pairs (Søgaard et al., 2018). Alaux et al. (2019) propose a joint optimization framework for learning bilingual lexicons and mappings between several pairs of languages. They obtain the bilingual lexicons using the Gromov-Wasserstein approach (Alvarez-Melis and Jaakkola, 2018) and mapping operators between languages using the RCSLS algorithm (Joulin et al., 2018). Heyman et al. (2019) propose to learn the shared multilingual space by incrementally adding languages to it, one in each iteration. Their approach is based on a reformulation of the bilingual self-learning algorithm proposed by Artetxe et al. (2018b).

This work proposes a two-stage framework for learning a shared MWE space in the unsupervised setting. The two stages aim at solving the following sub-problems: a) generating bilingual lexicons between a few pairs of languages, and *subsequently*

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2995–3001,
November 16–20, 2020. ©2020 Association for Computational Linguistics

b) learning the mapping operators between languages in a shared multilingual space. The subproblems are separately solved using existing techniques. In contrast, existing unsupervised multilingual approaches (Chen and Cardie, 2018; Heyman et al., 2019; Alaux et al., 2019) solve the above subproblems jointly. Though it appears like a simple baseline approach, the proposed framework provides the robustness and versatility often desired while learning an effective multilingual space for distant languages, which is a challenging setting for unsupervised methods (Søgaard et al., 2018; Glavaš et al., 2019; Vulić et al., 2019).

We evaluate our approach on the bilingual lexicon induction (BLI) task, cross-lingual word similarity task, and two downstream multilingual tasks: document classification and dependency parsing. We summarize our findings below.

- For a group consisting of similar languages, all multilingual approaches, including ours, benefit from transfer learning across languages and achieve similar BLI performance.
- In challenging scenarios involving distant languages, existing unsupervised approaches fail to learn an effective multilingual space. The proposed approach, however, is robust and outperforms other multilingual methods in such settings.
- The proposed approach performs better than existing methods on the cross-lingual word similarity, the document classification, and the dependency parsing tasks.

2 Unsupervised Multilingual Multi-stage Framework

We propose the following framework for unsupervised learning of MWEs:

- generate unsupervised word alignment between a few pairs of languages, and then
- use the above knowledge to learn the shared multilingual space.

We solve the above two stages sequentially using known techniques. Our methodology contrasts with the existing unsupervised MWE methods (Alaux et al., 2019; Chen and Cardie, 2018; Heyman et al., 2019), which learn the unsupervised word alignments and the cross-lingual word embedding mappings jointly. Despite its apparent simplicity, we empirically observe that the proposed approach illustrates remarkable generalization ability and robustness. We summarize the proposed approach in Algorithm 1 and discuss the details below.

Algorithm 1 Proposed Algorithmic Framework

```
Input: Monolingual embeddings $\mathbf{X}_i$ for each language $L_i$ and an undirected, connected graph $G(V, E)$ with $V = \{L_1, \ldots, L_n\}$.

/*Stage 1: Generate bilingual lexicons $\mathbf{Y}_{ij}$*/
for each unordered pair $(L_i, L_j) \in E$ do
  $\mathbf{Y}_{ij} \leftarrow$ UnsupWordAlign($\mathbf{X}_i, \mathbf{X}_j$)
end for

/*Stage 2: Learn MWE in a shared latent space*/
Run GeoMM on $G(V, E)$ with monolingual embeddings $\mathbf{X}_i$ for all languages $L_i$ and bilingual lexicons $\mathbf{Y}_{ij}$ for language pairs $(L_i, L_j) \in E$

The output of GeoMM:
a) metric $\mathbf{B}$ (a positive definite matrix), and
b) orthogonal matrices $\mathbf{U}_i\ \forall i = 1, \ldots, n$.

/*Represent word embedding $x$ of language $L_i$ in the common multilingual space*/
$x \to \mathbf{B}^{\frac{1}{2}}\mathbf{U}_i^\top x$.
```

2.1 Stage 1: Generating Bilingual Lexicons

We first generate bilingual lexicons for a few language pairs using existing unsupervised bilingual word alignment algorithms (Artetxe et al., 2018b; Alvarez-Melis and Jaakkola, 2018). The lexicons are learned in the bilingual setting, independent of each other. Our framework allows using different unsupervised bilingual word alignment algorithms for different language pairs as our second stage is agnostic to this process. More generally, one may obtain bilingual lexicons for language pairs using various algorithms/resources: unsupervised, weakly-supervised with bootstrapping (Artetxe et al., 2017), human supervision, etc. Such flexibility in getting bilingual lexicons is often desirable in real-world applications (Søgaard et al., 2018; Glavaš et al., 2019; Vulić et al., 2019). To the best of our knowledge, existing unsupervised MWE approaches do not discuss[1] applicability to such hybrid settings.

We experiment with two unsupervised bilingual word alignment algorithms (Artetxe et al., 2018b;

---

[1] Heyman et al. (2019), for example, state that their approach is impractical in the supervised setting as it requires pairwise dictionaries for all pair of languages.

Alvarez-Melis and Jaakkola, 2018) to generate bilingual lexicons, described in Section 2.3. It should be emphasized that the lexicons are learned only for a few language pairs. For instance, in our experiments, $n-1$ bilingual lexicons are generated for n languages.

2.2 Stage 2: Multilingual Word Embeddings

We now learn the MWEs using the bilingual lexicons obtained from the first stage. To achieve our objective, we propose to employ the Geometry-aware Multilingual Mapping (GeoMM) algorithm (Jawanpuria et al., 2019).

The setting of GeoMM may be formalized as an undirected, connected graph, whose nodes represent languages and edges between nodes imply the availability of bilingual dictionaries (for the corresponding language pairs). GeoMM represents multiple languages in a common latent space by learning language-specific rotations for each language ($d \times d$ orthogonal matrix $\mathbf{U}_i$ for each language L_i) and a Mahalanobis metric common across languages (a $d \times d$ symmetric positive-definite matrix $\mathbf{B}$), where d is the dimensionality of the monolingual word embeddings. The rotation matrices align the language embeddings to a common latent space, while the (shared) metric $\mathbf{B}$ governs how distances are measured in this latent space. Both the language-specific parameters ($\mathbf{U}_i\ \forall L_i$) and the shared parameter ($\mathbf{B}$) are learned via a joint optimization problem (Jawanpuria et al., 2019, Equation 3). The function that maps a word embedding x from language L_i's space to the shared latent space is given by: $x \rightarrow \mathbf{B}^{\frac{1}{2}}\mathbf{U}_i^{\top}x$.

2.3 Implementation Details

We develop two variants of the proposed approach, which differ in the unsupervised bilingual word alignment algorithm employed in the first stage. Both the variants use the GeoMM algorithm in the second stage.

SL-GeoMM: In this method, we employ the self-learning algorithm of Artetxe et al. (2018b) for generating bilingual lexicons (`UnsupWordAlign` subroutine in Algorithm 1). We simplify the self-learning algorithm for our purpose by using its unsupervised initialization followed by stochastic dictionary induction (without any pre/post -processing steps).

GW-GeoMM: We also experiment with the Gromov-Wasserstein (GW) word alignment algorithm (Alvarez-Melis and Jaakkola, 2018) as the `UnsupWordAlign` subroutine in Algorithm 1. The GW algorithm learns a doubly stochastic matrix. To further obtain a bilingual lexicon, we additionally run a CSLS (cross-domain similarity local scaling) based refinement procedure (Conneau et al., 2018).

3 Experiments

The proposed methods **SL-GeoMM** and **GW-GeoMM** are compared against existing unsupervised multilingual word embeddings approaches **UMWE** (Chen and Cardie, 2018) and **UMH** (Alaux et al., 2019) on various BLI and downstream tasks. As a bilingual baseline, we also include state-of-the-art unsupervised bilingual word embeddings approach **BilingUnsup** (Artetxe et al., 2018b) in our BLI experiments. In addition to gauging the effectiveness of the proposed two-staged framework, the experiments also study the multilingual approaches' robustness, especially when distant languages are involved. The evaluated tasks are detailed below.

Bilingual lexicon induction (BLI): We evaluate on the MUSE (Conneau et al., 2018) and the VecMap (Dinu and Baroni, 2015; Artetxe et al., 2018a) datasets. Following (Chen and Cardie, 2018; Alaux et al., 2019), we report Precision@1 in the BLI experiments and employ the CSLS based inference (Conneau et al., 2018).

Cross-lingual word similarity (CLWS): The CLWS task is evaluated using the SemEval 2017 dataset (Camacho-Collados et al., 2017).

Multilingual dependency parsing (MLDP): In this task (Ammar et al., 2016), we evaluate the quality of learned multilingual embeddings on ML-Parsing dataset sampled from the Universal Dependencies 1.1 corpus (Agić et al., 2015). The dataset has twelve languages: Bulgarian, Czech, Danish, German, Greek, English, Spanish, Finnish, French, Hungarian, Italian, and Swedish.

Multilingual document classification (MLDC): This task (Ammar et al., 2016) is evaluated on the ReutersMLDC dataset, which has documents in seven languages: Danish, German, English, Spanish, French, Italian, and Swedish.

More details of the experimental settings and additional results are discussed in the technical report (Jawanpuria et al., 2020b).

Table 2: Average Precision@1 for BLI on eleven European languages from the MUSE dataset. The results are obtained for every combination of source-target language pair.

3.1 Results on Standard BLI Setting

Table 1 reports the BLI results on a group of six relatively close European languages (Alaux et al., 2019): German, English, Spanish, French, Italian, and Portuguese. We observe that the proposed two-stage methods, GW-GeoMM and SL-GeoMM, obtain scores on par with state-of-the-art methods, UMWE and UMH. Thus, multilingual approaches can learn an effective multilingual space for close-by languages. We also observe that all the multilingual approaches outperform BilingUnsup, highlighting the benefits of transfer learning.

3.2 Results on Robust BLI Setting

We evaluate the robustness of the methods to distant languages by including five other European languages (Czech, Danish, Dutch, Polish, Russian) (Alaux et al., 2019) to the previous setup. Table 2 reports the summarized results. The proposed methods, GW-GeoMM and SL-GeoMM, perform better than UMH and UMWE for every language. We also observe that UMWE fails at mapping Dutch language embeddings in the multilingual space even though Dutch is close to English. However, in a separate bilingual experiment, UMWE learns an effective English-Dutch cross-lingual space (obtaining an average en-nl and nl-en score of 75.2). This contrasting behavior of the GAN-based UMWE algorithm between the bilingual and multilingual settings is possibly due to its optimization instability (Søgaard et al., 2018).

We also evaluate the methods in a highly diverse language group: Arabic, German, English, French, Hindi, and Russian. Table 3 reports the BLI performance on each language pair. We observe that the proposed SL-GeoMM learns a highly effective multilingual space and obtains the best overall result, illustrating its robustness in this challenging setting. On the other hand, other multilingual approaches fail to learn a reasonably good multilingual space. For instance, GW-GeoMM, UMWE, and UMH fail to obtain a good BLI score (< 1 Precision@1) in 10, 16, and 18 language pairs, respectively. Below, we analyze their results.

- The Gromov-Wasserstein alignment algorithm (Alvarez-Melis and Jaakkola, 2018), used in the first stage of GW-GeoMM, fails to align English and Hindi words. However, this misalignment does not adversely affect GW-GeoMM on language pairs not involving Hindi as GW-GeoMM performs similar to SL-GeoMM on those language pairs.
- UMH employs the Gromov-Wasserstein (GW) alignment formulation in its joint learning framework. As observed with GW-GeoMM, UMH also does not learn suitable Hindi embeddings in the MWE space. However, UMH also fails to learn

suitable Arabic embeddings in the MWE space even though the GW algorithm learns an effective bilingual alignment of English and Arabic words. Misalignment of one language's embeddings in the MWE space adversely affects other languages in the joint learning approaches like UMH.

• The GAN-based approach, UMWE, learns two groups of aligned languages in the shared multilingual space. The first group consists of Arabic, English, French, and Hindi languages. However, these languages are misaligned with the other group consisting of German and Russian. Such grouping cannot be attributed to language similarity (e.g., English and German are closer than English and Arabic) and maybe an outcome of optimization stability (Søgaard et al., 2018).

3.3 Cross-lingual Word Similarity Results

Table 4, first column, reports the SemEval 2017 cross-lingual word similarity (CLWS) task's results on four languages: English, German, Spanish, and Italian. For each method, we consider the MWEs of the four languages learned in the second BLI experiment (corresponding to Table 2) for the CLWS evaluation. We observe that the proposed approaches, SL-GeoMM and GW-GeoMM, obtain the best results.

3.4 Results on Downstream Applications

For each multilingual method, we first learn a shared multilingual space (as in BLI setup), followed by application-specific evaluation. Table 4, second and third columns, reports the multilingual document classification (MLDC) and multilingual document parsing (MLDP) tasks' performance, respectively. We observe that both the proposed two-stage approaches perform well on the downstream tasks with SL-GeoMM obtaining the best results.

4 Conclusion

We study a two-stage framework for learning unsupervised multilingual word embeddings. The two stages correspond to unsupervised generation of bilingual lexicons for a few language pairs and subsequently learning a shared latent multilingual space. We propose to solve each of them with existing techniques (Artetxe et al., 2018b; Alvarez-Melis and Jaakkola, 2018; Jawanpuria et al., 2019). Though the proposed framework seems simple compared to the joint optimization methods (Chen and Cardie, 2018; Alaux et al., 2019; Heyman et al., 2019), our main contribution has been to show that it is a strong performer. Empirical results on several different benchmarks on bilingual lexicon induction, cross-lingual word similarity, multilingual document classification, and multilingual document parsing tasks show remarkably good performance and robustness of the proposed framework. The proposed framework has the flexibility to be easily employed in hybrid setups where supervision is available for a few language pairs but is unavailable for others. Overall, our results encourage the development of simple multi-stage models for learning multilingual word embeddings.

Abstract

We show that Reinforcement Learning (RL) methods for solving Text-Based Games (TBGs) often fail to generalize on unseen games, especially in small data regimes. To address this issue, we propose **C**ontext **R**elevant **E**pisodic **S**tate **T**runcation (**CREST**) for irrelevant token removal in observation text for improved generalization. Our method first trains a base model using Q-learning, which typically overfits the training games. The base model's action token distribution is used to perform observation pruning that removes irrelevant tokens. A second bootstrapped model is then retrained on the pruned observation text. Our bootstrapped agent shows improved generalization in solving unseen TextWorld games, using 10x-20x fewer training games compared to previous state-of-the-art (SOTA) methods despite requiring fewer number of training episodes.[1]

1 Introduction

Reinforcement Learning (RL) methods are increasingly being used for solving sequential decision-making problems from natural language inputs, like text-based games (Narasimhan et al., 2015; He et al., 2016; Yuan et al., 2018; Zahavy et al., 2018) chat-bots (Serban et al., 2017) and personal conversation assistants (Dhingra et al., 2017; Li et al., 2017; Wu et al., 2016). In this work, we focus on Text-Based Games (TBGs), which require solving goals like *"Obtain coin from the kitchen"*, based on a natural language description of the agent's observation of the environment. To interact with the environment, the agent issues text-based action commands ("*go west*") upon which it receives a reward signal used for training the RL agent. TBGs serve as testbeds for interactive real-world tasks like virtual-navigation agents on cellular phones at a shopping mall with user rating as the reward.

Goal: Who's got a virtual machine and is about to play through an fast paced round of textworld? You do! Retrieve the coin in the balmy kitchen.

Observation: You've entered a studio. **You try to gain information on your surroundings by using a technique you call "looking."** You need an unguarded exit ? you should try going **east**. You need an unguarded exit? You should try **going south**. **You don't like doors?** Why not try going **west**, that entranceway is unblocked.
Bootstrapped Policy Action: *go south*

Figure 1: Our method retains context-relevant tokens from the observation text (shown in green) while pruning irrelevant tokens (shown in red). A second policy network re-trained on the pruned observations generalizes better by avoiding overfitting to unwanted tokens.

Traditional text-based RL methods focus on the problems of partial observability and large action spaces. However, the topic of generalization to unseen TBGs is less explored in the literature. We show that previous RL methods for TBGs often show poor generalization to unseen test games. We hypothesize that such overfitting is caused due to the presence of irrelevant tokens in the observation text, which might lead to action memorization. To alleviate this problem, we propose **CREST**, which first trains an overfitted *base* model on the original observation text in training games using Q-learning. Subsequently, we apply observation pruning for each training game, such that observation tokens that are not semantically related to the base policy's action tokens are pruned. Finally, we re-train a bootstrapped policy on the pruned observation text using Q-learning that improves generalization by removing irrelevant tokens. Figure 1 shows an

illustrative example of our method. Experimental results on TextWorld games (Côté et al., 2018) show that our proposed method generalizes to unseen games using almost 10x-20x fewer training games compared to SOTA methods; and features significantly faster learning.

2 Related Work

LSTM-DQN (Narasimhan et al., 2015) is the first work on text-based RL combining natural language representation learning and deep Q-learning. LSTM-DRQN (Yuan et al., 2018) is the state-of-the-art on TextWorld CoinCollector games, and addresses the issue of partial observability by using memory units in the action scorer. Fulda et al. (2017) proposed a method for affordance extraction via word embeddings trained on a Wikipedia corpus. AE-DQN (Action-Elimination DQN) – a combination of a Deep RL algorithm with an action eliminating network for sub-optimal actions – was proposed by Zahavy et al. (Zahavy et al., 2018). Recent methods (Adolphs and Hofmann, 2019; Ammanabrolu and Riedl, 2018; Ammanabrolu and Hausknecht, 2020; Yin and May, 2019; Adhikari et al., 2020) use various heuristics to learn better state representations for efficiently solving complex TBGs.

3 Our Method

3.1 Base model

We consider the standard sequential decision-making setting: a finite horizon Partially Observable Markov Decision Process (POMDP), represented as (s, a, r, s'), where s is the current state, s' the next state, a the current action, and $r(s, a)$ is the reward function. The agent receives state description $\boldsymbol{s}_t$ that is a combination of text describing the agent's observation and the goal statement. The action consists of a combination of verb and object output, such as "go north", "take coin", etc. The overall model has two modules: a representation generator, and an action scorer as shown in Figure 2. The observation tokens are fed to the embedding layer, which produces a sequence of vectors $\boldsymbol{x}^t = \{x_1^t, x_2^t, ..., x_{N_t}^t\}$, where N_t is the number of tokens in the observation text for time-step t. We obtain hidden representations of the input embedding vectors using an LSTM model as $h_i^t = f(x_i^t, h_{i-1}^t)$. We compute a context vector (Bahdanau et al., 2014) using attention on the j^{th} input token as,

$$e_j^t = v^T \tanh(W_h h_j^t + b_{attn}) \tag{1}$$

$$\alpha_j^t = \text{softmax}(e_j^t) \tag{2}$$

where W_h, v and b_{attn} are learnable parameters. The context vector at time-step t is computed as the weighted sum of embedding vectors as $c^t = \sum_{j=1}^{N_t} \alpha_j^t h_j^t$. The context vector is fed into the action scorer, where two multi-layer perceptrons (MLPs), $Q(s, v)$ and $Q(s, o)$ produce the Q-values over available verbs and objects from a shared MLP's output. The original works of Narasimhan et al. (2015); Yuan et al. (2018) do

Table 1: Average success rate of various methods on 20 unseen test games. Experiments were repeated on three random seeds. Our method trained on almost 20× fewer data has a similar success rate to state-of-the-art methods.

not use the attention layer. LSTM-DRQN replaces the shared MLP with an LSTM layer so that the model remembers previous states, thus addressing the partial observability in these environments.

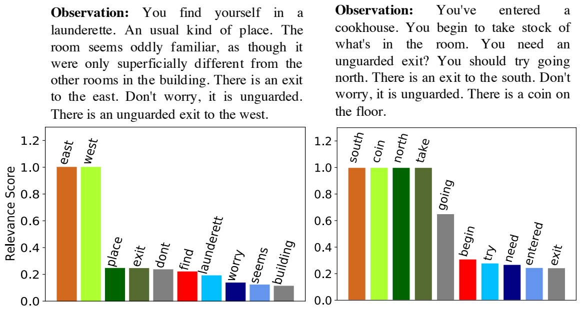
Q-learning (Watkins and Dayan, 1992; Mnih et al., 2015) is used to train the agent. The parameters of the model are updated by optimizing the following loss function obtained from the Bellman equation (Sutton et al., 1998),

$$\mathcal{L} = \left\| Q(s,a) - \mathbb{E}_{s,a}\left[r + \gamma \max_{a'} Q(s',a') \right] \right\|_2 \tag{3}$$

where $Q(s,a)$ is obtained as the average of verb and object Q-values, $\gamma \in (0,1)$ is the discount factor. The agent is given a reward of 1 from the environment on completing the objective. We also use episodic discovery bonus (Yuan et al., 2018) as a reward during training that introduces curiosity (Pathak et al., 2017) encouraging the agent to uncover unseen states for accelerated convergence.

3.2 Context Relevant Episodic State Truncation (CREST)

Traditional LSTM-DQN and LSTM-DRQN methods are trained on observation text containing irrelevant textual artifacts (like "You don't like doors?" in Figure 1), that leads to overfitting in small data regimes. Our **CREST** module removes unwanted tokens in the observation that do not contribute to decision making. Since the base policy overfits on the training games, the action commands issued by it can successfully solve the training games, thus yielding correct (observation text, action command) pairs for each step in the training games. Therefore, by only retaining tokens in the observation text that are contextually similar to the base model's action command, we can remove unwanted tokens in the observation, which might otherwise cause overfitting. Figure 2(a) shows an overview of our method.



Observation: You find yourself in a launderette. An usual kind of place. The room seems oddly familiar, as though it were only superficially different from the other rooms in the building. There is an exit to the east. Don't worry, it is unguarded. There is an unguarded exit to the west.

Observation: You've entered a cookhouse. You begin to take stock of what's in the room. You need an unguarded exit? You should try going north. There is an exit to the south. Don't worry, it is unguarded. There is a coin on the floor.

(a) Easy games (N50)

(b) Medium games (N50)

Figure 3: Ranking of context-relevant tokens from observation text by our token relevance distribution.

We use three embeddings to obtain token relevance: (1) Word2Vec (Mikolov et al., 2013); (2) Glove (Pennington et al., 2014); and (3) Conceptnet (Liu and Singh, 2004).

The distance between tokens is computed using cosine similarity, $D(\boldsymbol{a}, \boldsymbol{b})$.

Token Relevance Distribution (TRD): We run inference on the overfitted base model for each training game (indexed by k) and aggregate all the action tokens issued for that particular game as the Episodic Action Token Aggregation (EATA), $\mathcal{A}^k$. For each token w_i in a given observation text $\boldsymbol{o}_t^k$ at step t for the k^{th} game, we compute the Token Relevance Distribution (TRD), $\mathcal{C}$ as:

$$\mathcal{C}(w_i, \mathcal{A}^k) = \max_{a_j \in \mathcal{A}^k} D(w_i, a_j) \;\; \forall \, w_i \in \boldsymbol{o}_t^k, \tag{4}$$

where the i^{th} token w_i's score is computed as the maximum similarity to all tokens in $\mathcal{A}^k$. This relevance score is used to prune irrelevant tokens in the

Figure 4: Comparison of validation performance for various thresholds on (a) *easy* and (b) *medium* games, (c) Our method trained on $L15$ games and tested on $L20$ and $L25$ games significantly outperforms the previous methods.

observation text by creating a hard attention mask using a threshold value. Figure 3 presents examples of TRD's from observations highlighting which tokens are relevant for the next action. Examples of token relevance are shown in the appendix.

Bootstrapped model: The bootstrapped model is trained on the pruned observation text by removing irrelevant tokens using TRDs. The same model architecture and training methods as the base model are used. During testing, TRDs on unseen games are computed as $\mathcal{C}(w_i, \mathcal{G})$, by global aggregation of action tokens, $\mathcal{G} = \bigcup_k \mathcal{A}^k$, that combines the EATA for all training games. This approach retains all relevant action tokens to obtain the training domain information during inference, assuming similar domain distribution between training and test games.

4 Experimental Results

Setup: We used *easy*, *medium*, and *hard* modes of the Coin-collector Textworld (Côté et al., 2018; Yuan et al., 2018) framework for evaluating our model's generalization ability. The agent has to collect a *coin* that is located in a particular room. We trained each method on various numbers of training games (denoted by N#) to evaluate generalization ability from a few numbers of games.

Quantitative comparison: We compare the performance of our proposed model with LSTM-DQN (Narasimhan et al., 2015) and LSTM-DRQN (Yuan et al., 2018).

Figure 2(b) and 2(c) show the reward of various trained models, with increasing training episodes on *easy* and *medium* games. Our method shows improved out-of-sample generalization on validation games with about 10x-20x fewer training games (500 vs. $25, 50$) with accelerated training using drastically fewer training episodes compared to previous methods.

We report performance on unseen test games in Table 1. Parameters corresponding to the best validation score are used. Our method trained with $N25$ and $N50$ games for *easy* and *medium* levels respectively achieves performance similar to 500 games for SOTA methods. We perform an ablation study with and without attention in the policy network and show that the attention mechanism alone does not substantially improve generalization. We also compare the performance of various word embeddings for TRD computation and find that ConceptNet gives the best generalization performance.

Dropout: In Table 1, we also compare the performance of dropout (with probability 0.5) that randomly masks activations from the encoded state representation. We find that dropout improves performance compared to vanilla LSTM-DRQN. However, our method outperforms the model with dropout because dropout randomly drops tokens in an uninformed fashion. Our method uses a prior action token distribution from overfitted games to effectively remove irrelevant tokens.

Pruning threshold: In this experiment, we test our method's response to changing threshold values for observation pruning. Figure 4(a) and Figure 4(b) reveals that thresholds of 0.5 for easy games and 0.7 for medium games give the best validation performance. A very high threshold might remove relevant tokens, leading to failure in training, whereas a low threshold value would retain the most irrelevant tokens, leading to over-fitting.

Zero-shot transfer: In this experiment, agents

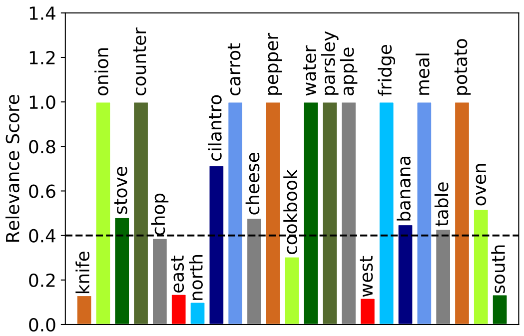

Figure 5: Token relevance scores for nouns in the test set for cooking games. The tokens having a score close to 1.0 correspond to overlaps between the train and test games. The other tokens were unseen during training. Our method can retain most tokens related to cooking using a threshold of 0.4, based on the training action token distribution obtained from an oracle.

trained on games with quest lengths of 15 rooms were tested on unseen game configurations with quest lengths of 20 and 25 rooms, respectively, without retraining, to study the zero-shot transferability of our learned agents to unseen configurations. The results in the bar charts of Figure 4(c) for $N50$ easy games show that our proposed method can generalize to unseen game configurations significantly better than previous state-of-the-art methods on the coin-collector game.

Generalizability to other games: In the above experimental section, we reported results on the coin-collector environment, where the nouns and verbs used in the train and test games have substantial overlap. We now present a discussion on our method's generalizability to other games, where the context-relevant tokens for a given game may never have occurred in any training game.

To test our method's generalizability, we performed experiments on the cooking games considered in Adolphs and Hofmann (2019). A sample observation from these games looks like this: "*You see a fridge. The fridge contains some water, a diced cilantro and a diced parsley. You wonder idly who left that here. Were you looking for an oven? Because look over there, it's an oven. Were you looking for a table? Because look over there, it's a table. The table is massive. On the table you make out a cookbook and a knife. You see a counter. However, the counter, like an empty counter, has nothing on it.*" The objective of this game is to prepare a meal by following the recipe found in the kitchen, and then eat it.

We took 20 train and 20 test games from the cooking domain, all featuring unseen items in the test observations. Training action commands were obtained from the oracle walkthrough games provided as part of the cooking world games, and not from the overfitted train games (since in this experiment we were evaluating the generalizability of the method across unseen tokens). From the training games, we obtain noun action tokens: {"onion", "potato", "parsley", "apple", "counter", "pepper", "meal", "water", "fridge", "carrot"}. Using our token relevance (TRD) method (using ConceptNet embeddings) described in Section 3.2, we obtain scores for unseen cooking related nouns during test as: {"banana": 0.45, "cheese": 0.48, "chop": 0.39, "cilantro": 0.71, "cookbook": 0.30, "knife": 0.13, "oven": 0.52, "stove": 0.48, "table": 0.43}.

Although these nouns were absent in the training action distribution, our proposed method can assign a high score to all these words (except "knife"), since they are similar in concept to the training actions. An appropriate threshold (for eg. th=0.4) can retain most tokens, as shown in Figure 5. The threshold value can be automatically tuned using validation games, as discussed in Section 4. Additionally, we believe that sampling action tokens from overfitted training games (our proposed method) instead of from an oracle (used for this result) would improve action token diversity and successfully retain more context-relevant words. Thus, assuming some overlap between training and testing knowledge domains, our method is generalizable and can reduce overfitting for RL in NLP tasks.

5 Conclusion

We present a method for improving generalization in TBGs by removing irrelevant tokens from observation texts. Our bootstrapped model – trained on the salient observation tokens – obtains generalization performance similar to SOTA methods – with 10x-20x fewer training games – due to better generalization; and shows accelerated convergence. In this paper, we have restricted our analysis to TBGs that feature similar domain distributions in train and test games. In the future, we will focus our attention on the topic of generalization in the presence of domain differences such as novel objects; and given goal statements in test games that were not seen by the agent during training.

Abstract

Pre-trained language models (e.g., BERT) have achieved significant success in various natural language processing (NLP) tasks. However, high storage and computational costs obstruct pre-trained language models to be effectively deployed on resource-constrained devices. In this paper, we propose a novel BERT distillation method based on many-to-many layer mapping, which allows each intermediate student layer to learn from any intermediate teacher layers. In this way, our model can learn from different teacher layers adaptively for various NLP tasks. In addition, we leverage Earth Mover's Distance (EMD) to compute the minimum cumulative cost that must be paid to transform knowledge from teacher network to student network. EMD enables the effective matching for many-to-many layer mapping. Furthermore, we propose a cost attention mechanism to learn the layer weights used in EMD automatically, which is supposed to further improve the model's performance and accelerate convergence time. Extensive experiments on GLUE benchmark demonstrate that our model achieves competitive performance compared to strong competitors in terms of both accuracy and model compression. For reproducibility, we release the code and data at `https://github.com/lxk00/BERT-EMD`.

1 Introduction

In recent years, pre-trained language models, such as GPT (Radford et al., 2018), BERT (Devlin et al., 2018), XL-Net (Yang et al., 2019), have been proposed and applied to many NLP tasks, yielding state-of-the-art performances. However, the promising results of the pre-trained language models come with the high costs of computation and memory in inference, which obstruct these pre-trained language models to be deployed on resource-constrained devices and real-time applications. For example, the original BERT-base model, which achieved great success in many NLP tasks, has 12 layers and about 110 millions parameters.

It is therefore critical to effectively accelerate inference time and reduce the computational workload while maintaining accuracy. This research issue has attracted increasing attention (Wang et al., 2019; Shen et al., 2019; Tang et al., 2019), of which knowledge distillation (Tang et al., 2019) is considered to be able to provide a practical way. Typically, knowledge distillation techniques train a compact and shallow student network under the guidance of a complicated larger teacher network with a teacher-student strategy (Watanabe et al., 2017). Once trained, this compact student network can be directly deployed in real-life applications.

So far, there have been several studies, such as DistilBERT (Tang et al., 2019), BERT-PKD (Sun et al., 2019), TinyBERT (Jiao et al., 2019), which attempt to compress the original BERT into a lightweight student model without performance sacrifice based on knowledge distillation. For example, BERT-PKD (Sun et al., 2019) and TinyBERT (Jiao et al., 2019) are two representative BERT compression approaches, which encourage the student model to extract knowledge from both the last layer and the intermediate layers of the teacher network.

Despite the effectiveness of previous studies, there are still several challenges for distilling comprehensive knowledge from the teacher model, which are not addressed well in prior works. **First**, existing compression methods learn one-to-one layer mapping, where each student layer is guided by only one specific teacher layer. For example, BERT-PKD uses the 2, 4, 6, 8, 10 teacher layers to guide the 1 to 5 student layers, respectively. How-

ever, these one-to-one layer mapping strategies are assigned based on empirical observations without theoretical guidance. **Second**, as revealed in (Clark et al., 2019), different BERT layers could learn different levels of linguistic knowledge. The one-to-one layer mapping strategy cannot learn an optimal, unified compressed model for different NLP tasks. In addition, most previous works do not consider the importance of each teacher layer and use the same layer weights among various tasks, which create a substantial barrier for generalizing the compressed model to different NLP tasks. Therefore, an adaptive compression model should be designed to transfer knowledge from all teacher layers dynamically and effectively for different NLP tasks.

To address the aforementioned issues, we propose a novel BERT compression approach based on many-to-many layer mapping and Earth Mover's Distance (EMD) (Rubner et al., 2000), called BERT-EMD. **First**, we design a many-to-many layer mapping strategy, where each intermediate student layer has the chance to learn from all the intermediate teacher layers. In this way, BERT-EMD can learn from different intermediate teacher layers adaptively for different NLP tasks, motivated by the intuition that different NLP tasks require different levels of linguistic knowledge contained in the intermediate layers of BERT. **Second**, to learn an optimal many-to-many layer mapping strategy, we leverage EMD to compute the minimum cumulative cost that must be paid to transform knowledge from teacher network to student network. EMD is a well-studied optimization problem and provides a suitable solution to transfer knowledge from the teacher network in a holistic fashion.

We summarize our main contributions as follows. (1) We propose a novel many-to-many layer mapping strategy for compressing the intermediate layers of BERT in an adaptive and holistic fashion. (2) We leverage EMD to formulate the distance between the teacher and student networks, and learn an optimal many-to-many layer mapping based on a solution to the well-known transportation problem. (3) We propose a cost attention mechanism to learn the layer weights used in EMD automatically, which can further improve the model's performance and accelerate convergence time. (4) Extensive experiments on GLUE tasks show that BERT-EMD achieves better performance than the state-of-the-art BERT distillation methods.

2 Related Work

Language models pre-trained on large-scale corpora can learn universal language representations, which have proven to be effective in many NLP tasks (Mikolov et al., 2013; Pennington et al., 2014; Joulin et al., 2016). Early efforts mainly focus on learning good word embeddings, such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). Although these pre-trained embeddings can capture semantic meanings of words, they are context-free and fail to capture higher-level concepts in context, such as syntactic structures and polysemous disambiguation. Subsequently, researchers have shifted attention to contextual word embeddings learning, such as ELMo (Peters et al., 2018), ULMFit (Howard and Ruder, 2018), GPT (Radford et al., 2018), BERT (Devlin et al., 2018), ENRIE (Zhang et al., 2019), XL-Net (Yang et al., 2019), RoBERTa (Liu et al., 2019). For example, Devlin et al. (2018) released the BERT-base of 110 million parameters and BERT-large of 330 million parameters, which achieved significantly better results than previous methods on GLUE tasks.

However, along with high-performance, the pre-trained language models (e.g., BERT) usually have a large number of parameters, which require a high cost of computation and memory in inference. Recently, many attempts have been made to reduce the computation overhead and model storage of pre-trained language models without performance sacrifice. Existing compression techniques can be divided into three categories: low-rank matrix factorization (Wang et al., 2019), quantization (Shen et al., 2019), and knowledge distillation (Tang et al., 2019). Next, we mainly review the related works that use knowledge distillation to compress the BERT model.

Knowledge distillation using the teacher-student strategy learns a lightweight student network under the guidance of a large and complicated teacher network. Mukherjee and Awadallah (2019) distilled BERT into an LSTM network via both hard and soft distilling methods. Sun et al. (2019) proposed the BERT-PKD model to transfer the knowledge from both the final layer and the intermediate layers of the teacher network. Jiao et al. (2019) proposed the TinyBERT model, which performed the Transformer distillation at both pre-training and fine-tuning processes. Xu et al. (2020) proposed the BERT-of-Theseus model to learn a compact student network by replacing the teacher layers with their substitutes. Sun et al. (2020) introduced the MobileBERT model, which has the same number of layers with the teacher network, but was much narrower via adopting bottleneck structures. Wang et al. (2020) distilled the self-attention module of the last Transformer layer of the teacher network.

However, the aforementioned BERT compression approaches struggle to find an optimal layer mapping between the teacher and student networks. Each student layer merely learns from a single teacher layer, which may lose rich linguistic knowledge contained in the teacher network. Different from previous methods, we propose a many-to-many layer mapping method for BERT distillation, where each intermediate student layer can learn from any intermediate teacher layers adaptively. In addition, an Earth Mover's Disepstance is applied to learn the optimal many-to-many layer mapping solution.

3 Methodology

In this section, we propose a novel BERT compression method based on many-to-many layer mapping and Earth Mover's Distance (called BERT-EMD). In addition, we also propose a cost attention mechanism to learn the layer weights used in EMD automatically.

3.1 Overview of BERT-EMD

The main idea behind BERT-EMD is to transfer knowledge from a large teacher network T (large BERT) to a small student network S (BERT-EMD). Both the student and teacher networks are implemented with an embedding layer, several Transformer layers, and a prediction layer. We assume that the teacher network has M Transformer layers and the student network has N Transformer layers. Each Transformer layer contains an attention layer and a hidden layer.

Similar to TinyBERT (Jiao et al., 2019), our method also includes three primary distillation components: the embedding-layer distillation, the Transformer distillation, and the prediction-layer distillation. Concretely, both the embedding-layer distillation and the prediction-layer distillation employ the one-to-one layer mapping as in TinyBERT and BERT-PKD, where the two student layers are guided by the corresponding teacher layers, respectively. However, different from the previous works, we propose to exploit the many-to-many layer mapping for Transformer (intermediate layers) distillation (attention-based distillation and hidden states based distillation), where each student attention layer (resp. hidden layer) can learn from any teacher attention layers (resp. hidden layers). In this way, BERT-EMD can learn from different intermediate teacher layers adaptively for different NLP tasks, motivated by the intuition that different NLP tasks require different levels of linguistic knowledge contained in the attention and hidden layers of BERT. Next, we will describe the four distillation strategies of BERT-EMD in detail.

3.2 Embedding-layer Distillation

Word embeddings are vital in NLP tasks and have been extensively studied in recent years. Better representations of words have come at the cost of huge memory footprints. Compressing embedding matrices without sacrificing model performance is essential for real-world applications. To this end, we minimize the mean squared error (MSE) between the embedding layers of the teacher and student networks:

$$\mathcal{L}_{\text{emb}} = \text{MSE}(\mathbf{E}^S \mathbf{W}_e, \mathbf{E}^T) \tag{1}$$

where the matrices $\mathbf{E}^S$ and $\mathbf{E}^T$ represent the embeddings of student and teacher networks, which have the same shape. $\mathbf{W}_e$ is a projection parameter to be learned.

3.3 Prediction-layer Distillation

The student network also learns from the probability logits provided by teacher network. We minimize the prediction-layer distillation function as:

$$\mathcal{L}_{\text{pred}} = -\text{softmax}(\mathbf{z}^{\text{T}}) \cdot \text{log\_softmax}(\mathbf{z}^{\text{S}}/\text{t}) \tag{2}$$

where $\mathbf{z}^T$ and $\mathbf{z}^S$ represent the probability logits predicted by the teacher and student, respectively. t indicates a temperature value.

3.4 Transformer Distillation with Earth Mover's Distance

Instead of imposing one-to-one layer mapping as in previous works (Sun et al., 2019; Jiao et al., 2019), our Transformer distillation approach allows many-to-many layer mapping and is capable of generalizing to various NLP tasks. The Earth Mover's Distance (EMD) is proposed to measure the dissimilarity (distance) between the teacher and student networks as the minimum cumulative cost

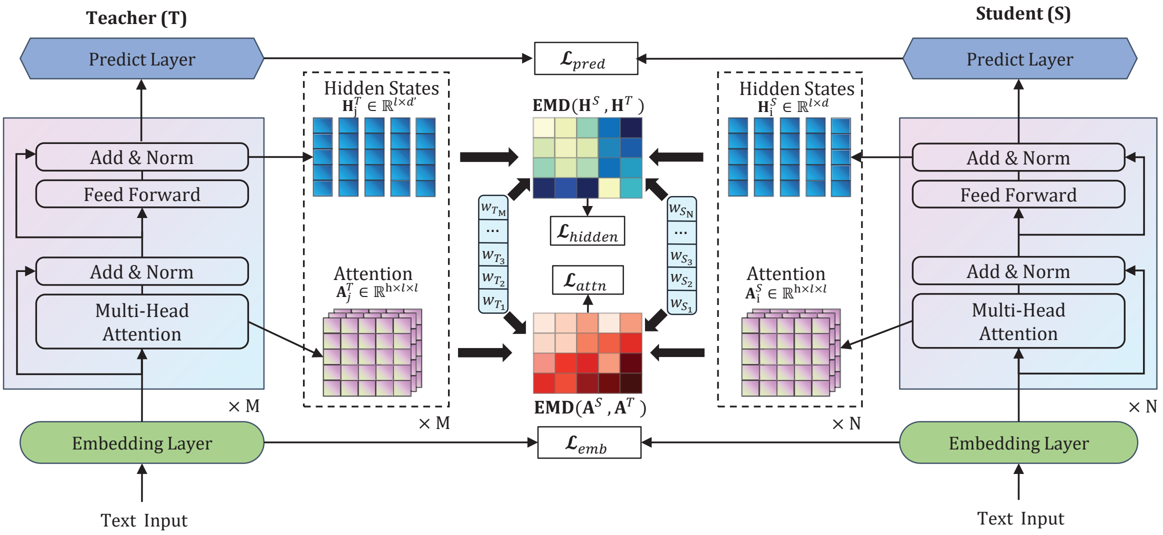

Figure 1: An overview of the proposed BERT-EMD method, which distills comprehensive knowledge from a large teacher (T) with M-layer Transformer to a small student (S) with N-layer Transformer. w_{T_i} and w_{S_j} are the weight of i-th teacher layer and j-th student layer used in EMD. Here, l denotes the length of the input sequence. h denotes the head number. d and d' are the hidden sizes of student and teacher Transformers, respectively.

of transforming knowledge from the teacher network to student network. The key insight is to view network layers as distributions, and the desired transformation should make the two distributions (teacher and student layers) close.

Attention-based Distillation We use the attention-based distillation to transform the linguistic knowledge from the teacher network to the student network based on EMD. Formally, let $\mathbf{A}^T = \{(\mathbf{A}^T_1, w^{\mathbf{A}}_{T_1}), \dots, (\mathbf{A}^T_M, w^{\mathbf{A}}_{T_M})\}$ be the teacher attention layers and $\mathbf{A}^S = \{(\mathbf{A}^S_1, w^{\mathbf{A}}_{S_1}), \dots, (\mathbf{A}^S_N, w^{\mathbf{A}}_{S_N})\}$ be the student attention layers, where M and N represent the numbers of the attention layers in the teacher and student networks, respectively. Each $\mathbf{A}^T_i$ (resp. $\mathbf{A}^S_i$) represents the i-th teacher (resp. student) attention layer and $w^{\mathbf{A}}_{T_i}$ (resp. $w^{\mathbf{A}}_{S_i}$) indicates corresponding layer weight that is initialized as $\frac{1}{M}$ (resp. $\frac{1}{N}$). We also define a "ground" distance matrix $\mathbf{D}^{\mathbf{A}} = [d^{\mathbf{A}}_{ij}]$, where $d^{\mathbf{A}}_{ij}$ represents the cost of transferring the attention knowledge from $\mathbf{A}^T_i$ to $\mathbf{A}^S_j$. Here, we use MSE to calculate the distance $d^{\mathbf{A}}_{ij}$ as:

$$d^{\mathbf{A}}_{ij} = \text{MSE}(\mathbf{A}^S_i, \mathbf{A}^T_j) \tag{3}$$

Then, we attempt to find a mapping flow $\mathbf{F}^{\mathbf{A}} = [f^{\mathbf{A}}_{ij}]$, with $f^{\mathbf{A}}_{ij}$ the mapping flow between $\mathbf{A}^T_i$ and $\mathbf{A}^S_j$, that minimizes the cumulative cost required to transform knowledge from the teacher attention layers $\mathbf{A}^T$ to the student attention layers $\mathbf{A}^S$:

$$\text{WORK}(\mathbf{A}^T, \mathbf{A}^S, \mathbf{F}^{\mathbf{A}}) = \sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{A}}_{ij} d^{\mathbf{A}}_{ij} \tag{4}$$

subject to the following constraints:

$$f^{\mathbf{A}}_{ij} \geq 0 \qquad 1 \leq i \leq M,\ 1 \leq j \leq N \tag{5}$$

$$\sum_{j=1}^{N} f^{\mathbf{A}}_{ij} \leq w^{\mathbf{A}}_{T_i} \qquad 1 \leq i \leq M \tag{6}$$

$$\sum_{i=1}^{M} f^{\mathbf{A}}_{ij} \leq w^{\mathbf{A}}_{S_j} \qquad 1 \leq j \leq N \tag{7}$$

$$\sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{A}}_{ij} = \min\Big(\sum_{i=1}^{M} w^{\mathbf{A}}_{T_i}, \sum_{j=1}^{N} w^{\mathbf{A}}_{S_j}\Big) \tag{8}$$

where the first constraint forces the mapping flow to be positive. The second constraint limits the amount of attention information that can be sent by $\mathbf{A}^T$ to their weights. The third constraint limits the attention information that can be received by $\mathbf{A}^S$. The fourth constraint limits the amount of total flow.

The above optimization is a well-studied transportation problem (Hitchcock, 1941), which can be solved by previously developed methods (Rachev, 1985). Once the optimal mapping flow $\mathbf{F}^{\mathbf{A}}$ is learned, we can define the Earth Mover's Distance as the work normalized by the total flow:

$$\text{EMD}(\mathbf{A}^S, \mathbf{A}^T) = \frac{\sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{A}}_{ij} d^{\mathbf{A}}_{ij}}{\sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{A}}_{ij}} \tag{9}$$

Finally, the objective function for the attention-based distillation can be defined by the EMD between $\mathbf{A}^T$ and $\mathbf{A}^S$:

$$\mathcal{L}_{\text{attn}} = \text{EMD}(\mathbf{A}^S, \mathbf{A}^T) \tag{10}$$

Hidden States-based Distillation Similar to attention-based distillation, we also learn the hidden layer mapping based on EMD. Formally, let $\mathbf{H}^T = \{(\mathbf{H}^T_1, w^{\mathbf{H}}_{T_1}), \ldots, (\mathbf{H}^T_M, w^{\mathbf{H}}_{T_M})\}$ be the teacher hidden layers and $\mathbf{H}^S = \{(\mathbf{H}^S_1, w^{\mathbf{H}}_{S_1}), \ldots, (\mathbf{H}^S_N, w^{\mathbf{H}}_{S_N})\}$ be the student hidden layers, where M and N represent the numbers of the hidden layers in the teacher and student networks, respectively. Each $\mathbf{H}^T_i$ represents the i-th hidden layer and $w^{\mathbf{H}}_{T_i}$ indicates corresponding layer weight that is initialized as $\frac{1}{M}$. We also define a "ground" distance matrix $\mathbf{D}^{\mathbf{H}} = [d^{\mathbf{H}}_{ij}]$, where $d^{\mathbf{H}}_{ij}$ represents the cost of transferring the hidden states knowledge from $\mathbf{H}^T_i$ to $\mathbf{H}^S_j$ and we use a learnable projection parameter as $\mathbf{W}_h$. MSE is applied to calculate the distance $d^{\mathbf{H}}_{ij}$:

$$d^{\mathbf{H}}_{ij} = \text{MSE}(\mathbf{H}^S_i \mathbf{W}_h, \mathbf{H}^T_j) \tag{11}$$

Then, a mapping flow $\mathbf{F}^{\mathbf{H}} = [f^{\mathbf{H}}_{ij}]$, with $f^{\mathbf{H}}_{ij}$ the mapping flow between $\mathbf{H}^T_i$ and $\mathbf{H}^S_j$, is learned by minimizing the cumulative cost required to transform knowledge from $\mathbf{H}^T$ to $\mathbf{H}^S$:

$$\text{WORK}(\mathbf{H}^T, \mathbf{H}^S, \mathbf{F}^{\mathbf{H}}) = \sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{H}}_{ij} d^{\mathbf{H}}_{ij} \tag{12}$$

subject to the following constraints:

$$f^{\mathbf{H}}_{ij} \geq 0 \qquad 1 \leq i \leq M, \; 1 \leq j \leq N \tag{13}$$

$$\sum_{j=1}^{N} f^{\mathbf{H}}_{ij} \leq w^{\mathbf{H}}_{T_i} \qquad 1 \leq i \leq M \tag{14}$$

$$\sum_{i=1}^{M} f^{\mathbf{H}}_{ij} \leq w^{\mathbf{H}}_{S_j} \qquad 1 \leq j \leq N \tag{15}$$

$$\sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{H}}_{ij} = \min\Big(\sum_{i}^{M} w^{\mathbf{H}}_{T_i}, \sum_{i}^{N} w^{\mathbf{H}}_{S_i}\Big) \tag{16}$$

After solving the above optimization problem, we obtain the optimal mapping flow $\mathbf{F}^{\mathbf{H}}$. The earth mover's distance can be then defined as the work normalized by the total flow:

$$\text{EMD}(\mathbf{H}^S, \mathbf{H}^T) = \frac{\sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{H}}_{ij} d^{\mathbf{H}}_{ij}}{\sum_{i=1}^{M} \sum_{j=1}^{N} f^{\mathbf{H}}_{ij}} \tag{17}$$

Finally, the objective function for the hidden states-based distillation can be defined by the earth mover's distance between $\mathbf{H}^T$ and $\mathbf{H}^S$:

$$\mathcal{L}_{\text{hidden}} = \text{EMD}(\mathbf{H}^S, \mathbf{H}^T) \tag{18}$$

3.5 Weight Update with Cost Attention

In the EMD defined in Section 3.4, each teacher layer (resp. student layer) is assigned an equal weight $w_T = \frac{1}{M}$ (resp. $w_S = \frac{1}{N}$). Since different attention and hidden layers of BERT can learn different levels of linguistic knowledge, these layers should have different weights for various NLP tasks. Therefore, we propose a cost attention mechanism to assign weights for each attention and hidden layers automatically.

The main idea behind the cost attention is to make the teacher and student Transformer networks be as close as possible. That is, we could reduce the overall cost of EMD by increasing the weights of the layers with low flow cost, while the weights of the layers with high flow cost should be decreased adaptively.

We take the weight updating process of the teacher network as an example. The cost attention mechanism can be performed by three steps after learning the optimal solution (flow matrices $\mathbf{F}^{\mathbf{A}}$ and $\mathbf{F}^{\mathbf{H}}$ in EMD). First, we learn the transferring cost between each teacher and student layers (unit transferring cost). Formally, let $\bar{C}^{\mathbf{A}}_{T_i}$ and $\bar{C}^{\mathbf{H}}_{T_i}$ be the unit transferring cost of each attention and hidden layers respectively, which can be computed as:

$$\bar{C}^{\mathbf{A}}_{T_i} = \frac{\sum_{j=1}^{N} d^{\mathbf{A}}_{ij} f^{\mathbf{A}}_{ij}}{w_{T_i}} \tag{19}$$

$$\bar{C}^{\mathbf{H}}_{T_i} = \frac{\sum_{j=1}^{N} d^{\mathbf{H}}_{ij} f^{\mathbf{H}}_{ij}}{w_{T_i}} \tag{20}$$

Second, we update the weights ($w^{\mathbf{A}}_{T_i}$ and $w^{\mathbf{H}}_{T_i}$) of the teacher attention and hidden layers based on the learned unit transferring cost. Specifically, we compute the updated weights $\bar{w}^{\mathbf{A}}_{T_i}$ and $\bar{w}^{\mathbf{H}}_{T_i}$ as the inverse ratio of the transferring costs:

$$\bar{w}^{\mathbf{A}}_{T_i} = \frac{\sum_{j=1}^{M} \bar{C}^{\mathbf{A}}_{j}}{\bar{C}^{\mathbf{A}}_{T_i}} \tag{21}$$

$$\bar{w}^{\mathbf{H}}_{T_i} = \frac{\sum_{j=1}^{M} \bar{C}^{\mathbf{H}}_{T_j}}{\bar{C}^{\mathbf{H}}_{T_i}} \tag{22}$$

Finally, we normalize the updated layer weights used in EMD via softmax, and introduce a temperature coefficient τ to smooth the results. In particular, we update weight $\bar{w_{T_i}}$ of the i-th Transformer layer used in EMD by averaging the corresponding weights of attention and hidden layers:

$$\bar{w_{T_i}} = \frac{1}{2}(\text{softmax}(\bar{w^{\mathbf{A}}_{T_i}}/\tau) + \text{softmax}(\bar{w^{\mathbf{H}}_{T_i}}/\tau)) \tag{23}$$

It is noteworthy that the learned new weights are leveraged as the constrains to optimize the EMD problem in the next batch. Specifically, we initialize the i-th teacher attention and hidden layer weights ($w^{\mathbf{A}}_{T_i}$ and $w^{\mathbf{H}}_{T_i}$) in the η-th batch with the updated weight $\bar{w_{T_i}}$ learned in the $\eta - 1$-th batch. In this way, we can further improve the performance of BERT-EMD and accelerate convergence time.

3.6 Overall Learning Objective

Finally, we combine the embedding-layer distillation, attention-based distillation, hidden states-based distillation, prediction-layer distillation objectives to form the overall knowledge distillation objective as follows:

$$\mathcal{L}_{\text{distill}} = \beta(\mathcal{L}_{\text{emb}} + \mathcal{L}_{\text{attn}} + \mathcal{L}_{\text{hidden}}) + \mathcal{L}_{\text{pred}} \tag{24}$$

where β is a factor that controls the weights of the three distillation objectives ($\mathcal{L}_{\text{emb}}$, $\mathcal{L}_{\text{attn}}$, $\mathcal{L}_{\text{hidden}}$).

4 Experimental Setup

4.1 Experimental Data

We evaluate our BERT-EMD model on the General Language Understanding Evaluation (GLUE) (Wang et al., 2018) benchmark, which is a collection of nine diverse sentence-level classification tasks. Concretely, GLUE consists of (i) Microsoft Research Paraphrase Matching (MRPC), Quora Question Pairs (QQP) and Semantic Textual Similarity Benchmark (STS-B) for paraphrase similarity matching; (ii) Stanford Sentiment Treebank (SST-2) for sentiment classification; (iii) Multi-Genre Natural Language Inference Matched (MNLI-m), Multi-Genre Natural Language Inference Mismatched (MNLI-mm), Question Natural Language Inference (QNLI) and Recognizing Textual Entailment (RTE) for natural language inference task; and (iv) the Corpus of Linguistic Acceptability (CoLA) for linguistic acceptability.

4.2 Evaluation Metrics

Following previous works (Sun et al., 2019; Jiao et al., 2019), we use classification accuracy as the evaluation metric for SST-2, MNLI-m, MNLI-mm, QNLI, and RTE datasets. For a fair comparison with TinyBERT (Jiao et al., 2019), the F1 metric is adopted for MRPC and QQP datasets, the Spearman correlation is adopted for STS-B, and the Matthew's correlation is adopted for CoLA. The results reported for the test set of GLUE are in the same format as on the official leaderboard.

4.3 Implementation Details

Similar to TinyBERT, our BERT-EMD method also contains a general distillation and a task-specific distillation. In particular, we initialize our student model with the general distillation model provided by TinyBERT [1]. The teacher model is implemented as a 12-layer BERT model ($\text{BERT}_{\text{BASE}_{12}}$), which is fine-tuned for each task to perform knowledge distillation.

We employ the grid search algorithm on the validation set to tune the hyper-parameters. Since there are many hyper-parameter combinations, we first do the grid search on β and the learning rate. Then, we fix the values of these two hyper-parameters and tune the values of the other hyper-parameters. Specifically, the batch size is 32, the learning rate is tuned from $\{5e-5, 2e-5, 1e-5\}$, the parameter t defined in Eq. (2) is tuned from $\{1, 3, 7, 10\}$, the temperature coefficient τ is tuned from $\{1, 2, 5, 10\}$, and β is tuned from $\{0.01, 0.001, 0.005\}$.

4.4 Baseline Methods

In this paper, we compare our BERT-EMD with several state-of-the-art BERT compression approaches, including the original 4/6-layer BERT models (Devlin et al., 2018), DistilBERT (Tang et al., 2019), BERT-PKD (Sun et al., 2019), TinyBERT (Jiao et al., 2019), BERT-of-Theseus (Xu et al., 2020). However, the original TinyBERT employs a data augmentation strategy in the training process, which is different from the other baseline models. For a fair comparison, we re-implement the TinyBERT model by eliminating the data augmentation strategy.

It is noteworthy that we do not compare BERT-EMD with the recent MobileBERT (Sun et al., 2020) and MiniLM (Wang et al., 2020), since

w/o EMD$_6$	84.2	71.2	70.4	84.7

Table 2: Ablation test results in terms of removing EMD (w/o EMD) and cost attention (w/o CA).

MiniLM does not report the results on the GLUE test set and the MobileBERT model employs the Transformer block with different architectures.

5 Experimental Results

5.1 Main Results

We summarize the experimental results on the GLUE test sets in Table 1. The number below each task denotes the number of training instances. Following previous works (Sun et al., 2019,?), we also report the average values of these nine tasks (the "AVE" column). From the results, we can observe that BERT-EMD substantially outperforms state-of-the-art baseline methods by a noticeable margin on most tasks.

Among all the 4-layer BERT approaches, our BERT-EMD$_4$ method achieves the best results on almost all the tasks except SST-2 and CoLA. First, BERT-EMD$_4$ achieves significantly better results than BERT$_{\text{SMALL}_4}$ on all the GLUE tasks with a large improvement of 4.48% on average. Second, BERT-EMD$_4$ also outperforms DistilBERT$_4$ and BERT-PKD$_4$ by a substantial margin, even with only 30% parameters and inference time. Furthermore, BERT-EMD$_4$ exceeds the TinyBERT model (the best competitor) by 2.3% accuracy on RTE, 2.2% F1 on MRPC, and 1.9% Spearman correlation on STS-B. This verifies the effectiveness of our BERT-EMD model in improving the performance of small BERT-based methods on various language understanding tasks.

We can observe similar trends in the 6-layer BERT models. Table 1 shows that the proposed BERT-EMD$_6$ method can effectively compress BERT$_{\text{BASE}_{12}}$ into a 6-layer BERT model without performance sacrifice. Specifically, BERT-EMD$_6$ performs better than the 12-layer BERT BERT$_{\text{BASE}_{12}}$ model on 7 out of 9 tasks, with only about 50% parameters and inference time of the original BERT$_{\text{BASE}_{12}}$ model. For example, BERT-EMD achieves a noticeable improvement of 5.3% accuracy on RTE and 1% Spearman correlation on STS-B, over the BERT$_{\text{BASE}_{12}}$ model.

5.2 Ablation Study

To verify the effectiveness of EMD and the cost attention mechanism, we perform ablation test of BERT-EMD on two large datasets (MNLI and QQP) and two small datasets (MRPC and RTE) in terms of removing EMD (denoted as w/o EMD) and cost attention (w/o CA), respectively. In particular, for the method of removing EMD, we retain the many-to-many layer mapping by simply replacing the EMD with the mean squared error when measuring the distance between the teacher and student layers.

The ablation test results are summarized in Table 2. Generally, both EMD and cost attention contribute noticeable improvement to our method. The performances decrease sharply, especially on the STS-B task, when removing the EMD module. This is within our expectation since the EMD module formulates the distance between the teacher and student networks as an optimal transport prob-

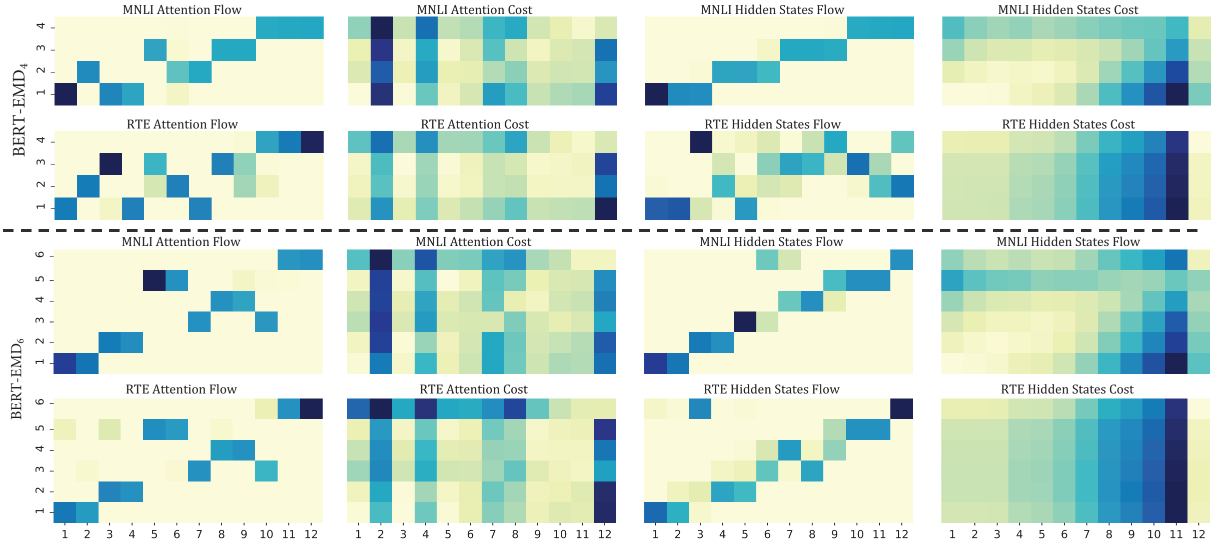

Figure 2: The visualization of flow matrices (**F**) and distance matrices (**D**) in developing BERT-EMD$_4$ (above) and BERT-EMD$_6$ (below) for two examples from MNLI and RTE tasks, respectively. The abscissa represents the Transformer layers of $\mathrm{BERT}_{\mathrm{BASE}_{12}}$, and the ordinate represents the Transformer layers of BERT-EMD$_4$/BERT-EMD$_6$. The color depth represents the values (weights) of the layers.

lem, which helps to learn an optimal many-to-many layer mapping. The cost attention also contributes to the effectiveness of BERT-EMD. This verifies that the cost attention can further improve the many-to-many layer mapping by learning the importance of each teacher layer in guiding the student network. It is noteworthy that when removing the EMD module in the many-to-many lay mapping process, our w/o EMD$_4$ performs slightly worse than TinyBERT$_4$ on the MNLI and QQP tasks. This is because we cannot automatically control the information flow during the many-to-many layer mapping without using EMD, which further verifies the effectiveness of EMD in the many-to-many layer mapping process.

5.3 Visualization of Compression Process

To better understand the many-to-many layer mapping process, we illustrate the flow matrices **F** and cost (distance) matrices **D** in developing BERT-EMD$_4$ (above) and BERT-EMD$_6$ (below) for two examples from MNLI and RTE tasks, respectively. In Figure 2, we report the averaged values of the flow and cost matrices of the entire epoch that achieves the best performance on the validation set with heat maps.

From the results in Figure 2, we have several key observations. First, different tasks could emphasize different teacher layers in compressing the Transformer. The diagonal positions of the matrices are almost always important for the MNLI task, which exhibits similar trends with TinyBERT with the one-to-one "Skip" layer mapping strategy. However, for the RTE task, each student Transformer layer can learn from any teacher Transformer layers. The previous one-to-one layer mapping methods cannot take full advantage of the teacher network. This argument can be verified by the quantitative results in Table 1, where our BERT-EMD has a much larger improvement on RTE than on MNLI over TinyBERT. Second, comparing BERT-EMD$_4$ and BERT-EMD$_6$, we can observe that BERT-EMD$_4$ usually needs to learn more comprehensive information from skipped teacher Transformer layers, resulting in more divergent many-to-many layer mappings.

6 Conclusion

In this paper, we propose a novel BERT compression method based on many-to-many layer mapping by Earth Mover's Distance (EMD). To our knowledge, BERT-EMD is the first work that allows each intermediate student layer to learn from any intermediate teacher layers adaptively. In addition, a cost attention mechanism is designed to further improve the model's performance and accelerate convergence time by learning the layer weights used in EMD automatically. Extensive experiments on GLUE tasks show that BERT-EMD can achieve competitive performances with the large BERT-Base model while significantly reducing the model size and inference time.

Abstract

Incompleteness of domain ontology and unavailability of some values are two inevitable problems of dialogue state tracking (DST). Existing approaches generally fall into two extremes: choosing models without ontology or embedding ontology in models leading to over-dependence. In this paper, we propose a new architecture to cleverly exploit ontology, which consists of Slot Attention (SA) and Value Normalization (VN), referred to as SAVN. Moreover, we supplement the annotation of supporting span for MultiWOZ 2.1, which is the shortest span in utterances to support the labeled value. SA shares knowledge between slots and utterances and only needs a simple structure to predict the supporting span. VN is designed specifically for the use of ontology, which can convert supporting spans to the values. Empirical results demonstrate that SAVN achieves the state-of-the-art joint accuracy of 54.52% on MultiWOZ 2.0 and 54.86% on MultiWOZ 2.1. Besides, we evaluate VN with incomplete ontology. The results show that even if only 30% ontology is used, VN can also contribute to our model.

1 Introduction

Dialogue state tracking (DST) is a core component in the pipeline-based task-oriented dialog systems. The goal of DST is to extract the dialogue states which are indicated by a set of *(domain, slot, value)* triples during conversation. The *(domain, slot, value)* triple represents that previous conversation involves the *slot* of the *domain* and the specific content is the *value*. For example, as shown in Figure 1, *(restaurant, price, expensive)* triple means that user wants to reserve an expensive restaurant. A high-quality DST model plays a significant role in the dialogue system, because the dialogue states determine the next system action (Chen et al., 2017).

Traditional DST approaches generally rely on ontology already defined, where all slots and their possible values are given. With a predefined ontology, DST is simplified to a classification problem. The goal is to choose the most appropriate value from ontology for the slot (Mrkšić et al., 2017; Zhong et al., 2018). However, in practical applications, a complete ontology is almost impossible to be defined in advance. To overcome the drawback, span-based (Xu and Hu, 2018; Gao et al., 2019) and generation (Wu et al., 2019) approaches spring up.

The second problem is that some values required by DST cannot be found in utterances due to the diverse descriptions during a conversation. As shown in Figure 1, value *expensive* was expressed as *high end* in the first turn. The problem gives rise to the powerlessness of span-based approaches. Recently, Zhang et al. (2019) show a dual strategy that combines the advantages of both the picklist-based and span-based methods. They use ontology in span-based approaches to deal with the problem and achieve the SOTA performance, which also shows that the ontology is powerful.

Budzianowski et al. (2018) introduced a large-scale multi-turn dialogue dataset (MultiWOZ) spanning over several domains and topics. As shown in Figure 1, the user initially wants to make a restaurant reservation, then requests information about attractions close to the restaurant, and finally books a taxi. During the conversation, the models for DST should determine whether each *(domain, slot)* pair has a value in each turn to obtain the most relevant *(domain, slot, value)* triples. However, unlike single domain DST problems, in which only a few slots need to be tracked, such as four slots in WOZ (Wen et al., 2017), there are a total of 30 *(domain, slot)* pairs of five domains in MultiWOZ, which

User	System	Dialogue state
I would like to find a high end restaurant in the center of the city.		(restaurant, price, expensive) (restaurant, area, centre)
Can i get a reservation for 7 at 14:00 this coming Friday?	There is an expensive restaurant called the Ugly Duckling.	(restaurant, price, expensive), … (restaurant, name, the Ugly Ducking), (restaurant, people, 7), (restaurant, time, 14:00), (restaurant, day, Friday)
I am also looking for some entertainment close to the restaurant.	I have successfully booked your reservation. Your reference number is ynceb914. Will this be all?	(restaurant, price, expensive), … (attraction, area, centre)
Why do not you try an architectural attraction.	Is there any type of attraction you would like me to search?	(restaurant, price, expensive), … (attraction, type, architectural)
That sounds good.	All Saints Church looks good , would you like to head there?	(restaurant, price, expensive), … (attraction, name, All Saints Church)
I also need to book a taxi between the restaurant and the church.	Is there anything else I can help you?	(restaurant, price, expensive), … (taxi, departure, the Ugly Ducking), (taxi, destination, All Saints Church)
20:00, please.	What time would you like the taxi from the Ugly Ducking?	(restaurant, price, expensive), (restaurant, area, centre), (restaurant, name, the Ugly Ducking), (restaurant, people, 7), (restaurant, time, 14:00), (restaurant, day, Friday), (attraction, area, centre), (attraction, name, All Saints Church), (taxi, departure, the Ugly Ducking), (taxi, destination, All Saints Church), (taxi, leaveAt, 20:00)

Figure 1: An example of dialogue state tracking in a conversation. Each turn contains a user utterance (left) and a system utterance (right). The blue words are supporting spans in the utterances and new *(domain, slot, value)* triples in the Dialogue state. In each turn, the DST models need to track slot values mentioned by the user for all the *(domain, slot)* pairs.

can be more in practical applications. Therefore, it requires DST models should determine the slots efficiently.

To tackle these challenges, we emphasize that DST models should optimize the structure of slots determination and utilize ontology more flexibly rather than abandon it. In this paper, we propose to divide the model of DST into Slot Attention (SA) and Value Normalization (VN). Simple and efficient processing of slots and flexible use of ontology are the main advantages of SAVN. Contributions in this work are summarized as [†]:

- SA shares knowledge between slots and utterances and is able to optimize the determination of all slots jointly. Compared to the span-based approach in DS-DST (Zhang et al., 2019), SA improves efficiency by nearly *count(slots)* times in determining the slots.
- Considering that the number of possible slot values in ontology could be large in the real scenario, VN is designed as a simple, flexible, and effective model to use an ontology, which only needs 8 minutes for training on a V100 GPU. VN can choose to directly output the supporting span from SA or select a value in the ontology.
- We supplement the annotation of supporting span for labeled values unavailable in utterances on MultiWOZ 2.1, which can help the span-based model learn semantics more fully and help ontology be better utilized.
- We fully evaluate VN with incomplete ontology. The results show that VN can gain positive performance for SAVN as long as the integrity of ontology is more than 30%. And as we expected, the more complete ontology is, the more VN can rely on it.

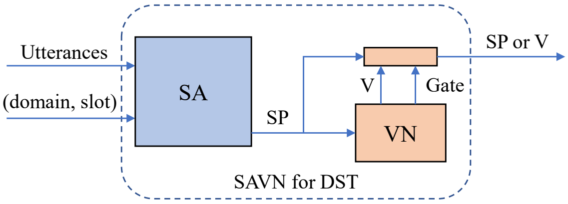

Figure 2: The overview of Slot Attention with Value Normalization for Dialogue State Tracking.

2 SAVN model

The overview of the model is shown in Figure 2, which consists of Slot Attention and Value Normalization. SA outputs the **S**upporting s**P**an (SP) from utterances for each *(domain, slot)* pair. And VN chooses to output supporting span directly or convert supporting span to the *value* in ontology according to the gate.

[†] The code will be released at `https://github.com/wyxlzsq/savn`.

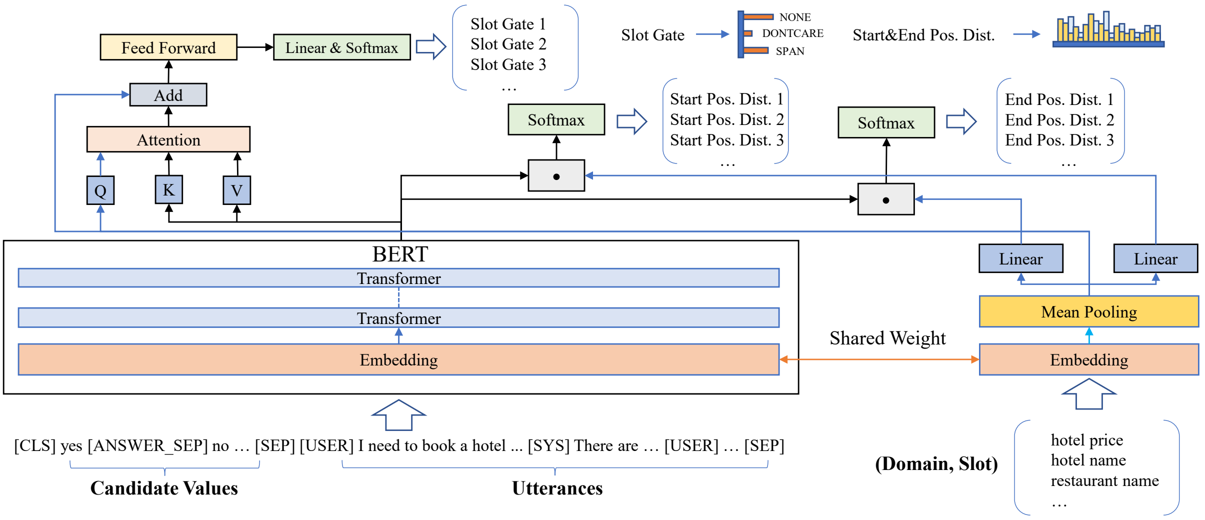

Figure 3: The model architecture of Slot Attention.

2.1 Slot Attention

As shown in Figure 3, Slot Attention (SA) accepts two inputs, one of which is the text of the previous conversations, and the other is a list of *(domain, slot)* pairs. Similar to DS-DST model (Zhang et al., 2019), we also employ BERT (Devlin et al., 2019) as the encoder for utterances. The difference is that we separate slots and utterances and share knowledge between them. Then we directly use the inner product to predict the span in utterances and use an attention module to interact with slots and utterances to classify. Benefiting from this structure, our model can determine the slots in parallel, optimize the determination jointly, and only needs to encode the utterances once for each turn while DS-DST needs to encode *count(slots)* times. Additionally, for SA to have the ability to output some special words, we added some fixed candidate values in front of the utterances such as *yes*, *no*.

Let us define $X = \{(u_1, r_1), ..., (u_n, r_n)\}$ as the set of user utterances and system responses in a conversation with n turns, $C = [a_1, a_2, ..., a_k]$ as the list of k fixed candidate values, and $S = [s_1, s_2, ..., s_j]$ as the list of j *(domain, slot)* pairs. Due to the limitation of the maximum sequence length of BERT, sometimes it is not possible to encode all utterances. Therefore, we set a parameter m to limit the number of turns entered. The input utterances for turn t should be :

$$X_t^m = \begin{cases} [U_1, ..., U_{t-1}, u_t] & \text{if } t \le m \\ [U_{t-m+1}, ..., u_t] & \text{otherwise}, \end{cases} \tag{1}$$

where U_1 represents $u_1 \oplus r_1$, the $\oplus$ means to concatenate the utterances of u_1 and r_1. r_t is the system response of turn t, so $r_t \notin X_t^m$.

Then by encoding the utterances of turn t by BERT and embedding the slots by the Embedding module of BERT, we can get the hidden states of utterances and slots as follows:

$$\begin{aligned} I &= C \oplus X_t^m, \\ H_t^u &= \text{BERT}(I), \\ E_t^s &= \text{Embedding}(S), \\ H_t^s &= \text{MeanPooling}(E_t^s), \end{aligned} \tag{2}$$

where $H_t^u \in \mathbb{R}^{p \times h}$ and $H_t^s \in \mathbb{R}^{q \times h}$. p is the sequence length of I, q is the number of *(domain, slot)* pairs and h is the dimension of the BERT hidden state.

2.1.1 Slot Gate Classification

As introduced in Section 1, There are many *(domain, slot)* pairs in Multi-domain DST problem, which make it more challenging than single-domain DST problem. Similar to TRADE model (Wu et al., 2019), we design a classification module with *none*, *dontcare* and *span* as a slot gate. For each *(domain, slot)* pair, if the slot gate predicts *none* or *dontcare*, we ignore the span predicted from utterances and fill the pair with “none” or “do not care”.

The module to classify slots is similar to a Transformer (Vaswani et al., 2017) block. We employ the “Scaled Dot-Product Attention” to get an utterances-aware slot representation A_u^s:

$$\begin{aligned} Q_t &= H_t^s \cdot W_q + b_q, \\ K_t &= H_t^u \cdot W_k + b_k, \\ V_t &= H_t^u \cdot W_v + b_v, \\ A_u^s &= \text{Softmax}(\frac{Q_t {K_t}^T}{\sqrt{d_k}})V_t, \end{aligned} \tag{3}$$

where $A_u^s \in \mathbb{R}^{q \times h}$.

Then in order to better integrate the states of slots and utterances, we add A_u^s and H_t^s to get H_c as the features to classify:

$$\begin{aligned} H_c' &= \text{GELU}(H_c \cdot W_c + b_c), \\ G_t &= \text{Softmax}(H_c' \cdot W_l + b_l) \in \mathbb{R}^{q \times 3}, \end{aligned} \tag{4}$$

where G_t is the slot gates of all *(domain, slot)* pairs at turn t.

2.1.2 Span-Based Value Prediction

For each *(domain, slot)* triple, span-based methods obtain the *value* by predicting a span with start and end position in utterances. In order to make the slot determination more efficient, we simplify the structure of span-based predictions. We can get the span predictions by:

$$\begin{aligned} D_t^s &= H_t^s \cdot W_s + b_s, \\ D_t^e &= H_t^s \cdot W_e + b_e, \\ P_t^s &= \text{Softmax}(D_t^s \cdot (H_t^u)^T) \in \mathbb{R}^{q \times p}, \\ P_t^e &= \text{Softmax}(D_t^e \cdot (H_t^u)^T) \in \mathbb{R}^{q \times p}, \end{aligned} \tag{5}$$

where P_t^s and P_t^e are the start position distributions and end position distributions of all *(domain, slot)* pairs at turn t respectively.

2.1.3 Optimization

We can optimize all slots determination jointly. The joint losses at turn t are as follows:

$$\begin{aligned} L_g &= \sum_{q=1}^{Q} -\log(G_q \cdot (y_q^g)^T), \\ L_s &= \sum_{q=1}^{Q} -\log(P_q^s \cdot (y_q^s)^T), \end{aligned} \tag{6}$$

where L_g is the loss of the slot gate predictions, L_s and L_e are the loss of the start and end position predictions respectively. And Q is the number of *(domain, slot)* pairs, y is the true one-hot label.

Similar to L_s, we can get the end loss L_e. Then we optimize the weighted-sum of these three loss functions using hyper-parameters α and β,

$$L = \alpha L_g + \beta(L_s + L_e). \tag{7}$$

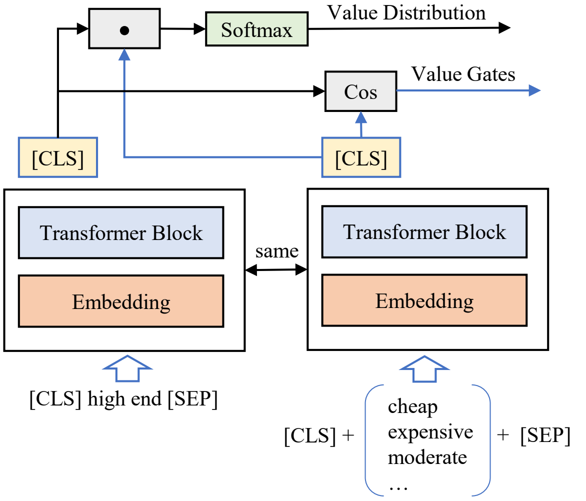

Figure 4: The model architecture of Value Normalization.

2.2 Value Normalization

Value Normalization is a flexible module for utilizing ontology, which can also be combined with other DST models. Considering that there are numerous possible values in the ontology and few data for training, we design a simple and effective model for VN, which can also benefit from the pre-trained BERT model.

As shown in Figure 4, VN is designed with one layer of the transformer block, which we call VN^1. By analogy, we can get VN^4 and VN^{12} (i.e., use BERT-base model as encoder). The model will load parameters from the corresponding layers of BERT. In Section 4.2, the experimental results show that VN^1 has done well enough for the MultiWOZ dataset.

Let us define T_0 is the hidden state of the first token ([CLS]) after transformer. Then we use $T_0^s \in \mathbb{R}^h$ as the hidden state of the supporting span after encoding and $T_0^o \in \mathbb{R}^{n \times h}$ as the hidden states of n possible values in ontology for the corresponding *(domain, slot)* pair. We use the inner products of the supporting span and the possible values as the matching scores, which is defined as:

$$M = \text{Softmax}(T_0^s \cdot (T_0^o)^T) \in \mathbb{R}^n. \tag{8}$$

Then we can get the max matching value. In addition, we employ the cosine similarity as the value gate since the ontology may be incomplete.

$$cos(T_0^{V^m}, T_0^s) = \frac{T_0^{V^m} \cdot (T_0^s)^T}{\|T_0^{V^m}\| \|(T_0^s)^T\|}, \tag{9}$$

	Labeled Value	**Supporting Span**

Table 1: Some examples of supporting span annotation.

the final output is:

$$\text{output} = \begin{cases} V^m & cos(T_0^{V^m}, T_0^s) > \theta \\ \text{SP} & cos(T_0^{V^m}, T_0^s) \le \theta, \end{cases} \quad (10)$$

where V^m is the max matching value, SP is the supporting span and θ is a hyper-parameter.

Our loss function for optimizing VN is defined as follows:

$$L_i = \begin{cases} -\log(M \cdot (y^v)^T) & r = 1 \\ \max(cos(T_0^o, T_0^s)) + 1 & r = 0, \end{cases} \quad (11)$$

where y^v is the true one-hot label and $r = 1$ means the value for the supporting span is in ontology. However, r will always be equal to 1 without preprocessing in training because ontology is invariably complete for the training set. In our experiments, we employ full training set to train VN with incomplete ontology in order to get dispersed vector representations for values.

3 Annotation for Supporting Span

Our annotation work is based on the MultiWOZ 2.1 dataset (Eric et al., 2019), which is a fixed version of the MultiWOZ 2.0 dataset (Budzianowski et al., 2018). MultiWOZ 2.1 dataset is a large-scale collection of human-human written conversations over multiple domains and topics, which has labeled 63,662 *(conversation, domain, slot, value)* quadruples (except “none” value) in the training set.

Annotation for supporting span is mainly to address the problem that some labeled value can not be found in the conversations. The causes of this problem can be divided into three categories: varied expressions, spelling mistakes, and annotation errors.

The criterion of annotations is to find the shortest span in the conversations, which can help us get the labeled value. Based on the criterion, we annotate 936 *(supporting span, value)* pairs on MultiWOZ 2.1 training set, in which varied expressions account for 637 (68%), spelling mistakes account for 123 (13%), and annotation errors account for 176 (19%). Table 1 shows some examples of supporting span annotation.

After annotation, we can change *(domain, slot, value)* triples in training set to *(domain, slot, supporting span, value)* quadruples, where the *supporting span* will be equal to the *value* if the *value* can be found in the conversations. Then we employ *(domain, slot, supporting span)* triples to train SA and *(supporting span, value)* pairs to train VN. Specifically, we do not use the annotation of annotation errors to train VN, for it should not convert Saturday to Sunday.

4 Experiments

We evaluate our model on two publicly available datasets: MultiWOZ 2.0 and MultiWOZ 2.1, both of which are fully-labeled task-oriented corpora comprised of human-human written conversations and contain 8,438 multi-turn dialogues with each dialogue having 13.68 turns on average in training set (Budzianowski et al., 2018). The difference between MultiWOZ 2.0 and MultiWOZ 2.1 is that MultiWOZ 2.1 has changed more than 32% of state annotations across 40% of the dialogue turns to fix the noisy state annotations in MultiWOZ 2.0 (Eric et al., 2019).

Following previous work (Wu et al., 2019), only five domains (i.e., restaurant, hotel, attraction, taxi, and train) are employed in our experiments because the dialogues that belong to the other two domains (i.e., hospital and police) are rare in the training set and do not appear in the test set. As introduced in Section 3, we get a new training set by using the supporting span annotations, which can be called the SP training set. Additionally, there are no changes to the test set and the dev set.

4.1 Training Details

We use the pre-trained BERT-base-uncased model as the utterance encoder in SA, which has 12 hid-

den layers with 768 units. For the limitation of the maximum sequence length, We set m (in equation 1) to 9. If the current conversation turn exceeds m, we will combine the predicted dialogue states with the previous dialogue states to complete dialogue states for the current turn.

In our experiments, SA and VN are both trained with Adam optimizer (Kingma and Ba, 2014) in which the learning rate linearly decreases from $5e^{-5}$ and $1e^{-4}$, respectively. We have trained SA with 3 epochs and VN with 5 epochs both on MultiWOZ 2.0 and MultiWOZ 2.1. Specifically for VN, we train VN^1 and VN^{12} (introduced in Section 2.2) to compare their performance.

Our results can be reproduced with a 16 GB V100 GPU in 2 hours (8 minutes for VN^1).

4.2 Results

Two standard metrics, joint accuracy and slot accuracy, can be employed to evaluate the performance of our model. Joint accuracy is the accuracy of dialogue states, which requires that all *(domain, slot, value)* triples in the dialogue states are predicted correctly. And slot accuracy is the accuracy of *(domain, slot, value)* triples, which requires that the predicted value of *(domain, slot)* pair is predicted correctly. The joint accuracy is a more challenging metric, for there is a considerable number of *(domain, slot)* pairs in dialogue states.

To better evaluate the role of supporting spans, we have trained two versions of SA, one of which utilizes the original training set called SA$_{raw}$ and the other employs the SP training set called SA$_{sp}$. And we make a comparison with the following existing models:

- GLAD (Zhong et al., 2018) shares parameters among slots by virtue of global modules and applies the local modules to learn slot-specific features.
- Neural Reading (Gao et al., 2019) formulates DST as a reading comprehension task. The model encodes the word tokens by a pre-trained BERT model, then obtains the contextual representation by LSTM.
- SUMBT (Lee et al., 2019) learns the slot and utterance representations by fine-tuning a pre-trained BERT model. Then they compute the similarity between possible values and utterances via a slot-utterance matching module.
- TRADE (Wu et al., 2019) employs an encoder-decoder architecture to generate the values for slots from the vocabulary and the dialogue history.
- DSTQA (Zhou and Small, 2019) models DST as a question answering problem, which generates a question to ask for the value of the slot at each turn.
- DS-DST (Zhang et al., 2019) proposes a Dual Strategy to combine the advantages of the picklist-based and span-based methods, which has been evaluated individually as DST-Picklist and DST-Span.

On MultiWOZ 2.0, as shown in Table 2, our model achieves the highest performance, 54.52% of joint accuracy in which VN gains 6.08% absolute improvement. And on MultiWOZ 2.1, as shown in Table 3, our model also achieves the highest performance, 54.86% of joint accuracy in which

θ	**10%**	**20%**	**30%**	**40%**	**50%**	**60%**	**70%**	**80%**	**90%**	**100%**

Table 4: The performance of SAVN with incomplete ontology on MultiWOZ 2.1. The percentage in the header refers to the usage rate of ontology and the θ is introduced in Equation 10.

VN gains 9.12% absolute improvement. Combining results from two tables, we demonstrate that the performance of SA is similar to TRADE and SA has about 5% higher absolute performance than DST-span, which is also a span-based method using BERT.

Comparing SA_{raw} with SA_{sp}, we find that their performance is similar without VN and the improvement of SA_{sp} performance is obviously greater than that of SA_{raw} by VN, which shows that SA_{sp} has learned more about semantics so that it could output the supporting span and can be better combined with VN. Furthermore, by comparing VN^1 with VN^{12}, we prove that VN has enough performance for the MultiWOZ dataset with only one transformer layer.

4.3 Incomplete Ontology

The experimental results in Table 2 and Table 3 show that ontology is a powerful resource for DST. However, it is impractical to get a full ontology in advance when the DST model is oriented to practical applications, which leads some models, such as TRADE, to abandon ontology. In this section, We choose SA_{sp} on MultiWOZ 2.1 as the base model to evaluate the performance of VN^1 with incomplete ontology.

There are many slots in the ontology. We can divide them into two categories, common-value slots and special-value slots. Common-value slots, such as *hotel-price* and *hotel-type*, are able to include all possible values as long as a few values are given. And for special-value slots, such as *restaurant-name* and *taxi-departure*, it is difficult to cover all possible values by predefined values. In our experiment, we only drop out values in special-value slots and always keep all values of common-value slots.

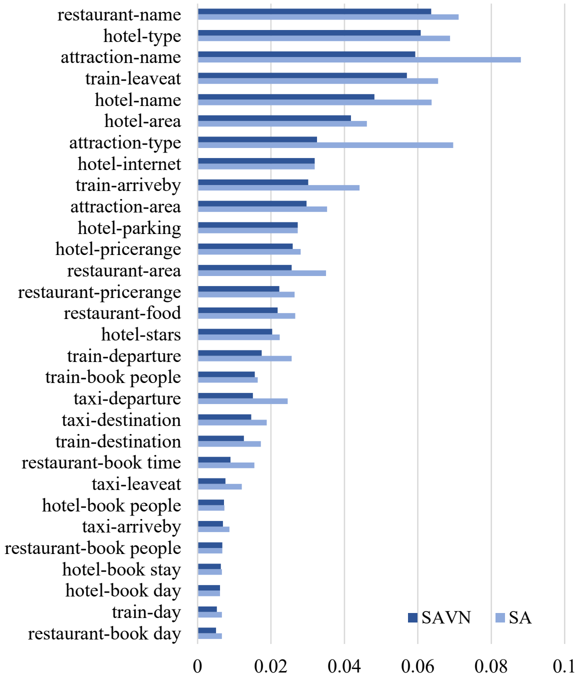

Figure 5: The error rate of slots on MultiWOZ 2.1.

The results are shown in Table 4. Even if there is only 30% ontology, VN can bring positive performance as long as θ is appropriate. Based on the results, we demonstrate that the performance of VN has steadily improved with the increased usage rate of ontology. Furthermore, the more complete ontology is, the smaller θ can be, which means VN can be more dependent on ontology.

5 Error Analysis

An error analysis of SA_{sp} with VN^1 on MultiWOZ 2.1 is shown in Figure 5. The three slots with the highest error rates are *restaurant-name* with 6.37%, *hotel-type* with 6.08% and *attraction-name* with 5.93%. Through the detailed analysis of error samples, we observe many labeled states do not include the name that only appears in system response. These states are similar to the example in Figure 1 with the restaurant-name and attraction-name removed. Once the difference occurs, it will lead to errors in the subsequent dialogue states, resulting in high error rates. And the labels of *hotel-type* are found to be confusing. For instance, for the sentence "I am looking for a hotel with ...", sometimes the label of *hotel-type* is *hotel* and sometimes it is *none*.

Compared with SA, SAVN has significantly lower error rates on *attraction-type* and *attraction-name*. The improvement of *attraction-name* is mainly due to the repair of spelling mistakes, and the improvement of *attraction-type* mainly benefits from the normalization of varied expressions. It is worth mentioning that VN can not improve the accuracy of some slots, which only need to be filled with *yes* or *no*, such as *hotel-internet* and *hotel-parking*.

6 Related Work

Traditional dialogue state tracking models extract utterance semantics by hand-crafted features and complex domain-specific lexicons (Wang and Lemon, 2013; Williams, 2014; Henderson et al., 2014) to predict the dialogue states, which is hard to adapt to new domains. Then, to overcome this drawback, Mrkšić et al. (2017) propose a novel Neural Belief Tracking (NBT) framework with learning n-gram representation of utterance by using a convolutional neural network, and achieve better performance. At the same time, Models for multi-domain DST have then been proposed. Rastogi et al. (2017) build a multi-domain DST model by two-layer bi-GRU and Ramadan et al. (2018) track domain and the dialogue states jointly through multiple bi-LSTM. They employ semantic similarity between utterances and the values in ontology and allow the knowledge to be shared across domains. To transfer knowledge between slots, Zhong et al. (2018) propose a global-local architecture to share parameters among slots and Ren et al. (2018) propose StateNet that shares all parameters among slots and fix the word embeddings during training to handle new slots.

After the pre-trained BERT model showed superior performance, encoding by BERT has become the mainstream. Lee et al. (2019) encode the slots and utterances with BERT, and then compute the similarity between possible values and utterances after a Multi-head attention layer. And Zhang et al. (2019) also employ BERT to encode the utterances. The difference is that they combine the picklist-based and span-based methods and get higher performance. In order to eliminate the dependence on ontology, Wu et al. (2019) propose an encoder-decoder architecture with a pointer network to generate the value for each slot. And Zhou and Small (2019) formulate multi-domain DST as a question answering problem and learn relationships between slots by a dynamically-evolving knowledge graph. Most recently, Heck et al. (2020) propose to use copy mechanisms to fill slots with values, which combine span-based methods with memory methods to avoid the use of value picklists.

7 Conclusion

We introduce a new architecture that divides the prediction of slots and the use of ontology. SA shares parameters not only among all slots but also between slots and utterances. And VN can handle ontology flexibly with a simple and effective structure, which is able to work with incomplete ontology. Combining SA with VN, SAVN has shown excellent performance on both MultiWOZ 2.0 and MultiWOZ 2.1. And we also introduce the annotation of supporting span. In future work, the supporting span annotation can be added to the datasets of a task-oriented dialog system, for the reason that supporting span serves as a bridge between diverse descriptions of users and the normative values in the system. Furthermore, DST models with supporting span allow for a fairer comparison regardless of whether the ontology is used.

Abstract

Most approaches to Open-Domain Question Answering consist of a light-weight retriever that selects a set of candidate passages, and a computationally expensive reader that examines the passages to identify the correct answer. Previous works have shown that as the number of retrieved passages increases, so does the performance of the reader. However, they assume all retrieved passages are of equal importance and allocate the same amount of computation to them, leading to a substantial increase in computational cost. To reduce this cost, we propose the use of *adaptive computation* to control the computational budget allocated for the passages to be read. We first introduce a technique operating on individual passages in isolation which relies on anytime prediction and a per-layer estimation of an early exit probability. We then introduce SKYLINEBUILDER, an approach for dynamically deciding on which passage to allocate computation at each step, based on a resource allocation policy trained via reinforcement learning. Our results on SQuAD-Open show that adaptive computation with global prioritisation improves over several strong static and adaptive methods, leading to a 4.3x reduction in computation while retaining 95% performance of the full model.

1 Introduction

Open-Domain Question Answering (ODQA) requires a system to answer questions using a large collection of documents as the information source. In contrast to context-based machine comprehension, where models are to extract answers from single paragraphs or documents, it poses a fundamental technical challenge in *machine reading at scale* (Chen et al., 2017) .

Most ODQA systems consist of two-stage pipelines, where *1*) a context retriever such as BM25 (Robertson, 2004) or DPR (Karpukhin et al., 2020) first selects a small subset of passages that are likely to contain the answer to the question, and *2*) a machine reader such as BERT (Devlin et al., 2019) then examines the retrieved contexts to extract the answer. This two-stage process leads to a computational trade-off that is indicated in Fig. 1. We can run computationally expensive deep networks on a large number of passages to increase the probability that we find the right answer ("All Layers, All Passages"), or cut the number of passages and layers to reduce the computational footprint at the possible cost of missing an answer ("6 Layers, Top-2 Passages").

We hypothesise that a better accuracy-efficiency trade-off can be found if the computational budget is not allocated statically, but based on the complexity of each passage, see "Adaptive Computation" in Fig. 1. If a passage is likely to contain the answer, allocate more computation. If it isn't, allocate less. The idea of conditioning neural network computation based on inputs has been pursued in previous work on *Adaptive Computation* (Bengio et al., 2015; Graves, 2016; Elbayad et al., 2020), however how to apply this idea to ODQA is still an open research question.

In this work, we introduce two adaptive computation methods for ODQA: TOWERBUILDER and SKYLINEBUILDER. TOWERBUILDER builds a *tower*, a composition of transformer layers on a single passage, until an early stopping condition is met—we find that this method already helps reducing the computational cost required for reading the retrieved passages. Then, for coordinating the construction of multiple towers in parallel, we introduce a global method, SKYLINEBUILDER, that incrementally builds multiple towers one layer at a time and learns a policy to decide which tower to extend one more layer next. Rather than building single transformer towers in isolation, it constructs

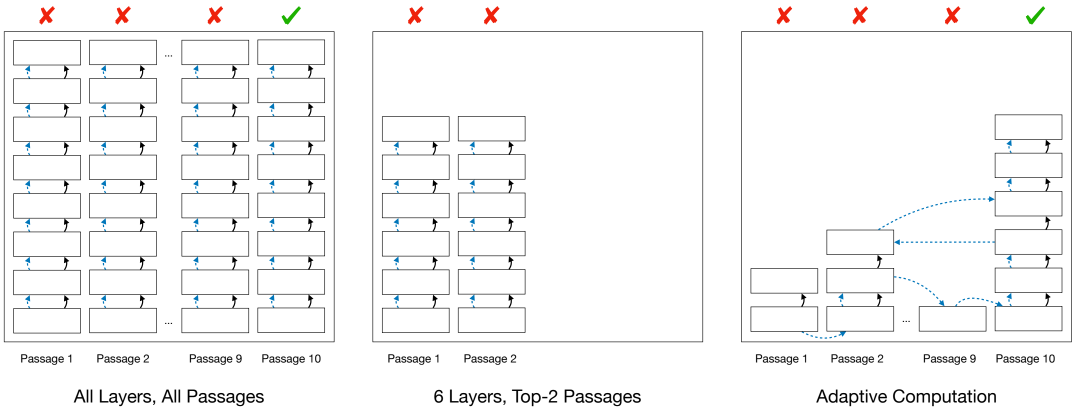

Figure 1: Static and adaptive computation for Open-Domain QA. Each block represents one layer of transformer computation on a passage. The solid arrows show how activations flow, and the dashed arrows indicate the order of computation. Only passage 10 contains the actual answer. Using all layers on all passages can find the answer, while processing only the top 2 retrieved passages with 6 layers is unable to find it. Adaptive computation can find the right passage, and allocates most computation budget to reading it.

a *skyline* of towers with different heights, based on which passages seem most promising to process further.

Our experiments on the SQuAD-Open dataset show that our methods are very effective at reducing the computational footprint of ODQA models. In particular, we find that SKYLINEBUILDER retains 95% of the accuracy of a 24-layer model using only 5.6 layers on average. In comparison, an adaptation of the method proposed by Schwartz et al. (2020) requires 9 layers for achieving the same results. Improvements are even more substantial for smaller number of layers—for example, with an average of 3 layers SKYLINEBUILDER reaches 89% of the full performance, whereas the approach of Schwartz et al. (2020) yields 57% and a model trained to use exactly 3 layers reaches 65%. Finally, SKYLINEBUILDER retains nearly the same accuracy at full layer count.

To summarise, we make the following contributions: *1)* we are the first to explore adaptive computation for ODQA by proposing two models: TOWERBUILDER and SKYLINEBUILDER; *2)* we experimentally show that both methods can be used for adaptively allocating computational resources so to retain the predictive accuracy with a significantly lower cost, and that coordinating the building of multiple towers via a learned policy yields more accurate results; *3)* when compared to their non-adaptive counterparts, our proposed methods can reduce the amount of computation by as much as 4.3 times.

2 Background

We first give an overview of ODQA and the relevant work in adaptive computation.

2.1 Open Domain Question Answering

In ODQA we are given a natural language query $\mathbf{q}$ and a large number of passages C—for example, all paragraphs in Wikipedia. The goal is to use C to produce the answer $\mathbf{y}$. In extractive ODQA this answer corresponds to a span in one of the documents of C. The corpus C can be very large, and a common approach to reduce computational costs is to first determine a smaller document set $D_{\mathbf{q}} \subseteq C$ by retrieving the most relevant n passages using an information retrieval module. Then we run a neural reader model on this subset. In most works, the reader model extracts answers by applying a per-passage reader to each input passage $\mathbf{x}_1, \ldots, \mathbf{x}_n \in D_{\mathbf{q}}$ and then apply some form of aggregation function on the per-passage answers to produce a final answer. Note that the passage reader can either produce an answer span as output, or $\mathrm{NoAnswer}$ in case the passage does not contain an answer for the given question.

2.2 Transformers for ODQA

Most current ODQA models rely on transformer-based architectures (Vaswani et al., 2017), usually pre-trained, to implement the $\mathrm{PReader}$ passage reader interface. In such models, an input passage is processed via a sequence of transformer layers; in the following, we denote the i-th transformer layer in the sequence as $\mathrm{TransformerLayer}_i$. Let

$\mathbf{h}_i$ be the input to the i-th transformer layer and $\mathbf{h}_{i+1} = \mathrm{TransformerLayer}_i(\mathbf{h}_i)$ its output. We set $\mathbf{h}_1 = \mathbf{x}$ to be the input passage. In standard non-adaptive Transformer-based models, we incrementally build a *tower*—a composition of Transformer layers—until we reach some pre-defined height n and use an output layer to produces the final output, $\mathbf{y} = \mathrm{OutputLayer}(\mathbf{h}_n)$. In this work, due to efficiency reasons, we restrict ourselves to pre-trained ALBERT (Lan et al., 2020) models. One critical property of these models is parameter tying across layers: $\mathrm{TransformerLayer}_i(\mathbf{h}) = \mathrm{TransformerLayer}_j(\mathbf{h})$ for any i, j.

2.3 Adaptive Computation

Our goal is to early-exit the iterative layer-by-layer process in order to save computation. We assume this can be happening adaptively, based on the input, since some passages might require less computation to produce an answer than others. Schwartz et al. (2020) show how this can be achieved for classification tasks. They first require internal layers to be able to produce outputs too, yielding an *anytime* algorithm. [1] This can be achieved with a suitable training objective. Next, for each candidate layer i, they calculate the exit probability given its hidden state $\mathbf{h}_i$, and use them for taking an early-exit decision: if the highest exit probability is above a global threshold τ, they return $\mathrm{OutputLayer}(\mathbf{h}_i)$ otherwise they continue with the following layers.

The output layer probabilities are not calibrated for exit decisions, and hence Schwartz et al. (2020) tune them on an held-out validation set via temperature calibration (Guo et al., 2017; Desai and Durrett, 2020), where a temperature T is tuned to adapt the softmax output probabilities at each layer.

3 Adaptive Computation in ODQA

Our goal is to incrementally build up towers of transformer layers for all passages in $D_{\mathbf{q}}$ in a way that minimises unnecessary computation. Our algorithms maintain a state, or *skyline*, $S = (H, A)$, consisting of current tower heights $H = (h_1, \ldots, h_n)$, indicating how many layers have been processed for each of the n towers, and the last representations $A = (\mathbf{a}_1, \ldots, \mathbf{a}_n)$ computed for each of the towers. We want to build up the skyline so that we reach an accurate solution fast and then stop processing.

3.1 Early Exit with Local Exit Probabilities

Our first proposal is to extend the method from Schwartz et al. (2020) in order to build up the skyline S. In particular, we will process each passage $\mathbf{x}_i \in D_{\mathbf{q}}$ in isolation, building up height h_i and representation $\mathbf{a}_i$ until an *exit probability* reaches a threshold. For Schwartz et al. (2020) the exit probability is set to be the probability of the most likely class. While ODQA is not a classification problem per se, it requires solving one as a sub-step, either explicitly or implicitly: deciding whether a passage contains the answer. In turn, our first method TOWERBUILDER, uses the probability $1 - \mathrm{HasAnswer}(\mathbf{a}_i)$ of the passage not containing the answer to calculate the exit probability at such given layer. In practice the probability $\mathrm{HasAnswer}(\mathbf{a}_i)$ is calculated as the $\mathrm{Sigmoid}$ output of an MLP applied the representation of the CLS token in $\mathbf{a}_i$. Moreover, models are trained to produce $\mathrm{HasAnswer}$ probabilities for each layer using a per-layer loss. Following Schwartz et al. (2020), we also conduct temperature calibration for the $\mathrm{HasAnswer}$ modules using the development set.

When building up the towers, TOWERBUILDER produces early exit decisions for each tower in isolation. Once all towers have been processed, the method selects the highest m towers in the final S^* to produce the final answer, where m is a hyperparameter. Since some of the selected towers in S^* may not have full height, we will need to continue unrolling them to full height to produce an answer. We will call this the $\mathrm{LastLayer}$ strategy. Alternatively, we can return the solution at the current height, provided that we use an anytime model not just for $\mathrm{HasAnswer}$ predictions but also for answer extraction. We will refer to this strategy as $\mathrm{AnyLayer}$. By default we use $\mathrm{LastLayer}$ but we will conduct ablation study of these two approaches in Section 5.3.

3.2 Global Scheduling

We can apply TOWERBUILDER independently to each passage $\mathbf{x}_i \in D_{\mathbf{q}}$. However, if we have already found an answer after building up one tower for a passage $\mathbf{x}_i$, we can avoid reading other passages. Generally, we imagine that towers that are more likely to produce the answers should be processed first and get more layers allocated to. To

---

[1] In practice, Schwartz et al. (2020) choose a subset of layers to be candidate output layers, so strictly speaking we cannot exit any time, but only when a candidate layer is reached.

assess if one tower is more likely to contain an answer, we need to compare them and decide which tower has highest *priority*. This type of strategy cannot be followed when processing passages in isolation, and hence we consider a global multi-passage view.

A simple approach for operating on multiple passages is to re-use information provided to the TOWERBUILDER method and select the next tower to extend using the HasAnswer probabilities. In particular, we can choose the next tower to build up as $j = \arg\max_i \text{HasAnswer}(\mathbf{a}_i)$, and then set $\mathbf{a}_j \leftarrow \text{TransformerLayer}(\mathbf{a}_j)$ and $h_j \leftarrow h_j + 1$ in the state S. To efficiently implement this strategy we use a priority queue. Every time a tower is expanded, its HasAnswer probability is re-calculated and used in a priority queue we choose the next tower from. Once we reach the limit of our computation budget, we can stop the reading process and return the results of the highest m towers S^* as inputs to its Output phase. The two aforementioned answer extraction methods (i.e., AnyLayer and LastLayer) also apply to this method.

3.3 Learning a Global Scheduler

Using HasAnswer probabilities to prioritise towers is a sensible first step, but not necessarily optimal. First, while the probabilities are calibrated, they are tuned for optimising the negative log-likelihood, not the actual performance of the method. Second, the HasAnswer probability might not capture everything we need to know about the towers in order to make decisions. For example, it might be important to understand what the rank of the tower's passage is in the retrieval result, as higher ranked passages might be more fruitful to expand. Finally, the HasAnswer probabilities are not learnt with the global competition of priorities across all towers, so they are not optimal for comparing priorities between towers that have different heights.

To overcome the above issues, we frame the tower selection process as a reinforcement learning (RL) problem: we consider each tower $i \in \{1, \ldots, n\}$ as a candidate action, and learn a policy $\pi(i|S)$ that determines which tower to expand next based on the current skyline. We present the corresponding details below.

3.3.1 Policy

Our policy calculates $\pi(i|S)$ using a priority vector $\mathbf{p}(S) \in \mathbb{R}^n$. The priority $p_i(S)$ of each tower i is calculated using a linear combination of the HasAnswer probability of that tower and the output of a multi-layer perceptron MLP_θ. The perceptron is parametrised by θ and uses a feature representation $\mathbf{f}_i(S)$ of tower i in state S as input. Concretely, we have:

$$p_i(S) = \alpha \text{HasAnswer}(\mathbf{a}_i) + \text{MLP}_\theta(\mathbf{f}_i(S))$$

where α is a learnable mixture weight. As feature representation we use $\mathbf{f}_i(S) = [\text{HeightEmb}(h_i), \text{IndexEmb}(i), \text{HasAnswer}(\mathbf{a}_i)]$ where the tower height h_i and index i are represented using embedding matrices $\text{HeightEmb} \in \mathbb{R}^{l \times d}$ and $\text{IndexEmb} \in \mathbb{R}^{n \times d}$ respectively. When a tower is currently empty, an initial priority p_i^0 will be provided: it can either be a fixed value or a learnable parameter, and its impact is analysed in Section 5.2. Given the above priority vector, the policy simply maps per tower priorities to the probability simplex:

$$\pi(i|S) = \text{Softmax}_i(\mathbf{p}(S)).$$

The parameters (α, θ) introduced by this policy do not introduce much computational overhead: with embedding size $d = 8$ and using 32-dimensional hidden representations in the MLP, this model only introduces 1,039 new parameters, a small amount compared to ALBERT ($\approx$ 18M).

3.3.2 Training

While executing a policy, the scheduler needs to make discrete decisions as which tower to pursue. These discrete decisions mean we cannot simply frame learning as optimising a differentiable loss function. Instead we use the REINFORCE algorithm (Williams, 1992) for training our policy, by maximising the expected cumulative reward. For us, this reward is defined as follows. Let $\mathbf{i}_1^m = i_1, \ldots, i_m$ and $\mathbf{S}_1^m = S_1, \ldots, S_m$ be a trajectory of (tower selection) actions and states, respectively. We then set the cumulative reward to $R(\mathbf{i}_t^m, \mathbf{S}_t^m) = r(i_t, S_t) + \gamma R(\mathbf{i}_{t+1}^m, \mathbf{S}_{t+1}^m)$ where $r(i_t, S_t)$ is a immediate per-step reward we describe below, and γ is a discounting factor.

We define an immediate per-step reward $r(i, S)$ of choosing tower i in state S as $r(i, S) = r - c$ where $r = 1$ if the selected tower contains an answer and $r = 0$ otherwise. $c \in \mathbb{R}_+$ is a penalty cost of taking a step. In our experiments, we set $c = 0.1$.

4 Related Work

Adaptive Computation One strategy to reduce a model's complexity consists in dynamically deciding which layers to execute during inference (Bengio et al., 2015; Graves, 2016). *Universal transformers* (Dehghani et al., 2019) can learn after how many layers to emit an output conditioned on the input. Elbayad et al. (2020) generalise universal transformers by also learning which layer to execute at each step. Schwartz et al. (2020); Liu et al. (2020) propose methods that can adaptively decide when to early stop the computation in sentence classification tasks. To the best of our knowledge, previous work has focused adaptive computation for a single input. We are the first to learn how to prioritise computation across instances in the context of ODQA.

Smaller Networks Another strategy consists in training smaller and more efficient models. In *layer-wise dropout* (Liu et al., 2018), during training, layers are randomly removed, making the model robust to layer removal operations. This idea was expanded Fan et al. (2020) to modern Transformer-based models. Other methods include *Distillation* (Hinton et al., 2015) of a teacher model into a student model, *Pruning* of architectures after training (LeCun et al., 1989) and *Quantisation* of the parameter space (Wróbel et al., 2018; Shen et al., 2019; Zafrir et al., 2019). These methods are not adaptive, but could be used in concert with the methods proposed here.

Open Domain Question Answering Most modern ODQA systems adopt a two-stage approach that consists of a retriever and a reader, such as DrQA (Chen et al., 2017), HardEM (Min et al., 2019), BERTserini (Yang et al., 2019), Multi-passage BERT (Wang et al., 2019), and PathRetriever (Asai et al., 2020). As observed by Chen et al. (2017); Yang et al. (2019); Karpukhin et al. (2020); Wang et al. (2019), the accuracy of such two-stage models increases with more passages retrieved. But it remains a challenge to efficiently read a large number of passages as the reader models are usually quite computationally costly.

5 Experiments

SQuAD-Open	train	dev_0	dev_1	test
Size	78,839	4,379	4,379	10,570
Hits@30	71.2%	72.7%	72.1%	77.9%

Table 1: Dataset sizes and retriever performances.

Dataset SQuAD-Open (Chen et al., 2017) is a popular open-domain question answering dataset based on SQuAD. We partition the dataset into four subsets: training set, two development sets (dev_0 and dev_1), and test set, and their details are summarised in Table 1.

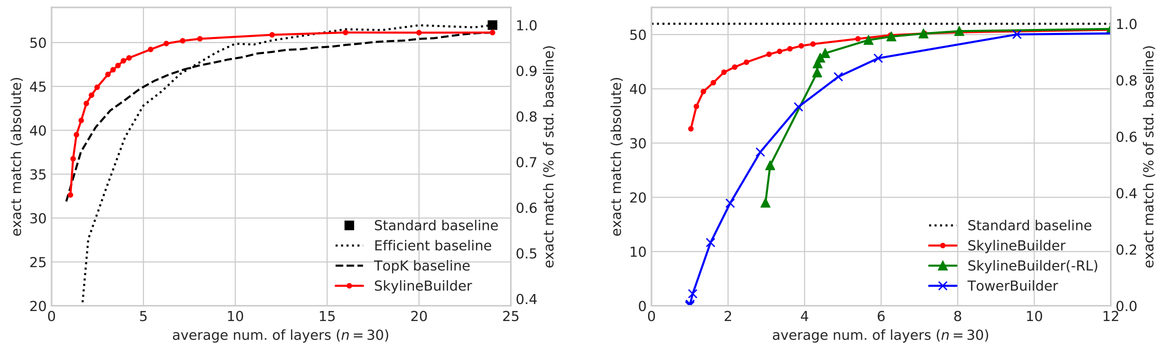
Experimental Setup We follow the preprocessing approached proposed by Wang et al. (2019) and split passages into 100-word long chunks with 50-word long strides. We use a BM25 retriever to retrieve the top n passages for each question as inputs to the reader and the Wikipedia dump provided by Chen et al. (2017) as source corpus. Following Wang et al. (2019), we set $n = 5$ for training and $n = 30$ for test evaluations. Table 1 shows the Hits@30 results of our BM25 retriever on the dataset and they are comparable with previous works (Yang et al., 2019; Wang et al., 2019).

Reader Model For all our experiments, we fine-tune a pre-trained ALBERT model (Lan et al., 2020), consisting of 24 transformer layers and cross-layer parameter sharing. We do *not* use global normalisation (Clark and Gardner, 2018) in our implementation, but our full system (without adaptive computation) achieves an EM score of 52.6 and is comparable to Multi-passage BERT (Wang et al., 2019) which uses global normalisation.

Training Pipeline The anytime reader models are first trained on training set and validated on dev_0. Then we conduct temperature calibration on dev_0. For SKYLINEBUILDER, the scheduler model is trained on dev_0 with the calibrated anytime model, and validated with dev_1.

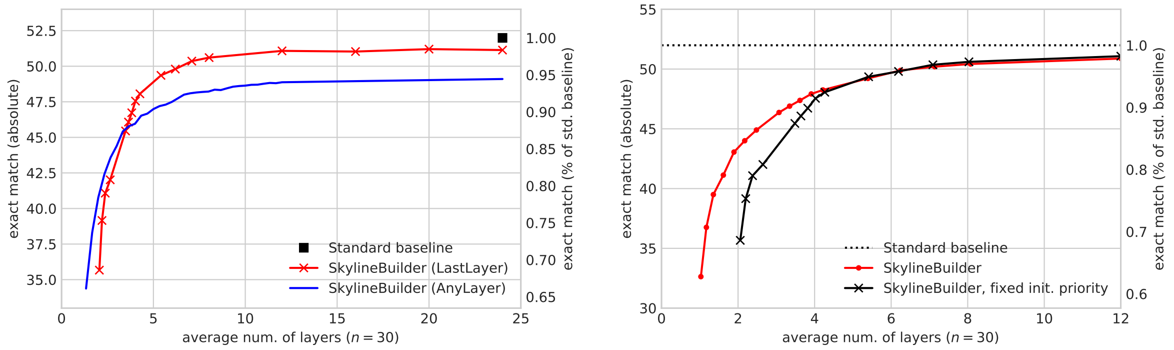
Baselines Following Schwartz et al. (2020), we use three types of baselines: *1*) the *standard baseline* that reads all passages and outputs predictions at the final layer, *2*) the *efficient baseline* that always exits at a given intermediate layer for all passages, and is optimised to do so, *3*) the *top-k baseline* that only reads the k top ranked passages and predicts the answer at their final layers.

Evaluation protocol Our goal is to assess the computational efficiency of a given method in terms of accuracy vs. computational budget used. We follow Fan et al. (2020) and consider the computation of one layer as a unit of computational



(a) SKYLINEBUILDER vs. baselines

(b) Local vs. Global Models



(c) AnyLayer vs. LastLayer

(d) Learnt vs. Fixed Initial Priorities

Figure 2: Evaluation results on the SQuAD-Open test set with 30 passages.

cost. In particular, we will assess how many layers, on average, each method builds up for each passage. Similarly to Schwartz et al. (2020), we show the accuracy-efficiency trade-off for different strategies by showing the computation cost on the x-axis, and the Exact Match (EM) [2] score on the y-axis.

5.1 Static vs. Adaptive Computation

We first investigate how adaptive computation compares to the static baselines. We will focus on a single adaptive method, SKYLINEBUILDER, and assess different adaptive variants later.

Fig. 2a shows the accuracy of SKYLINEBUILDER at different budgets when compared to the standard, efficient, and top-k baselines. We note that it reaches the similar results of the static baselines with much fewer layers. In particular, it yields substantially higher performance than static methods when the computational budget is smaller than ten layers. For example, when given four layers on average, SKYLINEBUILDER achieves EM score 48.0, significantly outperforming EM score 44.2 of the top-k baseline.

Method	**Avg. #layers**	**Reduction**
Standard baseline	24	1.0x
Efficient baseline	9.5	2.5x
Top-k baseline	14.4	1.7x
TOWERBUILDER	9.0	2.7x
SKYLINEBUILDER(-RL)	6.1	3.9x
SKYLINEBUILDER	**5.6**	**4.3x**

Table 2: Reduction in layer computations while achieving 95% of the accuracy of the standard baseline.

In Table 2 we consider a setting where SKYLINEBUILDER and the static baseline reach comparable (95%) performance of the full 24-layer model. We see that simply reducing the number of passages to process is giving a poor accuracy-efficiency trade-off, requiring 14.4 layers (or 18 passages) to achieve this accuracy. The efficient baseline fares better with 9.5 layers, but it is still outperformed by SKYLINEBUILDER, that only needs 5.6 layers on average to reach the desired accuracy.

	Var(h)	Avg(rank)	Flips	$h_+ - h_-$	HAP	Exact Match
Efficient Baselines	0.00	14.50	-	0.00	6.1%	23.47
TOWERBUILDER	11.05	13.38	-	3.68	22.0%	17.10
SKYLINEBUILDER(-RL)	7.46	13.06	13.37	3.46	27.4%	27.95
SKYLINEBUILDER	12.71	8.78	6.48	5.99	40.5%	**33.60**

Table 3: Quantitative analysis on SQuAD Open dev_1 set with top 30 passages and two layers of computation per passage on average.

5.2 Local vs. Global Models

What is the impact of globally selecting which towers to extend, rather than taking early-exit decisions on a per-tower basis? To answer this question, we consider two global methods: SKYLINEBUILDER and SKYLINEBUILDER(-RL), the method in Section 3.2 that uses HasAnswer probabilities as priorities without any RL-based selection policy. We compare both to the local method TOWERBUILDER.

Fig. 2b shows that, while for very low budgets TOWERBUILDER outperforms SKYLINEBUILDER(-RL), with a budget larger than 4 layers it is not the case anymore. This may be due to a tendency of SKYLINEBUILDER(-RL) spending an initial computation budget on exploring many towers—in Fig. 3 we show examples of this behaviour. It is also shown that SKYLINEBUILDER considerably outperforms both TOWERBUILDER and SKYLINEBUILDER(-RL). Along with the results in Table 2, the comparisons above indicate that *1*) global scheduling across multiple towers is crucial for improving efficiency, and *2*) optimising the adaptive policy with RL manage to exploit global features for tower selection, leading to further improvements.

5.3 Ablation Studies

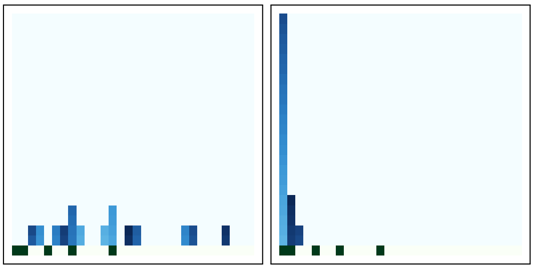
Any Layer vs. Last Layer Model For comparing the LastLayer and the AnyLayer strategies introduced in Section 3.1, we show the behaviour of these methods for the SKYLINEBUILDER scheduling algorithm in Fig. 2c. Using an anytime answer extraction model has a negative effect on accuracy. We see this clearly at 24 layers where AnyLayer lags substantially behind the standard baseline while LastLayer almost reaches it. We see this gap across the whole budget spectrum, leading to less accurate results except for very small budgets.

Learning Initial Priorities SKYLINEBUILDER uses a learnt initial priority for each tower. This not only enables it learn which towers to process first at the beginning, but also how long to wait until other towers are visited. Fig. 2d shows the benefit gained from adopting this strategy: without training the initialisation priorities, SKYLINEBUILDER spend more computation on passages that are likely not needed. Once an average of 4 layers have been added, the benefit disappears as SKYLINEBUILDER with learnt initial priorities will try to visit more candidates itself.

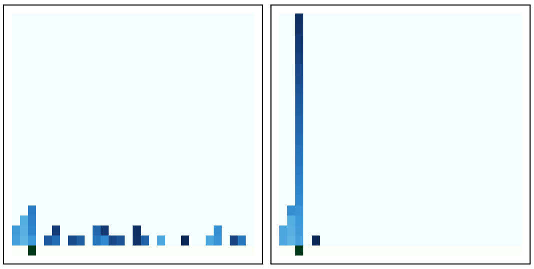
5.4 Quantitative Analysis

This section aims at understanding where and how our adaptive strategies behave differently, and what contributes to the gain in the accuracy-efficiency trade-off. We propose the following quantitative metrics: *1*) Var(h): variance of the heights of the towers. *2*) Avg(rank): average rank of the tower when the method chooses which tower to build on. *3*) Flips: how often does the strategy switch between towers, measuring the exploration-exploitation trade-off of a method. *4*) $h_+ - h_-$: h_+ (resp. h_-) is the average height of towers with (resp. without) an answer. Their difference measures the difference in amount of computation between passages with the answer and the ones without an answer. *5*) HasAnswer Precision (HAP): how often a tower selection action selects a tower whose passage contains the answer.

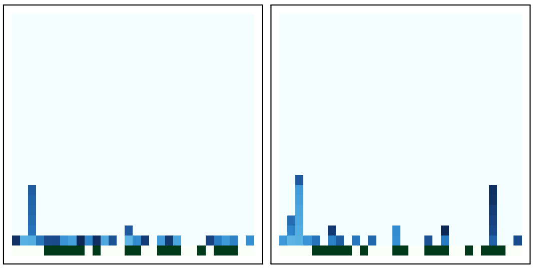
We analyse our proposed methods along with static baselines on the SQuAD development set; results are outlined in Table 3. Overall, the higher the HasAnswer Precision, the more accurate the method. This finding matches with our intuition that, if a tower selection strategy can focus its computation on passages that contain the answer, it yields more accurate results with smaller computation budgets.



(a) Example 1



(b) Example 2



(c) Example 3

Figure 3: Examples of the skylines built by SkylineBuilder(-RL) (left) and SkylineBuilder (right), with two layers per passage on average. The green blocks indicate towers that contain the answer.

Comparing SkylineBuilder(-RL) and SkylineBuilder gives more insights regarding what the RL training scheme learns. SkylineBuilder learns a policy with the highest Var(h), the lowest Avg(rank), and the lowest number of tower flips, suggesting that *1*) it focuses on a few towers rather than distributing its computation over all passages, *2*) it is more likely to select top-ranked passages, and *3*) it switches less between towers, and tends to build one tower before switching to another. SkylineBuilder also yields the highest HasAnswer Precision and $h_+ - h_-$, meaning that tends to prioritise the passages containing the answer.

5.5 Qualitative Analysis and Visualisation

Here we analyse how different methods build the skyline. Fig. 3 shows some examples of skylines built by SkylineBuilder(-RL) and SkylineBuilder. The towers are ordered by the rank of their associated passages in the retrieval results from left to right, and are built bottom-up. The colour gradient of the blues blocks reflects the order in which the layers are built: darker cells correspond to layers created later in the process.

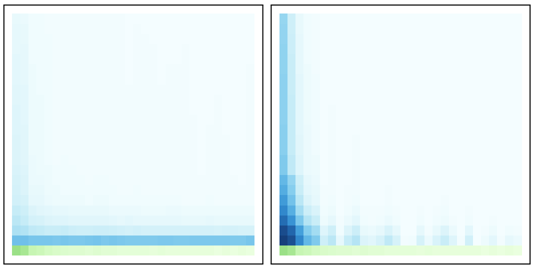


Figure 4: Heatmap of the tower selections by SkylineBuilder(-RL) (left) and SkylineBuilder (right). The colour gradient of the blues blocks reflects their selection frequencies.

In Fig. 3a and Fig. 3b we can see that SkylineBuilder tends to focus on one or two towers, whereas SkylineBuilder(-RL) has a more even distribution of computation across different towers. In Fig. 3b, even when only one tower contains the answer, SkylineBuilder manages to locate it and build a full-height tower on it.

Fig. 3c shows a case where none of the top 4 passages contains the answer. SkylineBuilder goes over these irrelevant towers quickly and start exploring later towers, until it reaches the tower with rank 27 and becomes confident enough to keep building on it. These examples shows how SkylineBuilder learns an efficient scheduling algorithm to locate passages containing the answer with very limited budgets.

To understand how our proposed methods work at macro level, we use heat-maps (Fig. 4) for showing how frequently each block is selected. The green row at the bottom indicates the frequency of each passage containing the answer. SkylineBuilder(-RL) explores all passages quite evenly, whereas SkylineBuilder learns to prioritise top-ranked towers. This preference is reasonable because, as shown by the green row at the bottom, top-ranked towers are more likely to contain the answer. Also note that SkylineBuilder does not naively process towers from left to right like the top-k baseline does, but instead it learns a trade-off between *exploration and exploitation*, leading to the significant improvement over the top-k baseline shown in Fig. 2a.

Models	Num. layers	EM
DistilBERT (Sanh et al., 2019)	6	40.5
SKYLINEBUILDER	1.6	41.1
SKYLINEBUILDER	3	46.4
SKYLINEBUILDER	6	**49.7**

Table 4: Comparing adaptive computation with distillation on SQuAD-Open test set.

5.6 Adaptive Computation vs. Distillation

Distillation is another orthogonal approach to reduce computational cost. We compare our adaptive computation method SKYLINEBUILDER with a static DistilBERT (Sanh et al., 2019) baseline, and the results are shown in Table 4. Our method significantly outperforms DistilBERT while computing much fewer layers.

6 Discussions and Future Works

In this paper, we focus on reducing the number of layers and operations of ODQA models, but the actual latency improvement also depends on the hardware specifications. On GPUs we cannot expect a reduction in the number of operations to translate 1:1 to lower execution times, since they are highly optimised for parallelism. [3] We leave the parallelism enhancements of SKYLINEBUILDER for future work.

We also notice that the distillation technique is complementary to the adaptive computation methods. It will be interesting to integrate these two approaches to achieve further computation reduction for ODQA models.

7 Conclusions

In this work we show that adaptive computation can lead to substantial efficiency improvements for ODQA. In particular, we find that it is important to allocate budget dynamically across a large number of passages and prioritise different passages according to various features such as the probability that the passage has an answer. Our best results emerge when we learn prioritisation policies using reinforcement learning that can switch between exploration and exploitation. On our benchmark, our method achieves 95% of the accuracy of a 24-layer model while only needing 5.6 layers on average.

Abstract

Complex reasoning over text requires understanding and chaining together free-form predicates and logical connectives. Prior work has largely tried to do this either symbolically or with black-box transformers. We present a middle ground between these two extremes: a compositional model reminiscent of neural module networks that can perform chained logical reasoning. This model first finds relevant sentences in the context and then chains them together using neural modules. Our model gives significant performance improvements (up to 29% relative error reduction when combined with a reranker) on ROPES, a recently-introduced complex reasoning dataset.

1 Introduction

Performing chained inference over natural language text is a long-standing goal in artificial intelligence (Grosz et al., 1986; Reddy, 2003). This kind of inference requires understanding how natural language statements fit together in a way that permits drawing conclusions. This is very challenging without a formal model of the semantics underlying the text, and when polarity needs to be tracked across many statements.

For instance, consider the example in Figure 1 from ROPES (Lin et al., 2019), a recently released reading comprehension dataset that requires applying information contained in a background paragraph to a new situation. To answer the question, one must associate each category of flowers with a polarity for having brightly colored petals, which must be done by going through the information about pollinators given in the situation and linking it to what was said about pollinators and brightly colored petals in the background paragraph, along with tracking the polarity of those statements.

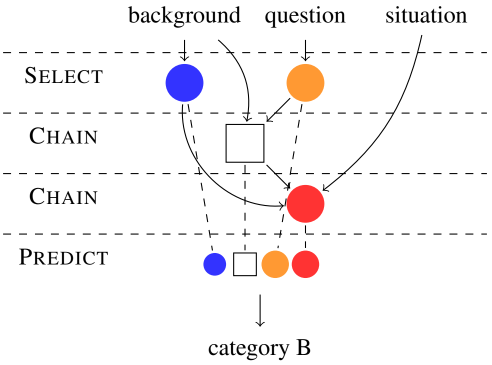
Background: Scientists think that the earliest flowers attracted *insects and other animals, which spread pollen* from flower to flower. *This greatly increased the efficiency of fertilization over wind-spread pollen*, which might or might not actually land on another flower. *To take better advantage of* *this animal labor*, *plants evolved traits such as* *brightly colored petals to attract pollinators.* In exchange for pollination, flowers gave the pollinators nectar.

Situation: Last week, John visited the national park near his city. He saw many flowers. His guide explained him that there are two categories of flowers, category A and category B. *Category A flowers spread pollen via wind, and category B flowers spread pollen via animals.*

Question: Which category of flowers would be *more likely to have brightly colored petals*?

Answer: category B

(a)



(b)

Figure 1: (a) An example in ROPES; (b) the chained reasoning that our model performs on the example. The model first (softly) selects relevant parts of the background and question, then successively chains them, making a prediction after including the situation in the chaining.

Prior work addressing this problem has largely

either used symbolic reasoning, such as markov logic networks (Khot et al., 2015) and integer linear programming (Khashabi et al., 2016), or blackbox neural networks (Jiang et al., 2019; Jiang and Bansal, 2019). Symbolic methods give some measure of interpretability and the ability to handle logical operators to track polarity, but they are brittle, unable to handle the variability of language. Neural networks often perform better on practical datasets, as they are more robust to paraphrase, but they lack any explicit notion of reasoning and are hard to interpret.

We present a model that is a middle ground between these two approaches: a compositional model reminiscent of neural module networks that can perform chained logical reasoning. The proposed model is able to understand and chain together free-form predicates and logical connectives. The proposed model is inspired by neural module networks (NMNs), which were proposed for visual question answering (Andreas et al., 2016b,a). NMNs assemble a network from a collection of specialized modules where each module performs some learnable function, such as locating a question word in an image, or recognizing relationships between objects in the image. The modules are composed together specific to what is asked in the question, then executed to obtain an answer. We design general modules that are targeted at the reasoning necessary for ROPES and compose them together to answer questions.

We design three kinds of basic modules to learn the neuro-symbolic multi-step inference over questions, situations, and background passages. The first module is called SELECT, which determines which information (in the form of spans) is essential to the question; the second module is called CHAIN, which captures the interaction from multiple statements; the last one is called PREDICT, which assigns confidence scores to potential answers. The three basic modules can be instantiated separately and freely combined.

In this paper, we investigate one possible combination as our multi-step inference on ROPES. The results show that with the multi-step inference, the model achieves significant performance improvement. Furthermore, when combined with a reranking architecture, the model achieves a relative error reduction of 29% and 8% on the dev and test sets in the ROPES benchmark. As ROPES is a relatively new benchmark, we also present some analysis of the data, showing that the official dev set is likely better treated as an in-domain test, while the official test set is more of an out-of-domain test set.[1]

2 Model

We first describe the baseline system, a typical QA span extractor built on ROBERTA (Liu et al., 2019), and then present the proposed system with multi-step inference. Furthermore, we introduce a reranker with multi-step inference given the output of the baseline system.

Following the standard usage of ROBERTA, we concatenate the background, the situation and question with two special determiners [S:] and [Q:] to be a long passage P = [CLS] B [S:] S [SEP] [SEP] [Q:] Q [SEP], where the background B and situation S are regarded as the first segment and the question Q is the second segment, and [CLS] and [SEP] are the reserved tokens in ROBERTA.

2.1 Baseline

Our baseline system is a span extractor built on the top of ROBERTA. Given the passage representations from ROBERTA $P_{\text{ROBERTA}} = [x_0, ..., x_{n-1}]$, two scores are generated for each token by span scorer, showing the chance to be the start and the end of the answer span:

$$\bar{S}, \bar{E} = \text{QA\_score}(P_{\text{ROBERTA}}),$$

where $\bar{S} = [\bar{s}, \bar{s}_1, ...\bar{s}_{n-1}]$ and $\bar{E} = [\bar{e}_0, \bar{e}_1, ..., \bar{e}_{n-1}]$ $(0 \leq k < n)$[2]are the scores of the start and the end of answer spans, respectively. $\text{QA\_score}(\cdot) : \mathbb{R}^{d_x} \Rightarrow \mathbb{R}^2$ is a linear function, where d_x is the output dimension of ROBERTA. The span with highest start and end scores is extracted as the answer by span extractor:

$$\begin{aligned}
[s_0, s_1, ..., s_n] &= \text{SOFTMAX}([\bar{s}_0, \bar{s}_1, ..., \bar{s}_n]) \\
[e_0, e_1, ..., e_n] &= \text{SOFTMAX}([\bar{e}_0, \bar{e}_1, ..., \bar{e}_n]) \\
i^*, j^* &= \arg\max_{i,j} s_i + e_j \quad (0 \leq i \leq j < n),
\end{aligned}$$

where the span_{i^*, j^*} is the answer.

---

[1] Model code is available at `https://github.com/LeonCrashCode/allennlp/blob/transf-exp1/allennlp/models/transformer_mc/roberta_models.py`

[2] The answer spans always appear in the situation and question passage, so we mask the scores for the background passage.

2.2 Multi-Step Inference for ROPES

Instead of a simple span prediction head on top of RoBERTa, our proposed multi-step inference model uses a series of neural modules targeted at chained inference. Like the baseline, our model begins with encoded RoBERTa passage representations P_{RoBERTa}, but replaces the QA_score function with a MS-Inference function, which similarly outputs a span start and end score for each encoded token x_k:

$$\bar{S}, \bar{E} = \text{MS-Inference}(P_{\text{RoBERTa}})$$

The MS-Inference$(\cdot)$ function consists of several modules. These modules SELECT relevant information from parts of the passage, CHAIN the selected text together, then PREDICT the answer to the question given the result of the chaining. These modules are applied on P_{RoBERTa} which is decomposed into $B_{\text{RoBERTa}}, S_{\text{RoBERTa}}, Q_{\text{RoBERTa}}$, denoting the token representations of RoBERTa for the background, the situation and the question, respectively.

As most of the questions in ROPES require the same basic reasoning steps, we use a fixed combination of these modules to answer every question, instead of trying to predict the module layout for each question, as was done in prior work (Hu et al., 2017). This combination is shown in Figure 2: we SELECT important parts of the question passage, and CHAIN them with the background passage to find a likely part of the background that supports answering the question (marked as red). Then we SELECT important parts of the background passage, which are combined with previous results that we have (marked as blue), and we CHAIN the combined information to find relevant parts of the situation passage (marked as green), and finally PREDICT an answer (marked as black), which is most often found in the situation text. The intuition for how these modules work together to piece together the information necessary to answer the question is shown in Figure 1. The actual operations performed by each of these modules is described below.

SELECT The select module, i.e. $z = \text{SELECT}(Y)$, where $Y \in \mathbb{R}^{n \times d_x}$ and $z \in \mathbb{R}^{d_x}$, aims to find the important parts of its input and summarize in a single vector. It first uses a learned linear scoring function, $f(\cdot) : \mathbb{R}^{d_x} \Rightarrow \mathbb{R}$, to determine which parts of its input are most important, then converts those scores into a probability distribution using a SOFTMAX operation, and computes a weighted sum of the inputs:

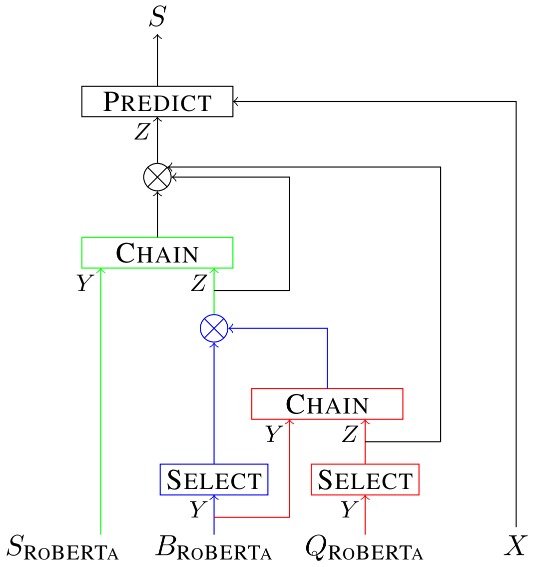

Figure 2: Multi-step inference model, where $\otimes$ is the operation to collect multiple vectors as a list, Z, Y are the interfaces of the modules, and X is a token representation to be scored as start/end of the answer span in the QA systems, or a candidate span representation to be scored in the reranking systems.

$$\begin{aligned} W &= f(Y) \\ A &= \text{SOFTMAX}(W) \\ z &= A^{\mathrm{T}}Y, \end{aligned}$$

CHAIN The chain module, i.e. $z = \text{CHAIN}(Y, Z)$, computes the interaction between an input matrix Y and a list of the input vectors $Z = [z_0, z_1, ..., z_{l-1}]$, where $Y \in \mathbb{R}^{n \times d_x}$, $z_k \in \mathbb{R}^{d_k}$ and d_k is the dimension of the kth input vector $(0 \leq k < l)$, and again outputs a summary vector of this interaction $z \in \mathbb{R}^{d_x}$. Intuitively, this module is supposed to chain together the inputs Y and Z and return a summary of the result. This is done with the following operations:

$$\begin{aligned} z' &= g([z_0; z_1; ...; z_{l-1}]) \\ z &= \text{ATTENTION}(z', Y, Y), \end{aligned}$$

where $g(\cdot) : \mathbb{R}^{(d_0+d_1+...+d_{l-1})} \Rightarrow \mathbb{R}^{d_x}$ is a linear function, ; is the concatenation, and attention$(\cdot)$ is instantiated with the multi-head attention:

$$\begin{aligned} \text{ATTENTION}(z', Y, Y) &= [\text{att}_1; \text{att}_2; ...; \text{att}_h]W^O \\ \text{att}_k &= \text{att}(z'W_k^Q, YW_k^K, YW_k^V) \\ \text{att}(Q, K, V) &= \text{SOFTMAX}(\frac{QK^{\mathrm{T}}}{\sqrt{d_x}})V, \end{aligned}$$

where W^O, W_k^Q, W_k^K and W_k^V are trainable parameters.

PREDICT The predict module, i.e. $S = \textsc{Predict}(Z, X)$, takes the list of output vectors $Z = [z_0, z_1, ..., z_{m-1}]$ from previous modules, where $z_k \in \mathbb{R}^{d_k}(0 \leq k < m)$ and m is the number of previous modules, and the candidates $X = [x_0, x_1, ..., x_{n-1}]$, where $x_k \in \mathbb{R}_x^d$ and n is the number of candidates, and produces scores for the candidates. In our base model, each candidate is a token in the situation or question, and the score is a pair of numbers representing span start and end probabilities for that token. When we use this module in a re-ranker (Section 2.3), the candidates X are already encoded spans, and so we produce just one number for each span. The PREDICT module simply uses a linear scoring function on the concatenation of its inputs:

$$\begin{aligned} S =& [s_0, s_1, ..., s_{n-1}] \\ s_k =& \textsc{Score}([z_0; z_1; ...; z_l; x_k]), \end{aligned}$$

where $\textsc{Score}(\cdot) : \mathbb{R}^{1\times(d_0+d_1+...+d_{m-1}+d_x)} \Rightarrow \mathbb{R}^r$ is a linear function, ; is the concatenation and $r = 2$ if the module is used to extract spans, while $r = 1$ if the module is used to score candidates for the reranker.

Full model Our full model combines these modules in the following way to compute span start and end scores for each token (depicted graphically in Figure 2):

$$\begin{aligned} S_{\text{RoBERTa}}, B_{\text{RoBERTa}}, Q_{\text{RoBERTa}} &= P_{\text{RoBERTa}} \\ X &= [S_{\text{RoBERTa}}; Q_{\text{RoBERTa}}] \\ z_0 &= \textsc{Select}(Q_{\text{RoBERTa}}) \\ z_1 &= \textsc{Select}(B_{\text{RoBERTa}}) \\ z_2 &= \textsc{Chain}(B_{\text{RoBERTa}}, [z_0]) \\ z_3 &= \textsc{Chain}(S_{\text{RoBERTa}}, [z_1, z_2]) \\ \bar{S}, \bar{E} = S &= \textsc{Predict}([z_0, z_1, z_2, z_3], X) \end{aligned}$$

2.3 Multi-Step Reranker

Most questions in ROPES have only two or three reasonable candidate answers (in Figure 1 these are “category A” and “category B”), and we find that the baseline model is able to reliably find these answers, though it has a hard time selecting between them. This suggests that a reranker that only focuses on deciding which of the candidates is correct could be effective. To do this, we take the top c spans output by the baseline system and score these candidates directly using our MS-Inference model instead of producing span start and end scores for each input token.

Scoring spans instead of tokens To feed the candidate spans into our multi-step inference model, we represent each span as a single vector by concatenating its endpoint tokens: $x_{(i,j)} = [x_i; x_j]$. We take all c candidates and concatenate them together as X, instead of $X = [S; Q]$ as is done in our base model. Similarly, $\textsc{Predict}(Z, X)$ outputs a single score $\bar{O}$ per candidate instead of a pair of start and end probabilities.

Ensemble We additionally use an ensemble strategy for the reranker. We train several rerankers and build a voting system where each reranker makes a vote for the candidate to be the best answer. The candidate with the most votes is chosen the best answer through the voting system.

3 Data bias in ROPES

We experiment with ROPES (Lin et al., 2019), a recently proposed dataset which focuses on complex reasoning over paragraphs for document comprehension. We noticed a very severe drop in performance between the ROPES dev and test sets during initial experiments, and we performed an analysis of the data to figure out the cause. ROPES used an annotator split to separate the train, dev, and test sets in order to avoid annotator bias (Geva et al., 2019), but we discovered that this led to a large distributional shift between train/dev and test, which we explore in this section. In light of this analysis, we recommend treating the dev set as an in-domain test set, and the original test set as an out-of-domain test.

Answer types Our analysis is based on looking at the syntactic category of the answer phrase. We use the syntactic parser of Kitaev and Klein (2018) to obtain constituent trees for the passages in ROPES. We take the constituent label of the lowest subtree that covers the answer span[3] as the answer type.

The four most frequent answer types in ROPES are noun phrase (NP), verb phrase (VP), adjective phrase (ADJP) and adverb phrase (ADVP). Table 1 shows examples for each type. Most NP answers

---

[3] The passages could have more than one span that matches the answer; we use the last occurrence of the answer span for our analysis.

Type	Passage
NP	...The child poured two spoonfuls of sugar into cup A and three spoonfuls of sugar into **cup B**... Which cup has a higher concentration of sugar ?
	...They labeled it as **plant B** . They wanted to find out what makes a plant drought-resistant... In which plant there would be more water loss ?
VP	...In test B he used higher concentration of reactants. Now, he needs to know about the science... Would test B **increase** or decrease the frequency...
	...induced higher respiration rate in sample A. Then he induced no respiration rate in sample B... make their own glucose or **acquire it from other organisms** ?
ADJP	... patient A and patient B. John found out that patient A had more LDL, but patient B had more HDL... B have higher or **lower** risk of heart attack than patient A?
	...visible light. He noted microwaves as case A, infrared as case B, and visible light as case C...Would case A have **longer** or shorter wavelengths than case B?
ADVP	...Sample A was a strong acid, and sample B was a weak acid. David needed to ...sample A lose a proton less or **more easily** than sample B?
	...There is only one ice cube left so she takes it out and sets it in the glass on the table. She then refills...in the ice cube moving closer together or **farther apart** ?
Others	...Their mother takes them to see a doctor and to have their testosterone tested. The tests reveal that...Will Jimothy finish his growth spurt before or **after** Dwight?
	...He cut down on how much he eats every day and monitors his calorie intake, making sure that he is...Given Greg's BMI us 41, is he considered obese, **yes** or no?

Table 1: The examples in ROPES, where the bold red spans are answers.

come from the situation, while the other answer types typically come from the question.

Bias The distribution of answer types in the train/dev/test sets of ROPES are shown in Table 2. We found that the distribution in the train set is similar to development set, where most of the answers are NPs (85%), with ADJP being the second most frequent. However, the test set has a very different distribution over answer types, where less than half of the answers NPs, and there are more VPs, ADJPs, ADVPs, and other types.

This distributional shift over answer types between train/dev and test raises challenges for reading comprehension systems; to perform well on test, the model must predict a significant number of answers from the question instead of from the situation, which only rarely happens in the training data. Given this distributional shift, it seems fair to characterize the official test as somewhat out-of-domain for the training data.

4 Experiments

In this section, we evaluate the performance of our proposed model relative to baselines on ROPES.

Answer type	Train	Dev	Test
NP	84.17	85.19	47.19
VP	3.35	1.24	17.37
ADJP	9.20	10.25	19.36
ADVP	2.50	3.32	10.23
Others	0.78	0.00	5.85

Table 2: The percentage (%) of question types in ROPES.

	Train	Dev	Test
# of backgrounds	513	51	171
# of situations	1,409	203	300
# of questions	10,924	1,688	1,710

Table 3: The ROPES dataset

4.1 Settings

Data We use the 10,924 questions as our training set, and 1,688 questions as dev set and 1,710 questions as test set, where each question has only one answer, which is a span from either the situation or the question. Table 3 shows the statistics on the ROPES benchmark. Due to the severe distributional shift between dev and test (described in

parameter	value
hidden size	1024
batch size	8
gradient accumulation	16
epoch	10
learning rate	1e-5
weight decay rate	0.1
warming up ratio	0.06
optimizer	adam
doc stride	150
maximum pieces	384

Table 4: The hyperparameters

Section 3), we additionally set up an experiment using the dev set as an in-domain test set, by partitioning the training set into train (9,824 questions) and train-dev (1,100 questions).

Training Following the settings of prior work (Lin et al., 2019), we fine-tune the ROBERTA-LARGE pre-trained transformer. The hidden sizes of all layers are set to 1024 which is the same to the output dimension of ROBERTA-LARGE, and the number of heads on multi-step attentions is 8. All the models share the same hyperparameters that are shown in Table 4.[4]

Metrics Though ROPES was released using both exact match (EM) and F1 as metrics, we only report EM here, as F1 has been shown to correlate poorly with human judgments on ROPES (Chen et al., 2019a). F1 assumes that answers that share many overlapping words are likely similar; while this is largely true on SQuAD (Rajpurkar et al., 2016), where this particular F1 score was introduced, it is not true on ROPES, where things like *Village A* and *Village B* are both plausible answers to a question. All the systems are trained in three runs with different random seeds, and we post the average performance over the three runs.

4.2 Results

Table 5 shows the performance of the three systems. The multi-step system and multi-step reranker outperform the baseline system with 8.1% and 11.7% absolute EM accuracy on dev set, respectively, and with 2.4% and 2.0% EM accuracy on test set, respectively, showing that with multi-step inference, the system can achieve improvements. With the ensemble, the multi-step reranker performs best on dev and test sets.

Model	Dev	Test	Dev-test
Baseline	59.7	55.4	56.2
Multi-step	67.8	57.8	61.6
Multi-step reranker	71.4	57.4	63.4
+ensemble	73.3	58.8	65.2

Table 5: The exact match scores by three systems. For the first two columns, we performed model selection on dev; for the third column, we performed model selection on a separate train-dev set.

As can be seen, the improvement of our model on the dev set is quite large. While performance is also better on the official test set, the gap is not nearly so large. To understand whether this was due to overfitting to the dev set or to the distributional shift mentioned in Section 3, Table 5 also shows the results on dev-test, our split that treats the official dev set as a held-out test set. Here, we still see large gains of 7.2% EM from our model, suggesting that it is indeed a distributional shift and not overfitting that is the cause of the difference in performance between the original dev and test sets. Properly handling the distributional shift in the ROPES test set is an interesting challenge for future work.

4.3 Analysis and Discussion

We conduct detailed analysis in this section, studying (1) the impact of various components of our model, (2) the gap between results on development and test set, (3) the strategy for sampling candidates for the reranker, and (4) the errors that the models cannot cover.

Ablation Study We perform an ablation study on the multi-step system and the multi-step reranker. Table 6 shows the results on dev set by various ablated systems. The performances of two systems drop down without any one module due to the property of the chained reasoning. The performance of the multi-step system without Q SELECT or B CHAIN drops (around) more than that of the multi-step system without B SELECT or S CHAIN (around -2.1% EM). So Q SELECT module and B CHAIN play relatively more important roles. The performance of the multi-step reranker without Q SELECT, B SELECT or S CHAIN drops (around -5.9% EM) more than that of the multi-step reranker without B CHAIN (-3.7% EM).

---

[4] The hyperparamters are manually tuned according to the performance on dev dataset.

Model	EM
Multi-step	67.8
w/o Q Select	62.8 (-5.0)
w/o B Chain	62.3 (-5.5)
w/o B Select	65.9 (-1.9)
w/o S Chain	65.5 (-2.3)
Multi-step reranker	71.4
w/o Q Select	65.8 (-5.6)
w/o B Chain	67.7 (-3.7)
w/o B Select	64.9 (-6.5)
w/o S Chain	65.7 (-5.7)

Table 6: The ablation results on development. Q Select denotes the question Select module; B Chain denotes the Chain module applied on the background and the question; B Select denotes the background select module; S Chain denotes the Chain module applied on the situation and the previous chained reasoning.

Model	NP	VP	ADJP	ADVP	avg
Baseline	60.0	38.1	60.4	62.7	53.03
Multi-step	68.8	39.7	61.3	72.6	58.65
Multi-step reranker	71.8	38.1	63.8	75.0	60.52
+ensemble	75.0	42.9	61.3	78.6	62.75

Table 7: The exact match accuracy of most four frequent question types in test dataset. avg is the weighted accuracy in terms of frequency of the four kinds of questions.

Answer Types We break down the overall accuracy by answer type, which is shown in Table 7. All three systems perform substantially better on NP, ADJP, and ADVP questions than on VP questions. The main reason is that the VP questions are associated with complex and long answers, e.g., *acquire it from other organisms* or *make their own glucose*. The major improvements happen on answering NP and ADVP questions, which explains the gap between the scores on the development set, with a large amount of NP questions, and the test set, with relatively more VP questions. The analysis can inspire the future work of investigating the specific inference programs for specific-type questions.

Candidate Sampling In order to train the reranker, we need training data with high-diversity candidates. However, a well-trained model does not generate similar candidates for the training set to what it generates for the dev and test sets, due to overfitting to the training set. In order to get useful candidates for the training set, we need a model that was not trained on the data that it generates candidates for. We investigate four strategies based on cross-validation to generate training data candidates: 10-fold, 5-fold, 2-fold and 3-turn. With the k-fold method, the training data is partitioned into k parts, and $(k-1)$ parts are used to train a model that generates candidates answers for the remaining part. With the k-turn method, the training data is partitioned into k parts, and the ith part is used to train a model that generates candidate answers for $(i+1)$th part.

	EM
10-fold	84.1
5-fold	82.4
2-fold	75.9
3-turn	59.9

Table 8: The average accuracy on training data for the multi-step reranker.

k	train	dev	test
1	59.9	59.7	55.4
2	81.4	64.8	61.9
3	92.0	97.4	80.2
4	93.8	98.3	83.6
5	94.9	98.7	85.9
10	96.1	99.4	88.5

Table 9: The oracle scores for top k candidates.

Table 8 shows the average accuracy on training data. The accuracy on training data generated by k-fold self-sampling method is very high, and they are not consistent with the dev and test set. The accuracy on training data generated by the 3-turn self-sampling method is most similar to the accuracy on dev set (59.7% EM) and test set (55.4% EM) by the baseline system. We adopt the 3-turn self-sampling method for our experiments.

Table 9 shows the oracle of top k candidates on train, development and test set. Because oracle scores are the upper bound of the reranker, there is a trade-off that the upper bound is lower as fewer candidates are sampled, while the noise increases as more incorrect candidates are sampled. We found that top 3 provides a good trade-off for the reranker on the development set, giving a large jump over just two candidates, and this is what we used during our main experiments.

Error Analysis and Future Work We analyze some errors that our proposed model made, aiming to discover the questions that our model could not cover. Table 10 shows some questions that our proposed model gives incorrect answers. The questions require model to get the numeric information from the passage, and then compare the numeric relation (e.g. larger, smaller and equal) and target the effect of the relation in the background passage, where positive correlation between the prices and the sold number in example 1, positive correlation between the tolerance degree and usage times in example 2 and negative correlation between the crash rate the the number of cyclists in example 3. It seems that the model is not sensitive to the numeric information and their reasonings.

Also, the situations give more than two entities with their related information, and although the questions narrow down the multiple choices to two choices, the systems are still distracted by these question-irrelevant entities. The distraction comes from the difficulty of associating the relevant information with the correct entities. Future work can be motivated by the discovery to design more modules to deal with this phenomenon.

5 Related Work

Neural Module Networks were originally proposed for visual question answering tasks (Andreas et al., 2016b,a), and recently have been used on several reading comprehension tasks (Jiang et al., 2019; Jiang and Bansal, 2019; Gupta et al., 2020), where they specialize the module functions such as FIND and COMPARE to retrieve the relevant entities with or without supervised signals for HotpotQA (Yang et al., 2018) or DROP (Dua et al., 2019). As ROPES is quite different from these datasets, the modules that we choose to use are also different, focusing on chained inference.

Multi-Hop Reasoning There are several datasets constructed for multi-hop reasoning e.g. HOTPOTQA (Yang et al., 2018; Jiang et al., 2019; Jiang and Bansal, 2019; Min et al., 2019; Feldman and El-Yaniv, 2019), QANGAROO (Welbl et al., 2018; Chen et al., 2019b; Zhuang and Wang, 2019; Tu et al., 2019) and WIKIHOP (Welbl et al., 2018; Song et al., 2018; Das et al., 2019; Asai et al., 2019) which aims to get the answer across the documents. The term "multi-hop" reasoning on these datasets is similar to relative information retrieval, where one entity is bridged to another entity with one hop. Differently, the multi-step reasoning on ROPES aims to do reasoning over the effects of a passage (background and situation passage) and then give the answer to the question in the specific situation, without retrieval on the background passage.

Example 1
Background: ... For many of the works, the price goes up as the edition sells out...
Situation: ...By the end of the week, they started to sell out. There were only 2 of the Mona Lisa,...,120 of The Kiss, 150 of The Arnolfini Portrait...
Question: Which limited edition most likely had it's price increased: The Kiss or Mona Lisa ? **Answer:** The Kiss
Ours:Mona Lisa
Example 2
Background: ...The tolerance for a drug goes up as one continues to use it after having a positive experience with a certain amount the first time...
Situation: ... Chris used it 12 times,...,Jimmy used it 42 times, Antonio used it 52 times, Danny used it 62 times, ...
Question: Who has a higher tolerance for roach: Jimmy or Antonio ? **Answer:** Antonio
Ours: Jimmy
Example 3
Background: ... That is to say, the crash rate per cyclist goes down as the cycle volume increases...
Situation: ...Day 1 had 500 cyclists left. Day 2 had 400 cyclists left. Day 3 had 300 cyclists left. Day 4 had 200 cyclists left....
Question: What day had a lower crash rate per cyclist: Day 1 or Day 2 ? **Answer:** Day 1
Ours: Day 2

Table 10: The examples of the answers to the questions by the multi-step reranker.

Models beyond Pre-trained Transformer As the emergence of fully pre-trained transformer (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; Radford et al.; Dai et al., 2019; Yang et al., 2019), most of NLP benchmarks got new state-of-the-art results by the models built beyond the pre-trained transformer on specific tasks (e.g. syntactic parsing, semantic parsing and GLUE) (Wang et al., 2018; Kitaev and Klein, 2018; Zhang et al., 2019; Tsai et al., 2019). Our work is in the same line to adopt the advantages of pre-trained transformer, which has already collected contextualized word representation from a large amount of data.

6 Conclusion

We propose a multi-step reading comprehension model that performs chained inference over natural language text. We have demonstrated that our model substantially outperforms prior work on ROPES, a challenging new reading comprehension dataset. We have additionally presented some analysis of ROPES that should inform future work on this dataset. While our model is not a neural module network, as our model uses a single fixed layout instead of different layouts per question, we believe there are enough similarities that future work could explore combining our modules with those used in other neural module networks over text, leading to a single model that could perform the necessary reasoning for multiple different datasets.

Abstract

State-of-the-art question answering (QA) relies upon large amounts of training data for which labeling is time consuming and thus expensive. For this reason, customizing QA systems is challenging. As a remedy, we propose a novel framework for annotating QA datasets that entails learning a cost-effective annotation policy and a semi-supervised annotation scheme. The latter reduces the human effort: it leverages the underlying QA system to suggest potential candidate annotations. Human annotators then simply provide binary feedback on these candidates. Our system is designed such that past annotations continuously improve the future performance and thus overall annotation cost. To the best of our knowledge, this is the first paper to address the problem of annotating questions with minimal annotation cost. We compare our framework against traditional manual annotations in an extensive set of experiments. We find that our approach can reduce up to 21.1% of the annotation cost.

1 Introduction

Question answering (QA) based on textual content has attracted a great deal of attention in recent years (Chen et al., 2017; Lee et al., 2018, 2019; Xie et al., 2020). In order for state-of-the-art QA models to succeed in real applications (e.g., customer service), there is often a need for large amounts of training data. However, manually annotating such data can be extremely costly. For example, in many realistic scenarios, there exists a list of questions from real users (e.g., search logs, FAQs, service-desk interactions). Yet, annotating such questions is highly expensive (Nguyen et al., 2016; He et al., 2018; Kwiatkowski et al., 2019): it requires the screening of a text corpus to find the relevant document(s) and subsequently screening the document(s) to identify the answering text span(s).

Motivated by the above scenarios, we study cost-effective annotation for question answering, whereby we aim to *accurately*[1] annotate a given set of user questions *with as little cost as possible*. Generally speaking, there has been extensive research on how to reduce effort in the process of data labeling (Haffari et al., 2009). For example, active learning for a variety of machine learning and NLP tasks (Siddhant and Lipton, 2018) aims to select a small, yet highly informative, subset of samples to be annotated. The selection of such samples is usually coupled with a particular model, and thus, the annotated samples may not necessarily help to improve a different model (Lowell et al., 2019). In contrast, we aim to annotate *all* given samples at low cost and in a manner that can subsequently be used to develop any advanced model. This is particularly relevant in the current era, where a dataset often outlives a particular model (Lowell et al., 2019). Moreover, there has also been some research into learning from distant supervision (Xie et al., 2020) or self-supervision (Sun et al., 2019). Despite being economical, such approaches often produce inaccurate or noisy annotations. In this work, we seek to reduce annotation costs without compromising the resulting dataset quality.

We propose a novel annotation framework which learns a cost-effective policy for choosing between different annotation schemes, namely the conventional manual annotation scheme (MAN) and a semi-supervised annotation scheme (SEM). Unlike the manual scheme, SEM does not require humans to screen a text corpus or document(s) in order to retrieve annotations. Instead, it leverages an initialized QA system, which can predict top-n candidate annotations for documents or answer spans and asks humans to provide binary feedback (e.g., cor-

---

[1] By "accurate," we mean that the resulting annotations will be of a similar quality to those from conventional manual annotation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3051–3062,
November 16–20, 2020.

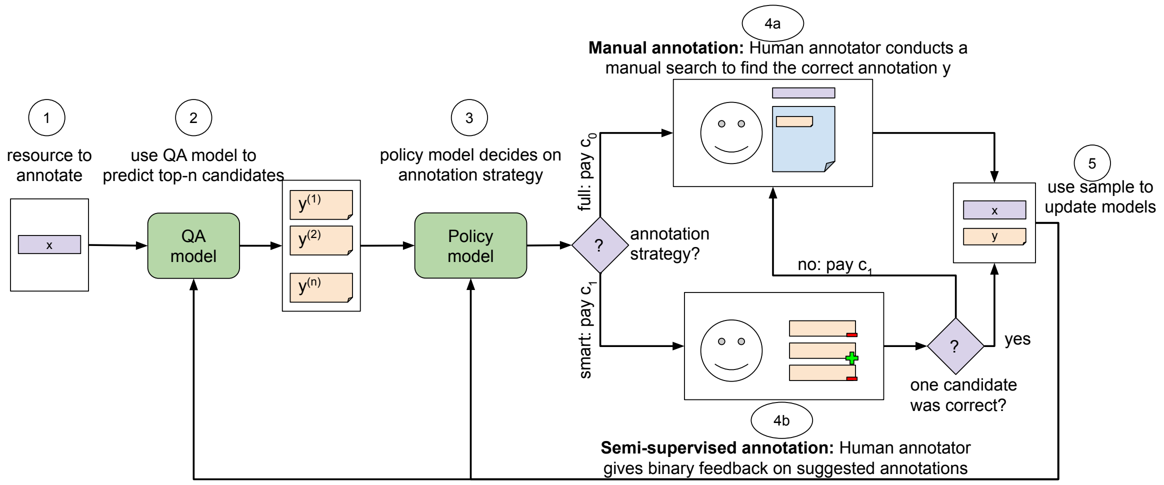

Figure 1: High-level overview of our framework: We leverage a QA model to predict candidate annotations for a given resource (e.g., x stands for a question or question-document pair, while y is the document or answer span). A policy model decides upon whether to invoke a MAN or SEM scheme based on those predictions. In the event that the semi-supervised strategy fails, we switch back to a manual annotation scheme. Finally, we use the annotated sample to update both the QA model and the policy model.

rect or incorrect) to the candidates. While this annotation scheme comes at a low cost, it fails when human annotators mark all candidates as incorrect. In such cases, the annotation cost has already been incurred and cannot be recouped. In order to produce an annotation, one must then draw upon the manual scheme (see Fig. 1), in which case the policy would have been more effective if it had chosen the manual annotation scheme instead. *Therefore, how to choose the best annotation scheme for each question is the challenge we must address for this task.*

To tackle the above challenge, we propose a novel approach for learning a cost-effective policy. Here the policy receives several candidates and decides on this basis which annotation scheme to invoke. We train the policy with a supervised objective and learn a cost-sensitive decision threshold. The inherent advantage of this method is that our policy immediately reacts to changing costs (without re-optimizing model parameters) and does not exceed the cost of conventional manual annotation. Our policy is updated iteratively as more annotations are obtained.

We compare our framework against conventional, manual annotations in an extensive set of experiments. We simulate the annotation of NaturalQuestions (Kwiatkowski et al., 2019), as it consists of real user questions from search logs. Models in our framework are initialized with an existing dataset (SQuAD, Rajpurkar et al., 2016) and, as more annotations on NaturalQuestions become available, the framework is continuously updated. We study the sensitivity of our framework to varying cost ratios between SEM and MAN. Our framework outperforms traditional manual annotation, even under conservative cost estimates for SEM, and in general reduces annotation costs in the range of 4.1% to 21.1%.

2 Related Work

Question answering: In this paper, we study cost-effective annotation for question answering over textual content. There have been extensive efforts to create large-scale datasets for text-based QA, which have facilitated the development of state-of-the-art neural network based models (e.g., Chen et al., 2017; Min et al., 2018; Lee et al., 2018; Kratzwald and Feuerriegel, 2018; Wang et al., 2018; Xie et al., 2020). Here we divide such datasets into two categories according to the way they were created: (1) Datasets whose questions were created by crowdsourcing during the annotation process. Prominent examples include the Stanford Question and Answer Dataset (SQuAD; Rajpurkar et al., 2016), HotPotQA (Yang et al., 2018), or NewsQA (Trischler et al., 2017). (2) “Natural” datasets in which real-world questions are a priori given. Here questions originate from, e.g., search logs or customer interactions. Prominent examples in this category include MS MARCO (Nguyen et al., 2016), DuReader (He et al., 2018), or NaturalQuestions (Kwiatkowski et al., 2019). This paper focuses on the latter category, that is, annotating "natural" datasets in a more cost-effective fashion where a set of questions is given.

Active Learning: In the fields of machine learning and NLP, extensive research has been conducted on ways to reduce labeling effort (e.g., Zhu et al., 2008). For example, the objective of active learning is to select only a small subset that is highly informative (e.g., Haffari et al., 2009) for annotation. To this end, researchers have developed various techniques based on, e.g., model uncertainty (cf. Siddhant and Lipton, 2018), expected model change (Cai et al., 2013), or functions learned directly from data (e.g., Fang et al., 2017). However, the success of active learning is often coupled with a particular model and domain (Lowell et al., 2019). For instance, a dataset actively acquired with the help of an SVM model might underperform when used to develop an LSTM model. These problems become even more salient when complex black-box models are used in NLP tasks (cf. Chang et al., 2019). To summarize, active learning reduces annotation costs by deciding *which* samples should be annotated. In our approach, we aim to annotate *all* samples and study *how* we should annotate them in order to reduce costs. Thus, the two approaches are orthogonal and can be combined.

Learning from weak supervision and user feedback: Another approach to reducing annotation costs is changing full supervision to some form of weak (but potentially noisier) supervision. This has been adopted for various tasks such as machine translation (Saluja, 2012; Petrushkov et al., 2018; Clark et al., 2018; Kreutzer and Riezler, 2019), semantic parsing (Clarke et al., 2010; Liang et al., 2017; Talmor and Berant, 2018), or interactive systems that learn from user interactions (Iyer et al., 2017; Gur et al., 2018; Yao et al., 2019, 2020). For instance, Iyer et al. (2017) used users to flag incorrect SQL queries. In contrast, similar approaches for text-based question answering are scarce. Joshi et al. (2017) used noisy distant supervision to annotate the answer span and document for given trivia questions and their answers. Kratzwald and Feuerriegel (2019) designed a QA system that continuously learns from noisy user feedback after deployment. In contrast to these works, this paper studies the problem of reducing labeling cost while maintaining accurate annotations.

Quality estimation and answer triggering: In a broader sense, this work is related to the literature on translation quality estimation (e.g., Martins et al., 2017; Specia et al., 2013). The goal in such works is to estimate (and possibly improve) the quality of translated text. Similarly, in question answering researchers use means of quality estimation for answer triggering (Zhao et al., 2017; Kamath et al., 2020). Here, QA systems are given the additional option to abstain from answering a question when the best prediction is believed to be wrong. In our work, we estimate the quality of a set of suggested label candidates and, on the basis of these estimates we decide which annotation scheme to invoke.

3 Proposed Annotation Framework

We study the problem of reducing the overall cost for annotating every given question $[q_1, \ldots, q_m]$. Specifically, our objective is to obtain the corresponding question-document-answer triples $\langle q_i, d_i, s_i \rangle$. In this paper, the natural language question q_i is given, while we want to obtain the following annotations: the document from a text corpus $d_i \in \mathcal{D}$ that contains the answer and the correct answer span s_i within the document d_i.

3.1 Framework Overview

Fig. 1 provides an overview of our framework for a cost-effective annotation of QA datasets. The framework comprises two main components: a **QA model** is used to suggest candidates for a resource to annotate while a **policy model** decides which annotation scheme to invoke (i.e., action). Our framework makes use of two annotation schemes: a traditional **manual annotation scheme (MAN)** and our **semi-supervised annotation scheme (SEM)**. Both annotation schemes incur different costs and, hence, the learning task is to find and update a cost-effective policy π for making that decision.

QA model: We define Ω as an arbitrary QA model over a text corpus $\mathcal{D}$ with the following properties. First, the model can be trained from annotated data samples, e.g., $\Omega \leftarrow \text{train}\,(\{\langle q_i, d_i, s_i \rangle\}_{0<i<\ldots})$. Second, for a given question the model can predict a number of top-n documents likely to contain the answer, i.e., $\Omega^D : q \rightarrow [d^{(1)}, \ldots, d^{(n)}] \in \mathcal{D}$. Third, for a given question-document pair the model can predict a number of top-n answer spans, i.e.,

$\Omega^S : \langle q, d \rangle \rightarrow [s^{(1)}, \ldots, s^{(n)}]$. These properties are fulfilled by recent QA systems dealing with textual content (e.g., Chen et al., 2017; Wang et al., 2018).

Policy model: For every question, we distinguish two policy models: a policy model π^D responsible for annotating documents and π^S for answer spans. For brevity, we sometimes drop the superscripts S and D and simply refer to them as π. The policy models decide whether a manual annotation scheme or rather our proposed semi-supervised annotation scheme is used, each of which is associated to different costs.

3.2 Annotation Schemes

Manual annotation (MAN) scheme: This scheme represents the status quo in which all annotations are determined manually. In order to annotate a question q_i, a human annotator must first manually search through the text corpus $\mathcal{D}$ in order to identify the document d_i that answers the question. In a second step, a human annotator manually reads through the document d_i and marks the answer span s_i.

We assume separate costs, which are fixed over time, for every annotation-level. The price of annotating a document for a given question is defined as c_0^D and the price of annotating an answer span to a given question-document tuple as c_0^S. We explicitly distinguish these costs as the tasks can be of differing difficulty.

Semi-supervised annotation (SEM) scheme: This scheme is supposed to reduce human effort by presenting candidates for annotation, so that only simple binary feedback is needed. In particular, human annotators no longer need to search through the entire document or corpus. Instead, we use the QA model Ω to generate a set of candidates (e.g., top-ranked documents or answer spans) and ask human annotators to give binary feedback in response (e.g., accept the candidate or reject it). This replaces the complex search task with a simpler form of interaction. As an example, to annotate the answer span for a question-document pair, the human annotator would not be required to read the entire document d_i, but only to determine which of the top-n answers provided by $\Omega^S(\langle q_i, d_i \rangle)$ are correct. We assume SEM costs c_1^D to annotate a document and c_1^S to annotate an answer span.

The SEM scheme should make annotations more straightforward, as providing binary feedback requires less time than reading through the texts. Hence, we assume that $c_1^S < c_0^S$ and $c_1^D < c_0^D$ hold. However, semi-supervised annotations might fail when none of the candidates is correct (i.e., the human annotators reject all candidates). In this case, our framework must revert to the MAN procedure in order to obtain a valid annotation. As a consequence, the associated cost will increase to the accumulated cost for both the SEM and the MAN schemes.

Note that, no matter which scheme is chosen in practice, all annotations are confirmed by human annotators and our resulting dataset will be equal in quality to those resulting from traditional annotation.

3.3 Annotation Costs

Both annotation schemes, MAN and SEM, incur different costs that further vary depending on whether annotation is provided at document level (c^D) or at answer span level (c^S). For annotating documents, the cost amounts to

$$c^D(a|q_i, d_i^*) = \begin{cases} c_a^D, \text{ if } a = 0 \text{ or } (a = 1 \text{ and} \\ \qquad\qquad d_i^* \in \Omega^D(q_i)), \\ c_0^D + c_1^D, \quad \text{otherwise} \end{cases} \tag{1}$$

where $a = \{0, 1\}$ is the selected annotation scheme and d_i^* is the ground-truth document annotation. Hence, $d_i^* \in \Omega^D(q_i)$ indicates the candidate set contains the ground-truth annotation and SEM is successful.

For annotating answer spans, the cost is given by

$$c^S(a|\langle q_i, d_i \rangle, s_i^*) = \begin{cases} c_a^S, \text{ if } a = 1 \text{ or } (a = 0 \text{ and} \\ \qquad\qquad s_i^* \in \Omega^S(\langle q_i, d_i \rangle)), \\ c_0^S + c_1^S, \quad \text{otherwise.} \end{cases} \tag{2}$$

Alternatively, we can write the cost function as a matrix of annotation costs (Tbl. 1). The diagonal entries reflect the costs paid for choosing the optimal scheme. The off-diagonals refer to the costs paid for a sub-optimal method (misclassification costs).

4 Learning a Cost-Effective Policy

4.1 Objective

We aim to minimize overall annotation cost via

$$\sum_i \mathbb{E}_{\pi^D, \pi^S} \left[c^D(a|q_i, d_i^*) + c^S(a|\langle q_i, d_i \rangle, s_i^*) \right]. \tag{3}$$

Annotation Costs for a Document d		
	Cost-optimal: MAN	Cost-optimal: SEM
Selected: MAN	c_0^D	c_0^D
Selected: SEM	$c_0^D + c_1^D$	c_1^D

Annotation Costs for an Answer Span s		
	Cost-optimal: MAN	Cost-optimal: SEM
Selected: MAN	c_0^S	c_0^S
Selected: SEM	$c_0^S + c_1^S$	c_1^S

Table 1: Costs for annotating documents (top) and answer spans (bottom). The costs depend on the selected annotation scheme (rows) and the scheme that would have been cost-optimal (columns).

It is important to see that the QA model and the policy model are intertwined, with both having an impact on Eq. 3. Updating the policy models learns the trade-off between SEM and MAN annotations and, hence, directly minimizes the overall costs. Updating the QA model Ω increases the number of times suggested candidates are correct and, therefore, the fraction of successful SEM annotations. For instance, when adapting to a new domain, only a small fraction of suggested candidate annotations are correct, limiting the effectiveness of the SEM annotation. However, as we annotate more samples, we improve Ω and thus more suggested candidate annotations will be correct. For this, we later specify suitable updates for both the QA model and the policy model.

4.2 Annotation Procedure and Learning

Our framework proceeds according to these nine steps when annotating a question q_i (see Alg. 1): First, we predict a number of top-n documents that would be shown to annotators in the case of SEM annotation (line 2). Next, we decide upon the annotation scheme conditional on the prediction from the QA model (line 3) and, based on the selected scheme, request the ground-truth document annotation (line 4). After receiving the ground-truth document and observing the annotation costs, we update our policy network in line 5 (see Sec. 4.3). Next, we predict a number of top-n answer span candidates for the question-document pair (line 6) and then decide upon the annotation scheme in line 7. After receiving the answer span annotation and observing a cost (line 8), we again update our policy model (line 9). Finally, we update the QA model with the newly annotated training sample in line 10 (see Sec. 4.4). In practice, both policy updates and QA model updates (lines 5, 9, and 10) are invoked after a batch of questions is annotated. Furthermore, we initialize all models with an existing dataset (e.g., SQuAD).

Algorithm 1: High-Level Procedure of Annotation and Learning

```
Input : list of questions $[q_1, \dots, q_m]$ text corpus $\mathcal{D}$;
        QA model $\Omega$; policy models $\pi^D$ and $\pi^S$
Result: annotated dataset $\{\langle q_i, d_i, s_i \rangle\}_{0<i<m}$
1  while $i \leq m$ do
2      $[d^{(1)}, \dots, d^{(n)}] \leftarrow \Omega^D(q_i)$; predict top-$n$
         documents
3      $a \leftarrow \pi^D(q_i, [d^{(1)}, \dots, d^{(n)}])$; decide upon
         annotation scheme
4      $d_i \leftarrow annotate(q_i|a)$; annotate document
5      update $\pi^D$ w.r.t. the observed costs $c^D(a|q_i, d_i)$;
6      $[s^{(1)}, \dots, s^{(n)}] \leftarrow \Omega^S(\langle q_i, d_i \rangle)$; predict top-$n$
         answer candidates
7      $a \leftarrow \pi^S(q_i, [s^{(1)}, \dots, s^{(n)}])$; decide upon
         annotation scheme
8      $s_i \leftarrow annotate(\langle q_i, d_i \rangle|a)$; annotate answer
         span
9      update $\pi^S$ w.r.t. the observed costs
         $c^S(a|\langle q_i, d_i \rangle, s_i)$;
10     update QA model $\Omega$ with $\langle q_i, d_i, s_i \rangle$
11 end
```

4.3 Policy Updates

Updating our policy model proceeds in three steps. (1) We calculate whether the chosen action for past annotations was cost-optimal (i.e., whether the policy should have chosen the other scheme for annotation or not). (2) We use this information to update the policy model with a supervised binary classification objective. This trains the policy to predict the probability of an annotation scheme given a new sample $p(a|x)$ without taking costs into account. (3) We find a cost-sensitive decision threshold that chooses the optimal action with respect to the costs. All three steps are repeated after a full batch of samples has been annotated.

Separating the policy update and the cost-sensitive decision threshold has several benefits. First, we know from cost-sensitive classification that we can calculate an optimal threshold point for ground-truth probabilities $p(a|x)$ (c.f. Elkan, 2001; Ting, 2000). Therefore, we can focus our effort on determining probabilities as accurate as possible. Second, the decision threshold is calculated only from the costs c_a^S and c_a^D and, hence, if costs change, we do not need to re-estimate parameters but can directly adjust our policy.

(1) Finding the cost-optimal action: In order to train the policy with a supervised update, we require labels for the cost-optimal annotation scheme for a given sample. If we choose the SEM annotation scheme, we immediately know whether the action was cost-optimal or not. This is due to the fact that, if the semi-supervised annotation fails, we have to switch to the MAN scheme to receive an annotation and pay both costs. On the other hand, if we choose the MAN scheme, we can observe the optimal action only after receiving the ground-truth annotation: We can then simply run the QA model and validate whether the annotation was contained within the top-n candidates. If so, the SEM action would have been the better choice; otherwise, choosing MAN would have been cost-optimal.

(2) Supervised model updates: Our policy model is a neural network with parameters θ that predicts an annotation scheme for a given sample x, i.e.,

$$p(a|x) = \text{NN}_\theta(x). \tag{4}$$

Note that we dropped the S and D indices here as both policies differ only in the neural network architecture used. We can then simply train the policy with a supervised binary cross-entropy loss given the cost-optimal action that we calculated beforehand. Since the SEM scheme is often suboptimal in the beginning, the training data is highly imbalanced. Therefore, we down-sample past annotations with a sampling ratio of α such that our training data is equally balanced.

(3) Cost-sensitive decision threshold: Choosing the annotation scheme with the highest probability does not take the actual costs into account. For instance, if SEM annotations are much cheaper than MAN annotations, we want to choose the semi-supervised scheme even if its probability for success is low. More formally, we want to choose the annotation scheme a that has the lowest expected cost $R(a|x)$, i.e.,

$$R(a \mid x) = \sum_{a'} p(a' \mid x)\, c(a, a') \tag{5}$$

where $c(a, a')$ is the annotation cost for choosing scheme a when the optimal scheme was a' (see Tab. 1). Since we used down-sampling in our training, we have to calibrate the probabilities $p(a|x)$ with the sampling ratio α (Pozzolo et al., 2015). Assuming the calibrated probabilities are accurate, there exists an optimal classification threshold β (Elkan, 2001) that minimizes Eq. 5 and Eq. 3. Therefore, we define our policy as follows:

$$\pi(a|x,\alpha,\beta) = \begin{cases} 1, \text{ if } \frac{\alpha\, p(a=1|x)}{(\alpha-1)\, p(a=1|x)+1} \geq \beta \\ 0, \text{ otherwise.} \end{cases} \tag{6}$$

The optimal β can be derived from the classification cost matrix (Elkan, 2001) via

$$\beta = \frac{c(1,0) - c(0,0)}{c(1,0) - c(0,0) + c(0,1) - c(1,1)}, \tag{7}$$

again omitting superscripts D and S for brevity. Eq. 7 is then simplified as the fraction of SEM annotation costs to MAN annotation costs. Therefore, we can derive β at document level

$$\beta^D = c_1^D / c_0^D, \tag{8}$$

and answer span level

$$\beta^S = c_1^S / c_0^S. \tag{9}$$

4.4 Model Updates

Periodically updating the QA model Ω allows the framework to adapt to the question style and domain at hand during the annotation process. Therefore, we improve the top-n accuracy and the success rate of the SEM scheme over time. For practical reasons, we refrain from updating Ω after every annotation but periodically retrain the model after a batch of samples is annotated. In order to update the QA model, we can use the fully annotated QA samples in combination with a supervised objective.

5 Experimental Setup

In this section, we introduce our experimental setup and implementation details.

5.1 Datasets

We base our experiments on the NaturalQuestion dataset (Kwiatkowski et al., 2019). We choose this dataset as it is composed of about 300,000 real user questions posed to the Google search engine along with human-annotated documents and answer spans. Simulating the annotation of this dataset is similar to what would happen for domain customization of QA models in real practice (e.g., for search logs, FAQs, logs of past customer interactions). We focus on questions from the training-split that possess an answer span annotation and leave the handling of questions that do not have an answer for future work. The corpus for annotations is fixed to the English Wikipedia,[2] containing more than 5 million text documents.

Simulation of annotations: Annotations in our experiments are simulated from the original dataset. If the framework chooses MAN annotation, we simply use the original annotation from the dataset. If a SEM annotation is chosen, we simulate users that give positive feedback only to the ground-truth document and to the answer spans where the text matches[3] the ground-truth annotation. We then construct the new annotation using the candidate with positive feedback. Since we simulate annotations, we conduct extensive experiments on how annotation costs influence the performance of our framework.

5.2 Baselines

To the best of our knowledge, there is no comparable prior work. Owing to this fact, we evaluate our framework against several customized baselines. First, we compare our approach against a manual annotation baseline in which we always invoke the full MAN method to annotate samples. This represents the traditional method of annotating QA datasets and thus our prime baseline. Second, we draw upon a clairvoyant oracle policy that always knows the optimal annotation method. We use this baseline to report an upper bound of the savings that our framework could theoretically achieve. Third, we use our framework without updates on the QA model Ω. This quantifies the cost-savings achieved by the interactive domain customization during annotation. Finally, we present a randomized baseline where the annotation scheme is decided by a randomized coin-toss.

5.3 Implementation Details

The QA model Ω is built as follows. We use a state-of-the-art BERT-based (Devlin et al., 2018) implementation of RankQA (Kratzwald et al., 2019). This combines a simple tf-idf-based information retrieval module with BERT as a module for machine comprehension. Both policy models π^D and π^S are implemented as three-layer feed-forward networks with dropout, ReLu activation, and a single output unit with sigmoid activation in the last layer. For the policy π^D, we use the information retrieval scores as input. For π^S, we use the statistical features of answer-span candidates as calculated by RankQA (Kratzwald et al., 2019) as input. We also experimented with convolutional neural networks directly on top of the last layer of BERT, but without yielding improvements that justified the additional model complexity. We initialize all models with the SQuAD dataset (see our supplements).

Hyperparameter setting: We set the number of candidates that are shown to annotators during a SEM annotation to $n = 5$. The policy networks decide upon the annotation method based on features of the $2n$ highest-ranked candidates, i.e., the top-10. The batch size for updates in Alg. 1 is set to 1,000 annotated questions. Details on hyperparameters of our QA and policy models are provided in the supplements.

6 Experimental Results

We group our experiments into three parts. First, we focus only on annotating the answer span for given question-document pairs, as this is the more challenging task.[4] Second, we carry out a sensitivity analysis in order to demonstrate how our framework adapts to different costs of SEM annotations and to show that we never exceed the cost of traditional annotation. Third, we evaluate our framework based on the annotation of a full dataset, including both answer span and document annotations, in order to quantify savings in practice by using our framework.

6.1 Performance on Answer Span Annotations

The annotation framework was used to annotate 45 batches of question-document pairs with the corresponding answer spans. The annotation costs are set to one price-unit for each MAN annotation and one third of the unit for each SEM annotation. (In the next section, we carry out an extensive sensitivity analysis where the ratio for annotation costs between MAN and SEM is varied.)

In Fig. 2 (left), we plot the average annotation costs in every batch with a dashed line, together with a running mean depicted as a solid line. Compared to conventional, manual annotation, our framework successfully reduces annotation cost by around 15% after only 20 batches. We further

---

[2] We extracted articles from the Wikipedia dump collected in October 2019, as this is close to the time period in which the NaturalQuestions dataset was constructed.

[3] Here we only count exact matches.

[4] Manually finding an answer span involves reading a document in depth. Manual document annotation is easier, as it can be supported with tools such as search engines. In such a case, our framework could still be used for answer span annotation, as is shown in Section 6.1.

compare it with an oracle policy that always picks the best annotation method. The latter provides a hypothetical upper bound according to which approximately 40–45% of annotation cost could be saved. Finally, we show the performance of our framework without updates of the QA model Ω. Here we can see that its improvement over time is lower, as the framework is not capable of adapting to the question style and domain used during annotation. In sum, our framework is highly effective in reducing annotation cost.

Fig. 2 (right) shows how many samples we could annotate (y-axis) with a restricted budget (x-axis). For instance, assume we have a budget of 40k price units available for annotation. Conventional, manual annotation would result in exactly 40k annotated samples as we fixed the cost for each MAN annotation to one unit. With the same budget, our annotation framework with semi-supervised annotations succeeds in annotating an additional ∼9,000 samples.

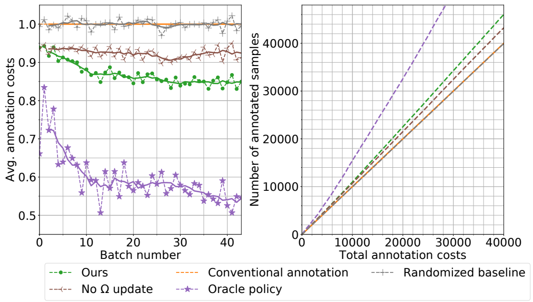

Figure 2: Left: average annotation costs in every batch as a dashed line, together with a running mean as a solid line. Right: how many samples we could annotate (y-axis) with a restricted available budget (x-axis).

6.2 Cost-Performance Sensitivity Analysis

The advantage of our framework over manual annotations depends on the cost ratio between the SEM and MAN schemes. In order to determine this, we identify the cost-range in which our framework is profitable as a function of SEM annotation costs. We study this via the following experiment: we repeatedly annotate 40k samples and keep the MAN annotation costs fixed to one price unit, while we increase the costs of smart annotations from 0.05 to 0.95 in increments of 0.05. Finally, we measure the average annotation costs for a single sample; see Fig. 3 (left).

Fig. 3 (left) demonstrates that our framework effectively lowers annotation costs when the price for SEM annotations drops below 0.6 as compared to manual annotations, which are fixed to one price-unit. Most notably, even when SEM annotations become expensive and almost equal the costs of MAN annotations, the average annotation costs do not exceed those of strictly manual annotation. This can be attributed to our cost-sensitive decision threshold, which does not require exploration as in reinforcement learning, but directly sets the threshold in Eq. 6 sufficiently high.

In Fig. 3 (right), we again show the number of samples that were annotated with a restricted budget of 40k price units. We marked the absolute gain in number of samples over traditional annotation in the plot. The benefit of our framework becomes evident once again when the ratio of SEM annotation costs to MAN annotations costs falls below 0.6.

To summarize, our framework is highly cost-effective: it reduces overall annotation costs or, alternatively, increases the number of annotated samples under a restricted budget if annotation costs of SEM are approximately half those of MAN. If the costs are less than half those of MAN annotation, the benefits are especially pronounced. Even if this assumption does not hold, our framework never exceeds the costs of manual annotation and never results in fewer annotated samples.

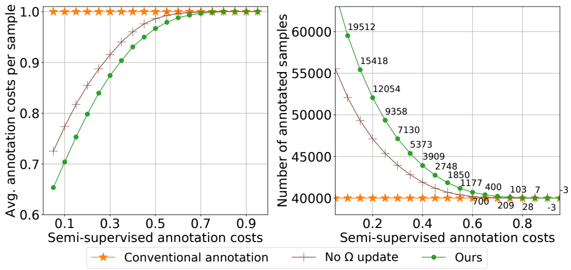

Figure 3: Left: average annotation costs when varying the ratio of SEM over MAN annotation costs. Right: number of samples that were annotated with a restricted budget for a given SEM annotation cost.

6.3 Performance on Full Dataset Annotation

In the last experiment, we simulate a complete annotation of the NaturalQuestions dataset, including annotations at both document level and answer span level. By annotating a complete dataset, we want to quantify the savings of our framework in practice. We again set the cost of each MAN annotation to one price-unit and repeated the experiment three times by setting the SEM annotation cost (c_1)

	Document-level			Answer span-level			Overall		
	$c_1 = 1/4$	$c_1 = 1/3$	$c_1 = 1/2$	$c_1 = 1/4$	$c_1 = 1/3$	$c_1 = 1/2$	$c_1 = 1/4$	$c_1 = 1/3$	$c_1 = 1/2$
Traditional Annotation	102.4	102.4	102.4	102.4	102.4	102.4	204.8	204.8	204.8
Ours	79.8	85.6	98.0	81.8	87.0	98.3	161.6	172.7	196.3
	(22.1%)	**(14.9%)**	**(4.2%)**	**(20.1%)**	**(14.9%)**	**(4.0%)**	**(21.1%)**	**(15.7%)**	**(4.1%)**

Table 2: Overall cost ($\times 10^3$ price unit) for annotating the NaturalQuestions dataset using our framework vs. conventional manual annotation for different SEM costs (c_1). Improvements are shown in parenthesis.

to one quarter, one third, and one half of the price unit. The results are shown in Tbl. 2. Depending on relative cost ratio c_1, we are able to save between 4.1% and 21.1% percent of the overall annotation cost. This amounts to a total of 40,000 to 8,000 price units.[5]

7 Discussion and Future Work

We assume for the purposes of this study that questions have an answer span contained in a single document and leave an extension to multi-hop questions and unanswerable questions to future research. The robustness of our framework is demonstrated in an extensive set of simulations and experiments. We deliberately choose to leave experiments including real human annotators to future research for the following reason. Outcomes of such an experiment would be sensitive to the design of the user interface as well as the study design itself. In this paper, we want to put the emphasis on the methodological innovation of our framework and the novel annotation scheme itself.

On the other hand, experiments involving real users would provide valuable insights concerning the annotation costs and the quality of a dataset annotated with our method. Furthermore, it would be worth investigating how inter-annotator agreement or potential human biases manifest in traditional datasets as compared to those generated with our framework.

8 Conclusion

We presented a novel annotation framework for question answering based on textual content, which learns a cost-effective policy to combine a manual annotation scheme with a semi-supervised annotation scheme. Our framework annotates all given questions accurately while limiting costs as much as possible. We show that our framework never incurs higher costs than traditional manual annotation. On the contrary, it achieves substantial savings. For example, it reduces the overall costs by about 4.1% when SEM annotations cost about half of MAN annotations. When that ratio is lowered to one fourth, our framework can reduce the total costs by up top 21.1%. We think that our framework could contribute to more accessible annotation of datasets in the future and possibly even be extended to other fields and applications in natural language processing.

[5] In these experiments, we obtain the overall cost by directly adding the costs of the two levels. Note that the cost can be different for document and answer span annotations, and that in such cases, our framework can still save costs at each level as shown in the table, although we cannot directly add up the costs as an overall sum.

A Source Code

All source code is available from github.com/bernhard2202/qa-annotation.

B Details on the QA Model

We use the same hyperparemter configuration as reported in Kratzwald et al. (2019) without further fine-tuning. The model was initialized by training on the training split of the SQuADv1.1. dataset (Rajpurkar et al., 2016).

Parameter	Values
Dropout z	0.0, **0.3**, 0.5
Hidden units k	32 64 **128**
Learning rate	**0.0001**, 0.0005, 0.001
Epochs	15, 20, **25**

Table 3: Values used for gridsearch in hyperparameter tuning for the policy π^S

Parameter	Values
Dropout z	0.0, **0.3**, 0.5
Hidden units k	32 64 **128**
Learning rate	**0.0001**, 0.0005, 0.001
Epochs	15, 20, **25**

Table 4: Values used for gridsearch in hyperparameter tuning for the policy π^D

C Details on the Policy Model

The policy models π^D and π^S are implemented as feed forward networks composed of a dense layer with k output units and relu actvation, a dropout layer with dropout probability z, a second dense layer with $k/2$ outputs and relu activation, a dropout layer with dropout probability z, and a dense layer with a single output and sigmoid activation.

Initialization: for the first batch of annotations we initialize the policy models on SQuAD. After the first batch is annotated we only use the new data for policy updates.

Hyperparameter search: We tune hyperparamters on the SQuAD dataset using gridsearch with the values displayed in Tab. 3 and Tab. 4. Bold values mark final choices. We annotated the first 10 batches of SQuAD and choose the hyperparamters that had the lowest anntation cost. No hyperparemter tuning or architecture search was performed on the NaturalQuestions dataset which our experiments are based on.

D Estimation of Real Annotation Costs

In order to provide additional insights on the actual annotation costs involving real users we conducted a pre-test on Amazon MTURK. For this we showed a textual explanation of the MAN and SEM annotation scheme to workers and provided them with mockups for both inputs (answer-span annotation). Next, we asked 40 workers to report how much money they think would be a fair compensation for each of the tasks. Workers reported on average a compensation of \$5.9 for MAN annotations and \$3.2 for SEM annotations. This ratio falls into the range where we make profits using our framework.

E System

All experiments were conducted with a Nvidia Titan Xp GPU on a Server with 192GB DDR4 RAM and two 10 Core Intel Xeon Silver 4210 2.2GHz Processors.

Scene Restoring for Narrative Machine Reading Comprehension

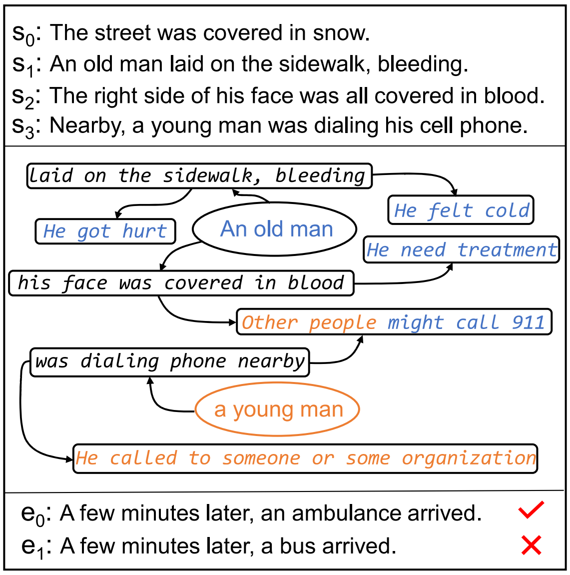
Abstract

This paper focuses on machine reading comprehension for narrative passages. Narrative passages usually describe a chain of events. When reading this kind of passage, humans tend to restore a scene according to the text with their prior knowledge, which helps them understand the passage comprehensively. Inspired by this behavior of humans, we propose a method to let the machine imagine a scene during reading narrative for better comprehension. Specifically, we build a scene graph by utilizing Atomic as the external knowledge and propose a novel Graph Dimensional-Iteration Network (GDIN) to encode the graph. We conduct experiments on the ROCStories, a dataset of Story Cloze Test (SCT), and CosmosQA, a dataset of multiple choice. Our method achieves state-of-the-art.

1 Introduction

Machine Reading Comprehension (MRC) is an NLP task designed to evaluate a machine's ability to understand human language. This direction has recently drawn much attention due to the fast development of deep learning techniques and large-scale datasets. As a basic form of MRC, the comprehension of narrative has attracted long-standing interests (Mostafazadeh et al., 2017; Kočiskỳ et al., 2018; Cui et al., 2019). In this paper, we focus on this kind of MRC task.

Unlike the other type of text, the narratives usually present a series of events, which are related to a scene in real life. In the field of perception, the scene is a kind of information that flows from a physical environment into a perceptual system (Ruderman and Bialek, 1993). When reading a narrative instead of being in a physical environment, humans tend to restore the scene in their mind according to the text with their prior knowledge for better perception and comprehension (Bower and Morrow, 1990; Zwaan et al., 1995). The scene restored is an immediate association about the event, and it could be composed of the event itself, the state of the person roles, the possible cause and effect, and so on. To approach human intelligence, an MRC model is supposed to have a similar ability to restore the scene. However, previous work (Wang et al., 2016; Cui et al., 2019; Zhou et al., 2019a) pay little attention to this ability of narrative MRC models.



s_0: The street was covered in snow.
s_1: An old man laid on the sidewalk, bleeding.
s_2: The right side of his face was all covered in blood.
s_3: Nearby, a young man was dialing his cell phone.

e_0: A few minutes later, an ambulance arrived. ✓
e_1: A few minutes later, a bus arrived. ✗

Figure 1: An example of Narrative MRC. Specifically, it is an example of Story Cloze Test (SCT), where given the first four sentences (s_0, s_1, s_2, s_3) of the story, a model is required to select the suitable ending from the candidates (e_0, e_1). The middle part is a presumable description of the scene restored by a human reader.

Figure 1 is an example of Narrative MRC. While reading the story sentence by sentence, a human tends to restore a scene in his or her mind as described in the figure. Subsequently, the human reader can infer that the suitable ending is e_0 based on information of the scene. Unfortunately, a ma-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3063–3073,

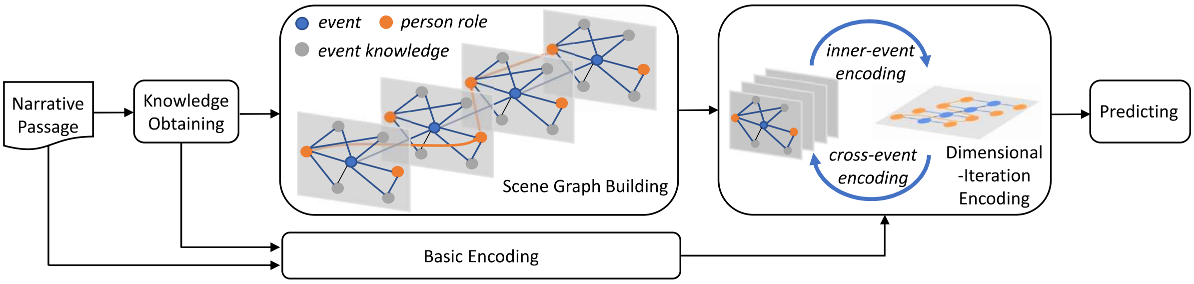

Figure 2: The basic overview of the proposed method

chine reader is not endowed with the ability to associate the prior knowledge, and cannot restore the scene according to the original narrative. As a result, It cannot thoroughly understand what happens in the story and possibly make a wrong decision. To address this problem, we proposed a novel method, which can restore the scene and utilize it to understand the narrative passages.

Firstly, we propose to employ external knowledge as the basic resource for restoring the scene. Some previous works (Chen et al., 2019; Guan et al., 2019) also employ external knowledge in Narrative MRC. However, most of them use the concept knowledge from ConceptNet (Liu and Singh, 2004), WordNet (Fellbaum, 1998), or other word-centered knowledge bases to obtain the association information for the noun phrases mentioned in the story. This kind of method is able to help the machine to understand what is mentioned in the story, but not what happens in the story. For example, with those methods, given the sentence "The right side of his face was all covered in blood.", the machine understand the noun phrases "right side" "face" and "blood" better, but is still unable to know exactly that a man is hurt, he needs medical assistance, and some others nearby might help him. **To this end, we select an event-based knowledge graph, Atomic (Sap et al., 2019), as the source of external knowledge.** Atomic is an atlas of everyday commonsense reasoning. Each center node of Atomic is an event like "PersonX's face is covered in blood", and the nodes associated with it are the cause, the effect, and the attribute of the roles of the events. Therefore, Atomic is beneficial for the machine to know "what happens".

Secondly, we utilize a structured description to restore the scene. **Specifically, we build a scene graph based on the original narrative and the knowledge from Atomic.** Compared with the unstructured text, graph data can represent the scene more intuitively. In MRC task, previous works (Kipf and Welling, 2016; Qiu et al., 2019) that utilize structured data generally regard the words or noun phrases as the nodes of the graph. Those methods have no specific for Narrative MRC, where the events and the roles are the key factors. Therefore, we build the scene graph by taking the events, the persons, and the external knowledge of the event as the nodes. Meanwhile, we design the connections of the graph from both the perspectives of each event and the whole passage. **Instead of the typical plane graph, we build a three-dimensional graph, which can not only model the relevance among the events in the passage but also retain the unique information of each event.** To encode the graph in a targeted manner, **we propose Graph Dimensional Iteration Network (GDIN).** GDIN can encode the scene graph iteratively and thus obtain the integrated representation of the scene graph. As a result, the machine will understand the narrative more comprehensively and make the decision more precisely.

To summarise, inspired by human behaviors, we propose a novel method to restore the scene for narrative MRC. Specifically, we introduce event knowledge from Atomic (Sap et al., 2019), and build the scene graph to describe the scene. To encode the graph, we propose a novel graph neural network, GDIN. We conduct experiments on two datasets, ROCStories (Mostafazadeh et al., 2017) and CosmosQA (Huang et al., 2019). The results show that our method achieves state-of-the-art.

2 Method

The overview of our method is shown in Figure 2. Our starting point is to let the machine restore the scene like a human while reading narrative passages and then utilize the information from the scene to better comprehension. As shown in Figure 2, given a narrative passage, we firstly obtain the knowledge for the events mentioned in the passage. Subsequently, we build a scene graph, a three-dimensional graph, whose nodes contain events, person roles, and event knowledge. The graph is composed of two kinds of plane graphs: one is the inner-event graph, which describes a single event; the other is the cross-event graph, which captures the relevance among the events. Meanwhile, we conduct a basic encoding for the narrative passage and the knowledge and then obtain their original representation. By utilizing our proposed Graph Dimensional-Iteration Network (GDIN), we encode the scene graph from the inner-event graph to cross-event graph iteratively. To this end, we obtain the representation of the scene and then make a prediction based on it.

2.1 Knowledge Obtaining

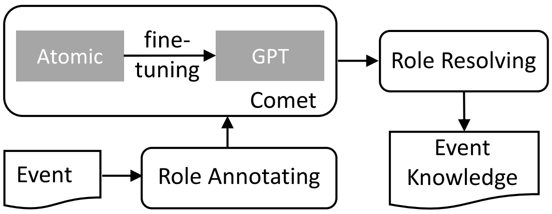

Figure 3: The process of obtaining event knowledge

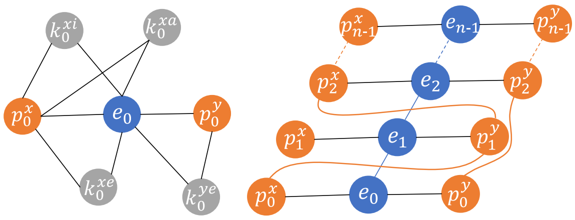
To endow the model with the ability to associate the event-relevant description, we introduce external knowledge from Atomic. Atomic is an event-based knowledge graph. It contains 24,313 central nodes (i.e., base events) like "PersonX repels PersonY's attack". Each of them is linked to multiple types of knowledge nodes, such as the effect on PersonX (e.g., Person X's heart races), the cause of PerosnX (e.g., X wanted to protect himself), the effect on PersonY (e.g., Y gets hurt) and so on. As those knowledge nodes are also events, there are totally 877,108 $\langle event, relation, event \rangle$ triples.

Nevertheless, due to the diversity of real-world events, Atomic cannot cover all the events. Meanwhile, even if the coverage is acceptable for everyday events, the accuracy of event linking (link a certain event text to Atomic) also cannot be ensured. Therefore, we employ the pre-training framework, Comet (Bosselut et al., 2019), which is originally proposed for the task of knowledge base completion. Specifically, Comet is obtained by fine-tuning GPT (Radford et al., 2018) on Atomic. The training task is inputting the start event and the relation $\langle event, relation, \_ \rangle$, and then generating the end event of the triple.

By employing Comet, we design the process of obtaining event knowledge, as shown in Figure 3. Given an event like "Jerry repels Tom's attack", to approximate the phrases in Atomic, we firstly annotate the person roles, that is, replacing the subject person with "PersonX" and the other person with "PersonY". Thus, we get "PersonX repels PersonY's attack". Secondly, **we input it to the Comet and obtain the event knowledge.** According to the demand of restoring the scene, we select four types of them, including **"xIntend"** (Why does X cause the event), **"xEffect"** (What effects does the event have on X), **"yEffect"** (What effects does the event have on Y), and **"xAttr"** (How would X be described). For example, "xIntend" here could be "PersonX wanted to protect himself". Finally, we resolve the normalized person roles, that is, replacing "PersonX" and "PersonY" with the original person names. For example "xIntend" will finally be "Jerry wanted to protect himself".

2.2 Scene Graph Building

Having annotated the person roles and obtained relevant knowledge for every event, we build a graph, named "scene graph", to present a structured description for the scene. We believe that compared with the unstructured text, the graph can provide a more intuitive description from the perspective of the events for the scene.



(a) inner-event graph (b) cross-event graph

Figure 4: Two types of plane graphs, which compose the three-dimensional scene graph. For i-th ($i \in \{0, 1, 2...n-1\}$) event, we denote the nodes as follows: e_i (event), p_i^x (PersonX), p_i^y (PersonY), k_i^{xa}(xAttr), k_i^{xi}(xIntend), k_i^{xe}(xEffect), k_i^{ye}(yEffect).

The "Scene Graph Building" part in Figure 2 shows the full view of a scene graph. It is a three-dimensional graph composed of two kinds of plane graphs: inner-event graph and cross-event graph as shown in Figure 4. **The nodes of event and person are the intersection between the two types**

of graphs. The inner-event graph describes a single event, and the cross-event graph captures the relevance among the events, including the narrative order and the person coreference. Accordingly, we build an inner-event graph for each event and a cross-event graph for the whole narrative passage.

The graph contains three kinds of nodes: event, person role, and event knowledge. The links of the graph are designed as follows: (1) In each inner-event graph, a) we link every event knowledge to the event; b) The person roles are linked to the event; c) Each knowledge is linked to its corresponding person. (2) In the cross-event graph, a) we link each event to the adjacent event, which could capture the narrative order; b) To pass information from the perspective of the role, we conduct a coreference resolution and build a connection between two mentions for the same person across the events. To this end, we obtain two kinds of adjacent matrixes for those plane graphs. They are formulated as $A_i^{inner} \in \mathbb{R}^{7\times 7}$ ($i \in \{0, 1, 2...n-1\}$) and $A^{cross} \in \mathbb{R}^{3n\times 3n}$, where $n-1$ is the total number of the events in the passage.

2.3 Basic Encoding

Before the process of graph encoding, we employ a pre-trained Language Model (LM) to conduct a basic encoding and obtain the original representation of the nodes. For a certain sequence (e.g., a sentence or a passage), the representation is calculated by

$$S^{seq}, S = \boldsymbol{LM}\left(sequence\right) \in \mathbb{R}^{L_s\times d}, \mathbb{R}^{d}$$

where L_s denotes the word-level length of the sequence, and d is the dimensional size of the representation. We take S as the sequence representation. Thus inputting the narrative passage to the LM, we can obtain $C^{seq} \in \mathbb{R}^{L_p\times d}$ and $C \in \mathbb{R}^{d}$. In a specific task, the passage will be concatenated with other text (e.g., question or candidate) together as the input sequence, which will be detailed in 2.5.

In practice, we regard each sentence in the narrative passages as an event, and thus from C^{seq} we can extract $E_i^{seq} \in \mathbb{R}^{L_e\times d}$, the representation of the words of i-th event, according to its sentence span. Then, we merge it by max-pooling, and obtain $E_i^{(0)} \in \mathbb{R}^{d}$, the original representation of i-th event. Meanwhile, the representation of the roles can be extracted from C^{seq} based on their position as well. Therefore, for the subject person, PersonX, we have $P_i^{x(0)} \in \mathbb{R}^{d}$; For the other person, PersonY, we have $P_i^{y(0)} \in \mathbb{R}^{d}$. Specifically, for each role, we take the representation of its first word as its overall representation. Moreover, taking each knowledge as the input of the LM, we can get the representation for it. Hence, for "xIntend", "xEffect", "yEffect", "xAttr", we have $K_i^{xi(0)}$, $K_i^{xe(0)}$, $K_i^{ye(0)}$, $K_i^{xa(0)} \in \mathbb{R}^{d}$, respectively.

2.4 Dimensional-Iteration Encoding

To encode the graph in a targeted manner and model the scene from both the perspectives of each event and the whole passage, we propose Graph Dimensional-Iteration Network (GDIN) based on Graph Convolutional Network (GCN) (Kipf and Welling, 2016). As shown in Figure 2, GDIN encodes the graph along the dimension of inner-event graph and then encodes it along the dimension of cross-event graph, which is an iterable process. As the original representation of every node has been obtained by the basic encoding, we conduct a dimensional-iteration encoding with GDIN as follows:

(1) Encoding along the dimension of inner-event graph: At t-step, for i-th inner-event graph, we formulate the representation of its nodes as $H_i^{(t)} = [E_i^{(t)}; P_i^{x(t)}; P_i^{y(t)}; K_i^{xi(t)}; K_i^{xe(t)}; K_i^{ye(t)}; K_i^{xa(t)}] \in \mathbb{R}^{7d}$, where the symbol";" denotes concatenation. Then we update the representation of all nodes by

$$H_i^{(t+1)} = \sigma\left(D^{in^{-\frac{1}{2}}} A_i^{\widetilde{inner}} D^{in^{-\frac{1}{2}}} H^{(t)} W^{in}\right)$$

$$A_i^{\widetilde{inner}} = A_i^{inner} + I$$

where I is the identity matrix. $W^{in} \in \mathbb{R}^{7d\times 7d}$ is a trainable matrix and σ is the activation function. ${D^{in}}_{pp} = \sum_q \left(A_i^{inner} + I\right)_{pq}$ is the degree matrix.

(2) Encoding along the dimension of cross-event graph: At (t+1)-step, for the cross-event graph, we collect the nodes of person and event from those above inner-event graphs, and then we formulate the representation of its nodes as $H^{(t+1)} = [E_0^{(t+1)}; P_0^{x(t+1)}; P_0^{y(t+1)}; E_1^{(t+1)}; P_1^{x(t+1)}; P_1^{y(t+1)}; ...; E_{n-1}^{(t+1)}; P_{n-1}^{x(t+1)}; P_{n-1}^{y(t+1)}] \in \mathbb{R}^{3nd}$ Subsequently, we update the representation of the nodes of person and event by

$$H^{(t+2)} = \sigma\left(D^{cs^{-\frac{1}{2}}} A^{\widetilde{cross}} D^{cs^{-\frac{1}{2}}} H^{(t+1)} W^{cs}\right)$$

$$A^{\widetilde{cross}} = A^{cross} + I$$

where $W^{cs} \in \mathbb{R}^{3nd \times 3nd}$ is a trainable matrix, and ${D^{cs}}_{pp} = \sum_q \left(A^{cross} + I\right)_{pq}$ is the degree matrix. Note that, in this step the representation of the knowledge does not change. Taking the xEffect knowledge as an example, at this step we have $K_i^{xe(t+2)} = K_i^{xe(t+1)}$.

Iterating: The nodes of event and person are the intersection between the two types of graphs. With iterating **(1)** and **(2)**, the information passes across different dimensions along those nodes. Therefore, **GDIN can model the three-dimensional scene graph from both the perspectives of each event and the whole passage**. Assuming it iterating for L loops, we obtain $H_i^{(T)} \in \mathbb{R}^{7d}$, where $T = 2L-1$. The representation of i-th event, $E_i^{(T)} \in \mathbb{R}^d$, can be extracted from $H_i^{(T)}$.

We merge the representation of all the events by $C^s = \sum_i \alpha_i E_i^{(T)}$. The weight α is calculated by

$$\alpha_i = \frac{\exp\left(\sigma\left(\mathbf{w_p} E_i^{(T)}\right)\right)}{\sum_{i'} \exp\left(\sigma\left(\mathbf{w_p} E_{i'}^{(T)}\right)\right)}$$

where $w_p \in \mathbb{R}^d$ is a trainable vector. C^s is the representation of the narrative passage built from the description of the scene. Subsequently, we obtain the final representation of the passage by a residual connection: $C^f = [C^s; C] \in \mathbb{R}^{2d}$.

2.5 Task-Specific Input and Output

We evaluate our method on two types of MRC test, story cloze test and multiple choice. Given a passage, the former requires the model to select a suitable ending from two candidates; the latter requires the model to select the answer for a certain question from four candidates. We prepare the input for the model following Devlin et al. (2018) and Radford et al. (2018). For the story cloze test, we concatenate each ending with the given passage as the input sequence of basic encoding. Then we can obtain an ending-aware passage representation C^{seq} and C. For multiple choice, we concatenate each option with the question and the passage as the input sequence. Thus we get a option-question-aware passage representation C^{seq} and C. After basic encoding and dimensional iteration encoding, we have the final representation C^f. In both the above tests, there is C_j^f, which is the passage representation for j-th candidate. To this end, we score each candidate by

$$score_j = \frac{\exp\left(C_j^f w_s\right)}{\sum_{j'} \exp\left(C_{j'}^f w_s\right)}$$

where $score_j$ is the normalized selection score of the j-th candidate. $w_s \in \mathbb{R}^{2d}$ is a trainable vector. Then we predict by taking the candidate with the highest score as the ending or the answer.

3 Experiments and Analysis

3.1 Datasets and Metrics

The datasets we choose are ROCStories (Mostafazadeh et al., 2017) and CosmosQA (Huang et al., 2019). The passages of both the above datasets are narrative.

ROCStories: a popular dataset of Story Cloze Test (SCT), annotated by Amazon Mechanical Turk (MTurk) workers based on a collection of short stories. In development and test set, each instance contains a four-sentence passage, and two candidate endings, while the train set only provides the original five-sentence story containing the proper ending. Following previous works (Cai et al., 2017; Chaturvedi et al., 2017; Cui et al., 2019), we take the development set for training and evaluate the performance on the test set.

CosmosQA: a recently proposed dataset formulated as multiple choice. The narratives are collected from the Spinn3r Blog dataset (Burton et al., 2009) and annotated by MTurk. We train and validate the model on the train set and the development set, respectively. As the label of the test set is not public, we evaluate our model by submitting the predictions to the official website[1].

Evaluation Metrics: As the targets of both the above tests are making a choice among the candidates, we use the common metric, accuracy, for evaluation.

3.2 Implementation Details

In practice, we regard each sentence in the narrative passages as an event. When annotating the person roles in a particular sentence, we employ spaCy[2] for dependency parsing. To link two mentions for the same person across the sentences while building a graph, we utilize Neural Coreference[3] for

coreference resolution. Particularly, in the case where person roles (PersonX or PersonY) could not be found in the sentence, we drop the corresponding nodes (person and relevant knowledge) while building the scene graph.

For a fair comparison with the state-of-the-art models, we employ pre-trained language model, BERT-large (Devlin et al., 2018) and ALBERT-xxlarge (Lan et al., 2020)for basic encoding, respectively. The optimizer we choose is Adam. The learning rates are 5×10^{-6} for the model based on BERT and 1×10^{-5} for that based on ALBERT. We train both the models for three epochs with a 0.1 dropout rate.

3.3 Baselines

We present a series of previous works as baselines for each dataset. For brevity, we only detail those recently published advanced methods.

LM-FT: a kind of model that combines a task-specific output layer with the pre-trained language model, LM. The model is fine-tuned on ROCStories or CosmosQA. LM could be GPT (Radford et al., 2018), BERT, RoBERTa (Liu et al., 2019) , or ALBERT. Note that the BERT model is BERT-large, which is the same as that in our method for ROCStories; The ALBERT model is ALBERT-xxlarger and which is the same as that in our method for CosmosQA.

Concept: a neural network model for SCT. This model employs a pre-trained language model, which is initialized from GPT and introduces the external knowledge from ConceptNet.

BERT+Diff-Net: the state-of-the-art model for SCT. It employs the pre-trained language model, BERT (BERT-large). In particular, it focuses on better modeling the differences of each ending and discriminates two endings in three semantic aspects: contextual representation, story-aware representation, and discriminative representation.

K-Adapter: a recently proposed advanced method. It contains multiple knowledge-specific adapters. Those adapters infuse entity and syntax knowledge from T-REx (Elsahar et al., 2019) and Book Corpus (Zhu et al., 2015), respectively, into the pre-trained language model (RoBERTa).

3.4 Overall Performance

Table 1 reports the results on the ROCStories dataset. Our proposed method, which restores the scene by the graph and GDIN, outperforms the state-of-the-art model, BERT+Diff-Net (Cui et al., 2019), by 1.9% in terms of accuracy. The results on the CosmosQA dataset are shown in Table 2. Our method outperforms the published state-of-the-art models, K-Adapter (Wang et al., 2020) and ALBERT-FT (Lan et al., 2020), by a considerable margin. Those results demonstrate the effectiveness of our overall method.

3.5 Effectiveness of the Event Knowledge

As stated in 2.1, Knowledge Obtaining, we choose the event relevant knowledge from Atomic instead of the concept knowledge from ConceptNet, WordNet, or other word-centered knowledge bases. To validate the effectiveness of the event knowledge, we employ GPT and RoBERTa for basic encoding. We combine them with GDIN, respectively, and conduct experiments on the two datasets. Table 3 shows the results of the experiments. Our model, GPT+GDIN, surpasses Concept, which utilizes GPT and the knowledge from ConceptNet. Meanwhile, the performance of RoBERTa+GDIN

Table 4: Comparison between different description of the scene

is better than that of K-Adapter, which employs RoBERTa and entity and syntax knowledge. To a certain extent, those pairs of comparison verify the effectiveness and suitability of the event knowledge we choose for narrative MRC.

3.6 Effectiveness of the Scene Graph

As stated in 2.2, Scene Graph Building, we propose a three-dimensional graph to describe the scene. To verify the advantages of this method, we build two baselines as follows:

BERT+Flat: a method that describes the scene by the flatten unstructured text. Specifically, BERT+Flat attaches the knowledge sentences to their corresponding event text, and organizes an unstructured description by the template:

$$\textbf{xAttr}+\text{and}+\textbf{xIntend}+\textbf{Event}+\textbf{xEffect}+\textbf{yEffect}$$

where the subject name of xIntend is dropped for fluency. During the process of encoding, the passage joined with the event knowledge is encoded as a whole, and the ending-aware (or option-question-aware) passage representation C is applied directly to predict. Figure 5 shows an example of the comparison between the unstructured description and the structured one for the scene.

BERT+Plane: a method that merges our proposed three-dimensional scene graph into a unified plane graph. Specifically, we put all of the inner-event graphs on a single plane and then build connects among them with the links of the cross-event graph, e.g., the link between e_0 and e_1. Because GDIN is

Iteration Step	Accuracy
1 (no iteration)	90.8
2	**91.9**
3	91.4
4	91.0
5	90.9

Table 5: Comparison between different iteration steps

not suitable for this plane graph, we encode it by a two-layer GCN instead. The other processes are the same as those in our proposed method.

The comparison results on ROCStories dataset are shown in Tabel 4. Compared with BERT+Flat, the graph-based method, BERT+GDIN shows significant advantages. The result further confirms our belief that the structured data provides a more intuitive and exploitable description of the scene for the machine. Besides, BERT+GDIN surpasses BERT+Plane, which verifies the effectiveness of our proposed three-dimensional graph. From our point of view, during the process of encoding, the unified plane graph can not retain the unique information of each event as well as the three-dimensional graph does.

3.7 Effectiveness of Iterable Encoding

As stated in 2.4, Dimensional-Iteration Encoding, we propose a novel neural network, GDIN, for encoding the three-dimensional scene graph in a targeted manner. To study the effectiveness of the iteration, we set a different number of iteration steps for our model and conduct experiments on ROCStories. The results are shown in Table 5. On the one hand, when the number is 1, where the model does not iterate actually, the performance lag obviously behind that of 2 steps. This demonstrates the effectiveness of the iteration. On the other hand, by increasing the step number, the performance rises up rapidly and then drops down slowly. This phenomenon indicates that in addition to enabling the iteration, it is also important to select a proper iteration step. We deduce that the proper step is the balance point where each event retains its unique information, and at the same time, also gets the associated information from the whole passage.

4 Related Work

Machine Reading Comprehension: Due to the fast development of deep learning techniques and large-scale datasets, Machine Reading Comprehension(MRC) has gained increasingly wide attention over the past few years. Richardson et al. (2013) build the multiple-choice dataset MCTest, and this dataset encourages the early research of machine reading comprehension, and a strand of MRC models (Sachan et al., 2015; Narasimhan and Barzilay, 2015) are inspired by the dataset. Hermann et al. (2015) propose a cloze test dataset CNN & Daily Mail, which is large-scale and more suitable than MCTest for deep learning methods. Based on this dataset, Hermann et al. (2015) proposes an attention-based LSTM model named Attentive Reader, and Chen et al. (2016) simplify this model by directly utilize the query-aware context representations to match the candidate answer. Moreover, Rajpurkar et al. (2016) release the span extraction dataset, SQuAD, which has become the most popular MRC dataset over recent years. This dataset enlightens a lot of classical MRC model, like Bidirectional Attention Flow (BiDAF) (Seo et al., 2016) and R-Net (Wang et al., 2017b). Recently, there are some new trends in this field, such as multi-passage MRC (Campos et al., 2016), knowledge-based MRC (Ostermann et al., 2018) and multi-hop MRC (Yang et al., 2018; Min et al., 2019).

Narrative Comprehension: Understanding narrative is a challenging task in natural language understanding, for the passages contain rich cause and effect relations. A large body of previous works focus on scripts learning (Schank and Abelson, 1977). Some previous works addressed script learning by focusing on the narrative cloze test (Chambers and Jurafsky, 2008). Story Cloze Test (Mostafazadeh et al., 2017) is then introduced as a new evaluation framework, and gains wide attention (Chaturvedi et al., 2017; Zhou et al., 2019b). Besides, recent works present other test frameworks for narrative comprehension, such as multiple choice (Huang et al., 2019) and answer generation (Kociský et al., 2018). Compared with the other complex forms of test, e.g., answer generation, the test frameworks we choose (selecting ending or answer) are more focused on narrative comprehension itself.

5 Conclusion

In this paper, we focus on Narrative Machine Reading Comprehension. Inspired by human behaviors, we propose a novel method to restore the scene for the narrative passage. Specifically, we introduce the event knowledge from Atomic and build a three-dimensional graph to describe the scene. To encode the scene graph, we propose Graph

Dimensional-Iteration Network (GDIN). We conduct experiments on two relevant datasets, ROCStories and CosmosQA. The result shows our method achieves state-of-the-art. Further experimental investigation shows that (1) compared with concept knowledge, the event knowledge we choose is more suitable for narrative MRC; (2) Our proposed graph models the scene more effectively than the unstructured text and the unified plane graph do; (3) Our proposed GDIN encodes the scene graph efficiently by iterating multiple steps.

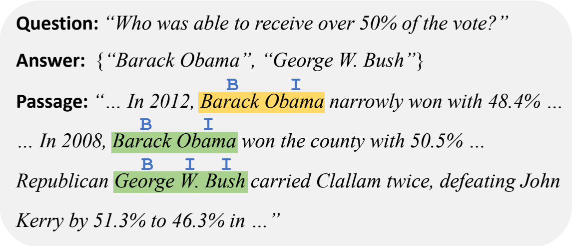
Abstract

Models for reading comprehension (RC) commonly restrict their output space to the set of all single contiguous spans from the input, in order to alleviate the learning problem and avoid the need for a model that generates text explicitly. However, forcing an answer to be a single span can be restrictive, and some recent datasets also include *multi-span questions*, i.e., questions whose answer is a set of non-contiguous spans in the text. Naturally, models that return single spans cannot answer these questions. In this work, we propose a simple architecture for answering multi-span questions by casting the task as a sequence tagging problem, namely, predicting for each input token whether it should be part of the output or not. Our model substantially improves performance on span extraction questions from DROP and QUOREF by 9.9 and 5.5 EM points respectively.

1 Introduction

The task of reading comprehension (RC), where given a question and context, one provides an answer, has gained immense attention recently. In most datasets and models (Rajpurkar et al., 2016; Trischler et al., 2016; Seo et al., 2017; Yu et al., 2018; Kwiatkowski et al., 2019), RC is set up as an *extractive* task, where the answer is constrained to be a single span from the input. This makes learning easier, since the model does not need to generate text *abstractively*, while still being expressive enough to capture a large set of questions.

However, for some questions, while the answer is indeed extractive, i.e., contained in the input, it is not *a single span*. For example, in Figure 1 the answer includes two people who appear as non-contiguous spans in the context. Existing models (Seo et al., 2017; Dua et al., 2019) are by design unable to provide the correct answer to such *multi-span questions*.



Question: *"Who was able to receive over 50% of the vote?"*

Answer: {*"Barack Obama", "George W. Bush"*}

Passage: *"... In 2012, Barack Obama narrowly won with 48.4% ... ... In 2008, Barack Obama won the county with 50.5% ... Republican George W. Bush carried Clallam twice, defeating John Kerry by 51.3% to 46.3% in ..."*

Figure 1: A *multi-span question* from DROP, and a `BIO` tagging for it (`O` tags omitted). The first occurrence of *Barack Obama* does not answer the question.

While most work has largely ignored this issue, recent work has taken initial steps towards handling multi-span questions. Hu et al. (2019) proposed to predict the number of output spans for each question, and used a non-differentiable inference procedure to find them in the text, leading to a complex training procedure. Andor et al. (2019) proposed a `Merge` operation that merges spans, but is constrained to at most 2 spans. Chen et al. (2020) proposed a non-differentiable symbolic approach which outputs programs that compose single-span extractions.

In this work, we propose a simple and fully differentiable architecture for handling multi-span questions that evades the aforementioned shortcomings, and outperforms prior work. Similar to Yao et al. (2013), who used a linear model over tree-based features, we cast question answering as a *sequence tagging task*, predicting for each token whether it is part of the answer. At test time, we decode the answer with standard decoding methods, such as Viterbi.

We show the efficacy of our approach on span-extraction questions from both the DROP (Dua et al., 2019) and QUOREF (Dasigi et al., 2019) datasets. Replacing the single-span architecture with our multi-span approach improves performance by 7.8 and 5.5 EM points respectively. Com-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3074–3080,
November 16–20, 2020.

bining the single-span and multi-span architectures further improves performance by 2.1 EM on DROP, surpassing results by other span-extraction methods on both datasets.

2 Background: Single-span Model

Setup Given a training set of question-context-answer triplets $(q_i, c_i, a_i)_{i=1}^N$, our goal is to learn a function that maps a question-context pair (q, c) to an answer a. We briefly review the standard *single-span architecture* for RC (Devlin et al., 2019), which we build upon.

First, we encode the question and context with a pre-trained language model, such as BERT (Devlin et al., 2019): $\boldsymbol{h} = \text{Encoder}([q, c])$, where $\boldsymbol{h} = (\boldsymbol{h}_1, \ldots, \boldsymbol{h}_m)$ is a sequence of contextualized representations for all input tokens. Then, two parameterized functions (feed-forward networks), $f_{\text{start}}(\boldsymbol{h}_i)$ and $f_{\text{end}}(\boldsymbol{h}_i)$, are used to compute a score for each token, corresponding to whether that token is the start or the end of the answer. Last, the start and end probability for each token i is computed as follows:

$$\boldsymbol{p}_i^{\text{start}} = \text{softmax}\left(f_{\text{start}}(\boldsymbol{h}_1), \ldots, f_{\text{start}}(\boldsymbol{h}_m)\right)_i,$$
$$\boldsymbol{p}_i^{\text{end}} = \text{softmax}\left(f_{\text{end}}(\boldsymbol{h}_1), \ldots, f_{\text{end}}(\boldsymbol{h}_m)\right)_i,$$

where both $\boldsymbol{p}^{\text{start}}, \boldsymbol{p}^{\text{end}} \in \mathbb{R}^{m \times 1}$. Training is done by minimizing cross entropy of the start and end indices of the gold span, and at test time the answer span is extracted by finding the indices (s, e):

$$(s, e) = \arg\max_{s \leq e} \ \boldsymbol{p}_s^{\text{start}} \boldsymbol{p}_e^{\text{end}}.$$

3 Multi-span Model

3.1 Span Extraction as Sequence Tagging

Extracting a variable number of spans from an input text is standard in many natural language processing tasks, such as Named Entity Recognition (NER) and is commonly cast as a sequence tagging problem (Ramshaw and Marcus, 1995). Here we apply this approach to multi-span questions.

Our model uses the same contextualized representations $\boldsymbol{h}$, but rather than predicting start and end probabilities, it outputs a probability distribution over a set of tags for each token. We experiment with two tagging schemes. First, the well-known `BIO` tagging (Sang, 2000; Huang et al., 2015), in which `B` denotes the first token of an output span, `I` denotes subsequent tokens in a span, and `O` denotes tokens that are not part of an output span. In addition, we experiment with a simpler `IO` tagging scheme, where words are tagged as either part of the answer (`I`) or not (`O`). Formally, given a tagging scheme with $|S|$ tags ($|S| = 3$ for `BIO` and $|S| = 2$ for `IO`), for each of the m tokens, the probability for the tag of the i-th token is

$$\boldsymbol{p}_i = \text{softmax}(f(\boldsymbol{h}_i)) \quad (1)$$

where $\boldsymbol{p} \in \mathbb{R}^{m \times |S|}$, and f is a parameterized function with $|S|$ outputs.

3.2 Training

Assume each answer a is a set of strings, where each string corresponds to a span in the input. We would like to train our model to predict the correct output for this set of spans. When the answer spans appear only once in the input, this is simple, since the ground-truth tagging is immediately available. However, there are many cases where a given answer span appears multiple times in the input. We next explain how to address this.

To illustrate, consider the following simple example (assume a `BIO` scheme). Given the input "X Y Z Y Z" and the correct multi-span answer {"X", "Z"}, there are three possible gold taggings: `B O B O B`, `B O B O O`, and `B O O O B`. Thus, the ground-truth `BIO` cannot be determined unambiguously in this case. Figure 1 illustrates this issue with a real example from DROP.[1]

To tackle the above issue, we enumerate over the set of all *possibly-correct taggings*, $\mathcal{T}$, where given a multi-span answer a, a possibly-correct tagging is one in which all gold answer spans are tagged as such at least once.[2] We train our models by maximizing the marginal probability of all possibly-correct taggings:

$$\log p(\mathcal{T} \mid \boldsymbol{h}) = \log \sum_{\boldsymbol{T} \in \mathcal{T}} \left(\prod_{i=1}^{m} \boldsymbol{p}_i[\boldsymbol{T}_i] \right),$$

where $\boldsymbol{p}_i[\boldsymbol{T}_i]$ (see Eq. (1)) is the probability the model assigns to token i having the tag $\boldsymbol{T}_i$. The loss is minimized when $\boldsymbol{p}$ gives probability 1.0 to one of the possibly-correct taggings in $\mathcal{T}$.

3.3 Decoding Spans from a Tagging

At test time, given predicted tag probabilities $\boldsymbol{p}$, we would like to find the most likely tagging $\hat{\boldsymbol{T}}$. Let $\mathcal{V}$

---

[1] In QUOREF, the indices of the gold answer spans are explicitly given, so a single gold tagging can be defined.

[2] While $|\mathcal{T}|$ can grow exponentially with the number of spans in an answer, in practice $|\mathcal{T}|$ is at most 1000 for 99.66% of the examples of DROP, and so we can enumerate over $\mathcal{T}$ directly in these cases. In the other 0.34%, we take a single tagging that marks all occurrences of the answer spans.

be the set of all valid taggings. We wish to find:

$$\hat{\boldsymbol{T}} = \arg\max_{\boldsymbol{T} \in \mathcal{V}} \prod_{i=1}^{m} \boldsymbol{p}_i[\boldsymbol{T}_i].$$

For `BIO` tags, the set $\mathcal{V}$ comprises all taggings that don't include an `I` after an `O`, and the maximization problem can be solved in linear time using Viterbi decoding (Viterbi, 1967) as in Yao et al. (2013); Mehta et al. (2018). For `IO` tags, all taggings are valid, and maximization is done by predicting the tag with highest probability in each token independently. Because answer spans are (practically) never adjacent in RC, an `IO`-tagging produces a set of spans by choosing all maximal spans that are contiguously tagged with `I`.

4 "Multi-Head" Models

Some RC datasets contain questions where the output is not necessarily a span. For example, in DROP, the answer to some questions is a number that is not in the text, but can be computed by performing arithmetic operations. To handle such cases, many models (Dua et al., 2019; Hu et al., 2019) employ a *multi-head architecture*. In these models, each *head* z is a small module that takes the contextualized representations $\boldsymbol{h}$ as input and computes a probability distribution over answers $p_z(a \mid q, c) = p_z(a \mid \boldsymbol{h})$. For example, in Hu et al. (2019), there are two heads that output spans, and three heads that output numbers. To determine which head to use for each question, an additional module is trained: $p_{\text{head}}(z \mid q, c) = p_{\text{head}}(z \mid \boldsymbol{h})$. Thus, the model probability for an answer is:

$$p(a \mid q, c) = \sum_{z} p_{\text{head}}(z \mid q, c) \cdot p_z(a \mid q, c).$$

With this architecture, we can seamlessly integrate our multi-span approach into existing RC models. Specifically, a model can include both a single-span head and a multi-span head, dynamically deciding which span extraction method to utilize based on the input.

5 Empirical Evaluation

Experimental setup As an encoder, we use the Hugging Face implementation of RoBERTa$_{\text{LARGE}}$ (Wolf et al., 2019; Liu et al., 2019), which produces the representations $\boldsymbol{h}$. For DROP, we add the arithmetic and count heads from Dua et al. (2019) to handle non-span questions. Full details of the experimental setup are in Appendix A.

5.1 Results

Table 1 shows development set results on the *span-extraction questions* of DROP (Dua et al., 2019) and QUOREF (Dasigi et al., 2019). We compare the previous best-performing multi-span models to a combination of our multi-span architecture (TASE: TAg-based Span Extraction) with the traditional single-span extraction (SSE), as well as to each separately.

Comparison to previous models For a fair comparison with prior work on DROP, we also train our model initialized with BERT$_{\text{LARGE}}$, as all prior work used it as an encoder. On DROP, TASE$_{\text{BIO}}$+SSE (BERT$_{\text{LARGE}}$) outperforms all prior models that handle multi-span questions, improving by at least 3.2 EM points. On multi-span questions, we dramatically improve performance over BERT-CALC and MTMSN, while obtaining similar performance to NeRd. On QUOREF, compared to CorefRoBERTa$_{\text{LARGE}}$ (Ye et al., 2020) which uses the same method as MTMSN for multi-span extraction, we achieve a substantial improvement of over 20 EM on multi-span questions and an improvement of 4.5 EM and 3.2 F$_1$ on the full development set, where the best results are achieved when using solely our multi-span architecture with `IO`-tagging.

Comparing span extraction architectures Table 1 also shows that in both DROP and QUOREF, *replacing* the single-span extraction architecture with our multi-span extraction results in dramatic improvement in multi-span question performance, while single-span question performance is either maintained or improved. Furthermore, although combining both architectures tends to yield the best overall performance,[3] the improvement over using only our multi-span architecture is not substantial, suggesting that the multi-span architecture may be used by itself as a general span extraction method.

Effects of tagging scheme Overall, the results are quite similar for the `BIO` and `IO` schemes. The slight advantage of `IO` could perhaps be explained by the fact that the model no longer requires distinguishing between `B` and `I`, in the presence of powerful contextualized representations.

---

[3] As single-span questions outnumber multi-span questions in DROP and QUOREF 1:7 and 1:10 respectively, the overall span performance ("All Spans") gives a much larger weight to single-span performance.

Model	DROP						QUOREF					
	All Spans		Multi-Span		Single-Span		All Spans		Multi-Span		Single-Span	
	EM	F1	EM	F1	EM	F1	EM	F1	EM	F1	EM	F1

TASE$_{\text{BIO}}$, NOMARG.	76.2	85.0	54.7	79.0	79.8	86.1	-	-	-	-	-	-

Table 1: Development set results on DROP and QUOREF questions whose answer is a span (or list of spans).

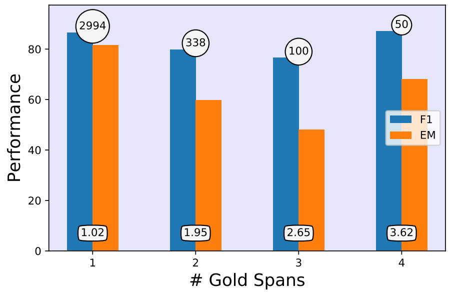

Figure 2: DROP Performance of TASE$_{\text{BIO}}$ by number of spans in the gold answer. Labels at the bottom indicate the average number of predicted spans. Circles at the top are the number of examples. These same trends are observed in QUOREF as well.

Effect of marginalization To check whether marginalizing over all possibly-correct taggings is beneficial, we ran TASE$_{\text{BIO}}$ in a setup where only a single tagging is considered, namely where all occurrences of a gold answer span are tagged. Table 1 shows that this indeed leads to a moderate drop of up to 2 points in performance.

Test set results We ran TASE$_{\text{IO}}$ on the QUOREF test set. Our model obtains 79.7 EM and 86.1 F1, an improvement of 3.9 EM points and 3.3 F1 points over the state-of-the-art CorefRoBERTa$_{\text{LARGE}}$. On DROP, our TASE$_{\text{IO}}$+SSE model achieves 80.4 EM and 83.6 F1 on the entire test set (including non-span questions).

We note that the top 10 models on the DROP leaderboard (as of September 15, 2020) have all incorporated our multi-span head using our code base which has been public for a while.

5.2 Analysis

Figure 2 shows that in both DROP and QUOREF the performance of TASE$_{\text{BIO}}$ decreases only moderately as the number of gold spans increases. This shows relative robustness to the number of answer spans. In addition, we can see that our architecture is quite accurate in predicting the correct number of spans, with a tendency for under-estimation.

We analyzed the performance of the p_{head} module in TASE$_{\text{BIO}}$+SSE. A non-multi-span head is selected erroneously for 3.7% and 7.2% of the multi-span questions in DROP and QUOREF respectively. The multi-span head is selected for 1.2% and 1.5% of the single-span questions in DROP and QUOREF respectively. However, this is reasonable as the multi-span head is capable of answering single-span questions as well, and indeed it returned a single span in 45% of these cases on both datasets.

We manually analyzed errors of TASE$_{\text{BIO}}$+SSE on DROP, and detected 3 main failure cases: (1) questions where the answer is a span, but requires some numerical computation internally, (2) questions where the number of output spans is explicitly mentioned in the question but is not followed by the model, and (3) questions where a single contiguous span is unnecessarily split into two shorter spans. An example for each case is given in Appendix B.

6 Conclusion

In this work, we cast the task of answering multi-span questions as a sequence tagging problem, and present a simple corresponding multi-span architecture. We show that replacing the standard single-span architecture with our multi-span architecture dramatically improves results on multi-span questions, without harming performance on single-span questions, leading to state-of-the-art results on QUOREF. In addition, integrating our multi-span architecture into existing models further improves performance on DROP, as is evident from the leading models on

DROP's leaderboard. Our code can be downloaded from https://github.com/eladsegal/tag-based-multi-span-extraction.

Appendix for "A Simple and Effective Model for Answering Multi-span Questions"

A Experimental Setup

We experiment with model variations that use either SSE, TASE, or their combination as a multi-head model. For DROP, we additionally use *arithmetic* and *count* heads based on (Dua et al., 2019; Kinley and Lin, 2019). Our model is implemented with PyTorch (Paszke et al., 2019) and AllenNLP (Gardner et al., 2017). For f in Eq. (1) we use a 2-layer feed-forward network with ReLU activations and $|S|$ outputs. We use the Hugging Face implementation of RoBERTa$_{\text{LARGE}}$ (Wolf et al., 2019; Liu et al., 2019) as the encoder in our model. 5% of DROP and 30% of QUOREF are inputs with over 512 tokens. Due to RoBERTa$_{\text{LARGE}}$'s limitation of 512 positional embeddings, we truncate inputs by removing over-flowing tokens from the passage, both at train and test time. We discard 3.87% of the training examples of DROP and 5.05% of the training example of QUOREF, which are cases when the answer cannot be outputted by the model (due to a dataset error, or truncation of the correct answer span). For training, the BertAdam[4] optimizer is used with default parameters and learning rates of either 5×10^{-6} or 10^{-5}. Hyperparameter search was not performed. We train on a single NVIDIA Titan XP with a batch size of 2 and gradient accumulation of 6, resulting in an effective batch size of 12, for 20 epochs with an early-stopping patience of 10. The average runtime per epoch is 3.5 hours. Evaluation was performed with the official evaluation scripts of DROP and QUOREF. Our full implementation can be found at https://github.com/eladsegal/tag-based-multi-span-extraction.

B Failure Cases Examples

Table 2 contains example failure cases of TASE$_{\text{BIO}}$+SSE on DROP.

Abstract

The growth of domain-specific applications of semantic models, boosted by the recent achievements of unsupervised embedding learning algorithms, demands domain-specific evaluation datasets. In many cases, content-based recommenders being a prime example, these models are required to rank words or texts according to their semantic relatedness to a given concept, with particular focus on top ranks. In this work, we give a threefold contribution to address these requirements: (*i*) we define a protocol for the construction, based on adaptive pairwise comparisons, of a relatedness-based evaluation dataset tailored on the available resources and optimized to be particularly accurate in top-rank evaluation; (*ii*) we define appropriate metrics, extensions of well-known ranking correlation coefficients, to evaluate a semantic model via the aforementioned dataset by taking into account the greater significance of top ranks. Finally, (*iii*) we define a stochastic transitivity model to simulate semantic-driven pairwise comparisons, which confirms the effectiveness of the proposed dataset construction protocol.

1 Introduction

In recent years, we have been witnessing a growth of Natural Language Processing (NLP) applications in a wide range of specific domains, such as recruiting (INDA; Qin et al., 2018), law (Sugathadasa et al., 2017), oil and gas (Nooralahzadeh et al., 2018), social media analysis (ALRashdi and O'Keefe, 2019), online education (Dessì et al., 2019), and biomedical (Patel et al., 2020). Embedding-based models have been playing a crucial role in this specialization, as they allow the application of the same learning algorithm to a variety of different corpora of unlabeled texts, obtaining domain-specific models (Bengio et al., 2003; Bojanowski et al., 2017; Devlin et al., 2018; Mikolov et al., 2013a, 2017, 2013b; Pennington et al., 2014).

The evaluation and validation of a domain-specialized model requires manually-annotated domain-specific datasets (Bakarov, 2018; Lastra-Díaz et al., 2019; Taieb et al., 2019). However, the construction of such datasets is a very resource-consuming process, and particular care is needed to ensure their ability to evaluate the desired features (Bakarov, 2018; Taieb et al., 2019; Wang et al., 2019). In particular, it is fundamental to carefully consider the so-called *downstream task* (i.e., the final purpose of the model), because the appropriate evaluation metric depends on this task (Bakarov, 2018; Blanco et al., 2013; Halpin et al., 2010; Rogers et al., 2018; Wang et al., 2019).

Semantic similarity and relatedness are related but distinct notions in linguistics, the first being associated with concepts which share taxonomic properties and being maximized by synonyms; on the other hand, semantically related concepts can share any kind of semantic relation, including antonym (Cai et al., 2010; Harispe et al., 2015). These notions underlie the downstream tasks of countless NLP applications, including information retrieval (Akmal et al., 2014; Chen et al., 2017; Gurevych et al., 2007; Hliaoutakis et al., 2006; Ji et al., 2017; Lopez-Gazpio et al., 2017; Srihari et al., 2000; Uddin et al., 2013), content-based recommendation (De Gemmis et al., 2008, 2015; Lops et al., 2011), semantic matching (Giunchiglia et al., 2004; Li and Xu, 2014; Wan et al., 2016), ontology learning and knowledge management (Aouicha et al., 2016a; Georgiev and Georgiev, 2018; Jiang et al., 2014; Sánchez and Moreno, 2008), and word sense disambiguation (Aouicha et al., 2016b; Patwardhan et al., 2003).

In view of the widespread of these applications, we propose a methodology to construct appropriate domain-specific datasets and metrics to assess the accuracy of relatedness and similarity estimations.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3081–3093,
November 16–20, 2020.

In particular, due to its suitability for non-expert human annotation, we mainly focus on semantic relatedness; however, the proposed protocol can be easily extended to semantic similarity.

A standard approach to evaluate a relatedness-based model is the comparison of the semantic ranking it produces with the corresponding ranking determined from human annotations. However, the relevance of rank mismatches may depend on the involved positions; in particular, top ranks are considered more important in many contexts, two prominent examples being content-based recommenders (De Gemmis et al., 2008, 2015; Lops et al., 2011; Mladenic, 1999) and semantic matching (Giunchiglia et al., 2004; Li and Xu, 2014; Wan et al., 2016). The greater significance of top ranks compared with low ranks is actually a pretty common phenomenon, as it can be argued from the attempts to overweight the former in the context of ranking correlation (Blest, 2000; Pinto da Costa and Soares, 2005; Dancelli et al., 2013; Iman and Conover, 1987; Maturi and Abdelfattah, 2008; Shieh, 1998; Vigna, 2015; Webber et al., 2010).

Our contribution is framed within the requirement to create domain-specific datasets to evaluate semantic relatedness measure with particular focus on top ranks and is threefold. (*i*) In Section 2, we define a protocol for the construction, based on adaptive pairwise comparisons, of a relatedness-based evaluation dataset tailored on the available resources and optimized to be particularly accurate in top-rank evaluation. (*ii*) In Section 3, we define appropriate metrics to evaluate a semantic model via the aforementioned dataset by taking into account the greater significance of top ranks; the proposed metrics are extensions of well-known ranking correlation measures and they can be used to compare rankings, independently from their origin, whenever top ranks are particularly important. Finally, (*iii*) in Section 4.1, we define a stochastic model to simulate semantic-driven pairwise comparisons, whose predictions (described in Section 4.2) confirm the effectiveness of the proposed dataset construction protocol; more in detail, we adapt a stochastic transitivity model, originally defined in the context of comparative judgment, in order to make it suitable for either similarity-driven or relatedness-driven comparisons.

2 Dataset Construction

In this section, we describe and justify a methodology to construct a dataset for the evaluation of a domain-specific relatedness-based model. Relatedness-based evaluation – known as *intrinsic evaluation* in the context of embedding-based models – requires the construction of a dataset of human annotations, which may be collected via two different approaches. The former relies on a small group of linguistic experts to create a gold standard dataset, which is reliable but very expensive and, due to the subjectivity of relatedness and to the limited number of annotations, highly susceptible to bias and lack of statistical significance (Blanco et al., 2013; Faruqui et al., 2016). The latter relies on a large group of non-experts, typically associated with a crowdsourcing service (e.g., Amazon MTurk, ProlificAcademic, SocialSci, CrowdFlower, ClickWorker, CrowdSource), it is typically more affordable, and it has been proven to be repeatable and reliable (Blanco et al., 2013).

In the next sections we describe and justify a protocol to construct a dataset based on semantic relatedness between pairs of tokens[1] collected via a crowdsourcing approach. To simplify the reading of the paper, Figure 1 shows the main steps for the practical construction of a dataset within the proposed approach, while Table 1 reports a summary of the most frequently used symbols.

2.1 Token Choice

The first step in the dataset construction is the choice of the tokens among which we want to estimate the semantic relatedness. These tokens must be carefully chosen to represent the semantic areas typically involved in the downstream tasks (Bakarov, 2018; Schnabel et al., 2015). Moreover, it is well-known that models based on high-dimensional embeddings tend to incorrectly identify as a semantic nearest neighbor to almost any concept one of a few common tokens called *hubs* (Dinu et al., 2014; Feldbauer et al., 2018; Francois et al., 2007; Radovanović et al., 2010a,b). In order to detect this undesirable feature, which goes under the name of *hubness problem*, an evaluation dataset must contain a relevant amount of rare[2] tokens

---

[1] Hereafter, we refer as *token* to a word or a sequence of words that should be considered together, as they identify a single concept (e.g., *machine learning*).

[2] A token can be considered *rare* within a particular domain if its frequency in a corpus of domain-specific texts is, e.g., lower than 10% of the average token frequency in the corpus.

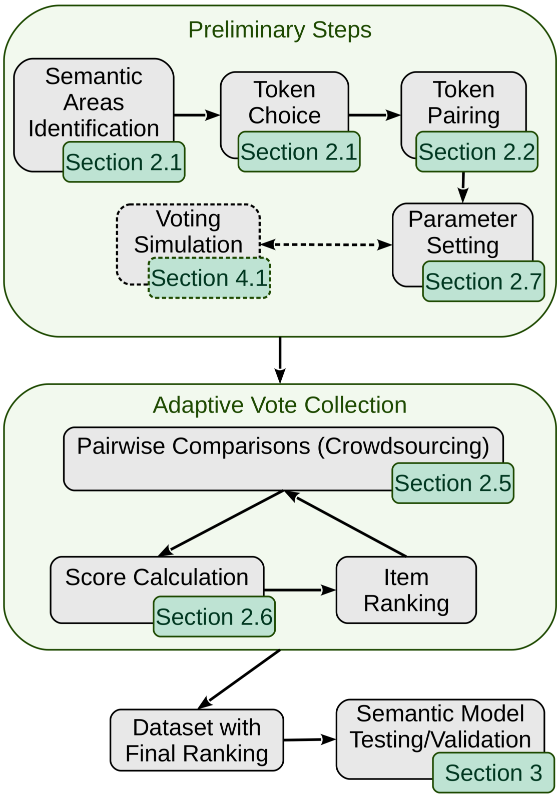

Figure 1: Main steps for the practical construction of a dataset within the proposed approach.

(Bakarov, 2018; Blanco et al., 2013). Henceforth, we consider as a concrete example a content-based recommender system in the recruitment domain (INDA); in this case, the designated tokens can be chosen among hard/soft skills, job titles, and other tokens found in resumes and job descriptions, including a relevant fraction of rare tokens.

Another potential issue of using relatedness to evaluate semantic models, is associated to lexical ambiguity, i.e., to the lack of one-to-one correspondence between tokens and meanings (Bakarov, 2018; Faruqui et al., 2016; Wang et al., 2019). To mitigate this problem, we suggest identifying a number of relevant semantic areas within the domain of interest and subdivide the tokens accordingly. For instance, *Sales & Marketing*, *Computer-related*, *Workforce*, and *Work & Welfare* are examples of semantic areas within the recruiting domain.

2.2 Token Pairing

The random sampling of pairs in the whole vocabulary is known to produce a large amount of unrelated pairs (Taieb et al., 2019), in contrast with the desired focus on the most related pairs. A standard approach to overcome this problem is pair selection based on either known semantic relations or the frequency of tokens’ co-occurrence within a corpus of texts. While the former information may be *a priori* unknown within the domain of interest, the latter may produce a bias in favor of distributional methods that compute relatedness based on similar knowledge sources (Taieb et al., 2019).

Table 1: Most commonly used symbols.

Dataset Construction	
N_{tok}	Number of tokens
N_{items}	Number of items (i.e., pairs of tokens)
N_{voters}	Number of voters
N_{comp}	Number of pairwise comparisons
n_{b}	Number of ballots
α	Fraction of selected items
i, j	Indices specifying the item
M	Number of times an item is presented to the voters in each ballot
k	Index specifying the ballot
$N^{(k)}_{\text{items}}$	Number of items in ballot k
$x^{(k)}_i$	Borda score (i.e., win ratio) for item i in ballot k
$y^{(k)}_i$	Rescaled score for item i in ballot k
Evaluation Metrics	
a_i (b_i)	Rank of item i according to the first (second) ranking
ρ_{w}	Weighted version of Spearman’s ρ
τ_{w}	Weighted version of Kendall’s τ
w^a_i (w^b_i)	Weight associated to a_i (b_i)
n_0	Offset in weight calculation
Stochastic Transitivity Model	
z_i	Underlying similarity of item i
v	Index specifying the voter
$o^{(v)}_i$	Opinion of voter v about item i
$\eta^{(v)}_i$	Gaussian-distributed random variable characterizing voter v
σ^*_v	Nonconformity level of voter v
ϵ_v	Probability of oversight for voter v

We suggest, therefore, separate token pairing in each of the semantic areas identified as described in Section 2.1: in this case, the relatedness distribution is substantially shifted towards larger values compared with random sampling in the whole vocabulary. This shift is shown in Figure 3 – based on a word embedding created with the word2vec algorithm (Mikolov et al., 2013a,b) trained on a corpus of resumes – where the relatedness distribution of pairs of distinct tokens selected within the same semantic area[3] (red plus) is compared with that of pairs randomly generated in the whole vocabulary (purple diamonds). The generation of all pairs of distinct tokens produces $N_{\text{tok}}(N_{\text{tok}}-1)/2$ pairs per semantic area, N_{tok} being the number of tokens. Although the pairs can be reduced via random sampling, an accurate evaluation requires a large number of pairs.

2.3 Vote Collection

Once we have defined the pairs of tokens, which will be referred to as *items* hereafter, we want to rank them, with particular emphasis on top ranks, according to the opinions of a large number N_{voters} of non experts. Due to the large number of items involved, the complete ranking of all items would be an unfeasible task for a human and it is convenient to reformulate it in terms of pairwise comparisons (Fürnkranz and Hüllermeier, 2010; Heckel et al., 2019, 2018; Jamieson and Nowak, 2011; Negahban et al., 2017; Park et al., 2015; Wauthier et al., 2013). Moreover, the complete exploration of the $N_{\text{items}}(N_{\text{items}}-1)/2$ pairs of distinct items would be extremely expensive in terms of votes; luckily enough, it has been proven to be non-necessary in many studies (Jamieson and Nowak, 2011; Negahban et al., 2017; Park et al., 2015; Wauthier et al., 2013).

Louviere and Woodworth (1991) (see also Kiritchenko and Mohammad (2017)) proposed a faster alternative to pairwise comparisons, known as *best-worst scaling*. In this case n-tuples (typically, $n = 4$), rather than pairs, are presented to the voter, who is required to identify the best and the worst items in each tuple, according to the relatedness of the corresponding tokens. This approach's drawbacks are a reduction, for $n > 3$, in the control on which pairs are actually checked and an increase in the complexity of each vote, which is particularly unwanted in crowdsourcing vote collections. For this reason, we rely on the standard pairwise comparison: we generate N_{comp} pairs of items (as described in Sections 2.4 and 2.5), each one to be presented to one voter, who is requested to identify the item formed by the most similar tokens.

2.4 Uniform Item Selection

In our setting, each item i is presented to the voters a total number of times M_i, and we define a score

$$x_i = \frac{n_i}{M_i}, \tag{1}$$

where n_i represents the total number of times item i was the winner[4] in the vote collection; note that x_i corresponds to an empirical approximation of the average probability[5] – known as *Borda score* in the context of social choice theory – that item i beats a randomly chosen item $j \neq i$, where the accuracy of the approximation increases as M_i increases (Borda, 1784; Heckel et al., 2019).

In the absence of *a priori* knowledge on the expected scores, a reasonable approach for the data collection consists of presenting each item the same number M_i of times to the voters. In this scenario, we randomly generate N_{comp} pairs of items, with the constraint that $M_i = 2N_{\text{comp}}/N_{\text{items}}\,\forall i$. The only way to increase M_i – which is a proxy of the accuracy of the x_i score defined in Equation 1 – is, therefore, to increase the total number of comparisons N_{comp}.

2.5 Adaptive Item Selection

Crompvoets et al. (2019), Heckel et al. (2019), Heckel et al. (2018), Jamieson and Nowak (2011), and Negahban et al. (2017) proposed so-called *adaptive approaches* to increase of the efficiency of pairwise comparisons by identifying, before each comparison, the optimal pair of items to be compared based on the votes already collected, on the task to be solved (typically, finding the global ranking or a ranking-induced partition), and on assumptions on the vote distribution.

The application of an adaptive approach in our context requires two additional ingredients which, to the best of our knowledge, are still missing in the literature: (*i*) in order to avoid overfitting on the opinion of the fastest voters and to allow simultaneous voting, the choice of the pairs to be presented must occur in a few events, as each of these events causes a discontinuity in the vote collection (namely, this choice requires to suspend the vote collection when the numbers of comparisons reach the desired distribution among the voters); (*ii*) the goal is a selective increase in the precision (proxied by M_i) of top ranks (with no need of *a*

---

[3] More in detail, 990 pairs of distinct tokens (associated with 45 tokens) have been considered within the semantic area *Sales & Marketing*.

[4] Ties can be accounted for by defining $n_i = n_i^{\text{w}} + n_i^{\text{t}}/2$, where n_i^{w} (n_i^{t}) represents the number of wins (ties) for item i.

[5] The average is intended over all voters.

priori knowledge on the semantic relatedness of the tokens), rather than a general improvement in the global ranking. In Section 3 we define an appropriate metric to quantify top-rank accuracy.

The key idea is to subdivide the voting procedure in n_b subsequent ballots in which pairwise comparisons, based on a list of pairs determined before the beginning of the ballot, are presented to the voters. During the first ballot, the pairs are randomly drawn from all items, with the constraint that each item appears M times[6], while in each subsequent ballot k, the pairs are drawn from the $N_\mathrm{items}^{(k)}$ top-rank items selected according to the results of the previous ballots, with analogous constraint. More in detail, we define

$$N_\mathrm{items}^{(k)} = \mathrm{round}(\alpha N_\mathrm{items}^{(k-1)}) \sim \alpha^{k-1} N_\mathrm{items}, \quad (2)$$

where α represents the fraction of items selected at each ballot. Since each item contained in ballot k appears M times within the pairs of such ballot, the total number of comparisons can be written as

$$N_\mathrm{comp} = \sum_{k=1}^{n_\mathrm{b}} \frac{M N_\mathrm{items}^{(k)}}{2} \sim \frac{1-\alpha^{n_\mathrm{b}}}{2(1-\alpha)} M N_\mathrm{items}. \quad (3)$$

Thus, each item i which survives up to the last ballot, is presented to the voters a number of times

$$M_\mathrm{top} = n_\mathrm{b} M \sim (1-\alpha) n_\mathrm{b} M_\mathrm{unif}, \quad (4)$$

where $M_\mathrm{unif} = 2N_\mathrm{comp}/N_\mathrm{items}$ is the number of comparisons per item in the case of uniform item selection with the same total number of comparisons; the last approximation holds whenever $\alpha^{n_\mathrm{b}} \ll 1$, i.e., when the fraction of items which survive up to the last ballot is small. According to Equation 4, the score precision for top-rank items can be increased by decreasing the fraction α of selected items or by increasing the number n_b of ballots; in Section 2.7 we discuss bounds on these values.

2.6 Score Calculation

At each ballot k and for each item i contained in k, we can evaluate a score $x_i^{(k)}$ defined as in Equation 1. Nonetheless, since the pool of competing items is narrowed around top ranks at each ballot, the winning chances of a given item i decrease accordingly. For this reason, the expected value of $x_i^{(k)}$ is smaller than the expected value of $x_i^{(k-1)}$, and this discrepancy must be taken into account in order to average scores from different ballots.

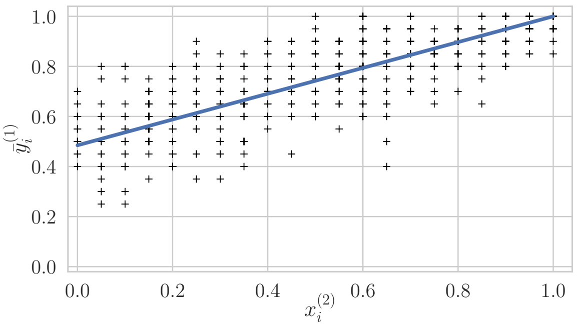

Figure 2: The coordinates of this scatterplot represent the scores $x_i^{(2)}$ and $\bar{y}_i^{(1)} = x_i^{(1)}$, for each item i present in the second ballot; the data are obtained with the model described in Section 4.1 with exponential underlying similarity, $N_\mathrm{items} = 990$, $\alpha = 0.5$, $M = 20$, $N_\mathrm{voters} = 100$, $\sigma_v^* = 0.1$, $\epsilon_v = 0.01$. The blue line represents the interpolation described in the text.

We define therefore a rescaled score $y_i^{(k)} = f_\mathrm{resc}^{(k)}(x_i^{(k)})$, where f_resc is the identity function for $k = 1$, while it is obtained as a linear interpolation between $\{x_j^{(k)}\}$ and $\{\bar{y}_j^{(k-1)}\}$ for $k > 1$, where $\bar{y}_i^{(k)}$ is defined as the average of all rescaled scores up to ballot k, i.e.,

$$\bar{y}_i^{(k)} = \frac{1}{k} \sum_{k'=1}^{k} y_i^{(k')}. \quad (5)$$

We enforce the $f_\mathrm{resc}^{(k)}(1) = 1$ constraint in the linear interpolation, obtaining[7], for $k > 1$,

$$\begin{cases} y_i^{(k)} &= 1 - \hat{b}^{(k)} + \hat{b}^{(k)} x_i^{(k)} \\ \hat{b}^{(k)} &= \frac{\sum_j [1-x_j^{(k)}][1-\bar{y}_j^{(k-1)}]}{\sum_j [1-x_j^{(k)}]^2} \end{cases}. \quad (6)$$

Figure 2 shows an example of the interpolation on data simulated via the stochastic model described in Section 4.1. Note that Equation 5 provides a sequence of approximations of the Borda scores with accuracy increasing with k; top ranks are expected to survive up to the last ballot, and therefore to be highly accurate.

2.7 Choice of Parameter Values

We provide here heuristics to identify ranges of values for the parameters of the adaptive approach.

---

[6] We recommend an even value for M; otherwise, if both M and N_items are odd, one item should appear $M+1$ times.

[7] Since the winning chances of a given item j decrease at each ballot, on average, $x_j^{(k)} \le \bar{y}_j^{(k-1)}$. Heuristically, we expect that, on average, $[1-x_j^{(k)}][1-\bar{y}_j^{(k-1)}] \le [1-x_j^{(k)}]^2$, which implies $\hat{b}^{(k)} \le 1$, which in turns ensures $y_i^{(k)} \le 1$.

Number n_b of Ballots. We need $n_\mathrm{b} \geq 2$ for the adaptive approach to be meaningful, while, to limit the discontinuities in the vote collection, a reasonable upper bound is $n_\mathrm{b} \lesssim 10$.

Fraction α of Selected Items. As the purpose of the adaptive approach is to focus votes on top rank items, a reasonable request is to have no more than 10% of items surviving up to the last ballot, which gives an upper bound $\alpha \lesssim (0.1)^{1/(n_\mathrm{b}-1)}$. On the other hand, at least two items must be present in the last ballot; according to Equation 2, this implies a lower bound $\alpha \gtrsim (2/N_\mathrm{items})^{1/(n_\mathrm{b}-1)}$.

Number N_comp of Comparisons. To achieve the desired precision (namely, the statistical significance of the averages) on top-rank scores, a reasonable request is $M_\mathrm{top} \gtrsim 100$; using Equation 2 in the $\alpha^{n_\mathrm{b}} \ll 1$ limit, this implies $N_\mathrm{comp} \gtrsim 50 N_\mathrm{items}/[(1-\alpha)n_\mathrm{b}]$. On the other hand, the only upper bound on N_comp is the cost of the voting, which can be estimated from Equation 10.

Number M of Comparisons per Ballot. M can be computed from Equation 3 once the other parameters have been fixed. Note the existence of two competing phenomena: (*i*) decreasing M (i.e., increasing α) we increase the fluctuations in the x_i scores defined in Equation 1; (*ii*) for given x_i fluctuations, decreasing α we increase the probability of top ranks' premature loss due to stricter selection. A rigorous derivation of the optimal values of M and α as a trade-off between these phenomena is beyond the scope of this section, as the bounds discussed above provide heuristic ranges.

3 Evaluation Metrics

Although the approximations of the Borda scores described in Sections 2.4 and 2.5 can be thought as estimates of the semantic relatedness, we rely on rankings rather than scores to avoid inconsistency issues that frequently emerge in score comparisons (Ammar and Shah, 2011; Negahban et al., 2017).

Kendall (1948) proposed the quite general form for a ranking correlation coefficient

$$\Gamma = \frac{\sum_{i,j} a_{ij} b_{ij}}{\sqrt{\sum_{ij} a_{ij}^2 \sum_{ij} b_{ij}^2}}, \tag{7}$$

where a_{ij} (resp., b_{ij}) is a matrix that depends on the first (second) ranking to be compared, with indices i, j running over all items. This definition contains Spearman's ρ (Spearman, 1961) as a particular case with $a_{ij} = a_j - a_i$ and $b_{ij} = b_j - b_i$, while Kendall's τ (Kendall, 1938; Kruskal, 1958) is obtained with $a_{ij} = \mathrm{sign}(a_j - a_i)$ and $b_{ij} = \mathrm{sign}(b_j - b_i)$, where $\{a_i\}$ and $\{b_i\}$ are the rankings to be compared.

In order to take into account the larger importance of top ranks in our context, we define weighted versions of ρ and τ, with increasing weight at the increasing of the rank position. Namely, we define (*i*) $a_{ij} = \sqrt{w_i w_j}\,(a_j - a_i)$, $b_{ij} = \sqrt{w_i w_j}\,(b_j - b_i)$ and (*ii*) $a_{ij} = \sqrt{w_i w_j}\,\mathrm{sign}(a_j - a_i)$, $b_{ij} = \sqrt{w_i w_j}\,\mathrm{sign}(b_j - b_i)$, where w_i is the normalized weight associated to the i-th position in the rankings. These coefficients can be rewritten respectively as

$$\begin{aligned} \rho_\mathrm{w} &= \frac{\sum_i w_i (a_i - \bar{a})(b_i - \bar{b})}{\sigma_a \sigma_b} \\ \tau_\mathrm{w} &= \frac{\sum_{ij} w_i w_j \,\mathrm{sign}(a_j - a_i)\,\mathrm{sign}(b_j - b_i)}{Z(\{w_i\})} \end{aligned} \quad , \tag{8}$$

where $\bar{a} = \sum_i w_i a_i$, $\sigma_a^2 = \sum_i w_i (a_i^2 - \bar{a}^2)$, $\bar{b} = \sum_i w_i b_i$, $\sigma_b^2 = \sum_i w_i (b_i^2 - \bar{b}^2)$, while $Z(\{w_i\})$ is a normalization factor, which corresponds to $1 - \sum_i w_i^2$ in the absence of ties; these metrics have been emerging, albeit some notation differences, as extensions of the ρ and τ coefficients to take into account the larger importance of top ranks (Pinto da Costa and Soares, 2005; Dancelli et al., 2013; Vigna, 2015).

Different weighting schemes have been proposed in the literature (Dancelli et al., 2013; Vigna, 2015); here we adopt the additive scheme

$$w_i = \frac{w_i^a + w_i^b}{\sum_j (w_j^a + w_j^b)}, \tag{9}$$

with $w_i^a = f(a_i)$ and $w_i^b = f(b_i)$, where $f(n)$ is a monotonically decreasing function, in view of its ability in discriminating different rankings even when they only differ by the exchange of a top rank and a low rank (Dancelli et al., 2013).

A common choice is $f(n) = 1/n$ (Dancelli et al., 2013; Vigna, 2015); however, in the large N_items limit, it causes the divergence of the denominator in Equation 9 and makes thus any w_i negligible. This phenomenon is responsible for the decreased sensitivity on top ranks, observed by Dancelli et al. (2013), in case of long rankings. For this reason, we prefer to use $f(n; n_0) = 1/(n + n_0)^2$, where the offset n_0 has been introduced to control the weight fraction associated to the first rank in the large N_items limit, i.e., $R(n_0) = f(1; n_0) / \sum_{n=1}^{\infty} f(n; n_0)$, which can be expressed as $R(n_0) = 1/[(n_0 + 1)^2\, \psi^{(1)}(n_0 + 1)]$, where $\psi^{(1)}(x)$ is the first derivative of the digamma function. With this choice, both ρ_{w} and τ_{w} defined in Equation 8 represent a family of correlation coefficients, depending on the value of n_0, whose choice depends on the particular task (namely, on the relative importance of the first rank). The value $n_0 = 0$ causes an extremely high sensitivity on the first rank ($R(0) \sim 0.61$), which may be excessive; hereafter, we focus therefore on the value $n_0 = 2$, which appears to be a reasonable trade-off ($R(2) \sim 0.28$) that allows focusing on the first rank while avoiding neglecting other ranks.

The metrics ρ_{w} and τ_{w} are suitable to compare rankings, whenever top ranks are particularly important; in particular, they can be used to evaluate a semantic model using a dataset produced as described in this paper.

4 Evaluation of the Data-Collection Framework

The collection of human annotations to construct a domain-specific dataset is a resource-consuming process, even within the proposed optimized data collection approach, whose *person-hours* cost can be estimated as

$$C \sim \bar{t}_{\mathrm{comp}} N_{\mathrm{comp}}, \qquad (10)$$

where $\bar{t}_{\mathrm{comp}}$ is the average time needed for a single comparison. For this reason, in Section 4.1, we define a stochastic model for semantic pairwise comparisons, which can be used to simulate the voting before the collection of human annotations, e.g., for checking or tuning the parameters of the data collection approach. This stochastic model will be used in Section 4.2 to compare the effectiveness of the adaptive and the uniform approaches, using the metrics defined in Section 3.

4.1 Semantic Pairwise Comparisons

We want to model N_{voters} voters to whom are proposed N_{comp} pairwise comparisons and who are asked to identify the item containing the most semantically related tokens. The model will be used to reconstruct an approximate ranking of the items.

For the sake of mathematical simplicity, we firstly focus on similarity-driven comparisons, where the similarity z takes value in the symmetric interval $[-1, 1]$, where $z = 1$, 0, and -1 correspond respectively to synonyms, unrelated tokens, and antonyms. The model will eventually be adapted to semantic relatedness by using the fact that, since antonyms correspond to semantically related tokens (Cai et al., 2010; Harispe et al., 2015), the absolute value $|z|$ is a reasonable proxy for semantic relatedness.

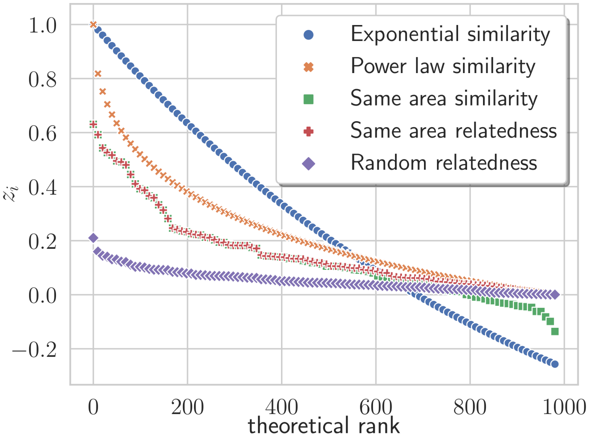

Figure 3: We represent the three underlying similarity distributions described in Section 4.1.1 and the two relatedness distributions described in Section 2.2; relatedness is quantified by $|\cos\theta|$, where θ is the angle between the corresponding vectors in the embedding.

4.1.1 Similarity-Driven Comparisons.

A convenient way to model similarity-driven pairwise comparisons assumes the existence of an underlying (unknown) similarity distribution $\{z_i\}$, which determines the theoretical ranks of the items, which in turn can be compared with the ranks estimated via the model. We consider here three examples:(*i*) an exponential $z_i = 2\exp(-i/N_{\mathrm{items}}) - 1$, (*ii*) a power law $z_i = 2/(1 + \sqrt{i/N_{\mathrm{items}}}) - 1$, and (*iii*) the distribution of the cosine similarity[8] between pairs of tokens in the word embedding described in Section 2.2; these distributions are represented in Figure 3.

A fundamental aspect to be considered in modelling similarity-driven pairwise comparisons is the task's subjectivity, as many potential linguistic, psychological, and social factors could introduce biases (Bakarov, 2018; Faruqui et al., 2016; Gladkova and Drozd, 2016). A possible approach to account for this problem is via a stochastic transitivity model, firstly introduced in the context of comparative judgment of physical stimuli by Thurstone (1927) (see also Cattelan, 2012; Ennis, 2016); this model describes the opinion $o_i^{(v)}$ of voter v about item i as a stochastic function

---

[8] Despite a certain ambiguity observed by Faruqui et al. (2016), cosine similarity is typically considered a proxy of semantic similarity (Auguste et al., 2017; Banjade et al., 2015).

$o_i^{(v)} = z_i + \sigma_v \eta_i^{(v)}$, where z_i is the underlying similarity, $\eta_i^{(v)}$ is a Gaussian-distributed random variable with zero mean and unit variance, while σ_v represents the *nonconformity amplitude*, i.e., the discrepancy between the voter's opinion and the underlying similarity.[9]

Here we define a modified version of the Thurstonian model, with a stochastic amplitude σ_v depending on the underlying similarity, so that

$$o_i^{(v)} = F(z_i + \sigma_v(z_i)\, \eta_i^{(v)}), \qquad (11)$$

where $F(x) = \max(-1, \min(1, x))$ has been introduced to enforce the constraint $-1 \leq o_i^{(v)} \leq 1$, analogous to the one discussed above for z. In the absence of z_i dependence in the nonconformity amplitude, the probability $P_{\text{out}}(z_i)$ to have $z_i + \sigma_v \eta_i$ outside the interval $[-1, 1]$ would tend to $1/2$ as z_i approaches one of the boundaries of the interval, causing, due to the F constraint, the collapse of a relevant fraction of opinion o_i to either -1 or 1. This degeneracy can be avoided with $\sigma_v(z_i)$ proportional to $1 - z_i$ and $1 + z_i$ as z_i approaches 1 and -1 respectively. Here we consider the simplest form with these features, i.e., $\sigma_v(z_i) = \sigma_v^* (1 - z_i^2)$, which makes particularly sense in our context, where each item i represents a pair of tokens, and the closest the similarity is to $z_i = 1$ ($z_i = -1$), the higher is the relation (the opposition) between the tokens in the corresponding pair, and the stronger is expected to be the agreement in the voters' opinions on their similarity.

In order to increase the accuracy of the model, we introduce another source of randomness that represents the *distraction level* of the voter, i.e., its tendency – observed, e.g., by Bakarov (2018) and Bruni et al. (2014) – to unintentionally vote for the item perceived as lower rank. This tendency is accounted for by assuming that the result of a pairwise comparison presented to voter v is actually the item with the highest perceived score $o_i^{(v)}$ with probability $1 - \epsilon_v$ (with $\epsilon_v \ll 1$), while the other item is voted (oversight) with probability ϵ_v.

The proposed model depends on the underlying similarity distribution[10], on the number of voters, on the random variables $\eta_i^{(v)}$, and on the voter-distinctive parameters σ_v^* and ϵ_v, whose distribution could be experimentally determined by analyzing human voting. In the absence of such analysis, it seems reasonable to uniformly draw σ_v^* and ϵ_v from ranges covering one order of magnitude to encompass human variability; heuristic upper bounds are $\epsilon_v \lesssim 0.05$ and $\sigma_v^* \lesssim 0.2$, as oversights are supposed to be rare, and the probability $P_{\text{out}}(0)$ that two completely unrelated tokens ($z_i = 0$) are deliberately considered as maximally related ($o_i^{(v)} = \pm 1$) should be extremely low: the aforementioned bound corresponds indeed to $P_{\text{out}}(0) \lesssim 0.001\%$.

4.1.2 Relatedness-Driven Comparisons.

As discussed in Section 4.1, we consider the absolute value of similarity as a proxy of relatedness. The model defined in Section 4.1.1 is thus extended to relatedness-driven comparisons by (*i*) including an absolute value in Equation 11, so that $o_i^{(v)} = |F(z_i + \sigma_v^*(z_i)\, \eta_i^{(v)})|$ and (*ii*) defining the theoretical rank of item i according to $|z_i|$.

4.2 Results

We estimated the accuracy of a data collection approach by comparing, via the metrics defined in Section 3, the ranking that it produces with the underlying theoretical ranks. We considered the semantic area described in Section 2.2, containing 990 items, and we simulated a relatedness-driven data collection based on (*i*) the adaptive approach described in Section 2.5, with $N_{\text{comp}} = 39000$, $M = 20$, $\alpha = 0.5$, $n_{\text{b}} = 7$ and (*ii*) the uniform approach described in Section 2.4, with the same total number of comparisons. The voting was simulated with the stochastic model described in Section 4.1, with $N_{\text{voters}} = 100$ and based on all three discussed distributions for the underlying similarity; for each voter v, the nonconformity level σ_v^* and the distraction level ϵ_v were randomly chosen in the intervals $[0.02, 0.2]$ and $[0.005, 0.05]$ respectively, while each $\eta_i^{(v)}$ was randomly drawn from a normal distribution with zero mean and unit variance. Each simulation was repeated 50 times (by resampling all voters' parameters σ_v^*, ϵ_v, and $\eta_i^{(v)}$ at each simulation) in order to obtain statistically significant results.

The code for our experiments is available at `https://github.com/interviewweb-datascience/adaptive-comp` and was run on a local machine equipped with an Intel Core i7-7700HQ (2.80GHz x8), with

---

[9] Contrary to the original formulation, no covariance terms are present here, as the voters are supposed to be non-interacting. Moreover, in the original formulation, voters and items are respectively referred to as *judges* and *stimuli*.

[10] However, as shown in Table 2, the dependence is mild.

Table 2: Mean ± standard deviation (unbiased estimation over 50 simulations of relatedness-driven comparisons, as described in text) for ρ_{w} and τ_{w} metrics, defined in Equation 8, and for Spearman's ρ and Kendall's τ coefficients.

		ρ_{w}	τ_{w}	ρ	τ
Exponential	Uniform	.778 ± .058	−0.11 ± .20	.8097 ± .0088	.6265 ± .0091
	Adaptive	.9452 ± .0028	.66 ± .17	.8015 ± .0087	.6330 ± .0098
Power Law	Uniform	.800 ± .062	−0.11 ± .20	.9713 ± .0013	.8491 ± .0035
	Adaptive	.9800 ± .0014	.63 ± .18	.9632 ± .0019	.8406 ± .0040
Embedding	Uniform	.741 ± .058	−0.11 ± .21	.7229 ± .0078	.5463 ± .0072
	Adaptive	.9146 ± .0042	.73 ± .12	.7258 ± .0093	.5611 ± .0097

average runtimes of 30.9 s and 33.2 s respectively for the adaptive and the uniform approaches. The results of the simulations are presented in Table 2, which contains, as measures of the accuracy of the proposed approaches, the ρ_{w} and τ_{w} coefficients defined in Equation 8 and discussed in Section 3; in order to check the overall rank accuracy, we also report the standard Spearman's ρ and Kendall's τ coefficients. For each coefficient, we report the average value and the unbiased estimator of the standard deviation over the 50 simulations. The adaptive approach, compared with the uniform approach, determines a relevant increase in both ρ_{w} and τ_{w} for any of the underlying similarity distributions considered, with no relevant changes in the overall rank precision measured by ρ and τ. Moreover, the results suggest that the proposed stochastic model is robust for changes in the underlying similarity distribution.

Figure 4 displays the scores $x_i^{(k)}$ calculated in the first 5 ballots and the final approximation $\bar{y}_i$, obtained in a simulation based on the adaptive approach with exponential underlying similarity and the parameters described above; the figure clearly shows that, as desired, the $\bar{y}_i$ precision is substantially larger for top ranks.

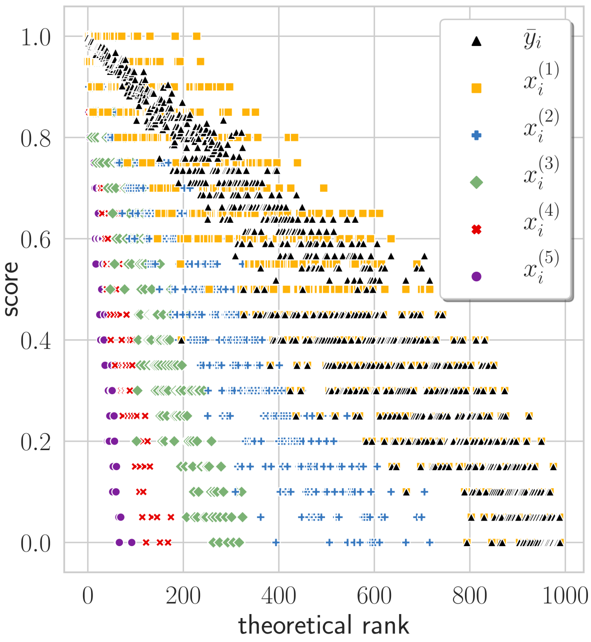

Figure 4: The scores $x_i^{(k)}$ calculated in the first 5 ballots and the final approximation $\bar{y}_i$ are displayed as functions of the theoretical ranks. All values are obtained in the simulation described in the text.

5 Conclusion & Future Work

In this paper, we provided a protocol for the construction – based on adaptive pairwise comparisons and tailored on the available resources – of a dataset, which can be used to test or validate any relatedness-based domain-specific semantic model and which is optimized to be particularly accurate in top-rank evaluation. Moreover, we defined the metrics ρ_{w} and τ_{w}, extensions of well-known ranking correlation coefficients, to evaluate a semantic model via the aforementioned dataset by taking into account the greater significance of top ranks. Finally, we defined a stochastic transitivity model to simulate semantic-driven pairwise comparisons, which allows tuning the parameters of the data collection approach and which confirmed a significant increase in the performance metrics ρ_{w} and τ_{w} of the proposed adaptive approach compared with the uniform approach (see Table 2).

As future work, we plan to collect human annotations (*i*) to test the proposed data collection approach on real data and (*ii*) to assess the validity and estimate the parameters of the proposed stochastic transitivity model. Additional future investigations may include a deeper analysis of the mathematical and statistical properties of the weighted coefficients ρ_{w}, τ_{w}, as well as a rigorous derivation of the optimal values for the parameters of the data collection approach.

Abstract

Pre-trained neural language models bring significant improvement for various NLP tasks, by fine-tuning the models on task-specific training sets. During fine-tuning, the parameters are initialized from pre-trained models directly, which ignores how the learning process of similar NLP tasks in different domains is correlated and mutually reinforced. In this paper, we propose an effective learning procedure named *Meta Fine-Tuning* (MFT), serving as a meta-learner to solve a group of similar NLP tasks for neural language models. Instead of simply multi-task training over all the datasets, MFT only learns from typical instances of various domains to acquire highly transferable knowledge. It further encourages the language model to encode domain-invariant representations by optimizing a series of novel domain corruption loss functions. After MFT, the model can be fine-tuned for each domain with better parameter initialization and higher generalization ability. We implement MFT upon BERT to solve several multi-domain text mining tasks. Experimental results confirm the effectiveness of MFT and its usefulness for few-shot learning. [1]

1 Introduction

Recent years has witnessed a boom in pre-trained neural language models. Notable works include ELMo (Peters et al., 2018), BERT (Devlin et al., 2019), Transformer-XL (Dai et al., 2019), ALBERT (Lan et al., 2019), StructBERT (Wang et al., 2019b) and many others. These models revolutionize the learning paradigms of various NLP tasks. After pre-training, only a few *fine-tuning* epochs are required to train models for these tasks.

The "secrets" behind this phenomenon owe to the models' strong representation learning power to encode the semantics and linguistic knowledge from massive text corpora (Jawahar et al., 2019; Kovaleva et al., 2019; Liu et al., 2019a; Tenney et al., 2019). By simple fine-tuning, models can transfer the universal Natural Language Understanding (NLU) abilities to specific tasks (Wang et al., 2019a). However, state-of-the art language models mostly utilize *self-supervised* tasks during pre-training (for instance, masked language modeling and next sentence prediction in BERT (Devlin et al., 2019)). This unavoidably creates a *learning gap* between pre-training and fine-tuning. Besides, for a group of similar tasks, conventional practices require the parameters of all task-specific models to be initialized from the same pre-trained language model, ignoring how the learning process in different domains is correlated and mutually reinforced.

A basic solution is fine-tuning models by multi-task learning. Unfortunately, multi-task fine-tuning of BERT does not necessarily yield better performance across all the tasks (Sun et al., 2019a). A probable cause is that learning too much from other tasks may force the model to acquire non-transferable knowledge, which harms the overall performance. A similar finding is presented in Bingel and Søgaard (2017); McCann et al. (2018) on multi-task training of neural networks. Additionally, language models such as BERT do not have the "shared-private" architecture (Liu et al., 2017) to enable effective learning of domain-specific and domain-invariant features. Other approaches modify the structures of language models to accommodate multi-task learning and mostly focus on specific applications, without providing a unified solution for all the tasks (Stickland and Murray, 2019; Zhou et al., 2019b; Gulyaev et al., 2020).

A recent study (Finn et al., 2017) reveals that meta-learning achieves better parameter initialization for a group of tasks, which improves the models' generalization abilities in different domains

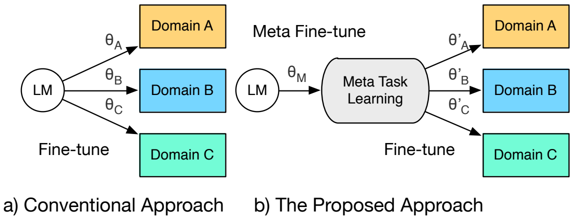

Figure 1: Comparison between fine-tuning and MFT. "LM" refers to pre-trained language models.

and makes them easier to fine-tune. As pre-trained language models have general NLU abilities, they should also have the ability to learn solving a group of similar NLP tasks. In this work, we propose a separate learning procedure, inserted between pre-training and fine-tuning, named *Meta Fine-Tuning* (MFT). This work is one of the early attempts for improving fine-tuning of neural language models by meta-learning. Take the review analysis task as an example. MFT only targets at learning the polarity of reviews (positive or negative) in general, ignoring features of specific aspects or domains. After that, the learned model can be adapted to any domains by fine-tuning. The comparison between fine-tuning and MFT is shown in Figure 1. Specifically, MFT first learns the embeddings of *class prototypes* from multi-domain training sets, and assigns *typicality scores* to individuals, indicating the transferability of each instance. Apart from minimizing the multi-task classification loss over typical instances, MFT further encourages the language model to learn *domain-invariant* representations by jointly optimizing a series of novel *domain corruption loss* functions.

For evaluation, we implement the MFT strategy upon BERT (Devlin et al., 2019) for three multi-domain text mining tasks: i) natural language inference (Williams et al., 2018) (sentence-pair classification), ii) review analysis (Blitzer et al., 2007) (sentence classification) and iii) domain taxonomy construction (Luu et al., 2016) (word-pair classification). Experimental results show that the effectiveness and superiority of MFT. We also show that MFT is highly useful for multi-domain text mining in the few-shot learning setting. [2]

2 Related Work

We overview recent advances on pre-trained language models, transfer learning and meta-learning.

2.1 Pre-trained Language Models

Pre-trained language models have gained much attention from the NLP community recently (Qiu et al., 2020). Among these models, ELMo (Peters et al., 2018) learns context-sensitive embeddings for each token form both left-to-right and right-to-left directions. BERT (Devlin et al., 2019) is usually regarded as the most representative work, employing transformer encoders to learn language representations. The pre-training technique of BERT is improved in Liu et al. (2019c). Follow-up works employ transformer-based architectures, including Transformer-XL (Dai et al., 2019), XLNet (Yang et al., 2019), ALBERT (Lan et al., 2019), StructBERT (Wang et al., 2019b) and many more. They change the unsupervised learning objectives of BERT in pre-training. MT-DNN (Liu et al., 2019b) is the representative of another type of pre-trained language models, which employs supervised learning objectives across tasks to learn representations.

After language models are pre-trained, they can be fine-tuned for a variety of NLP tasks. The techniques of fine-tuning BERT are summarized in Sun et al. (2019a). Cui et al. (2019) improve BERT's fine-tuning by sparse self-attention. Arase and Tsujii (2019) introduce the concept of "transfer fine-tuning", which injects phrasal paraphrase relations into BERT. Compared to previous methods, fine-tuning for multi-domain learning has not been sufficiently studied.

2.2 Transfer Learning

Transfer learning aims to transfer the resources or models from one domain (the source domain) to another (the target domain), in order to improve the model performance of the target domain. Due to space limitation, we refer readers to the surveys (Pan and Yang, 2010; Lu et al., 2015; Zhuang et al., 2019) for an overview. For NLP applications, the "shared-private" architecture (Liu et al., 2017) is highly popular, which include sub-networks for learning domain-specific representations and a shared sub-network for knowledge transfer and domain-invariant representation learning. Recently, adversarial training has been frequently applied (Shen et al., 2018; Hu et al., 2019; Cao et al., 2018; Li et al., 2019b; Zhou et al., 2019a), where the domain adversarial classifiers are trained to help the models to learn domain-invariant features. Multi-domain learning is a special case of transfer learning whose goal is to transfer knowl-

---

[2] Although we focus on MFT for BERT only, MFT is general and can be applied to other language models easily.

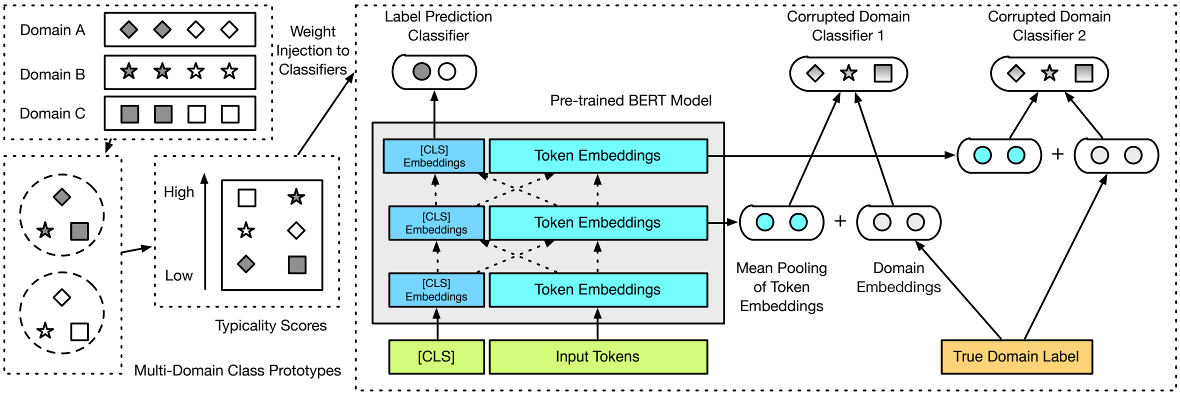

Figure 2: The neural architecture of MFT for BERT (Devlin et al., 2019). Due to space limitation, we only show two corrupted domain classifiers and three layers of transformer encoders, with others omitted.

edge across multiple domains for mutual training reinforcement (Pei et al., 2018; Li et al., 2019a; Cai and Wan, 2019). Our work also addresses multi-domain learning, but solves the problem from a meta-learning aspect.

2.3 Meta-learning

Compared to transfer learning, meta-learning is a slightly different learning paradigm. Its goal is to train meta-learners that can adapt to a variety of different tasks with little training data (Vanschoren, 2018), mostly applied to few-shot learning, which is typically formulated as a K-way N-shot learning problem. In NLP, existing meta-learning models mostly focus on training meta-learners for single applications, such as link prediction (Chen et al., 2019), dialog systems (Madotto et al., 2019), lexical relation classification (Wang et al., 2020) and semantic parsing (Guo et al., 2019). Dou et al. (2019) leverage meta-learning for low-resource NLU.

Compared with traditional meta-learning research, the task of our work is not K-way N-shot. Instead, we aim to employ meta-learning to train a better "meta-learner" which captures transferable knowledge across domains. In this sense, our work can be also viewed as a transfer learning algorithm which employs meta-learning for better knowledge transfer and fast domain adaptation.

3 MFT: The Proposed Framework

In this section, we start with some basic notations and an overview of MFT. After that, we describe the algorithmic techniques of MFT in detail.

3.1 Overview

Denote $\mathcal{D}^k = \{x_i^k, y_i^k | i \in [1, N^k]\}$ as the training set of the kth domain, where x_i^k and y_i^k are the input text and the class label of the ith sample, respectively[3]. N^k is the number of total samples in $\mathcal{D}^k$. The goal of MFT is to train a meta-learner initialized from a pre-trained language model, based on the training sets of K domains: $\mathcal{D} = \bigcup_{k=1}^{K} \mathcal{D}^k$. The meta-learner provides better parameter initializations, such that it can be easily adapted to each of the K domains by fine-tuning the meta-learner over the training set of the kth domain separately.

Due to the large parameter space of neural language models, it is computationally challenging to search for the optimal values of the meta-learner's parameters. As discussed earlier, building a trivial multi-task learner over $\mathcal{D}$ does not guarantee satisfactory results either (Sun et al., 2019a). Here, we set up two design principles for MFT: *Learning from Typicality* and *Learning Domain-invariant Representations*, introduced as follows:

Learning from Typicality To make the meta-learner easier to be fine-tuned to any domains, the encoded knowledge should be highly general and transferable, not biased towards specific domains. Hence, only *typical* instances w.r.t. all the domains should be the priority learning targets. We first generate *multi-domain class prototypes* from $\mathcal{D}$ to summarize the semantics of training data. Based on the prototypes, we compute *typicality scores* for all training instances, treated as weights for MFT.

Learning Domain-invariant Representations A good meta-learner should be adapted to any domains quickly. Since BERT has strong representation power, this naturally motivates us to learn *domain-invariant representations* are vital for fast

---

[3] Note that x_i^k can be either a single sentence, a sentence pair, or any other possible input texts of the target NLP task.

domain adaptation (Shen et al., 2018). In MFT, besides minimizing the classification loss, we jointly minimize new learning objectives to force the language model to have domain-invariant encoders.

Based on the two general principles, we design the neural architecture of MFT, with the example for BERT (Devlin et al., 2019) shown in Figure 2. The technical details are introduced subsequently.

3.2 Learning from Typicality

Denote $\mathcal{M}$ as the class label set of all K domains. $\mathcal{D}_m^k$ is the collection of input texts in $\mathcal{D}^k$ that have class label $m \in \mathcal{M}$, i.e., $\mathcal{D}_m^k = \{x_i^k | (x_i^k, y_i^k) \in \mathcal{D}^k, y_i^k = m\}$. As class prototypes can summarize the key characteristics of the corresponding data (Yao et al., 2020), we treat the class prototype $\mathbf{c}_m^k$ as the averaged embeddings of all the input texts in $\mathcal{D}_m^k$. Formally, we have $\mathbf{c}_m^k = \frac{1}{|\mathcal{D}_m^k|}\sum_{x_i^k \in \mathcal{D}_m^k} \mathcal{E}(x_i^k)$ where $\mathcal{E}(\cdot)$ maps x_i^k to its d-dimensional embeddings. As for BERT (Devlin et al., 2019), we utilize the mean pooling of representations of x_i^k from the last transformer encoder as $\mathcal{E}(x_i^k)$.

Ideally, we regard a training instance (x_i^k, y_i^k) to be *typical* if it is semantically close to its class prototype $\mathbf{c}_m^k$, and also is not too far away from class prototypes generated from other domains for high transferability. Therefore, the *typicality score* t_i^k of (x_i^k, y_i^k) can be defined as follows:[4]

$$t_i^k = \alpha \cos(\mathcal{E}(x_i^k), \mathbf{c}_m^k) + \frac{1-\alpha}{K-1} \cdot \sum_{\tilde{k}=1}^{K} \mathbf{1}_{(\tilde{k} \neq k)} \cos(\mathcal{E}(x_i^k), \mathbf{c}_m^{\tilde{k}}),$$

where α is the pre-defined balancing factor ($0 < \alpha < 1$), $\cos(\cdot, \cdot)$ is the cosine similarity function and $\mathbf{1}_{(\cdot)}$ is the indicator function that returns 1 if the input Boolean function is true and 0 otherwise.

As one prototype may not be insufficient to represent the complicated semantics of the class (Cao et al., 2017), we can also generate multiple prototypes by clustering, with the jth prototype to be $\mathbf{c}_{m_j}^k$. Here, t_i^k is extended by the following formula:

$$t_i^k = \alpha \frac{\sum_{n \in \mathcal{M}} \beta_n \cos(\mathcal{E}(x_i^k), \mathbf{c}_n^k)}{\sum_{n \in \mathcal{M}} \beta_n} + \frac{1-\alpha}{K-1} \cdot \sum_{\tilde{k}=1}^{K} \frac{\mathbf{1}_{(\tilde{k} \neq k)} \sum_{n \in \mathcal{M}} \beta_n \cos(\mathcal{E}(x_i^k), \mathbf{c}_n^{\tilde{k}})}{\sum_{n \in \mathcal{M}} \beta_n},$$

where $\beta_n > 0$ is the cluster membership of x_i^k w.r.t. each class label $n \in \mathcal{M}$.

After typicality scores are computed, we discuss how to set up the learning objectives for MFT. The first loss is the multi-task *typicality-sensitive label classification loss* $\mathcal{L}_{TLC}$. It penalizes the text classifier for predicting the labels of typical instances of all K domains incorrectly, which is defined as:[5]

$$\mathcal{L}_{TLC} = -\frac{1}{|\mathcal{D}|} \sum_{(x_i^k, y_i^k) \in \mathcal{D}} \sum_{m \in \mathcal{M}} \mathbf{1}_{(y_i^k = m)} t_i^k \cdot \log \tau_m(\mathbf{f}(x_i^k)),$$

where t_i^k serves as the weight of each training instance. $\tau_m(\mathbf{f}(x_i^k))$ is the predicted probability of x_i^k having the class label $m \in \mathcal{M}$, with the d-dimensional "[CLS]" token embeddings of the last layer of BERT (denoted as $\mathbf{f}(x_i^k)$) as features.

3.3 Learning Domain-invariant Representations

Based on previous research of domain-invariant learning (Shen et al., 2018; Hu et al., 2019), we could add an additional domain adversarial classifier for MFT to optimize. However, we observe that adding such classifiers to models such as BERT may be sub-optimal. For ease of understanding, we only consider two domains k_1 and k_2. The loss of the adversarial domain classifier $\mathcal{L}_{AD}$ is:

$$\mathcal{L}_{AD} = -\frac{1}{N^{k_1} + N^{k_2}} \sum_{(x_i^k, y_i^k) \in \mathcal{D}^{k_1} \cup \mathcal{D}^{k_2}} (y_i^k \log \sigma(x_i^k) + (1 - y_i^k) \log(1 - \sigma(x_i^k))),$$

where $y_i^k = 1$ if the domain is k_1 and 0 otherwise. $\sigma(x_i^k)$ is the predicated probability of such adversarial domain classifier. In the min-max game of adversarial learning (Shen et al., 2018), we need to maximize the loss $\mathcal{L}_{AD}$ such that the domain classifier fails to predict the true domain label. The min-max game between encoders and adversarial classifiers is computationally expensive, which is less appealing to MFT over large language models. Additionally, models such as BERT do not have the "shared-private" architecture (Liu et al., 2017), frequently used for transfer learning. One can also replace $\mathcal{L}_{AD}$ by asking the classifier to predict the flipped domain labels directly (Shu et al., 2018; Hu

---

[4] Here, we assume that the training instance (x_i^k, y_i^k) has the class label $m \in \mathcal{M}$. Because each instance is associated with only one typicality score, for simplicity, we denote it as t_i^k, instead of $t_{i,m}^k$.

[5] For clarity, we omit all the regularization terms in objective functions throughout this paper.

et al., 2019). Hence, we can instead minimize the flipped domain loss $\mathcal{L}_{FD}$:

$$\mathcal{L}_{FD} = -\frac{1}{N^{k_1}+N^{k_2}} \sum_{(x_i^k, y_i^k)\in\mathcal{D}^{k_1}\cup\mathcal{D}^{k_2}} ((1-y_i^k)\log\sigma(x_i^k) + y_i^k\log(1-\sigma(x_i^k))).$$

We claim that, applying $\mathcal{L}_{FD}$ to BERT as an auxiliary loss does not necessarily generate domain-invariant features. When $\mathcal{L}_{FD}$ is minimized, $\sigma(x_i^k)$ always tends to predict the *wrong* domain label (which predicts k_1 for k_2 and k_2 for k_1). The optimization of $\mathcal{L}_{FD}$ still makes the learned features to be *domain-dependent*, since the domain information is encoded implicitly in $\sigma(x_i^k)$, only with domain labels inter-changed. A similar case holds for multiple domains where we only force the classifier to predict the domain of the input text $x_i^{k_j}$ into any one of the reminder $K-1$ domains (excluding k_j). Therefore, it is necessary to modify $\mathcal{L}_{FD}$ which truly guarantees domain invariance and avoids the expensive (and sometimes unstable) computation of adversarial training.

In this work, we propose the *domain corruption* strategy to address this issue. Given a training instance (x_i^k, y_i^k) of the kth domain, we generate a corrupt domain label z_i from a corrupted domain distribution $\Pr(z_i)$. z_i is unrelated to the true domain label k, which may or may not be the same as k. The goal of the domain classifier is to approximate $\Pr(z_i)$ instead of always predicting the incorrect domains as in Hu et al. (2019). In practice, $\Pr(z_i)$ can be defined with each domain uniformly distributed, if the K domain datasets are relatively balanced in size. To incorporate prior knowledge of domain distributions into the model, $\Pr(z_i)$ can also be non-uniform, with domain probabilities estimated from $\mathcal{D}$ by maximum likelihood estimation.

Consider the neural architecture of transformer encoders in BERT (Devlin et al., 2019). Let $\mathbf{h}_l(x_i^k)$ be the d-dimensional mean pooling of the token embeddings of x_i^k in the lth layer (excluding the "[CLS]" embeddings), i.e.,

$$\mathbf{h}_l(x_i^k) = \text{Avg}(\mathbf{h}_{l,1}(x_i^k), \cdots, \mathbf{h}_{l,Max}(x_i^k)),$$

where $\mathbf{h}_{l,j}(x_i^k)$ represents the l-the layer embedding of the jth token in x_i^k, and Max is the maximum sequence length. Additionally, we learn a d-dimensional domain embedding of the true domain label of (x_i^k, y_i^k), denoted as $\mathcal{E}_D(k)$. The input features are constructed by adding the two embeddings: $\mathbf{h}_l(x_i^k) + \mathcal{E}_D(k)$, with the *typicality-sensitive domain corruption loss* $\mathcal{L}_{TDC}$ as:

Algorithm 1 Learning Algorithm for MFT

```
Restore BERT's parameters from the pre-trained model,
  with others randomly initialized;
for each domain $k$ and each class $m$ do
    Compute prototype embeddings $\mathbf{c}_m^k$;
end for
for each training instance $(x_i^k, y_i^k) \in \mathcal{D}$ do
    Compute typicality score $t_i^k$;
end for
while number of training steps do not reach a limit do
    Sample a batch $\{(x_i^k, y_i^k)\}$ from $\mathcal{D}$;
    Shuffle domain labels of $\{(x_i^k, y_i^k)\}$ to generate $\{z_i\}$;
    Estimate model predictions of inputs $\{(x_i^k, k)\}$ and
      compare them against $\{(y_i^k, z_i)\}$;
    Update all model parameters by back propagation;
end while
```

$$\mathcal{L}_{TDC} = -\frac{1}{|\mathcal{D}|} \sum_{(x_i^k, y_i^k)\in\mathcal{D}} \sum_{k=1}^{K} \mathbf{1}_{(k=z_i)} t_i^k \cdot \log\delta_{z_i}(\mathbf{h}_l(x_i^k) + \mathcal{E}_D(k)),$$

where $\delta_{z_i}(\cdot)$ is the predicted probability of the input features having the corrupted domain label z_i. We deliberately feed the true domain embedding $\mathcal{E}_D(k)$ into the classifier to make sure even if the classifier knows the true domain information from $\mathcal{E}_D(k)$, it can only generate corrupted outputs. In this way, we force the BERT's representations $\mathbf{h}_l(x_i^k)$ to hide any domain information from being revealed, making the representations of x_i^k domain-invariant.

We further notice that neural language models may have deep layers. To improve the level of domain invariance of all layers and create a balance between effectiveness and efficiency, we follow the work (Sun et al., 2019b) to train a series of *skip-layer* classifiers. Denote L_s as the collection of selected indices of layers (for example, one can set $L_s = \{4, 8, 12\}$ for BERT-base). The *skip-layer domain corruption loss* $\mathcal{L}_{SDC}$ is defined as the average cross-entropy loss of all $|L_s|$ classifiers, defined as follows:

$$\mathcal{L}_{SDC} = -\frac{1}{|L_s|\cdot|\mathcal{D}|} \sum_{(x_i^k, y_i^k)\in\mathcal{D}} \sum_{l\in L_s} \sum_{k=1}^{K} \mathbf{1}_{(k=z_i)} t_i^k \cdot \log\delta_{z_i}(\mathbf{h}_l(x_i^k) + \mathcal{E}_D(k)).$$

In summary, the overall loss $\mathcal{L}$ for MFT to minimize is a linear combination of $\mathcal{L}_{TLC}$ and $\mathcal{L}_{SDC}$, i.e., $\mathcal{L} = \mathcal{L}_{TLC} + \lambda\mathcal{L}_{SDC}$, where $\lambda > 0$ is a tuned hyper-parameter.

3.4 Joint Optimization

We describe how to optimize $\mathcal{L}$ for MFT. Based on the formation of $\mathcal{L}$, it is trivial to derive that:

$$\mathcal{L} = -\frac{1}{|\mathcal{D}|}\sum_{(x_i^k,y_i^k)\in\mathcal{D}} (\sum_{m\in\mathcal{M}} \mathbf{1}_{(y_i^k=m)} t_i^k \cdot \log \tau_m(\mathbf{f}(x_i^k)) + \frac{\lambda}{|L_s|}\sum_{l\in L_s}\sum_{k=1}^{K} \mathbf{1}_{(k=z_i)} t_i^k \cdot \log \delta_{z_i}(\mathbf{h}_l(x_i^k)+\mathcal{E}_D(k))).$$

As seen, MFT can be efficiently optimized via gradient-based algorithms with slight modifications. The procedure is shown in Algorithm 1. It linearly scans the multi-domain training set $\mathcal{D}$ to compute prototypes $\mathbf{c}_m^k$ and typicality scores t_i^k. Next, it updates model parameters by batch-wise training. For each batch $\{(x_i^k, y_i^k)\}$, as an efficient implementation, we shuffle the domain labels to generate the corrupted labels $\{z_i\}$, as an approximation of sampling from the original corrupted domain distribution $\Pr(z_i)$. This trick avoids the computation over the whole dataset, and be adapted to the changes of domain distributions if new training data is continuously added to $\mathcal{D}$ through time. When the iterations stop, we remove all the additional layers that we have added for MFT, and fine-tune BERT for the K domains over their respective training sets, separately.

4 Experiments

We conduct extensive experiments to evaluate MFT on multiple multi-domain text mining tasks.

4.1 Datasets and Experimental Settings

We employ the Google's pre-trained BERT model[6] as the language model, with dimension $d = 768$. Three multi-domain NLP tasks are used for evaluation, with statistics of datasets reported in Table 1:

- **Natural language inference**: predicting the relation between two sentences as "entailment", "neutral" or "contradiction", using the dataset *MNLI* (Williams et al., 2018). MNLI is a large-scale benchmark corpus for evaluating natural language inference models, with multi-domain data divided into five genres.

- **Review analysis**: classifying the product review sentiment of the famous Amazon Review Dataset (Blitzer et al., 2007) (containing product reviews of four domains crawled from the Amazon website) as positive or negative.

- **Domain taxonomy construction**: predicting whether there exists a hypernymy ("is-a") relation between two terms (words/noun phrases) for taxonomy derivation. Labeled term pairs sampled from three domain taxonomies are used for evaluation. The domain taxonomies are constructed by Velardi et al. (2013). with labeled datasets created and released by Luu et al. (2016) [7] .

Dataset	Domain	#Train	#Dev	#Test
MNLI	Telephone	83,348	2,000	-
	Government	77,350	2,000	-
	Slate	77,306	2,000	-
	Travel	77,350	2,000	-
	Fiction	77,348	2,000	-
Amazon	Book	1,763	120	117
	DVD	1,752	120	128
	Electronics	1,729	144	127
	Kitchen	1,756	119	125
Taxonomy	Animal	8,650	1,081	1,076
	Plant	6,188	769	781
	Vehicle	842	114	103

Table 1: Statistical summarization of datasets.

Because MNLI does not contain public labeled test sets that can be used for single-genre evaluation, we hold out 10 thousand training instances from the original training set for parameter tuning and report the performance of the original development sets. We hold out 2,000 labeled reviews from the Amazon dataset (Blitzer et al., 2007) and split them into development and test sets. As for the taxonomy construction task, because BERT does not naturally support word-pair classification, we combine a term pair to form a sequence of tokens separated by the special token "[SEP]" as input. The ratios of training, development and testing sets of the three domain taxonomy datasets are set as 80%:10%:10%.

The default hyper-parameter settings of MFT are as follows: $\alpha = 0.5$, $L_s = \{4, 8, 12\}$ and $\lambda = 0.1$. During model training, we run $1 \sim 2$ epochs of MFT and further fine-tune the model in $2 \sim 4$ epochs for each domain, separately. The initial learning rate is set as 2×10^{-5} in all experiments. The regularization hyper-parameters, the

---

[6] We use the uncased, base version of BERT. See: `https://github.com/google-research/bert`.

[7] Following Luu et al. (2016), in this task, we only do the binary classification of domain term pairs as hypernymy or non-hypernymy and do not consider reconstructing the graph structures of the domain taxonomies.

optimizer and the reminder settings are the same as in Devlin et al. (2019). In MFT, only 7K$\sim$11.5K additional parameters need to be added (depending on the number of domains), compared to the original BERT model. All the algorithms are implemented with TensorFlow and trained with NVIDIA Tesla P100 GPU. The training time takes less than one hour. For evaluation, we use *Accuracy* as the evaluation metric for all models trained via MFT and fine-tuning. All the experiments are conducted three times, with the average scores reported.

4.2 General Experimental Results

We report the general testing results of MFT. For fair comparison, we implement following the fine-tuning methods as strong baselines:

- **BERT (S)**: It fine-tunes K BERT models, each with single-domain data.
- **BERT (Mix)**: It combines all the domain data and fine-tunes a single BERT model only.
- **BERT (MTL)**: It fine-tunes BERT by multi-task fine-tuning (Sun et al., 2019a).
- **BERT (Adv)**: It fine-tunes BERT by BERT (C) with an additional adversarial domain loss proposed in Hu et al. (2019).

We also evaluate the performance of MFT and its variants under the following three settings:

- **MFT (DC)**: It is MFT with domain corruption. All the typicality scores in the objective function are removed.
- **MFT (TW)**: It is MFT with typicality weighting. The domain corruption loss is removed.
- **MFT (Full)**: It is the full implementation.

The results of three multi-domain NLP tasks are reported in Table 2, Table 3 and Table 4, respectively. Generally, the performance trends of all three tasks are pretty consistent. With MFT, the accuracy of fine-tuned BERT boosts 2.4% for natural language inference, 2.6% for review analysis and 3% for domain taxonomy construction. The simple multi-task fine-tuning methods do not have large improvement, of which the conclusion is consistent with Sun et al. (2019a). Our method has the highest performance in 10 domains (genres) out of a total of 12 domains of the three tasks, outperforming previous fine-tuning approaches. For ablation study, we compare MFT (DC), MFT (TW) and MFT (Full). The results show that domain corruption is more effective than typicality weighting in MNLI, but less effective in Amazon and Taxonomy.

(b) Dataset: Taxonomy

Figure 3: Tuning the learning epochs of MFT.

4.3 Detailed Model Analysis

In this section, we present more experiments on detailed analysis of MFT. We first study how many training steps of MFT we should do before fine-tuning. As datasets of different tasks vary in size, we tune the epochs of MFT instead. In this set of experiments, we fix parameters as default, vary the training epochs of MFT and then run fine-tuning for 2 epochs for all domains. The results of two NLP tasks are shown in Figure 3. It can be seen that too many epochs of MFT can hurt the performance because BERT may learn too much from other domains before fine-tuning on the target domain. We suggest that a small number of MFT epochs are sufficient for most cases. Next, we tune the hyper-parameter λ from 0 to 0.5, with the results shown in Figure 4. The inverted-V trends clearly reflect the balance between the two types of losses in MFT, with very few exceptions due to the fluctuation of the stochastic learning process.

We also vary the number of corrupted domain classifiers by changing L_s. Due to space limitation, we only report averaged accuracy across all

Method	Telephone	Government	Slate	Travel	Fiction	Average

domains, shown in Table 7. In a majority of scenarios, adding more corrupted domain classifiers slightly improve the performance, as it poses strong domain-invariance constraints to deeper layers of transformer encoders in BERT.

For more intuitive understanding of MFT, we present some cases from Amazon Review Dataset with relatively extreme (low and high) typicality scores, shown in Table 5. As seen, review texts with low scores are usually related to certain aspects of specific products (for example, "crooked spoon handle" and "fragile glass"), whose knowledge is non-transferable on how to do review analysis in general. In contrast, reviews with high typicality scores may contain expressions on the review polarity that can be frequently found in various domains (for example, "huge deal" and "a waste of money"). From the cases, we can see how MFT can create a meta-learner that is capable of learning to solve NLP tasks in different domains.

4.4 Experiments for Few-shot Learning

Acquiring a sufficient amount of training data for emerging domains often poses challenges for NLP researchers. In this part, we study how MFT can benefit few-shot learning when the size of the training data in a specific domain is small [8]. Because the original MNLI dataset (Williams et al., 2018) is large in size, we randomly sample 5%, 10% and 20% of the original training set for each genre, and do MFT and fine-tuning over BERT. For model evaluation, we use the entire development set without sampling. In this set of experiments, we do not tune any hyper-parameters and set them as default. Due to the small sizes of our few-shot training sets, we run MFT for only one epoch, and then fine-tune BERT for 2 epochs per genre.

In Table 6, we report the few-shot learning results, and compare them against fine-tuned BERT without MFT. From the experimental results, we

---

[8] Note that this experiment is not conducted using the K-way N-shot setting. Refer to Related Work for discussion.

Typicality	Domain	Label	Review Text
Low	Book	NEG	More hate books. How could anyone write anything so wrong.
	Kitchen	NEG	The spoon handle is crooked and there are marks/damage to the wood. Avoid.
	Kitchen	NEG	The glass is quite fragile. I had two breaks.
High	Kitchen	POS	I would recommend them to everyone..and at their price, it's a HUGE DEAL!
	Electronics	NEG	What a waste of money. For $300 you shouldn't HAVE to buy a protection plan for...
	Electronics	NEG	Do not waste your money, this was under recommendations, but I would NOT...

Table 6: Few-shot natural language inference results over MNLI in terms of accuracy (%).

$L_s \downarrow$ **Dataset**$\rightarrow$	**Amazon**	**Taxonomy**
$\{12\}$	90.7	91.3
$\{6, 12\}$	90.8	92.0
$\{4, 8, 12\}$	91.4	92.5
$\{3, 6, 9, 12\}$	91.2	92.8

Table 7: Change of prediction accuracy when the selected layer indices L_s take different values (%).

can safely come to the following conclusions. i) MFT improves the performance for text mining of all genres in MNLI, regardless of the percentages of the original training sets we use. ii) MFT has a larger impact on smaller training sets (a 3.9% improvement in accuracy for 5% few-shot learning, compared to a 2.6% improvement for 20%). iii) The improvement of applying MFT before fine-tuning is almost the same as doubling the training data size. Therefore, MFT is highly useful for few-shot learning when the training data of other domains are available.

5 Conclusion and Future Work

In this paper, we propose a new training procedure named Meta Fine-Tuning (MFT) used in neural language models for multi-domain text mining. Experimental results show the effectiveness of MFT from various aspects. In the future, we plan to apply MFT to other language models (e.g., Transformer-XL (Dai et al., 2019) and ALBERT (Lan et al., 2019)) and for other NLP tasks.

Incorporating Behavioral Hypotheses for Query Generation

Ruey-Cheng Chen
SEEK Ltd
rcchen@seek.com.au

Chia-Jung Lee
Microsoft
cjlee@microsoft.com

Abstract

Generative neural networks have been shown effective on query suggestion. Commonly posed as a conditional generation problem, the task aims to leverage earlier inputs from users in a search session to predict queries that they will likely issue at a later time. User inputs come in various forms such as querying and clicking, each of which can imply different semantic signals channeled through the corresponding behavioral patterns. This paper induces these behavioral biases as hypotheses for query generation, where a generic encoder-decoder Transformer framework is presented to aggregate arbitrary hypotheses of choice. Our experimental results show that the proposed approach leads to significant improvements on top-k word error rate and Bert F1 Score compared to a recent BART model.

1 Introduction

Query suggestion is key to the usability of a search engine in the way it helps users formulating more effective queries or exploring related search needs. Prior work tackles this problem by employing primarily two strategies. The first one is based on a discriminative characterization, with candidate queries drawn from production logs ranked to align with what users may most likely issue next. Although effective (Ahmad et al., 2018), this strategy is inherently restricted by what is available in the logs, which in turn can penalize tail queries (Dehghani et al., 2017). In this work, we pursue the second strategy where query suggestion is cast as a natural language generation problem, aiming at producing effective continuations of the user's intent by using generative modeling.

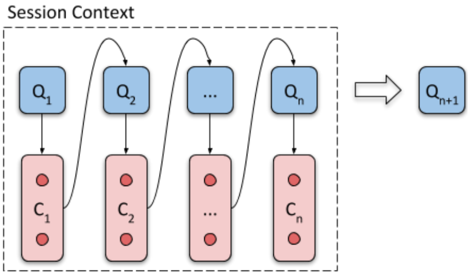

Figure 1: An example search session where a user issues queries and optionally performs clicking at timestamps 1 to n. At time n+1, the user issues q_{n+1} following the previous search context of length n.

For query generation, prior research has focused mostly on extending standard Seq2Seq models where the input is a concatenation of earlier queries a user has submitted in a session (Sordoni et al., 2015; Dehghani et al., 2017). However, literature often leaves out the influence of clickthrough actions (i.e., red blocks in Figure 1), which we argue should be taken into account in the generative process as they could be surrogates of the user's implicit search intent (Yin et al., 2016). Users may exhibit diverse behaviors such as consecutively issuing queries without further engagement, or following up a single query with extensive clickthrough actions. These vastly different patterns are indicative of information pieces that the users find most relevant, which we conjecture can help producing suggestions better aligned to the user needs.

We present an encoder-decoder Transformer model for the generative task that includes these patterns that we called behavioral hypotheses. One challenge that arises with Transformers is that they make minimal assumptions about input (i.e., a single string of tokens), making it non-trivial to add multiple hypotheses directly. To address this issue, we propose a generic approach that leverages tokenwise attention to aggregate multiple behavior hypotheses encoded by a shared Transformer encoder BART (Lewis et al., 2019). The resulting end-to-end model can capture the underlying user-induced belief while maintaining the same order

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3105–3110,
November 16–20, 2020. ©2020 Association for Computational Linguistics

of complexity as the original BART. For evaluation, we conduct experiments by sampling over 600K search sessions from a major commercial job search engine in Australia. With evaluation metrics including word error rate and BertScore (Zhang et al., 2020), we show that the approach outperforms prior competitive baselines and a recent Transformer model BART, suggesting attending to behavioral patterns is crucial to reflect users' intent.

2 Related Work

Generative approaches have been studied extensively in machine translation (Sutskever et al., 2014; Bahdanau et al., 2014), dialogue systems (Wen et al., 2015), and many other related areas (Gatt and Krahmer, 2018). The methodology was first applied to the query domain in Sordoni et al. (2015). Query suggestion has traditionally been a web search usability task. Ranking based approaches that leverage query co-occurrence and discriminative modeling are known to be most effective (Ozertem et al., 2012), but also likely to suffer from the lack of appropriate candidates for rarely seen queries. Some recent work sought to characterize the generative nature (Sordoni et al., 2015; Dehghani et al., 2017) of this process. The hierarchical formulation of sequence-to-sequence model (Sordoni et al., 2015) can effectively capture the query transitions, but does not offer a mechanism to incorporate implicit user signals (Wu et al., 2018). Our approach combines heterogeneous behavioral hypotheses by leveraging large-scale encoders and cross-structure attentions. Apart from similar attempts regarding encoding multiple sentences (Dai et al., 2019; Zhao et al., 2020), our work in a generative setting tackles a different problem of decoding over a meshed representation originated from multiple sources.

3 Approach

Let $\mathcal{Q} = (Q_1, Q_2, \ldots, Q_n)$ represent a sequence of queries submitted by a user in a consecutive fashion, where each Q_i comprises a sequence of terms. Each Q_i can lead to a succession of follow-up user interactions, among which we are mostly interested in textual matching cues C_i that enticed clicking on some underlying documents. The full list of such matching cues are denoted as $\mathcal{C} = (C_1, C_2, \ldots, C_n)$, in which each C_i is a set of text excerpts $t_{i1}, \ldots, t_{im}$, such as document title or metadata, displayed in response to Q_i. Given such a search context $(\mathcal{Q}, \mathcal{C})$, the query generation task aims to create a candidate query Q_{n+1} that the user is most likely to follow up with. The overall process is depicted in Figure 1.

Behavioral Hypotheses. We conjecture that, when making a new query, the assumed user takes inspiration from his/her preceding search context, following some *behavioral hypotheses* formed by preceding queries or matching cues. In this paper we seek to characterize this influence to formulated queries as follows:

$$\begin{aligned} K_1 &= (Q_1, Q_2, \ldots, Q_n) \\ K_2 &= \bigoplus\nolimits_{i<n} \{(t)_{t \in C_i}\} \oplus (Q_n) \\ K_3 &= \bigoplus\nolimits_{Q_i : C_i \neq \varnothing} \{(Q_i) \oplus (t)_{t \in C_i}\} \oplus (Q_n) \\ K_4 &= (Q_n) \oplus (t)_{t \in C_n} \end{aligned} \tag{1}$$

Each of these definitions loosely specifies a generative story behind the process: influence may come directly from preceding queries (K_1), preceding matching cues (K_2), interacted queries and the respective matching cues (K_3) , or the most recently submitted query and observed cues (K_4).

Vanilla Encoder-Decoder Transformer. Recent advances in transfer learning has popularized the use of pretrained encoder-decoder Transformer networks, setting state-of-the-art across the board (Vaswani et al., 2017; Raffel et al., 2019; Lewis et al., 2019). Query generation can be cast as a sequence-to-sequence problem and fine-tuned on any of these pretrained models. A simplistic but typical approach is, on the input side, to concatenate all items in a behavioral hypothesis regardless of their types into one sentence with the separator token inserted in between, and on the output side to simply put in the ground truth to be generated, i.e., Q_{n+1}. All input/output sentences are first tokenized using the same byte-pair encoding, and properly formatted by adding start/end tokens to the sentence beginning and sentence end. Following this preparation step, the input sentence is encoded into a vector representation by multiple layers of Transformer, and decoded on the other side using a similar stack.

In this paper we use the BART model (Lewis et al., 2019) to implement this encoder-decoder network. BART leverages specialized pretraining objectives such as text infilling and is known to be performant on text generation problems such as machine translation and summarization.

Meshed Representations. One caveat of the above process is that the model is agnostic of the presence of multiple behavioral hypotheses in the input. To solve this problem, we propose a new approach that derives a *meshed* representation of the input hypotheses $K_1, \ldots, K_4$ by reusing one single BART instance. Each hypothesis is first encoded using a shared BART encoder, and a tokenwise attention mechanism is leveraged to learn effective ways to contextualize the individual representations together. This is essentially combining four input streams in a token-by-token fashion so that each hypothesis can contribute to the aggregate at each token step, in varying degrees as determined by the attention weights. We expect this change to help surfacing regularities across different hypotheses, in the way regularization or multi-task learning does to ease learning trajectories. Tokenwise attention is also designed to encourage early correction in the hope that a more robust representation can be formed at the end of the meshed sequence.

The procedure can be described as follows. Let $[S_i^{(1)}; \ldots; S_i^{(T)}] = \text{BART}_{\text{enc}}(K_i)$ for all K_i, and T is the sequence length. We have:

$$\begin{aligned} \alpha_i^{(j)} &\propto \exp(W_{\text{attn}} S_i^{(j)}) \\ F^{(j)} &= \textstyle\sum_i \alpha_i^{(j)} S_i^{(j)} \\ O &= \text{BART}_{\text{dec}}([F^{(1)}; \ldots; F^{(T)}]) \end{aligned} \tag{2}$$

where W_{attn} is the attention weight matrix to be learned and O the output. On the decoder side, the attention mask is set to the union of attention masks from all underpinning hypotheses. This approach does not require multiple BART instances but may take extra GPU memory, linear to the output batch size, to cache processed representations and additional computation cycles to work through all four behavioral hypotheses.

4 Experimental Setup

Our main testbed was a sample of session logs from the SEEK job search engine[1]. This task domain is known for its characteristic query topics, surrounding role titles, skills, and entities such as company names or geo-locations, and distinctively different user behaviors to general web search. This dataset is preferred over the AOL logs for the availability of clicked document texts, but our approach should be equally applicable to other search domains.

We collected textual queries Q_i and the titles of documents that were clicked on in response to Q_i as C_i. All search sessions were anonymized to ensure that the query and click information cannot be linked back to individual users. Session boundaries were determined by an inactivity of 30 minutes or more between two consecutive actions. In each session the latest query was held out as the ground truth. Training sessions (500K) were initially gathered from a two-week span starting from Oct 1, 2019, and out of the same period a separate split was selected as a dev set (1K); then, the latter two weeks from the same month were sampled to form the test sessions (100K). About 15% of the collected sessions were found to exceed the maximum sequence length of the BART encoder, and were removed from the experiment to avoid inadvertently favoring the proposed approach for that the baseline may only see truncated input. Standard preprocessing steps were performed to remove noisy queries that occurred 10 times or less across the periods, and singleton sessions that contain only one query. In our experiments we compare the following approaches:

Seq2Seq+Attn A standard sequence-to-sequence model using a two-layer bidirectional GRU (Cho et al., 2014) as the encoder and a uni-directional attentive GRU as the decoder (Bahdanau et al., 2014). Our implementation used 1,000 hidden dimensions and the same byte-pair encodings as other methods.

MPS (Most Popular Suggestion) A simple yet effective baseline used in (Hasan et al., 2011; Sordoni et al., 2015; Dehghani et al., 2017), based on co-occurrence frequencies of the last query in the search context and all candidate queries.

BART The vanilla BART model (Lewis et al., 2019). We took the full concatenated search context as input, and fine-tuned on pretrained weights for BART-Large model, complete with 12 transformer layers in total.

MeshBART The proposed meshed variant of BART, configured to have the same model capacity. It takes multiple input hypotheses and combines them using the proposed tokenwise attentions before entering the decoding phrase.

We report word error rate (WER) and Bert F1

---

[1] `https://www.seek.com.au`

	WER	BertF1	MRR@3	S@3
Seq2Seq+Attn	88.3	53.1	9.8	14.1
MPS	49.7	72.6	33.9	47.1
BART	41.5	76.1	42.5	54.6
MeshBART	**40.9**	**76.5**	**42.7**	**55.0**

Table 1: Top-3 test performance. Differences between BART and MeshBART on WER and BertF1 are significant ($p < 10^{-4}$) on the Wilcoxon sign-rank test.

scores (BertF1) (Popović and Ney, 2007; Zhang et al., 2020) adapted to the top-k setting, with respect to the reference (ground truth) across the given k hypotheses.

$$\mathrm{WER@}k = \min_{i=1,\ldots,k} \mathrm{EditDist}(ref, hyp^{(i)})/|ref|$$

$$\mathrm{BertF1@}k = \max_{i=1,\ldots,k} \mathrm{BertF1}(ref, hyp^{(i)})$$

In addition to generation quality, we also measure ranking performance by mean reciprocal rank (MRR@k) and success at k (S@k) following prior work. To train the encoder-decoder models, cross entropy loss was used throughout. All neural models were trained up to 3 epochs (roughly 83k steps) and early-stopped if no further gain on dev WER@3 was observed in the next 10k steps. At inference time, up to 5 suggestions were generated for each session using beam search (width = 8). For Seq2Seq+Attn the batchsize was set to 128 and both BART-based methods to 16. All experiments were conducted on a single NVIDIA T4 GPU.

5 Results

Quality of Generated Queries. We present the effectiveness scores of different generation models in Table 1. The results show that query generation remains a difficult task: the top-3 beam search output from a standard Seq2Seq with attention baseline achieves on average 0.88 errors per token. Consistent with prior work (Sordoni et al., 2015), MPS delivers competitive performance, bolstering its wide adoption in production systems. The word error rates are pushed down further by a vanilla BART that simply encodes sessions as long sequences, showcasing the superior modeling power of pretrained Transformer networks. Among these results, MeshBART consistently demonstrates the best effectiveness across all metrics, suggesting that combining critical signals from the given behavioral hypotheses can improve generation quality.

We also investigate if generation quality is influenced by other factors of the test population.

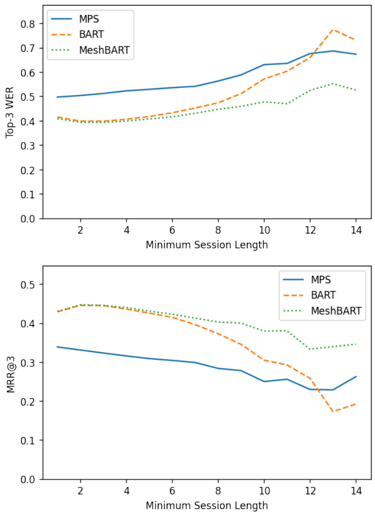

Figure 2: A breakdown of top-3 word error rate and MRR@3 by minimum session length. Each bucket on x-axis indicates a sub-population of test sessions that contain at least X queries.

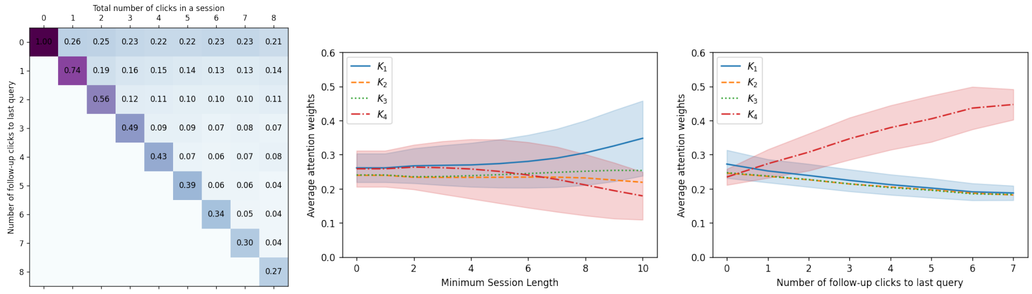
Placing a limit on session length, in Figure 2 we find that long sessions result in lower performance across all models. The diverse and complex intents commonly involved in long sessions make next-query prediction particularly challenging. Interestingly, WER@3 and MRR@3 appear to respond differently to the increased session length for different methods, e.g. BART can perform worse than MPS on excessively long sessions. Apart from that, MeshBART remains the most competitive across all buckets, suggesting it being a robust approach for query generation.

Further comparisons with non-generative MPS also shed light on the superiority of the proposed approach. In a W/T/L analysis on top-3 ranking performance, we find that across all test sessions MeshBART has seen 30% wins, 52% ties, and 18% losses to MPS on MRR@3. Another analysis conditioned on sessions with only one preceding query shows that MeshBART can produce at least one novel suggestion (i.e. queries not seen in the candidate pool) for 39.2% of the test sessions. The effect is more pronounced when the preceding query is rare or has a relatively smaller candidate pool. Examples given in Table 2 show that the proposed approach can formulate reasonable follow-up queries by generalizing seen query parts.

Analysis of Behavioral Hypotheses. Our design of behavioral hypotheses in Section 3 is inspired by the users' interaction patterns. Figure 3a illustrates the intensity of user clicking with respect

Preceding Query (Q_n)	Candidates	Generative Suggestions (MeshBART)
environmental technology	environmental, environment	environmental, environmental science, sustainability, environmental scientist
part time adobe	part time, part time marketing	part time marketing, marketing, digital marketing, graphic design
aviation security adelaide	adelaide airport security	aviation security, security, security officer, airport security

Table 2: Query generation examples on tail queries, based on test sessions with only one preceding query that the logs fail to produce enough candidates for due to scarcity. Generative models such as MeshBART can produce reasonable suggestions regardless of candidate pool coverage.



(a) (b) (c)

Figure 3: (a) Column-normalized contingency table illustrating clicking behavior. (b)(c) Average attention weights for all four behavioral hypotheses vary across different session type buckets. Shaded areas for K_1 and K_4 indicate the standard error. (Best viewed in color.)

to the last query in a session, suggesting that the majority of clicks are predominately centered on the last query irrespective of the total number of clicks. Job search users are found to be more persistent on articulating an effective query, and from there consume extensively most returned results before disengaging from the search session. This interesting perk is best reflected by the use of K_4 hypothesis in our modeling framework.

To understand the inner workings of the meshed attentions, Figure 3b visualizes the actual attention values assigned to all four of the presented hypotheses across different length buckets. On the one hand, the attention weight associated with K_1 (i.e., all preceding queries) are found to positively correlate with the growth of session length. Longer search sessions might be due to the user actively exploring the search space, and this increased attribution signals the importance of explicit search intents from the modeling perspective. On the other hand, K_4 tends to receive less attention as the search session grows, indicating that the importance of the most recent interactions become diluted in long, exploratory search journeys. The value of recent interactions in generative modeling is best illustrated by Figure 3c, where the attention weight of K_4 appears to positively correlate with the intensity of last-round clicking in a search session. These results suggest that our approach has the flexibility to draw information from different hypotheses in a unified query generation process.

6 Conclusions

This paper presents an effective approach for incorporating user-induced interaction patterns as behavioral hypotheses into the query generation process. Under an encoder-decoder Transformer framework, the proposed tokenwise attentions demonstrate the desirable modeling working by placing emphasis on different behavioral hypotheses at different occasions. On a domain-specific search benchmark, our model outperforms all reference methods in aggregate and across varying session properties, demonstrating its effectiveness in a robust way. In future work, we will focus on producing novel continuations of the user's search intent, extending the approach to other domains, and automating the design of behavioral hypotheses. Qualitative evaluation for open-ended generation is also an interesting topic on the roadmap.

Conditional Causal Relationships between Emotions and Causes in Texts

Abstract

The causal relationships between emotions and causes in text have recently received a lot of attention. Most of the existing works focus on the extraction of the causally related clauses from documents. However, none of these works has considered the possibility that the causal relationships among the extracted emotion and cause clauses may only be valid under a specific context, without which the extracted clauses may not be causally related. To address such an issue, we propose a new task of determining whether or not an input pair of emotion and cause has a valid causal relationship under different contexts, and construct a corresponding dataset via manual annotation and negative sampling based on an existing benchmark dataset. Furthermore, we propose a prediction aggregation module with low computational overhead to fine-tune the prediction results based on the characteristics of the input clauses. Experiments demonstrate the effectiveness and generality of our aggregation module.

1 Introduction

Recently, the research on the causal relationships between human emotions and their corresponding causes has received much attention. Recognizing the causes of a specific emotion in a document is considered as more useful than only identifying the emotion, due to the great potential of helping people make reasonable decisions and avoid unnecessary loss (Gui et al., 2017; Li et al., 2018; Xia et al., 2019; Ding et al., 2019).

There are currently two well-designed tasks concerning the causal relationships between emotions and their causes, the Emotion Cause Extraction (ECE) task (Lee et al., 2010; Chen et al., 2010; Gui et al., 2016a,b) and the Emotion-Cause Pair Extraction (ECPE) task (Xia and Ding, 2019; Chen et al., 2018). Specifically, the ECE task focuses on extracting the causes for a given emotion, while the ECPE task focuses on extracting emotions and the corresponding causes as pairs.

Despite their increasing popularity, both tasks only aim to extract the clauses containing causal relationships, and have neglected the possibility that the context clauses may be indispensable for the extracted clauses to have a valid causal relationship. Let us consider the following example:

- *Wu was diagnosed with advanced liver cancer at the beginning of 2014,*
- *since when he began to update his health condition in Microblog and has attracted much attention from many users.*
- *If Wu didn't update his microblog for a long time,*
- *people worried that he may have passed away.*
- *There was one time that Wu hadn't updated his microblog for about two months,*
- *and he had received a lot of messages concerned about his health conditions.*
- ...

Figure 1: Example document, where the yellow-green color clauses are the context clauses with important information, the red one is the corresponding cause clause, and the blue one is the targeted emotion clause.

In the above example, the cause and emotion clauses may not have a causal relationship if we ignore the context clauses, since the reasons of not updating one's social media account can be more than the owner passing away (e.g., forgetting his/her password, using a new account, etc.). Only when extra information contained in the context clauses is available, can these two clauses have a valid causal relationship.

Therefore, it is essential to consider the context clauses as seriously as the targeted emotion and cause clauses when determining their causal relationships. With these context-dependent causal relations figured out, more complete and meaningful information about these causal relationships

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3111–3121,
November 16–20, 2020. ©2020 Association for Computational Linguistics

can be extracted. Specifically, we can learn that some types of events may evoke different types of emotions under different circumstances, while some will always evoke one type of emotion under any circumstance. Such useful information about causal relationships can be beneficial in many emotion-related applications, such as accurately predicting one's emotions with context taken into consideration when a specific event occurs.

Despite the ubiquitousness of the context-dependent causal relationships described above, few works have paid attention to them. In this work, we articulate the importance of context in the problem of causal relationship recognition, and make the first step of studying such special causal relationships in text data.

We propose a task to determine whether or not the input pair of emotion and cause clauses has a causal relationship given some specific context clauses. As our task is new without any existing dataset available, we manually label the documents in the ECPE dataset constructed by Xia and Ding (2019) and follow the procedure of negative sampling (Mikolov et al., 2013) to build our own dataset. The constructed dataset can be further processed and used in some other important tasks that we aim to focus on in the future, such as quantifying the effect of context on the causal relationships.

Furthermore, we propose a prediction aggregation module with low computational overhead to fine-tune the prediction results according to the characteristics of the input clauses. The experiments on our constructed dataset demonstrate the effectiveness and generality of our aggregation module.

The contributions of this work can be summarized as follows.

- To address the issue that context can be indispensable for some causal relationships to be valid, we define a new task to determine whether or not an input pair of emotion and cause has a causal relationship under different contexts.

- Based on the ECPE dataset, we construct a dataset for our proposed task via manual annotation and negative sampling, which can also be used in some other important tasks, such as quantifying the effect of context on the causal relationships.

- We propose a general prediction aggregation module with low computational overhead, which can be used together with most existing models and significantly improve the prediction results on our proposed task.

2 Related Works

As known to all, context has been utilized in many text-related applications to provide semantic information and improve task performance (Kruengkrai et al., 2017; Kayesh et al., 2019; Zhou et al., 2016; Li and Mao, 2019).

In traditional causal reasoning, the term "context" is mostly discussed in the task of *causal effect estimation*, which is to estimate the influence of the cause variable on the effect variable (Guo et al., 2018). In some cases, the change of the effect variable relies not only on the cause variable, but also on some other relevant variables which can be viewed as the context variables and called *confounders*. Therefore, these confounders should be discovered and "removed" by some specially designed algorithms in order to accurately estimate the causal effect, such as propensity score method (Gu and Rosenbaum, 1993; Austin, 2011; Imbens, 2004; Lunceford and Davidian, 2004), front-door criterion (Pearl, 1995), instrumental variable estimator combined with structural causal models or potential outcome framework (Guo et al., 2018), etc.

Unfortunately, most of these existing works are not designed for text data of unstructured data format. Also, before the noisy causal effect from the confounders can be removed, these confounders need to be discovered and represented in an explicit form, which is another challenge for text data to fit in the existing causal effect estimation models. A potential solution proposed by Sridhar and Getoor (2019) is to represent the confounders in text data as the topic distribution vectors achieved by Latent Dirichlet Allocation model. However, such a representation is not theoretically explainable to carry enough information to represent these confounders. Also, before estimating the causal effect, we need to first discover these causal relationships which are determined together by cause and context in text data.

The tasks concerning causality extraction in text can be mainly divided into two categories, causal phrase extraction and causal clause extraction, where the former focuses on extracting word

Table 1: Examples of documents containing conditional emotion-cause pairs and non-conditional ones

Type	Document content
Document with a conditional pair	Wu was diagnosed with advanced liver cancer at the beginning of 2014, since when he began to update his health condition in Microblog. If Wu didn't update his microblog for a long time, people worried that he may have passed away. ...
Document with a non-conditional pair	The convenience store was at the corner of the street. Recalling the bloody murder in the early morning, the store owner still felt terrified. She was tallying the goods when she heard a scream from the outside. ...

phrases that have causal relationship in one sentence (Hashimoto et al., 2014; Zhao et al., 2017), and the later focuses on extracting multiple clauses from a document (Gui et al., 2016a,b; Xia and Ding, 2019; Chen et al., 2018). Existing models for causal phrase extraction are mostly based on combinations of syntactic patterns and machine learning techniques, which first extract candidate phrases based on predefined templates, and then train a classifier to classify the candidate causal pairs. On the other hand, existing models for causal clause extraction are mostly based on deep learning models to extract abstract features for each clause, in order to accurately classify whether or not some clauses are causally related. Although the context of the input document is always involved in providing more semantic information to enhance the embedding vectors of clauses, none of these works has paid attention to the possible effect of context on the causal relationship itself.

Moreover, as we focus on emotion causal relationships in this paper, for some emotions (e.g., shame, envy, guilt, etc.) to arise in the first place, a particular social setting may be necessary. Therefore, taking the social contexts into consideration may be an essential step to study whether a specific event can cause an emotion (Wilutzky, 2015; Marsella et al., 2010; Jurafsky, 2004). In our work, we articulate the importance of context in the problem of causal relationship recognition, in view that the context can be essential in order for a pair of emotion and cause to have a valid causal relationship.

3 Task Definition

In this section, we first formally define the term "conditional" based on the concept of emotion-cause pair used in the ECE and ECPE tasks, and then formulate our proposed task based on such conditional emotion-cause pairs.

As defined by Xia and Ding (2019), an emotion-cause pair (ECP) contains an emotion clause indicating an emotion (e.g., Happiness) and a set of corresponding cause clauses. We define "conditional ECP" as follows.

Definition 1 (Conditional Emotion-Cause Pair) *If an emotion-cause pair is considered to have causal relationship only when a specific context is given, it is called a conditional emotion-cause pair.*

Examples of documents with a conditional pair and a non-conditional pair can be found in Table 1. Specifically, for the document with a conditional pair, in general, most people would not worry about whether a social media user updates his/her account or not, but with specific context like the one in the document, Wu had already gained much attention and hence people cared about his life. As for the document with a non-conditional pair, one shall feel frightened whenever he/she witnesses a bloody murder, which is unlikely to change with different contexts.

Definition 1 indicates that the conditional pairs should not be judged to have causal relationship when an irrelevant context or no context is given. Considering such a property, our task is formulated as follows.

The proposed task Given a specific context con_i and an emotion-cause pair $x_i = (C_i, e_i)$ containing a set of cause clauses C_i and an emotion clause e_i, determine a binary label y_i to indicate whether or not the input pair x_i has causal relationship under the context con_i.

As defined above, our proposed task is not to directly distinguish the conditional pairs from the non-conditional ones. The reason is that the recognition of a conditional pair is based on its different labels under different contexts instead of the text

Table 2: Details of the manually labeled dataset

	Conditional (N_{con})	Non-conditional (N_{noncon})
# of documents	561	1524

itself. Therefore, such a task formulation spares the models from worrying about how to transform the labels of causal relationship to the labels of conditional pairs, and simplifies the process of training.

4 Dataset Construction

Different from the ECPE task (Xia and Ding, 2019), the ECPs are directly given in our task and the goal of our task is to judge whether or not they are causally related under a specific context. Therefore, our proposed task is new without any existing annotation available, so we construct our own dataset based on the ECPE dataset (Xia and Ding, 2019) by the following two steps: manual annotation and negative sampling.

4.1 Manual Annotation

In the ECPE dataset, each document contains one ECP composed of an emotion clause and a set of cause clauses. These documents are mainly snippets of news articles or social media documents. To manually annotate the documents with the labels of conditional pairs, we have recruited three human experts who are required to give a binary label to each document: 1 indicates the ECP in this document is conditional, and 0 indicates it is not. Specifically, these three experts are experienced academic partners in the area of emotion cause extraction.

To label an ECP as a conditional one, the cause events and the effect emotions should be less or not relevant under normal circumstances. For example, in general one shall not reject the care of nurses when he/she is ill, but someone with racial prejudice may feel disgusted with foreign nurses. Such context information contained outside of the cause and emotion clauses is what the three experts are required to find and judge whether these context information is essential for the targeted ECP to have a causal relationship.

We have inspected the labels provided by the three experts and the average kappa value among them is $\underline{\mathbf{0.8675}}$, which indicates the fidelity of these manual labels. With three labels from the three human experts, we adopt the majority voting scheme to determine the final label for each document. For example, given a document, if two experts agree on labeling the ECP in this document as a conditional pair, then the final label for this document is 1. The details of the annotated dataset are shown in Table 2, where N_{noncon} denotes the number of documents with non-conditional pairs, and N_{con} denotes the number of documents with conditional pairs.

4.2 Negative Sampling

Although through manual annotation we have obtained the labels of conditional pairs, all ECPs in the resultant dataset are supposed to have valid causal relationships, since the conditional ones are all given their correct contexts and the non-conditional ones do not depend on any context. In other words, the current dataset only has “positive” instances, but for our proposed task we also need “negative” instances to train a classification model.

To generate such “negative” samples, we follow the procedure of negative sampling (Mikolov et al., 2013). Specifically, we define the following two types of “negative” samples:

- **Context-type**: The context-type negative sample of a document is generated by replacing its original context with a randomly sampled context from the other documents, while keeping the ECP unchanged.

- **Emotion-type** : The emotion-type negative sample of a document is generated by replacing its emotion clause with a randomly sampled emotion clause (indicating a different emotion) from the other documents, while keeping the other clauses unchanged.

Table 3 shows examples of the two types of generated “negative” samples. Specifically, compared with the original document, the generated context-type document has a totally different set of context clauses (i.e., the italic clauses enclosed by “⟨” and “⟩”), which does not provide the information that Wu was diagnosed with cancer and has been updated his health condition in Microblog. Therefore, the generated context-type document is expected to have no causal relationship due to the irrelevant context. As for the generated emotion-type document, the emotion clause is replaced with a clause of Happiness, which makes no sense since the cause clause and the new emotion clause are now irrelevant.

Table 3: Examples of two types of generated "negative" documents

Type	Document content
Original	Wu was diagnosed with advanced liver cancer at the beginning of 2014 and began to update his health condition in Microblog. If Wu didn't update his microblog for a long time, people worried that he may have passed away. ...
Context-type	⟨ *When Bai was notified that his advice was adopted by the National public security bureau, he was cooking dinner for his children.* ⟩ If Wu didn't update his microblog for a long time, people worried that he may have passed away. ⟨ ... ⟩
Emotion-type	Wu was diagnosed with advanced liver cancer at the beginning of 2014 and began to update his health condition in Microblog. If Wu didn't update his microblog for a long time, ⟨ *he was really happy that he could finally afford his dream house.* ⟩ ...

[1] The italic clauses enclosed by the angle brackets are the replaced clauses in the generated documents.

Table 4: Details of the constructed dataset with $n = 2$

	Positive	Negative
# of documents	5133	5292

To summarize the labels of causal relationships of the generated documents, for the generated context-type documents, those with a conditional pair will not have causal relationships due to their irrelevant contexts, while those with a non-conditional pair will still have causal relationships. As for the generated emotion-type documents, all of them will not have causal relationships, since the original cause clauses should only lead to the original emotion given the original context.

Therefore, suppose that n denotes the number of each type of "negative" documents generated for each original document, we can calculate the number of documents with and without causal relationships in the constructed dataset as follows:

$$\begin{aligned} N_{pos} &= N_{noncon} * n + N_{noncon} + N_{con} \\ N_{neg} &= N_{noncon} * n + N_{con} * 2 * n \end{aligned} \tag{1}$$

where N_{pos} denotes the number of documents with causal relationships, N_{neg} denotes the number of documents without causal relationships.

In order to generate a balanced dataset for our proposed task, we need to make sure that:

$$\frac{N_{pos}}{N_{neg}} \approx 1 \tag{2}$$

from which n should be around 1.858. Since n should be an integer, the possible choices are $n = 1$ and $n = 2$, while a larger n may create an imbalanced dataset with too many negative samples and cause the models biased towards the negative labels. Based on our preliminary experiments conducted to validate the setting of n, the results show that the constructed dataset with $n = 1$ is not reasonable[1]. Therefore, we set n to 2 to construct our dataset and the details of the constructed dataset are shown in Table 4.

5 Architecture

In this section, we introduce our architecture for our task, and propose a simple, general and effective prediction aggregation module based on the characteristics of conditional ECPs.

5.1 The Framework

As shown in Figure 2, our framework contains three main modules: a clause embedding module, a context encoding module, and a newly proposed prediction aggregation module. First, in the clause embedding module, the word embedding vectors of the input clauses are passed into a Bi-directional Long Short-Term Memory (BiLSTM) model to obtain informative clause embedding vectors for each clause. Then, in the context encoding module, context information is encoded into the clause embedding vectors of the input ECPs by using one of the three classic methods: explicit concatenation, implicit encoding and attention-based method. Finally, the context-encoded embedding vectors and the original ones of the input ECPs are passed to the proposed prediction aggregation module to

---

[1] More details and discussion on the preliminary experiment results are given in Section 6.3.

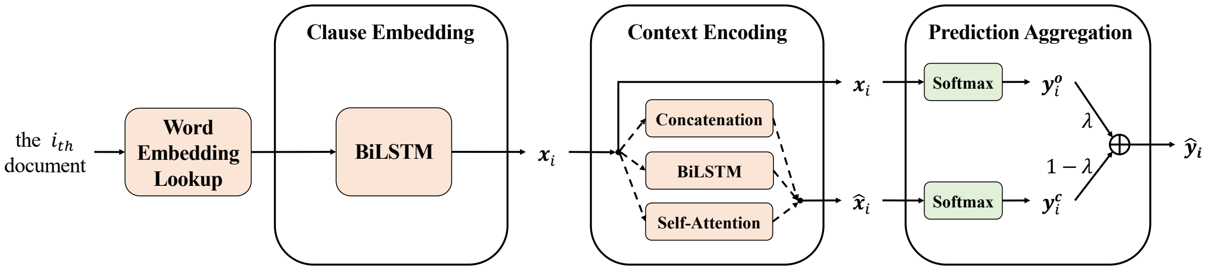

Figure 2: Architecture of our framework, where the dashed arrows indicate that we have three different ways to encode context information.

generate the final prediction.

Below, we introduce these three modules in detail. For simplicity, the formulas in subsequent discussions only consider the case where there is only one cause clause. Note that it can be easily extended to multiple cause clauses by concatenating their embedding vectors together.

5.2 Clause Embedding Module

To obtain an embedding vector for each word, we use the word embedding vectors released by Xia and Ding (2019), which are trained using the word2vec algorithm (Mikolov et al., 2013). To encode words' embedding vectors into a clause embedding vector, we adopt BiLSTM model, which is capable of generating an informative vector for each clause by passing words' information along the clause forwards and backwards. Specifically, for the i-th document, the input of this module includes three parts: the cause clause c_i, the emotion clause e_i, and the context clauses con_i. Note that the cause clauses and the emotion clause are already annotated in the dataset, so the remaining clauses of the input document are denoted as the context clauses.

$$\begin{aligned}\mathbf{c}_i &= BiLSTM(c_i)\\ \mathbf{e}_i &= BiLSTM(e_i)\\ \mathbf{con}_i &= BiLSTM(con_i)\\ \mathbf{x}_i &= [\mathbf{c}_i;\mathbf{e}_i]\end{aligned} \tag{3}$$

5.3 Context Encoding Module

After we retrieve an embedding vector for each clause, in order to determine the causal relationship of the input ECP under a specific context, we need to encode context information into the embedding vectors of the input ECP for the subsequent prediction. In this aspect, we consider three classic methods used most frequently in the area of text processing: explicit concatenation, implicit encoding, and attention-based method. The performance of these methods will be shown and discussed in Section 6.

Explicit concatenation As indicated by the name, this method directly concatenates the embedding vectors of the context clauses to those of the input pair, and passes them to the next module so that the final prediction is based on all clauses, i.e.,

$$\hat{\mathbf{x}}_i = [\mathbf{c}_i;\mathbf{e}_i;\mathbf{con}_i] \tag{4}$$

Implicit encoding The second method aims to encode context information implicitly into the embedding vectors of the input ECP via an extra layer, such as BiLSTM or Convolutional Neural Network (CNN). Considering that the relevant information may locate anywhere of the context clauses, CNN may not be a good choice due to its fixed neighborhood size. Therefore, we adopt BiLSTM model for implicit encoding of context information.

$$\begin{aligned}\hat{\mathbf{c}}_i &= BiLSTM(\mathbf{c}_i)\\ \hat{\mathbf{e}}_i &= BiLSTM(\mathbf{e}_i)\\ \hat{\mathbf{x}}_i &= [\hat{\mathbf{c}}_i;\hat{\mathbf{e}}_i]\end{aligned} \tag{5}$$

Attention-based method The third method is based on the self-attention module proposed by Vaswani et al. (2017), which has achieved great success recently in translation work. We adopt the 1-layer-multi-head self-attention module to encode context information. Specifically, instead of calculating the attention scores among all sentences in the original self-attention module, we only calculate the attention scores between the input pair and the context clauses, which reduces unnecessary attention weights, and targets at generating the context-encoded embedding vectors of the input

ECP for the subsequent prediction.

$$
\begin{aligned}
\hat{\mathbf{c}}_i &= \mathbf{c}_i + \sum_{j \in con_i} \alpha_{c,j} \cdot \mathbf{con}_{i,j} \\
\hat{\mathbf{e}}_i &= \mathbf{e}_i + \sum_{j \in con_i} \alpha_{e,j} \cdot \mathbf{con}_{i,j} \\
\alpha_{c,j} &= \frac{\exp(\mathbf{c}_i \cdot \mathbf{con}_{i,j})}{\sum_{k \in con_i} \exp(\mathbf{c}_i \cdot \mathbf{con}_{i,k})} \\
\alpha_{e,j} &= \frac{\exp(\mathbf{e}_i \cdot \mathbf{con}_{i,j})}{\sum_{k \in con_i} \exp(\mathbf{e}_i \cdot \mathbf{con}_{i,k})} \\
\hat{\mathbf{x}}_i &= [\hat{\mathbf{c}}_i; \hat{\mathbf{e}}_i]
\end{aligned} \tag{6}
$$

5.4 Prediction Aggregation Module (PAM)

As defined in Section 3, the conditional pairs will no longer have causal relationships if an irrelevant context or no context is given, whereas the non-conditional pairs will always have valid causal relationships. Taking such a difference into consideration, here we propose a simple, general and effective prediction aggregation module.

First, to get the prediction with context, we pass the context-encoded embedding vectors of the input pair, $\hat{\mathbf{x}}_i$, to a fully-connected layer with a softmax activation function:

$$P(y_i^c) = softmax(W_c \hat{\mathbf{x}}_i)) \tag{7}$$

where W_c is a trainable weight matrix.

Next, we add an extra step of predicting the labels of causal relationship directly based on the original embedding vectors of the input pair, without encoding the context information. Specifically, we pass the original embedding vectors achieved in the clause embedding module, $\mathbf{x}_i$, to a fully-connected layer with a softmax activation function:

$$P(y_i^o) = softmax(W_o \mathbf{x}_i) \tag{8}$$

where W_o is a trainable weight matrix.

The proposed module works as follows. If $P(y_i^o)$ has already shown that the input pair has a valid causal relationship (i.e., $P(y_i^o = 1) > P(y_i^o = 0)$), then this pair is more likely to still have a causal relationship under any specific context, and the final result should depend more on the prediction without encoding context information. On the other hand, if the input pair is predicted to have no causal relationship without context, the final result should give more weight to the prediction taking context information into consideration. Following this logic, we can have the following aggregation formula:

$$
\begin{aligned}
P(y_i) &= \lambda * P(y_i^o) + (1 - \lambda) * P(y_i^c), \\
\lambda &= P(y_i^o = 1)
\end{aligned} \tag{9}
$$

With this aggregation module, the model can handle both conditional and non-conditional pairs, and give a better prediction on the causal relationship of an input pair under a specific context.

6 Experiment

In Section 4, we have described the process of dataset construction and the details of the constructed dataset[2]. In this section, we conduct experimental studies to evaluate our approach, and analyze the experiment results pragmatically.

6.1 Baseline Models

As mentioned in Section 5.3, there are three options for the context encoding module. Therefore, we consider three baseline models without PAM, each of which contains one of the three context encoding methods we described.

- **BiLSTM + Concatenation**: this baseline model uses BiLSTM at word level to get the clause embedding vectors and directly concatenates the context clauses' vectors to those of the input pair.
- **BiLSTM + BiLSTM**: this model uses BiLSTM at both word level and clause level to get the context-encoded embedding vectors of the input pair for the final prediction.
- **BiLSTM + Self-Attention**: this model uses BiLSTM at word level and uses Self-Attention at clause level to encode the context information.

6.2 Experiment Settings

We randomly select 90% of the data for training and the remaining 10% for testing. To avoid the effect of randomness, we divide the whole dataset into 10 folds and repeat the experiments 10 times with each fold being testing data. The average experiment results are reported in the following sections. Since our proposed task is a binary classification task, we adopt the traditional precision, recall and F1 scores to evaluate the prediction performance.

---

[2] The constructed dataset and our programs can be found in: https://github.com/mark-xhchen/Conditional-ECPE.

Table 5: Preliminary experiment results of baselines

Models	BiLSTM + Concatenation		BiLSTM + BiLSTM		BiLSTM + Self-Attention	
Parameter	$n = 1$	$n = 2$	$n = 1$	$n = 2$	$n = 1$	$n = 2$
Precision (%)	57.34	54.12	57.93	66.06	57.81	57.66
Recall (%)	98.29	71.19	99.64	74.00	99.58	77.70
F1 (%)	72.77	61.27	73.26	69.76	73.16	66.05

[1] The values in gray cells are too high to be reasonable.

Table 6: Performance of models with and without PAM

Models	Containing PAM (✓or ×)	P(%)	R(%)	F1(%)
BiLSTM + Concatenation	×	54.12	71.19	61.27
	✓	60.24	75.91	**67.10**‡ ($\uparrow$ 5.83)
BiLSTM + BiLSTM	×	66.06	74.00	69.76
	✓	65.11	78.30	**71.10**† ($\uparrow$ 1.34)
BiLSTM + Self-Attention	×	57.66	77.70	66.05
	✓	61.95	78.65	**69.29**‡ ($\uparrow$ 3.24)

- † and ‡ denote the statistical significance for $p < 0.01$ and $p < 0.001$, respectively.

As for the detailed design of the models, the hidden units in BiLSTM is set to 100, and the heads in Self-Attention module is set to 2. All weight matrices are randomly initialized with uniform distribution. For training, we use the stochastic gradient descent algorithm and Adam optimizer, with batch size set to 32 and learning rate set to 0.005. Also, for regularization, dropout is applied with dropout rate set to 0.2, and a L2-norm regularization term is added to constraint the softmax parameters, where the weight of the regularization term is set to $1e^{-5}$.

6.3 Experiment Results

In this section, we report the experiment results in Table 5 to validate our setting of n. We conduct experiments on the constructed datasets by setting n to 1 and 2. We notice that all our baseline models achieve unbelievably high recall values (i.e., $0.98 \sim 0.99$, see gray cells in Table 5) when $n = 1$. After looking into the detailed predictions, we find that when $n = 1$, the models unreasonably predict all test samples to have positive labels, which reveals that the models are heavily biased towards the positive labels due to insufficient negative samples. In contrast, the performance of the baseline models becomes more reasonable when $n = 2$. Therefore, we conduct our following experiments on the constructed dataset using $n = 2$.

6.4 Effect of PAM

To validate the effectiveness of PAM, we conduct experiments on the three baselines and report the results in Table 6. As shown in the table, before we add PAM, "BiLSTM + BiLSTM" achieves the highest F1 score compared with the other two models, possibly due to that the Self-Attention module needs a larger-scale dataset to train well, while simple concatenation cannot get semantic embedding vectors. After adding PAM, the F1 scores of the three baseline models are improved on average by **3.47%**, and the results with p-value attached indicate the models containing PAM significantly outperform those without PAM.

Specifically, the effect of adding PAM from high to low is "BiLSTM + Concatenation", "BiLSTM + Self-Attention", and "BiLSTM + BiLSTM". This seems to imply that the improvement of PAM should be small when the model without PAM can already encode contexts well. The above results demonstrate the generality of PAM that it can be easily used together with existing classic models, and for our proposed task, PAM can improve their prediction performance significantly.

6.5 Case Study

To further illustrate how our aggregation module (i.e., PAM) improves the performance, we inspect the predictions of four examples given by the "BiLSTM + Concatenation + PAM" model. As shown in Table 7, Documents #1 and #2 share the same conditional ECP, and Documents #3 and #4 share the same non-conditional pair.

For Documents #1 and #2, since people would not care about Wu's health condition if he did

Table 7: Examples of predictions from the model "BiLSTM + Concatenation + PAM"

Index	Document	$P(y_i^o)$	$P(y_i^c)$	$P(y_i)$	True Label
#1	Wu was diagnosed with advanced liver cancer at the beginning of 2014 and began to update his health condition in Microblog. If Wu didn't update his microblog for a long time, people worried that he may have passed away. ...	$[0.657, 0.343]$	$[0.265, 0.735]$	$[0.3995,$ **0.6005**$]$	1
#2	When Bai was notified that his advice was adopted by the National public security bureau, he was cooking dinner for his children. If Wu didn't update his microblog for a long time, people worried that he may have passed away. ...	$[0.657, 0.343]$	$[0.712, 0.288]$	$[$**0.6931**$, 0.3069]$	0
#3	The convenience store was at the corner of the street. Recalling the bloody murder in the early morning, the store owner still felt terrified. She was tallying the goods when she heard a scream from the outside. ...	$[0.211, 0.789]$	$[0.182, 0.818]$	$[0.2049,$ **0.7951**$]$	1
#4	Yu came to visit her relatives in ChuanCang Village early in the morning of April 5. Recalling the bloody murder in the early morning, the store owner still felt terrified. She didn't notice rushing river from upstream due to her poor hearing. ...	$[0.211, 0.789]$	$[0.254, 0.746]$	$[0.2201,$ **0.7799**$]$	1

[1] $P(y_i^o)$ is the prediction based on only the input pair, $P(y_i^c)$ is the prediction with context encoded, and $P(\hat{y})$ is the final predicted probability.

[2] Red clause is the cause clause and blue clause is the emotion clause

not begin to update his information in his social media account, we can judge that Document #1 should have a causal relationship while document #2 should not, corresponding to their true labels being 1 and 0, respectively. The prediction without context $P(y_i^o)$ indicates that both documents have no causal relationship since the pair is a conditional pair. Taking context into consideration, the prediction with context $P(y_i^c)$ indicates that document #1 has a causal relationship, while document#2 still has no causal relationship due to its irrelevant context. The difference among these predictions corresponds to the characteristics of the conditional ECPs, which is to depend more on $P(y_i^c)$ when $P(y_i^o)$ indicates no causal relationship.

As for Documents #3 and #4, one shall feel frightened whenever he/she witnesses a bloody murder around him/her, which is unlikely to change with different contexts. Therefore, both documents should have causal relationships. As shown in the table, $P(y_i^o)$ already indicates that the pair is causally related regardless of context and hence the final prediction indicates the same result.

The above cases illustrate that our simple aggregation module enables the model to simultaneously deal with documents containing conditional and non-conditional ECPs, and to fine-tune the final predictions accordingly.

7 Conclusion and Future Work

In this paper, we articulate the importance of context in determining the causal relationships between emotions and their causes. To address this problem, we define a new task of determining whether or not an input emotion-cause pair has a causal relationship under a specific context. We construct a dataset for our task through manual annotation and negative sampling based on the ECPE dataset. Furthermore, we propose a prediction aggregation module (PAM) with low computational complexity, to enable the models to dynamically adjust the final prediction according to the type of emotion-cause pair contained in a document. Experiments demonstrate the effectiveness and generality of our proposed PAM.

In view of the importance of context in the conditional causal relationships we define in this work, what we have done is only the first step. There remain many important and interesting problems ahead of us. For example, how to quantify the effect of context on the targeted causal relationship is another important task to study this type of causal relationship. Besides, how to enable the existing emotion-cause pair extraction models to consider the effect of context is also a meaningful task.

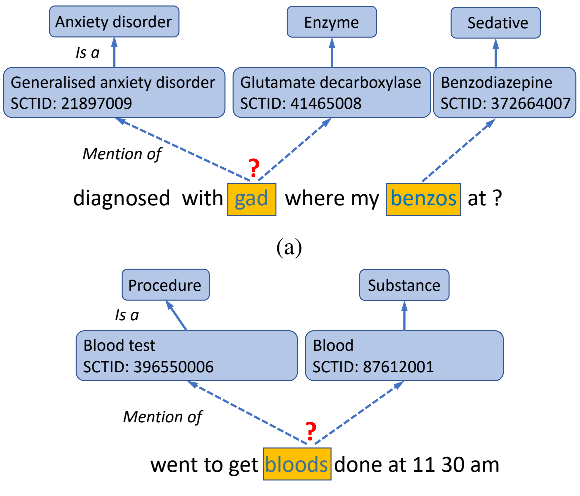
Abstract

Whilst there has been growing progress in Entity Linking (EL) for general language, existing datasets fail to address the complex nature of health terminology in layman's language. Meanwhile, there is a growing need for applications that can understand the public's voice in the health domain. To address this we introduce a new corpus called COMETA, consisting of 20k English biomedical entity mentions from Reddit expert-annotated with links to SNOMED CT, a widely-used medical knowledge graph. Our corpus satisfies a combination of desirable properties, from scale and coverage to diversity and quality, that to the best of our knowledge has not been met by any of the existing resources in the field. Through benchmark experiments on 20 EL baselines from string- to neural-based models we shed light on the ability of these systems to perform complex inference on entities and concepts under 2 challenging evaluation scenarios. Our experimental results on COMETA illustrate that no golden bullet exists and even the best mainstream techniques still have a significant performance gap to fill, while the best solution relies on combining different views of data.

1 Introduction

Social media has become a dominant means for users to share their opinions, emotions and daily experience of life. A large body of work has shown that informal exchanges such as online forums can be leveraged to supplement traditional approaches to a broad range of public health questions such as monitoring suicidal risk and depression (Benton et al., 2017b), domestic abuse (Schrading et al., 2015), cancer (Nzali et al., 2017), and epidemics (Aramaki et al., 2011; Joshi et al., 2019).



(a)

(b)

Figure 1: Examples of the EL inference challenges for user generated text in the health domain.

One of the widely exercised steps to establish a semantic understanding of social media is Entity Linking (EL), i.e., the task of linking entities within a text to a suitable concept in a reference Knowledge Graph (KG) (Liu et al., 2013; Yang and Chang, 2015; Yang et al., 2016; Ran et al., 2018). However, it is well-documented that poorly composed contexts, the ubiquitous presence of colloquialisms, shortened forms, typing/spelling mistakes, and out-of-vocabulary words introduce challenges for effective utilisation of social media text (Baldwin et al., 2013; Michel and Neubig, 2018).

These challenges are exacerbated in EL for user generated content (UGC) in the health domain for two main reasons: lack of dedicated annotated resources for training EL models, and entanglement of the aforementioned challenges in general social media with the inherent complexity of the health domain and its terminology (see Table 1).

For example, in Figure 1 we show sentences taken from social media where the semantics of the concept linking is complex and context-dependent. In the first case, "*diagnosed with gad where by*

Input term	**Gold SNOMED label**	**Challenge**
scratchy throat	Pharyngeal dryness	*Colloquial symptom*
lower right abdomen	Structure of right lower quadrant of abdomen	*Term compositionality*
anti nausea meds	Medicinal product acting as antiemetic agent	*Negated term*
MSM	Dimethul sulfone	*Alternative product name*
up all night cleaning	Obsessive compulsive disorder	*Complex inference*

Table 1: Challenging examples of laymen's terms in COMETA and their target SNOMED concepts.

benzos at", *benzos* is a colloquial form of benzodiazepines, a type of *sedative*, and if correctly resolved can provide a contextual clue to assign the appropriate sense to the polysemous term *gad*: an abbreviation for *generalised anxiety disorder* rather than e.g. *glutamate decarboxylase*. In the second example, "*went to get bloods done at 11 30*", the word *bloods* could be interpreted literally as *blood*; however, in this case it clearly refers to a *blood test*, and it can be correctly resolved only by considering the full context in which it is used.

In this paper we open up a new avenue for EL research specifically targeted at the important domain of health in social media through the release of a new resource: the Corpus of Online Medical EnTities (COMETA), consisting of 20K biomedical entity mentions in English from publicly available and anonymous health discussions on Reddit. Each mention has been been expert-annotated with KG concepts[1] from SNOMED CT (Donnelly, 2006)[2], a structured medical vocabulary of ca.350K concepts widely used to code Electronic Health Records (EHRs). As we show, COMETA provides a high quality yet challenging benchmark for developing EL techniques, especially for concepts not encountered during training (*zero-shot concepts*). Due to its semantic diversity the corpus represents an important pathway to knowledge integration between layman's language, EHRs and research evidence.

Through a set of experiments we shed light on the challenges in this domain for several EL baselines utilising a diverse range of techniques from basic string-matching to low-dimensional entity embeddings (Bojanowski et al., 2017), KG structure embeddings (Grover and Leskovec, 2016; Agarwal et al., 2019), and context aware BERT embeddings (Devlin et al., 2019; Lee et al., 2020). We show a simple augmentation of the mainstream BERT model with a Multi-Level Attention module can improve its effectiveness in capturing the contextual nuances of highly diverse layman's language in the health domain. Our experimental results illustrate that the best solution needs to combine multiple views of data and still heavily relies on basic techniques, while the remaining performance gap highlights the challenging nature of COMETA. We summarise these challenges and underline some of the key areas that are indispensable for further progress in this domain.

2 Related Work and Datasets

Entity Linking. EL (Bunescu and Pasca, 2006) is an important task that has sparked attention in recent years due to its wide-scale potential to aid in knowledge acquisition, e.g. the complementary problems of cross-document coreference resolution (Dredze et al., 2016), semantic relatedness (Dor et al., 2018), geo-coding (Gritta et al., 2017) and relation extraction (Koch et al., 2014).

Systems that link entities to Wikipedia (*Wikification*) (Liu et al., 2013; Roth et al., 2014) and scientific literature to biomedical ontologies (Zheng et al., 2015) have been the focus of attention for many years. Generic EL systems such as Babelfy (Moro et al., 2014) and Tagme (Ferragina and Scaiella, 2011) identify and map entities to Wikipedia and WordNet (Miller et al., 1990) but do not directly integrate the coding standards of healthcare KGs such as SNOMED. Medical EL systems such as cTAKES (Savova et al., 2010) and MetaMap (Aronson and Lang, 2010) were designed to perform medical EL on EHRs but limited evidence e.g. (Denecke, 2014) points to a large drop in recall on UGC such as patient forums.

Medical EL in Social Media. There are several medical EL corpora based on scientific publications (Verspoor et al., 2012; Mohan and Li, 2019), EHRs (Suominen et al., 2013) and death certificates

---

[1] Throughout the paper *concept* refers to nodes in a KG (i.e., SNOMED), *term/entity* refers to the surface form mention of a concept in text, and *context* refers to the text in which a term appears. Also, SCTID denotes SNOMED CT Identifier.

[2] We use the July 2019 release of the international edition.

(Goeuriot et al., 2017). However, none of these EL corpora dealt with the challenges of UGC.

Due to under-reporting of drug side effects (Freifeld et al., 2014) pharmacovigilance datasets have been among the popular UGC benchmarks for evaluating medical EL. The earliest corpus in this domain was CADEC (Karimi et al., 2015) where 1253 AskAPatient posts (6754 concept mentions) were annotated based on a search for the drugs Diclofenac and Lipitor. Another dataset, Twitter ADR (Nikfarjam et al., 2015), consists of 1784 posts (1280 concept mentions) based on a search for 81 drug names, while TwiMed (Alvaro et al., 2017) provides a comparable corpus of 1K PubMed and 1K Twitter texts (3144 concept mentions) based on a search for 30 drugs. Limsopatham and Collier (2016) introduced two Twitter datasets (201 and 1436 concept mentions) with mappings to the SIDER-4 database (Kuhn et al., 2016), and RedMed (Lavertu and Altman, 2019) used Reddit to build a lexicon of alternative spellings for 2978 drugs to improve EL on social media. Closest to our work is MedRed (Scepanovic et al., 2020), a medical Named Entity Recognition corpus of 2K Reddit posts based on forums for 18 diseases. However we note several key differences to our work: our corpus is four times larger, provides two levels of mapping to general and context-specific concepts and has a much greater diversity of concepts rather than just symptoms and drugs (§3.3).

3 The COMETA Corpus

The COMETA corpus satisfies multiple properties which we will explain throughout this section:

CONSISTENCY. COMETA has been annotated by biomedical experts to a high quality using SNOMED CT concepts (SCTIDs) - a standard for clinical information interchange (§3.2);

SCALE AND SCOPE. To the best of our knowledge, with at 20K concept mentions, it is the largest UGC corpus for medical EL. Annotated entities cover a wide range of concepts including symptoms, diseases, anatomical expressions, chemicals, genes, devices and procedures across a range of conditions (§3.3);

DISTRIBUTION. We release the full corpus along with two sampling strategies (*Stratified* and *Zero-shot*) to prevent over-optimistic reporting of performance (Tutubalina et al., 2018): while *Stratified* is designed to show the ability of systems to recognise known concepts with possibly novel mentions, *Zero-shot* is designed to test for recognising novel concepts (§3.4).

3.1 Collection

In order to build our corpus, we crawled health-themed forums on Reddit using Pushshift (Baumgartner et al., 2020) and Reddit's own APIs. We choose forums satisfying strict constraints, i.e. selecting *subreddits* where: (i) new content was posted daily, (ii) the quality of the content was sufficient (e.g. avoiding spam-ridden forums), (iii) the focus was the personal experiences or questions of the users.[3] Applying these criteria, we selected a list of 68 subreddits (see Appendix A.1 for the full list) and crawled all the threads from 2015 to 2018, obtaining a collection of more than 800K discussions. This collection was then pruned by removing deleted posts, comments by bots or moderators, and so on.

In order to obtain the candidate entities, we trained the Flair NER system (Akbik et al., 2018) on a corpus of patient discussions from the health forum HealthUnlocked[4]; we then used this system to find medical entities in a random sub-sample of 100K discussions of our Reddit set, resulting in over 65K distinct named entities being discovered.

Following the standard practices for ethical health research in social media outlined in (Benton et al., 2017a), we then anonymised the corpus to preserve, as far as possible, the privacy of the users. We removed personally identifiable data from messages and we selected terms that were mentioned by at least five users to avoid using terminology particular to a specific user.

Finally, after anonymisation, we hired two professional annotators with Ph.D. qualification in the biomedical domain to annotate the most popular 8K tagged entities with SNOMED concepts.

3.2 Consistency

The annotation process consisted of two steps:

FIRST STEP. We showed the first annotator an entity and up to six random sentences in which it appeared. If the entity was unambiguous, e.g. *left*

---

[3] For example, acceptable subreddits were `r/health`, `r/cancer`, `r/mentalhealth`, but not `r/medical_news/`.

[4] The data for this system was provided by HealthUnlocked (`https://healthunlocked.com/`) and cannot be publicly released in compliance with our data access agreement. The usage of this data was approved by the University of Cambridge's School of Humanities and Social Sciences Ethics Committee.

ankle, the annotator had to associate it to the relevant SCTID (e.g. SCTID: 51636004 – *Left Ankle*) and up to three sentences correctly representing it. Moreover, the first annotator was required to mark NER system mistakes (e.g., wrong type, wrong span, or non-medical entity) to ensure the inclusion of high quality entities. Only 2.1% of the entities were rejected, confirming the quality of our NER system.

SECOND STEP. The second annotator then tackled the ambiguous entities, selecting up to three possible *specific* senses, and associating each sense to the relevant examples. This way, we obtained two levels of annotation: The *General* level, concerned with the literal meaning of the term, and the *Specific* level, which takes into account the *context* in which the entity appears.

For example in the sentence "*Regarding my eyes, I'm not experiencing cloudiness.*", the literal interpretation of the entity *cloudiness* corresponds to the *General* SNOMED concept SCTID: 81858005 – *Cloudy (qualifier value)*; however, a context-sensitive assignment which takes into account the word *eyes* maps the entity to the *Specific* concept SCTID: 246636008 – *Hazy vision*. The *specific* level requires contextual information to be effectively incorporated in the linking step, hence constitutes a more challenging EL task.

The final corpus contains 20015 entities, each are assigned a *General* and *Specific* SCTIDs and accompanied by an example sentence from Reddit where the entity is used. We also provide the link to the Reddit thread where the sentence appears (see Appendix A.2 for a sample). Also, contrary to other corpora, we exclude NIL entities, i.e. entities without a corresponding concept in SNOMED.

3.2.1 Assessing Annotation Quality

Similar to Mohan and Li (2019), we assessed the quality of the annotation process by asking two pairs of assessors[5] to assess the quality of 1K random annotations (500 per pair of assessors).

Assessor Guidelines. We asked the assessors to evaluate the correctness of the expert assigned concepts on a discrete scale $[1, 5]$, 1 being completely incorrect, and 5 being completely correct assignments. For example, mapping "*chronic back pain*" in the sentence "*I have chronic low back pain.*" to SCTID: 134407002 – *Chronic back pain* entails a score of 5, to SCTID: 61968008 – *Syringe* entails a score of 1, and to SCTID: 77568009 – *Back* entails a score of 3, since the selected node is not correct but it identifies the location of the concept; see Table 8 in the Appendix A.3 for more details on the instructions we provided to the assessors.

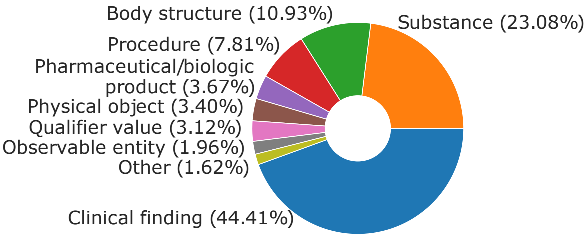

Figure 2: The semantic diversity of SNOMED concepts in COMETA.

Outcome. Out of 1K examples, both assessors assigned the maximum score of 5 to 93.5% and at least 4 to 96.8% of both the *general* and *specific* level annotations. This is a good indication of the quality of the annotations and is in line with Mohan and Li (2019)'s findings. Further investigation of weakly scored entities (3.2% of examples) highlights the unique challenges that emerge in this domain. We provide two representative examples:

EXAMPLE 1. Regarding the entity "*UI*" in the sentence "*If you're having GI problems, UI issues and/or ED issues please get the breath test for H.Pylori.*", the annotator assigned the SCTID: 68566005 – *Urinary tract infectious disease*. One assessor agreed with the annotator's judgement on considering "*UI*" as an abbreviation of "*Urinary infection*", while the other assessor assigned only a score of 3, considering it as the abbreviation of "*Urinary incontinence*". Given the sentence, however, both interpretations are plausible.

EXAMPLE 2. Consider the entity "*pissed off*" in the sentence "*And to top it off my stomach becomes bloated and pissed off.*". Here, "*pissed off*" is used figuratively to indicate some form of discomfort; however, the annotator assigned SCTID: 75408008 – *Feeling angry* which both assessors flagged as incorrect. Nevertheless, both assessors couldn't suggest a better SNOMED concept, as this phrase does not identify a precise disease.

These ambiguities exemplify why performing EL in the UGC domain can be hard even for humans and highlight the complexity found in laymen's medical conversations.

---

[5] 3 senior Ph.D. graduates and a PhD candidate in NLP. Note that there was no overlap between Annotators and Assessors.

3.3 Scale and Scope

The corpus contains 6404 unique terms, 19911 unique example strings, 3645 unique *general* concepts (SCTIDs), and 4003 unique *specific* concepts (SCTIDs). Each *general* and *specific* concept is represented on average with more than 1 surface form, while some concepts had more than 15 surface forms, like for example SCTID: 5935008 – *Oral contraception*, SCTID: 225013001 – *Feeling bad*, and SCTID: 34000006 – *Chrohn's Disease*.

Additionally, each concept was accompanied by an average of at least 5 example sentences (median of 3), while 4.5% of entities were linked to different *general* and *specific* SNOMED concepts (i.e., due to polysemy or contextual cues). We note that 31 entities are associated to more than one *general* SCTID, while 453 are associated to more than one *specific* SCTID.

As illustrated in Figure 2, the most popular SNOMED domains in COMETA are Clinical finding (44.4%), Substance (23.1%), Body structure (10.9%), Procedure (7.8%), and Pharmaceutical / biologic product (3.7%), covering more than 90% of all the entities in the corpus (see Appendix A.4 for more details).

3.4 Distribution

We provide the COMETA corpus in two different sampled splits:

- **STRATIFIED SPLIT.** Each SNOMED concept appearing in the test/development sets, appears at least once in the training set. The stratification by SCTID results in 100% coverage of concepts in test/development, but on the surface form it covers only 58% of the entities in the test set.
- **ZERO-SHOT SPLIT.** Development and test sets contain only novel concepts for which no training data was available.

In other words, the Stratified split is designed to ensure that the model encounters the same concepts in the training, development and test set, but possibly with different surface forms; the Zero-Shot split, instead, exposes models to unseen terms *and* concepts in the development and testing sets, making it the hardest of the two settings (§4). We argue that Zero-Shot is a more realistic setting since obtaining training data that covers all 350K SNOMED concepts involves a very expensive annotation effort. The statistics for the splits are shown in Table 2.

		Training	**Dev**	**Test**
Stratified	**General**	13489	2176	4350
	Specific	13441	2205	4369
Zero-Shot	**General**	14062	1958	3995
	Specific	13714	2018	4283

Table 2: Number of examples in COMETA's splits.

4 Experiments and Results

In this section we conduct a diverse set of EL experiments, where we apply different simple and complex paradigms to link the annotated entities (and the sentences in which they appear) with the corresponding SNOMED concepts. We follow previous works in biomedical entity linking and use top-k Accuracy ($k \in \{1, 10\}$) to evaluate performance of EL systems (D'Souza and Ng, 2015). Note that Acc@10 is only computed for systems returning a ranked list and measures if the correct concept is contained within the top 10 concepts returned by the system. We also report Mean Reciprocal Rank (MRR, Craswell (2018)), which instead measures the *position* of the correct concept in the list of concepts returned by the system. Details about training as well as model and hardware configurations are available in Appendix A.5.

Our baselines cover both string/dictionary-based algorithms (§4.1) which are good at capturing surface-level similarities, and neural models capable of incorporating contextual information (§4.2), where we experiment with a new Multi-Level Attention mechanism based on BERT to allow more efficient incorporation of context. Finally, to achieve the best possible performance, we combine these models in a back-off setting where we leverage the benefits of each paradigm (§4.3). When describing the results, we will report the results on the general split and place the results on the specific split in parentheses.

4.1 Dictionary and String-based Baselines

As a first step, we experimented with a set of naïve systems based on string matching and edit distance.[6] These baselines ignore the context around the entities, since they simply try to match entities against SNOMED labels.

Dictionary. A lookup table is built by traversing the training data, recording every entity and its corresponding SCTID, and directly applied on the test

---

[6] For this set of experiments, we transform all entities and labels to lower-case.

#	Method	Acc@1 Stratified Split	Acc@1 Zero-Shot Split
s.1	Dictionary	.51 (.45)	0 (0)
s.2	Exact matching	.40 (.38)	.37 (.35)
s.3	Levenshtein ratio	.49 (.47)	.52 (.49)
s.4	Stoilos distance	.51 (.49)	.53 (.51)
s.5	cTAKES	.51 (.48)	.53 (.47)
s.6	QuickUMLS	.31 (.30)	.43 (.38)

Table 3: Comparison for Dictionary, String-Matching, cTAKES and QuickUMLS baselines on stratified and zero-shot splits for general and (specific) levels.

set. If an entity is mapped to multiple SNOMED labels, the dictionary records the most frequent one.

String-Matching Edit-Distance. For every term, a string-matching search is conducted on its surface form against all the SNOMED node labels. Note that every SNOMED node has multiple alternative surface forms resulting in 2-36 comparisons per each entity. We count as a hit if the entity is matched with any of the node's surface forms based on exact match, Levenshtein ratio or Stolois distance, two strong string matching heuristics, which are defined as follows: given two strings x, y the Levenshtein ratio (or normalised Levenshtein distance, Yujian and Bo (2007)) is defined as $\frac{\mathrm{Lev}(x,y)}{\max(|x|,|y|)}$ where Lev is the Levenshtein distance (Levenshtein, 1966) between x and y; the Stoilos distance (Stoilos et al., 2005) is defined as the similarity of two strings as $\mathtt{comm}(x, y) - \mathtt{diff}(x, y) + \mathtt{winkler}(x, y)$ where the first and second terms are commonality and difference scores computed based on lengths of substrings of x, y that are matched/unmatched and the third term is Jaro-Winkler distance (Winkler, 1999). Both edit distance metrics were tuned to offer the best trade-off between true and false positives in the development set; further details are provided in Appendix A.6.

cTAKES. cTAKES (Savova et al., 2010) is a heavily engineered system for processing clinical text. We report on its EL pipeline which is based on several dictionary-based and advanced string matching techniques for resolving abbreviations, acronyms, spelling variants, and synonymy.[7]

QuickUMLS. QuickUMLS (Soldaini and Goharian, 2016) is a fast approximate dictionary matching system for medical concept extraction using SimString (Okazaki and Tsujii, 2010) as its back-end. We restrict its search space to the SNOMED CT subset of UMLS. As QuickUMLS predicts UMLS CUI instead of SCTID, we map predicted CUIs to SCTIDs through the UMLS api.[8] When multiple plausible mappings exist, we count a hit if anyone of them matches.[9]

Results. Table 3 summarises the results for the dictionary and string-based baselines. The dictionary method can serve as a strong baseline on the Stratified split, where its performance is barely matched by the more complex string-matching techniques. The most complex strategy, Stoilos distance, outperforms the other string-based techniques, and interestingly is on par with the highly complex cTAKES system while performing significantly better than QuickUMLS. It is worth noting that cTAKES obtained 95.7% in an EL task on an EHR dataset (Savova et al., 2010), highlighting the greater difficulty of the task when performed on the layman's language typical of UGC.

Additionally, contrary to cTAKES, none of the string-based baselines are relying on external resources which might offer an improvement in resolving some abbreviations or acronyms that our string-based systems miss and cTAKES disambiguates correctly (e.g. "*ADHD*" to SCTID: 406506008 – *Attention deficit hyperactivity disorder*). We leave further exploitation of such resources for future work.

4.2 Neural-based Baselines

For our neural setting, we define the problem as a cross-space mapping task by representing COMETA entities (along with their contexts) and SNOMED concepts using different text- and graph-based representation learning techniques, and then mapping the learned representations from the textual space to SNOMED concepts space.

Entity Embeddings. We experimented both with "traditional" and contextual embedding techniques. To generate the entity embeddings we use FastText (FT, Bojanowski et al. (2017)) and BioBERT (Lee et al., 2020), a PubMed-specialised version of BERT (Devlin et al., 2019). The former

---

[7] We also experimented with feeding the full text (including the entity) to cTAKES, but results were substantially worse.

[8] `https://documentation.uts.nlm.nih.gov/rest/home.html`

[9] Unlike cTAKES, we found that feeding the full text to QuickUMLS yields slightly better results than using the entity only.

was trained and the latter was further specialised on the set of 800K Reddit discussions described earlier (§3.1).[10] In the case of multi-word terms, their embeddings were generated via averaging.[11] The dimensionality of the embeddings was 300 for FastText and 768 for BERT, and we denote them as FT-term and BERT-term, respectively. Note that we acknowledge there are alternative options of BioBERT like SciBERT (Beltagy et al., 2019) and ClinicalBERT (Alsentzer et al., 2019). In our own experiments, we discovered that the further specialisation on Reddit discussions is more important than the choice of base model. That said, we leave explorations of other ∗BERT models on COMETA for future work.

Multi-Level Attention for BERT. As noted by Ethayarajh (2019) the deeper BERT goes, the more "contextualized" its representation becomes. However, interpreting semantics of entities requires contextual knowledge in different degrees and always taking the last layer's output may not be the best solution. In order to address this issue, we propose a Multi-Level Attention (denoted as BERT-term$_{\text{MLA}}$) module on top of BERT to further enhance the representation extracted from BERT by learning how much to attend to each layer for producing an entity representation. The attention weights of the i-th layer is computed as $a_i = [\, \mathbf{B}_i \cdot \mathbf{A} \,]_+$, where $[\cdot]_+ = \max(0, \cdot)$, and $\mathbf{B}_i \in \mathbb{R}^d$ denotes the representation from the i-th level of BERT, d denotes the dimensionality (i.e., here $d = 768$), and $\mathbf{A} \in \mathbb{R}^d$ denotes a trainable attention memory vector. We further normalise a_i using a softmax layer, $w_i \overset{\text{def}}{=} \texttt{softmax}(a_i)$. Finally, a weighted sum over all layers produces the attention-fused representation, i.e. BERT-term$_{\text{MLA}} = \sum_i^L w_i \mathbf{B}_i$.

Concept Embeddings. We experimented by embedding SNOMED concepts with two modalities: (i) their labels, to exploit textual information, and (ii) their corresponding nodes in the KG, to incorporate the graph structure. Label embeddings were produced by running FastText (denoted as FT-label) and BERT (denoted as BERT-label) on the label, both trained as described above; for concepts with multiple labels (e.g., SCTID: 61685007 - *Lower extremity*, *Lower limb*, *Leg*), the mean of the label representations is used. For node embeddings, we based our choice of model on the findings reported in Agarwal et al. (2019) and opted for their best reported model for SNOMED, i.e. node2vec (Grover and Leskovec, 2016) with the suggested parameters and vector size 300.[12]

Ensemble Embeddings. We also considered several embeddings that integrate multiple views of the data via (i) concatenation (denoted as ⊕) of the entity embeddings (e.g, FT-term ⊕ BERT-term$_{\text{MLA}}$), and (ii) concatenation of label and node2vec embeddings for concepts (e.g., FT-label ⊕ BERT-label ⊕ node2vec).

Alignment Model. We adopt a linear transformation followed by ReLU (Nair and Hinton, 2010) for aligning entity and concept embeddings, and we train the model with a max-margin triplet loss:

$$\mathcal{L} = \sum_{\mathbf{p} \in \mathcal{P}} \max_{\bar{\mathbf{t}} \in \mathcal{T} \setminus \{\mathbf{t}\}} [\, \alpha - s(\mathbf{p}, \mathbf{t}) + s(\mathbf{p}, \bar{\mathbf{t}}) \,]_+ \quad (1)$$

where α $(= 0.2)$ is a pre-set margin, $s(\cdot, \cdot)$ is the cosine similarity, $\mathcal{P}$ and $\mathcal{T}$ are the sets of all predictions and target embeddings in a mini-batch, and given a prediction $\mathbf{p}$ and its corresponding ground truth $\mathbf{t}$, $\bar{\mathbf{t}}$ denotes a negative target embedding.

Results. The results of the neural baselines are presented in Table 4. All individual baselines (n.1 to n.4) fall behind the string-matching methods on Acc@1. This can be due the fact that on average for each entity-concept pair there are less than 4 examples even in the stratified training set, making it difficult for the trained model to generalise well. This issue is more evident in the zero-shot setting.

The ensemble neural baselines compensate for the lack of training signal by leveraging multiple views of the data. As expected, combining both surface and node embeddings of the concepts (n.5) offers a slight improvement, but still fails to match the string-matching baselines. Finally, concatenation of the entity embeddings with our proposed BERT-term$_{\text{MLA}}$ representation, and of the label embeddings with BERT-label (n.6) outperforms all

---

[10] Note that BERT here is used as a feature extractor. We tried finetuning BERT jointly with the alignment model, but performance got worse due to overfitting. We leave properly finetuned BERT models on COMETA as future work.

[11] We tried replacing the entity embeddings with sentence embeddings via RNN/transformers, however, the performance was much worse. We speculate this was due to polluting the informative signal of an entity with its surrounding words. We leave further exploration of this to future work.

[12] We also compared node2vec with more sophisticated model of Kartsaklis et al. (2018) but we observed worse performance. We speculate this is due to the reliance of their model on the presence of textual definitions in SNOMED labels, which is only available in $< 4\%$ of SNOMED nodes.

			Stratified Split			Zero-Shot Split

***** : A transformation is applied to FT-term ($[\, \mathbf{W} \cdot \text{FT-term} + \mathbf{b}\,]_{+}$) before concatenation.
****** : Alignment model used for these marked cases is just a linear transformation (without ReLU).

Table 4: Comparison for neural-based baselines on stratified and zero-shot splits for general and (specific) levels.

previous baselines on the stratified split, but still falls behind the string-based baselines on zero-shot.

Compared to Acc@1, while the overall ranking of models remains the same, MRR and Acc@10 are more forgiving. The significant gap between Acc@1 and Acc@10 suggests that a re-ranking step (Liu, 2009) applied to top-10 candidates could further boost the performance. We leave further exploration of this idea to our future work.

		Acc@1

Table 5: Back-off baselines on stratified and zero-shot splits for general and (specific) levels.

4.3 Back-off Baselines

To obtain the best possible performance, we experimented with a deterministic back-off procedure (denoted as +) that applies the Dictionary and backs-off to a String-Matching model (§4.1) and finally to the best ensemble model (§4.2; model n.6 in Table 4) for handling the missed cases.

Results. Table 5 reports the Back-off baseline results. The immediate gain on performance compared to each individual counterpart indicates that each model is equipped to tackle only a subset of the underlying challenges in the data. The back-off model combining dictionary, Stoilos distance, and the ensemble neural approach achieves our best performance across both splits (model b.8 in Table 5). As expected, the neural baselines contribute much less in the Zero-Shot split with a meagre 4%(3%) improvement, compared to the 8%(7%) increase on the Stratified split. Even if their overall contribution is limited, we were able to verify that our neural baselines are actually able to exploit the context as expected. For example w.r.t. the issues typical of the UGC domain we identified in Section 1, we found neural methods helpful in resolving acronyms (“UTIs” to SCTID: 68566005 – *Urinary Tract Infection*), colloquial synonyms (“bloodwork” to SCTID: 396550006 – *Blood Test*), compositionality (“drenched in sweat” to SCTID: 415690000 – *Sweating*), complex inference (e.g., “Oral Cancer” to SCTID: 363505006 – *Malignant tumour of oral cavity*), or even spelling errors combined with alternative product names (“Remicaid” to SCTID: 386891004 – *Infliximab*, i.e. the active principle of *Remicade*). This last example is specifically interesting, since the label *Remicade* is not present in SNOMED but the pre-training of embeddings on medical texts (§4.2) allowed the neural baselines to pick up the correct node.

5 Discussion

The COMETA corpus introduces a challenging scenario for entity linking systems from both ML and NLP perspectives. In this section we summarise these challenges, our findings, and shed light on aspects that demand future attention:

Domain-Specific Language. EL systems similar to our baselines are not uncommon in the biomedical domain: Furrer et al. (2019) used a similar dictionary-BERT ensemble model to achieve the best performance in the 2019 CRAFT Shared Task (Baumgartner et al., 2019) on biomedical literature. However, in their case, the neural component offered a much higher contribution highlighting the underlying challenges in medical layman's language. Additionally, probing our proposed Multi-Level Attention for BERT, we observed that a more flexible utilisation of context is effective in understanding the diverse contextual cues.

Low-Resource Regime and Learning. Compared to similar corpora, COMETA has the largest scale. However, from a learning perspective the lack of sufficient regularity in the data could still leave its toll at test phase. This is a natural consequence of high productivity of layman's language in social media, while emerging and unforeseen topics such as pandemics (i.e., COVID19) could also contribute to the problem. In fact, we observed the daunting task that systems face in the zero-shot setting, where in the absence of sufficient training signal, string-based methods offer a strong baseline which is hard to beat for neural counterparts. While we artificially control this in the stratified split we still believe the zero-shot setting draws a more detailed picture of challenges an EL system needs to tackle in a real-world scenario. Further exploration of solutions such as transfer learning across domains (i.e., from medical literature to layman's domain) is beyond the focus of this work, nonetheless COMETA provides the framework for designing and testing such solutions.

Cross-Modality Alignment. While Agarwal et al. (2019) report superior performance of node2vec embeddings on several graph-based tasks on SNOMED, this success does not translate into EL as it relies on mapping across modalities (i.e., text-to-graph). Alternatively, when we replaced the node2vec with concept-label embeddings (produced by FT/BERT) the performance was significantly improved. This suggests that aligning different modalities may require a more complex alignment model or stronger training signals. We leave further exploration of this to future work.

6 Conclusion

We presented COMETA, a unique corpus for its scale and coverage which is curated to maintain high quality annotations of medical terms in layman's language on Reddit with concepts from SNOMED knowledge graph. Different evaluation scenarios were designed to compare the performance of conventional dictionary/string-matching techniques against the mainstream neural counterparts and revealed that these models complement each other very well and the best performance is achieved by combining these paradigms. Nonetheless, the missing performance of 28-46% (depending on the evaluation scenario) encourages future research on this area to take this corpus as a challenging yet reliable evaluation benchmark for further development of models specific to this domain.

COMETA is available by contacting the last author via e-mail or following the instructions on `https://www.siphs.org/`. We release the pre-trained embeddings and the code to replicate our baselines online at `https://github.com/cambridgeltl/cometa`.

A Appendices

A.1 Full List of Subreddits

Table 6 reports the list of 68 subreddits crawled for COMETA.

A.2 Example from COMETA

Table 7 provides examples from COMETA and illustrates the structure of each line in the corpus.

A.3 Example from Assessor Guidelines

Table 8 provides an example from the guideline sent to assessors.

A.4 Distribution of Concepts in Stratified and Zero-Shot Splits

Figure 3 provides the detailed distribution of SNOMED Concepts in Stratified and Zero-Shot splits.

A.5 Reproducibility

Table 9 and Table 10 describe the hardware and hyperparameters used for the experiments we describe.

A.6 Stoilos Distance

The commonality function $\texttt{comm}(x, y)$, is defined as

$$\texttt{comm}(x, y) = \frac{2 \cdot \sum_i |\text{max\_common\_substring}|}{(|x| + |y|)/2}$$

Where the max_common_substring between x, y is computed in an iterative manner: first, that of the original x, y are computed; then the common sub-string is removed and search is done again for the next max_common_substring until a threshold of length 3 is met (common sub-strings with < 3 length are not considered).

The difference function, $\texttt{diff}(x, y)$, is based on the unmatched part of x, y from the last step. We denote them as u_x, u_y. And the length of them are normalised using a Hamacher product (Hamacher et al., 1978) (a parametric triangular norm):

$$\texttt{diff}(x, y) = \frac{|u_x| \cdot |u_y|}{p + (1-p)(|u_x| + |u_y| - |u_x| \cdot |u_y|)}$$

We choose $p = 0.6$.

$i+1$	acid	34957004	698065002	acid in my throat	cancer
$\dots$	$\dots$	$\dots$	$\dots$	$\dots$	$\dots$

Table 7: The structure of the dataset; column names are denoted by **bold** text, and column types are denoted by `monospaced` text. The released dataset contains two additional columns, marking the label for the corresponding General and Specific SCTID respectively. However, since a label may appear in multiple nodes, we recommend to *always* use SCTIDs to retrieve the target nodes.
Please note that the data in this table is used for illustration purposes only and it might not be contained in the released corpus.

Quality	**Evaluation**	**Term**	**Proposed Node**	**Explanation**
5:Excellent	The SNOMED node **matches exactly** the term or is a **synonym** of the term.	Chronic back pain	Chronic back pain, 134407002	Exact match.
4:Good	The SNOMED node is **conceptually similar and taxonomically close** (1-2 edges) to the target term, e.g. is a close ancestor/descendant or a sibling.	Chronic back pain	Back pain, 161891005	'Back pain' is the direct ancestor of 'Chronic back pain'.
3:Fair	The SNOMED node is **conceptually related** and reasonably close (1 to 3 edges) to the target term, both taxonomically or via attributes (finding site, etc.)	Chronic back pain	Back, 77568009	'back' is the 'finding site' of 'Chronic back pain'.
2:Poor	The SNOMED node is **conceptually distant** from the term, and there is a reasonably long (3-4 edges) path from it to the correct node	Chronic back pain	Torso, 22943007	'Chronic Back Pain' is located in the 'Torso', so they are somewhat related, and the two nodes are not far (distance 3)
1:Very Poor	The SNOMED node is **completely unrelated** with the term, and the path between the correct node and the target one is very long (> 5).	Chronic back pain	Syringe, 61968008	'Chronic Back Pain' and 'Syringe' have high distance (5), **and** the concepts are completely unrelated.

Table 8: An example from assessor guidelines.

Abstract

The question of how to probe contextual word representations for linguistic structure in a way that is both principled and useful has seen significant attention recently in the NLP literature. In our contribution to this discussion, we argue for a probe metric that reflects the fundamental trade-off between probe complexity and performance: the Pareto hypervolume. To measure complexity, we present a number of parametric and non-parametric metrics. Our experiments using Pareto hypervolume as an evaluation metric show that probes often do not conform to our expectations—e.g., why should the non-contextual fastText representations encode more morpho-syntactic information than the contextual BERT representations? These results suggest that common, simplistic probing tasks, such as part-of-speech labeling and dependency arc labeling, are inadequate to evaluate the linguistic structure encoded in contextual word representations. This leads us to propose full dependency parsing as a probing task. In support of our suggestion that harder probing tasks are necessary, our experiments with dependency parsing reveal a wide gap in syntactic knowledge between contextual and non-contextual representations. Our code can be found at `https://github.com/rycolab/pareto-probing`.

1 Introduction

Neural networks are a pillar of modern NLP systems. However, their inner workings are poorly understood; indeed, for this reason, they are often referred to as black-box systems (Psichogios and Ungar, 1992; Orphanos et al., 1999; Cauer et al., 2000). This lack of understanding, coupled with the rising adoption of neural NLP systems in both industry and academia, has fomented a rapidly growing literature devoted to "cracking open the black box," as it were (Alishahi et al., 2019; Linzen et al., 2019). One popular method for studying the linguistic content of neural networks is **probing**, which we define in this work as training a supervised classifier (known as a **probe**) on top of pretrained models' frozen representations (Alain and Bengio, 2017). By analyzing the classifier's performance, one can assess how much 'knowledge' the representations contain about language.

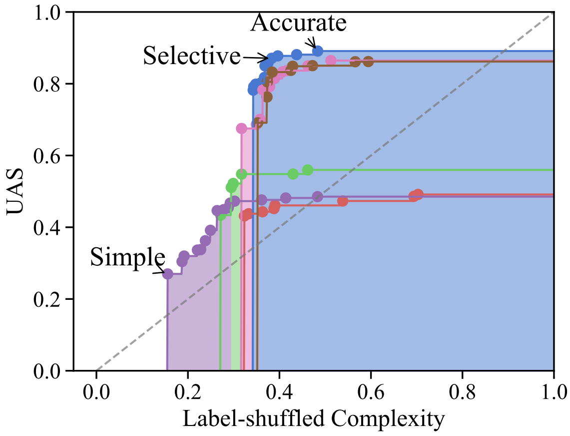

Figure 1: Probe results on dependency parsing in English. The x-axis corresponds to complexity and measures a probe's ability to memorize the training data. The y-axis measures the probes performance on the task. Probing the representations: ALBERT, BERT, RoBERTa, fastText, one-hot, and random.

Much work in probing advocates for the need for simple probes (Hewitt and Manning, 2019; Hall Maudslay et al., 2020). Indeed, on this point, Alain and Bengio (2017) write:

> "The task of a deep neural network classifier is to come up with a representation for the final layer that can be easily fed to a linear classifier (i.e. the most elementary form of useful classifier)."

as a justification for their operationalization of **complexity** as the restriction of the probe to linear models (as opposed to deep neural networks). Most

saliently, Hewitt and Liang (2019) attempts to operationalize complexity in terms of control tasks, which constrain a probe's capacity for memorization.[1] Voita and Titov (2020) follow in this vein with an information-theoretic estimate of complexity: a model's minimum description length.

In opposition to the complexity of a probe is its **accuracy**, i.e., its ability to perform the target probing task. From an information-theoretic perspective, Pimentel et al. (2020) argues for the use of more complex probes, since they better estimate the amount of mutual information between a representation and the target linguistic property. From a different perspective, Saphra and Lopez (2019) also criticize the indiscriminate use of simple probes, because most neural representations are not estimated with the explicit aim of making information linearly separable; thus, it is unlikely that they will *naturally* do so, and foolish, perhaps, to expect them to.

This paper proposes to directly acknowledge the existence of a trade-off between the two when considering the development of probes. We argue—in part based on experimental evidence—that naïvely selecting a family of probes either for its complexity or its performance leads to degenerate edge-cases; see Fig. 1. We conclude that the nuanced trade-off between accuracy and complexity in probing should thus be treated as a bi-objective optimization problem: One objective encourages low complexity and another encourages high accuracy. We then propose a novel evaluation paradigm for probes. We advocate for **Pareto optimal probes**, i.e., probes that are both simpler and more accurate than all others. The set of such optimal probes can then be taken in aggregate to form a **Pareto frontier**, which allows for broader analysis and easier comparison between representations.

We run a battery of probing experiments for part-of-speech labeling and dependency-arc labeling, using both parametric and non-parametric complexity metrics. Our experiments show that if we desire simple probes, then we are forced to conclude that one-hot encoding representations and randomly generated ones almost always encode more linguistic structure than those representations derived from BERT—a nonsensical result. On the other hand, seeking the most accurate probes is equivalent to performing NLP task-based research (e.g. part-of-speech tagging) in the classic way. We contend our Pareto curve–based measurements strike a reasonable balance.

To wrap up our paper, we levy a criticism at the probing tasks themselves; we argue that "toyish" probing tasks are not very useful for revealing how much more linguistic information BERT manages to capture than standard baseline representations. With this in mind, we advocate for more challenging probing tasks, e.g., dependency *parsing* instead of its toyish cousin dependency *arc labeling*. We find that using actual NLP tasks as probing tasks reveals much more about the advantages BERT provides over non-contextual representations.

2 Performance and Complexity

We argue in favor of treating probing for linguistic structure in neural representations as a two part optimization problem. On the one hand, we must optimize our probe for *high accuracy* on our chosen probing task: If we do not directly train the probe to accurately extract the linguistic features from the representation, how else can we determine whether they are implicitly encoded? On the other hand, the received wisdom in the probing community is that probes should be simple (Alain and Bengio, 2017; Hewitt and Manning, 2019): If the probe is an overly *complex* model, we might ascribe high accuracy on the probing task to the probe itself, meaning the probe has "learned the task" to a large extent. In this section, we argue that a probing framework that does not *explicitly* take into account the accuracy–complexity trade-off may be easily gamed. Indeed, we demonstrate how to game both accuracy and complexity respectively below.

2.1 The Nature of Probing Tasks

Most **probing tasks** are relatively "toy" in nature (Hupkes et al., 2018).[2] For instance, two of the most common probing tasks are **part-of-speech labeling** (POSL; Hewitt and Liang, 2019; Belinkov et al., 2017) and **dependency arc labeling** (DAL; Tenney et al., 2019a,b; Voita and Titov, 2020). Both tasks are treated as multi-way classification problems. POSL requires a model to assign a part-of-speech tag to a word in context *without*

---

[1] Hewitt and Liang (2019) define **selectivity** as the difference between a model's accuracy on a task versus its accuracy on a control version of that task. The control version of the tasks are built by randomly shuffling labels across word types and measures a probe's capacity for memorization. Our non-parametric measures of complexity differ from control tasks; we describe these differences in § 5.

[2] Not all though, several people have looked into e.g. parse tree reconstruction tasks (Jawahar et al., 2019; Hewitt and Manning, 2019; Vilares et al., 2020)

modeling the entire sequence of part-of-speech tags. Likewise, DAL requires a model to assign a dependency-arc label to an arc independently of the larger dependency tree. These word-oriented probing approaches force models to rely on information about context indirectly encoded in the feature vectors generated by the probed model. Importantly, both are simplified versions of their structured prediction cousins—part-of-speech tagging and dependency parsing—which require the modeling of entire sentences. Accuracy on POSL and DAL is then considered indicative of probed representations' "knowledge" of the linguistic structure encoded in the probing task. Limiting *explicit* access to context therefore allows an analysis constrained to how context is *implicitly* encoded in a particular representation. Furthermore, because POSL and DAL do not require complex structured prediction models, their simplicity is seen as a virtue to the mindset of disfavoring complexity (discussed further in § 2.3).

2.2 Optimizing for Performance

We first will argue that it is problematic to judge a probe either only by its performance on the probing task or by its complexity. Pimentel et al. (2020) showed that, under a weak assumption, any contextualized representation contains as much information about a linguistic task as the original sentence. They write:

> "under our operationalization, the endeavour of finding syntax in contextualized embeddings sentences is nonsensical. This is because, under Assumption 1, we know the answer *a priori*."

We agree that under their operationalization probing is nonsensical—purely optimizing for performance does not tell us anything about the representations, but only about the sentence itself.

Researchers, of course, have realized that choosing the most accurate probe is not wise for analysis; see Hewitt and Manning (2019) and the references therein for a good articulation of this point. To compensate for this tension, researchers have imposed explicit restrictions on the complexity of the probe, resulting in wider differences between contextual and non-contextual representations. Indeed, this is the logic behind the study of Hewitt and Liang (2019) who argue that **selective** probes should be chosen to judge whether the target linguistic property is well encoded in the representations. Relatedly, other researchers have explicitly focused on linear classifiers as probes with the explicit reasoning that linear models are simpler than non-linear ones (Alain and Bengio, 2017; Hewitt and Manning, 2019; Hall Maudslay et al., 2020).

2.3 Reducing a Probe's Complexity

In § 2.2, we argued that solely optimizing for accuracy does not lead to a reasonable probing framework. Less commonly discussed, however, is that we also cannot directly optimize for simplicity. Let us consider the POSL probing task and the case where we are using a linear model as our probabilistic probe:

$$p(t \mid \mathbf{h}) = \text{softmax}\,(\mathbf{W}\mathbf{h}) \tag{1}$$

where $t \in \mathcal{T}$ is the target, e.g. a universal part-of-speech tag (Petrov et al., 2012), $\mathbf{h} \in \mathbb{R}^d$ is a contextual embedding and $\mathbf{W} \in \mathbb{R}^{|\mathcal{T}| \times d}$ is a linear projection matrix.

A natural measure of probe complexity in this framework is the **rank** of the projection matrix: $\text{rank}(\mathbf{W})$. Indeed, this complexity metric was considered in one of the experiments in Hewitt and Manning (2019) to show that BERT representations strictly dominate ELMo representations for all ranks in their analyzed task. That experiment, though, left out some important baselines—the simplest of which is the encoding of words as one-hot representations. We take inspiration from those experiments and expand upon them (but rely instead on the nuclear norm as a convex relaxation of the matrix rank § 4) to produce the more complete plots in Figs. 2 and 3. These results are quite stunning; they show that, if we only cared about representations that simple probes could extract linguistic properties from, then a one-hot encoding of the word types is the best choice.

It is easy to see why the one-hot encoding does so well. For many of the toy probing tasks, the identity of the word is the single most important factor. It seems natural to expect that a low-complexity probe will be unable to exploit much more than a word's identity, so a one-hot embedding is really the best you can do—the word's identity is trivially encoded. Our point here is that both accuracy and complexity matter and neither can be sensibly optimized without the other.

3 An Invitation to Pareto Probing

We now advocate for a probing evaluation metric that combines both accuracy *and* complexity. We argued in § 2 that probe accuracy and complexity exist in a trade-off. Because of this trade-off, we should search for models that are Pareto optimal. A probe is considered **Pareto optimal** (with respect to a family of probes) if there is no competing probe where both the accuracy is higher *and* the complexity is lower on the task. The set of Pareto optimal points may be called the **Pareto frontier** and is generally connected, as is shown in Fig. 2. As can also be seen in Fig. 2, we can compare different representations according to their Pareto frontiers. The set of representations that appear on the Pareto frontier should be sufficient–the other representations are **Pareto dominated**, since you can improve in one aspect (complexity or accuracy) without sacrificing the other. We call the set of representations which are on the frontier **Pareto dominant**.

We can also analyze each representation's frontier individually. This notion leads us to a very natural metric for evaluating probes: **Pareto hypervolume** (PH; Auger et al., 2012).[3] One important technical caveat involving evaluating the hypervolume is that it is undefined when the metric of model complexity for the experiment is unbounded. Thus, it is necessary to restrict model complexity to a bounded interval so that the PH is always finite.

4 Parametric Metrics of Complexity

We consider two types of probe complexity metrics. We term the first **parametric complexity**, which we discuss in this section. The second type is **non-parametric complexity**, which we discuss in § 5. For the parametric one, we first require a family of probes, e.g. the family of linear probes—which are all those that take the form of eq. (1), without restriction on the representation's dimension d.

4.1 Parametric Complexity for Linear Probes

In the case of linear probes, we explore two metrics of parametric complexity: the nuclear norm and rank. The **nuclear norm** is defined as

$$||\mathbf{W}||_* = \sum_{i=1}^{\min(|\mathcal{T}|,d)} \sigma_i(\mathbf{W}) \tag{2}$$

where $\sigma_i(\mathbf{W})$ is the i^{th} singular value of $\mathbf{W}$—which, in a way, measures the "size" of the matrix. This yields the following objective for $\lambda \geq 0$:

$$\underbrace{-\sum_{i=1}^{n} \log p(t^{(i)} \mid \mathbf{h}^{(i)})}_{\text{cross-entropy}} + \lambda \cdot \underbrace{||\mathbf{W}||_*}_{\text{nuclear norm}} \tag{3}$$

Training a probe to minimize this objective is equivalent to trading off its performance (high likelihood on the training data) for a lower complexity (nuclear norm of $\mathbf{W}$). This trade-off can be controlled through the hyper-parameter λ.

As a parametric complexity metric, we also consider the **rank** of the matrix. One definition of a matrix's rank is the number of non-zero singular values $\sigma_i(\mathbf{W})$. The rank can easily be restricted to a maximum value $r \in \mathbb{N}_+$ by splitting the matrix in two $\mathbf{W} = \mathbf{W}_l^\top \mathbf{W}_r$, where $\mathbf{W}_l \in \mathbb{R}^{r \times |\mathcal{T}|}$ and $\mathbf{W}_r \in \mathbb{R}^{r \times d}$. The nuclear norm is the tightest convex relaxation of the rank (Recht et al., 2010).[4]

While low-rank regularization is assumed to produce models that generalize better (Hinton and Van Camp, 1993; Langenberg et al., 2019), contrary to the classic bias–variance tradeoff, Goldblum et al. (2020) found that biasing towards small nuclear norms instead *hurts* generalization. Furthermore, our probe family consists of linear transformations, which are fed a relatively small number of features and trained with large training sets. As such, we are in an underfitting situation and any regularization should indeed hurt test performance.

4.2 Relation to Minimum Description Length

A recent proposal by Voita and Titov (2020) suggests that minimum description length (MDL; Rissanen, 1978) is a useful approach to the problem of balancing performance and complexity. The idea behind MDL is analogous to that of Bayesian evidence: We have a family of probabilistic models and a prior over those models. The likelihood term tells us how well we have coded the data and the prior term tells us the length of the model's code:

$$\underbrace{\prod_{i=1}^{n} p(t^{(i)} \mid \mathbf{h}^{(i)}, \mathbf{W})}_{\text{likelihood}} \times \underbrace{p(\mathbf{W})}_{\text{prior}} \tag{4}$$

If we define our distribution over matrices as

$$p(\mathbf{W}) \propto \exp\left(-{}^{\lambda}\!/\!{}_{2} \cdot ||\mathbf{W}||_*^2\right) \tag{5}$$

---

[3] We note that we do not endorse only presenting PH scores, though, since it would again reduces this analysis to a single number. Such scores should be presented together with their Pareto curves to be maximally illustrative.

[4] Note that one may want to augment the linear probe with a padded vector, i.e. $\tilde{\mathbf{h}} = [\mathbf{h}; 1]$ to include a bias term in the model. In this case, our probe takes the form of $p(t \mid \mathbf{h}) = \mathrm{softmax}(\mathbf{W}\,\tilde{\mathbf{h}})$ where, now, $\mathbf{W} \in \mathbb{R}^{|\mathcal{T}| \times (d+1)}$.

we recover our nuclear norm complexity term as the log of the prior. The distribution defined in eq. (5) is mathematically equivalent to the matrix normal distribution. To show this, we note that $-\frac{\lambda}{2}||\mathbf{W}||_*^2 = -\frac{1}{2}\mathrm{tr}\left(\mathbf{W}^\top \left(\lambda^{-1}\mathbf{I}\right)^{-1}\mathbf{W}\right)$ and present the definition of the matrix normal (Gupta and Nagar, 2018, Chapter 2) as

$$p(\mathbf{W} \mid \mathbf{M}, \mathbf{V}, \mathbf{U}) = \frac{\exp\left(-\frac{1}{2}\mathrm{tr}[\mathbf{V}^{-1}(\mathbf{W}-\mathbf{M})^\top \mathbf{U}^{-1}(\mathbf{W}-\mathbf{M}))\right]}{2\pi^{kd/2}\mathbf{V}^{k/2}\mathbf{U}^{d/2}} \tag{6}$$

where $k = |\mathcal{T}|$ and d are the sizes of matrix $\mathbf{W}$, $\mathbf{M}$ is the matrix's expected value, and $\mathbf{V}$ and $\mathbf{U}$ are analogous to the covariance matrices of typical Gaussian distributions. By setting the mean to the zero matrix, $\mathbf{V}$ to $\mathbf{I}$ (the identity matrix) and $\mathbf{U}$ to $\lambda^{-1}\mathbf{I}$, we recover eq. (5).

Naturally, there are many extensions within the MDL framework, e.g. variational coding MDL (Blier and Ollivier, 2018). In the case of non-linear models, Bayesian neural networks (Neal, 2012) are a natural choice. However, a fundamental problem will always remain—the results are dependent on the choice of prior. Indeed, in the simple case of linear probes, we can always "hack" the prior to favor certain probes over others that may not correspond to our intuitions of model complexity. For this reason, we also analyze a set of non-parametric metrics of complexity that do not require the probe user to pre-specify a prior over models.

5 Non-Parametric Metrics of Complexity

The parametric metrics of model complexity in § 4 have an explicit constraint that the models must belong to the same parametric family. Specifically, it requires that we are able to define a penalty (generally dependent on the parameters) that enforces how complex each model should be. In this section, we move away from parametric notions of model complexity to non-parametric metrics.

We opt to work with a notion of non-parametric complexity based on the ease with which a model can memorize training data. These non-parametric measures are rarely explicitly discussed as complexity metrics—although they are intuitive for that purpose—and have become common recently: Zhang et al. (2017) originated this trend by shuffling outputs of image data so the images were no longer predictive of the labels, using this result to illustrate the effective memorization capacity of modern neural networks. The first of our two experiments to obtain non-parametric complexity measures is similar to theirs. We train our probe in a dataset with shuffled labels and get its accuracy in this training set. We will refer to this complexity metric as the **label-shuffled** scenario.[5]

Neural networks can take advantage of structured input (e.g. real images as opposed to noisy ones) to easily memorize their labels (Zhang et al., 2017). These structured inputs may be easier to represent internally regardless of the outputs, given current theories that early stages of training are committed to memorizing inputs (Arpit et al., 2017). As such, we may also want to analyze a probe's capacity to memorize unstructured input—in the case of language, we can easily remove structure by shuffling the word sequences themselves, creating random Zipfian-distributed noise, which are harder for neural networks to exploit (Liu et al., 2018). By providing probes with unstructured input, we measure a more domain-independent sense of complexity than the ability to map structured inputs to random labels, because the model cannot rely on syntactic patterns when memorizing shuffled training data. We will refer to this second scenario, wherein both labels and inputs are shuffled, as **fully shuffled**.

The distinction between memorization of real data and memorization of unstructured data is crucial, as experimenters choose the class of probes being learned. A comparison between label-shuffled and fully shuffled compression exposes the degree to which the class of probes employs a bias towards the true input structure in its compression. Similarly, comparisons between different classes of probes can test the same assumed bias.

We highlight that, while our non-parametric complexity metrics permit arbitrary classes of probes to be included in a probe hypothesis space, the selection criteria of possible probes may still reflect the assumed structure of the data, affecting compression and generalization. For example, linear probes reflect an assumption that the information lies in an Euclidean (sub)space; however, this assumption may not be true: Reif et al. (2019) reveal that a word's sequential position often rests on a

---

[5] Hewitt and Liang (2019) use similar methods to create control tasks for their probing experiments. Our use of shuffled labels is different from Hewitt and Liang's (2019) in two important aspects: While they shuffled labels at the type level, we shuffle them at the token level. Furthermore, since we are evaluating a modelâĂŹs capacity for memorization, we look at its accuracy on *the training set*, whereas they consider the accuracy on the *test set*.

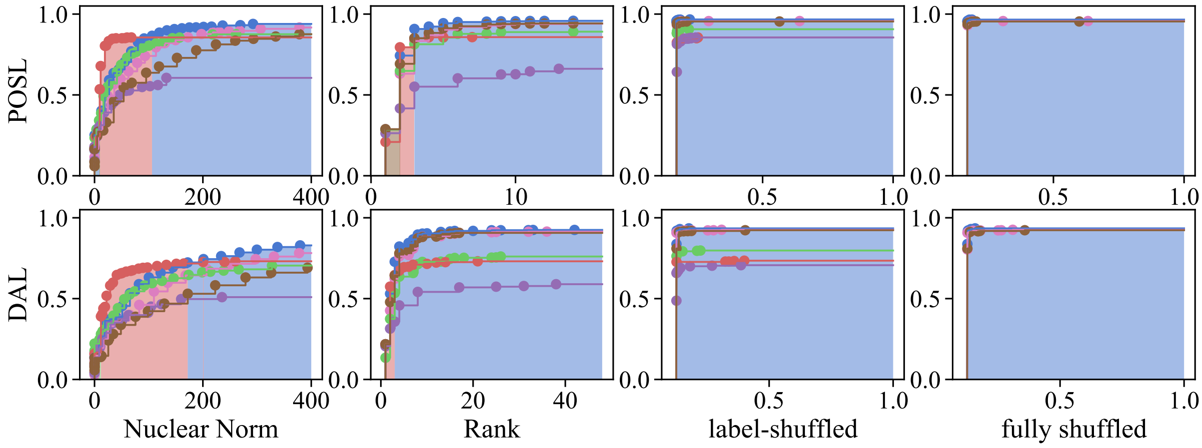

Figure 2: Pareto curves for experiments in English, using both parametric and non-parametric complexity metrics. The x-axis corresponds to the probe's complexity. The y-axis measures the probes accuracy on the task. Probing the representations: ALBERT, BERT, RoBERTa, fastText, one-hot, and random.

spiral manifold in BERT, while the syntactic distances described by Hewitt and Manning (2019) are Pythagorean in nature. One advantage of these methods is the ability to compare between probe classes, which offers a test of the geometric assumptions behind model selection.[6] Another advantage is that, unlike regularization-based parametric methods, they require no modification of the training procedure and can therefore run much faster.

6 POSL and DAL Experiments

We present our experimental findings on the previously discussed part-of-speech labeling (POSL) and dependency arc labeling (DAL) probing tasks using both our parametric complexity metrics (§ 4) and the non-parametric ones (§ 5). For both tasks, we use data from Universal Dependencies Treebanks version 2.5 (Zeman et al., 2019) and we probe a set of 5 typologically diverse languages: Basque (Aranzabe et al. 2015; BDT licensed under CC BY-NC-SA 3.0), English (Bies et al. 2012; Silveira et al. 2014; EWT licensed under CC BY-SA 4.0), Finnish (Haverinen et al. 2014, TDT licensed under CC BY-SA 4.0), Marathi (Ravishankar 2017, UFAL licensed under CC BY-SA 4.0) and Turkish (Sulubacak et al. 2016, IMST licensed under CC BY-NC-SA 3.0). When investigating POSL, we take the target space $\mathcal{T}$ to be the set of universal part-of-speech tags for a specific language. We then train a classifier to predict these POS tags from word representations obtained from the analyzed model (e.g., BERT). Similarly, for DAL, the target space $\mathcal{T}$ is defined as the set of arc dependency labels in the language, but we predict these labels from pairs of representations—the two words composing the arc.

We analyze the contextual representations from BERT (Devlin et al., 2019), ALBERT (Lan et al., 2020) and RoBERTa (Liu et al., 2019)—noting that ALBERT and RoBERTa are trained in English alone, so we only evaluate their performance on that language.[7] For each of these models, we feed it a sentence and average the output word piece (Wu et al., 2016) representations for each word, as tokenized in the treebank. We further analyze fastText's non-contextual representations (Bojanowski et al., 2017) as well as one-hot and random representations such as those considered by Pimentel et al. (2020). One-hot and random representations map each word type in the training data to a vector we sample from a standard normal distribution (zero mean and unit variance). New representations are sampled on the spot (untrained) for any out of vocabulary words. All representations are kept fixed during training, except for one-hot, which are learned with the other network parameters.

6.1 Linear Probes with Norm Constraints

For each language–representation–task triple, we train 100 linear probes, 50 optimizing eq. (3)[8] and 50 others with the rank constraint. The left-half of

---

[6] Another non-parametric method, online coding MDL (Voita and Titov, 2020) can likewise be compared across arbitrary model classes, because its complexity metric is based on probabilities produced and not probe parameters.

[7] We use the base versions (as opposed to the large ones) of ALBERT, RoBERTa and multilingual BERT—as implemented by Wolf et al. (2019)

[8] We vary λ in log-uniform intervals from 2^{-10} and 8.0—while also including experiments with no nuclear norm constraint (i.e., with $\lambda = 0$) for completion.

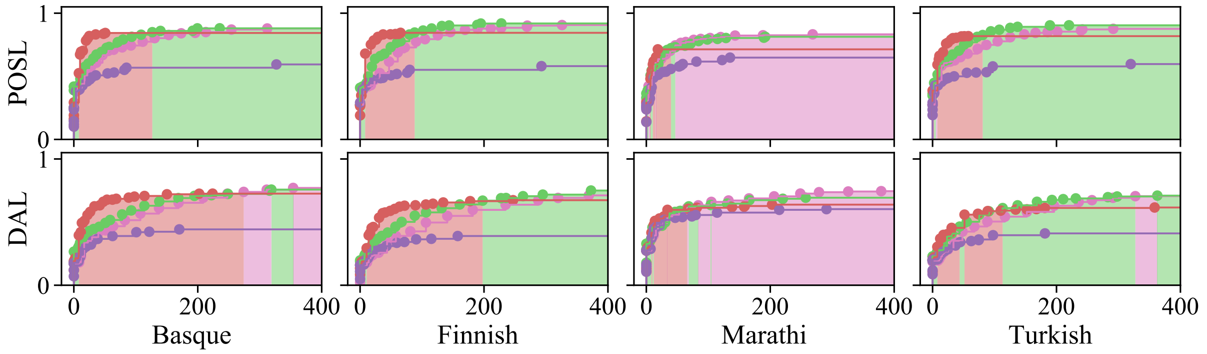

Figure 3: Results for multiple languages using the nuclear norm complexity metric. The x-axis corresponds to the probe's complexity. The y-axis measures the probes accuracy on the task. BERT, fastText, one-hot, and random.

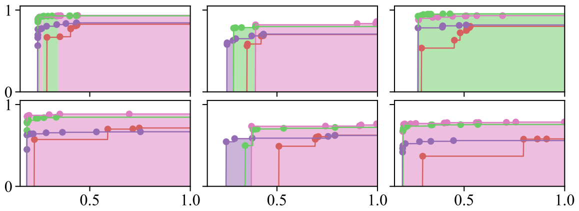

Figure 4: Results using the label-shuffled complexity metric in (left) Basque, (middle) Marathi, and (right) Turkish on (top) POSL, and (bottom) DAL. The x-axis corresponds to the probe's complexity. The y-axis measures the probes accuracy on the task. Probing the representations: BERT, fastText, one-hot, and random.

Fig. 2 presents the Pareto frontiers for both these probes trained on English, while Fig. 3 show the nuclear norm experiments in other languages.[9] As discussed in § 2.3, optimizing for complexity alone leads to trivial results—in all these languages one-hot representations would result in the best accuracy when using the nuclear norm complexity metric. We show that, counter-intuitively, fastText and one-hot representations Pareto-dominate BERT on the POSL task in Basque, Finnish and Turkish, producing higher accuracies with probes of any complexity (as defined by their nuclear norms). Thus, from the POSL experiments we cannot conclude BERT has any more syntactic information. In English, the one-hot and ALBERT representations form the Pareto-dominant set; the former in the simple scenario and the later in the complex scenario.

6.2 MLPs and Memorization

When using our non-parametric complexity metrics, we again train a number of classifiers for each language–representation–task triple. The classifiers chosen for this analysis were multilayer perceptrons (MLP) with ReLU non-linearities. We trained 50 MLPs for each language–representation–task triple, sampling the number of layers uniformly from $[0, 5]$, the dropout from $[0.0, 0.5]$, and the hidden size log-uniformly from $[2^5, 2^{10}]$. Note that zero layers is a linear probe. Each of these architectures was trained both on the standard training set as in this set's label-shuffled and fully shuffled alternatives.

Fig. 4 presents POSL and DAL multilingual results under the non-parametric complexity metric; the right half of Fig. 2 presents English results.[10] The most striking characteristic of the Pareto frontiers is how simple architectures (i.e. with relatively low memorization capacity) achieve as high an accuracy as the more complex ones. This is not surprising, though, when we compare this finding to the parametric ones; there we see linear probes are already almost as good as MLPs on these tasks. We take this as support for our intuition that toyish probing tasks are not very interesting or informative. We discuss this point in the next section.

7 A Call for Harder Probing Tasks

7.1 The False Promise of Toy Probing Tasks

In § 2.1, we reviewed arguments that researchers have put forth to justify toy tasks, while the argument for toy tasks from a standpoint of model complexity is addressed in § 2.3. Nevertheless, BERT, ELMo and other pre-trained representations rose to fame based on their ability to boost neural models

---

[9] Since rank constrained results showed a similar trend to the nuclear norm ones, results for other languages were moved into the appendices. The interested reader will also find zoomed-in versions (in the y-axis) of these plots there, as well as Pareto hypervolume tables.

[10] Experiments using the fully shuffled complexity metric only apply to contextual representations, since shuffling the sentence does not affect non-contextual ones. As such we only present them for English—we only analyze one contextual representation in other languages, i.e. BERT.

Language	POSL	DAL
Basque	86%	67%
English	86%	68%
Finnish	87%	63%
Marathi	72%	62%
Turkish	83%	58%

Table 1: Test accuracies for a dictionary lookup strategy based on the labels in the training set.

to human-level scores on large, non-trivial tasks, e.g. natural language inference (Liu et al., 2019) and question answering (Lan et al., 2020)—with different performance patterns being observed on the toyish probing tasks.

As reported by Pimentel et al. (2020), BERT embeddings do not yield substantial improvements over non-contextual-embedding baselines, e.g. fastText, on toyish probing tasks. We reproduce similar experiments, albeit with our methodology, in § 6.2. In the case of POSL, we observe that fastText's embeddings achieve higher accuracy in many cases. In the case of DAL, however, we do observe that BERT leads to relatively small improvements over fastText across a typologically diverse set of languages. This result is not surprising because DAL is a more complex task than POSL: When one probes on simple tasks, models pretrained on more data do not help much. Furthermore, a quick visual analysis of § 6.1 reveals that one can achieve relatively high accuracy on both POSL and DAL with a linear probe. This is confirmed by § 6.2, which shows that simple probes, i.e. probes with less capacity for memorization, result in as high accuracy as complex ones. In fact, we run an extra experiment, shown in Tab. 1, which shows that a trivial dictionary lookup strategy (details are presented in App. B) already achieves relatively high accuracies in POSL in all languages.

We interpret this to mean that current probing tasks are uninteresting—hiding from us the amount of syntactic information contextual representations actually encode. Furthermore, the simplicity of such toyish tasks artificially makes type-level embeddings—e.g. fastText—seem nearly as good as contextual ones.

7.2 Dependency Parsing

Following the previous argument, we believe *harder* probing tasks should be used. We take the lead by looking at dependency parsing, which depends on the whole sentence's context, and is much harder than toyish tasks like POSL and DAL. We train a simplified version of Dozat and Manning's (2017) biaffine parser, removing its power to process context by discarding its LSTM—as we describe in detail in App. A. This parser gives us the probability of a head for each word in a sentence, which allows us to recover the whole dependency tree. We then evaluate these trees using unlabeled attachment score (UAS). For our label-shuffled experiments, we permute the heads per sentence—creating non-tree dependencies.

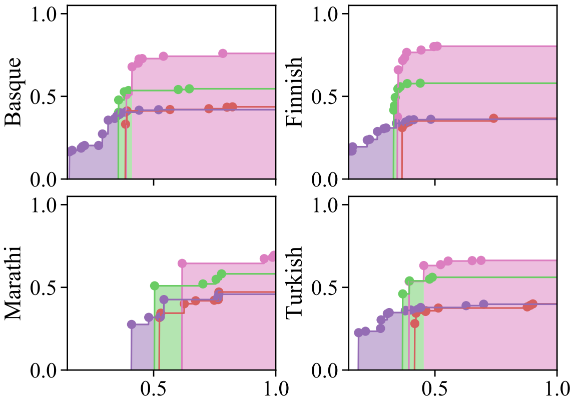

Figure 5: Dependency parsing Pareto curves using the label-shuffled complexity metric in a diverse set of languages. The x-axis corresponds to the probe's complexity. The y-axis measures the probes accuracy on the task. BERT, fastText, one-hot, and random.

Representation	Basque	English	Finnish	Marathi	Turkish
random	0.32	0.39	0.28	0.24	0.30
one-hot	0.26	0.32	0.22	0.20	0.22
fastText	0.35	0.40	0.38	**0.27**	0.35
BERT	**0.45**	**0.57**	**0.51**	0.25	**0.39**
ALBERT	-	**0.57**	-	-	-
RoBERTa	-	0.54	-	-	-

Table 2: Pareto hypervolume results on dependency parsing under the label-shuffled complexity metric.

Figs. 1 and 5 present label-shuffled results for this task. Such figures are much more interesting than the POSL and DAL ones, showing the expected trade-off between accuracy and complexity. Tab. 2 makes the amount of syntax encoded in contextual representations much clearer when compared to fastText. This is specially true if we compare these results to the Pareto hypervolumes of the POSL and DAL tasks (presented in Tab. 3 in the appendix). We take this experiment to conclude two things: (i) harder tasks are necessary to study neural representations; (ii) contextual representations encode much more knowledge about syntax (as expected) then do non-contextual ones.

8 A Closer Look at Model Complexity

This work represents a new entry into a growing literature on taking the capabilities of probes into account when analyzing a model (Hewitt and Liang, 2019; Voita and Titov, 2020; Whitney et al., 2020). The fundamental point we wish to espouse in this paper is that evaluating a probe for linguistic structure is fundamentally asking a question about a trade-off between accuracy and complexity. However, we wish to highlight that evaluating a probe's complexity is a very open problem. Indeed, the larger question of model complexity has been treated for over 50 years in a number of disciplines. In statistics, model complexity is researched in the model selection literature, e.g. the classical techniques of **Bayesian information criterion** (Schwarz, 1978) and **Akaike information criterion** (Akaike, 1974). In computer science, learning theorists have introduced the **Vapnik–Chervonenkis dimension** (Vapnik and Chervonenkis, 1971), **Pollard's pseudo-dimension** (Pollard, 1984), and **Rademacher complexity** (Bartlett and Mendelson, 2002). Algorithmic information theorists provide **Kolmogorov complexity** (Kolmogorov, 1963)—closely related to MDL—encoding the size of the model.

A concrete discussion of complexity requires several distinctions regarding these measures. The first is the **object of analysis** of the complexity measure which can be either a **model family**, i.e the whole set of functions realizable by a choice of architecture and hyperparameters, or a **learned model**, which takes into account a specific set of learned parameters. The second is the **aspect being analyzed** by the used measure which could be, for example, the **capacity** of the function class (i.e., whether it is possible to set model weights so the architecture represents a specific target function—its hard constraints) or its **bias** (i.e., the soft constraints that influence whether the training process is likely to guide a model towards this target function).

Importantly, the measure of complexity the scientist employs will impact their scientific findings about how much linguistic structure they read into a neural network's hidden states. For instance, in some of our experiments we regularize the probe directly with a relaxation of a nuclear norm constraint, thus imposing a bias without modifying the total capacity of the model. Meanwhile, our rank-based method controls the capacity of the probe directly, enforcing a model family's complexity. Finally, our non-parametric methods, and selectivity, estimate the capacity of a model family (under a specific hyperparameter choice) by approximating a "hard" function in which labels are randomly assigned—differences in accuracy between these three complexity measures indicate a complex relationship between implicit regularization; input language structure; and model capacity. In comparison to our **computable** complexity measures, popular **hypothetical** notions also vary in how they explore the data's domain space to analyze a model family: Rademacher complexity uses true observations as inputs, but VC dimension considers adversarially selected data—being defined according to the "worst" possible sample allowed in the input domain.

As new techniques for considering the complexity of models emerge, it is critical to develop in parallel tools for reasoning about what aspect and object of "complexity" is really being measured. When one introduces a metric as modeling complexity, it can be explicitly situated within such a taxonomy; these considerations should be made explicit in the presentation. A sufficiently developed theory of probing will reveal not only the information contained in a representation, but the underlying geometry of the representation space, by comparing the performance of different model families. Such developments are left to future work.

9 Conclusion

In this paper, we argued for a new approach to probing, treating it as a bi-objective optimization problem. It has no single optimal solution, but can be analyzed—under the lens of Pareto efficiency—to arrive on a set of optimal solutions. These Pareto optimal solutions make explicit the trade-off between accuracy and complexity, also permitting for a deeper analysis of the probed representations.

The second part of our paper argues that we need to select harder tasks for the purpose of probing representations for syntactic knowledge. For tasks such as POSL or DAL, which require only shallow notions of syntax, non-contextual representations can do almost as well as contextual ones—pretraining on large amounts of data, or encoding contextual knowledge in the representations, does not help much for these tasks. We then run a battery of experiments on the harder task of dependency parsing; these show that contextual representations indeed provide much more useable syntactic knowledge than non-contextual ones.

Appendices

A Dependency Parser

Our dependency parser is inspired in Dozat and Manning's (2017) biaffine parser. We simplify it though, e.g. by not giving it an LSTM, to reduce its complexity and restrict its access to context. While looking at whole sentences $[\mathbf{h}_0, \ldots, \mathbf{h}_{|s|}]$, we train two MLPs with the same architecture as in § 6.2—one is used to process heads of dependencies, while the other is used for tails—and pass each individual token representation through both.

$$\mathbf{h}_{i,\text{head}} = \text{MLP}_{\text{head}}(\mathbf{h}_i) \quad (7)$$
$$\mathbf{h}_{i,\text{tail}} = \text{MLP}_{\text{tail}}(\mathbf{h}_i)$$

We further define a biaffine transformation, through which we pass both representations.

$$l_{i,j} = \mathbf{h}_{i,head} \cdot \mathbf{W} \cdot \mathbf{h}_{j,tail}$$

Finally, the output of this biaffine projection are then used as logits, which we normalize to get the probabilities of all possible heads for a specific word j.

$$p_{\text{parse}}(head = i | tail = j) = \frac{e^{l_{i,j}}}{\sum_{i'} e^{l_{i',j}}} \quad (8)$$

Such a probability distribution allows us to recover the whole dependency tree.

B Lookup Model

In this section, we present the design of a very simple lookup model for the POSL and DAL tasks. We present the detailed implementation of both models below, but their general idea is looking at the training set for an instance's most frequent label, and falling back to an overall general label frequency in case it is not found.

POSL In this task, the lookup model has two behaviors: (i) for a word which appear in the training set, it guesses its most common label; (ii) for an out of vocabulary word, it guesses the most overall frequent label in the training set.

DAL In the DAL task, the lookup model has four behaviors: (i) for an arc which appear in the training set, it guesses its most common label; (ii) for an unknown arc, it guesses the most overall frequent label in the training set for the arc's tail word; (iii) if the tail of the arc is an an out of vocabulary word, it guesses the most frequent label in the training set for the head word; (iv) finally, if the head is also out of vocabulary word, it guesses the most overall frequent arc label in the training set.

C Detailed results

In this section, we present further results which did not fit into the main text. We initially present results in dependency parsing, using the Nuclear Norm as our parametric complexity metric. Figs. 7 and 8 show that, again, the one-hot representation produces the best results in highly constrained scenarios (i.e. with very simple probes). Furthermore, comparing this results with § 7.2 we see that linear probes cannot do as well as MLPs in this task; suggesting it is indeed harder. Fig. 6 presents fully shuffled results for dependency parsing in English. Comparing it to § 7.2 we see the probes' capacity to memorize is much smaller on unstructured input.

Tab. 3 presents the Pareto hypervolume for all the analyzed models, in all languages, for POSL and DAL. Analyzing this table we again see that contextual representations do not improve over the non-contextual ones on these tasks by much—even producing worse results in some.

Finally, Fig. 9 presents results using the Rank parametric complexity metric, while Fig. 10 presents zoomed-in (in the y-axis) results for the Nuclear Norm parametric complexity metric.

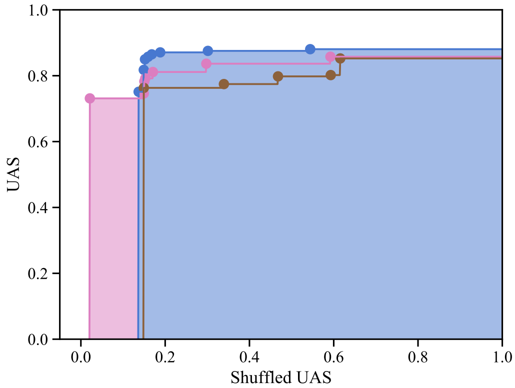

Figure 6: Pareto curves on dependency parsing with the fully shuffled complexity metric in English.

Abstract

To demystify the "black box" property of deep neural networks for natural language processing (NLP), several methods have been proposed to interpret their predictions by measuring the change in prediction probability after erasing each token of an input. Since existing methods replace each token with a predefined value (i.e., zero), the resulting sentence lies out of the training data distribution, yielding misleading interpretations. In this study, we raise the out-of-distribution problem induced by the existing interpretation methods and present a remedy; we propose to marginalize each token out. We interpret various NLP models trained for sentiment analysis and natural language inference using the proposed method.

1 Introduction

The advent of deep learning has greatly improved the performances of natural language processing (NLP) models. Consequently, the models are becoming more complex (Yang et al., 2019; Liu et al., 2019), rendering it difficult to understand the rationale behind their predictions. To use deep neural networks (DNNs) for making high-stakes decisions, the interpretability must be guaranteed to instill the trust in the public. Hence, various attempts have been undertaken to provide an interpretation along with a prediction (Gilpin et al., 2018).

Research in computer vision aims to interpret a target model by measuring attribution scores, i.e., how much each pixel in an input image contributes to the final prediction (Simonyan et al., 2013; Arras et al., 2017; Zeiler and Fergus, 2014; Lundberg and Lee, 2017). Since a pixel of an image corresponds to a token in a sentence, the attribution score of each token can provide an insight into the NLP model's internal reasoning process. A straightforward approach is to ask, "How would the model reaction change if each token was not there?" and the change can be measured by the difference in softmax probabilities after *erasing* each token. Li et al. (2016) proposed to erase each token by replacing it with a predefined value, i.e., zero. This became a representative method for interpreting NLP models, followed by several papers using the similar erasure scheme (Feng et al., 2018; Prabhakaran et al., 2019; Jin et al., 2019).

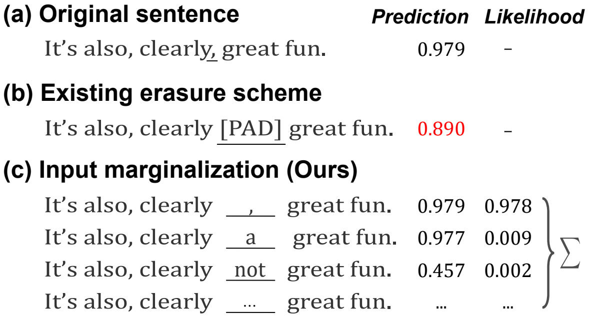

Figure 1: Given the original sentence (a), the existing erasure scheme (b) replaces each token with zero, i.e., [PAD] token. Our method (c) marginalizes each token out considering the likelihoods of candidate tokens.

However, such an erasure scheme can cause out-of-distribution (OOD) problem, where the erased sentence deviates from the target model's training data distribution. DNNs tend to assign a lower prediction probability to OOD samples than in-distribution samples (Hendrycks and Gimpel, 2016), as shown in Fig. 1, which results in overestimated contribution of an unimportant token. The OOD problem induced by the existing erasure scheme makes it difficult to identify whether high-scoring tokens actually contribute significantly to the prediction. In computer vision, several studies have highlighted the problem and attempted to address it (Zintgraf et al., 2017; Chang et al., 2018; Yi et al., 2020). To the best of our knowledge, the OOD problem has not been raised in the field of NLP, hence no solution has been suggested yet.

In this study, we ask instead; "How would the model react differently if there were other tokens

---

instead of each token?”, as proposed by Chang et al. (2018); Yi et al. (2020). We propose to marginalize each token out to mitigate the OOD problem of the existing erasure scheme. During the marginalization, our method measures the contribution of all probable candidate tokens considering their likelihoods. To calculate the likelihoods, we use the masked language modeling (MLM) of bidirectional encoder representations from transformers (BERT) (Devlin et al., 2019).

Our contributions are as follows:

i) To the best of our knowledge, we first raise the OOD problem that can arise when interpreting NLP models through the existing erasure schemes.

ii) To avoid the OOD problem, we propose a new interpretation method, i.e., input marginalization using MLM for likelihood modeling.

iii) We apply the proposed method to interpret various NLP models and quantitatively verify the correctness of the resulting interpretation.

2 Related Works

2.1 Interpretation of NLP models

Model-aware interpretation methods for DNNs use model information such as gradients. Saliency map (Simonyan et al., 2013) interprets an image classifier by computing the gradient of a target class logit score with respect to each input pixel. Since a token index is not ordinal as an image pixel, the gradient with respect to a token is meaningless. Hence, Li et al. (2016) computed the gradient in an embedding space and Arras et al. (2017) distributed the class score to input embedding dimensions through layer-wise relevance propagation. Both methods sum up the scores of each embedding dimension to provide the attribution score of a token. Because the score can have a negative or positive sign, the sum may offset each other, so the contribution of the token may become zero even if it does contribute to the prediction.

Recently, the attention mechanism has been widely adopted to various NLP tasks (Bahdanau et al., 2014; Vaswani et al., 2017; Zhang et al., 2018) and there have been attempts to use the attention score as an interpretation. (Jain and Wallace, 2019). However, its validity is still controversial (Wiegreffe and Pinter, 2019).

Model-agnostic approaches aim to interpret any types of model with no information other than its feed-forward outputs. They observe how much the prediction changes after erasing each unit of input. If it differs significantly, then the unit obtains a high attribution score. In computer vision, the measurement of prediction difference varies from the subtraction of probabilities (Zeiler and Fergus, 2014) to a log-odds probability difference (Zintgraf et al., 2017). In the field of NLP, Li et al. (2016) interpreted NLP models by erasing each dimension of the embedding vector or the token itself, where the erasure was implemented by simply setting the value to a predefined value, i.e., zero. Such an erasure scheme can push the embedding vector or the input out of the training data distribution, thereby resulting in an inaccurate interpretation.

2.2 Interpretation without OOD problem

Several interpretation methods to mitigate the OOD problem have been proposed in computer vision. Zintgraf et al. (2017) proposed to marginalize each pixel out by assuming that the pixel value follows a Gaussian distribution. It had limitations in that the Gaussian distribution differed from the real pixel distribution. Chang et al. (2018) improved it by replacing an image segment with a plausible values generated from a deep generative model. Yi et al. (2020) proposed to adopt an additional DNN to model the pixel distribution, which motivated our work the most.

The method recently proposed by Jin et al. (2019) may appear similar to ours as it marginalizes context words out to obtain the context-free attribution of a token. However, it still cannot overcome the OOD problem because it replaces the token with zero, similar to the existing methods. To the best of our knowledge, no attempt has been undertaken to raise and overcome the OOD problem that arises when interpreting NLP models.

2.3 MLM of BERT

BERT (Devlin et al., 2019), one of the state-of-the-art natural language representations, is trained with two pre-training tasks: MLM and next sentence prediction. The MLM aims to infer the probability of a token to appear in the masked position of an input. As BERT is deeply bidirectional, it can consider the entire context of the sentence which enables the exact likelihood modeling. The likelihoods of the candidate tokens for marginalization are easily and accurately attainable using the MLM of BERT.

3 Methods

We propose input marginalization to mitigate the OOD issue. In the following subsections, we measure the attribution score using the weight of evidence and marginalize over all possible candidate tokens using the MLM of BERT. We extend the method to multi-token cases and introduce adaptively truncated marginalization for an efficient computation. Finally, we propose a new metric, $\mathrm{AUC}_{\mathrm{rep}}$, to evaluate the proposed method faithfully. The overall algorithm is provided in Algorithm 1.

3.1 Measurement of model output difference

To measure the changes in the model output, we adopt the widely used weight of evidence (WoE) (Robnik-Šikonja and Kononenko, 2008), which is a log odds difference of prediction probabilities. We define θ as the target model parameter, y_c as a target class to be explained, and $\boldsymbol{x}$ as an input sentence. We introduce $\boldsymbol{x}_{-i}$, i.e., $\boldsymbol{x}$ without i-th token x_i, to quantify the contribution of x_i to predicting y_c. WoE is formulated as follows:

$$\begin{aligned}\mathrm{WoE}_{\theta,i}(y_c|\boldsymbol{x}) = &\log_2(\mathrm{odds}_\theta(y_c|\boldsymbol{x})) \\ &- \log_2(\mathrm{odds}_\theta(y_c|\boldsymbol{x}_{-i})),\end{aligned} \tag{1}$$

where $\mathrm{odds}_\theta(y_c|\boldsymbol{x}) = p_\theta(y_c|\boldsymbol{x})/(1 - p_\theta(y_c|\boldsymbol{x}))$. $p_\theta(y_c|\boldsymbol{x}_{-i})$ captures the notion of the model response without the i-th token. The first term of Eq. 1 can be easily obtained as it is the original prediction probability, while the second term is computed by input marginalization.

3.2 Input marginalization

We rewrite the term $p(y_c|\boldsymbol{x}_{-i})$ of Eq. 1 using marginalization as follows:

$$\begin{aligned}p(y_c|\boldsymbol{x}_{-i}) &= \sum_{\tilde{x}_i \in \mathcal{V}} p(y_c, \tilde{x}_i|\boldsymbol{x}_{-i}) \\ &= \sum_{\tilde{x}_i \in \mathcal{V}} p(y_c|\tilde{x}_i, \boldsymbol{x}_{-i}) \cdot p(\tilde{x}_i|\boldsymbol{x}_{-i}).\end{aligned} \tag{2}$$

Here, $\tilde{x}_i$ is a candidate token that can appear instead of x_i, and $\mathcal{V}$ is a set of vocabulary. $p(y_c|\tilde{x}_i, \boldsymbol{x}_{-i})$ can be easily obtained by a single feed forward to the target model with the i-th token replaced with $\tilde{x}_i$. We compute $p(\tilde{x}_i|\boldsymbol{x}_{-i})$, the likelihood of $\tilde{x}_i$ appearing in the i-th position, by substituting the x_i with the "[MASK]" token and feed forwarding it to BERT. The process of computing the attribution score of a token is repeated for all tokens in the sentence.

Algorithm 1 Input marginalization

```
Input Target model $\theta$, input $\boldsymbol{x}$, vocabulary $\mathcal{V}$, likelihood threshold $\sigma$, and target class $y_c$
Output Attribution score $\boldsymbol{a}$
for $i = 0$ to length($\boldsymbol{x}$) do
    $m \leftarrow 0$    ▷ Initialize attribution score
    $\boldsymbol{s} \leftarrow$ copy $\boldsymbol{x}$
    $\boldsymbol{s}_i \leftarrow$ "[MASK]" token
    for all $\tilde{s}_i$ in $\mathcal{V}$ do
        $p(\tilde{s}_i|\boldsymbol{s}_{-i}) \leftarrow \mathrm{BERT}_{\mathrm{MLM}}(\boldsymbol{s})$
        if $p(\tilde{s}_i|\boldsymbol{s}_{-i}) > \sigma$ then
            $\boldsymbol{s}_i \leftarrow \tilde{s}_i$
            $m \leftarrow m + p(\tilde{s}_i|\boldsymbol{s}_{-i}) \cdot p_\theta(y_c|\boldsymbol{s})$
        end if
    end for
    $\boldsymbol{a}_i = \mathrm{logodds}_\theta(y_c|\boldsymbol{x}) - \mathrm{logodds}_\theta(m)$
        ▷ Prediction difference measurement
end for
```

3.3 Multi-token marginalization

We can compute the attribution score for multiple tokens similarly. Let us assume that we wish to measure the joint contribution of two tokens x_i and x_j. Eq. 2 then becomes

$$p(y_c|\boldsymbol{x}_{-i,j}) = \sum_{\tilde{x}_j \in \mathcal{V}} \sum_{\tilde{x}_i \in \mathcal{V}} p(y_c, \tilde{x}_i, \tilde{x}_j|\boldsymbol{x}_{-i,j}). \tag{3}$$

Applying Bayes' theorem, $p(y_c, \tilde{x}_i, \tilde{x}_j|\boldsymbol{x}_{-i,j})$ becomes $p(y_c|\tilde{x}_i, \tilde{x}_j, \boldsymbol{x}_{-i,j}) \cdot p(\tilde{x}_i, \tilde{x}_j|\boldsymbol{x}_{-i,j})$. The latter term of the multiplication can be decomposed into the multiplication of $p(\tilde{x}_i|\boldsymbol{x}_{-i}, \tilde{x}_j)$ and $p(\tilde{x}_j|\boldsymbol{x}_{-i,j})$. Each term can be easily obtained by masking the corresponding position and feed-forwarding it to BERT even when x_i and x_j are distant. For more than two tokens, the attribution scores can be obtained in the similar way.

3.4 Adaptively truncated marginalization

The computational complexity for obtaining an attribution score of one token is $O(|\mathcal{V}|)$, where $|\mathcal{V}|$ is the size of a vocabulary set. For the tokenizer used in BERT, $|\mathcal{V}|$ is greater than 30,000, and the same number of marginalization is required, which is computationally burdensome. For the efficient computation, we propose adaptively truncated marginalization. If the magnitude of $p(\tilde{x}_i|\boldsymbol{x}_{-i})$ is insignificantly small, the contribution of $p(y_c|\tilde{x}_i, \boldsymbol{x}_{-i})$ to the summation in Eq. 2 becomes negligible. Therefore, we marginalize only over candidates whose likelihoods are greater than a likelihood threshold

"pre" and "hypo" in (b) denote premise and hypothesis of SNLI, respectively. Red and blue colors denote positive and negative contributions to the denoted classes, respectively.

(σ) and normalize the score. Adaptively truncated marginalization approximates Eq. 2 as follows:

$$p(y_c|\boldsymbol{x}_{-i}) \approx \frac{\sum_{\tilde{x}_i \in \tilde{\mathcal{V}}} p(y_c|\tilde{x}_i, \boldsymbol{x}_{-i}) \cdot p(\tilde{x}_i|\boldsymbol{x}_{-i})}{\sum_{\tilde{x}_i \in \tilde{\mathcal{V}}} p(\tilde{x}_i|\boldsymbol{x}_{-i})}, \tag{4}$$

where $\tilde{\mathcal{V}} = \{\, \tilde{x}_i \in \mathcal{V} \mid p(\tilde{x}_i|\boldsymbol{x}_{-i}) > \sigma \,\}$.

Since the likelihood distributions depend on a token's position in the sentence, the number of marginalization varies for every i. We will demonstrate the efficiency of adaptively truncated marginalization and find an optimal σ in Section 4.

3.5 Evaluation of interpretation

Inspired by Petsiuk et al. (2018) and Chang et al. (2018), we propose a metric AUC_{rep} to evaluate interpretation methods for NLP models. Given the attribution scores of a sentence, Petsiuk et al. (2018) plotted a prediction probability curve as pixels filled with zero in the order of importance. If the interpretation is faithful, then the curve will drop rapidly, resulting in a small area under a curve (AUC). However, replacing the token with zero or removing it from a sentence can cause the OOD problem again. Instead, we replace it with a token sampled from the distribution inferred by BERT MLM, as Chang et al. (2018) gradually replaced image segments with a generated sample. As MLM is trained by masking only a part of the input sentence, replacing too many tokens can degrade its modeling performance. Therefore, we calculate the AUC until 20% of the tokens are replaced, and refer to it as AUC_{rep}.

4 Experimental Results

4.1 Experimental setup

To show the model-agnostic and task-agnostic property of our method, we present interpretations of several types of DNNs trained for two tasks: sentiment analysis and natural language inference.

SST-2 For sentiment analysis, we used the Stanford Sentiment Treebank binary classification corpus (SST-2) (Socher et al., 2013), which is a set of movie reviews labeled as positive or negative. We trained an 1-dimensional convolutional neural networks (CNNs) and a bidirectional long short-term memory (LSTM) with attention mechanism, and fine-tuned BERT (Devlin et al., 2019).

SNLI For natural language inference, we used the Stanford natural language inference (SNLI) corpus (Young et al., 2014), a collection of pairs of two sentences, premise and hypothesis, annotated with three relationships between them: entailment, contradiction, and neutral. We trained the bidirectional LSTM for SNLI.

The final test accuracy of the target models is provided in Table 1. Note that the architectures of LSTM used for SST-2 and SNLI are distinct. Please refer to the Appendix for the detailed descriptions. Throughout the experiments, we used the same tokenizer as BERT, where the zero-th token is "[PAD]". After training the target models, we interpreted their predictions through the proposed input marginalization. We used pre-trained BERT (Wolf et al., 2019) for likelihood modeling and σ was set to 10^{-5}.

Table 1: Test accuracy of the target models

Corpus	**Model**		
	LSTM	BERT	CNN
SST-2	0.7753	0.8578	0.7300
SNLI	0.6314	-	-

4.2 Interpretation results

The interpretation results of the proposed method are shown in Fig. 2. The color indicates the contribution of each token to the final prediction, with blue and red representing a negative and positive contribution, respectively. Its intensity represents the magnitude of the attribution score. More examples are provided in Appendix.

Fig. 2 (a) shows the interpretations of correct predictions for SST-2. The labels are shown in front of the sentences. For predicting the positive class, affirmative tokens such as "brilliant" and "funny" were attributed highly (a1, a9); if they are replaced with other tokens, the prediction probability will decrease significantly. Likewise, negative tokens such as "disappointing" and "suffers" were highlighted for predicting the negative class (a7, a8). If positive and negative tokens appear in one sentence simultaneously, our method successfully assigned the opposite scores to those tokens: positive score to "disappointing" and negative score to "dead brilliant" for predicting negative class (a7).

The interpretations of the LSTM for SNLI are shown in Fig. 2 (b). The sentences were correctly classified to the denoted class. For predicting a class entailment, the token with a similar meaning were assigned high attribution score, such as "swim" (b3). In contrast, tokens that makes two sentences contradicting were highlighted for predicting contradiction, such as "cafe" vs. "bar" (b4).

4.3 Comparison to the existing erasing scheme

In this section, we compare our method with the existing method proposed by Li et al. (2015) through interpretations of models for SST-2. We refer to the existing method as zero erasure throughout the experiments as it replaces tokens with zero.

Qualitative comparison Interpretation results using input marginalization (Marg) and zero erasure (Zero) are depicted in Fig. 3 (a). Fig. 3 (a1-a6) and (a7-a8) were classified to positive and negative class, respectively. As shown in the figure, zero erasure often completely failed to interpret the prediction (a1). Zero erasure also assigned high attribution scores to uninformative tokens such as punctuation and "to" (a3-a6). Our method showed clearer interpretations where unimportant tokens were given low attribution scores, while correctly highlighting the important ones. Moreover, the negative attribution was captured better than zero erasure. For example, in Fig. 3 (a7-a8), the token "bit" reduces the degree of negativity of "disappointing". Compared to potentially more assertive tokens (e.g. "very"), the specific token diluted the negative sentiment of the sentence. The negative contribution of "bit" to predicting the class "negative" was captured only with our method.

Quantitative comparison using AUC$_{\text{rep}}$ We quantitatively compared our method with zero erasure using the AUC$_{\text{rep}}$ proposed in Section 3. Another baseline using "[UNK]" token instead of zero was tested to verify that the OOD problem occurs no matter what predefined value is used. We would like to clarify that we did not consider the "[MASK]" token because it is a special token dedicated for the pre-training of BERT. It will obviously cause the OOD problem because it never appears during the training of target classifiers.

The deletion curves in Fig. 3 (b) shows the change in prediction probabilities as tokens with high attribution score are gradually replaced. The

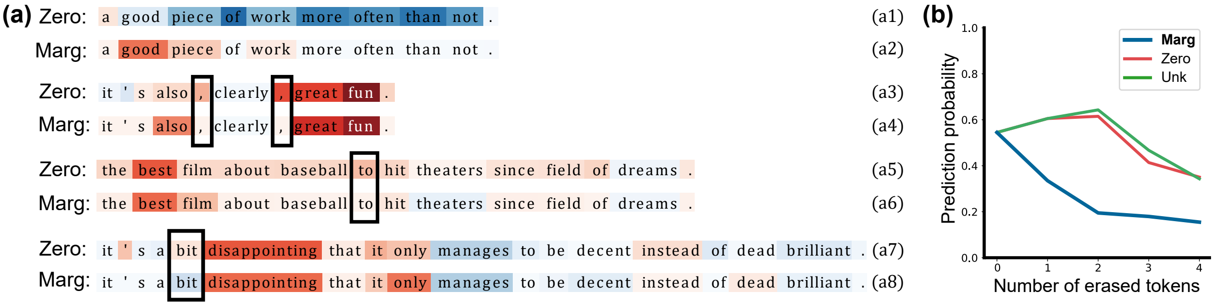

Figure 3: (a) shows examples of interpretations obtained by zero erasure and input marginalization (ours). Red and blue colors denote positive and negative contributions to the predicted classes, respectively. (a1-a6) are correctly classified as positive, and (a7-a8) are correctly classified to negative. (b) shows deletion curves of input marginalization, zero erasure, and "[UNK]" erasure, which are abbreviated as "Marg", "Zero", and "Unk", respectively.

curves show that the deletion curve drawn using our method dropped more rapidly compared to the zero and "[UNK]" erasures. The average AUC_{rep} values for 700 SST-2 sentences are provided in Table 2, and the proposed method showed the lowest AUC_{rep}. This result demonstrates that our method more accurately captures the importance of tokens than the existing erasure scheme.

Table 2: Comparison of AUC_{rep} with the existing erasure scheme (the lower the better).

	Interpretation method		
	Zero	Unk	Ours
$\mathbf{AUC_{rep}}$	0.5284	0.5170	**0.4972**

Quantitative comparison using SST-2 tags The SST-2 corpus provides not only sentence-level labels, but also five-class word-level sentiment tags ranging from very negative to very positive. We can verify the validity of the attribution scores by comparing them with the word-level tags. For simplicity, we merged very positive and positive, very negative and negative into positive (pos) and negative (neg), respectively, such that each token is given one tag among three. If a sentence is correctly classified to positive, then three cases exist:

i) pos-tagged word: contributes positively and significantly to the prediction
ii) neut-tagged word: does not contribute much to the prediction
iii) neg-tagged word: contributes negatively to the prediction,

where neut denotes neutral.

To assess if our method can assign high score to case i), we measured the intersection of tokens (IoT) between pos-tagged tokens and highly attributed tokens in one sentence, motivated by intersection of union (IoU) which is a widely used interpretation evaluation metric in the vision field (Chang et al., 2018). IoT is defined as $|P \cap T| \, / \, |P|$, where P denotes a set of + tagged tokens, and T denotes a set of top-10 highly attributed tokens. The average IoT for 100 sentences was 0.72 and 0.64 for our method and zero erasure, respectively. This demonstrates that the tokens assigned with the highest attribution scores by our methods are likely to have a significant impact on the sentiment annotation.

A faithful interpretation method is expected to assign a small attribution score for the tokens belonging to ii). For 500 interpretations, the average attribution score of the neutral words was 0.053 and 0.175 with our method and zero erasure, respectively. With our method, the candidate tokens inducing the OOD problem like zero have an insignificant effect on the final attribution score because they are assigned relatively low likelihoods.

4.4 Additional analysis using input marginalization

The experimental results above demonstrates that our method can provide faithful interpretations. It thus can be used to analyze DNNs. First, we can compare the rationale of various models by analyzing their interpretations. Fig. 4 (a1-a4) show the interpretations of SST-2 samples correctly classified to positive by both BERT and LSTM. BERT tended to focus more on affirmative tokens such as "full" and "memorable" (a2) and successfully identified the role of the token "but" (a4) where the sentiment is reversed after it from negative to positive. Fig. 4 (a5-a8) show the interpretations of samples that are labeled as positive but misclassified as negative by

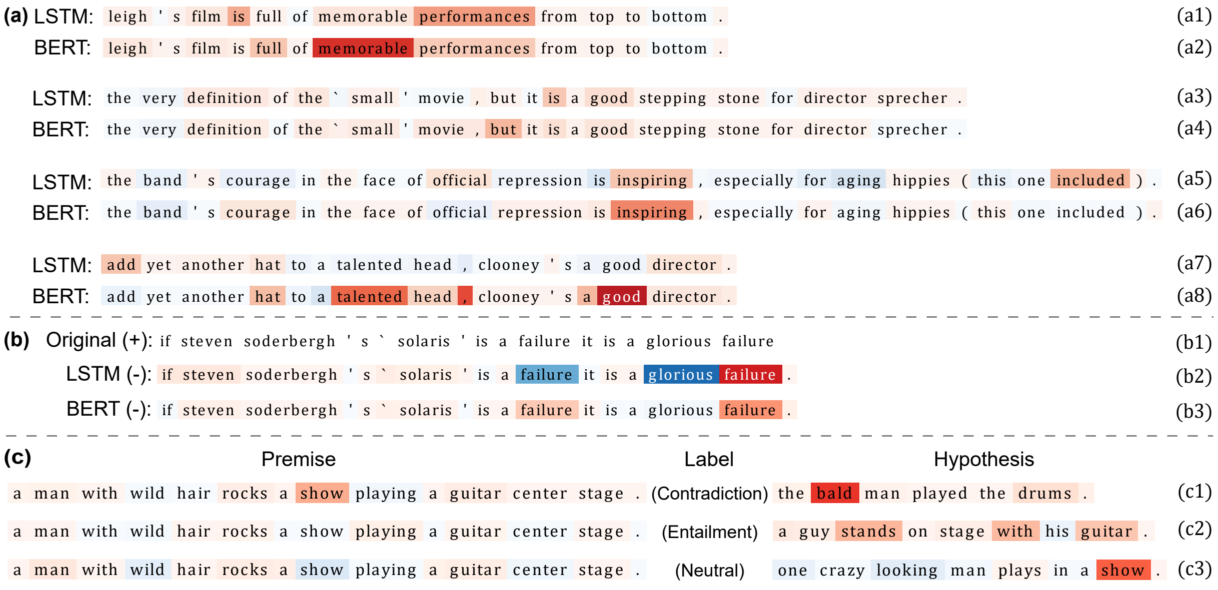

Figure 4: Interpretation results using input marginalization. Red and blue colors denote positive and negative contributions to the predicted classes. (a) shows interpretations of SST-2 predictions. (a1-a6) are correctly classified to positive, and (a7-a8) are correctly classified to negative. (b) shows positive sentences which are misclassified to negative by both LSTM and BERT. (c) shows the interpretations of SNLI predictions.

LSTM. The decisions of LSTM were significantly influenced by the word "included" and "add" (a5, a7). In contrast, BERT correctly classified them as positive by focusing on "inspiring" and "good".

Our method enables debugging the model by analyzing the misclassification case. Fig. 4 (b) shows the sentences whose true labels are positive but incorrectly classified as negative by both models. We measured the attribution score with respect to the negative class. For both models, the word "failure" was assigned significantly high attribution score indicating that both models failed to recognize the overall positive sentiment of the sentence by focusing on the negativity inherent in the word.

Fig. 4 (c) shows different attribution scores assigned to the same premise when the hypothesis changes. It is shown that the tokens in the hypotheses received higher scores than those in the premises. In fact, they obtained attribution scores twice as high as those in the premises for 500 interpretations. We can potentially conclude that the model was trained to pay more attention to hypothesis, since the SNLI corpus consists of repetitive premises and varying hypotheses. Moreover, (c1) shows that even if there are two contradictory word pairs, "wild hair"-"bald" and "guitar"-"drum", the model focused more on the the former. Our method allows potential model debugging when the interpretation turns out to be counterintuitive.

4.5 Effect of language modeling

In Eq. 2, an exact modeling of the likelihood $p(\tilde{x}_i|\boldsymbol{x}_{-i})$ is important for the accurate calculation of the attribution scores. Hence, the high agreement between the modeled and the real-world distributions will result in a more accurate interpretation. We analyzed the effect of the likelihood modeling capability on the accuracy of interpretation results. We tested three additional likelihood modeling: uniform distribution, prior probability, and fine-tuned BERT MLM.

Uniform $p(\tilde{x}_i|\boldsymbol{x}_{-i}) = 1/|\mathcal{V}| = 1/30522$ in the case of BERT tokenizer.

Prior $p(\tilde{x}_i|\boldsymbol{x}_{-i}) = p(\tilde{x}_i)$, defined by counting the frequency of each token in the training data.

Fine-tuned MLM We fine-tuned the MLM of BERT with the SST-2 dataset for two epochs (MLM_{fine}).

Using each likelihood distribution modeling, we interpreted the BERT classifier trained for the SST-2 corpus. The results are shown in Fig. 5. The uniform distribution failed to provide an accurate interpretation. The result with prior probability modeling appeared slightly clearer, but was still misleading. MLM_{pre} successfully highlighted important tokens, but it assigned high scores to tokens that were not expected to contribute significantly to predicting the sentiment of a movie review (e.g., "film" and "movie" marked with box). MLM_{fine} yielded

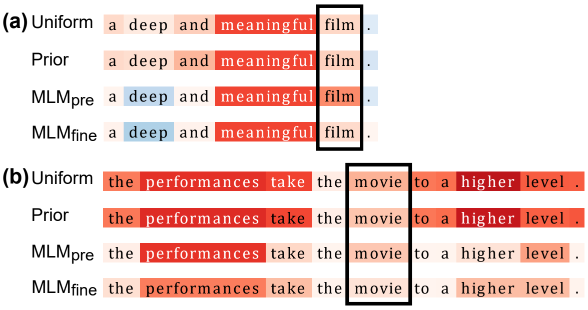

Figure 5: Interpretation results using different likelihood modelings. Each sentence is correctly classified to positive. Red and blue colors denote positive and negative contributions to the predicted classes.

the most reasonable interpretation, where the attribution score of "film" and "movie" was reduced from 0.256 and 0.631 to 0.007 and 0.321, respectively, compared to MLM_{pre}. We can expect the interpretation results to become more plausible as the likelihood modeling improves.

4.6 Ablation study on adaptively truncated marginalization

We introduced adaptively truncated marginalization in Section 3.4 for a faster computation. The full marginalization over all possible tokens yields the most exact attribution scores. Thus, we searched for an optimal threshold σ of adaptively truncated marginalization that reduces the computational complexity while maintaining a high correlation to the scores from full marginalization. We measured the correlation using the Pearson correlation coefficients. Furthermore, we tested fixed truncation, which calculates top-n likely candidates without considering the varying likelihoods depending on the position.

Table 3 shows the Pearson correlation coefficient and the average number of marginalization under various thresholds. $\sigma = 10^{-5}$ and 10^{-6} showed very similar interpretations to the full marginalization while the average marginalization number reduced to 2.5% and 10.4%, respectively, compared to 30,522 of the full marginalization. We regarded $\sigma = 10^{-5}$, which showed a lower number of marginalization under a similar correlation, as the optimal value. The fixed truncation showed a lower correlation under the similar average number of marginalization. The computational complexity can be further reduced by accepting a slight loss in the accuracy.

Table 3: The Pearson correlation with full marginalization and the average number of marginalization under various thresholds. σ: likelihood threshold, n: marginalization number threshold for fixed truncation.

		Corr	**Avg #**
Threshold	$\sigma = 10^{-6}$	**0.9999**	3,186
	$\sigma = 10^{-5}$	**0.9999**	791
	$\sigma = 10^{-4}$	0.9988	171
	$\sigma = 10^{-3}$	0.9928	33
	$n = 10^{3}$	0.9958	1,000
	$n = 10^{2}$	0.9823	100

5 Conclusion

Interpretability is becoming more important owing to the increase in deep learning in NLP. Hence, several interpretation methods have been proposed, and we reviewed their limitations throughout the paper. Among them, we focused on the OOD problem arising from the widely used zero erasure scheme, which results in misleading interpretation. To the best of our knowledge, neither the OOD problem has been raised in interpreting NLP models nor the attempt to resolve it has been undertaken. Our proposed input marginalization, which can mitigate the OOD problem, can result in a faithful interpretation, thereby enabling better understanding of "black box" DNNs.

The scope of this study was primarily focused on interpreting DNNs for sentiment analysis and natural language inference. Regarding the model-agnostic and task-agnostic properties of our method, they are applicable to any types of NLP model for various tasks, such as neural machine translation and visual question answering. It will be meaningful to interpret the state-of-the-art models such as XLNet (Yang et al., 2019) and ELECTRA (Clark et al., 2019). In addition, as experimentally analyzed, the interpretation result of our method is affected by the likelihood modeling performance. We can expect even more faithful interpretation if the modeling performance improves.

Appendix

A1 Details of the experimental setup

A1.1 Dataset description

Stanford Sentiment Treebank (SST-2) SST-2 corpus (Socher et al., 2013) contains 11,855 sentences of movie review. Each sentence is labeled with five sentiments: very positive, positive, neutral, negative, very negative. We merged very positive and positive into positive and very negative and negative into negative, thereby resulting in binary class.

Stanford Natural Language Inference (SNLI) SNLI corpus (Young et al., 2014) contains 570k English sentence pairs annotated with one of three relationships: entailment, contradiction, and neutral. We used the dataset with the same split provided by Torchtext (Paszke et al., 2019). The dataset distributions used to train the target models are as below:

Table A1: Dataset distribution

	Train	**Dev**	**Test**	**Total**
SST-2	6,920	872	1,821	9,613
SNLI	549,367	9,842	9,824	569,033

A1.2 Target model architecture

We trained three models for SST-2 and one model for SNLI. For all models, we set an embedding dimension to 100 and activation function to ReLU. An output dimension was set to two and three for SST-2 and SNLI, respectively. We note that we did not conduct extensive hyper-parameter search because the accuracy is not important for evaluating our method.

LSTM for SST-2 Bidirectional LSTM with attention mechanism consists of an embedding layer, two bidirectional LSTM layers with a hidden dimension of 200, and a fully connected (FC) layer. The dropout rate for the embedding layer, LSTM, and the fully connected layer was 0.3, 0.5, and 0.5, respectively.

BERT We fine-tuned BERT-base classifier whose pre-trained weights are provided by Wolf et al. (2019) for five epochs.

CNN CNN consists of an embedding layer, three convolution layers and an FC layer. Each convolution layer contains 100 filters with size three, four, and five, respectively. The dropout rate for the convolution layer was set to 0.5.

LSTM for SNLI LSTM for SNLI comprises an embedding layer, a projection layer, a bidirectional LSTM layer, and four FC layers. The projection layer is an FC layer with an output dimension of 300. The encoder consists of one bidirectional LSTM layer with a hidden dimension of 300. Both premise and hypothesis are encoded with the same encoder and concatenated before the FC layer.

A1.3 Computing infrastructure

For all experiments, we used Ubuntu 16.04 on Intel i7-9800X(3.8GHz, 16.5MB) with four GTX Titan X Pascal (12GB).

A2 Interpretation results

A2.1 Statistical comparison

Pearson correlation coefficient and Spearman rank order correlation between the attribution scores from our method and zero erasure are shown in the table below.

Table A2: Dataset distribution

	Pearson	**Spearman**
Corr coef	0.5877	0.5383

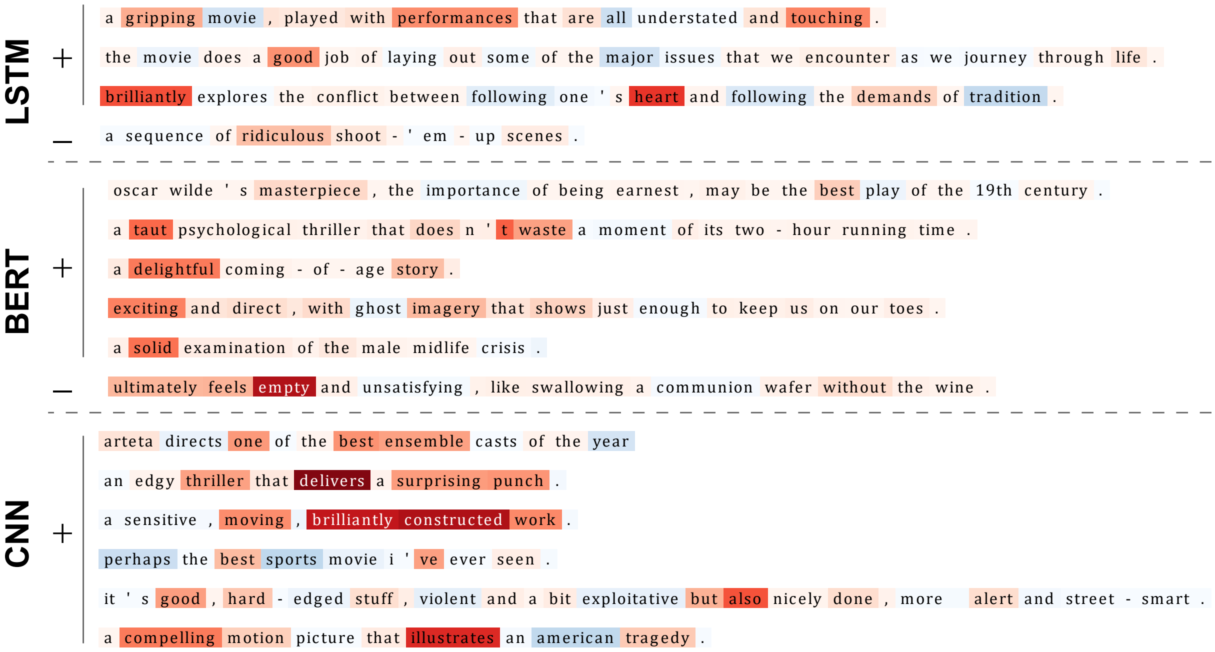
A2.2 Additional comparison

We additionally compared our method to existing interpretation methods for further comparison, including DeepLIFT (DLIFT) (Shrikumar et al., 2017), Integrated Gradients (IG) (Sundararajan et al., 2017), gradient Shapley (SHAP) (Lundberg and Lee, 2017), and LIME (Ribeiro et al., 2016) We used a widely used open source interpretable AI library, captum (Kokhlikyan et al., 2020). The table below shows that our method exhibited the lowest AUC_{rep} among various baselines (lower is better).

Table A3: Quantitative comparison to the existing methods

Methods				
DLIFT	IG	SHAP	LIME	Ours
0.5261	0.5387	0.5588	0.6618	**0.4971**

A2.3 Interpretation results of SST-2



a gripping movie , played with performances that are all understated and touching .

the movie does a good job of laying out some of the major issues that we encounter as we journey through life .

brilliantly explores the conflict between following one ' s heart and following the demands of tradition .

a sequence of ridiculous shoot - ' em - up scenes .

oscar wilde ' s masterpiece , the importance of being earnest , may be the best play of the 19th century .

a taut psychological thriller that does n ' t waste a moment of its two - hour running time .

a delightful coming - of - age story .

exciting and direct , with ghost imagery that shows just enough to keep us on our toes .

a solid examination of the male midlife crisis .

ultimately feels empty and unsatisfying , like swallowing a communion wafer without the wine .

arteta directs one of the best ensemble casts of the year

an edgy thriller that delivers a surprising punch .

a sensitive , moving , brilliantly constructed work .

perhaps the best sports movie i ' ve ever seen .

it ' s good , hard - edged stuff , violent and a bit exploitative but also nicely done , more alert and street - smart .

a compelling motion picture that illustrates an american tragedy .

Figure A1: Interpretations of SST-2 trained models using input marginalization (ours). The characters before sentences denote the target class of the interpretation: + denotes positive and - denotes negative. Red and blue color denote a positive and negative contribution to the predicted class. All sentences were correctly classified.

A2.4 Interpretation results of SNLI

Contradiction

pre: woman in white in foreground and a man slightly behind walking with a sign for john ' s pizza and gyro in the background .
hypo: olympic swimming .

pre: woman in white in foreground and a man slightly behind walking with a sign for john ' s pizza and gyro in the background .
hypo: the man is sitting down while he has a sign for john ' s pizza and gyro in his arms .

pre: bicyclists waiting at an intersection .
hypo: bicyclists riding along a freeway .

pre: bicyclists waiting at an intersection .
hypo: the bicyclists ride through the mall on their bikes .

pre: bicyclists waiting at an intersection .
hypo: the bicyclists are dead .

Entailment

pre: two young girls are playing outside in a non - urban environment .
hypo: two girls are playing outside .

pre: one man sits inside and plays the banjo , there are trees behind him outside .
hypo: a male sitting indoors .

pre: two children play outside in a field .
hypo: kids are playing outdoors .

pre: a man with wild hair rocks a show playing a guitar center stage .
hypo: a guy stands on stage with his guitar .

Neutral

pre: many people relax in the yard .
hypo: a family enjoys the sunny day in their backyard .

pre: a woman stands behind an outdoor grill with a blue basket of food in her hands .
hypo: a woman holding a blue basket full of food at a family cookout .

pre: a man walking proudly down the street .
hypo: the man is part of the gay pride parade .

pre: woman in white in foreground and a man slightly behind walking with a sign for john ' s pizza and gyro in the background .
hypo: they are working for john ' s pizza .

Figure A2: Interpretations of models trained for SNLI using input marginalization (ours). Red and blue color denote a positive and negative contribution to the predicted class. All sentences were correctly classified.

A2.5 Comparison to zero erasure

Zero a quiet , pure , elliptical film
Marg a quiet , pure , elliptical film

Generating Label Cohesive and Well-Formed Adversarial Claims

Pepa Atanasova[*] and **Dustin Wright**[*] and **Isabelle Augenstein**
Dept. of Computer Science
University of Copenhagen
Denmark
`{pepa|dw|augenstein}@di.ku.dk`

Abstract

Adversarial attacks reveal important vulnerabilities and flaws of trained models. One potent type of attack are *universal adversarial triggers*, which are individual n-grams that, when appended to instances of a class under attack, can trick a model into predicting a target class. However, for inference tasks such as fact checking, these triggers often inadvertently invert the meaning of instances they are inserted in. In addition, such attacks produce semantically nonsensical inputs, as they simply concatenate triggers to existing samples. Here, we investigate how to generate adversarial attacks against fact checking systems that preserve the ground truth meaning and are semantically valid. We extend the HotFlip attack algorithm used for universal trigger generation by jointly minimizing the target class loss of a fact checking model and the entailment class loss of an auxiliary natural language inference model. We then train a conditional language model to generate semantically valid statements, which include the found universal triggers. We find that the generated attacks maintain the directionality and semantic validity of the claim better than previous work.

1 Introduction

Adversarial examples (Goodfellow et al., 2015; Szegedy et al., 2013) are deceptive model inputs designed to mislead an ML system into making the wrong prediction. They expose regions of the input space that are outside the training data distribution where the model is unstable. It is important to reveal such vulnerabilities and correct for them, especially for tasks such as fact checking (FC).

In this paper, we explore the vulnerabilities of FC models trained on the FEVER dataset (Thorne et al., 2018), where the inference between a claim and evidence text is predicted. We particularly construct *universal adversarial triggers* (Wallace et al., 2019) – single n-grams appended to the input text that can shift the prediction of a model from a source class to a target one. Such adversarial examples are of particular concern, as they can apply to a large number of input instances.

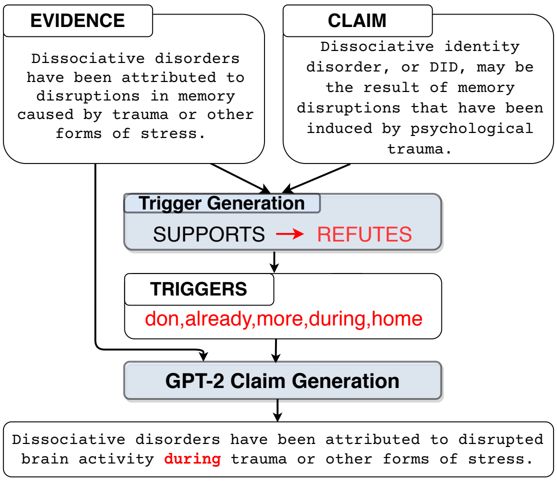

Figure 1: High level overview of our method. First, universal triggers are discovered for flipping a source to a target label (e.g. SUPPORTS → REFUTES). These triggers are then used to condition the GPT-2 language model to generate novel claims with the original label, including at least one of the found triggers.

However, we find that the triggers also change the meaning of the claim such that the true label is in fact the target class. For example, when attacking a claim-evidence pair with a 'SUPPORTS' label, a common unigram found to be a universal trigger when switching the label to 'REFUTES' is 'none'. Prepending this token to the claim drastically changes the meaning of the claim such that the new claim is in fact a valid 'REFUTES' claim as opposed to an adversarial 'SUPPORTS' claim. Furthermore, we find adversarial examples constructed in this way to be nonsensical, as a new token is simply being attached to an existing claim.

---

[*] denotes equal contribution

Our **contributions** are as follows. We *preserve the meaning* of the source text and *improve the semantic validity* of universal adversarial triggers to automatically construct more potent adversarial examples. This is accomplished via: 1) a *novel extension to the HotFlip attack* (Ebrahimi et al., 2018), where we jointly minimize the target class loss of a FC model and the attacked class loss of a natural language inference model; 2) a *conditional language model* trained using GPT-2 (Radford et al., 2019), which takes trigger tokens and a piece of evidence, and generates a semantically coherent new claim containing at least one trigger. The resulting triggers maintain potency against a FC model while preserving the original claim label. Moreover, the conditional language model produces semantically coherent adversarial examples containing triggers, on which a FC model performs 23.8% worse than with the original FEVER claims. The code for the paper is publicly available.[1]

2 Related Work

2.1 Adversarial Examples

Adversarial examples for NLP systems can be constructed as automatically generated text (Ren et al., 2019) or perturbations of existing input instances (Jin et al.; Ebrahimi et al., 2018). For a detailed literature overview, see Zhang et al. (2019).

One potent type of adversarial techniques are universal adversarial attacks (Gao and Oates, 2019; Wallace et al., 2019) – single perturbation changes that can be applied to a large number of input instances and that cause significant performance decreases of the model under attack. Wallace et al. (2019) find universal adversarial triggers that can change the prediction of the model using the HotFlip algorithm (Ebrahimi et al., 2018).

However, for NLI tasks, they also change the meaning of the instance they are appended to, and the prediction of the model remains correct. Michel et al. (2019) address this by exploring only perturbed instances in the neighborhood of the original one. Their approach is for instance-dependent attacks, whereas we suggest finding *universal* adversarial triggers that also preserve the original meaning of input instances. Another approach to this are rule-based perturbations of the input (Ribeiro et al., 2018) or imposing adversarial constraints on the produced perturbations (Dia et al., 2019). By contrast, we extend the HotFlip method by including an auxiliary Semantic Textual Similarity (STS) objective. We additionally use the extracted universal adversarial triggers to generate adversarial examples with low perplexity.

2.2 Fact Checking

Fact checking systems consist of components to identify check-worthy claims (Atanasova et al., 2018; Hansen et al., 2019; Wright and Augenstein, 2020), retrieve and rank evidence documents (Yin and Roth, 2018; Allein et al., 2020), determine the relationship between claims and evidence documents (Bowman et al., 2015; Augenstein et al., 2016; Baly et al., 2018), and finally predict the claims' veracity (Thorne et al., 2018; Augenstein et al., 2019). As this is a relatively involved task, models easily overfit to shallow textual patterns, necessitating the need for adversarial examples to evaluate the limits of their performance.

Thorne et al. (2019a) are the first to propose hand-crafted adversarial attacks. They follow up on this with the FEVER 2.0 task (Thorne et al., 2019b), where participants design adversarial attacks for existing FC systems. The first two winning systems (Niewinski et al., 2019; Hidey et al., 2020) produce claims requiring multi-hop reasoning, which has been shown to be challenging for fact checking models (Ostrowski et al., 2020). The other remaining system (Kim and Allan, 2019) generates adversarial attacks manually. We instead find universal adversarial attacks that can be applied to most existing inputs while markedly decreasing fact checking performance. Niewinski et al. (2019) additionally feed a pre-trained GPT-2 model with the target label of the instance along with the text for conditional adversarial claim generation. Conditional language generation has also been employed by Keskar et al. (2019) to control the style, content, and the task-specific behavior of a Transformer.

3 Methods

3.1 Models

We take a RoBERTa (Liu et al., 2019) model pretrained with a LM objective and fine-tune it to classify claim-evidence pairs from the FEVER dataset as SUPPORTS, REFUTES, and NOT ENOUGH INFO (NEI). The evidence used is the gold evidence, available for the SUPPORTS and REFUTES classes. For NEI claims, we use the system of Malon (2018) to retrieve evidence sentences. To measure the semantic similarity between the claim

---

[1] https://github.com/copenlu/fever-adversarial-attacks

before and after prepending a trigger, we use a large RoBERTa model fine-tuned on the Semantic Textual Similarity Task.[2] For further details, we refer the reader to §A.1.

3.2 Universal Adversarial Triggers Method

The Universal Adversarial Triggers method is developed to find n-gram trigger tokens $\mathbf{t}_\alpha$, which, appended to the original input x, $f(x) = y$, cause the model to predict a target class $\widetilde{y} : f(t_\alpha, x) = \widetilde{y}$. In our work, we generate unigram triggers, as generating longer triggers would require additional objectives to later produce well-formed adversarial claims. We start by initializing the triggers with the token 'a'. Then, we update the embeddings of the initial trigger tokens $\mathbf{e}_\alpha$ with embeddings $\mathbf{e}_{w_i}$ of candidate adversarial trigger tokens w_i that minimize the loss $\mathcal{L}$ for the target class $\widetilde{y}$. Following the HotFlip algorithm, we reduce the brute-force optimization problem using a first-order Taylor approximation around the initial trigger embeddings:

$$\underset{\mathbf{w}_i \in \mathcal{V}}{\arg\min} \left[\mathbf{e}_{w_i} - \mathbf{e}_\alpha\right]^\top \nabla_{\mathbf{e}_\alpha} \mathcal{L} \tag{1}$$

where $\mathcal{V}$ is the vocabulary of the RoBERTa model and $\nabla_{\mathbf{e}_\alpha} \mathcal{L}$ is the average gradient of the task loss accumulated for all batches. This approximation allows for a $\mathcal{O}(|\mathcal{V}|)$ space complexity of the brute-force candidate trigger search.

While HotFlip finds universal adversarial triggers that successfully fool the model for many instances, we find that the most potent triggers are often negation words, e.g., 'not', 'neither', 'nowhere'. Such triggers change the meaning of the text, making the prediction of the target class correct. Ideally, adversarial triggers would preserve the original label of the claim. To this end, we propose to include an auxiliary STS model objective when searching for candidate triggers. The additional objective is used to minimize the loss $\mathcal{L}'$ for the maximum similarity score (5 out of 0w) between the original claim and the claim with the prepended trigger. Thus, we arrive at the combined optimization problem:

$$\underset{\mathbf{w}_i \in \mathcal{V}}{\arg\min} ([\mathbf{e}_{w_i} - \mathbf{e}_\alpha]^\top \nabla_{\mathbf{e}_\alpha} \mathcal{L} + [\mathbf{o}_{w_i} - \mathbf{o}_\alpha]^\top \nabla_{\mathbf{o}_\alpha} \mathcal{L}') \tag{2}$$

where $\mathbf{o}_w$ is the STS model embedding of word w. For the initial trigger token, we use "[MASK]" as STS selects candidates from the neighborhood of the initial token.

3.3 Claim Generation

In addition to finding highly potent adversarial triggers, it is also of interest to generate coherent statements containing the triggers. To accomplish this, we use the HuggingFace implementation of the GPT-2 language model (Radford et al., 2019; Wolf et al., 2019), a large transformer-based language model trained on 40GB of text. The objective is to generate a coherent claim, which either entails, refutes, or is unrelated a given piece of evidence, while also including trigger words.

The language model is first fine tuned on the FEVER FC corpus with a specific input format. FEVER consists of claims and evidence with the labels `SUPPORTS`, `REFUTES`, or `NOT ENOUGH INFO` (NEI). We first concatenate evidence and claims with a special token. Next, to encourage generation of claims with certain tokens, a sequence of tokens separated by commas is prepended to the input. For training, the sequence consists of a single token randomly selected from the original claim, and four random tokens from the vocabulary. This encourages the model to only select the one token most likely to form a coherent and correct claim. The final input format is `[trigger tokens]`||`[evidence]`||`[claim]`. Adversarial claims are then generated by providing an initial input of a series of five comma-separated trigger tokens plus evidence, and progressively generating the rest of the sequence. Subsequently, the set of generated claims is pruned to include only those which contain a trigger token, and constitute the desired label. The latter is ensured by passing both evidence and claim through an external NLI model trained on SNLI (Bowman et al., 2015).

4 Results

We present results for universal adversarial trigger generation and coherent claim generation. Results are measured using the original FC model on claims with added triggers and generated claims (macro F1). We also measure how well the added triggers maintain the claim's original label (semantic similarity score), the perplexity (PPL) of the claims with prepended triggers, and the semantic quality of generated claims (manual annotation). PPL is measured with a pretrained RoBERTa LM.

4.1 Adversarial Triggers

Table 1 presents the results of applying universal adversarial triggers to claims from the source class.

---

[2] https://huggingface.co/SparkBeyond/roberta-large-sts-b

The top-performing triggers for each direction are found in §A.2. The adversarial method with a single FC objective successfully deteriorates model performance by a margin of 0.264 F1 score overall. The biggest performance decrease is when the adversarial triggers are constructed to flip the predicted class from SUPPORTS to REFUTES. We also find that 8 out of 18 triggers from the top-3 triggers for each direction, are negation words such as 'nothing', 'nobody', 'neither', 'nowhere' (see Table 4 in the appendix). The first of these triggers decreases the performance of the model to 0.014 in F1. While this is a significant performance drop, these triggers also flip the meaning of the text. The latter is again indicated by the decrease of the semantic similarity between the claim before and after prepending a trigger token, which is the largest for the SUPPORTS to REFUTES direction. We hypothesise that the success of the best performing triggers is partly due to the meaning of the text being flipped.

Including the auxiliary STS objective increases the similarity between the claim before and after prepending the trigger for five out of six directions. Moreover, we find that now only one out of the 18 top-3 triggers for each direction are negation words. Intuitively, these adversarial triggers are worse at fooling the FC model as they also have to preserve the label of the original claim. Notably, for the SUPPORTS to REFUTES direction the trigger performance is decreased with a margin of 0.642 compared to the single FC objective. We conclude that including the STS objective for generating Universal Adversarial triggers helps to preserve semantic similarity with the original claim, but also makes it harder to both find triggers preserving the label of the claim while substantially decreasing the performance of the model.

4.2 Generation

We use the method described in §3.3 to generate 156 claims using triggers found with the additional STS objective, and 156 claims without. 52 claims are generated for each class (26 flipping to one class, 26 flipping to the other). A different GPT-2 model is trained to generate claims for each specific class, with triggers specific to attacking that class used as input. The generated claims are annotated manually (see §B.3 for the procedure). The overall average claim quality is 4.48, indicating that most generated statements are highly semantically coherent. The macro F1 of the generative model w.r.t. the intended label is 58.9 overall. For the model without the STS objective, the macro F1 is 56.6, and for the model with the STS objective, it is 60.7, meaning that using triggers found with the STS objective helps the generated claims to retain their intended label.

Class	**F1**	**STS**	**PPL**

Table 1: Universal Adversarial Trigger method performance. Triggers are generated given claims from a source class to fool the classifier to predict a target class (column *Class*, with SUPPORTS (S), REFUTES (R), NEI). The results are averaged over the top 10 triggers.

We measure the performance of the original FC model on generated claims (Table 3). We compare between using triggers that are generated with the STS objective (Ex2) and without (Ex1). In both cases, the adversarial claims effectively fool the FC model, which performs 38.4% worse and 23.8% worse on Ex1 and Ex2, respectively. Additionally, the overall sentence quality increases when the triggers are found with the STS objective (Ex2). The FC model's performance is higher on claims using triggers generated with the STS objective but still significantly worse than on the original claims. We provide examples of generated claims with their evidence in Table 2.

Comparing FC performance with our generated claims vs. those from the development set of adversarial claims from the FEVER shared task , we see similar drops in performance (0.600 and 0.644 macro F1, respectively). While the adversarial triggers from FEVER cause a larger performance drop,

Table 3: FC performance for generated claims.

they were manually selected to meet the label coherence and grammatical correctness requirements. Conversely, we automatically generate claims that meet these requirements.

5 Conclusion

We present a method for automatically generating highly potent, well-formed, label cohesive claims for FC. We improve upon previous work on universal adversarial triggers by determining how to construct valid claims containing a trigger word. Our method is fully automatic, whereas previous work on generating claims for fact checking is generally rule-based or requires manual intervention. As FC is only one test bed for adversarial attacks, it would be interesting to test this method on other NLP tasks requiring semantic understanding such as question answering to better understand shortcomings of models.

A Appendices

A.1 Implementation Details

Models. The RoBERTa FC model (125M parameters) is fine-tuned with a batch size of 8, learning rate of 2e-5 and for a total of 4 epochs, where the epoch with the best performance is saved. We used the implementation provided by HuggingFace library. We performed a grid hyper-parameter search for the learning rate between the values 1e-5, 2e-5, and 3e-5. The average time for training a model with one set of hyperparameters is 155 minutes (±3). The average accuracy over the different hyperparameter runs is 0.862(± 0.005) F1 score on the validation set.

For the models that measure the perplexity and the semantical similarity we use the pretrained models provided by HuggingFace– RoBERTa large model (125M parameters) fine tuned on the STS-b task and RoBERTa base model (355M parameters) pretrained on a LM objective.

We used the HuggingFace implementation of the small GPT-2 model, which consists of 124,439,808 parameters and is fine-tuned with a batch size of 4, learning rate of 3e-5, and for a total of 20 epochs. We perform early stopping on the loss of the model on a set of validation data. The average validation loss is 0.910. The average runtime for training one of the models is 31 hours and 28 minutes.

We note that, the intermediate models used in this work and described in this section, are trained on large relatively general-purpose datasets. While, they can make some mistakes, they work well enough and using them, we don't have to rely on additional human annotations for the intermediate task.

Adversarial Triggers. The adversarial triggers are generated based on instances from the validation set. We run the algorithm for three epochs to allow for the adversarial triggers to converge. At each epoch the initial trigger is updated with the best performing trigger for the epoch (according to the loss of the FC or FC+STS objective). At the last step, we select only the top 10 triggers and remove any that have a negative loss. We choose the top 10 triggers as those are the most potent ones, adding more than top ten of the triggers preserves the same tendencies in the results, but smooths them as further down the list of adversarial attacks, the triggers do not decrease the performance of the model substantially. This is also supported by related literature (Wallace et al., 2019), where only the top few triggers are selected.

The adversarial triggers method is run for 28.75 (± 1.47) minutes for with the FC objective and 168.6(± 28.44) minutes for the FC+STS objective. We perform the trigger generation with a batch size of four. We additionally normalize the loss for each objective to be in the range [0,1] and also re-weight the losses with a wieht of 0.6 for the FC loss and a weight of 0.4 for the SST loss as when generated with an equal weight, the SST loss tends to preserve the same initial token in all epochs.

Datasets. The datasets used for training the FC model consist of 161,249 SUPPORTS, 60,227 REFUTES, and 69,885 NEI claims for the training split; 6,207 SUPPORTS, 6,235 REFUTES, and 6,554 NEI claims for the dev set; 6,291 SUPPORTS, 5,992 REFUTES, and 6522 NEI claims. The evidence for each claim is the gold evidence provided from the FEVER dataset, which is available for REFUTES and SUPPORTS claims. When there is more than one annotation of different evidence sentences for an instance, we include them as separate instances in the datasets. For NEI claims, we use the system of Malon (2018) to retrieve evidence sentences.

A.2 Top Adversarial Triggers

Table 4 presents the top adversarial triggers for each direction found with the Universal Adversarial Triggers method. It offers an additional way of estimating the effectiveness of the STS objective by comparing the number of negation words generated by the basic model (8) and the STS objective (2) in the top-3 triggers for each direction.

B Supplemental Material

B.1 Computing Infrastructure

All experiments were run on a shared cluster. Requested jobs consisted of 16GB of RAM and 4 Intel Xeon Silver 4110 CPUs. We used two NVIDIA Titan RTX GPUs with 12GB of RAM for training GPT-2 and one NVIDIA Titan X GPU with 8GB of RAM for training the FC models and finding the universal adversarial triggers.

B.2 Evaluation Metrics

The primary evaluation metric used was macro-F1 score. We used the sklearn implementation of `precision_recall_fscore_support`, which can be found here: `https://scikit-learn.org/stable/modules/generated/sklearn.`

`metrics.precision_recall_fscore_support.html`. Briefly:

$$p = \frac{tp}{tp + fp}$$

$$r = \frac{tp}{tp + fn}$$

$$F1 = \frac{2 * p * r}{p + r}$$

where tp are true positives, fp are false positives, and fn are false negatives.

B.3 Manual Evaluation

After generating the claims, two independent annotators label the overall claim quality (score of 1-5) and the true label for the claim. The inter-annotator agreement for the quality label using Krippendorff's alpha is 0.54 for the quality score and 0.38 for the claim label. Given this, we take the average of the two annotator's scores for the final quality score and have a third expert annotator examine and select the best label for each contested claim label.

Abstract

Existing algorithms for aligning cross-lingual word vector spaces assume that vector spaces are approximately isomorphic. As a result, they perform poorly or fail completely on non-isomorphic spaces. Such non-isomorphism has been hypothesised to result from typological differences between languages. In this work, we ask whether non-isomorphism is also crucially *a sign of degenerate word vector spaces*. We present a series of experiments across diverse languages which show that variance in performance across language pairs is not only due to typological differences, but can mostly be attributed to the size of the monolingual resources available, and to the properties and duration of monolingual training (e.g. "under-training").

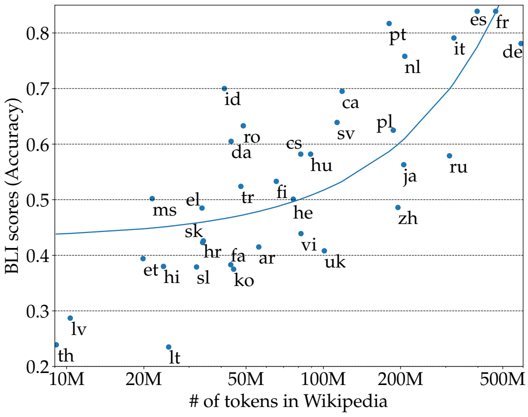

Figure 1: Performance of a state-of-the-art BLI model mapping from English to a target language and the size of the target language Wikipedia are correlated. Linear fit shown as a blue line (log scale).

1 Introduction

Word embeddings have been argued to reflect how language users organise concepts (Mandera et al., 2017; Torabi Asr et al., 2018). The extent to which they really do so has been evaluated, e.g., using semantic word similarity and association norms (Hill et al., 2015; Gerz et al., 2016), and word analogy benchmarks (Mikolov et al., 2013c). If word embeddings reflect more or less language-independent conceptual organisations, word embeddings in different languages can be expected to be near-isomorphic. Researchers have exploited this to learn linear transformations between such spaces (Mikolov et al., 2013a; Glavaš et al., 2019), which have been used to induce bilingual dictionaries, as well as to facilitate multilingual modeling and cross-lingual transfer (Ruder et al., 2019).

In this paper, we show that near-isomorphism arises only with sufficient amounts of training. This is of practical interest for applications of linear alignment methods for cross-lingual word embeddings. It furthermore provides us with an explanation for reported failures to align word vector spaces in different languages (Søgaard et al., 2018; Artetxe et al., 2018a), which has so far been largely attributed *only* to inherent typological differences.

In fact, the amount of data used to induce the monolingual embeddings is predictive of the quality of the aligned cross-lingual word embeddings, as evaluated on bilingual lexicon induction (BLI). Consider, for motivation, Figure 1; it shows the performance of a state-of-the-art alignment method—RCSLS with iterative normalisation (Zhang et al., 2019)—on mapping English embeddings onto embeddings in other languages, and its correlation ($\rho = 0.72$) with the size of the tokenised target language Polyglot Wikipedia (Al-Rfou et al., 2013).

We investigate to what extent the amount of data available for some languages and corresponding training conditions provide a *sufficient* explanation for the variance in reported results; that is, whether it is the full story or not: The answer is 'almost',

that is, its interplay with inherent typological differences does have a crucial impact on the 'alignability' of monolingual vector spaces.

We first discuss current standard methods of quantifying the degree of near-isomorphism between word vector spaces (§2.1). We then outline training settings that may influence isomorphism (§2.2) and present a novel experimental protocol for learning cross-lingual word embeddings that simulates a low-resource environment, and also controls for topical skew and differences in morphological complexity (§3). We focus on two groups of languages: **1)** Spanish, Basque, Galician, and Quechua, and **2)** Bengali, Tamil, and Urdu, as these are arguably spoken in culturally related regions, but have very different morphology. Our experiments, among other findings, indicate that a low-resource version of Spanish is as difficult to align to English as Quechua, challenging the assumption from prior work that the primary issue to resolve in cross-lingual word embedding learning is language dissimilarity (instead of, e.g., procuring additional raw data for embedding training). We also show that by controlling for different factors, we reduce the gap between aligning Spanish and Basque to English from 0.291 to 0.129. Similarly, under these controlled circumstances, we do not observe any substantial performance difference between aligning Spanish and Galician to English, or between aligning Bengali and Tamil to English.

We also investigate the learning dynamics of monolingual word embeddings and their impact on BLI performance and near-isomorphism of the resulting word vector spaces (§4), finding training duration, amount of monolingual resources, preprocessing, and self-learning all to have a large impact. The findings are verified across a set of typologically diverse languages, where we pair English with Spanish, Arabic, and Japanese.

We will release our new evaluation dictionaries and subsampled Wikipedias controlling for topical skew and morphological differences to facilitate future research at: `github.com/cambridgeltl/iso-study`.

2 Isomorphism of Vector Spaces

Studies analyzing the qualities of monolingual word vector spaces have focused on intrinsic tasks (Baroni et al., 2014), correlations (Tsvetkov et al., 2015), and subspaces (Yaghoobzadeh and Schütze, 2016). In the cross-lingual setting, the most important indicator for performance has been the *degree of isomorphism*, that is, how (topologically) similar the structures of the two vector spaces are.

Mapping-based approaches The prevalent way to learn a cross-lingual embedding space, especially in low-data regimes, is to learn a mapping between a source and a target embedding space (Mikolov et al., 2013a). Such mapping-based approaches assume that the monolingual embedding spaces are isomorphic, i.e., that one can be transformed into the other via a linear transformation (Xing et al., 2015; Artetxe et al., 2018a). Recent unsupervised approaches rely even more strongly on this assumption: They assume that the structures of the embedding spaces are so similar that they can be aligned by minimising the distance between the transformed source language and the target language embedding space (Zhang et al., 2017; Conneau et al., 2018; Xu et al., 2018; Alvarez-Melis and Jaakkola, 2018; Hartmann et al., 2019).

2.1 Quantifying Isomorphism

We employ measures that quantify isomorphism in three distinct ways—based on graphs, metric spaces, and vector similarity.

Eigenvector similarity (Søgaard et al., 2018) Eigenvector similarity (EVS) estimates the degree of isomorphism based on properties of the nearest neighbour graphs of the two embedding spaces. We first length-normalise embeddings in both embedding spaces and compute the nearest neighbour graphs on a subset of the top most frequent N words. We then calculate the Laplacian matrices L_1 and L_2 of each graph. For L_1, we find the smallest k_1 such that the sum of its k_1 largest eigenvalues $\sum_{i=1}^{k_1} \lambda_{1i}$ is at least 90% of the sum of all its eigenvalues. We proceed analogously for k_2 and set $k = \min(k_1, k_2)$. The eigenvector similarity metric Δ is now the sum of the squared differences of the k largest Laplacian eigenvalues: $\Delta = \sum_{i=1}^{k}(\lambda_{1i} - \lambda_{2i})^2$. The lower Δ, the *more* similar are the graphs and the more isomorphic are the embedding spaces.

Gromov-Hausdorff distance (Patra et al., 2019) The Hausdorff distance is a measure of the worst case distance between two metric spaces $\mathcal{X}$ and $\mathcal{Y}$ with a distance function d:

$$\mathcal{H}(\mathcal{X}, \mathcal{Y}) = \max\{ \sup_{x \in \mathcal{X}} \inf_{y \in \mathcal{Y}} d(x, y), \\ \sup_{y \in \mathcal{Y}} \inf_{x \in \mathcal{X}} d(x, y)\}$$

Intuitively, it measures the distance between the nearest neighbours that are farthest apart. The Gromov-Hausdorff distance (GH) in turn minimises this distance over all isometric transforms (orthogonal transforms in our case as we apply mean centering) $\mathcal{X}$ and $\mathcal{Y}$ as follows:

$$\mathcal{GH}(\mathcal{X},\mathcal{Y}) = \inf_{f,g} \mathcal{H}(f(\mathcal{X}), g(\mathcal{Y}))$$

In practice, $\mathcal{GH}$ is calculated by computing the Bottleneck distance between the metric spaces (Chazal et al., 2009; Patra et al., 2019).

Relational similarity As an alternative, we consider a simpler measure inspired by Zhang et al. (2019). This measure, dubbed RSIM, is based on the intuition that the similarity distributions of translations within each language should be similar. We first take M translation pairs (m_s, m_t) from our bilingual dictionary. We then calculate cosine similarities for each pair of words (m_s, n_s) on the source side where $m_s \neq n_s$ and do the same on the target side. Finally, we compute the Pearson correlation coefficient ρ of the sorted lists of similarity scores. Fully isomorphic embeddings would have a correlation of $\rho = 1.0$, and the correlation decreases with lower degrees of isomorphism.[1]

2.2 Isomorphism and Learning

Non-isomorphic embedding spaces have been attributed largely to typological differences between languages (Søgaard et al., 2018; Patra et al., 2019; Ormazabal et al., 2019). We hypothesise that non-isomorphism is not solely an intrinsic property of dissimilar languages, but also a result of a poorly conditioned training setup. In particular, languages that are regarded as being dissimilar to English, i.e. non-Indo-European languages, are often also low-resource languages where comparatively few samples for learning word embeddings are available.[2] As a result, embeddings trained for low-resource languages may often not match the quality of their high-resource counterparts, and may thus constitute the main challenge when mapping embedding spaces. To investigate this hypothesis, we consider different aspects of poor conditioning as follows.

Corpus size It has become standard to align monolingual word embeddings trained on Wikipedia (Glavaš et al., 2019; Zhang et al., 2019). As can be seen in Figure 1, and also in Table 1, Wikipedias of low-resource languages are more than a magnitude smaller than Wikipedias of high-resource languages.[3] Corpus size has been shown to play a role in the performance of monolingual embeddings (Sahlgren and Lenci, 2016), but it is unclear how it influences their structure and isomorphism.

Training duration As it is generally too expensive to tune hyper-parameters separately for each language, monolingual embeddings are typically trained for the same number of epochs in large-scale studies. As a result, word embeddings of low-resource languages may be "under-trained".

Preprocessing Different forms of preprocessing have been shown to aid in learning a mapping (Artetxe et al., 2018b; Vulić et al., 2019; Zhang et al., 2019). Consequently, they may also influence the isomorphism of the vector spaces.

Topical skew The Wikipedias of low-resource languages may be dominated by few contributors, skewed towards particular topics, or generated automatically.[4] Embeddings trained on different domains are known to be non-isomorphic (Søgaard et al., 2018; Vulić et al., 2019). A topical skew may thus also make embedding spaces harder to align.

3 Simulating Low-resource Settings

As low-resource languages—by definition—have only a limited amount of data available, we cannot easily control for all aspects using only a low-resource language. Instead, we modify the training setup of a high-resource language to simulate a low-resource scenario. For most of our experiments, we use English (EN) as the source language and modify the training setup of Spanish (ES). Additional results where we modify the training setup of English instead are available in the appendix; they further corroborate our key findings. We choose this language pair as both are similar, i.e. Indo-European, high-resource, and BLI performance is typically very high. Despite this high performance, unlike English, Spanish is a highly inflected language. In

---

[1] There are other measures that quantify similarity between word vectors spaces based on network modularity (Fujinuma et al., 2019), singular values obtained via SVD (Dubossarsky et al., 2020), and external resources such as sense-aligned corpora (Ammar et al., 2016), but we do not include them for brevity, and because they show similar relative trends.

[2] There are obvious exceptions to this, such as Mandarin.

[3] Recent initiatives replace training on Wikipedia with training on larger CommonCrawl data (Grave et al., 2018; Conneau et al., 2020), but the large differences in corpora sizes between high-resource and low-resource languages are not removed.

[4] As one prominent example, a bot has generated most articles in the Swedish, Cebuano, and Waray Wikipedias.

ES Wikipedia sample		
# Sentences	# Tokens	Comparable Wikis

500k	13.4M	Telugu, Tatar, Afrikaans
1M	26.8M	Armenian, Uzbek, Latvian
2M	53.7M	Croatian, Slovak, Malay
5M	134.1M	Finnish, Indonesian
10M	268.3M	Catalan, Ukrainian

Table 1: Spanish Wikipedia samples of different sizes and comparable Wikipedias in other languages.

order to inspect if similar patterns also hold across typologically more dissimilar languages, we also conduct simulation experiments with two other target languages with large Wikipedias in lieu of Spanish: Japanese (JA, an agglutinative language) and Arabic (AR, introflexive).

When controlling for *corpus size*, we subsample the target language (i.e., Spanish, Japanese, or Arabic) Wikipedia to obtain numbers of tokens comparable to low-resource languages as illustrated in Table 1. When controlling for *training duration*, we take snapshots of the "under-trained" vector spaces after seeing an exact number of M word tokens (i.e., after performing M *updates*).

To control for *topical skew*, we need to sample similar documents as in low-resource languages. To maximise topical overlap, we choose low-resource languages that are spoken in similar regions as Spanish and whose Wikipedias might thus also focus on similar topics—specifically Basque (EU), Galician (GL), and Quechua (QU). These four languages have very different morphology. Quechua is an agglutinative language, while Spanish, Galician, and Basque are highly inflected. Basque additionally employs case marking and derivation. If non-isomorphism was entirely explained by language dissimilarity, we would expect even low-resource versions of Spanish to have high BLI performance with English. We repeat the same experiment with another set of languages with distinct properties but spoken in similar regions: Bengali, Urdu, and Tamil.

Typological differences however, may still explain part of the difference in performance. For instance, as we cannot simulate Basque by changing the typological features of Spanish[5], we instead make Spanish, Basque, Galician, and Quechuan "morphologically similar": we remove inflections and case marking through lemmatisation. We follow the same process for Bengali, Urdu, and Tamil.

4 Experiments and Analyses

4.1 Experimental Setup

Embedding algorithm Previous work has shown that learning embedding spaces with different hyper-parameters leads to non-isomorphic spaces (Søgaard et al., 2018; Hartmann et al., 2018). To control for this aspect, we train monolingual embeddings with fastText in the standard setup (skip-gram, character n-grams of sizes 3 to 6, a learning rate of 0.025, 15 negative samples, a window size of 5) (Bojanowski et al., 2017).[6] Unless specified otherwise, we train for 15 epochs.

Mapping algorithm We use the supervised variant of VecMap (Artetxe et al., 2018a) for our experiments, which is a robust and competitive choice according to the recent empirical comparative studies (Glavaš et al., 2019; Vulić et al., 2019; Hartmann et al., 2019). VecMap learns an orthogonal transformation based on a seed translation dictionary with additional preprocessing and postprocessing steps, and it can additionally enable *self-learning* in multiple iterations. For further details we refer the reader to the original work (Artetxe et al., 2018a).

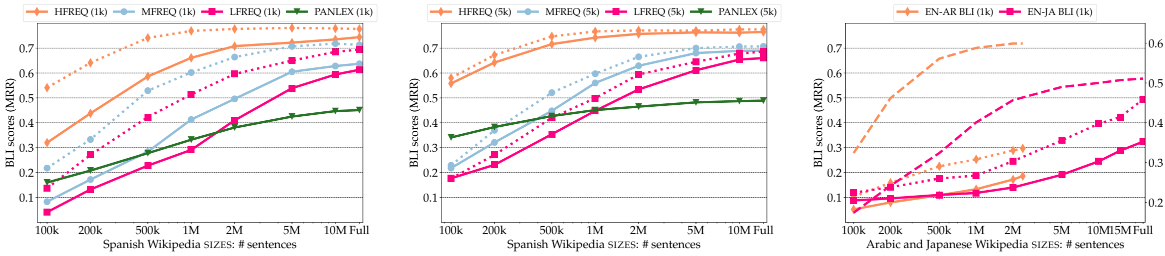
Evaluation We measure isomorphism between monolingual spaces using the previously described intrinsic measures: eigenvector similarity (EVS), Gromov-Hausdorff distance (GH), and relational similarity (RSIM). In addition, we evaluate on bilingual lexicon induction (BLI), a standard task for evaluating cross-lingual word representations. Given a list of N_s source words, the task is to find the corresponding translation in the target language as a nearest neighbour in the cross-lingual embedding space. The list of retrieved translations is then compared against a gold standard dictionary. Following prior work (Glavaš et al., 2019), we employ mean reciprocal rank (MRR) as evaluation measure, and use cosine similarity as similarity measure.

Training and test dictionaries Standard BLI test dictionaries over-emphasise frequent words (Czarnowska et al., 2019; Kementchedjhieva et al.,

---

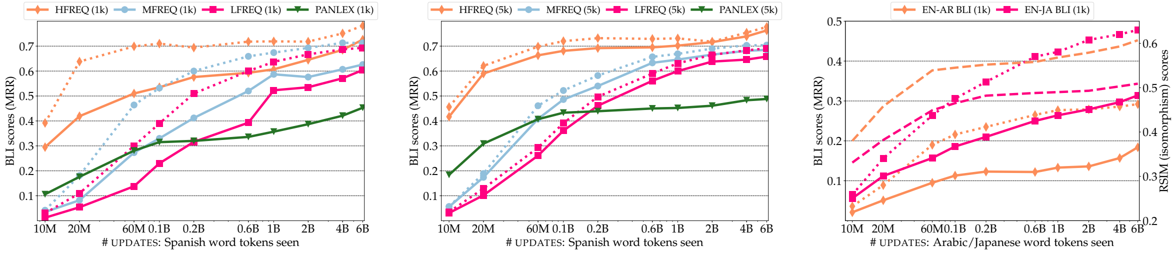
[5] Ravfogel et al. (2019) generate synthetic versions of English that differ from English in a single typological parameter. This process requires a treebank and is infeasible for all typological parameters of a language.

[6] We ran experiments and observed similar results with `word2vec` algorithms (Mikolov et al., 2013b), GloVe (Pennington et al., 2014) and fastText CBOW (Grave et al., 2018).



(a) EN → ES (1k) (b) EN → ES (5k) (c) EN → AR/JA (1k)

Figure 2: Impact of **dataset size** on BLI when aligning ES, AR, and JA vector spaces fully trained on corpora of different sizes (obtained through sampling from the full corpus) to an EN space fully trained on complete data. We report scores without self-learning (solid lines) and with self-learning (dotted lines; same colour) with seed dictionary sizes of **(a)** 1k and **(b)** 5k on our EN–ES BLI evaluation sets, while the corresponding isomorphism scores are provided in Figure 6 for clarity. **(c)** We again report scores without and with self-learning on EN–AR/JA BLI evaluation sets from the MUSE benchmark with 1k seed translation pairs. The results with 5k seed pairs for EN–AR/JA are available in the appendix. Dashed lines without any marks show isomorphism scores (computed by RSIM; higher is better) computed across different AR and JA snapshots.



(a) EN → ES (1k) (b) EN → ES (5k) (c) EN → AR/JA (1k)

Figure 3: Impact of **training duration** on BLI when aligning a partially trained Spanish (ES), Arabic (AR), and Japanese (JA) vector space, where snapshots are taken after seeing M word tokens in training, to the fully trained EN space. We report scores without self-learning (solid lines) and with self-learning (dotted lines; same colour) with seed dictionary sizes of **(a)** 1k and **(b)** 5k on our EN–ES BLI evaluation sets. For clarity, the corresponding isomorphism scores (and impact of training duration on isomorphism of vector spaces) over the same training snapshots for Spanish are shown in Figure 5. **(c)** We again report scores without and with self-learning on EN–AR/JA BLI evaluation sets from the MUSE benchmark with 1k seed translation pairs. The results with 5k seed pairs for EN–AR/JA are available in the appendix. Dashed lines without any marks show isomorphism scores (computed by RSIM; higher is better) computed across different AR and JA snapshots.

2019) whose neighbourhoods may be more isomorphic (Nakashole, 2018). We thus create new evaluation dictionaries for English–Spanish that consist of words in different frequency bins: we sample EN words for 300 translation pairs respectively from (i) the top 5k words of the full English Wikipedia (HFREQ); (ii) the interval [10k, 20k] (MFREQ); (iii) the interval [20k, 50k] (LFREQ). The entire dataset (ALL-FREQ; 900 pairs) consists of (i) + (ii) + (iii). We exclude named entities as they are over-represented in many test sets (Kementchedjhieva et al., 2019) and include nouns, verbs, adjectives, and adverbs in all three sets. All 900 words have been carefully manually translated and double-checked by a native Spanish speaker. There are no duplicates. We also report BLI results on the PanLex test lexicons (Vulić et al., 2019).

For English–Spanish, we create training dictionaries of sizes 1k and 5k based on PanLex (Kamholz et al., 2014) following Vulić et al. (2019). We exclude all words from ALL-FREQ from the training set. For EN–JA/AR BLI experiments, we rely on the standard training and test dictionaries from the MUSE benchmark (Conneau et al., 2018). Isomorphism scores with RSIM for EN–JA/AR are computed on a fixed random sample of 1k one-to-one translations from the respective MUSE training dictionary.[7] For learning monolingual embeddings, we use tokenised and sentence-split Polyglot

---

[7] Note that the *absolute* isomorphism scores between different pairs of languages are not directly comparable. The focus of the experiments is to follow the patterns of isomorphism change for each language pair separately.

Wikipedias (Al-Rfou et al., 2013). In §4.6, we process Wiki dumps, using Moses for tokenisation and sentence splitting. For lemmatisation of Spanish, Basque, Galician, Tamil, and Urdu we employ the UDPipe models (Straka and Straková, 2017). For Quechua and Bengali, we utilise the unsupervised Morfessor model provided by Polyglot NLP.

4.2 Impact of Corpus Size

To evaluate the impact of the corpus size on vector space isomorphism and BLI performance, we shuffle the target language (i.e., Spanish, Arabic, Japanese) Wikipedias and take N sentences where $N \in \{$10k, 20k, 500k, 100k, 500k, 1M, 2M, 10M, 15M$\}$ corresponding to a range of low-resource languages (see Table 1). Each smaller dataset is a subset of the larger one. We learn target language embeddings for each sample, map them to the English embeddings using dictionaries of sizes 1k and 5k and supervised VecMap with and without self-learning, and report their BLI performance and isomorphism scores in Figure 2. Both isomorphism and BLI scores improve with larger training resources.[8] Performance is higher with a larger training dictionary and self-learning but shows a similar convergence behaviour irrespective of these choices. What is more, despite different absolute scores, we observe a similar behaviour for all three language pairs, demonstrating that our intuition holds across typologically diverse languages.

In English–Spanish experiments performance on frequent words converges relatively early, between 1-2M sentences, while performance on medium and low-frequency words continues to increase with more training data and only plateaus around 10M sentences. Self-learning improves BLI scores, especially in low-data regimes. Note that isomorphism scores increase even as BLI scores saturate, which we discuss in more detail in §4.6.

4.3 Impact of Training Duration

To analyse the effect of under-training, we align English embeddings with target language embeddings that were trained for a certain number of iterations/updates and compute their BLI scores. The results for the three language pairs are provided in Figure 3. As monolingual vectors are trained for longer periods, BLI and isomorphism scores improve monotonously, and this holds for all three language pairs. Even after training for a large number of updates, BLI and isomorphism scores do not show clear signs of convergence. Self-learning again seems beneficial for BLI, especially at earlier, "under-training" stages.

4.4 Impact on Monolingual Mapping

As a control experiment, we repeat the two previous experiments controlling for corpus size and training duration when mapping an English embedding space to another EN embedding space. Previous work (Hartmann et al., 2018) has shown that EN embeddings learned with the same algorithm achieve a perfect monolingual "BLI" score of 1.0 (mapping EN words to the same EN word). If typological differences were the only factor affecting the structure of embedding spaces, we would thus expect to achieve a perfect score also for shorter training and smaller corpus sizes. For comparison, we also provide scores on a standard monolingual word similarity benchmark, SimVerb-3500 (Gerz et al., 2016). We show results in Figure 4. We observe that BLI scores only reach 1.0 after 0.4B and 0.6B updates for frequent and infrequent words or with corpus sizes of 1M and 5M sentences respectively, which is more than the size of most low-resource language Wikipedias (Table 1). This clearly shows that even aligning EN to EN is challenging in a low-resource setting due to different vector space structures, and we cannot attribute performance differences to typological differences in this case.

4.5 Impact of Preprocessing

We next evaluate the impact of different forms of preprocessing. Specifically, we consider: **1)** No preprocessing (unnormalised vectors); **2)** Length normalisation (L2) only (required for orthogonal Procrustes); **3)** L2, mean centering (MC), followed by L2; used by VecMap (Artetxe et al., 2018a); and **4)** Iterative normalisation (Zhang et al., 2019).

Iterative normalisation consists of multiple steps of L2 +MC +L2.[9] We have found it to achieve performance nearly identical to L2 +MC +L2, so we do not report it separately. We show results for the remaining methods in Figure 5 and Figure 6. For GH, using no preprocessing leads to much less isomorphic spaces, particularly for infrequent words during very early training. For RSIM with cosine similarity, L2 is equivalent to no normalisation as cosine applies length normalisation. L2 +MC +L2

---

[8] We observe similar trends when estimating isomorphism on the 5k and 10k most frequent words in both languages.

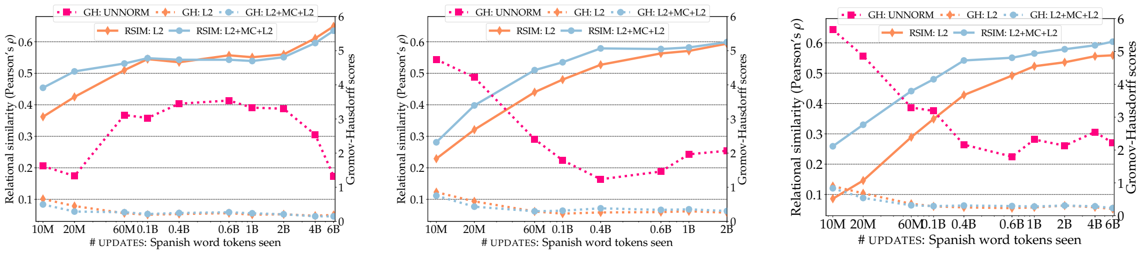
(a) Updates: EN (b) Different Wiki sizes: EN

Figure 4: Monolingual "control" experiments when aligning **(a)** a partially trained EN vector space (after M updates, that is, seen word tokens) to a fully trained vector space, and **(b)** an EN vector space fully trained on Wikipedia of different sizes (number of sentences). We show RSIM scores, mapping performance (i.e., monolingual "BLI") on HFREQ and LFREQ EN words, and monolingual word similarity scores on SimVerb-3500.



(a) HFREQ subset (ES) (b) MFREQ subset (ES) (c) LFREQ subset (ES)

Figure 5: Impact of different monolingual vector space preprocessing strategies on isomorphism scores when aligning a partially trained ES vector space, where snapshots are taken after seeing M word tokens in training, to a fully trained EN vector space. We report RSIM (solid; higher is better, i.e., more isomorphic) and GH distance (dashed; lower is better) on **(a)** HFREQ, **(b)** MFREQ, and **(c)** LFREQ test sets.

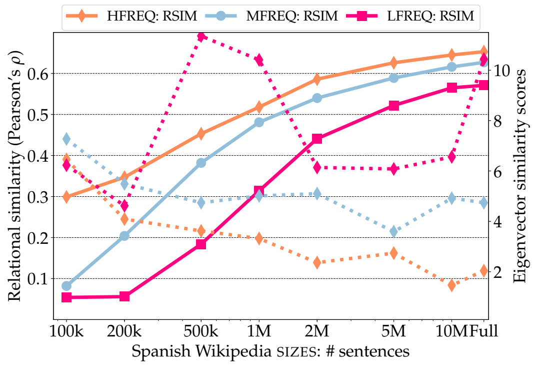


Figure 6: Impact of **dataset size** on vector space isomorphism when aligning an ES vector space fully trained on corpora of different sizes to an EN space fully trained on complete data. RSIM (solid lines; higher is better, i.e. more isomorphic) and Eigenvector similarity (dotted lines; lower is better) scores are reported. See Figures 2a-2b for the corresponding EN–ES BLI scores.

leads to slightly better isomorphism scores overall compared to L2 alone, though it has a slightly negative impact on Gromov-Hausdorff scores over longer training duration. Most importantly, the results demonstrate that such preprocessing steps do have a profound impact on near-isomorphism between monolingual vector spaces.

4.6 Impact of Topical Skew and Morphology

To control for topical skew, we sample the Spanish Wikipedia so that its topical distribution is as close as possible to that of low-resource languages spoken in similar regions—Basque, Galician, and Quechua. To this end, for each language pair, we first obtain document-level alignments using the Wiki API[10]. We only consider documents that occur in both languages. We then sample sentences from the ES Wikipedia so that the number of tokens per document and the number of tokens overall is similar to the document-aligned sample of the low-resource Wikipedia. This results in topic-adjusted Wikipedias consisting of 14.3M tokens for ES and

Figure 7: Monolingual learning dynamics and isomorphism (RSIM): We align a partially trained ES vector space, after seeing M word tokens, with a fully trained EN vector space, and evaluate on (a) HFREQ, (b) MFREQ, and (c) LFREQ test sets. While BLI performance plateaus, the isomorphism score (computed with RSIM) does not.

EU, 26.1M tokens for ES and GL, and 409k tokens for ES and QU. We additionally control for morphology by lemmatising the Wikipedia samples. For Spanish paired with each other language, we use training dictionaries that are similar in size and distribution. We learn monolingual embeddings on each subsampled Wikipedia corpus and align the resulting embeddings with English. We follow the same process to sample the Bengali Wikipedia to make its topical distribution aligned with the samples of the Urdu and Tamil Wikipedias: this results in topic-adjusted Wikipedias consisting of 3.8M tokens for Bengali–Urdu, and 8.1M word tokens for Bengali–Tamil.

The results are provided in Table 2. We observe that inequality in training resources accounts for a large part of the performance gap. Controlling for topical skew and morphology reduces the gap further and results in nearly identical performance for Spanish compared to Quechua and Galician, respectively. For Galician, lemmatisation slightly widens the gap, likely due to a weaker lemmatiser. For Basque, the remaining gap may be explained by the remaining typological differences between the two languages.[11] We also observe similar patterns in experiments with BN, UR, and TA in Table 2: training with comparable samples with additional morphological processing reduces the observed gap in performance between EN–BN and EN–TA, as well as between EN–BN and EN–UR. This again hints that other factors besides inherent language dissimilarity are at play and contribute to reduced isomorphism between embedding spaces.

Does isomorphism increase beyond convergence? In our experiments, we have measured how training monolingual word embeddings improves their isomorphism with embeddings in other languages. In doing so, we observed that *isomorphism increases even as validation (BLI) scores and training losses plateau* (see Figure 7). One possible explanation is that the random oscillations of SGD may lead the weights towards a high-entropy solution, which is more likely to be isomorphic. We highlight and discuss connections to work in opti-

---

[11] The drop in performance for EN–ES in the setup with full Wikipedias when we analyze Spanish and Quechua is attributed to a smaller and lower-quality training lexicon (to make it comparable to the corresponding EN–QU lexicon).

mization and generalization in the appendix. There, we also discuss more speculative implications and connections between (non-)isomorphism and vocabulary alignment across different languages.

5 Conclusion

We have provided a series of analyses that demonstrate together that non-isomorphism is not—as previously assumed—primarily a result of typological differences between languages, but in large part due to degenerate vector spaces and discrepancies between monolingual training regimes and data availability. Through controlled experiments in simulated low-resource scenarios, also involving languages with different morphology that are spoken in culturally related regions, we found that such vector spaces mainly arise from poor conditioning during training. The study suggests that besides improving our alignment algorithms for distant languages (Vulić et al., 2019), we should also focus on improving monolingual word vector spaces, and monolingual training conditions to unlock a true potential of cross-lingual learning.

A Further Discussion

A.1 Does isomorphism increase beyond convergence?

Recent studies of learning dynamics in deep neural nets observe that flatter optima generalise better than sharp optima (Zhang et al., 2018): intuitively, it is because sharp minima correspond to more complex, likely over-fitted, models. Zhang et al. (2018) show that analogous to the energy-entropy competition in statistical physics, wide but shallow minima can be optimal if the system is undersampled. SGD is assumed to generalise well because its inherent anisotropic noise biases it towards higher entropy minima. We hypothesise a similar explanation of our observations in terms of energy-entropy competition. Once loss is minimised, the random oscillations due to SGD noise lead the weights toward a high-entropy solution. We hypothesise monolingual high-entropy minima are more likely to be isomorphic. A related possible explanation is that the increased isomorphism results from model compression. This is analogous to the idea of two-phase learning (Shwartz-Ziv and Tishby, 2017), whereby the initial fast convergence of SGD is related to sufficiency of the representation, while the later asymptotic phase is related to compression of the activations.

A.2 Do vocabularies align?

If languages reflect the world, they should convey semantic knowledge in a similar way, and it is therefore reasonable to assume that with enough data, induced word embeddings should be isomorphic. On the other hand, if languages impose structure on our conceptualisation of the world, non-isomorphic word embeddings could easily arise. Studies that engage with speakers of different languages in the real world (Majid, 2010) are naturally limited in scope. Large-scale studies, on the other hand, have generally relied on distributional methods (Thompson et al., 2018), leading to a chicken-and-egg scenario. Vossen (2002) discuss mismatches between WordNets across languages, including examples of hypernyms without translation equivalents, e.g., *dedo* in Spanish (*fingers* and *toes* in English). Such examples break isomorphism between languages, but are relatively rare. Another approach to the question of vocabulary alignment is to study lexical organisation in bilinguals and how it differs from that of monolingual speakers (Pavlenko, 2009). While this paper obviously does not provide hard evidence for or against Sapir-Whorf-like hypotheses, our results suggest that the variation observed in BLI performance cannot trivially be attributed only to linguistic differences.

B Additional Experiments

Additional experiments that further support the main claims of the paper have been relegated to the appendix for clarity and compactness of presentation. We provide the following additional information:

- **Table** 3. It provides "reference" BLI scores and scores stemming from isomorphism measures when we align fully trained EN and ES spaces, that is, when we rely on standard 15 epochs of fastText training on respective Wikipedias.

- **Figure** 8 and **Figure** 9 show BLI and isomorphism scores at very early stages of training, both for EN and ES. In other words, one vector space is fully trained, while we take early-training snapshots (after seeing only 10M, 20M, . . . , 100M word tokens in training) of the other vector space. The results again stress the importance of training corpus size as well as training duration—early training stages clearly lead to suboptimal performance and non-isomorphic spaces. However, such shorter training durations (in terms of the number of tokens) are often encountered "in the wild" with low-resource languages.

- **Figure** 10a and **Figure** 10b show the results with 5k seed translation pairs in different training regimes for EN-AR and EN-JA experiments. The results with 1k seed translation pairs are provided in the main paper.

- **Figure** 11a and **Figure** 11b demonstrate the impact of vector space preprocessing (only L2-normalization versus L2 + mean centering + L2) on the RSIM isomorphism scores in different training regimes for EN-AR and EN-JA experiments.

- **Table** 4 provides additional isomorphism scores, not reported in the paper, again stressing the importance of monolingual vector space preprocessing before learning any cross-lingual mapping.

(The actual tables and figures start on the next page for clarity.)

C Reproducibility: Data and Code

- Polyglot Wikipedias are available at: https://sites.google.com/site/rmyeid/projects/polyglot
- Used fastText code is available at: https://github.com/facebookresearch/fastText
- MUSE dictionaries: https://github.com/facebookresearch/MUSE/tree/master/data
- VecMap framework accessible at: https://github.com/artetxem/vecmap
- Iterative normalisation code available at: https://github.com/zhangmozhi/iternorm
- Bilingual lexicons used in the study: https://github.com/cambridgeltl/iso-study
- Subsampled corpora for all languages: https://github.com/cambridgeltl/iso-study

For BLI, we use evaluation scripts from Glavaš et al. (2019), available here: https://github.com/codogogo/xling-eval.

Our (research) code available for computing near-isomorphism via RSIM, EVS, and GH is also hosted online at: https://github.com/cambridgeltl/iso-study. The code relies on standard Python's stack for scientific computing (e.g., it uses `numpy`, `scipy`, `scikit-learn`, `networkx`).

Abstract

Neural networks can achieve impressive performance on many natural language processing applications, but they typically need large labeled data for training and are not easily interpretable. On the other hand, symbolic rules such as regular expressions are interpretable, require no training, and often achieve decent accuracy; but rules cannot benefit from labeled data when available and hence underperform neural networks in rich-resource scenarios. In this paper, we propose a type of recurrent neural networks called FA-RNNs that combine the advantages of neural networks and regular expression rules. An FA-RNN can be converted from regular expressions and deployed in zero-shot and cold-start scenarios. It can also utilize labeled data for training to achieve improved prediction accuracy. After training, an FA-RNN often remains interpretable and can be converted back into regular expressions. We apply FA-RNNs to text classification and observe that FA-RNNs significantly outperform previous neural approaches in both zero-shot and low-resource settings and remain very competitive in rich-resource settings.

1 Introduction

Over the past several years, neural network approaches have rapidly gained popularity in natural language processing (NLP) because of their impressive performance and flexible modeling capacity. Nevertheless, symbolic rules are still an indispensable tool in various industrial NLP applications. Regular expressions (RE) are one of the most representative and useful forms of symbolic rules and are widely used for solving tasks such as pattern matching (Hosoya and Pierce, 2001; Zhang et al., 2018) and intent classification (Luo et al., 2018). RE-based systems are highly interpretable and therefore support fine-grained human inspection and manipulation. For example, individual RE rules in a system can be easily added, revised, or removed to quickly adapt the system to changes in the task specification. Moreover, RE-based systems do not require a training stage with labeled data and hence can be quickly deployed with decent performance in zero-shot scenarios. However, REs rely on human experts to write and often have high precision but moderate to low recall; RE-based systems cannot evolve by training on labeled data when available and thus usually underperform neural networks in rich-resource scenarios.

How to combine the advantages of symbolic rules and neural networks is an open question and is drawing increasing attention recently. One possible way is to use rules to constrain neural networks, usually in the manner of regularization via knowledge distillation (Hu et al., 2016) and multi-task learning (Awasthi et al., 2020; Xu et al., 2018), or by tuning the output logits of neural networks (Li and Srikumar, 2019; Luo et al., 2018). In this way, information from rules can be injected into neural networks, though the neural networks still require training and remain black boxes that are hard to interpret and manipulate. Another way of utilizing rules is to design novel neural network architectures inspired by rule systems (Schwartz et al., 2018; Graves et al., 2014; Peng et al., 2018; Lin et al., 2019). Models designed based on this idea usually achieve better interpretability, but they must be trained on labeled data and cannot be directly converted from rules or manually specified by human experts because of their structural differences from rule systems.

In this paper, we propose finite-automaton recurrent neural networks (FA-RNN), a novel type of recurrent neural networks that is designed based on the computation process of weighted finite-state automata. Because of the equivalence between

REs and finite-state automata, we can convert any REs into an FA-RNN, which can be deployed in zero-shot and cold-start scenarios. When there are labeled data, the FA-RNN can also be trained in the same way as any neural network, which improves its prediction accuracy over the original REs. The FA-RNN has good interpretability. When converted from REs, it is (approximately) equivalent to the REs and is fully interpretable. Even after training, it often remains highly interpretable and can be converted back into REs. The interpretability of FA-RNNs opens the possibility of fine-grained manipulation such as integrating new REs into a trained FA-RNN and disabling old REs that are used to initialize an FA-RNN.

We apply FA-RNNs to the text classification task and compare them with neural network baselines as well as existing approaches of integrating REs and neural networks. Our experiments find that FA-RNNs show clear advantages in both zero-shot and low-resource settings and remain very competitive in rich-resource settings.

2 Background

2.1 Regular Expressions

Regular expressions (RE) are patterns usually used for searching or matching a string and are a succinct way to denote regular languages. We show a simple example RE for matching sentences[1] in Table 1.

2.2 RE System for Text Classification

The text classification task aims to assign a class label to an input sentence. Let $\boldsymbol{x} = \langle x_0, \cdots, x_N \rangle$ be a sentence and $\mathcal{L} = \{l_1, \cdots, l_k\}$ be the label set. One common and straight-forward way to use REs

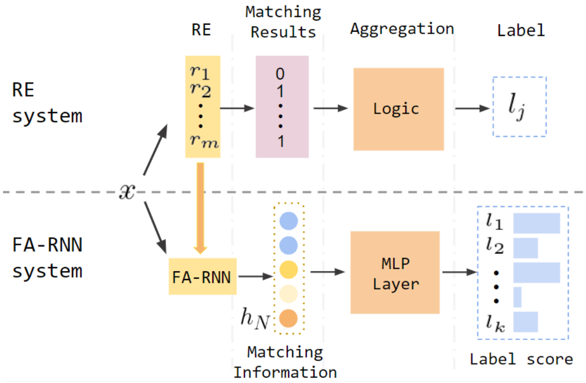

Figure 1: RE and FA-RNN systems for text classification.

for classification is as follows. Firstly, write m REs $\mathcal{R} = \{r_1, \cdots, r_m\}$, where each RE corresponds to some label in $\mathcal{L}$. Then, for each sentence $\boldsymbol{x}$, apply these REs to get matching results. Finally, aggregate the matching results to produce a final label for sentence $\boldsymbol{x}$ based on a set of propositional logic rules. Each rule specifies a logical expression of matching results that implies a specific label. For example, let M_i represent whether RE r_i is matched, then we may have a rule: $(M_i \vee M_j) \wedge \neg M_k \rightarrow l_p$. The whole procedure is shown in the top half of Figure.1.

2.3 Finite-State Automaton

Finite-state automata (FA) are machines with finite numbers of states. An FA can transit from one state to another in response to an input. It has a start state s_0 and a set of final states $\mathcal{S}_\infty$. Every RE can be converted into an FA expressing the same language by Thompson's construction algorithm (Thompson, 1968). For a sequence $\boldsymbol{x} = \langle x_1, \cdots, x_N \rangle$, an RE matches the sequence if and only if the converted FA starts from s_0 and finally reaches a final state after consuming $\boldsymbol{x}$. Table 1 shows an FA converted from the example RE. Further, for every RE, there exists a *unique* FA with a minimum number of states and deterministic transitions (m-DFA) such that they express the same language (Hopcroft et al., 2001). Deterministic transitions mean that given a current state and an input, there is a unique next state. The m-DFA can be obtained by running the powerset construction algorithm (Rabin and Scott, 1959) and the DFA minimization algorithm (Hopcroft, 1971).

---

[1] Example taken from the ATIS intent classification dataset.

2.4 Weighted Finite-State Automaton

A weighted finite-state automaton (WFA) assigns a weight to each transition, which is formally defined as a 5-tuple: $\mathcal{A} = \langle\, \Sigma, \mathcal{S}, \boldsymbol{T}, \boldsymbol{\alpha}_0, \boldsymbol{\alpha}_\infty \,\rangle$.

- Σ: a finite input vocabulary. $|\Sigma| = V$.
- $\mathcal{S}$: a finite set of states. $|\mathcal{S}| = K$.
- $\boldsymbol{T} \in \mathbb{R}^{V \times K \times K}$: a tensor of transition weights. $\boldsymbol{T}[\sigma, i, j]$ is the weight of transiting from s_i to s_j in response to input σ. $\boldsymbol{T}[\sigma] \in \mathbb{R}^{K \times K}$ denotes the transition matrix of σ.
- $\boldsymbol{\alpha}_0 \in \mathbb{R}^K$: initial weights. $\boldsymbol{\alpha}_0[i]$ is the weight of staying at state s_i at time $t = 0$.
- $\boldsymbol{\alpha}_\infty \in \mathbb{R}^K$: final weights. $\boldsymbol{\alpha}_\infty[i]$ is the weight of staying at state s_i after reading all the inputs.

An FA can be seen as a WFA with 0/1 weights. $\boldsymbol{T}[\sigma, i, j]$ is 1 if s_i can transit to s_j in response to σ and 0 otherwise. $\boldsymbol{\alpha}_0[i] = \mathbb{1}\{s_i \in \mathcal{S}_0\}$ and $\boldsymbol{\alpha}_\infty[i] = \mathbb{1}\{s_i \in \mathcal{S}_\infty\}$, where $\mathbb{1}()$ is the indicator function and $\mathcal{S}_0$ denote the set of start states[2].

For sequence $\boldsymbol{x}$, the score of WFA $\mathcal{A}$ accepting $\boldsymbol{x}$ can be calculated using the forward (Baum and Petrie, 1966) and Viterbi (Viterbi, 1967) algorithms. Let path $\boldsymbol{p} = \langle u_1, \cdots, u_{N+1} \rangle$ be a sequence of indexes of the states that we visit when consuming $\boldsymbol{x}$. The score $\mathcal{B}(\mathcal{A}, \boldsymbol{p})$ of path $\boldsymbol{p}$ can be computed by:

$$\boldsymbol{\alpha}_0[u_1] \cdot \left(\prod_{i=1}^{N} \boldsymbol{T}[x_i, u_i, u_{i+1}] \right) \cdot \boldsymbol{\alpha}_\infty[u_{N+1}] \qquad (1)$$

Let $\pi(\boldsymbol{x})$ be the set of all paths that start from start state s_0 and reach a final state $s_i \in \mathcal{S}_\infty$ after consuming sequence $\boldsymbol{x}$. The forward algorithm computes the sum of path scores.

$$\begin{aligned} \mathcal{B}_{\text{forward}}(\mathcal{A}, \boldsymbol{x}) &= \sum_{\boldsymbol{p} \in \pi(\boldsymbol{x})} \mathcal{B}(\boldsymbol{\mathcal{A}}, \boldsymbol{p}) \\ &= \boldsymbol{\alpha}_0^T \cdot \left(\prod_{i=1}^{N} \boldsymbol{T}[x_i] \right) \cdot \boldsymbol{\alpha}_\infty \end{aligned} \qquad (2)$$

The Viterbi algorithm computes the maximum of path scores.

$$\mathcal{B}_{\text{Viterbi}}(\mathcal{A}, \boldsymbol{x}) = \max_{\boldsymbol{p} \in \pi(\boldsymbol{x})} \mathcal{B}(\mathcal{A}, \boldsymbol{p}) \qquad (3)$$

It can be computed by replacing matrix multiplication in Eqa.2 with the max-plus operator. For an FA $\mathcal{A}$, the forward score is exactly the number of paths in $\pi(\boldsymbol{x})$ while the Viterbi score indicates whether $\pi(\boldsymbol{x})$ is non-empty.

3 Method

We show step-by-step how we can convert REs to a novel type of recurrent neural networks called FA-RNNs.

3.1 From REs to Recurrent Neural Networks

RE to FA As mentioned in Sec.2.3, we can convert an RE into an m-DFA. In order to obtain a concise FA with better interpretability and faster computation speed, we treat the wildcard '\$' as a special word in the vocabulary and run the algorithms mentioned in Sec.2.3 to obtain a "pseudo" m-DFA $\mathcal{A}$.

FA as RNN As discussed in Sec.2.4, the FA $\mathcal{A}$ can be seen as a WFA with 0/1 weights which is parameterized by $\Theta = \langle \boldsymbol{\alpha}_0, \boldsymbol{T}, \boldsymbol{\alpha}_\infty \rangle$.

The computation of the WFA forward score (Eqa.2) can be rewritten into a recurrent form. Let $\boldsymbol{h}_t \in \mathbb{R}^K$ be the forward score vector after consuming t words in $\boldsymbol{x}$. $\boldsymbol{h}_t[i]$ can be interpreted as the number of paths starting from s_0 and reaching s_i at step t.

$$\begin{aligned} \boldsymbol{h}_0 &= \boldsymbol{\alpha}_0^T \\ \boldsymbol{h}_t &= \boldsymbol{h}_{t-1} \cdot \boldsymbol{T}[x_t],\ 1 \leq t \leq N \\ \mathcal{B}_{\text{forward}}(\mathcal{A}, \boldsymbol{x}) &= \boldsymbol{h}_N \cdot \boldsymbol{\alpha}_\infty \end{aligned} \qquad (4)$$

The computation of the WFA Viterbi score can be formulated in a similar way. Therefore, we can view a WFA as a form of recurrent neural networks (RNN) parameterized by Θ.

3.2 Decomposing the Parameter Tensor

Despite the equivalence to FAs and hence better interpretability, the RNNs proposed in Sec.3.1 has much more parameters than a traditional RNN because of the tensor $\boldsymbol{T} \in \mathbb{R}^{V \times K \times K}$. To reduce the parameter number, we propose to apply tensor rank decomposition (explained in the Appendix.A) and decompose $\boldsymbol{T}$ into three matrices $\boldsymbol{E}_\mathcal{R} \in \mathbb{R}^{V \times r}, \boldsymbol{D}_1 \in \mathbb{R}^{K \times r}, \boldsymbol{D}_2 \in \mathbb{R}^{K \times r}$, where r is a hyper-parameter. Note that if r is smaller than the rank of $\boldsymbol{T}$, then the decomposition is approximate. We empirically find that, for a 100-state FA converted from RE, we can obtain a small decomposition error ($\leq 1\%$) if $r \geq 100$.

Now the RNN is parameterized by $\Theta_D = \langle \boldsymbol{\alpha}_0, \boldsymbol{\alpha}_\infty, \boldsymbol{E}_\mathcal{R}, \boldsymbol{D}_1, \boldsymbol{D}_2 \rangle$. $\boldsymbol{E}_\mathcal{R}$ has a dimension associated with vocabulary size V and can be viewed as a word embedding matrix containing RE information for each word. Let $\boldsymbol{v}_t \in \mathbb{R}^r$ be the embedding of word x_t contained in $\boldsymbol{E}_\mathcal{R}$. The recurrent

---

[2] Normally, we define that an FA has only one start state, but any FA with multiple start states can be converted into an FA with one start state by adding ϵ-transitions from a new start state to all the original start states.

update in Eqa.4 becomes:

$$\begin{aligned} \boldsymbol{a} &= (\boldsymbol{h}_{t-1} \cdot \boldsymbol{D}_1) \circ \boldsymbol{v}_t \\ \boldsymbol{h}_t &= \boldsymbol{a} \cdot \boldsymbol{D}_2^T \end{aligned} \tag{5}$$

where $\circ$ denotes element-wise product. Eqa.5 produces the same result as Eqa.4 with sufficiently large r.

Note that the size of $\boldsymbol{h_t}$ is determined by the state number K of the m-DFA converted from RE. In some cases, K may be too small, resulting in limited representational power of the RNN. A simple method to solve this problem is to concatenate $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$ with a $K' \times r$ zero matrix, hence increasing the hidden state size by K'. Subsequent training (to be introduced later) would update $\boldsymbol{D}_1$ and $\boldsymbol{D}_2$ so that these added dimensions can be utilized. This is equivalent to adding K' isolated states in the FA and relying on training to establish transitions between the old and new states.

3.3 Integrating Pretrained Word Embedding

Pretrained word embeddings have been found very useful in bringing external lexical knowledge into neural networks. Let $\boldsymbol{E}_w \in \mathbb{R}^{V \times D}$ be the word embedding matrix and $\boldsymbol{u}_t \in \mathbb{R}^D$ be the word embedding of x_t in $\boldsymbol{E}_w$. We introduce another matrix $\boldsymbol{G} \in \mathbb{R}^{D \times r}$ that can transform the D-dimensional word embedding $\boldsymbol{u}_t$ into r-dimension, which can then replace $\boldsymbol{v}_t$ in the recurrent update of Eqa.5. We initialize $\boldsymbol{G}$ by setting $\boldsymbol{G} = \boldsymbol{E}_w^{\dagger} \boldsymbol{E}_{\mathcal{R}}$, where $\boldsymbol{E}_w^{\dagger}$ is the pseudo-inverse of $\boldsymbol{E}_w$. In this way, we approximate $\boldsymbol{v}_t$ with $\boldsymbol{u}_t \boldsymbol{G}$ and hence the initialized RNN still tries to mimic the FA. After training, however, the RNN will be able to utilize the additional information contained in pretrained word embeddings and hence may outperform the original FA.

In practice, we find it beneficial to interpolate the two r-dimension embeddings $\boldsymbol{v}_t$ and $\boldsymbol{u}_t \boldsymbol{G}$ with a hyper-parameter $\beta \in [0, 1]$. When β is 1, we only use RE information. When β gets closer to 0, we integrate more external lexical information into the model. The recurrent update formula becomes:

$$\begin{aligned} \boldsymbol{z}_t &= \beta \boldsymbol{v}_t + (1 - \beta) \boldsymbol{u}_t \boldsymbol{G} \\ \boldsymbol{a} &= (\boldsymbol{h_{t-1}} \cdot \boldsymbol{D}_1) \circ \boldsymbol{z}_t \\ \boldsymbol{h_t} &= \boldsymbol{a} \cdot \boldsymbol{D}_2^T \end{aligned} \tag{6}$$

We name this new form of RNNs as *FA-RNNs*, i.e., recurrent neural networks built from finite-state automata.

3.4 Extensions of FA-RNN

Gated Extension (FA-GRU) Inspired by the Gated Recurrent Unit (Chung et al., 2014), we sacrifice some interpretability and add an update gate $\boldsymbol{f}_t$ and a reset gate $\boldsymbol{r}_t$ into the FA-RNN. The update gate determines how much information from the past shall be retained. The reset gate determines whether to reset the previous score vector to $\boldsymbol{h}_0$, The recurrent update is as follows.

$$\begin{aligned} \boldsymbol{z}_t &= \beta \boldsymbol{v}_t + (1 - \beta) \boldsymbol{u}_t \boldsymbol{G} \\ \boldsymbol{f}_t &= \boldsymbol{\sigma}(\boldsymbol{W}_f \boldsymbol{z}_t + \boldsymbol{U}_f \boldsymbol{h}_{t-1} + \boldsymbol{b}_f) \\ \boldsymbol{r}_t &= \boldsymbol{\sigma}(\boldsymbol{W}_r \boldsymbol{z}_t + \boldsymbol{U}_r \boldsymbol{h}_{t-1} + \boldsymbol{b}_r) \\ \hat{\boldsymbol{h}}_{t-1} &= (1 - \boldsymbol{r}_t) \circ \boldsymbol{h}_0 + \boldsymbol{r_t} \circ \boldsymbol{h_{t-1}} \\ \boldsymbol{a} &= (\hat{\boldsymbol{h}}_{\boldsymbol{t-1}} \cdot \boldsymbol{D}_1) \circ \boldsymbol{z}_t \\ \hat{\boldsymbol{h}}_t &= \boldsymbol{a} \cdot \boldsymbol{D}_2^T \\ \boldsymbol{h}_t &= (1 - \boldsymbol{f}_t) \circ \boldsymbol{h}_{t-1} + \boldsymbol{f}_t \circ \hat{\boldsymbol{h}}_t \end{aligned} \tag{7}$$

$\boldsymbol{\sigma}$ is the sigmoid activation function and $\boldsymbol{W}_f$, $\boldsymbol{W}_r$, $\boldsymbol{U}_f$, $\boldsymbol{U}_r$ are additional parameters for gates. Note that when $\boldsymbol{f}_t$ and $\boldsymbol{r}_t$ is close to $\boldsymbol{1}$, the FA-GRU degenerates to the FA-RNN. Therefore, we initialize $\boldsymbol{b}_f, \boldsymbol{b}_r$ to a large value and $\boldsymbol{W}_f, \boldsymbol{W}_r, \boldsymbol{U}_f, \boldsymbol{U}_r$ randomly using Xavier initialization (Glorot and Bengio, 2010) to ensure that the initialized FA-GRU is approximately equivalent to the FA-RNN and hence the original REs.

Bidirectional Extension (BiFA-RNN) Our networks can be easily extended to their bidirectional variants. For any RE, we can reverse it by simply reversing its word order (e.g., "*free $* (phone | phones) $**" can be reversed to "*$* (phone | phones) $* free*") and then convert the reversed RE into WFA $\overleftarrow{\mathcal{A}}$ and the corresponding FA-RNN. Score vector $\overleftarrow{\boldsymbol{h}_{\boldsymbol{N}}}$ can be computed by applying Eqa.6 or Eqa.7 on the reversed input sentence $\overleftarrow{\boldsymbol{x}}$. Then we take the average of $\overleftarrow{\boldsymbol{h}_{\boldsymbol{N}}}$ and the left-to-right score vector $\overrightarrow{\boldsymbol{h}_{\boldsymbol{N}}}$ to obtain the final score vector $\boldsymbol{h}_N = (\overrightarrow{\boldsymbol{h}_{\boldsymbol{N}}} + \overleftarrow{\boldsymbol{h}_{\boldsymbol{N}}})/2$.

3.5 Aggregation Layer for Text Classification

As introduced in Sec.2.2, an RE system for text classification contains multiple REs that are aggregated to form a class label prediction. Here we describe how to convert such an RE system to an FA-RNN system for text classification (the bottom half of Figure.1).

For each RE r_i in the RE system, we convert it into a WFA $\mathcal{A}_i$ with K_i states, start weights $\boldsymbol{\alpha}_{0,i}$, and final weights $\boldsymbol{\alpha}_{\infty,i}$. We can view these WFAs

Logic	Soft Logic
$\neg A$	$1 - a$
$A \vee B$	$\min(1, a + b)$
$A \wedge B$	$\max(0, a + b - 1)$

Table 2: Soft logic. A, B are proposition symbols with soft truth values a, b.

as a single WFA $\mathcal{A}$ with a total number of $K = \sum_i K_i$ states and multiple start states. We then convert this WFA to an FA-RNN. After we run this FA-RNN on sentence $\boldsymbol{x}$, the last state vector $\boldsymbol{h}_N$ contains the matching information of all the REs.

To predict a class label from $\boldsymbol{h}_N$, we create a soft aggregation layer. First, we extract the forward or Viterbi score of each RE from $\boldsymbol{h}_N$. For forward scoring, we follow Eqa.4 and have:

$$\mathcal{B}_{\text{forward}}(\mathcal{A}_i, \boldsymbol{x}) = \boldsymbol{h}_N \cdot \bar{\boldsymbol{\alpha}}_{\infty,i} \tag{8}$$

where $\bar{\boldsymbol{\alpha}}_{\infty,i}$ expands $\boldsymbol{\alpha}_{\infty,i}$ by filling zeros for states not belonging to $\mathcal{A}_i$. For Viterbi scoring, we replace matrix multiplication with max-plus. The computed score for $\mathcal{A}_i$ can be seen as a soft matching result of RE r_i. Second, we rewrite the logical RE aggregation rules introduced in Sec.2.2 to soft logic expressions (Kimmig et al., 2012; Li and Srikumar, 2019) (Table 2). Instead of predicting a single label, the soft aggregation layer outputs the label logits $\boldsymbol{l} \in \mathbb{R}^k$. When all the elements in $\boldsymbol{h}_N$ are close to either 0 or 1, the output of the soft aggregation layer is approximately equivalent to that of the RE aggregation layer of Sec.2.2.

Since the logical RE aggregation rules can be expressed in the conjunctive normal form, we can implement the corresponding soft aggregation layer with a two-layer MLP with ReLU-like activation functions. This is similar to the MLP layer commonly used at the end of traditional neural networks to map the hidden representation to label logits. In practice, we find it sometimes beneficial to not use any activation function in the MLP.

3.6 Training with Labeled Data

So far we have introduced how to initialize an FA-RNN system that is approximately equivalent to an RE classification system. When there are labeled data, the FA-RNN can also be trained to improve its performance. We simply use the output logits $\boldsymbol{l}$ to compute the cross-entropy loss on the training data and use a gradient-based method such as Adam (Kingma and Ba, 2014) to optimize it.

	#Train	#Dev	#Test	$\lvert\mathcal{L}\rvert$	$\lvert\mathcal{R}\rvert$	K	%Acc
ATIS	3982	996	893	26	27	107	87.0
	*$ * flights | flight | ((go | get | fly) from $ * to $ *) $ * → FLIGHT*

BiGRU+*o*+*u*	83.03	64.95	93.05
BiGRU+*io*+*u*	86.14	64.75	92.70
BiGRU+*pr*+*u*	85.67	64.60	93.5
BiGRU+*kd*+*u*	87.37	63.70	93.55

Table 4: Accuracy of zero-shot classification. The RE system and baselines trained on RE-labeled data are included for reference.

Note that we typically fix $\boldsymbol{E}_{\mathcal{R}}$ during training because we find that updating $\boldsymbol{E}_{\mathcal{R}}$ is not helpful. Therefore, the number of trainable parameters in an FA-RNN is similar to (usually smaller than) that of an RNN. We compare the number of parameters of different models in Appendix.C.

4 Experiments

We use the forward score version of FA-RNNs by default in our experiments. We use GloVe (Pennington et al., 2014) as the word embedding and keep it fixed for our methods and all the baselines. We tune the learning rate, number of additional isolated states K', and interpolation coefficient β for our methods on the development set. We provide more details of hyper-parameter tuning for FA-RNNs and all the baselines in Appendix.D.

4.1 Datasets

We evaluate the performance of our methods on three text classification datasets that have been used in previous work of integrating REs and neural networks: ATIS (Hemphill et al., 1990), Question Classification (QC) (Li and Roth, 2002) and SMS (Alberto et al., 2015). ATIS is a popular dataset consisting of queries about airline information and services. QC contains questions that can be classified into general categories like *LOCATION*, *ENTITY*, etc. SMS is a spam-classification dataset. We write REs for ATIS and use a modified version of REs from Awasthi et al. (2020) for QC and SMS. We show dataset statistics and RE examples in Table 3.

4.2 Baselines

Basic Networks We compare FA-RNN with traditional recurrent neural networks including RNN (Elman, 1990), GRU (Chung et al., 2014), LSTM (Hochreiter and Schmidhuber, 1997), and their bidirectional variants. We also experiment with a 4-layer CNN (Kim, 2014) and a 4-layer DAN (Iyyer et al., 2015), which are also frequently used in text classification. We feed the hidden representation produced by these models into an MLP to obtain the label logits and use the cross-entropy loss as the objective function. We tune the learning rates and the number of hidden states in [50, 100, 150, 200] on the development set for each dataset.

RE-enhanced Basic Networks We also compare our method with the basic neural networks enhanced by existing methods of combining rules and neural networks. Luo et al. (2018) propose three ways to utilize RE matching results in a neural model: 1) use the results as additional input features; 2) use the results to guide attention; 3) use the results to directly tune the output logits. As our basic networks do not involve attention, we enhance them using 1), 3) or both, denoted as $+i$, $+o$ and $+io$ respectively. Another method of utilizing rules is the knowledge distillation framework (Hinton et al., 2015). It treats the RE system as the teacher and its label logits as the soft targets, and distills this knowledge into the basic networks. We denote this method as $+kd$. Hu et al. (2016) combines knowledge distillation with posterior regularization by iteratively projecting the student network into the rule-regularized space. We denote this method as $+pr$. Finally, in the zero-shot setting, we also enhance these baselines by training them using unlabeled data tagged by regular expressions. We denote this enhancement by $+u$.

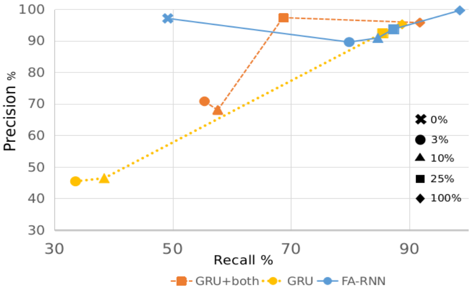

Figure 2: Precision and recall with different amounts of training data on SMS.

4.3 Zero-Shot Classification

We compare our methods with the RE system and RE-enhanced BiGRU in the zero-shot scenario, in which no training data (including the development set) is available. All the methods use or are initialized by exactly the same set of REs. For the $+u$ enhancement, we use the full training data with their labels removed as unlabeled data. We show the results in Table 4.

The results show that our methods are comparable to the RE system. The small differences in accuracy between the RE system and our methods are caused by approximation errors in decomposing the parameter tensor and integrating word embedding, as well as the introduction of gates in FA-GRUs. Our methods have much better performance than RE-enhanced BiGRUs, because RE-enhanced BiGRUs without training perform random guesses, except that in the cases of $+o$ and $+io$, RE matching results directly influence the outputs and hence improve the predictions. Baselines with the $+u$ enhancement can also match the accuracy of the RE system, but unlike our methods, they require training on sufficient RE-labeled data.

We also report the results of the other baselines in Appendix E. Without any training, the basic networks not enhanced by RE just perform random guesses. The other RE-enhanced basic networks have similar behaviors to RE-enhanced BiGRUs.

4.4 Low-Resource and Full Training

We compare all the methods trained on 1%, 10%, and 100% of the training data. We use the original development set for the 10% and 100% experiments; but for the 1% experiment, we sample a smaller development set containing the same

amount of data as 1% of the training data to simulate the low-resource setting. Table 5 shows the results. Because of space limit, for RE-enhanced networks, we only report the results of RE-enhanced BiGRUs, which perform the best among all the RE-enhanced networks. The complete results of all the methods with standard deviations can be found in Appendix.E.

From the results we can see that our methods outperform all the other methods in the low-resource settings, especially on 1% training data. With 100% training data, overall our methods are much better than RNN, DAN and CNN, and are either slightly better than or comparable to BiLSTM, BiGRU, and RE-enhanced BiGRUs. RE-enhanced BiGRUs are indeed better than non-enhanced BiGRU in general, and +*pr* and +*kd* seem to be more data-hungry than +*i*, +*o* and +*io*.

SMS is a binary classification task of spam detection, so we regard [*spam*] as the positive label and calculate the precisions and recalls of FA-RNN and two baselines GRU and GRU+*io* given different amounts of training data (Fig.2). With no training data, FA-RNN is almost equivalent to REs and has high precision but moderate recall; but with just 3% data, its recall is greatly improved and its precision drops only moderately; and with additional data, its precision and recall are both improved. For the baselines, the precision and recall of GRU always increase with more data, while the changes of the precision and recall of GRU+*io* seem less stable.

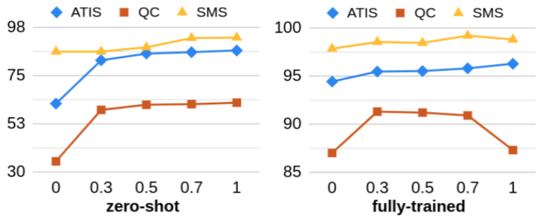

Figure 3: Performance of FA-RNN with different β.

5 Analysis

Impact of β β from Eqa.6 controls the influence of pretrained word embedding. Fig.3 shows how β impacts the performance of FA-RNN on the zero-shot and fully-trained scenarios. It can be seen that using pretrained word embedding does not help in the zero-shot scenario but can be helpful in the fully-trained scenario. One possible explanation is that word similarities encoded in the pretrained word embedding may not be compatible with a classification task, but training with data could adapt the model (in particular, by updating $\boldsymbol{G}$) to better utilize the information contained in the pretrained word embedding.

Ablation Study Table 6 shows the results of variants of FA-RNN when trained on the full datasets. From the results we can conclude that: 1) forward scoring outperforms Viterbi scoring; 2) tensor decomposition described in Sec.3.2 results in not only fewer parameters but also better overall performance; 3) RE initialization is helpful because it is much better than random initialization; 4) integrating pretrained word embedding is beneficial because the performance drops by a large margin if using random word embedding; 5) training $\boldsymbol{E}_{\mathcal{R}}$ does not result in better performance on average, possibly because it introduces too many trainable parameters.

6 Interpretability

We regard the approximate equivalence between RE/WFA and our RE-initialized model as indication of good interpretability based on the following two reasons: 1) for people who are familiar with REs and automata, our model is interpretable once converted back into a WFA; 2) for non-experts who are unfamiliar with automata and REs, we may run a RE/WFA of a specific classification label on an input sentence and show which part of the sentence contributes to the (best) matching of the RE/WFA with the sentence, which can be easily understood by non-experts.

Note that not only can an FA-RNN be easily converted back into a RE/WFA at initialization, but the conversion can also be done after training. We can use the trained parameters of the FA-RNN $\Theta_{\mathrm{RE}} = \left\langle \hat{\boldsymbol{E}}_{\mathcal{R}}, \hat{\boldsymbol{D}}_1, \hat{\boldsymbol{D}}_2, \hat{\boldsymbol{G}} \right\rangle$ and word embedding matrix $\boldsymbol{E}_w$ to reconstruct the WFA tensor $\boldsymbol{T}$.

$$\begin{aligned} \hat{\boldsymbol{E}}_{w\mathcal{R}} &= \beta \cdot \hat{\boldsymbol{E}}_{\mathcal{R}} + (1-\beta) \cdot \boldsymbol{E}_w \hat{\boldsymbol{G}} \\ \hat{\boldsymbol{T}}_{(1)} &= (\hat{\boldsymbol{D}}_2 \odot \hat{\boldsymbol{D}}_1) \hat{\boldsymbol{E}}_{w\mathcal{R}}^T \end{aligned} \quad (9)$$

where $\hat{\boldsymbol{T}}_{(1)}$ denotes the mode-1 unfolding of the reconstructed tensor $\hat{\boldsymbol{T}}$ and $\odot$ denotes the Khatri-Rao product. Further, we can use a thresholding function $f(x) = \mathbb{1}\{x \geq \gamma\}$ to convert the weights into $\{0, 1\}$ to recover an FA, where γ is a fixed scalar. Similarly, we can round the weights in the soft aggregation layer to reconstruct the logical aggregation layer. In this way, we can convert a trained FA-RNN back into an RE system.

In our experiments, we find that although the reconstructed RE systems underperform the corresponding trained FA-RNNs because of thresholding and rounding during reconstruction, they often outperform the original REs. The reconstructed RE systems achieve 73.6% accuracy for QC (+9.2% compared with the original REs) and 87.45% for ATIS (+0.45% compared with the original REs). For SMS, the reconstructed REs underperform the original ones (−1.2%) probably because the original REs are already good enough. We show an example in Fig.4, in which our model can be seen to learn interesting new patterns such as 'jet' and '737'. We show another example in Appendix.F.

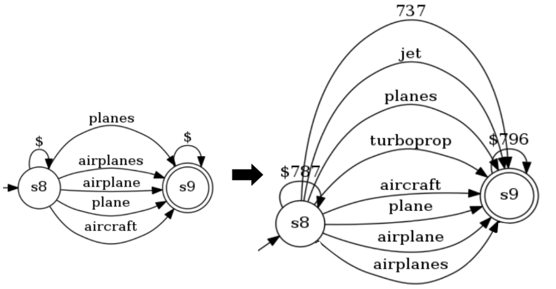

Figure 4: Part of an original RE and a reconstructed RE corresponding to label [*aircraft*]. On the right, '$787' means 787 words can activate the transition. Similar for '$796'. They are stricter than wildcard '$' that allows all possible words in the vocabulary.

Good interpretability of our models opens the possibility of fine-grained manipulation of the model, e.g., adding new REs without retraining the model. To inject a new set of REs, we convert them to a new FA-RNN with parameters $\Theta_{\text{new}} = \langle \boldsymbol{E}_{\mathcal{R}}, \boldsymbol{D}_1, \boldsymbol{D}_2, \boldsymbol{G} \rangle$ and merge it into the original trained FA-RNN with parameters Θ_{RE} by concatenating the parameter matrices:

$$\left\langle [\hat{\boldsymbol{E}}_{\mathcal{R}}\ \boldsymbol{E}_{\mathcal{R}}], \begin{bmatrix} \hat{\boldsymbol{D}}_1 & \mathbf{0} \\ \mathbf{0} & \boldsymbol{D}_1 \end{bmatrix}, \begin{bmatrix} \hat{\boldsymbol{D}}_2 & \mathbf{0} \\ \mathbf{0} & \boldsymbol{D}_2 \end{bmatrix}, [\hat{\boldsymbol{G}}\ \boldsymbol{G}] \right\rangle \quad (10)$$

To add new logical aggregation rules, we can update the aggregation layer parameters similarly by concatenation. To disable an RE in an FA-RNN, we reconstruct the WFA, remove all the states of the RE from the WFA except those that can be reached from states of other REs, and finally convert the WFA back to an FA-RNN.

7 Related Work

Neural Networks Enhanced by Rules Hu et al. (2016); Li and Rush (2020) use rules to constrain neural networks by knowledge distillation and posterior regularization. Awasthi et al. (2020) inject rule knowledge into neural networks using multi-task learning. Lin et al. (2020) train a trigger matching network using additional annotation and use the output of trigger matching results as the attention of a sequence labeler. Rocktäschel et al. (2015); Xu et al. (2018); Hsu et al. (2018) use parsed rule results to regularize neural network predictions by additional loss terms. Li and Srikumar (2019); Luo et al. (2018) inject declarative knowledge in the form of parsed RE results or first-order expressions into neural networks by hacking the prediction logits or the attention scores. Hu et al. (2016); Hsu et al. (2018) use rules as additional input features.

All these previous methods use matching results or truth values of rules to enhance existing neural models. In contrast, we directly turn REs into a novel type of trainable networks.

Relating Neural Networks and WFA Schwartz et al. (2018) propose a type of neural networks for learning soft surface patterns (a subset of REs), which is inspired by WFAs but cannot be converted from WFAs or surface patterns. In contrast, our FA-RNN can be initialized from REs and converted back to REs. Peng et al. (2018); Dodge et al. (2019) formulate the update of each hidden dimension of various RNN architectures as a small WFA (2-4 states). Weiss et al. (2018); Merrill (2019) provide theoretical analysis of various neural networks and their accepting languages. Our work differs from these more theoretical studies in that we aim for a practical text classification approach. Omlin et al. (1998); Giles et al. (1999) show the equivalence between WFA and second-order RNN. The main differences between our model and theirs include the following. First, compared with the undecomposed version of our FA-RNN, their RNN model involves nonlinear activation functions which complicate the model. Second, our FA-RNN further decomposes the tensor parameter, integrate word embeddings, and propose the gated and bidirectional extensions. Third, while their work is mostly theoretical, we empirically show the usefulness of our model in text classification.

8 Conclusion and Future Work

We propose a type of recurrent neural networks called FA-RNN. It can be initialized from REs and can also learn from data, hence applicable to various scenarios including zero-shot, cold-start, low-resource and rich-resource scenarios. It is also interpretable and can be converted back into REs. Our experiments on text classification show that it outperforms previous neural approaches in both zero-shot and low-resource scenarios and is very competitive in rich-resource scenarios. In the future, we plan to apply FA-RNN to other tasks and explore other variants of FA-RNN. We release our data, RE rules and code at https://github.com/jeffchy/RE2RNN.

A Tensor Rank Decomposition (CPD)

A 3-way tensor $\boldsymbol{T} \in \mathbb{R}^{d_1 \times d_2 \times d_3}$ can be approximated using r rank-1 tensors.

$$\begin{aligned} \boldsymbol{T} \approx \hat{\boldsymbol{T}} &= \sum_{i=1}^{r} \boldsymbol{a_i} \otimes \boldsymbol{b_i} \otimes \boldsymbol{c_i} \\ \hat{\boldsymbol{T}}_{(1)} &= (\boldsymbol{C} \odot \boldsymbol{B}) \boldsymbol{A}^T \\ \boldsymbol{A} &= [\boldsymbol{a_1} \cdots \boldsymbol{a_r}], \boldsymbol{A} \in \mathbb{R}^{d_1 \times r}, \\ \boldsymbol{B} &= [\boldsymbol{b_1} \cdots \boldsymbol{b_r}], \boldsymbol{B} \in \mathbb{R}^{d_2 \times r}, \\ \boldsymbol{C} &= [\boldsymbol{c_1} \cdots \boldsymbol{c_r}], \boldsymbol{C} \in \mathbb{R}^{d_3 \times r}, \end{aligned} \tag{11}$$

$\hat{\boldsymbol{T}}_{(1)}$ denotes the mode-1 unfolding of tensor $\hat{\boldsymbol{T}}$. $\odot$ denotes the Khatri-Rao product while $\otimes$ denotes the outer product. When the rank of $\boldsymbol{T}$ is less than or equal to r, then the decomposition can be made exact.

B Tricks for CPD

Speeding up CPD Decomposing the WFA tensor $\boldsymbol{T}^{V \times K \times K}$ is hard when the vocabulary size V is large. However, if we neglect the wildcard '\$', other words appear in RE usually form a small subset Σ' of the whole vocabulary. Denote V_1 the size of Σ', we can use a wildcard matrix $\boldsymbol{W} \in \mathbb{R}^{K \times K}$ and a much smaller tensor $\boldsymbol{T}_1^{V_1 \times K \times K}$ to represent $\boldsymbol{T}$. $\boldsymbol{W}[i,j] = 1$ when the WFA transits from s_i to s_j in respond to '\$', otherwize 0. Similarly, $\boldsymbol{T}_1[\sigma, i, j] = 1$ when the WFA transits from s_i to s_j in respond to Σ'_σ, otherwize 0. By this construction, if $\Sigma_{\sigma_1} = \Sigma'_{\sigma_2}$, $\boldsymbol{T}[\boldsymbol{\sigma_1}] = \boldsymbol{W} + \boldsymbol{T}_1[\sigma_2]$.

Because Σ' is small, it is much easier to decompose T_1 to get $\boldsymbol{E}'_{\mathcal{R}} \in \mathbb{R}^{V_1 \times r}, \boldsymbol{D}'_1 \in \mathbb{R}^{K \times r}, \boldsymbol{D}'_2 \in \mathbb{R}^{K \times r}$. After obtaining these matrices, we pad the $\boldsymbol{E}'_{\mathcal{R}}$ back into a matrix $\boldsymbol{E}''_{\mathcal{R}}$ sized $V \times r$ with 0s, such that $\boldsymbol{E}''_{\mathcal{R}}[\sigma] = \boldsymbol{0}$ if $\Sigma_\sigma \notin \Sigma'$, and $\boldsymbol{E}''_{\mathcal{R}}[\sigma] = \boldsymbol{E}'_{\mathcal{R}}[\sigma_1]$ if $\Sigma_\sigma = \Sigma'_{\sigma_1} \in \Sigma'$.

Model	Parameters
FA-RNN	$2Kr + Dr$
FA-GRU	$2(Kr + KK + K) + 2Kr + Dr$
RNN	$DH + HH$
GRU	$3(DH + HH + H)$
LSTM	$4(DH + HH + H)$

Table 7: Formulas of parameter numbers.

Let $\boldsymbol{v}_t \in \mathbb{R}^r$ be the embedding of word x_t contained in $\boldsymbol{E}''_{\mathcal{R}}$, the recurrent update of FA-RNN now becomes:

$$\begin{aligned} \boldsymbol{a} &= (\boldsymbol{h}_{t-1} \cdot \boldsymbol{D}_1) \circ \boldsymbol{v}_t \\ \boldsymbol{h_t} &= \boldsymbol{a} \cdot \boldsymbol{D}_2^T + \boldsymbol{h}_{t-1} \boldsymbol{W} \end{aligned} \tag{12}$$

We do not train the wildcard matrix $\boldsymbol{W}$ by default. The new recurrent update will get exactly same result as the one without this trick.

Normalizing $\boldsymbol{E}_{\mathcal{R}}, \boldsymbol{D}_1$ and $\boldsymbol{D}_2$ We find normalizing $\boldsymbol{E}_{\mathcal{R}}, \boldsymbol{D}_1$ and $\boldsymbol{D}_2$ to ensure they have similar average Frobenius norm results in better performance of our methods. The average Frobenius norm is the Frobenius norm divided by the number of matrix elements. Denote a, b and c the average Frobenius norms for $\boldsymbol{E}_{\mathcal{R}}, \boldsymbol{D}_1$ and $\boldsymbol{D}_2$ respectively, and $y = (abc)^{1/3}$. We can normalize $\boldsymbol{E}_{\mathcal{R}}, \boldsymbol{D}_1$ and $\boldsymbol{D}_2$ by multiplying them with the factors $y/a, y/b$ and y/c respectively. The tensor reconstructed by the normalized matrices is the same as the tensor reconstructed by the original ones.

C Number of Parameters

We show calculation of model parameters of our FA-RNN and traditional recurrent neural networks in Table 7. K is the number of WFA states, r is the tensor decomposition rank, D is the word embedding dimension, and H is the hidden dimension in recurrent neural networks. In most cases, K, r are smaller than or comparable to H.

Table 8 shows the numbers of trainable parameters. The model sizes are tuned and selected using the development set. The parameters associated with the aggregation layer or the MLP layer are also included. The result shows that our methods usually have fewer trainable model parameters than baselines.

	ATIS	QC	SMS
FA-RNN	56100	57600	30900
FA-GRU	102312	113060	61500
BiFA-RNN	94200	121200	52524
BiFA-GRU	204624	244240	104236
GRU	185226	113406	112802
BiGRU	232826	181206	225602
CNN	283126	281106	451052

Table 8: Numbers of model parameters after tuning on different datasets.

D Hyper-parameters

We report the ranges of each hyper-parameters. For all methods and baselines, we select learning rates (lr) from $[0.01, 0.005, 0.001, 0.0005, 0.0001]$, For FA-RNN and its variants, we select ranks r from $[150, 200]$, additional hidden states from $[0, 30]$, and β from $[0.3, 0.5, 0.7, 1.0]$. For traditional neural networks, we select the hidden dimensions from $[50, 100, 150, 200]$. For *+i, +o, +io*, we select the RE tag dimension from $[20, 50]$, for *+pr, +kd*, we select the α from $[0.3, 0.5, 0.7]$, it is used for balancing between imitating the teacher and predicting the true hard labels. We select the best hyper-parameters for each methods based on the averaged development set accuracy.

E Full Experimental Results

Table 9, 10, 11 show the full experimental results with standard deviations. We run each model under each setting for four times with different random seeds. The standard deviations are large on low-resource scenarios because we also randomly choose the training data.

F Additional Interpretability Example

We present a more complicated example of original and reconstructed REs from the ATIS dataset in Fig.5. The trained RE contains a more sophisticated pattern with more transitions and a slightly different structure.

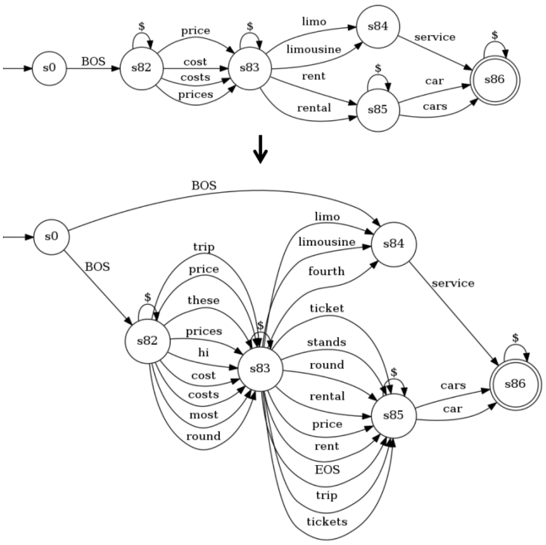

Figure 5: An untrained and trained RE corresponding to the label [*ground_fare*], which covers questions about ground service costs in airports.

Abstract

Large Transformer-based models were shown to be reducible to a smaller number of self-attention heads and layers. We consider this phenomenon from the perspective of the lottery ticket hypothesis, using both structured and magnitude pruning. For fine-tuned BERT, we show that (a) it is possible to find subnetworks achieving performance that is comparable with that of the full model, and (b) similarly-sized subnetworks sampled from the rest of the model perform worse. Strikingly, with structured pruning even the worst possible subnetworks remain highly trainable, indicating that most pre-trained BERT weights are potentially useful. We also study the "good" subnetworks to see if their success can be attributed to superior linguistic knowledge, but find them unstable, and not explained by meaningful self-attention patterns.

1 Introduction

Much of the recent progress in NLP is due to the transfer learning paradigm in which Transformer-based models first try to learn task-independent linguistic knowledge from large corpora, and then get fine-tuned on small datasets for specific tasks. However, these models are overparametrized: we now know that most Transformer heads and even layers can be pruned without significant loss in performance (Voita et al., 2019; Kovaleva et al., 2019; Michel et al., 2019).

One of the most famous Transformer-based models is BERT (Devlin et al., 2019). It became a must-have baseline and inspired dozens of studies probing it for various kinds of linguistic information (Rogers et al., 2020b).

We conduct a systematic case study of fine-tuning BERT on GLUE tasks (Wang et al., 2018) from the perspective of the lottery ticket hypothesis (Frankle and Carbin, 2019). We experiment with and compare magnitude-based weight pruning and importance-based pruning of BERT self-attention heads (Michel et al., 2019), which we extend to multi-layer perceptrons (MLPs) in BERT.

With both techniques, we find the "good" subnetworks that achieve 90% of full model performance, and perform considerably better than similarly-sized subnetworks sampled from other parts of the model. However, in many cases even the "bad" subnetworks can be re-initialized to the pre-trained BERT weights and fine-tuned separately to achieve strong performance. We also find that the "good" networks are unstable across random initializations at fine-tuning, and their self-attention heads do not necessarily encode meaningful linguistic patterns.

2 Related Work

Multiple studies of BERT concluded that it is considerably overparametrized. In particular, it is possible to ablate elements of its architecture without loss in performance or even with slight gains (Kovaleva et al., 2019; Michel et al., 2019; Voita et al., 2019). This explains the success of multiple BERT compression studies (Sanh et al., 2019; Jiao et al., 2019; McCarley, 2019; Lan et al., 2020).

While NLP focused on building larger Transformers, the computer vision community was exploring the Lottery Ticket Hypothesis (LTH: Frankle and Carbin, 2019; Lee et al., 2018; Zhou et al., 2019). It is formulated as follows: *"dense, randomly-initialized, feed-forward networks contain subnetworks (winning tickets) that – when trained in isolation – reach test accuracy comparable to the original network in a similar number of iterations"* (Frankle and Carbin, 2019). The "winning tickets" generalize across vision datasets (Morcos et al., 2019), and exist both in LSTM and Transformer models for NLP (Yu et al., 2020).

Table 1: GLUE tasks (Wang et al., 2018), dataset sizes and the metrics reported in this study

However, so far LTH work focused on the "winning" random initializations. In case of BERT, there is a large pre-trained language model, used in conjunction with a randomly initialized task-specific classifier; this paper and concurrent work by Chen et al. (2020) are the first to explore LTH in this context. The two papers provide complementary results for magnitude pruning, but we also study structured pruning, posing the question of whether "good" subnetworks can be used as an tool to understand how BERT works. Another contemporaneous study by Gordon et al. (2020) also explores magnitude pruning, showing that BERT pruned before fine-tuning still reaches performance similar to the full model.

Ideally, the pre-trained weights would provide transferable linguistic knowledge, fine-tuned only to learn a given task. But we do not know what knowledge actually gets used for inference, except that BERT is as prone as other models to rely on dataset biases (McCoy et al., 2019b; Rogers et al., 2020a; Jin et al., 2020; Niven and Kao, 2019; Zellers et al., 2019). At the same time, there is vast literature on probing BERT architecture blocks for different linguistic properties (Rogers et al., 2020b). If there are "good" subnetworks, then studying their properties might explain how BERT works.

3 Methodology

All experiments in this study are done on the "BERT-base lowercase" model from the Transformers library (Wolf et al., 2020). It is fine-tuned[2] on 9 GLUE tasks, and evaluated with the metrics shown in Table 1. All evaluation is done on the dev sets, as the test sets are not publicly distributed. For each experiment we test 5 random seeds.

3.1 BERT Architecture

BERT is fundamentally a stack of Transformer encoder layers (Vaswani et al., 2017). All layers have identical structure: a multi-head self-attention (MHAtt) block followed by an MLP, with residual connections around each.

MHAtt consists of N_h independently parametrized heads. An attention head h in layer l is parametrized by $W_k^{(h,l)}, W_q^{(h,l)}, W_v^{(h,l)} \in \mathbb{R}^{d_h \times d}$, $W_o^{(h,l)} \in \mathbb{R}^{d \times d_h}$. d_h is typically set to d/N_h. Given n d-dimensional input vectors $\mathrm{x} = x_1, x_2, ..x_n \in \mathbb{R}^d$, MHAtt is the sum of the output of each individual head applied to input x:

$$\text{MHAtt}^{(l)}(\mathrm{x}) = \sum_{h=1}^{N_h} \text{Att}^{(l)}_{W_k^{(h,l)}, W_q^{(h,l)}, W_v^{(h,l)}, W_o^{(h,l)}}(\mathrm{x})$$

The MLP in layer l consists of two feed-forward layers. It is applied separately to n d-dimensional vectors $\mathrm{z} \in \mathbb{R}^d$ coming from the attention sub-layer. Dropout (Srivastava et al., 2014) is used for regularization. Then inputs of the MLP are added to its outputs through a residual connection.

3.2 Magnitude Pruning

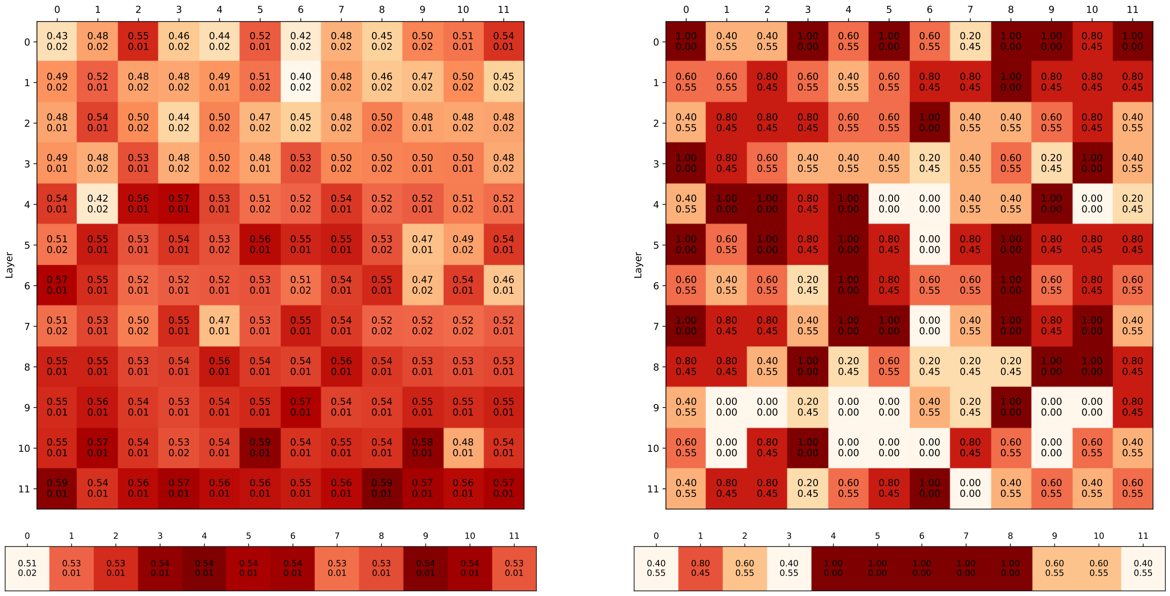
For magnitude pruning, we fine-tune BERT on each task and iteratively prune 10% of the lowest magnitude weights across the entire model (excluding the embeddings, since this work focuses on BERT's body weights). We check the *dev* set score in each iteration and keep pruning for as long as the performance remains above 90% of the full fine-tuned model's performance. Our methodology and results are complementary to those by Chen et al. (2020), who perform *iterative* magnitude pruning while fine-tuning the model to find the mask.

3.3 Structured Pruning

We study structured pruning of BERT architecture blocks, masking them under the constraint that at

---

[2] All experiments were performed with 8 RTX 2080 TI GPUs, 128 Gb of RAM, 2x CPU Intel(R) Xeon(R) CPU E5-2630 v4 @ 2.20GHz. Code repository: `https://github.com/sai-prasanna/bert-experiments`.



(a) M-pruning: each cell gives the percentage of surviving weights, and std across 5 random seeds.

(b) S-pruning: each cell gives the average number of random seeds in which a given head/MLP survived and std.

Figure 1: The "good" subnetworks for QNLI: self-attention heads (top, 12 x 12 heatmaps) and MLPs (bottom, 1x12 heatmaps), pruned together. Earlier layers start at 0.

least 90% of full model performance is retained. Combinatorial search to find such masks is impractical, and Michel et al. (2019) estimate the importance of attention heads as the expected sensitivity to the mask variable $\xi^{(h,l)}$:

$$I_h^{(h,l)} = E_{x\sim X}\left|\frac{\partial\mathcal{L}(x)}{\partial\xi^{(h,l)}}\right|$$

where x is a sample from the data distribution X and $\mathcal{L}(x)$ is the loss of the network outputs on that sample. We extend this approach to MLPs, with the mask variable $\nu^{(l)}$:

$$I_{mlp}^{(l)} = E_{x\sim X}\left|\frac{\partial\mathcal{L}(x)}{\partial\nu^{(l)}}\right|$$

If $I_h^{(h,l)}$ and $I_{mlp}^{(l)}$ are high, they have a large effect on the model output. Absolute values are calculated to avoid highly positive contributions nullifying highly negative contributions.

In practice, calculating $I_h^{(h,l)}$ and $I_{mlp}^{(l)}$ would involve computing backward pass on the loss over samples of the evaluation data[3]. We follow Michel et al. in applying the recommendation of Molchanov et al. (2017) to normalize the importance scores of the attention heads layer-wise (with $\ell 2$ norm) before pruning. To mask the heads, we use a binary mask variable $\xi^{(h,l)}$. If $\xi^{(h,l)} = 0$, the head h in layer l is masked:

$$\mathrm{MHAtt}^{(l)}(\mathrm{x}) = \sum_{h=1}^{N_h} \xi^{(h,l)} \mathrm{Att}^{(l)}_{W_k^{(h,l)},W_q^{(h,l)},W_v^{(h,l)},W_o^{(h,l)}}(\mathrm{x})$$

Masking MLPs in layer l is performed similarly with a masking variable $\nu^{(l)}$:

$$\mathrm{MLP}^{(l)}_{\mathrm{out}}(\mathrm{z}) = \nu^{(l)} MLP^{(l)}(\mathrm{z}) + \mathrm{z}$$

We compute head and MLP importance scores in a single backward pass, pruning 10% heads and one MLP with the smallest scores until the performance on the *dev* set is within 90%. Then we continue pruning heads alone, and then MLPs alone. The process continues iteratively for as long as the pruned model retains over 90% performance of the full fine-tuned model.

We refer to magnitude and structured pruning as *m-pruning* and *s-pruning*, respectively.

4 BERT Plays the Lottery

4.1 The "Good" Subnetworks

Figure 1 shows the heatmaps for the "good" subnetworks for QNLI, i.e. the ones that retain 90% of full model performance after pruning.

For s-pruning, we show the number of random initializations in which a given head/MLP survived

---

[3] The GLUE dev sets are used as oracles to obtain the best heads and MLPs for the particular model and task.

the pruning. For m-pruning, we compute the percentage of surviving weights in BERT heads and MLPs in all GLUE tasks (excluding embeddings). We run each experiment with 5 random initializations of the task-specific layer (the same ones), and report averages and standard deviations. See Appendix A for other GLUE tasks.

Figure 1a shows that in m-pruning, all architecture blocks lose about half the weights (42-57% weights), but the earlier layers get pruned more. With s-pruning (Figure 1b), the most important heads tend to be in the earlier and middle layers, while the important MLPs are more in the middle. Note that Liu et al. (2019) also find that the middle Transformer layers are the most transferable.

In Figure 1b, the heads and MLPs were pruned together. The overall pattern is similar when they are pruned separately. While fewer heads (or MLPs) remain when they are pruned separately (49% vs 22% for heads, 75% vs 50% for MLPs), pruning them together is more efficient overall (i.e., produces smaller subnetworks). Full data is available in Appendix B. This experiment hints at considerable interaction between BERT's self-attention heads and MLPs: with fewer MLPs available, the model is forced to rely more on the heads, raising their importance. This interaction was not explored in the previous studies (Michel et al., 2019; Voita et al., 2019; Kovaleva et al., 2019), and deserves more attention in future work.

4.2 Testing LTH for BERT Fine-tuning: The Good, the Bad and the Random

LTH predicts that the "good" subnetworks trained from scratch should match the full network performance. We experiment with the following settings:

- *"good" subnetworks*: the elements selected from the full model by either technique;
- *random subnetworks*: the same size as "good" subnetworks, but with elements randomly sampled from the full model;
- *"bad" subnetworks*: the elements sampled from those that did *not* survive the pruning, plus a random sample of the remaining elements so as to match the size of the "good" subnetworks.

For both pruning methods, we evaluate the subnetworks (a) after pruning, (b) after retraining the same subnetwork. The model is re-initialized to pre-trained weights (except embeddings), and the task-specific layer is initialized with the same random seeds that were used to find the given mask.

As mentioned earlier, the evaluation is performed on the GLUE[4] *dev* sets, which have also been used to identify the the "good" subnetworks originally. These subnetworks were chosen to work well on this specific data, and the corresponding "bad" subnetworks were defined only in relation to the "good" ones. We therefore do not expect these subnetworks to generalize to other data, and believe that they would best illustrate what exactly BERT "learns" in fine-tuning.

Performance of each subnetwork type is shown in Figure 2.The main LTH prediction is validated: the "good" subnetworks can be successfully retrained alone. Our m-pruning results are consistent with contemporaneous work by Gordon et al. (2020) and Chen et al. (2020).

We observe the following differences between the two pruning techniques:

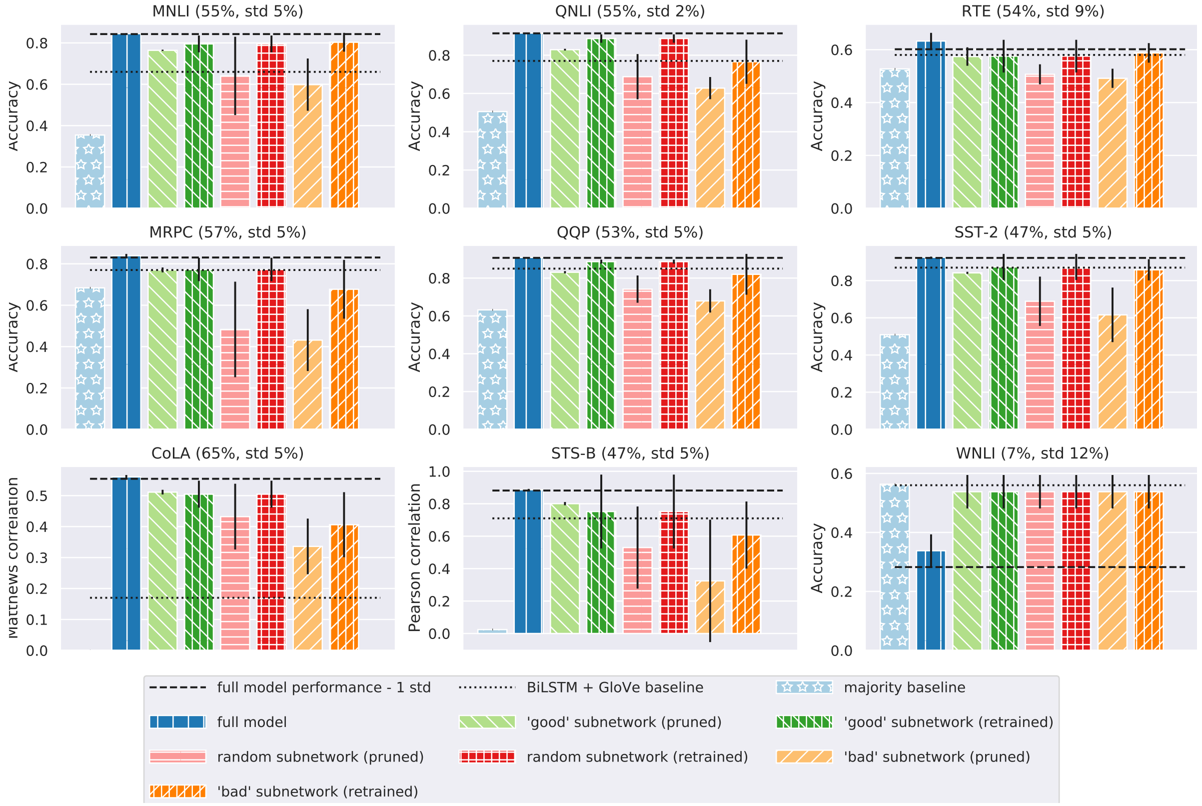
- For 7 out of 9 tasks m-pruning yields considerably higher compression (10-15% more weights pruned) than s-pruning.
- Although m-pruned subnetworks are smaller, they mostly reach[5] the full network performance. For s-pruning, the "good" subnetworks are mostly slightly behind the full network performance.
- Randomly sampled subnetworks could be expected to perform better than the "bad", but worse than the "good" ones. That is the case for m-pruning, but for s-pruning they mostly perform on par with the "good" subnetworks, suggesting the subset of "good" heads/MLPs in the random sample suffices to reach the full "good" subnetwork performance.

Note that our pruned subnetworks are relatively large with both pruning methods (mostly over 50% of the full model). For s-pruning, we also look at "super-survivors": much smaller subnetworks consisting only of the heads and MLPs that consistently survived across all seeds for a given task. For most tasks, these subnetworks contained only about 10-26% of the full model weights, but lost only about 10 performance points on average. See Appendix E for the details for this experiment.

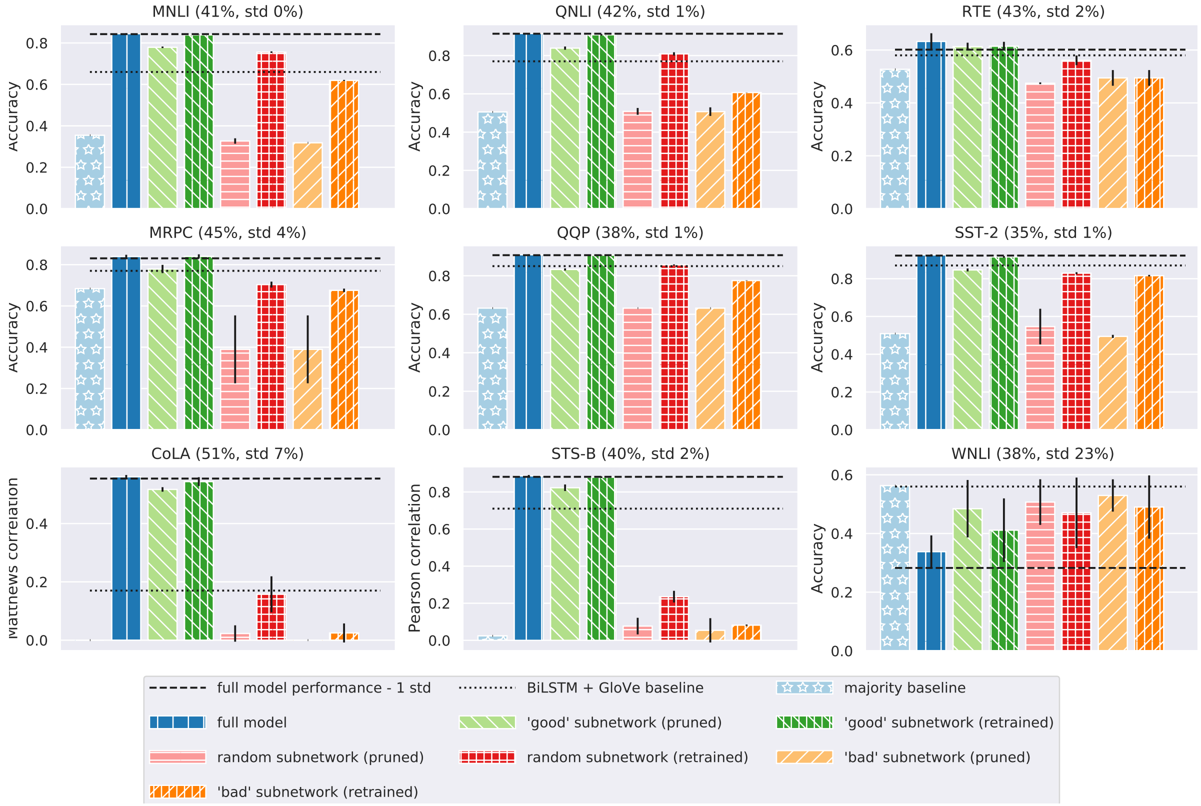
---

[4] The results for WNLI are unreliable: this dataset has similar sentences with opposite labels in train and dev data, and in s-pruning the whole model gets pruned away. See Appendix A for discussion of that.

[5] For convenience, Figure 2 shows the performance of the full model minus one standard deviation – the success criterion for the subnetwork also used by Chen et al. (2020).



(a) S-pruning



(b) M-pruning

Figure 2: The "good" and "bad" subnetworks in BERT fine-tuning: performance on GLUE tasks. 'Pruned' subnetworks are only pruned, and 'retrained' subnetworks are restored to pretrained weights and fine-tuned. Subfigure titles indicate the task and percentage of surviving weights. STD values and error bars indicate standard deviation of surviving weights and performance respectively, across 5 fine-tuning runs. See Appendix C for numerical results, and subsection 4.3 for GLUE baseline discussion.

Model	CoLA	SST-2	MRPC	QQP	STS-B	MNLI	QNLI	RTE	WNLI	Average[6]

Table 2: “Bad” BERT subnetworks (the best one is underlined) vs basic baselines (the best one is bolded). The randomly initialized BERT is randomly pruned by importance scores to match the size of s-pruned ‘bad’ subnetwork.

4.3 How Bad are the “Bad” Subnetworks?

Our study – as well as work by Chen et al. (2020) and Gordon et al. (2020) – provides conclusive evidence for the existence of “winning tickets”, but it is intriguing that for most GLUE tasks random masks in s-pruning perform nearly as well as the “good” masks - i.e. they could also be said to be “winning”. In this section we look specifically at the “bad” subnetworks: since in our setup, we use the *dev* set both to find the masks and to test the model, these parts of the model are the *least* useful for that specific data sample, and their trainability could yield important insights for model analysis.

Table 2 shows the results for the “bad” subnetworks pruned with both methods and re-fine-tuned, together with *dev* set results of three GLUE baselines by Wang et al. (2018). The m-pruned ‘bad’ subnetwork is at least 5 points behind the s-pruned one on 6/9 tasks, and is particularly bad on the correlation tasks (CoLA and STS-B). With respect to GLUE baselines, the s-pruned “bad” subnetwork is comparable to BiLSTM+ELMO and BiLSTM+GloVe. Note that there is a lot of variation between tasks: the ‘bad’ s-pruned subnetwork is competitive with BiLSTM+GloVe in 5/9 tasks, but it loses by a large margin in 2 more tasks, and wins in 2 more (see also Figure 2).

The last line of Table 2 presents a variation of experiment with fine-tuning randomly initialized BERT by Kovaleva et al. (2019): we randomly initialize BERT and also apply a randomly s-pruned mask so as to keep it the same size as the s-pruned “bad” subnetwork. Clearly, even this model is in principle trainable (and still beats the majority class baseline), but on average[6] it is over 15 points behind the “bad” mask over the pre-trained weights. This shows that even the worst possible selection of pre-trained BERT components for a given task still contains a lot of useful information. In other words, some lottery tickets are “winning” and yield the biggest gain, but all subnetworks have a non-trivial amount of useful information.

Note that even the random s-pruning of a randomly initialized BERT is slightly better than the m-pruned “bad” subnetwork. It is not clear what plays a bigger role: the initialization or the architecture. Chen et al. (2020) report that pre-trained weights do not perform as well if shuffled, but they do perform better than randomly initialized weights. To test whether the “bad” s-pruned subnetworks might match the “good” ones with more training, we trained them for 6 epochs, but on most tasks the performance went down (see Appendix D).

Finally, BERT is known to sometimes have degenerate runs (i.e. with final performance much lower than expected) on smaller datasets (Devlin et al., 2019). Given the masks found with 5 random initializations, we find that standard deviation of GLUE metrics for both “bad” and “random” s-pruned subnetworks is over 10 points not only for the smaller datasets (MRPC, CoLA, STS-B), but also for MNLI and SST-2 (although on the larger datasets the standard deviation goes down after re-fine-tuning). This illustrates the fundamental cause of degenerate runs: the poor match between the model and final layer initialization. Since our “good” subnetworks are specifically selected to be the best possible match to the specific random seed, the performance is the most reliable. As for m-pruning, standard deviation remains low even for the “bad” and “random” subnetworks in most tasks except MRPC. See Appendix C for full results.

5 Interpreting BERT’s Subnetworks

In subsection 4.2 we showed that the subnetworks found by m- and s-pruning behave similarly in fine-tuning. However, s-pruning has an advantage in

---

[6] GLUE leaderboard uses macro average of metrics to rank the participating systems. We only consider the metrics in Table 1 to obtain this average.

that the functions of BERT architecture blocks have been extensively studied (see detailed overview by Rogers et al. (2020b)). If the better performance of the "good" subnetworks comes from linguistic knowledge, they could tell a lot about the reasoning BERT actually performs at inference time.

5.1 Stability of the "Good" Subnetworks

Random initializations in the task-specific classifier interact with the pre-trained weights, affecting the performance of fine-tuned BERT (McCoy et al., 2019a; Dodge et al., 2020). However, if better performance comes from linguistic knowledge, we would expect the "good" subnetworks to better encode this knowledge, and to be relatively stable across fine-tuning runs for the same task.

We found the opposite. For all tasks, Fleiss' kappa on head survival across 5 random seeds was in the range of 0.15-0.32, and Cochran Q test did not show that the binary mask of head survival obtained with five random seeds for each tasks were significantly similar at $\alpha = 0.05$ (although masks obtained with some *pairs* of seeds were). This means that the "good" subnetworks are unstable, and depend on the random initialization more than utility of a certain portion of pre-trained weights for a particular task.

The distribution of importance scores, shown in Figure 3, explains why that is the case. At any given pruning iteration, most heads and MLPs have a low importance score, and could all be pruned with about equal success.

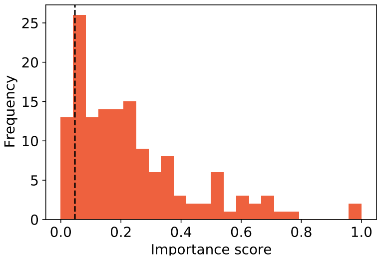

Figure 3: Head importance scores distribution (this example shows CoLA, pruning iteration 1)

5.2 How Linguistic are the "Good" Subnetworks?

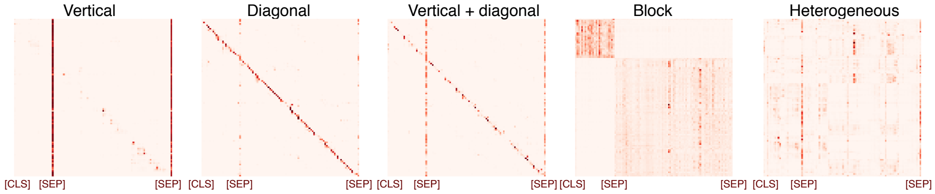
A popular method of studying functions of BERT architecture blocks is to use probing classifiers for specific linguistic functions. However, "the fact that a linguistic pattern is not observed by our probing classifier does not guarantee that it is not there, and the observation of a pattern does not tell us how it is used" (Tenney et al., 2019).

In this study we use a cruder, but more reliable alternative: the types of self-attention patterns, which Kovaleva et al. (2019) classified as diagonal (attention to previous/next word), block (uniform attention over a sentence), vertical (attention to punctuation and special tokens), vertical+diagonal, and heterogeneous (everything else) (see Figure 4a). The fraction of heterogeneous attention can be used as an *upper bound estimate* on non-trivial linguistic information. In other words, these patterns do not guarantee that a given head has some interpretable function – only that it could have it.

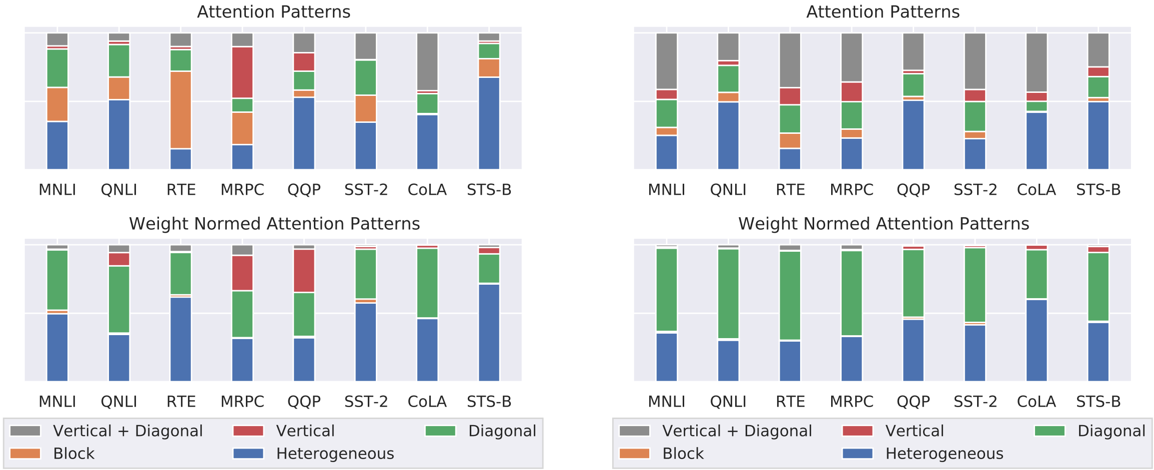
This analysis is performed by image classification on generated attention maps from individual heads (100 for each GLUE task), for which we use a small CNN classifier with six layers. The classifier was trained on the dataset of 400 annotated attention maps by Kovaleva et al. (2019).

Note that attention heads can be seen as a weighted sum of linearly transformed input vectors. Kobayashi et al. (2020) recently showed that the input vector norms vary considerably, and the inputs to the self-attention mechanism can have a disproportionate impact relative to their self-attention weight. So we consider both the raw attention maps, and, to assess the true impact of the input in the weighted sum, the L2-norm of the transformed input multiplied by the attention weight (for which we annotated 600 more attention maps with the same pattern types as Kovaleva et al. (2019)). The weighted average of F_1 scores of the classifier on annotated data was 0.81 for the raw attention maps, and 0.74 for the normed attention.

Our results suggest that the super-survivor heads do *not* preferentially encode non-trivial linguistic relations (heterogeneous pattern), in either raw or normed self-attention (Figure 4b). As compared to all 144 heads (Figure 4c) the "raw" attention patterns of super-survivors encode considerably more block and vertical attention types. Since norming reduces attention to special tokens, the proportion of diagonal patterns (i.e. attention to previous/next tokens) is increased at the cost of vertical+diagonal pattern. Interestingly, for 3 tasks, the super-survivor subnetworks still heavily rely on the vertical pattern even after norming. The vertical pattern indicates a crucial role of the special tokens, and it is unclear why it seems to be less important for MNLI rather than QNLI, MRPC or QQP.



(a) Reference: typical BERT self-attention patterns by Kovaleva et al. (2019).



(b) Super-survivor heads, fine-tuned

(c) All heads, fine-tuned

Figure 4: Attention pattern type distribution

The number of block pattern decreased, and we hypothesize that they are now classified as heterogeneous (as they would be unlikely to look diagonal). But even with the normed attention, the utility of super-survivor heads cannot be attributed only to their linguistic functions (especially given that the fraction of heterogeneous patterns is only a rough upper bound). The Pearson's correlation between heads being super-survivors and their having heterogeneous attention patterns is 0.015 for the raw, and 0.025 for the normed attention. Many "important" heads have diagonal attention patterns, which seems redundant.

We conducted the same analysis for the attention patterns in pre-trained vs. fine-tuned BERT for both super-survivors and all heads, and found them to not change considerably after fine-tuning, which is consistent with findings by Kovaleva et al. (2019). Full data is available in Appendix F.

Note that this result does not exclude the possibility that linguistic information is encoded in certain *combinations* of BERT elements. However, to date most BERT analysis studies focused on the functions of individual components (Voita et al., 2019; Htut et al., 2019; Clark et al., 2019; Lin et al., 2019; Vig and Belinkov, 2019; Hewitt and Manning, 2019; Tenney et al., 2019, see also the overview by Rogers et al. (2020b)), and this evidence points to the necessity of looking at their interactions. It also adds to the ongoing discussion of interpretability of self-attention (Jain and Wallace, 2019; Serrano and Smith, 2019; Wiegreffe and Pinter, 2019; Brunner et al., 2020).

Once again, heterogenerous pattern counts are only a crude upper bound estimate on potentially interpretable patterns. More sophisticated alternatives should be explored in future work. For instance, the recent information-theoretic probing by minimum description length (Voita and Titov, 2020) avoids the problem of false positives with traditional probing classifiers.

5.3 Information Shared Between Tasks

While the "good" subnetworks are not stable, the overlaps between the "good" subnetworks may still be used to characterize the tasks themselves. We leave detailed exploration to future work, but as a brief illustration, Figure 5 shows pairwise overlaps in the "good" subnetworks for the GLUE tasks.

The overlaps are not particularly large, but still

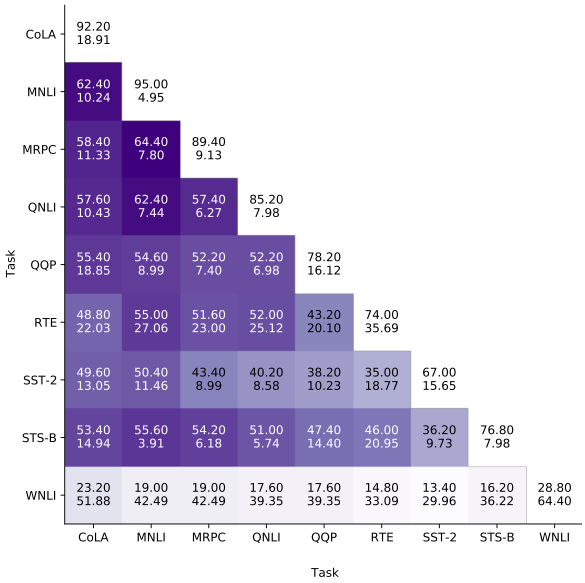


Figure 5: Overlaps in BERT's "good" subnetworks between GLUE tasks: self-attention heads.

more than what we would expect if the heads were completely independent (e.g. MRPC and QNLI share over a half of their "good" subnetworks). Both heads and MLPs show a similar pattern. Full data for full and super-survivor "good" subnetworks is available in Appendix G.

Given our results in subsection 5.2, the overlaps in the "good" subnetworks are not explainable by two tasks' relying on the same linguistic patterns in individual self-attention heads. They also do not seem to depend on the type of the task. For instance, consider the fact that two tasks targeting paraphrases (MRPC and QQP) have less in common than MRPC and MNLI. Alternatively, the overlaps may indicate shared heuristics, or patterns somehow encoded in combinations of BERT elements. This remains to be explored in future work.

6 Discussion

This study confirms the main prediction of LTH for pre-trained BERT weights for both m- and s-pruning. An unexpected finding is that with s-pruning, the "random" subnetworks are still almost as good as the "good" ones, and even the "worst" ones perform on par with a strong baseline. This suggests that the weights that do not survive pruning are not just "inactive" (Zhang et al., 2019).

An obvious, but very difficult question that arises from this finding is whether the "bad" subnetworks do well because even they contain some linguistic knowledge, or just because GLUE tasks are overall easy and could be learned even by *random* BERT (Kovaleva et al., 2019), or even any sufficiently large model. Given that we did not find even the "good" subnetworks to be stable, or preferentially containing the heads that could have interpretable linguistic functions, the latter seems more likely.

Furthermore, should we perhaps be asking the same question with respect to not only subnetworks, but also full models, such as BERT itself and all the follow-up Transformers? There is a trend to automatically credit any new state-of-the-art model with with better knowledge of language. However, what if that is not the case, and the success of pre-training is rather due to the flatter and wider optima in the optimization surface (Hao et al., 2019)? Can similar loss landscapes be obtained from other, non-linguistic pre-training tasks? There are initial results pointing in that direction: Papadimitriou and Jurafsky (2020) report that even training on MIDI music is helpful for transfer learning for LM task with LSTMs.

7 Conclusion

This study systematically tested the lottery ticket hypothesis in BERT fine-tuning with two pruning methods: magnitude-based weight pruning and importance-based pruning of BERT self-attention heads and MLPs. For both methods, we find that the pruned "good" subnetworks alone reach the performance comparable with the full model, while the "bad" ones do not. However, for structured pruning, even the "bad" subnetworks can be fine-tuned separately to reach fairly strong performance. The "good" subnetworks are *not* stable across fine-tuning runs, and their success is *not* attributable exclusively to non-trivial linguistic patterns in individual self-attention heads. This suggests that most of pre-trained BERT is potentially useful in fine-tuning, and its success could have more to do with optimization surfaces rather than specific bits of linguistic knowledge.

Carbon Impact Statement. This work contributed 115.644 kg of CO_{2eq} to the atmosphere and used 249.068 kWh of electricity, having a NLD-specific social cost of carbon of \$-0.14 (\$-0.24, \$-0.04). The social cost of carbon uses models from (Ricke et al., 2018) and this statement and emissions information was generated with *experiment-impact-tracker* (Henderson et al., 2020).

Acknowledgments

The authors would like to thank Michael Carbin, Aleksandr Drozd, Jonathan Frankle, Naomi Saphra and Sri Ananda Seelan for their helpful comments, the Zoho corporation for providing access to their clusters for running our experiments, and the anonymous reviewers for their insightful reviews and suggestions. A “Good” Subnetworks in BERT Fine-tuned on GLUE Tasks

Each figure in this section shows the “good” subnetwork of heads and layers that survived the pruning process described in section 3. Each task was run with 5 different random seeds. The top number in each cell indicates how likely a given head or MLP was to survive pruning, with 1.0 indicating that it survived on every run. The bottom number indicates the standard deviation across runs.

The figures in this appendix show that each task has a varying number of heads and layers that survive pruning on all fine-tuning runs, while some heads and layers were only “picked up” by some random seeds. Note also that in addition to the architecture elements that survive across many runs, there are also some that are useful for over half of the tasks, as shown in Figure 15, and some *always* survive the pruning.

Visualizing the “good” subnetwork illustrates the core problem with WNLI, the most difficult task of GLUE. Figure 14 shows that each run is completely different, indicating that BERT fails to find any consistent pattern between the task and the information in the available pre-trained weights. WNLI is described as “somewhat adversarial” by Wang et al. (2018) because it has similar sentences in train and dev sets with opposite labels.

B Iterative Pruning Modes

We conducted additional experiments with the following settings for iterative pruning based on importance scores:

- *Heads only*: in each iteration, we mask as many of the unmasked heads with the lowest importance scores as we can (144 heads in the full BERT-base model).
- *MLPs only*: we iteratively mask one of the remaining MLPs that has the smallest importance score (subsection 3.3).
- *Heads and MLPs*: we compute head (subsection 3.3) and MLP (subsection 3.3) importance scores in a single backward pass, pruning 10% heads and one MLP with the smallest scores until the performance on the *dev* set is within 90%. Then we continue pruning heads alone, and then MLPs alone. This strategy results in a larger number of total components pruned within our performance threshold.

Figure 16: The mean of GLUE tasks metrics evaluated on five seeds at different epochs (the best one is bolded). *Slight divergence in metrics from the previously reported ones due to this being an new fine-tuning run.

E Performance of the “Super Survivor” Subnetworks

In this experiment, we explore three settings:

- *“good” subnetworks*: the subnetworks consisting only of “super-survivors”: the self-attention heads and MLPs that survived in all random seeds, shown in Appendix A. These subnetworks are much smaller than the pruned subnetworks discussed in subsection 4.2 (10-30% vs 50-70% of the full model);
- *“bad” subnetworks*: the subnetworks the same size as the super-survivor subnetworks, but selected from heads and MLPs the *least* likely to survive importance pruning;
- *random subnetworks*: same size as super-survivor subnetworks, but selected from elements that were neither super-survivors, nor the ones in the “bad” subnetworks.

The striking conclusion is that on 6 out of 9 tasks the bad and random subnetworks behaved nearly as well as the “good” ones, suggesting that the “super-survivor” self-attention heads and MLPs did *not* survive importance pruning because of their encoding some unique linguistic information necessary for solving the GLUE tasks.

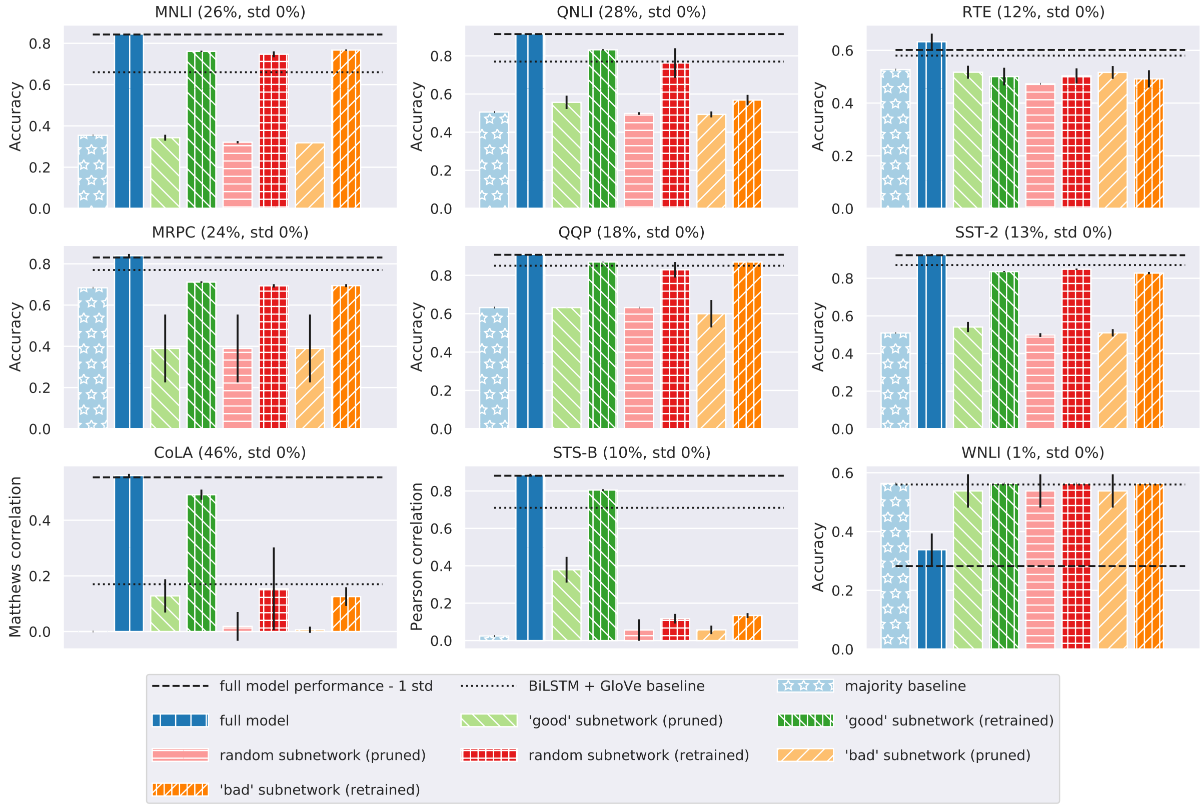

Figure 17: The performance of “super survivor” subnetworks in BERT fine-tuning: performance on GLUE tasks (error bars indicate standard deviation across 5 fine-tuning runs). The size of the super-survivor subnetwork as % of full model weights is shown next to the task names.

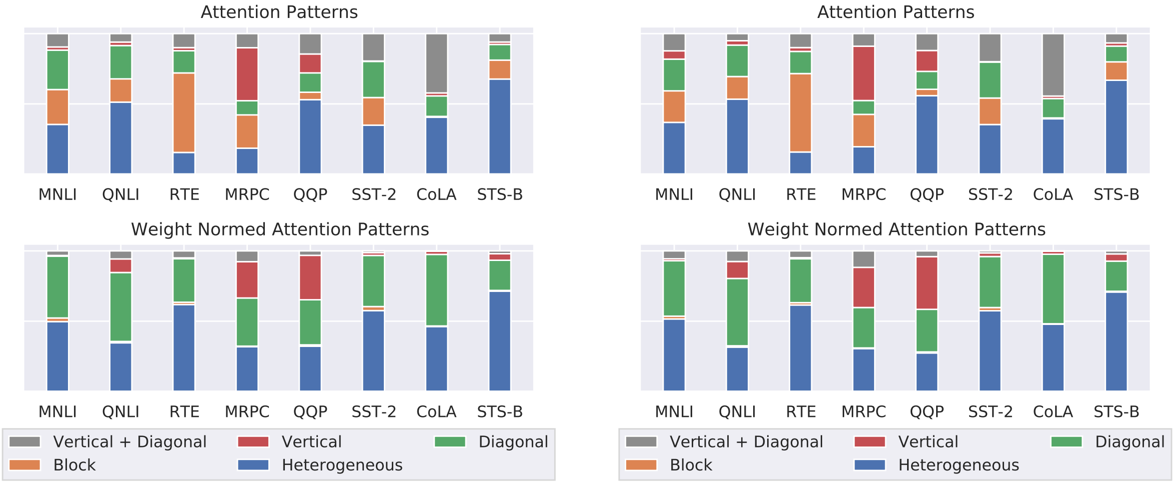
F Attention Pattern Type Distribution

We use two separately trained CNN classifiers to analyze the BERT's self-attention maps, both "raw" head outputs and weight-normed attention, following Kobayashi et al. (2020). For the former, we use 400 annotated maps by Kovaleva et al. (2019), and for the latter we additionally annotate 600 more maps.

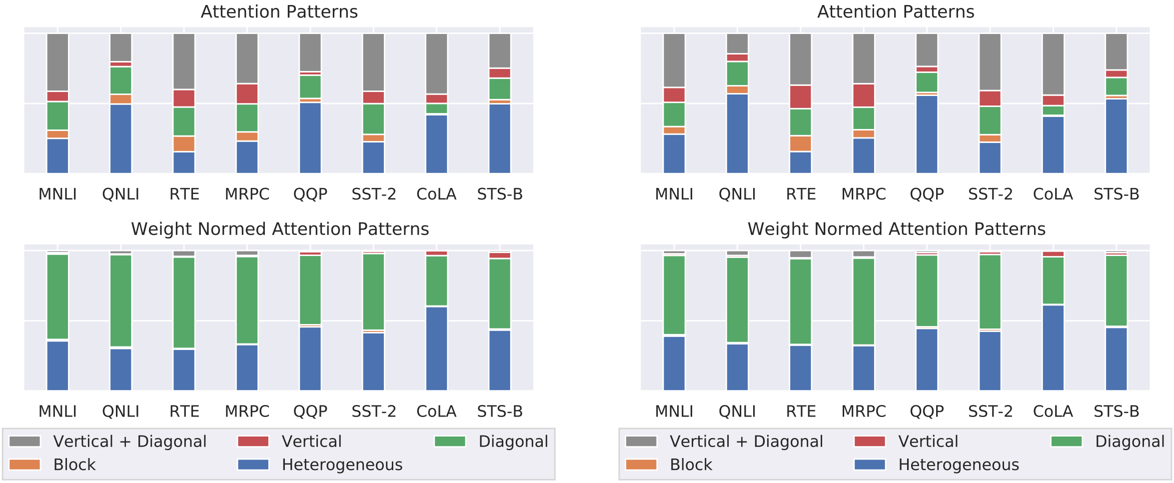
We run the classifiers on pre-trained and fine-tuned BERT, both the full model and the model pruned by the "super-survivor" mask (only the heads and MLPs that survived across GLUE tasks). For each experiment, we report the fraction of attention patterns estimated from a hundred dev-set samples for each task across five random seeds.

See Figure 4a for attention types illustration.



(a) Super-survivor heads, fine-tuned

(b) Super-survivor heads, pre-trained



(c) All heads, fine-tuned

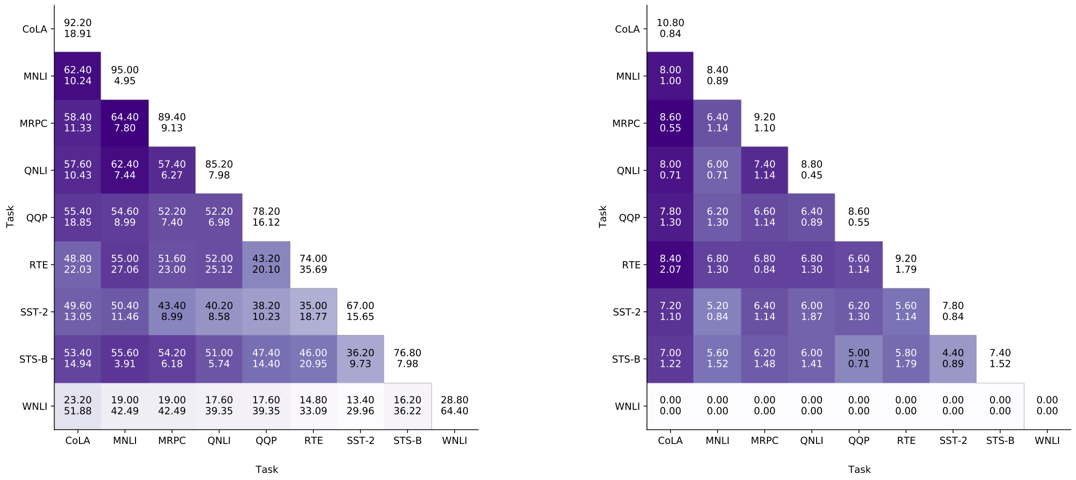
(d) All heads, pre-trained

Figure 18: Attention pattern distribution in all BERT self-attention heads and the "super-survivor" heads.

G How Task-independent are the “Good” Subnetworks?

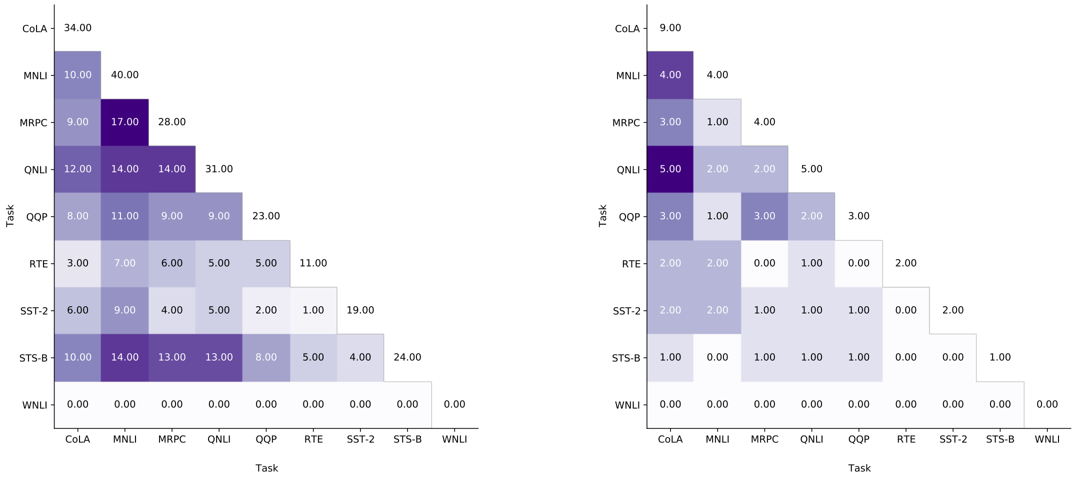
The parts of the “good” subnetworks that are only relevant for some specific tasks, but consistently survive across fine-tuning runs for that task, should encode the information useful for that task, even if it is not deeply linguistic. Therefore, the degree to which the “good” subnetworks overlap across tasks may be a useful way to characterize the tasks themselves.

Figure 19 shows pairwise comparisons between all GLUE tasks with respect to the number of shared heads and MLPs in two conditions: the “good” subnetworks found by structured importance pruning that were described in subsection 4.1, and super-survivors (the heads/MLPs that survived in all random seeds).



(a) Heads shared between tasks

(b) MLPs shared between tasks



(c) Super-survivor Heads shared between tasks

(d) Super-survivor MLPs shared between tasks

Figure 19: The “good” subnetwork: The diagonal represents the BERT architecture components that survive pruning for a given task and remaining elements represent the common surviving components across GLUE tasks. Each cell gives the average number of heads (out of 144) or layers (out of 12), together with standard deviation across 5 random initializations (for (a) and (b)).

On the weak link between importance and prunability of attention heads

Abstract

Given the success of Transformer-based models, two directions of study have emerged: interpreting role of individual attention heads and down-sizing the models for efficiency. Our work straddles these two streams: We analyse the importance of basing pruning strategies on the interpreted role of the attention heads. We evaluate this on Transformer and BERT models on multiple NLP tasks. Firstly, we find that a large fraction of the attention heads can be randomly pruned with limited effect on accuracy. Secondly, for Transformers, we find no advantage in pruning attention heads identified to be important based on existing studies that relate importance to the location of a head. On the BERT model too we find no preference for top or bottom layers, though the latter are reported to have higher importance. However, strategies that avoid pruning middle layers and consecutive layers perform better. Finally, during fine-tuning the compensation for pruned attention heads is roughly equally distributed across the un-pruned heads. Our results thus suggest that interpretation of attention heads does not strongly inform pruning.

1 Introduction

The acclaimed success of Transformer-based models across NLP tasks has been followed by two important directions of research. In the first direction, interpretability studies aim to understand how these models work. Given that multi-headed attention is an important feature of these models, researchers have focused on attention heads as the units of interpretation. These studies comment on the role of each attention head and the relation between a head's position and its significance (Clark et al., 2019; Michel et al., 2019; Voita et al., 2019b,a; Liu et al., 2019; Belinkov et al., 2017). These studies show that certain heads are more important based on (i) their position in the network (top, middle, bottom), or (ii) the component to which they belong (encoder self-attention, decoder self-attention, encoder-decoder cross attention), or (iii) the functional role they play (e.g., syntactic/semantic).

In the other major direction, these large Transformer-based models have been down-sized to be more time and space efficient. Different methods for down-sizing have been studied such as pruning (McCarley, 2019; Gordon et al., 2020; Sajjad et al., 2020), distillation (Sanh et al., 2019; Liu et al., 2019; Jiao et al., 2019), weight quantization (Zafrir et al., 2019; Shen et al., 2019), and weight factorization and parameter sharing (Lan et al., 2019). Pruning techniques have been particularly successful in reinforcing the folk-lore that these models are highly over-parameterized. These pruning methods prune parameters based on magnitude (Gordon et al., 2020), importance (McCarley, 2019) or layer-wise (Sajjad et al., 2020).

In this paper, we straddle these two directions of work by asking the following question: *Can we randomly prune heads, thus completely ignoring any notion of importance of heads?* To answer this, we systematically study the effect of randomly pruning specific subsets of attention heads on the accuracy on different tasks. Across experiments, we modify the random sampling to vary the percentage of heads pruned and their location in the network (components and layers).

We evaluate these experiments both on the Transformer and BERT models. Our results show that a large fraction of attention heads can be pruned randomly: 75% of the attention heads of Transformer can be randomly pruned with a drop of less than 1 BLEU point on NMT tasks. Similarly, half of the attention heads of BERT can be randomly pruned with an average drop in accuracy of less

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3230–3235,
November 16–20, 2020.

than 1% across a chosen set of GLUE tasks[1]. Significantly for Transformers, we find no evidence for pruning methods preferring specific attention heads based on their location; even when the locations are chosen to match attention heads identified to be more important in existing studies. Similarly on the BERT model, pruning top and bottom layers do not show significant difference, even though existing studies attribute higher importance to the latter (Sajjad et al., 2020). However, we identify a preference to avoid pruning the middle layers and consecutive layers. Lastly, we check if during fine-tuning certain heads compensate more for the pruned heads. If so, such heads would perhaps be more important. However, we find no such evidence. In particular, during fine-tuning, the un-pruned heads change similarly across most pruning configurations. Overall, our experiments suggest that interpretation of attention heads does not strongly inform pruning.

The rest of the paper is organized as follows: Section 2 mentions about the models and the datasets used for this work followed by Section 3 which provides details of the experimental process. This section reports results on both Transformer and BERT models. We summarize our work in Section 4.

2 Models and Datasets

2.1 Multi-headed Self Attention

In each multi-headed attention layer we have multiple attention heads which transform the representation of inputs of a given sequence of tokens. Given the d_v dimensional representation of T tokens as $X \in \Re^{T \times d_v}$, the output of multi-headed self attention with N attention heads is given by

$$\text{Concat}_{i=1}^{N}\left(\text{softmax}\left(\frac{(XW_i^q)(XW_i^k)^T}{\sqrt{d_k}}\right)XW_i^v\right), \quad (1)$$

where $W_i^k, W_i^q, W_i^v \in \Re^{d_v \times d_k}$ are parameters of the i-th attention head.

2.2 Transformers

We use the Transformer-Base model (Vaswani et al., 2017) which has 6 layers each in the three components: encoder self-attention (ES), encoder-decoder cross-attention (ED), and decoder self-attention (DS). In each layer of each of the three components, we have 8 attention heads, totalling to $3 \times 6 \times 8 = 144$ attention heads. We train the models with 2.5 million sentence pairs each from the WMT'14 English-Russian (EN-RU) and English-German (EN-DE) datasets. We report BLEU scores on WMT's *newstest2014*. We use Adam optimizer (Kingma and Ba, 2014) with parameters $\beta_1 = 0.9$, $\beta_2 = 0.997$, and $\epsilon = 10^{-9}$. We vary the learning rate according to the formula described in Vaswani et al. (2017) with *warmup_steps* = 16k. We use large batch sizes of 32k and 25k for EN-RU and EN-DE, respectively, as it has been established that large batch sizes are inherent to the performance of Transformers (Popel and Bojar, 2018; Voita et al., 2019b). We achieve effectively large batch sizes using the technique of gradient accumulation on single NVIDIA V100 and 1080Ti GPUs.

2.3 BERT

In all experiments involving BERT, we use the BERT Base-uncased model (Devlin et al., 2018). It has 12 layers and each layer contains 12 attention heads, summing to 144 attention heads. We fine-tune and evaluate the pre-trained model[2] on sentence entailment task MNLI-M, the question similarity task QQP, the question-answering task QNLI, and the movie review task SST-2 from the GLUE Benchmark (Wang et al., 2018). We report accuracies on the official development sets of the considered GLUE tasks. For each of the four GLUE tasks, namely MNLI-M, QQP, QNLI and SST-2, we tried combinations of batch size and learning rate from {8, 16, 32, 64, 128} and $\{2, 3, 4, 5\} \times 10^{-5}$ respectively and selected the best performing configuration. The exact hyperparameters used for each of the tasks have been made available with the code released[3]. Each BERT experiment was run on a single Cloud TPU (v2-8).

3 Experiments

3.1 Experimental Process

In all the experiments, we perform random pruning where a subset of attention heads chosen by random sampling are zeroed out. Formally, each attention head is assigned a weight ξ which is 0 if the head is pruned and 1 otherwise. Then, the output of an attention layer is given by

$$\text{Concat}_{i=1}^{N}\left(\xi_i\text{softmax}\left(\frac{(XW_i^q)(XW_i^k)^T}{\sqrt{d_k}}\right)XW_i^v\right) \quad (2)$$

After pruning, we fine-tune the Transformer model for 30 epochs and the BERT model for 10 epochs.

---

[1] We avoid WNLI, RTE, MRPC, STS-B, CoLA as the results on these datasets tend to be noisy and unstable as reported in (Gordon et al., 2020; Sajjad et al., 2020)

[2] https://github.com/google-research/bert

[3] https://github.com/iitmnlp/head_importance_and_pruning

Since the values ξ are randomly sampled, in each experiment we report the average of three different samplings of ξ. The standard deviations are 0.668% and 0.778% of the reported average values for Transformer and BERT respectively.

3.2 Experimental Results on Transformers

Varying Pruning Percentage. We randomly prune attention heads across all components and layers varying the percentage of pruning from 25% to 87% (Table 1). We observed that in the case of extreme pruning, i.e., keeping just one head in each layer of each of the three components (which corresponds to a pruning percentage of 87%), the drop in BLEU was 1.62 (EN-RU) and 1.03 (EN-DE) as can be seen from Table 1. Across both EN-RU and EN-DE tasks, 60% of the attention heads can be pruned with a maximum drop in BLEU score by only 0.15. As can be observed from Figure 1, the drop is sharper as we increase the pruning percentage beyond 60%.

% Pruning	EN-RU	EN-DE
0 (Baseline)	29.09	27.95
25	29.59 (+0.50)	28.19 (+0.24)
35	29.29 (+0.20)	27.94 (-0.01)
50	29.38 (+0.29)	28.02 (+0.07)
55	29.00 (-0.09)	28.24 (+0.29)
60	28.94 (-0.15)	27.88 (-0.07)
75	28.22 (-0.87)	27.49 (-0.46)
81	27.97 (-1.12)	26.80 (-1.15)
87	27.47 (-1.62)	26.92 (-1.03)

Table 1: BLEU scores for Transformer on EN-RU and EN-DE datasets when subject to varying pruning percentages. Difference from the baseline score is indicated in brackets.

Pruning based on Layer Numbers. Voita et al. (2019b) identify that attention heads in specific layers of the Transformer – lower layers of Self-Attention components, i.e., Encoder-Self (ES) and Decoder-Self (DS), and higher layers of Encoder-Decoder cross attention (ED) – are more important. We evaluate the correspondence of this importance to pruning. We choose 5 pruning percentages from 25% to 75% and in each case two pruning configurations: One where the heads considered important are retained and the other where the important heads are pruned. The configurations and the corresponding BLEU scores on the EN-RU dataset are shown in Table 2 where each configuration is specified as a string. For example, the string 777322 indicates that 7 heads each were retained in the first three layers, 3 in the fourth layer and 2 each in the last two layers. For each pruning percentage, the first row corresponds to the configuration in which heads considered important (Voita et al., 2019b) were retained and the second row corresponds to the adversarial configuration in which heads considered important were pruned. We identify no preference in pruning as for each pruning percentage the performance of both configurations is very similar.

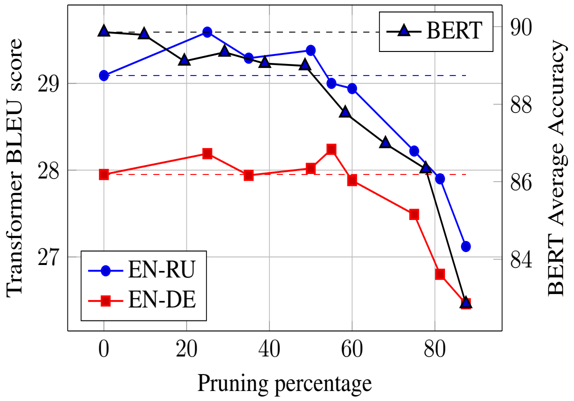

Figure 1: Effect of random pruning on the performance of Transformer and BERT for various pruning percentages.

%	Configuration			BLEU Scores
	ES	ED	DS	
0	888888	888888	888888	29.09
25	888444	444888	888444	29.62 (+0.53)
	444888	888444	444888	29.43 (+0.34)
40	777322	233777	777332	29.17 (+0.08)
	223777	777332	233777	29.57 (+0.48)
50	666222	222666	666222	29.01 (-0.08)
	222666	666222	222666	29.35 (+0.26)
60	555211	112555	555211	28.99 (-0.10)
	112555	555211	112555	28.78 (-0.31)
75	333111	111333	333111	28.48 (-0.61)
	111333	333111	111333	28.35 (-0.74)

Table 2: BLEU scores for different pruning configurations of Transformer. Every row has 2 configurations: first, where the important heads are retained, and second, where the important heads are pruned.

Pruning Based on Component. Some studies show that heads in the ED component are most important while those in the ES module are least important (Voita et al., 2019b). We choose 4 different pruning percentages and in each case consider three configurations where the number of attention heads is least in one chosen component (ES, ED, DS). The configurations and corresponding BLEU scores on the EN-RU dataset are shown in Table 3.

Pruning %	Configuration	BLEU Score
Baseline	(48,48,48)	29.09
48%	(14,31,30)	28.96 (-0.13)
	(31,14,30)	29.00 (-0.09)
	(30,31,14)	29.13 (+0.04)
60%	(12,21,25)	28.48 (-0.61)
	(21,12,25)	28.78 (-0.31)
	(25,21,12)	28.48 (-0.61)
75%	(8,13,15)	27.95 (-1.14)
	(13,8,15)	27.96 (-1.13)
	(15,13,8)	28.04 (-1.05)
82%	(5,9,12)	27.24 (-1.85)
	(9,5,12)	26.95 (-2.14)
	(12,9,5)	27.83 (-1.26)

Table 3: BLEU scores for different pruning configurations of Transformer specified by the triple denoting the number of heads retained in the Encoder-Self, Encoder-Decoder, and Decoder-Self attention components.

We identify no consistent preference in the pruning strategy: In the 4 cases considered, each of the 3 configurations has the highest BLEU score in at least one case. Note that we chose the number of heads in each layer (14, 31, etc) to be consistent with those used in (Voita et al., 2019b).

3.3 Experimental Results on BERT

% Pruning	MNLI-M	QQP	QNLI	SST-2
0	83.69	91.22	91.66	92.88
10	83.70	91.39	91.60	92.48
20	82.80	91.09	90.33	92.25
30	82.87	91.19	90.84	92.48
40	82.48	91.05	90.40	92.27
50	83.02	90.90	90.04	92.00
60	81.35	90.56	87.31	91.89
70	80.40	89.83	86.85	90.86
80	78.93	90.03	86.40	89.96
90	75.08	87.44	81.80	87.11

Table 4: Performance of random pruning on BERT for different pruning percentages. The accuracies are reported on the official GLUE development datasets.

Varying Pruning Percentage. We vary the pruning percentage from 10 to 90% and report the accuracy on the 4 GLUE tasks: MNLI-M, QQP, QNLI, and SST-2 (Table 4). We observe that half of the attention heads can be pruned with an average accuracy drop of under 1%. As shown in Figure 1, beyond 50% pruning, the accuracy drop is sharper.

Pruning based on Layer Numbers. To identify any preference to pruning heads in specific layers, we consider several configurations as shown in Table 5, where we prune a subset of layers entirely, i.e. we prune all the attention heads of particular layers. When all the self-attention heads of a layer *l* are pruned, only the feed-forward network of that layer will be active whose input will just be the output from the previous layer *l-1*.

Layers Pruned	MNLI-M	QQP	QNLI	SST-2
0 (Baseline)	83.69	91.22	91.66	92.88
Top 1	82.95	91.33	91.48	91.85
Bottom 1	83.65	91.42	91.17	93.11
Top 3	82.58	90.85	89.2	92.31
Bottom 3	83.36	90.95	90.88	92.54
Top 6	80.98	90.52	87.44	90.02
Bottom 6	79.29	90.17	87.40	91.05
Top 8	77.59	89.34	85.08	88.53
Bottom 8	78.07	89.67	84.22	87.95
Top 1, Bottom 1	83.33	91.23	90.70	92.88
Middle 2	83.60	91.08	90.80	91.74
Top 2, Bottom 2	82.41	91.11	90.48	92.20
Middle 4	81.84	90.87	86.14	90.94
Top 3, Bottom 3	81.72	90.67	88.30	92.31
Middle 6	80.08	90.49	87.07	87.84
Top 4, Bottom 4	79.47	89.57	86.01	90.36
Middle 8	78.88	89.55	83.67	88.87

Table 5: Accuracy on GLUE tasks for multiple layer-wise pruned configurations of BERT.

Bottom layers of BERT have been identified to model word morphology (Liu et al., 2019; Belinkov et al., 2017) and are considered to be important (Sajjad et al., 2020). Further, recent work has identified high cosine-similarity between output vectors of the top layers, indicating reduced importance of top layers (Goyal et al., 2020). We relate these studies to pruning by comparing the pruning of the same number of top and bottom layers (rows 2-9 in Table 5). Amongst the four cases, two cases each favor pruning top layers and bottom layers, revealing no preference in pruning.

The middle layers in BERT have been shown to have specific characteristics of higher attention entropy and greater attention to specific tokens (Clark et al., 2019). We thus considered configurations where we compare pruning top and bottom layers against pruning middle layers (last eight rows of Table 5). The results indicate a clear preference: In 14 out of 16 cases, pruning the middle layers performs worse that pruning equal number of layers distributed among top/bottom layers. Indeed, we incur an additional over 2% average drop in accuracy for QNLI and SST-2 tasks, indicating a task-specific sensitivity to pruning middle layers.

Recent work has identified that consecutive lay-

Figure 2: Head-wise average magnitude change of weights during fine-tuning for the following pruning configurations of BERT for the MNLI-M task: (a) 10% pruned (b) 50% pruned (c) 90% pruned (d) Top three layers pruned (e) Bottom three layers pruned (f) Alternate layers pruned.

ers of BERT have similar functionality (Lan et al., 2019). To study this, we considered configurations where six even and odd alternate layers are pruned and compare it with other strategies of pruning 50% layers of BERT (Table 6). We observe that the odd configuration performs better than the Top 6 and Bottom 6 configurations, indicating a preference to avoid pruning of consecutive layers.

Layers Pruned	MNLI-M	QQP	QNLI	SST-2
Top 6	80.98	90.52	87.44	90.02
Bottom 6	79.29	90.17	87.40	91.05
Even 6	81.54	90.74	86.39	90.36
Odd 6	81.95	90.58	90.18	92.20
Top 3, Bottom 3	81.72	90.67	88.30	92.31
Middle 6	80.08	90.49	87.07	87.84

Table 6: Accuracy on GLUE tasks when half of the layers of BERT are pruned. Pruning odd numbered layers retains the maximal accuracy across most of the tasks.

Effect of Fine-Tuning. Recent studies (Kovaleva et al., 2019; Houlsby et al., 2019) have reported that when fine-tuning BERT for specific tasks, the top layers change much more than the lower layers. We now evaluate this for fine-tuning after pruning. In Figure 2, we plot the average change in magnitude of parameters for different attention heads (W^q, W^k, W^v in Equation 1) for the MNLI-M task. We observe no spatial patterns in the parameter changes or with respect to relative distance from pruned heads. In particular, for all experiments in Table 5 and 6, the average change in attention parameters for any two layers differs by less than 10%. This shows that the compensation for pruned attention heads is roughly equally distributed across the unpruned heads.

4 Conclusion

We systematically studied the effect of pruning attention heads in Transformer and BERT models. We confirmed the general expectation that a large number of attention heads can be pruned with limited impact on performance. For Transformers we observed no preference for pruning attention heads which have been identified as important in interpretability studies. Similarly, for BERT we found no preference between pruning top and bottom layers. However, pruning middle layers and consecutive layers led to a larger drop in accuracy. We also observe that the recovery during fine-tuning was uniformly distributed across attention heads. We conclude that there is often no direct entailment between importance of an attention head as characterised in several recent studies, and low prunability of the respective head using random pruning.

Abstract

BERT and its variants have achieved state-of-the-art performance in various NLP tasks. Since then, various works have been proposed to analyze the linguistic information being captured in BERT. However, the current works do not provide an insight into how BERT is able to achieve near human-level performance on the task of Reading Comprehension based Question Answering. In this work, we attempt to interpret BERT for RCQA. Since BERT layers do not have predefined roles, we define a layer's role or functionality using Integrated Gradients. Based on the defined roles, we perform a preliminary analysis across all layers. We observed that the initial layers focus on query-passage interaction, whereas later layers focus more on contextual understanding and enhancing the answer prediction. Specifically for quantifier questions (how much/how many), we notice that BERT focuses on confusing words (i.e., on other numerical quantities in the passage) in the later layers, but still manages to predict the answer correctly. The fine-tuning and analysis scripts will be publicly available at `https://github.com/iitmnlp/BERT-Analysis-RCQA`.

1 Introduction

The past decade has witnessed a surge in the development of deep neural network models to solve NLP tasks. Pretrained language models such as ELMO (Peters et al., 2018a), BERT (Devlin et al., 2018) , XLNet (Yang et al., 2019) etc. have achieved state-of-the-art results on various NLP tasks. This success motivated various studies to understand how BERT achieves human-level performance on these tasks. Tenney et al. (2019); Peters et al. (2018b) analyze syntactic and semantic roles played by different layers in such models. Clark et al. (2019) specifically analyze BERT's attention heads for syntactic and linguistic phenomena. Most of these works focus on tasks such as sentiment classification, syntactic/semantic tags prediction, natural language inference, and so on. However, to the best of our knowledge, BERT has not been thoroughly analyzed for complex tasks like RCQA. It is a challenging task because of 1) the large number of parameters and non-linearities in BERT, and 2) the absence of pre-defined roles across layers in BERT as compared to pre-BERT models like BiDAF (Seo et al., 2016) or DCN (Xiong et al., 2016). In this work, we take the first step to identify each layer's role using the attribution method of Integrated Gradients (Sundararajan et al., 2017). We then try to map these roles to the following functions, deemed necessary in pre-BERT models to reach the answer: (i) learn contextual representations for the passage and the question, individually, (ii) attend to information in the passage specific to the question and, (iii) predict the answer.

We perform analysis on the SQuAD (Rajpurkar et al., 2016) and DuoRC (Saha et al., 2018) datasets. We observe that the initial layers primarily focus on question words that are present in the passage. In the later layers, the focus on question words decreases, and more focus is on the supporting words that surround the answer and the predicted answer span. Further, through a focused analysis of quantifier questions (questions that require a numerical entity as the answer), we observe that BERT pays importance to many words similar to the answer (same type, such as numbers) in later layers. We find this intriguing since, even after marking confusing words spread across passage as important, BERT's prediction accuracy is high. We also provide qualitative analysis to demonstrate the above trends.

2 Related Work

In the past few years, various large-scale datasets have been proposed for the RCQA task (Nguyen et al., 2016; Joshi et al., 2017; Rajpurkar et al., 2016; Saha et al., 2018) which have led to various deep neural-network (NN) based architectures such as Seo et al. (2016); Dhingra et al. (2016). Additionally, with complex pretraining, models such as Liu et al. (2019); Lan et al. (2019); Devlin et al. (2018) are very close to human-level performance. Due to the large number of parameters and non-linearity of deep NN models, the answer to the question "how did the model arrive at the prediction?", is not known; hence, they are termed as *blackbox models*. Motivated by this question, there have also been many works that analyze the interpretability of deep NN models on NLP tasks; many of them analyze models based on in-built attention mechanisms (Jain and Wallace, 2019; Serrano and Smith, 2019; Wiegreffe and Pinter, 2019). Further, various attribution methods such as Bach et al. (2015); Sundararajan et al. (2017) have been proposed to analyze them. Tenney et al. (2019) and Peters et al. (2018b) perform a layerwise analysis of BERT and BERT-like models to assign them syntactic and semantic meaning using probing classifiers. Si et al. (2019) question BERT's working on QA tasks through adversarial attacks, similar to Jia and Liang (2017); Mudrakarta et al. (2018). They point out that BERT is prone to be fooled by such attacks. Unlike these earlier works, we focus on analyzing BERT's layers specifically for RCQA to understand their QA-specific roles and their behavior on potentially confusing quantifier questions.

3 Experimental Setup

For our BERT analysis, we use the BERT-BASE model, which has 12 Transformer blocks (layers), each with a multi-head self-attention and a feed-forward neural network. We use the official code and pre-trained checkpoints[1] and fine-tune it for two epochs for the SQuAD and DuoRC datasets to achieve F1 scores of 88.73 and 54.80 on their respective dev-splits. We use SQuAD (Rajpurkar et al., 2016) 1.1 with 90k/10k train/dev samples, each with a 100-300 words passage and the SelfRC dataset in DuoRC (Saha et al., 2018) with 60k/13k train/dev samples, each with a 500 (on average) words passage. For each passage, both datasets have a natural language query and answer span in the passage itself.

4 Layer-wise Functionality

As discussed earlier, we aim to understand each BERT layer's functionality for the RCQA task; we want to identify the passage words that are of primary importance at each layer for the answer. Intuitively, the initial layers should focus on question words, and the latter should zoom in on contextual words that point to the answer. To analyze the above, we use the attribution method Integrated Gradients (Sundararajan et al., 2017) on BERT at a layerwise level.

For a given passage P consisting of n words $[w_1, w_2, \ldots, w_n]$, query Q, and model f with θ parameters, answer prediction is modeled as:

$$p(w_s, w_e) = f(w_s, w_e | P, Q, \theta)$$

where w_s, w_e are the predicted answer start and end words or positions.
For any given layer l, the above is equivalent to:

$$p(w_s, w_e) = f_l(w_s, w_e | E_{l-1}(P), E_{l-1}(Q), \theta)$$

where f_l is the forward propagation from layer l to the prediction. $E_l(.)$, is the representation learnt for passage or query words by a given layer l. To elaborate, we consider the network below the layer l as a blackbox which generates *input* representations for layer l. The **Integrated Gradients** for a Model M, a passage word w_i, embedded as $x_i \in \mathbf{R}^L$ is:

$$IG(x_i) = \int_{\alpha=0}^{1} \frac{\partial M(\tilde{x} + \alpha(x_i - \tilde{x}))}{\partial x_i} \, d\alpha$$

where $\tilde{x}$ is a zero vector, that serves as a baseline to measure integrated gradient for w_i. We calculate the integrated gradients at each layer $IG_l(x_i)$ for all passage words w_i using Algorithm 1. We approximate the above integral across 50 uniform samples of $\alpha \in [0, 1]$. We then compute importance scores for each w_i by taking the euclidean norm of $IG(w_i)$ and normalizing it to get a probability distribution I_l over the passage words.

4.1 JSD with top-k retained/removed

We quantify and visualize a layer's function as its distribution of importance over the passage words I_l. To compute the similarity between any

---

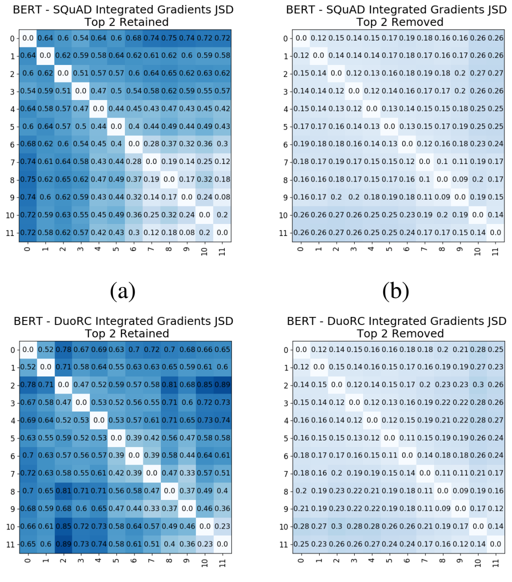
Algorithm 1 To compute Layer-wise Integrated Gradients for layer l

```
$\tilde{p} = 0$    //zero baseline
$m = 50$
$G_l(p) = \frac{1}{m} \sum_{k=1}^{m} \frac{\partial f_l(\tilde{p} + \frac{k}{m}(p - \tilde{p}))}{\partial E_l}$
$IG_l(p) = [(p - \tilde{p}) \times G_l(p)]$
// Compute squared norm for each word
$\tilde{I}_l([w_1, \ldots, w_k]) = ||IG_l(p)|| \in \mathrm{R}^k$
Normalize $\tilde{I}_l$ to a probability distribution $I_l$
```



(a) (b)

(c) (d)

Figure 1: JSD between I_l's with top-2 items removed/retained (SQuAD - (a), (b), DuoRC - (c), (d))

two layers x, y, we measure the *Jensen-Shannon Divergence (JSD)* between their corresponding importance distributions I_x, I_y. We calculate the JSD scores between every pair of layers in the model and visualize it as a $n_l \times n_l$ heatmap (n_l - number of layers in the model). A higher JSD score corresponds to the two layers being more different. This further means the two layers consider different words as salient. We visualize heatmaps for the dev-splits of SQuAD (Figures 1a, 1b) and DuoRC (Figures 1c, 1d), averaging over 1000 samples in each case.

We analyze the distribution in two parts: (i) we retain only top-k scores in each layer and zero out the rest, which denotes the distribution's head. (ii) we zero the top-k scores in each layer and retain the rest, which denotes the distribution's tail. In either case, we re-normalize to get a probability distribution. When comparing just the top-2 items, we see higher values (min 0.08/max 0.72) in heatmap 1a than in heatmap 1b (min 0.09/max 0.26). Similarly, we see higher values (min 0.23/max 0.89) in heatmap 1c than in heatmap 1d (min 0.12/max 0.28).We conclude that a layer's function is reflected in words high up in the importance distribution. As we remove them, we encounter an almost uniform distribution across the less important words. Hence to correctly identify a layer's functionality, we need to focus only on the head (top-k words) and not on the tail.

5 Results and Discussions

5.1 Probing layers: QA functionality

Based on the defined layers' functionality I_l, we try to identify which layers focus more on the question, the context around the answer, etc. We segregate the passage words into three categories: *answer words, supporting words, and query words*, where supporting words are the words surrounding the answer within a window size of 5. Query words are the question words which appear in the passage. We take the top-5 words marked as important in I_l for any layer l and compute how many words from each of the above-defined categories appear in the top-5 words (results in Tables 1 and 2). We observe

Table 3: Heatmap visualisation of the I_l distribution over BERT's first and last 3 layers, for a sample from SQuAD. The initial layers focus on question specific words and latter focus on supporting words that lead to answer

.

similar overall trends for both SQuAD and DuoRC. From Column 3, it is evident that the model first tries to identify the part of the passage where the question words are present. As it gets more confident about the answer (Column 2), the question words' importance decreases. From Col. 4, we infer that the layers' contextual role increases from the initial to the final layers.

Qualitative Example: We present a visualization of the top-5 words of the first and last three layers (with respect to I_l) in Table 3 for a sample from SQuAD. We see that all six layers give a high score to the answer span itself ('disastrous', 'situation'). Further, we see that the initial layers 0,1 and 2 are also trying to connect the passage and the query ('relegated', 'because', 'Polonia' get high importance scores). Hence, in this example, we see that the initial layers incorporate interaction between the query and passage. In contrast, the last layers focus on enhancing and verifying the model's prediction.

Passage: the panthers finished the regular season with a 15 – 1 record, ... the broncos ... finished the regular season with a 12 – 4 record. They joined the patriots , dallas cowboys , and pittsburgh steelers as one of teams that have made **eight** appearances in the super bowl .

Question: **How many appearances have the Broncos made in the super bowl?**

Table 4: Sample from the dev-split of SQuAD. **Blue** shows the answer, purple shows the contextual passage words and **green** shows the query

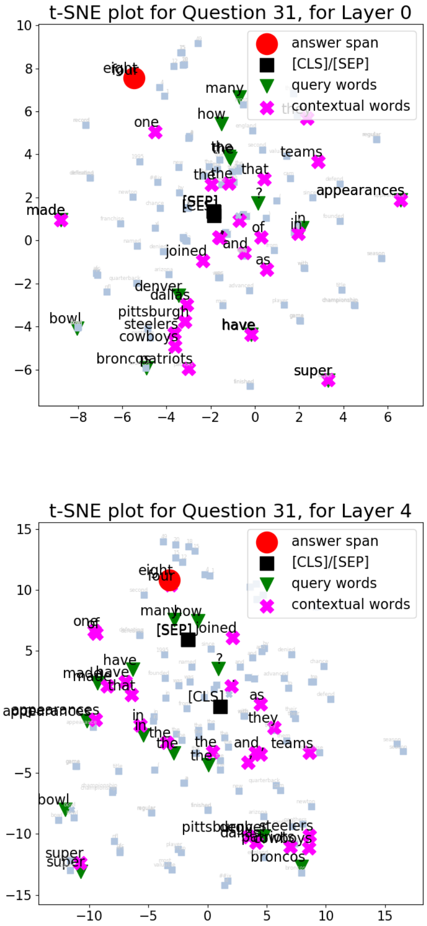
.

5.2 Visualizing Word Representations

We now qualitatively analyze the word representations of each layer. We visualize the t-SNE plot for one such passage, question,answer triplet from SQuAD (refer Table 4) in Figures 2, 3. We visualize the answer, supporting words, query words, and special tokens. Note that we have grayed out the other words in the passage. In initial layers (such as layer 0), we observe that similar words such as stop-words, team names, numbers {eight, four}, etc., are close to each other. In Layer 4, the passage, question, and answer come closer to each other. By layer 9, we see that the answer words are segregated from the rest of the words, even though the passage word 'four', which is of the same type as the answer 'eight' (number), is still close to 'eight'. We see more interesting observations yet here: (i) in later layers, the question words separate from the answer and the supporting words, (ii) Across all 12 layers, embeddings for *four, eight* remain very close together, which could have easily led to the model making a wrong prediction. However, the model still predicts the answer 'eight' correctly. We were not able to identify the layer where the distinction between the two confusing answers occurs.

Quantifier questions: For a detailed analysis of quantifier questions like *how many, how much* that could have many confusing answers (i.e., numerical words) in the passage, we perform further analysis. Based on our layer-level functionality I_l, we compute the number of words that are numerical quantities in the top-5 words, and the entire passage, and compute their ratio. This represents the ratio of confusing words that are marked as important by each layer. There are 799 and 310 such questions in SQuAD and DuoRC, respectively.

Interestingly, we observe that this ratio *increases* as we go higher up (SQuAD: L0 - 5.6%, L10 - 17.7%, L11 - 15.5%, DuoRC: L0 - 12.9%, L10 - 21.6%, L11 - 22.6%). For the example in Table 4, we observed that in its later layers, BERT gives high importance to the words 'eight', 'four', and

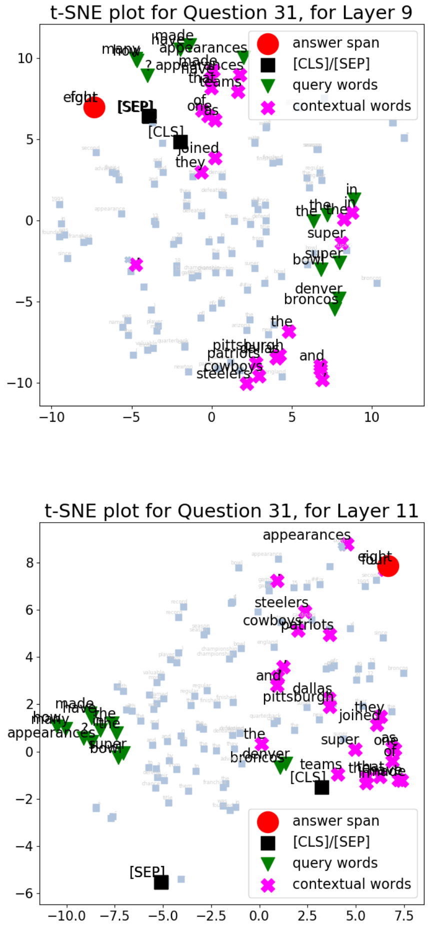


t-SNE plot for Question 31, for Layer 0

t-SNE plot for Question 31, for Layer 4

Figure 2: t-SNE plots - word embeddings of layers 0, 4 for the example in Table 4. For layer 0 similar words (e.g., team names, stop words) are close to each other. For intermediate layers like Layer 4, all the contextual, answer and question words intermingle.

'second' (numerical quantities), even though the latter are not related or necessary to answer the question. This shows that BERT, in its later layers, distributes its focus over confusing words. However, it *still* manages to predict the correct answer for such questions (87.35% EM for such questions for SQuAD, and 53.5% in DuoRC); BERT also has high confidence in predicting the answer for such questions (86.5% vs 80.4% for quantifier questions with more than one numerical entity in the passage vs non-quantifier questions in SQuAD, 95.2% vs 87.2% in DuoRC). This behavior is very different from the assumed roles a layer might take to answer the question, as it is expected that such words were considered in the initial rather than final layers. This shows the complexity of BERT and the difficulty of interpreting it for the RCQA task.



t-SNE plot for Question 31, for Layer 9

t-SNE plot for Question 31, for Layer 11

Figure 3: t-SNE plots- word embeddings of layers 9, 11 for the example in Table 4. In layers 9-11, the answer *eight* segregates from other words. However, numerical entity *four*, is very close to the answer.

6 Conclusion

In this work, we highlight that the lack of predefined roles for layers adds to the difficulty of interpreting highly complex BERT-based models. We first define each layer's functionality using Integrated Gradients. We present results and analysis to show that BERT is learning some form of passage-query interaction in its initial layers before arriving at the answer. We found the following observations interesting and with a potential to be probed further: (i) why do the question word representations move away from contextual and answer representation in later layers? (ii) If the focus on confusing words increases from the initial to later layers, how does BERT still have a high accuracy? We hope that this work will help the research community interpret BERT for other complex tasks and explore the above open-ended questions.

A Probing layers: POS Tags

Based on the layers' functionality I_l, we analyze the top-5 important words in each layer on the basis of POS tags. The results can be found in Tables 5 and 6. We note that all 12 layers are majorly focused on entity based words (common nouns, proper nouns and numerical entities). Surprisingly, all layers give approximately 10% of their importance to punctuation marks and stopwords each, the same level of importance that is given to verbs and adjectives. It is worth noting that on average, answer spans in SQuAD on 82.04% entites, and answer spans in DuoRC are 79.78% entities.

How do Decisions Emerge across Layers in Neural Models? Interpretation with Differentiable Masking

Abstract

Attribution methods assess the contribution of inputs to the model prediction. One way to do so is *erasure*: a subset of inputs is considered irrelevant if it can be removed without affecting the prediction. Though conceptually simple, erasure's objective is intractable and approximate search remains expensive with modern deep NLP models. Erasure is also susceptible to the *hindsight bias*: the fact that an input can be dropped does not mean that the model 'knows' it can be dropped. The resulting pruning is over-aggressive and does not reflect how the model arrives at the prediction. To deal with these challenges, we introduce Differentiable Masking. DIFFMASK learns to mask-out subsets of the input while maintaining differentiability. The decision to include or disregard an input token is made with a simple model based on intermediate hidden layers of the analyzed model. First, this makes the approach efficient because we predict rather than search. Second, as with probing classifiers, this reveals what the network 'knows' at the corresponding layers. This lets us not only plot attribution heatmaps but also analyze how decisions are formed across network layers. We use DIFFMASK to study BERT models on sentiment classification and question answering.[1]

1 Introduction

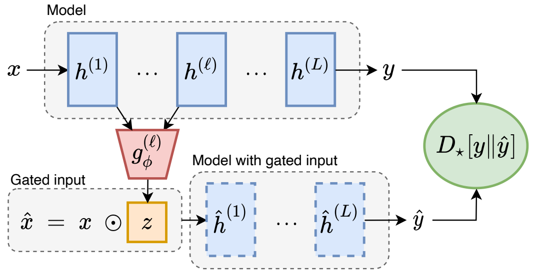

Figure 1: DIFFMASK: hidden states up to layer ℓ from a model (top) are fed to a classifier g that predicts a mask z. We use this to mask the input and re-compute the forward pass (bottom). The classifier g is trained to mask the input as much as possible without changing the output (minimizing a divergence $\mathrm{D}_\star$).

Deep neural networks have become standard tools in NLP demonstrating impressive improvements over traditional approaches on many tasks (Goldberg, 2017). Their power typically comes at the expense of interpretability, which may prevent users from trusting predictions (Kim, 2015; Ribeiro et al., 2016), makes it hard to detect model or data deficiencies (Gururangan et al., 2018; Kaushik and Lipton, 2018) or verify that a model is fair and does not exhibit harmful biases (Sun et al., 2019; Holstein et al., 2019).

These challenges have motivated work on interpretability, both in NLP and generally in machine learning; see Belinkov and Glass (2019) and Jacovi and Goldberg (2020) for reviews. In this work, we study *post hoc interpretability* where the goal is to explain the prediction of a trained model and to reveal how the model arrives at the decision. This goal is usually approached with attribution methods (Bach et al., 2015; Shrikumar et al., 2017; Sundararajan et al., 2017), which explain the behavior of a model by assigning relevance to inputs.

One way to perform attribution is to use *erasure* where a subset of features (e.g., input tokens) is considered irrelevant if it can be removed without affecting the model prediction (Li et al., 2016; Feng et al., 2018). The advantage of erasure is that it is conceptually simple and optimizes a well-defined objective. This contrasts with most other attribution methods which rely on heuristic rules to define feature salience; for example, attention-based attri-

(f) Our DIFFMASK non-amortized.

Figure 2: Question Answering token attribution: (b) and (c), are misleading (i.e., not faithful) as they attribute the prediction mostly to the answer span itself (underlined). Our method (d) reveals that the model pays attention to other named entities and the predicate 'practice' in both sentences. Predictions of the path-based methods (a) are more spread-out. Exact search (e) as well as approximate search (f) leads to pathological attributions.

bution (Rocktäschel et al., 2016; Serrano and Smith, 2019; Vashishth et al., 2019) or back-propagation methods (Bach et al., 2015; Shrikumar et al., 2017; Sundararajan et al., 2017). These approaches received much scrutiny in recent years (Nie et al., 2018; Sixt et al., 2020; Jain and Wallace, 2019), as they cannot guarantee that the network is ignoring low-scored features. They are often motivated as approximations of erasure (Baehrens et al., 2010; Simonyan et al., 2014; Feng et al., 2018) and sometimes evaluated using erasure as ground-truth (Serrano and Smith, 2019; Jain and Wallace, 2019).

Despite its conceptual simplicity, subset erasure is not commonly used in practice. First, it is generally **intractable**, and beam search (Feng et al., 2018) or leave-one-out estimates (Zintgraf et al., 2017) are typically used instead. These approximations may be inaccurate. For example, leave-one-out can underestimate the contribution of features due to saturation (Shrikumar et al., 2017). More importantly, even these approximations remain very expensive with modern deep (e.g., BERT-based; Devlin et al., 2019) models, as they require multiple computation passes through the model. Second, the method is **susceptible to the hindsight bias**: the fact that a feature *can be* dropped does not mean that the model 'knows' that it can be dropped and that the feature *is not* used by the model when processing the example. This results in over-aggressive pruning that does not reflect what information the model uses to arrive at the decision. The issue is pronounced in NLP tasks (see Figure 2d and Feng et al., 2018), though it is easier to see on an artificial example (Figure 3a). A model is asked to predict if there are more 8s than 1s in the sequence. The erasure attributes the prediction to a single 8 digit, as this reduced example yields the same decision as the original one. However, this does not reveal what the model was relying on: it has counted digits 8 and 1 as otherwise, it would not have achieved the perfect score on the test set.

We propose a new method, Differentiable Masking (DIFFMASK), which overcomes the aforementioned limitations and results in attributions that are more informative and help us understand how the model arrives at the prediction. DIFFMASK relies on learning sparse stochastic gates (a.k.a., masks), guaranteeing that the information from the masked-out inputs does not get propagated while maintaining end-to-end differentiability without having to resort to REINFORCE (Williams, 1992). The decision to include or disregard an input token is made with a simple model based on intermediate hidden layers of the analyzed model (see Figure 1). First, this *amortization* circumvents the need for combinatorial search making the approach efficient at test time. Second, as with probing classifiers (Adi et al., 2017; Belinkov and Glass, 2019), this reveals whether the network 'knows' at the corresponding layer what input tokens can be disregarded. During training inputs are *truly* masked whenever we sample zeros. After training, attribution scores correspond to the expectation of sampling non-zeros.

The amortization lets us not only plot attribution

(e) Our DiffMask conditioned on embedding layer (left) and hidden states (right).

Figure 3: Input attributions of several methods on a toy task: Given a sequence x of digits and a query $\langle n, m\rangle$ (8 and 1 in this example) of two digits, determine whether there are more n than m in x. Attributions are computed at the vector level and normalized to sum to 1.

heatmaps, as in Figure 2e, but also analyze how decisions are formed across network layers. In our artificial example, we see that in the bottom embedding layer the model cannot discard any tokens, as it does not 'know' which digits need to be counted (Figure 3e, left). In the second layer, it 'knows' that these are 8s and 1s, so the rest gets discarded (Figure 3e, right). In question answering (see Figure 8a), where we use a 24-layer model, it takes 13–16 layers for the model to 'realize' that *'Santa Clara Marriott'* is not relevant to the question and discard it. We also adapt our method to measuring the importance of intermediate states rather than inputs. This, as we discuss later, lets us analyze which states in every layer store information crucial for making predictions, giving us insights about the information flow.

Contributions We introduce DiffMask, a technique addressing limitations of attribution-based methods (especially erasure and its approximations), and demonstrate that it is stable and faithful to the analyzed models. We then use this technique to analyze BERT-based models fined-tuned on sentiment classification and question answering.

2 Method

We aim to understand how a trained model processes an input (i.e., a sequence of embedded tokens) to produce an output (e.g., a vector of class probabilities). First, for an input $x = \langle x_1, \ldots, x_n\rangle$, we obtain the output $y = f(x)$ of the model along with its hidden states $\langle h^{(0)}, \ldots, h^{(L)}\rangle$, where $h^{(0)} = x$. We then probe the model using a shallow *interpreter* network which takes hidden states up to a certain layer ℓ and outputs a binary mask $z = \langle z_1, \ldots, z_n\rangle$ indicating which input tokens are necessary and which can be disregarded. To assess whether the masked input $\hat{x} = \langle \hat{x}_1, \ldots, \hat{x}_n\rangle$ is sufficient, we re-feed the model with it and compute the output $\hat{y} = f(\hat{x})$. As long as $\hat{y}$ approximates the original output y well, we deem the inputs masked by z unnecessary.

Masking, however, as in multiplication by *zero*, makes a strong assumption about the geometry of the feature space, in particular, it assumes that the zero vector bears no information. Instead, we replace some of the inputs by a learned baseline vector b, i.e., $\hat{x}_i = z_i \cdot x_i + (1 - z_i) \cdot b$.

See Figure 1 for an overview. The interpreter model consists of $L+1$ classifiers, the ℓth of which conditions on the stack of hidden states up to $h^{(\ell)}$ to predict binary 'votes' $v^{(\ell)} = g_\phi^{(\ell)}(h^{(0)}, \ldots, h^{(\ell)})$ towards keeping or masking input tokens. Each classifier is a one-hidden-layer MLP, details and hyperparameters are provided in Appendix A. For a given depth ℓ, the interpreter decides to mask x_i out as soon as $v_i^{(k)} = 0$ for some $k \leq \ell$, i.e., $z_i = \prod_{k=0}^{\ell} v_i^{(k)}$. That is, in order to deem x_i unnecessary, it is sufficient to do so based on any subset of hidden states up until $h^{(\ell)}$.

Clearly, there is no direct supervision to estimate the parameters ϕ of the probe and the baseline b, thus we borrow erasure's objective: namely, we train the probe to mask-out as many input tokens as possible constrained to keeping $f(\hat{x}) \approx f(x)$. Since often, the output of f parameterizes a likelihood (e.g., a categorical distribution), we formulate the constraint in terms of a divergence $\mathrm{D}_\star$ between the two functions' outputs. We cast this, rather naturally, in the language of constrained optimization.

Objective A practical way to minimize the number of non-zeros predicted by g is minimizing the L_0 'norm'.[2] Thus, our $\mathcal{L}_0$ loss is defined as the

---

[2] L_0, denoted $\|z\|_0$ and defined as $\#(i|z_i \neq 0)$, is the number of non-zeros entries in a vector. Contrary to L_1 or L_2, L_0 is not a homogeneous function and, thus, not a proper norm. However, contemporary literature refers to it as a norm, and we do so as well to avoid confusion.

total number of positions that are not masked:

$$\mathcal{L}_0(\phi, b|x) = \sum_{i=1}^{n} \mathbf{1}_{[\mathbb{R}_{\neq 0}]}(z_i) \ , \qquad (1)$$

where $\mathbf{1}(\cdot)$ is the indicator function. We minimize $\mathcal{L}_0$ for all data-points in the dataset $\mathcal{D}$ subject to a constraint that predictions from masked inputs have to be similar to the original model predictions:

$$\begin{aligned} \min_{\phi,b} \quad & \sum_{x\in\mathcal{D}} \mathcal{L}_0(\phi, b|x) \\ \text{s.t.} \quad & \mathrm{D}_\star[y\|\hat{y}] \leq m \quad \forall x \in \mathcal{D} \ , \end{aligned} \qquad (2)$$

where $\hat{y} = f(\hat{x})$, $y = f(x)$, and the margin $m \in \mathbb{R}_{>0}$ is a hyperparameter. Since non-linear constrained optimisation is generally intractable, we employ Lagrangian relaxation (Boyd et al., 2004) optimizing instead

$$\max_{\lambda} \min_{\phi,b} \sum_{x\in\mathcal{D}} \mathcal{L}_0(\phi, b|x) + \lambda(\mathrm{D}_\star[y\|\hat{y}] - m) \ , \quad (3)$$

where $\lambda \in \mathbb{R}_{\geq 0}$ is the Lagrangian multiplier.

Stochastic masks Our objective poses two challenges: i) L_0 is discontinuous and has zero derivative almost everywhere, and ii) to output binary masks, g needs a discontinuous output activation such as the step function. A strategy to overcome both problems is to make the binary variables stochastic and treat the objective in expectation, in which case one option is to resort to REINFORCE (Williams, 1992), another is to use a sparse relaxation to binary variables (Louizos et al., 2018; Bastings et al., 2019). As we shall see (we compare the two aforementioned options in Table 2 and discuss them in Section 3.2), the latter proved more effective. Thus we opt to use the Hard Concrete distribution, a mixed discrete-continuous distribution on the closed interval $[0, 1]$. This distribution assigns a non-zero probability to exactly zero while it also admits continuous outcomes in the unit interval via the *reparameterization trick* (Kingma and Welling, 2014). We refer to Louizos et al. (2018) for details, but also provide a brief summary in Appendix B. With stochastic masks, the objective is computed in expectation, which addresses both sources of non-differentiability. Note that during training inputs are *truly* masked-out whenever we sample exact zeros. After training, attribution scores correspond to the expectation of sampling non-zero masks since any non-zero value corresponds to a leak of information.

Masking hidden states To reveal which hidden states store information necessary for realizing the prediction, we modify the probe slightly. For a given depth ℓ, we use a mask $z^{(\ell)} = g_\phi^{(\ell)}(h^{(\ell)})$ to replace some of the *states* in $h^{(\ell)} = \langle h_1^{(\ell)}, \ldots, h_n^{(\ell)} \rangle$ by a layer-specific baseline $b^{(\ell)}$, i.e. $\hat{h}_i^{(\ell)} = z_i^{(\ell)} \cdot h_i^{(\ell)} + (1 - z^{(\ell)}) \cdot b^{(\ell)}$. The resulting state $\hat{h}^{(\ell)}$ is used to re-compute subsequent states, $\hat{h}^{(\ell+1)}, \ldots, \hat{h}^{(L)}$, as well as the output, which we denote by $\hat{y}$. Here we do not aggregate 'votes' with a product because for this probe we want to discover whether hidden states are predictive of their own *usefulness*. See Figure 10 in Appendix D for an overview of this variant of DIFFMASK.

3 Experiments

The goal of this work is to uncover a *faithful* interpretation of an existing model, i.e. revealing, as accurately as possible, the process by which the model arrives at the prediction. Human-provided labels, such as human rationales (Camburu et al., 2018; DeYoung et al., 2020), will not help us in demonstrating this, as humans cannot judge if an interpretation is faithful (Jacovi and Goldberg, 2020). More precisely, human-provided labels do not show how the model behaves – e.g., annotations of what parts of the input are relevant for solving a particular task do *not* constitute a guarantee that a model relies on those parts more than others when making a prediction. When we evaluate an attribution method by comparing its outputs with human annotations, we are not measuring whether it provides faithful attributions but only if they are *plausible* according to humans. This goes against our goals as we aim to use the interpretation method to detect model deficiencies, which are usually cases where the model does not behave like humans. The ground-truth explanations of how a model makes certain predictions depend not only on the data but also on the model, and, unfortunately, are generally not known for real tasks and with complex models. This makes the evaluation and comparison of attribution methods non-trivial.

Our strategy is to i) show the effectiveness of DIFFMASK in a controlled setting (i.e., a toy task) where ground-truth is available; ii) test the effectiveness of our relaxation for learning discrete masks (on a real model for sentiment classification); and iii) demonstrate that the method is stable and models behave the same when masking is ap-

plied. Once we have established that DIFFMASK can be trusted, we use it to analyze BERT-based models (Devlin et al., 2019) fine-tuned on sentiment classification, and on question answering. We report hyperparameters in Appendix C, and additional plots, examples and analysis in Appendix D.

3.1 Toy task

Our toy task is defined as: given a sequence x of digits (i.e., $x_i \in \{0, \cdots, 9\}$), and a query $\langle n, m \rangle$ of two digits, determine whether $\#n > \#m$ in x.

Model The query and input are embedded, concatenated, and then fed to a single-layer feed-forward NN, followed by a single-layer unidirectional GRU (Cho et al., 2014).[3] The classification is done by a linear layer that acts on the last hidden state of the GRU. See Appendix C.1 for all hyperparameters and a more precise definition of the architecture. Unsurprisingly, the model solves the task almost perfectly (accuracy on test is $>99\%$).

Ground-truth for hidden-state attribution We plot the distribution of hidden states (we use dimensionality 2, with the purpose of having a bottleneck and to support clear visualization) and observe a linear separation between states of digits present in the query and states not in the query. This means that the role of the feed-forward layer is to decide which digits to keep. Since the model solves the task, the role of the GRU must then be to count which digit occurred the most. The prediction must be attributed uniformly to *all* the hidden states corresponding to either n or m. For completeness, Figure 11 in the Appendix D.1 shows this plot.

Results We start with an example of *input attributions*, see Figure 3, which illustrates how DIFFMASK goes beyond input attribution as typically known.[4] The attribution provided by erasure (Figure 3a) is not informative: for each datapoint the search always finds a single digit that is sufficient to maintain the original prediction and discards all the other inputs. The perturbation methods by Schulz et al. (2020) and Guan et al. (2019) (Figure 3b and 3d) are also over-aggressive in pruning. They assign low attribution to some items in the query even though those had to be considered when making the prediction. Differently from other methods, DIFFMASK reveals input attributions conditioned on different levels of depth. Figure 3e shows both input attributions according to the input itself and according to the hidden layer. It reveals that at the embedding layer there is no information regarding what part of the input can be erased: attribution is uniform over the input sequence. After the model has observed the query, hidden states predict that masking input digits other than n and m will not affect the final prediction: attribution is uniform over digits in the query. This reveals the role of the feed-forward layer as a filter for positions relevant to the query. Other methods do not allow for this type of inspection. These observations are consistent across the entire test set.

For *attribution to hidden states* (i.e., the output of the feed-forward layer) we can compare methods in terms of how much their attributions resemble the ground-truth across the test set. Table 1 shows how the different approaches deviate from the gold-truth in terms of Kullback-Leibler (D_{KL}) and Jensen–Shannon (D_{JS}) divergences.[5]

3.2 Sentiment Classification

We turn now to a real task and analyze models fine-tuned for sentiment classification on the Stanford Sentiment Treebank (SST; Socher et al., 2013).

Erasure search as learning masks Before diving into an analysis of a BERT sentiment model, we would like to demonstrate that we can approximate the result of erasure well through our differentiable relaxations. For that, we train a single-layer GRU sentiment classifier and compare the analyses by DIFFMASK to solutions provided by

---

[3] We use a feed-forward NN to incorporate the query information, rather than another GRU layer, to ensure that counting cannot happen in the first layer. This helps us define the ground-truth for the method.

[4] To enable comparison across methods, the attributions in this Section are normalized between 0 and 1.

[5] We use $D_{KL}[p||q]$ and $D_{JS}[p||q]$ where p is the *ground-truth* distribution and q is the predicted attribution distribution.

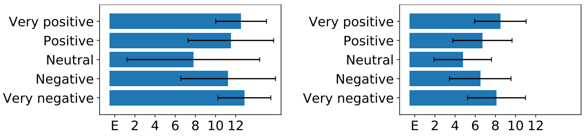
Metric	REINFORCE+	DIFFMASK
Precision	74.69	**81.26**
Recall	80.82	**85.89**
F_1	73.57	**80.75**
Optimality	8.83	**32.67**
L_0	33.13	**30.58**

Table 2: Sentiment classification: optimization with DIFFMASK and REINFORCE (not amortised – with a moving average baseline for variance reduction) vs. erasure with exact search. All metrics are computed at token level; optimality is measured at sentence level.

erasure (exact search). To isolate the impact of our objective, we disable amortization, thus estimating Hard Concrete parameters for each example independently. We compare DIFFMASK to REINFORCE (Williams, 1992) with a moving average baseline for variance reduction. Since erasure is prohibitive for long sentences, we limit our evaluation to sentences up to 25 words (54% of the data). Table 2 shows that DIFFMASK and REINFORCE achieve comparable levels of sparsity, but our method reaches an optimal solution much more often (33% of the times vs 9%) and is, on average, closer to an optimal solution (81% F_1 vs 75% F_1).

Faithfulness and Plausibility Now, we get back to the fully-amortized DIFFMASK approach applied to a 12-layers $\text{BERT}_{\text{BASE}}$ model and verify that there is no performance degradation when applying masking. Training hyperparameters are reported in Appendix C.2. The F_1 score of the model on the validation set moved from 37.9% to 38.3% while masking 46.3% input tokens, and to 38.9% while masking 67.6% hidden states. The explanations provided by DIFFMASK are also stable. Across 5 runs with different seeds, the standard deviation of input attributions are 0.05 and 0.03 for inputs and hidden states, respectively.

While we cannot use human labels to evaluate faithfulness of our method, comparing them and DIFFMASK attribution will tell us whether the sentiment model relies on the same cues as humans. Specifically, we compare to SST token level annotation of sentiment. In Figure 4a, we show after how many layers on average an input token is dropped, depending on its sentiment label. This suggests that the model relies more heavily on strongly positive or negative words and, thus, is generally consistent with human judgments (i.e., *plausible*).



(a) Input.

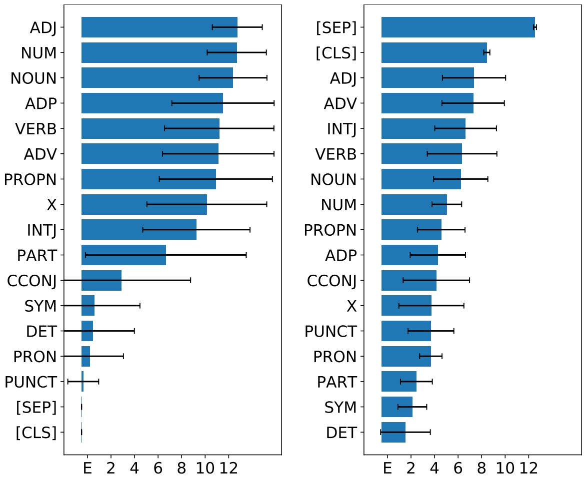
(b) Hidden states.

Figure 4: Sentiment classification: average number of layers that predict to keep input tokens or hidden states aggregated by token level sentiment annotations.

Analysis We used DIFFMASK to analyse the behavior of our BERT model. In Figure 5, we report the average number of layers that input tokens or hidden states are kept for (or, equivalently, after how many layers they are dropped on average), aggregating by part-of-speech tags (PoS). It turns out that determinants, punctuation, and pronouns can be completely discarded from the input across all validation set, while adjectives and nouns should be kept. Also the `[CLS]` and `[SEP]` tokens can be ignored indicating that the model does not need such markers. Examining the POS tags distribution for hidden states leads to further conclusions. Here, the `[CLS]` and `[SEP]` tokens are the most important ones. This is not surprising as the classifier on top of BERT uses the `[CLS]` hidden state which gets progressively updated through all layers. Both these special tokens are not important as inputs because BERT can infer these markers in other layers, however, they are heavily used in the computation.

Figure 6e we show a visual example of that. We see that the model, even in the bottom layers, knows that the punctuation and both separators can be dropped from the input. This contrasts with hidden states attribution (Figure 6f) which indicates that the separator states (especially `[SEP]`) are very important. By putting this information together, we can hypothesize that the separator is used to aggregate information from the sentence, relying on self-attention. In fact, this aggregation is still happening in layer 12; at the very top layers, states corresponding to almost all non-separator tokens can be dropped.

Comparison to other methods In Figure 6, we visually compare different techniques on one example form validation set. While previous techniques (e.g., integrated gradient) do not let us test what a model 'knows' in a given layer (i.e. attribution to input conditioned on a layer), they can be used to perform attribution to hidden layers. All methods except attention correctly highlight the last hidden



(a) Inputs. (b) Hidden states.

state of the `[CLS]` token as important. Its importance is due to the top-level classifier using the `[CLS]` hidden state. Although for DiffMask we show the expectation of keeping states, it assigns much sharper attributions. For instance, on the validation set, it assigns to the last hidden state of the `[CLS]` the biggest attribution 99% of the times where Schulz et al. (2020) only 71%. Raw attention (Figure 6a) does not seem to highlight any significant patterns in that example except that start and end of sentence tokens (`[CLS]` and `[SEP]`, respectively) receive more attention than the rest.[6] Attributions by Schulz et al. (2020) and Guan et al. (2019) assign slightly higher importance to hidden states corresponding to 'highly' and 'enjoyable', whereas it is hard to see any informative patterns provided by integrated gradient. Notice that for DiffMask, a near-zero attribution has a very clear interpretation: such a state is not used for prediction since in expectation it is dropped (not gated).

3.3 Question Answering

We turn now to QA where we analyse a fine-tuned $\text{BERT}_{\text{LARGE}}$ model on the Stanford Question Answering Dataset (SQuAD; Rajpurkar et al., 2016).

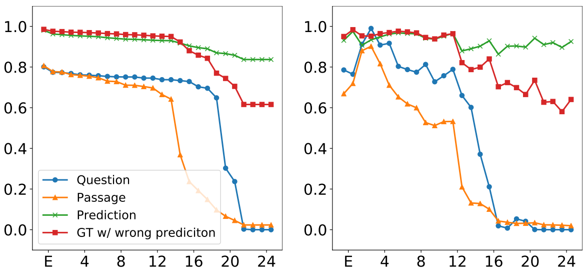
Analysis We start by asking DiffMask **which tokens does the model keep?** We do a similar analysis as for sentiment classification of POS tags over the entire validation set. We summarize the results in Figure 14 in Appendix D.2. It turns out that conjunctions and adpositions are dropped by the embedding and first layer, respectively, on average. On the contrary, proper nouns and punctuation are usually predicted to be dropped only after the 14th layer. We argue that due to the pre-training objective, BERT could infer well missing parts of the input, especially if they are trivial to infer (e.g., as often the case for prepositions). On the contrary, nouns and proper nouns are important as they count for 84% of the answers on SQuAD. For example, in Figure 8a, we can see that it takes 13–16 layers for the model to 'realize' that *'Santa Clara Marriot'* is not relevant to the question and discard it.

Unlike in sentiment classification, separator tokens as well as punctuation assume a central role as inputs (i.e., punctuation is considered the most important POS tag as for both questions and passages is usually dropped after the 17th layer). Punctuation serves to demarcate sentence boundaries, useful for QA but not for sentiment classification.

Tokens from questions are generally masked by higher layers than tokens from passages as we show in Figure 7a, which suggests that they are more important. We highlight that even in higher

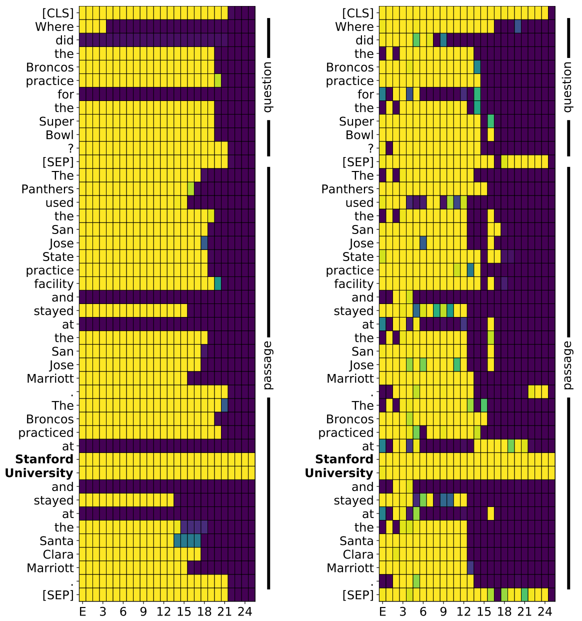
---

[6] Voita et al. (2019b) and Michel et al. (2019) pointed out that many Transformer heads play no or minor role.



(a) Input. (b) Hidden states.

Figure 7: QA: average expectation of keeping input (a) and hidden states (b) from different layers.



(a) Gating the input. (b) Gating hidden states.

Figure 8: QA: attribution the inputs (a) and hidden states (b). The correct answers is highlighted in bold.

layers when DiffMask masks $> 95\%$ of the tokens, the original model prediction is almost always kept $> 90\%$. Noticeably, when the original BERT makes wrong predictions, the tokens annotated as the ground truth answer are kept $\sim 60\%$ of the time. This may suggest that when this happens the model still considers other options (e.g., valid options such as the ground truth) as plausible, thus DiffMask detects them as important.

Now, we inspect hidden states attributions to answer **where is the information stored?** In Figure 7b we can see a similar trend as for masking input, i.e., question's hidden states are kept more on average and deeper in the computation. States on layers 2–3 are dropped less than from the embedding and first layer. This is consistent with findings of Voita et al. (2019a) which show that frequent tokens, such as determiners, accumulate contextual information. However, they are not important as inputs as we show in an example in Figure 8b.

The hidden states corresponding to separator tokens are always kept across all layers except the last one across the validation set. Notice that, this token is also used as a delimiter between the question and the passage, and hence indicates where questions as well as passages end.

The level of hidden states pruning is quite incremental (after layer 3) and gets strong, after layer 9 more than 50% of them can be masked out. A steep increase in superfluous states 13–14 (visible on both parts of Figure 7) may indicate that some states, at that point in computation, contain enough information needed for the classification while all the others can indeed be removed without affecting the model prediction. Our observation that higher layers are more predictive is in line with findings of Kovaleva et al. (2019). They pointed out that the final layers of BERT change most and are more task-specific. Again, the fact that states corresponding to the ground truth answer are still active on top layers when the model makes a wrong prediction indicates that the model is still considering different span options across top layers as well.

Comparison to other methods As we do not have access to the ground-truth, we start by contrasting DiffMask qualitatively to other attribution methods on a few examples. We highlight some common pitfalls that afflict other methods (such as the hindsight bias) and how DiffMask overcomes those. This helps demonstrate our method's faithfulness to the original model.

Figure 2 shows input attributions by different methods on an example from the validation set. Erasure (Figure 2d), as expected, does not provide useful insights, it essentially singles out the answer discarding everything else including the question. This cannot be faithful and is a simple consequence of erasure's hindsight bias: when only the span that contains the answer is presented as input, the model predicts that very span as the answer, but this does not imply that the model ignores everything else when presented with the complete document as input. The methods of Schulz et al. (2020) and Guan et al. (2019) optimize attributions on single examples and thus also converge to assigning high importance mostly to words that support the current prediction and that indicate the question type. Integrated gradient does not seem to highlight any discernible pattern, which we speculate is mainly because a zero baseline is not suitable for word embeddings. Choosing a more adequate baseline is not straightforward and remains an important open issue (Sturmfels et al., 2020). Note that, DIFFMASK without amortization (Figure 2f) resembles erasure (as shown in § 3.2 for SST).

Differently from all other methods, our DIFFMASK probes the network to understand what it 'knows' about the input-output mapping in different layers. In Figure 2e we show the expectation of keeping input tokens conditioned on any one of the layers in the model to make such predictions (see Figure 8a for a per-layer visualization). Our input attributions highlight that the model, in expectation across layers, *wants* to keep words in the question, the predicate 'practice' in both sentences as well as all potential candidate answers (i.e., named entities). But eventually, the most important spans are in the question and the answer itself.

4 Related Work

While we motivated our approach through its relation to erasure, an alternative way of looking at our approach is considering it as a *perturbation-based* method. This recently introduced class of attribution methods (Ying et al., 2019; Guan et al., 2019; Schulz et al., 2020; Taghanaki et al., 2019), instead of erasing input, injects noise. Besides back-propagation and attention-based methods discussed in the introduction, another class of interpretation methods (Murdoch and Szlam, 2017; Singh et al., 2019; Jin et al., 2020) builds on prior work in cooperative game theory (e.g., Shapley value of Shapley, 1953). These methods are not trivial to apply to a new model, as they are architecture-specific. Their hierarchical versions (e.g., Singh et al., 2019; Jin et al., 2020) also make a strong assumption about the structure of interaction (e.g., forming a tree) which may affect their faithfulness. Also Chen et al. (2018) share some similarities to our work as they also do amortization but use the *Gumbel softmax trick* (Maddison et al., 2017; Jang et al., 2017) to approximate minimal subset selection. They assume that the subset contains exactly k elements where k is a hyperparameter. Moreover, their explainer is a separate model predicting input subsets, rather than a 'probe' on top of the model's hidden layers, and hence cannot be used to reveal how decisions are formed across layers.

A large body of literature analyzed BERT and Transformed-based models. For example, Tenney et al. (2019) and van Aken et al. (2019) probed BERT layers for a range of linguistic tasks, while Hao et al. (2019) analyzed the optimization surface. Rogers et al. (2020) provides a comprehensive overview of recent BERT analysis papers.

There is a stream of work on learning interpretable models by means of extracting latent rationales (Lei et al., 2016; Bastings et al., 2019). Some of the techniques underlying DIFFMASK are related to that line of work. They employ stochastic masks to *learn an interpretable model*, which they train by minimizing a downstream loss subject to constraints on L_0, whereas we employ stochastic masks to *interpret an existing model*, and for that, we minimize L_0 subject to constraints on that model's output distribution. In our very recent work Schlichtkrull et al. (2020), we also employ stochastic masks and L_0 regularization for analyzing graph neural networks. We learn which edges are relevant in multi-hop question answering and graph-based semantic role labeling (Marcheggiani and Titov, 2017; De Cao et al., 2019).

5 Conclusion

We have introduced a new *post hoc* interpretation method which learns to completely remove subsets of inputs or hidden states through masking. We circumvent an intractable search by learning an end-to-end differentiable prediction model. To overcome the hindsight bias problem, we probe the model's hidden states at different depths and amortize predictions over the training set. Faithfulness is validated in a controlled experiment pointing more clearly to some flaws of other attribution methods. We used our method to study BERT-based models on sentiment classification and question answering. DIFFMASK sheds light on what different layers 'know' about the input and where information about the prediction is stored in different layers.

`{pepa, simonsen, c.lioma, augenstein}@di.ku.dk`

Abstract

Recent developments in machine learning have introduced models that approach human performance at the cost of increased architectural complexity. Efforts to make the rationales behind the models' predictions transparent have inspired an abundance of new explainability techniques. Provided with an already trained model, they compute saliency scores for the words of an input instance. However, there exists no definitive guide on (i) how to choose such a technique given a particular application task and model architecture, and (ii) the benefits and drawbacks of using each such technique. In this paper, we develop a comprehensive list of diagnostic properties for evaluating existing explainability techniques. We then employ the proposed list to compare a set of diverse explainability techniques on downstream text classification tasks and neural network architectures. We also compare the saliency scores assigned by the explainability techniques with human annotations of salient input regions to find relations between a model's performance and the agreement of its rationales with human ones. Overall, we find that the gradient-based explanations perform best across tasks and model architectures, and we present further insights into the properties of the reviewed explainability techniques.

1 Introduction

Understanding the rationales behind models' decisions is becoming a topic of pivotal importance, as both the architectural complexity of machine learning models and the number of their application domains increases. Having greater insight into the models' reasons for making a particular prediction has already proven to be essential for discovering potential flaws or biases in medical diagnosis (Caruana et al., 2015) and judicial sentencing (Rich, 2016). In addition, European law has mandated "the right . . . to obtain an explanation of the decision reached" (Regulation, 2016).

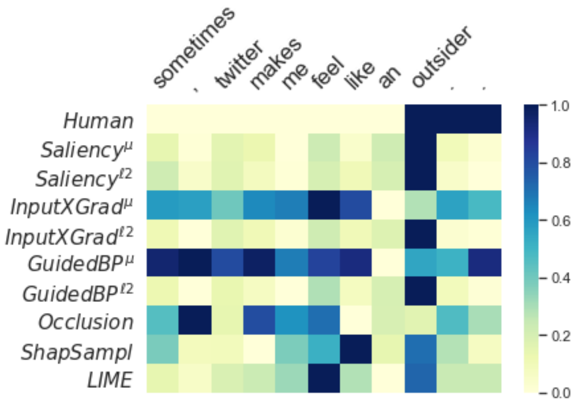

Figure 1: Example of the saliency scores for the words (columns) of an instance from the Twitter Sentiment Extraction dataset. They are produced by the explainability techniques (rows) given a `Transformer` model. The first row is the human annotation of the salient words. The scores are normalized in the range $[0, 1]$.

Explainability methods attempt to reveal the reasons behind a model's prediction for a single data point, as shown in Figure 1. They can be produced post-hoc, i.e., with already trained models. Such post-hoc explanation techniques can be applicable to one specific model (Martens et al., 2008; Wagner et al., 2019) or to a broader range thereof (Ribeiro et al., 2016; Lundberg and Lee, 2017). They can further be categorised as: employing model gradients (Sundararajan et al., 2017; Simonyan et al., 2013), being perturbation based (Shapley, 1953; Zeiler and Fergus, 2014) or providing explanations through model simplifications (Ribeiro et al., 2016; Johansson et al., 2004). There also exist explainability methods that generate textual explanations (Camburu et al., 2018) and are trained post-hoc or jointly with the model at hand.

While there is a growing amount of explainability methods, we find that they can produce vary-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3256–3274,
November 16–20, 2020.

ing, sometimes contradicting explanations, as illustrated in Figure 1. Hence, it is important to *assess existing techniques* and to *provide a generally applicable and automated methodology* for choosing one that is suitable for a particular model architecture and application task (Jacovi and Goldberg, 2020). Robnik-Šikonja and Bohanec (2018) compiles a list of property definitions for explainability techniques, but it remains a challenge to evaluate them in practice. Several other studies have independently proposed different setups for probing varied aspects of explainability techniques (DeYoung et al., 2020; Sundararajan et al., 2017). However, existing studies evaluating explainability methods are discordant and do not compare to properties from previous studies. In our work, we consider properties from related work and extend them to be applicable to a broader range of downstream tasks.

Furthermore, to create a thorough setup for evaluating explainability methods, one should include at least: (i) different groups of explainability methods (explanation by simplification, gradient-based, etc.), (ii) different downstream tasks, and (iii) different model architectures. However, existing studies usually consider at most two of these aspects, thus providing insights tied to a specific setup.

We propose a number of diagnostic properties for explainability methods and evaluate them in a comparative study. We consider explainability methods from different groups, all widely applicable to most ML models and application tasks. We conduct an evaluation on three text classification tasks, which contain human annotations of salient tokens. Such annotations are available for Natural Language Processing (NLP) tasks, as they are relatively easy to obtain. This is in contrast to ML sub-fields such as image analysis, for which we only found one relevant dataset – 536 manually annotated object bounding boxes for Visual Question Answering (Subramanian et al., 2020).

We further compare explainability methods across three of the most widely used model architectures – `CNN`, `LSTM`, and `Transformer`. The `Transformer` model achieves state-of-the-art performance on many text classification tasks but has a complex architecture, hence methods to explain its predictions are strongly desirable. The proposed properties can also be directly applied to Machine Learning (ML) subfields other than NLP. The code for the paper is publicly available.[1]

In summary, the **contributions** of this work are:

- We compile a comprehensive list of diagnostic properties for explainability and automatic measurement of them, allowing for their effective assessment in practice.
- We study and compare the characteristics of different groups of explainability techniques in three different application tasks and three different model architectures.
- We study the attributions of the explainability techniques and human annotations of salient regions to compare and contrast the rationales of humans and machine learning models.

2 Related Work

Explainability methods can be divided into explanations by simplification, e.g., LIME (Ribeiro et al., 2016); gradient-based explanations (Sundararajan et al., 2017); perturbation-based explanations (Shapley, 1953; Zeiler and Fergus, 2014). Some studies propose the generation of text serving as an explanation, e.g., (Camburu et al., 2018; Lei et al., 2016; Atanasova et al., 2020a). For extensive overviews of existing explainability approaches, see Arrieta et al. (2020).

Explainability methods provide explanations of different qualities, so assessing them systematically is pivotal. A common attempt to reveal shortcomings in explainability techniques is to reveal a model's reasoning process with counter-examples (Alvarez-Melis and Jaakkola, 2018; Kindermans et al., 2019; Atanasova et al., 2020b), finding different explanations for the same output. However, single counter-examples do not provide a measure to evaluate explainability techniques (Jacovi and Goldberg, 2020).

Another group of studies performs human evaluation of the outputs of explainability methods (Lertvittayakumjorn and Toni, 2019; Narayanan et al., 2018). Such studies exhibit low inter-annotator agreement and reflect mostly what appears to be reasonable and appealing to the annotators, not the actual properties of the method.

The most related studies to our work design measures and properties of explainability techniques. Robnik-Šikonja and Bohanec (2018) propose an extensive list of properties. The *Consistency* property captures the difference between explanations of different models that produce the same prediction; and the *Stability* property measures the difference between the explanations of similar instances given

---

[1] https://github.com/copenlu/xai-benchmark

a single model. We note that similar predictions can still stem from different reasoning paths. Instead, we propose to explore instance activations, which reveal more of the model's reasoning process than just the final prediction. The authors propose other properties as well, which we find challenging to apply in practice. We construct a comprehensive list of diagnostic properties tied with measures that assess the degree of each characteristic.

Another common approach to evaluate explainability methods is to measure the sufficiency of the most salient tokens for predicting the target label (DeYoung et al., 2020). We also include a sufficiency estimate, but instead of fixing a threshold for the tokens to be removed, we measure the decrease of a model's performance, varying the proportion of excluded tokens. Other perturbation-based evaluation studies and measures exist (Sundararajan et al., 2017; Adebayo et al., 2018), but we consider the above, as it is the most widely applied.

Another direction of explainability evaluation is to compare the agreement of salient words annotated by humans to the saliency scores assigned by explanation techniques (DeYoung et al., 2020). We also consider the latter and further study the agreement across model architectures, downstream tasks, and explainability methods. While we consider human annotations at the word level (Camburu et al., 2018; Lei et al., 2016), there are also datasets (Clark et al., 2019; Khashabi et al., 2018) with annotations at the sentence-level, which would require other model architectures, so we leave this for future work.

Existing studies for evaluating explainability heavily differ in their scope. Some concentrate on a **single model architecture** - BERT-LSTM (DeYoung et al., 2020), RNN (Arras et al., 2019), CNN (Lertvittayakumjorn and Toni, 2019), whereas a few consider **more than one** model (Guan et al., 2019; Poerner et al., 2018). Some studies concentrate on one **particular dataset** (Guan et al., 2019; Arras et al., 2019), while only a few generalize their findings over **downstream tasks** (DeYoung et al., 2020; Vashishth et al., 2019). Finally, existing studies focus on one (Vashishth et al., 2019) or a single group of explainability methods (DeYoung et al., 2020; Adebayo et al., 2018). Our study is the first to propose a unified comparison of different groups of explainability techniques across three text classification tasks and three model architectures.

3 Evaluating Attribution Maps

We now define a set of diagnostic properties of explainability techniques, and propose how to quantify them. Similar notions can be found in related work (Robnik-Šikonja and Bohanec, 2018; DeYoung et al., 2020), and we extend them to be generally applicable to downstream tasks. We first introduce the prerequisite notation. Let $X = \{(x_i, y_i, w_i) | i \in [1, N]\}$ be the test dataset, where each instance consists of a list of *tokens* $x_i = \{x_{i,j} | j \in [1, |x_i|]\}$, a *gold label* y_i, and a *gold saliency score* for each of the tokens in x_i: $w_i = \{w_{i,j} | j \in [1, |x_i|]\}$ with each $w_{i,j} \in \{0, 1\}$. Let ω be an explanation technique that, given a model M, a class c, and a single instance x_i, computes saliency scores for each token in the input: $\omega^M_{x_i,c} = \{\omega^M_{(i,j),c} | j \in [1, |x_i|]\}$. Finally, let $M = M_1, \ldots M_K$ be models with the same architecture, each trained from a randomly chosen seed, and let $M' = M'_1, \ldots M'_K$ be models of the same architecture, but with randomly initialized weights.

Agreement with human rationales (HA). This diagnostic property measures the degree of overlap between saliency scores provided by human annotators, specific to the particular task, and the word saliency scores computed by an explainability technique on each instance. The property is a simple way of approximating the quality of the produced feature attributions. While it does not necessarily mean that the saliency scores explain the predictions of a model, we assume that explanations with high agreement scores would be more comprehensible for the end-user as they would adhere more to human reasoning. With this diagnostic property, we can also compare how the type and the performance of a model and/or dataset affect the agreement with human rationales when observing one type of explainability technique.

During evaluation, we provide an estimate of the average agreement of the explainability technique across the dataset. To this end, we start at the instance level and compute the Average Precision (AP) of produced saliency scores $\omega^M_{x_i,c}$ by comparing them to the gold saliency annotations w_i. Here, the label for computing the saliency scores is the gold label: $c = y_i$. Then, we compute the average across all instances, arriving at Mean AP (MAP):

$$\text{MAP}(\omega, M, X) = \frac{1}{N} \sum_{i \in [1,N]} AP(w_i, \omega^M_{x_i,y_i}) \quad (1)$$

Confidence Indication (CI). A token from a single instance can receive several saliency scores, indicating its contribution to the prediction of each of the classes. Thus, when a model recognizes a highly indicative pattern of the predicted class k, the tokens involved in the pattern would have highly positive saliency scores for this class and highly negative saliency scores for the remaining classes. On the other hand, when the model is not highly confident, we can assume that it is unable to recognize a strong indication of any class, and the tokens accordingly do not have high saliency scores for any class. Thus, the computed explanation of an instance i should indicate the confidence $p_{i,k}$ of the model in its prediction.

We propose to measure the predictive power of the produced explanations for the confidence of the model. We start by computing the Saliency Distance (SD) between the saliency scores for the predicted class k to the saliency scores of the other classes K/k (Eq. 2). Given the distance between the saliency scores, we predict the confidence of the class with logistic regression (LR) and finally compute the Mean Absolute Error – MAE (Eq. 3), of the predicted confidence to the actual one.

$$\text{SD} = \sum_{j \in [0,|x|]} D(\omega^M_{x_{i,j},k}, \omega^M_{x_{i,j},K/k}) \tag{2}$$

$$\text{MAE}(\omega, M, X) = \sum_{i \in [1,N]} |p_{i,k} - \text{LR}(\text{SD})| \tag{3}$$

For tasks with two classes, D is the subtraction of the saliency value for class k and the other class. For more than two classes, D is the concatenation of the max, min, and average across the differences of the saliency value for class k and the other classes. Low MAE indicates that model's confidence can be easily identified by looking at the produced explanations.

Faithfulness (F). Since explanation techniques are employed to explain model predictions for a single instance, an essential property is that they are faithful to the model's inner workings and not based on arbitrary choices. A well-established way of measuring this property is by replacing a number of the most-salient words with a mask token (DeYoung et al., 2020) and observing the drop in the model's performance. To avoid choosing an unjustified percentage of words to be perturbed, we produce several dataset perturbations by masking 0, 10, 20, …, 100% of the tokens in order of decreasing saliency, thus arriving at X^{ω^0}, $X^{\omega^{10}}$, …, $X^{\omega^{100}}$. Finally, to produce a single number to measure faithfulness, we compute the area under the threshold-performance curve (AUC-TP):

$$\begin{aligned} \text{AUC-TP}(\omega, M, X) = \\ \text{AUC}([(i, P(M(X^{\omega^0})) - M(X^{\omega^i}))]) \end{aligned} \tag{4}$$

where P is a task specific performance measure and $i \in [0, 10, \dots, 100]$. We also compare the AUC-TP of the saliency methods to a random saliency map to find whether there are explanation techniques producing saliency scores without any contribution over a random score.

Using AUC-TP, we perform an ablation analysis which is a good approximation of whether the most salient words are also the most important ones for a model's prediction. However, some prior studies (Feng et al., 2018) find that models remain confident about their prediction even after stripping most input tokens, leaving a few that might appear nonsensical to humans. The diagnostic properties that follow aim to facilitate a more in-depth analysis of the alignment between the inner workings of a model and produced saliency maps.

Rationale Consistency (RC). A desirable property of an explainability technique is to be consistent with the similarities in the reasoning paths of several models on a single instance. Thus, when two reasoning paths are similar, the scores provided by an explainability technique ω should also be similar, and vice versa. Note that we are interested in similar reasoning paths as opposed to similar predictions, as the latter does not guarantee analogous model rationales. For models with diverse architectures, we expect rationales to be diverse as well and to cause low consistency. Therefore, we focus on a set of models with the same architecture, trained from different random seeds as well as the same architecture, but with randomly initialized weights. The latter would ensure that we can have model pairs (M_s, M_p) with similar and distant rationales. We further claim that the similarity in the reasoning paths could be measured effectively with the distance between the activation maps (averaged across layers and neural nodes) produced by two distinct models (Eq. 5). The distance between the explanation scores is computed simply by subtracting the two (Eq. 6). Finally, we compute Spearman's ρ between the similarity of the explanation scores and the similarity of the attribution maps (Eq. 7).

$$D(M_s, M_p, x_i) = D(M_s(x_i), M_p(x_i)) \quad (5)$$

$$D(M_s, M_p, x_i, \omega) = D(\omega^{M_s}_{x_i,y_i}, \omega^{M_p}_{x_i,y_i}) \quad (6)$$

$$\rho(M_s, M_p, X, \omega) = \rho(D(M_s, M_p, x_i), D(M_s, M_p, x_i, \omega) | i \in [1, N]) \quad (7)$$

The higher the positive correlation is, the more consistent the attribution method would be. We choose Spearman's ρ as it measures the monotonic correlation between the two variables. On the other hand, Pearson's ρ measures only the linear correlation, and we can have a non-linear correlation between the activation difference and the saliency score differences. When subtracting saliency scores and layer activations, we also take the absolute value of the vector difference as the property should be invariant to order of subtraction. An additional benefit of the property is that low correlation scores would also help to identify explainability techniques that are not faithful to a model's rationales.

Dataset Consistency (DC). The next diagnostic property is similar to the above notion of rationale consistency but focuses on consistency across instances of a dataset as opposed to consistency across different models of the same architecture. In this case, we test whether instances with similar rationales also receive similar explanations. While Rationale Consistency compares instance explanations of the same instance for different model rationales, Dataset Consistency compares explanations for pairs of instances on the same model. We again measure the similarity between instances x_i and x_j by comparing their activation maps, as in Eq. 8. The next step is to measure the similarity of the explanations produced by an explainability technique ω, which is the difference between the saliency scores as in Eq. 9. Finally, we measure Spearman's ρ between the similarity in the activations and the saliency scores as in Eq. 10. We again take the absolute value of the difference.

$$D(M, x_i, x_j) = D(M(x_i), M(x_j)) \quad (8)$$

$$D(M, x_i, x_j, \omega) = D(\omega^{M}_{x_i,y_i}, \omega^{M}_{x_j,y_i}) \quad (9)$$

$$\rho(M, X, \omega) = \rho(D(M, x_i, x_j), D(M, x_i, x_j, \omega) | i, j \in [1, N]) \quad (10)$$

4 Experiments

4.1 Datasets

Dataset	Example	Size	Length
e-SNLI (Camburu et al., 2018)	*Premise:* An adult dressed in black **holds a stick.** *Hypothesis:* An adult is walking away, **empty-handed**. *Label*: contradiction	549 367 Train 9 842 Dev 9 824 Test	27.4 inst. 5.3 expl.
Movie Reviews (Zaidan et al., 2007)	*Review:* he is one of **the most exciting martial artists on the big screen**, continuing to perform his own stunts and **dazzling audiences** with his flashy kicks and punches. *Class:* Positive	1 399 Train 199 Dev 199 Test	834.9 inst. 56.18 expl.
Tweet Sentiment Extraction (TSE) [2]	*Tweet:* im soo **bored**...im deffo missing my music channels *Class:* Negative	21 983 Train 2 747 Dev 2 748 Test	20.5 inst. 9.99 expl.

Table 1: Datasets with human-annotated saliency explanations. The *Size* column presents the dataset split sizes we use in our experiments. The *Length* column presents the average number of instance tokens in the test set *(inst.)* and the average number of human annotated explanation tokens *(expl.)*.

Table 1 provides an overview of the used datasets. For e-SNLI, models predict inference – contradiction, neutral, or entailment – between sentence tuples. For the Movie Reviews dataset, models predict the sentiment – positive, negative, or neutral – of reviews with multiple sentences. Finally, for the TSE dataset, models predict tweets' sentiment – positive, negative, or neutral. The e-SNLI dataset provides three dataset splits with human-annotated rationales, which we use as training, dev, and test sets, respectively. The Movie Reviews dataset provides rationale annotations for nine out of ten splits. Hence, we use the ninth split as a test and the eighth split as a dev set, while the rest are used for training. Finally, the TSE dataset only provides rationale annotations for the training dataset, and we therefore randomly split it into 80/10/10% chunks for training, development and testing.

4.2 Models

We experiment with different commonly used base models, namely `CNN` (Fukushima, 1980), `LSTM` (Hochreiter and Schmidhuber, 1997), and the `Transformer` (Vaswani et al., 2017) architecture BERT (Devlin et al., 2019). The selected models allow for a comparison of the explainability techniques on diverse model architectures. Table 4 presents the performance of the separate models on the datasets.

For the `CNN` model, we use an embedding, a con-

Table 2: Models' F1 score on the test and the validation datasets. The results present the average and the standard deviation of the Performance measure over five models trained from different seeds. The random versions of the models are again five models, but only randomly initialized, without training.

volutional, a max-pooling, and a linear layer. The embedding layer is initialized with GloVe (Pennington et al., 2014) embeddings and is followed by a dropout layer. The convolutional layer computes convolutions with several window sizes and multiple-output channels with ReLU (Hahnloser et al., 2000) as an activation function. The result is compressed down with a max-pooling layer, passed through a dropout layer, and into a fine linear layer responsible for the prediction. The final layer has a size equal to the number of classes in the dataset.

The `LSTM` model again contains an embedding layer initialized with the GloVe embeddings. The embeddings are passed through several bidirectional LSTM layers. The final output of the recurrent layers is passed through three linear layers and a final dropout layer.

For the `Transformer` model, we fine-tune the pre-trained basic, uncased language model (LM) (Wolf et al., 2019). The fine-tuning is performed with a linear layer on top of the LM with a size equal to the number of classes in the corresponding task. Further implementation details for all of the models, as well as their F1 scores, are presented in A.1.

4.3 Explainability Techniques

We select the explainability techniques to be representative of different groups – gradient (Sundararajan et al., 2017; Simonyan et al., 2013), perturbation (Shapley, 1953; Zeiler and Fergus, 2014) and simplification based (Ribeiro et al., 2016; Johansson et al., 2004).

Starting with the **gradient-based** approaches, we select *Saliency* (Simonyan et al., 2013) as many other gradient-based explainability methods build on it. It computes the gradient of the output w.r.t. the input. We also select two widely used improvements of the *Saliency* technique, namely *InputX-Gradient* (Kindermans et al., 2016), and *Guided Backpropagation* (Springenberg et al., 2014). InputXGradient additionally multiplies the gradient with the input and *Guided Backpropagation* overwrites the gradients of ReLU functions so that only non-negative gradients are backpropagated.

From the **perturbation-based** approaches, we employ *Occlusion* (Zeiler and Fergus, 2014), which replaces each token with a baseline token (as per standard, we use the value zero) and measures the change in the output. Another popular perturbation-based technique is the *Shapley Value Sampling* (Castro et al., 2009). It is based on the Shapley Values approach that computes the average marginal contribution of each word across all possible word perturbations. The Sampling variant allows for a faster approximation of Shapley Values by considering only a fixed number of random perturbations as opposed to all possible perturbations.

Finally, we select the **simplification-based** explanation technique LIME (Ribeiro et al., 2016). For each instance in the dataset, LIME trains a linear model to approximate the local decision boundary for that instance.

Generating explanations. The saliency scores from each of the explainability methods are generated for each of the classes in the dataset. As all of the gradient approaches provide saliency scores for the embedding layer (the last layer that we can compute the gradient for), we have to aggregate them to arrive at one saliency score per input token. As we found different aggregation approaches in related studies (Bansal et al., 2016; DeYoung et al., 2020), we employ the two most common methods – L2 norm and averaging (denoted as μ and $\ell2$ in the explainability method names).

Saliency	e-SNLI	IMDB	TSE
`Transformer`			
Random	0.201	0.517	0.185
ShapSampl	0.479	0.481	0.667

Table 3: Mean of the diagnostic property measures for all tasks and models. The best result for the particular model architecture and downstream task is in bold and the second-best is underlined.

5 Results and Discussion

We report the measures of each diagnostic property as well as FLOPs as a measure of the computing time used by the particular method. For all diagnostic properties, we also include the randomly assigned saliency as a baseline.

5.1 Results

Of the three model architectures, unsurprisingly, the `Transformer` model performs best, while the `CNN` and the `LSTM` models are close in performance. It is only for the IMDB dataset that the `LSTM` model performs considerably worse than the `CNN`, which we attribute to the fact that the instances contain a large number of tokens, as shown in Table 1. As this is not the core focus of this paper, detailed results can be found in the supplementary material.

Overall results. Table 3 presents the mean of all properties across tasks and models with all property measures normalized to be in the range [0,1]. We see that gradient-based explainability techniques always have the best or the second-best performance for the diagnostic properties across all three model architectures and all three downstream tasks. Note that, *InputXGrad*$^{\mu}$ and *GuidedBP*$^{\mu}$, which are computed with a mean aggregation of the scores, have some of the worst results. We conjecture that this is due to the large number of values that are averaged – the mean smooths out any differences in the values. In contrast, the L2 norm aggregation amplifies the presence of large and small values in the vector. From the non-gradient based explainability methods, *LIME* has the best performance, where in two out of nine cases it has the best performance. It is followed by *ShapSampl* and *Occlusion*. We can conclude that the occlusion based methods overall have the worst performance according to the diagnostic properties.

Furthermore, we see that the explainability methods achieve better performance for the e-SNLI and the TSE datasets with the `Transformer` and `LSTM` architectures, whereas the results for the IMDB dataset are the worst. We hypothesize that this is due to the longer text of the input instances in the IMDB dataset. The scores also indicate that the explainability techniques have the highest diagnostic property measures for the `CNN` model with the e-SNLI and the IMDB datasets, followed by the `LSTM`, and the `Transformer` model. We suggest that the performance of the explainability tools can be worse for large complex architectures with a huge number of neural nodes, like the `Transformer` one, and perform better for small, linear architectures like the `CNN`.

Diagnostic property performance. Figure 2 shows the performance of each explainability technique for all diagnostic properties on the e-SNLI dataset, and Figure 3 – for the TSE dataset, which are considerably bigger than IMDB. The IMDB dataset shows similar tendencies and a corresponding figure can be found in the supplementary material.

Agreement with human rationales. We observe that the best performing explainability technique for the `Transformer` model is *InputXGrad*$^{\ell 2}$ followed by the gradient-based ones with L2 norm aggregation. While for the `CNN` and the `LSTM` models, we observe similar trends, their MAP scores are always lower than for the `Transformer`, which indicates a correlation between the performance of a model and its agree-

ment with human rationales. Furthermore, the MAP scores of the `CNN` model are higher than for the `LSTM` model, even though the latter achieves higher F1 scores on the e-SNLI dataset. This might indicate that the representations of the `LSTM` model are less in line with human rationales. Finally, we note that the mean aggregations of the gradient-based explainability techniques have MAP scores close to or even worse than those from the randomly initialized models.

Faithfulness. We find that gradient-based techniques have the best performance for the Faithfulness diagnostic property. On the e-SNLI dataset, it is particularly *InputXGrad*$^{\ell 2}$, which performs well across all model architectures. We further find that the `CNN` exhibits the highest Faithfulness scores for seven out of nine explainability methods. We hypothesize that this is due to the simple architecture with relatively few neural nodes compared to the recurrent nature of the `LSTM` model and the large number of neural nodes in the `Transformer` architecture. Finally, models with high Faithfulness scores do not necessarily have high Human agreement scores and vice versa. This suggests that these two are indeed separate diagnostic properties, and the first should not be confused with estimating the faithfulness of the techniques.

Confidence Indication. We find that the Confidence Indication of all models is predicted most accurately by the *ShapSampl*, *LIME*, and *Occlusion* explainability methods. This result is expected, as they compute the saliency of words based on differences in the model's confidence using different instance perturbations. We further find that the `CNN` model's confidence is better predicted with *InputXGrad*$^{\mu}$. The lowest MAE with the balanced dataset is for the `CNN` and `LSTM` models. We hypothesize that this could be due to these models' overconfidence, which makes it challenging to detect when the model is not confident of its prediction.

Rationale Consistency. There is no single universal explainability technique that achieves the highest score for Rationale Consistency property. We see that *LIME* can be good at achieving a high performance, which is expected, as it is trained to approximate the model's performance. The latter is beneficial, especially for models with complex architectures like the `Transformer`. The gradient-based approaches also have high Rationale Consistency scores. We find that the *Occlusion* technique is the best performing for the `LSTM` across all tasks, as it is the simplest of the explored explainability techniques, and does not inspect the model's internals or try to approximate them. This might serve as an indication that `LSTM` models, due to their recurrent nature, can be best explained with simple perturbation based methods that do not examine a model's reasoning process.

Dataset Consistency. Finally, the results for the Dataset Consistency property show low to moderate correlations of the explainability techniques with similarities across instances in the dataset. The correlation is present for LIME and the gradient-based techniques, again with higher scores for the L2 aggregated gradient-based methods.

Overall. To summarise, the proposed list of diagnostic properties allows for assessing existing explainability techniques from different perspectives and supports the choice of the best performing one. Individual property results indicate that gradient-based methods have the best performance. The only strong exception to the above is the better performance of *ShapSampl* and *LIME* for the Confidence Indication diagnostic property. However, *ShapSampl*, *LIME* and *Occlusion* take considerably more time to compute and have worse performance for all other diagnostic properties.

6 Conclusion

We proposed a comprehensive list of diagnostic properties for the evaluation of explainability techniques from different perspectives. We further used them to compare and contrast different groups of explainability techniques on three downstream tasks and three diverse architectures. We found that gradient-based explanations are the best for all of the three models and all of the three downstream text classification tasks that we consider in this work. Other explainability techniques, such as *ShapSampl*, *LIME* and *Occlusion* take more time to compute, and are in addition considerably less faithful to the models and less consistent with the rationales of the models and similarities in the datasets.

A Appendices

A.1 Experimental Setup

Model	Time	Score
	e-SNLI	
`Transformer`	244.763 (±62.022)	0.523 (±0.356)
`CNN`	195.041 (±53.994)	0.756 (±0.028)
`LSTM`	377.180 (±232.918)	0.708 (±0.205)
	Movie Reviews	
`Transformer`	3.603 (±0.031)	0.785 (±0.226)
`CNN`	4.777 (±1.953)	0.756 (±0.058)
`LSTM`	5.344 (±1.593)	0.584 (±0.061)
	TSE	
`Transformer`	9.393 (±1.841)	0.783 (±0.006)
`CNN`	2.240 (±0.544)	0.730 (±0.035)
`LSTM`	3.781 (±1.196)	0.713 (±0.076)

Table 4: Hyper-parameter tuning details. *Time* is the average time (mean and standard deviation in brackets) measured in minutes required for a particular model with all hyper-parameter combinations. *Score* is the mean and standard deviation of the performance on the validation set as a function of the number of the different hyper-parameter searches.

Machine Learning Models . The models used in our experiments are trained on the training splits, and the parameters are selected according to the development split. We conducted fine-tuning in a grid-search manner with the ranges and parameters we describe next. We use superscripts to indicate when a parameter value was selected for one of the datasets e-SNLI – 1, Movie Review – 2, and TSE – 3. For the `CNN` model, we experimented with the following parameters: embedding dimension $\in \{50, 100, 200, 300^{1,2,3}\}$, batch size $\in \{16^2, 32, 64^3, 128, 256^1\}$, dropout rate $\in \{0.05^{1,2,3}, 0.1, 0.15, 0.2\}$, learning rate for an Adam optimizer $\in \{0.01, 0.03, 0.001^{2,3}, 0.003, 0.0001^1, 0.0003\}$, window sizes $\in \{[2,3,4]^2, [2,3,4,5], [3,4,5]^3, [3,4,5,6], [4,5,6], [4,5,6,7]^1\}$, and number of output channels $\in \{50^{2,3}, 100, 200, 300^1\}$. We leave the stride and the padding parameters to their default values – one and zero.

For the `LSTM` model we fine-tuned over the following grid of parameters: embedding dimension $\in \{50, 100^{1,2}, 200^3, 300\}$, batch size $\in \{16^{2,3}, 32, 64, 128, 256^1\}$, dropout rate $\in \{0.05^3, 0.1^{1,2}, 0.15, 0.2\}$, learning rate for an Adam optimizer $\in \{0.01^1, 0.03^2, 0.001^{2,3}, 0.003, 0.0001, 0.0003\}$, number of LSTM layers $\in \{1^{2,3}, 2, 3, 4^1\}$, LSTM hidden layer size $\in \{50, 100^{1,2,3}, 200, 300\}$, and size of the two linear layers $\in \{[50,25]^2, [100,50]^1, [200,100]^3\}$. We also experimented with other numbers of linear layers after the recurrent ones, but having three of them, where the final was the prediction layer, yielded the best results.

The `CNN` and `LSTM` models are trained with an early stopping over the validation accuracy with a patience of five and a maximum number of training epochs of 100. We also experimented with other optimizers, but none yielded improvements.

Finally, for the `Transformer` model we fine-tuned the pre-trained basic, uncased LM (Wolf et al., 2019)(110M parameters) where the maximum input size is 512, and the hidden size of each layer of the 12 layers is 768. We performed a grid-search over learning rate of $\in \{1e-5, 2e-5^{1,2}, 3e-5^3, 4e-5, 5e-5\}$. The models were trained with a warm-up period where the learning rate increases linearly between 0 and 1 for 0.05% of the steps found with a grid-search. We train the models for five epochs with an early stopping with patience of one as the Transformer models are easily fine-tuned for a small number of epochs.

All experiments were run on a single NVIDIA TitanX GPU with 8GB, and 4GB of RAM and 4 Intel Xeon Silver 4110 CPUs.

The models were evaluated with macro F1 score, which can be found here `https://scikit-learn.org/stable/modules/generated/sklearn.metrics.precision_recall_fscore_support.html` and is defined as follows:

$$Precision(P) = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FP}}$$

$$Recall(R) = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}}$$

$$F1 = \frac{2 * \mathrm{P} * \mathrm{R}}{\mathrm{P} + \mathrm{R}}$$

where TP is the number of true positives, FP is the number of false positives, and FN is the number of false negatives.

Explainability generation. When evaluating the Confidence Indication property of the explainability measures, we train a logistic regression for 5 splits and provide the MAE over the five test splits. As for some of the models, e.g. `Transformer`, the confidence is always very high, the LR starts to predict only the average confidence. To avoid this, we additionally randomly up-sample the training instances with a smaller confidence, making the number of instances in each confidence interval [0.0-0.1],...[0.9-1.0]) to be the same as the maximum number of instances found in one of the separate intervals.

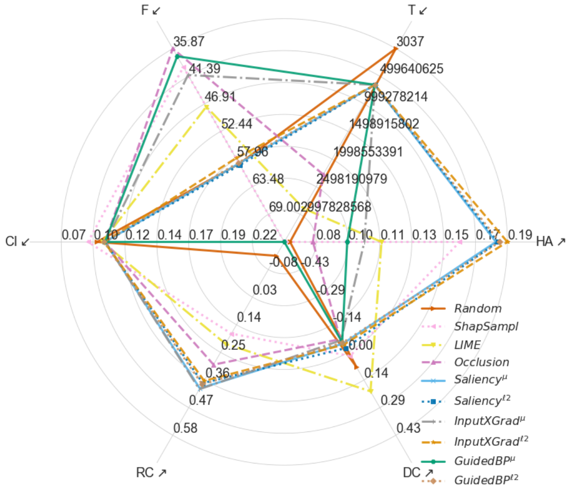
For both Rationale and Dataset Consistency properties, we consider Spearman's ρ. While Pearson's ρ measures only the linear correlation between two variables (a change in one variable should be proportional to the change in the other variable), Spearman's ρ measures the monotonic correlation (when one variable increases, the other increases, too). In our experiments, we are interested in the monotonic correlation as all activation differences don't have to be linearly proportional to the differences of the explanations and therefore measure Spearman's ρ.

The Dataset Consistency property is estimated over instance pairs from the test dataset. As computing it for all possible pairs in the dataset is computationally expensive, we select 2 000 pairs from each dataset in order of their decreasing word overlap and sample 2 000 from the remaining instance pairs. This ensures that we compute the diagnostic property on a set containing tuples of similar and different instances.

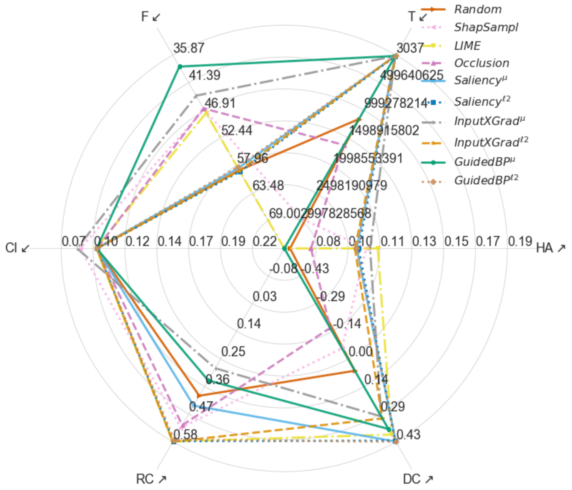
Both the Dataset Consistency property and the Rationale Consistency property estimate the difference between the instances based on their activations. For the `LSTM` model, the activations of the LSTM layers are limited to the output activation also used for prediction as it isn't possible to compare activations with different lengths due to the different token lengths of the different instances. We also use min-max scaling of the differences in the activations and the saliencies as the saliency scores assigned by some explainability techniques are very small.

A.2 Spider Figure for the IMDB dataset

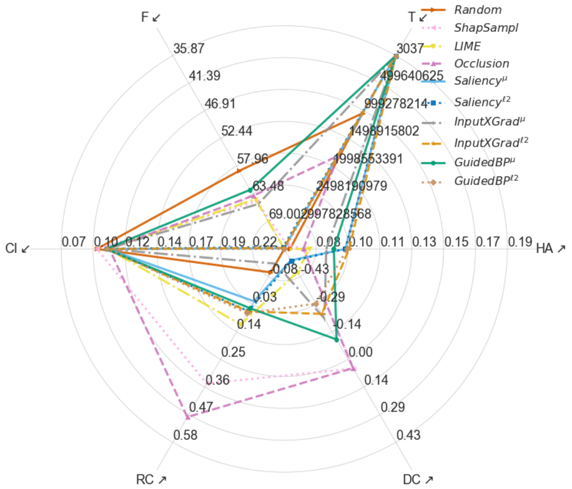
A.3 Detailed explainability techniques evaluation results.



(a) `Transformer`



(b) `CNN`



(c) `LSTM`

Figure 4: Diagnostic property evaluation for all explainability techniques, on the IMDB dataset. The ↗ and ↙ signs following the names of each explainability method indicate that higher, correspondingly lower, values of the property measure are better.

Table 6: Faithfulness-AUC for thresholds $\in [0, 10, 20, \ldots, 100]$. *Lower scores* indicate the ability of the saliency approach to assign higher scores to words more responsible for the final prediction. The presented scores are averaged over the different random initializations and the standard deviation is shown in brackets. Explainability methods with the smallest AUC for a particular dataset and model are in bold, while the smallest AUC across all models for a dataset is underlined as well. Methods that have AUC worse than the randomly generated saliency are in red.

STL-CQA: Structure-based Transformers with Localization and Encoding for Chart Question Answering

Abstract

Chart Question Answering (CQA) is the task of answering natural language questions about visualisations in the chart image. Recent solutions, inspired by VQA approaches, rely on image-based attention for question/answering while ignoring the inherent chart structure. We propose STL-CQA which improves the question/answering through sequential elements localization, question encoding and then, a structural transformer-based learning approach. We conduct extensive experiments while proposing pre-training tasks, methodology and also an improved dataset with more complex and balanced questions of different types. The proposed methodology shows a significant accuracy improvement compared to the state-of-the-art approaches on various chart Q/A datasets, while outperforming even human baseline on the DVQA Dataset. We also demonstrate interpretability while examining different components in the inference pipeline.

1 Introduction

Charts Question Answering (CQA) (Kafle et al., 2018; Kahou et al., 2017; Chaudhry et al., 2020; Methani et al., 2020a) is the task designed on the lines of Visual Question Answering (VQA) (Antol et al., 2015; Malinowski and Fritz, 2014) which requires answering natural language questions about the data visualisations such as bar charts, pie charts, etc. The problem provides us with ability to understand charts using natural language queries, as well as grounding to the natural language statements for the reasoning operations being carried out to retrieve the final answer to the query.

CQA is a challenging task because of the following reasons - (a) large question/answer vocabulary due to chart-specific words, (b) Requirements of multi-modal *fine-grained* reasoning through understanding of natural language question as well as the visualizations. This is different from VQA, where the answer dictionary is typically limited, and the reasoning is coarse-grained as compared to that required for data visualisations, where finer details like bar length and color can heavily influence both the reasoning and the answer.

Despite data visualisations being ubiquitous in documents, the problem has received sparse attention in the literature. The earlier datasets like DVQA (Kafle et al., 2018) and FigureQA (Kahou et al., 2017) consist of charts generated from synthetic data, though there has been a push for data charts generated from real sources (Chaudhry et al., 2020; Methani et al., 2020a) as well. Due to the problems discussed above, the prior work noted that VQA algorithms cannot be applied directly to CQA. Hence, different CQA methods introduce modifications for the problem, while building on the backbone of VQA approaches. While FigureQA (Kahou et al., 2017) uses relational networks for question/answering, DVQA (Kafle et al., 2018) combines text detection and VQA-based attention modules to answer chart questions. LEAF-QA (Chaudhry et al., 2020) encodes question/answers in terms of chart elements, to handle infinite vocabulary problem, while resorting to a VQA-based model as the backbone.

Though the approaches improve performance for various chart datasets, the challenges of robust reasoning over varied chart varieties, are far from being solved. We posit that this is mainly due to the non-exploitation of the significant characteristics of charts that distinguish them from plain natural images - the structure and set of chart elements. The structure of the charts along with the position of different chart elements must be exploited by the learning models to enable reasoning over them from natural language questions. In this paper, we propose a transformer-based model to exploit such structural properties of data visualisations, while

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3275–3284,
November 16–20, 2020.

also showing that our model can provide a much deeper and better interpretations to the generated answers. Our key contributions can be summarized as follows:

- We propose a transformers-based framework to *fully* utilize the structural properties of charts and achieves state-of-the-art performance on the task of charts question answering.
- We define a set of pre-training tasks for inducing structural knowledge of charts or data visualisations into the proposed model and demonstrate its effectiveness.
- We conduct a range of interpretability experiments to dissect the reasoning process of our model.
- We extend the recently proposed LEAF-QA dataset (Chaudhry et al., 2020) to generate a *harder* and *more* balanced dataset.

2 Related Works

Visual Question Answering: The problem of Visual Question/Answering (VQA) has been explored extensively with a variety of datasets (Malinowski and Fritz, 2014; Antol et al., 2015; Ren et al., 2015; Krishna et al., 2017; Kafle and Kanan, 2017) with various approaches for joint understanding of images and text. A more closely related work to our problem is, however, TextVQA (Singh et al., 2019) which focuses on the problem of question/answering with scene texts, having *infinite* vocabulary. Correspondingly, a variety of solutions have also been proposed - the most successful have been based on attention (Xu et al., 2015; Yang et al., 2016; Anderson et al., 2018) and joint multimodal learning (Tan and Bansal, 2019; Lu et al., 2019; Chen et al., 2019; Li et al., 2020).

Pre-training: The success of pre-training with ELMo (Peters et al., 2018), GPT (Radford et al., 2018), GPT-2 (Radford et al., 2019), BERT (Devlin et al., 2019) has led to significant advancements in natural language understanding. These pre-training frameworks also motivated some of the recent works on multi-modal understanding (Tan and Bansal, 2019; Lu et al., 2019; Chen et al., 2019; Sun et al., 2019). Our pre-training framework borrows ideas from these works with additional tasks designed specifically for understanding chart structure. To the best of our knowledge, ours is one of the first work to demonstrate the effectiveness of pre-training in inducing structural knowledge of charts.

Charts Questions Answering: There has been several works lately addressing the problem of CQA. One line of work relies on using the chart figures and questions directly (Kahou et al., 2017; Kafle et al., 2018, 2020; Chaudhry et al., 2020) while others (Methani et al., 2020a; Qian et al., 2020) are focused on parsing out the chart data first to perform the task. Our approach falls in the first category. Apart from chart question answering, there have been works focused on chart data parsing (Cliche et al., 2017; Kallimani et al., 2013; Savva et al., 2011) or visual structure extraction (Tsutsui and Crandall, 2017; Poco and Heer, 2017). While they do not focus on natural language based understanding of charts, their components form the basis for our structural understanding of charts.

3 STL-CQA

In this section, we describe our overall framework which is the first method to *fully* utilize the structural knowledge of charts for both question encoding and reasoning to perform the task of Charts Question Answering (CQA). We refer to our framework as STL-CQA - **S**tructure-based **T**ransformers with **L**ocalization and encoding for CQA. Even though prior works have attempted to utilize the chart structure for encoding questions, their reasoning frameworks still do not exploit this knowledge resulting in sub-optimal performances and offering much less insight into the reasoning process of these models. We divide our overall framework into three stages - Localization, Encoding, and Transformers-based structural attention. While the first two stages have been adopted from the existing state of the art frameworks, the novel reasoning stage makes our algorithm much more powerful and interpretable as discussed in the later sections.

3.1 Localization

The first step in our multi-stage framework is the detection or localization of the chart elements used in different types of data visualisations. For this purpose, we leverage the advances in the object detection frameworks and use the Mask-R CNN (He et al., 2017) with a Resnet-101 backbone. We enlist the different categories of our elements and train the network from scratch on the training sub-

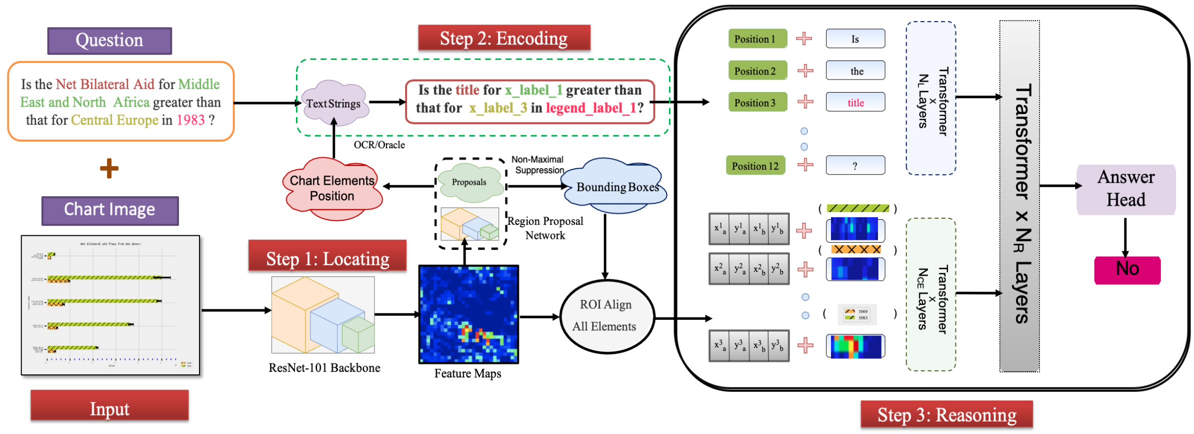

Figure 1: Overview of our pipeline showing the three different stages of our overall pipeline. We first encode both the question string and chart image by locating the different chart elements. The reasoning module, then, processes both the encoded question as well as the encoded chart elements structurally in order to provide the final answer.

set (described in Section 4.1) of around 198K images. Since the metadata provided in the public datasets such as DVQA (Kafle et al., 2018)/LEAF-QA (Chaudhry et al., 2020)[1] consist of only bounding boxes, we convert them into masks using several approximations specially for pie/donut charts where we utilize the geometry of different figures to prepare masks (refer supplementary for details). The implementation is carried out through Detectron2 (Wu et al., 2019) framework with a learning rate initialization of 0.00025 for 150, 000 iterations.

3.2 Encoding

Unlike VQA, the text vocabulary in the case of CQA is much larger if not *infinite*. For each chart, a question about it consist of words whioch are very specific to that chart. For example - A chart showing GDP of different countries can have words like 'USA' or 'Canada' which might not be present in other charts at all. We, therefore, follow dynamic encoding scheme (Chaudhry et al., 2020; Kafle et al., 2020) to encode the questions. In this paper, we only report performance with a text oracle, which is same as the previous work (Kafle et al., 2020; Chaudhry et al., 2020). The oracle is a perfect OCR which provides access to the bounding boxes and content of different text areas on charts, while the role of the text area (`x-title`, `y-title, etc.`) is taken from our localization system. We use the bounding box information to assign the relative *position* to each of the text string. The positioning scheme (shown in Fig 2) is based on (Chaudhry et al., 2020) where `x-axis` labels are assigned positions in increasing order from left-right, `y-axis` labels and `legend` labels are assigned *positions* bottom-top and (left-right, top-bottom) respectively. For pie charts and donut charts, the *positions* are assigned in an anti-clockwise manner.

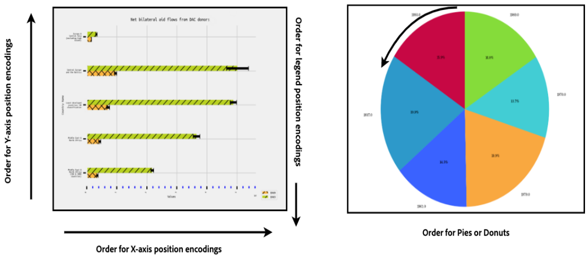

Figure 2: Position Encoding Scheme Used for encoding the chart strings as well as different chart elements.

The extracted strings and their *positions* are then used to replace the string of the question with standardized tokens. For example - if the token in the question string is 'USA' which is present as an `x-axis` label as its third element from the origin, we replace the token 'USA' with `xlabel_3`. The vocabulary of questions, thus, consists of both standardized tokens as well as natural language tokens such as *greater*, *which* etc. which are common to all questions. The vocabulary (or classes) of answers is determined in the exact similar manner.

3.3 Structure-based Transformers

This is the novel and most important module of our framework which performs **(a)** chart structure

---

[1] Another popular dataset FigureQA does not provide the bounding box

understanding, **(b)** question understanding, and **(c)** reasoning over the chart to find the answer. We adapt the transformer-based frameworks from (Tan and Bansal, 2019; Lu et al., 2019; Chen et al., 2019; Li et al., 2020) to perform reasoning over charts. We demonstrate, empirically, that the architecture is strongly suited for the task of CQA through extensive experiments. The architecture can be broken down into 4 stages:

Input: The inputs to the model are two sequences of features. The question Q is broken down into a sequence of words $\{w_0, w_1, ..., w_n\}$ and encoded as a sequence of word embeddings $\{e_0, e_1, ..., e_n\}$ of dimension d_e also taking the position into account:

$$e_i = \text{word-emb}(w_i) + \text{pos-emb}(i) \qquad (1)$$

A normalisation layer is applied before providing the word embedding sequence as input to our model.

For the chart image C, the model input is prepared by utilizing the output of Mask-RCNN (Anderson et al., 2018). We extract the features using the Resnet-101 backbone of our detection network and use the bounding boxes of different m chart elements $\{c_0, c_1, ..., c_m\}$ as well to encode the chart. Although natural images have larger number of possible class elements, in the case of data visualizations, more class elements are present simultaneously in an image. Further, reasoning in charts depends heavily on the correct detection of the geometry and type of each box. Hence, unlike (Tan and Bansal, 2019), where a fixed number of objects are extracted for every image even if there are several overlaps, we apply non-maximal suppression (Neubeck and Van Gool, 2006) to choose the most confident and distinct bounding boxes. Finally, the Resnet-101 network is used to extract the features of the final bounding boxes. A plot class which provides a bounding box of the plot region to provide a global picture, is also taken. This is necessary for answering the global information questions about the images (such as *Is there a grid in the chart?*). We found the performance to improve significantly after adding the global plot representation. Since, different images can have different number of chart elements, we pad the sequences to have a fixed length M for all charts. The chart input sequence is computed as below:

$$f_i = \textbf{LayerNorm}(W_F r_i + b_f) \qquad (2)$$

$$p_i = \textbf{LayerNorm}(W_P x_i + b_p) \qquad (3)$$

$$c_i = \frac{f_i + p_i}{2} \qquad (4)$$

where, r_i corresponds to the Resnet-101 features of i^{th} chart element, x_i refers to corresponding bounding box coordinates, (W_F, b_f) and (W_P, b_p) are learnable parameters.

Chart Relation Transformer: The chart features computed in Eq. 4 are fed to a transformer with N_{CE} layers each having a self-attention block and a feed-forward block both with residual connections as proposed originally by (Vaswani et al., 2017) . The chart-only transformer learns relationships between chart elements, agnostic of the question. We discuss more details about these relationships and their interpretation in Section 4.4.

Question Transformer: This is again a transformer with N_L layers each having a self-attention block and a feed-forward block with residual connections to encode the meaning of the question. The input to the encoder is as computed in Eq. 1. We also tried using token IDs along with positional embedding to distinguish between words from common vocabulary (eg. how, many) and standardized words for chart vocabulary (e.g. `xtitle`, `legend_title`). but it did not yield any further improvement.

Reasoning Module: The reasoning module is the cross-attention transformer block with N_R layers which takes as input the contextual features generated by chart transformer and question transformer. Each layer consists of three blocks - cross-attention, self-attention, and feed-forward. In the cross-attention block of chart stream, chart features act as *query* in the attention formulation (Bahdanau et al., 2014) and the features from question *stream* act as *keys* as well as *values* while the vice-versa happens in the cross-attention block of question stream. This block is followed by a self-attention block and a feed-forward block acting independently in their own streams. All of the three blocks have residual connections. If the i^{th} question token's features and j^{th} chart element's features being used as input for k^{th} layer are represented by

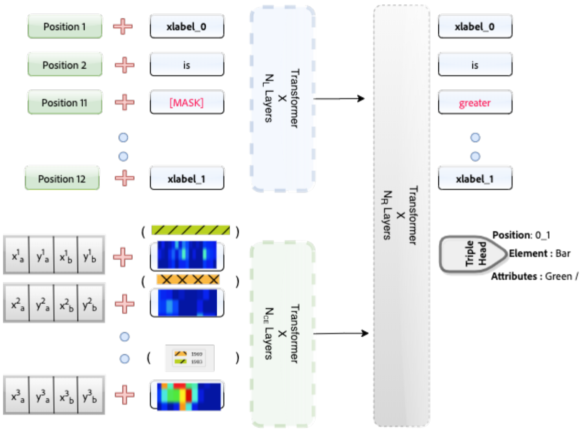

Figure 3: Overview of our pre-training task. MLM is used to recover the language tokens thus inducing both language structure and cross-modality understanding. NSP-like task is also used for the same properties. The triple head on each vision element predicts the position, the chart element class or category, and its attributes.

Q^i_{k-1} and C^j_{k-1} and attention with q query, k keys, and v values is represented by $attn(q, k, v)$ then cross attention block for question stream can be represented as in Eq. 5 and self-attention block as in Eq. 6

$$Q^i_{k_{cross}} = attn(Q^i_{k-1}, C_{k-1}, C_{k-1}) \quad (5)$$

$$Q^i_{k_{self}} = attn(Q^i_{k_{cross}}, Q_{k_{cross}}, Q_{k_{cross}}) \quad (6)$$

where $Q_k : \{Q^0_k, ..., Q^n_k\}$ and $C_k : \{C^0_k, ..., C^m_k\}$.

We show the reasoning module as a single large block in Fig. 1. Since the cross attention module is followed by self-attention module for each layer, the information (what is asked) from the cross-attention is used by the self-attention layers to perform various operations with each other. We discuss more about the reasoning operations carried out by the model in Section 4.4. The **[CLS]** token prepended to the question tokens captures the entire cross-modal information and is used to retrieve the final answer by applying a two layer perceptron over the contextual embedding for this token. The whole system is trained using a cross-entropy loss.

3.4 Pre-training

In this section, we propose a set of pre-training tasks for our STL-CQA model. To the best of our knowledge, this is the first use of pre-training for charts question answering. Our proposed tasks are on the lines of pre-training literature in language modelling (Devlin et al., 2019) and VQA (Tan and Bansal, 2019). Our tasks can be primarily grouped into three categories:

Chart Structure tasks consists of the tasks designed to induce the sense of different parameters which make up the properly defined structure of the chart. We focus on three major things - (a) Types of chart elements (b) Position of chart elements (c) Color and pattern of non-textual elements in charts. Unlike (Tan and Bansal, 2019; Lu et al., 2019), we do not pre-train our model on the features regression task. For the type of chart elements, we consider 23 chart categories and use a cross-entropy classification loss for each element over them. For the position of chart elements, we use positioning scheme similar to the one discussed in Section 3.2. Since, even along x-axis (or y-axis in case of horizontal graphs), we can have multiple groups, we use a positioning scheme for chart elements as well. For example, a stacked bar chart having a bar at third position on x-axis (left to right) and second position in legend box (top to bottom) is assigned a position `2_1` (zero-indexing). These positions are then treated as targets for a classification task using a linear position head like that for types of charts elements. For colors and patterns, we use the chart metadata. We treat a particular color and pattern combination as a category and train the model on identifying the color and patterns as a classification problem.

Language/Question: For language tasks, as is prevalent in recent works, we train the model on standard MLM i.e. Masked Language Modelling task (Devlin et al., 2019) task. However, in our case, we do not just randomly mask any word. We specifically focus on chart vocabulary words or words which modify the meaning of the sentence such as *higher*, *lower* etc. During caption generation, we keep track of such words and pass their indices to random masking function so that only those indices are masked during the training stage.

Cross Modal: For the reasoning module, we use only one pre-training task which is similar to the next sentence prediction task of BERT. We replace the original sentence with a mismatched sentence with a probability of 0.5 and then train a classifier to identify the mismatched sentence.

4 Experiments

We conduct a range of experiments to demonstrate the efficacy of our proposed STL-CQA network. In this section, we describe the different datasets which were used along with the models and the obtained results.

4.1 Dataset

Split	Structure	Data	Reasoning	Overall
Train	605,176	715,697	742,588	2,063,461
Test-Familiar	120,884	143,029	148,589	412,502
Test-Novel	35,094	40,611	37,687	113,392

Table 1: Numbers of questions by type for the LEAF-QA++ Corpus.

We evaluate the proposed STL-CQA method on recent chart question/answering datasets. DVQA (Kafle et al., 2018) has a large corpus of bar charts and associated question/answers. We use the splits as provided in (Kafle et al., 2018) for our experiments. We demonstrate that the proposed STL-CQA method outperforms the prior baselines.

LEAF-QA (Chaudhry et al., 2020), is a comprehensive chart question/answering dataset, covering 10 different types of charts and over 35 question templates. Using the publicly available chart annotations[2], we further develop a more comprehensive question/answering corpus, LEAF-QA++. The original LEAF-QA utilizes automatic paraphrasing of questions to generate variations. We manually curate 3-8 paraphrase variations of question templates to greatly increase the diversity and naturalness of the questions. We further, add new data question types, increasing the number of template questions from 35 to 75. We add data questions, not present in the original corpus, which ask about chart component positional or values. The question set is balanced to avoid pre-dominant values in answers, especially for questions with common chart answers (like yes/no). We refer the reader to the supplementary for further details on the proposed LEAF-QA++ corpus.

To prepare the data for pre-training, we generate 35 sentence templates for LEAF-QA++ using the metadata. Such templates are also augmented with a small list for each sentence which provides information about which are the relevant tokens for MLM masking. For each template, we use paraphrases which are written manually and also combine it with the templates of one-another with a probability of 0.5 thus producing a very high number of combinations.

4.2 Model Settings

For all the experiments, we use $N_{CE} = 5$, $N_L = 4$, and $N_R = 5$. We use 4 layers in language model, as the template-based questions even with paraphrasing, are less complex than the natural language. In fact, increasing the number of layers resulted in a deteriorated performance as the model overfitted to the vocabulary. For element relationship and reasoning blocks, we set N_{CE} and N_R to be 5 layers each. We use $d_e = 2048$ for consistency, the maximum length for questions is 30 and the maximum number of chart elements is taken to be 45.

Pre-training Details: We use 23 object categories, 5301 color and patterns combinations for attributes, and 63 different position combinations. We pre-train the model for 4 epochs on 4 V100 GPUs using an Adam Optimizer (Kingma and Ba, 2014) with an initial learning rate of $5 * 10^{-5}$ and batch size of 512.

Fine Tuning Details: We fine-tune the model for 6 Epochs if it has been pre-trained or for 10 epochs if the model is being trained from the scratch. The batch size used is 512 and an Adam optimizer is used with an initial learning rate of 10^{-4}.

4.3 Results

We show results on two datasets - DVQA and LEAF-QA++. We do not show our results on the LEAF-QA corpus as LEAF-QA++ is a superset of it. As discussed in Section 3.2, we assume access to an oracle in our experiments. We show comparisons with the current state-of-the-art models on these datasets. For DVQA comparison, we enlist the results from prior models, viz. QUES, IMG+QUES and SANDY (Kafle et al., 2018), PReFIL (Kafle et al., 2020), Plot-QA (Methani et al., 2020b). As shown in Table 3, both STL-CQA and PreFIL outperform human baselines. STL-CQA further improves over PReFIL, specially in the complex reasoning questions. For LEAF-QA++, we use the LEAF-Net model, the state-of-the-art on LEAF-QA and train it with the hyper-parameters mentioned in (Chaudhry et al., 2020). As discussed in (Chaudhry et al., 2020), previous models trained on DVQA are not directly applicable to LEAF-QA, due to the higher complexity of charts in the latter. Our model shows a significant improvement in ac-

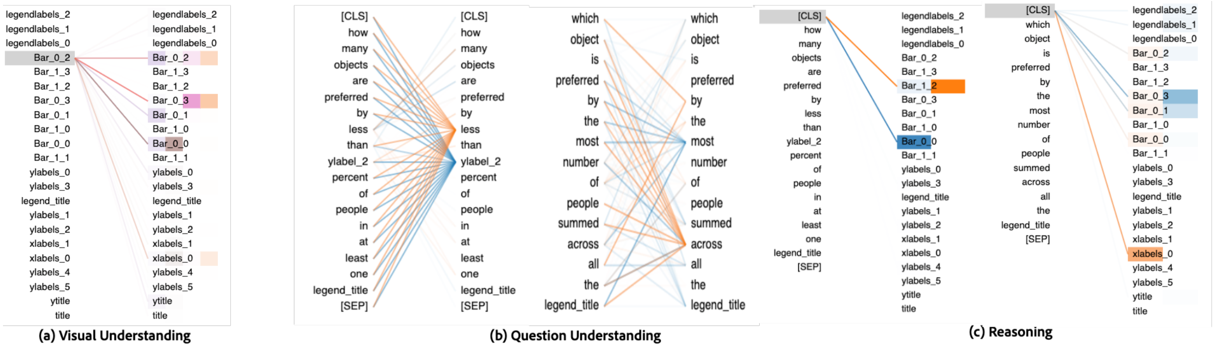
Table 5: Result over Test-Novel Split For LEAF-QA++ Dataset.

curacy over LEAF-Net with an overall increase of over 28%. The improvement is particularly remarkable for data and reasoning questions, showing that the VQA-based image attention network used in LEAF-Net do not generalize well for complex questions. The models on DVQA datasets have been able to outperform human baseline with significant margins which points towards the capability of the algorithms in performing crisp and consistent reasoning as compared to humans who are prone to data interpretation errors resulting in inconsistency, despite having better cognitive capabilities than the algorithms.

Pretraining: After pre-training , we fine-tune the model on our training subset for 6 epochs. While pre-training does help in score improvement across all three categories (Table 4 and 5), there is still a part of structural knowledge that the model fails to capture. Better and more focused pre-training tasks coupled with improved detection systems and larger datasets could help solve these problems in future.

4.4 Interpretability

One of the advantages of using structure-based interpretable elements in key, query and value of attention is the ease in grounding the attention weights to chart structure. In our case, each element in the language stream is a discrete token and elements in the visual stream correspond to chart elements. Thus, we are able to dissect the attention heads and interpret the semantic grounding of the attention weights. We isolate a single chart image with two questions in Fig. 4 to demonstrate the functions of three separate blocks as discussed in Section 3.3. Chart structure understanding is carried out with the visual understanding block. In this case, attention visualisa-



(a) Visual Understanding

(b) Question Understanding

(c) Reasoning

Figure 4: Interpretability over the steps performed to recover the answer. Color Coding denotes heads. For the same chart, visual understanding remains same. We show visualisation using certain selected heads depending upon the function for visual understanding while limiting to two heads only (max values) for Question and Reasoning

tion shows that it is organising the grouped bar chart into families on the basis of their group. `Bar_0_2` means a bar from group at `xlabels_0` present at 2^{nd} position from left (for a vertical chart) and its attention is linked to the other bars in this same group, (`Bar_0_0`, `Bar_0_1`, `Bar_0_2`, `Bar_0_3` and the class of that group `xlabels_0`). We find these heads to be consistent even for other bars. We also find some attention heads establishing relationship between those bars which are from the same legend group. The question understanding visualisations (for two specific heads of last layer) for first question show a heavy focus on the two important parts of the question, contributing to determination of the answer i.e. less and `ylabel_2` with some focus on 'how many' which determines that this is a *counting* question. The language understanding visualisation for these two heads for the second question also shows similar functions for them.

The last layers of the reasoning block for first question shows **[CLS]** token (which is used in the answer head) putting almost all its attention in two bars. We find these two bars to be the one satisfying the criteria of being 'less than `ylabel_2`'. The answer of this question ('two') is predicted correctly by the model. For the second question **[CLS]** token puts all almost all its attention on `xlabel_0` which is the correct answer while putting some attention on the bars which are contributing to the sum. Infact, the second highest attention is on the bar having highest value.

5 Discussion and Limitations

While our proposed model is able to reason very effectively achieving state-of-the-art on the recent datasets, it is able to do so with an assumption of perfect OCR. Thus, it will be pertinent to have better OCR models for chart images. While reasoning in a fine grained manner has been an important part of CQA, the proposed STL-CQA method shows that reasoning could be performed with a high accuracy, given the elements of the charts have been detected accurately.

Even though our model achieves near perfect accuracy on the public datasets, the current datasets are synthetic and may not represent the plethora of chart visualisation styles used in real life. Despite the significant progress in simulating real world chart understanding scenarios, especially in LEAF-QA++, there are underlying biases in the generation process (for e.g. due to using a single software like `Matplotlib` for generation). However, we believe that these are important steps towards the eventual goal of understanding charts in the wild.

A further limitation is that the questions used in the existing datasets are template-based. Even though we make an attempt in LEAF-QA++ to increase the number of templates as well as manual generation of paraphrases to bring more diversity, the current templates do not capture the full range of variations in the questions which can be asked from the visualizations. The manually generated questions will also bring different ways to address the same text on chart images. For example - Gross Domestic Product could be addressed with its more common short form, 'GDP'. The current approach relies on text-string matches to encode questions, and works because the questions have been generated using the original chart text strings. This approach, will however fail in scenarios where the entity could be addressed through its variations. However, bringing human-generated questions into the proposed datasets is a challenge since human subjects would be required to possess a deep understanding of the different charts, before being able to ask reasonable and difficult questions.

6 Conclusion and Future Works

In this work, we proposed an extension to the LEAF-QA data using the public metadata provided for the charts. We also proposed a transformers-based framework while emphasizing on the need to exploit the structural properties of chart, and showed its strong effectiveness by achieving state-of-the-art with a significant margin on the recent Chart Q/A datasets. We also defined and experimented with a set of pre-training tasks and showed the improvement due to pre-training on the problem of CQA. We used attention to dissect our model to show how each of its module functions to retrieve the final answer. We discussed the current line of CQA work and proposed future directions by outlining the limitations of the current datasets and models.

Abstract

In the task of Visual Question Answering (VQA), most state-of-the-art models tend to learn spurious correlations in the training set and achieve poor performance in out-of-distribution test data. Some methods of generating counterfactual samples have been proposed to alleviate this problem. However, the counterfactual samples generated by most previous methods are simply added to the training data for augmentation and are not fully utilized. Therefore, we introduce a novel self-supervised contrastive learning mechanism to learn the relationship between original samples, factual samples and counterfactual samples. With the better cross-modal joint embeddings learned from the auxiliary training objective, the reasoning capability and robustness of the VQA model are boosted significantly. We evaluate the effectiveness of our method by surpassing current state-of-the-art models on the VQA-CP dataset, a diagnostic benchmark for assessing the VQA model's robustness.

1 Introduction

To develop human-like visual and language understanding of AI, the task of answering a question about the given visual content has been proposed, *i.e.*, Visual Question Answering (VQA) (Antol et al., 2015). Although the current state-of-the-art methods (Fukui et al., 2016; Anderson et al., 2018; Cadene et al., 2019a) can achieve good results on the VQA benchmarks such as VQA v2 (Goyal et al., 2017), recent researches (Agrawal et al., 2016; Kafle and Kanan, 2017; Agrawal et al., 2018) have found that these methods tend to explore superficial correlations in the training set and perform poorly when transferred to real world setting. Specifically, given a question "What color is the banana?", the models prefer to take the shortcut and "assume" that the answer should be "yellow" since it is the most common answer in the training set, rather than be grounded on the image. To overcome the language bias problems in VQA, (Agrawal et al., 2018) have proposed a dataset named VQA-CP, where the answer distribution of the training set differs from the test set vastly. The performance of most current state-of-the-art models (Andreas et al., 2016; Teney et al., 2018; Shrestha et al., 2019) drop significantly on the VQA-CP due to the language bias. Hence, it has become the standard out-of-distribution benchmark for VQA.

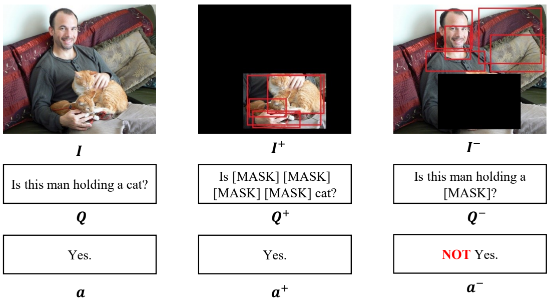

Figure 1: An informal examples of original sample (I, Q), factual sample (I^+, Q^+) and counterfactual sample (I^-, Q^-) generated by the counterfactual sample synthesizing algorithm (Chen et al., 2020).

A successful robust and unbiased VQA system is supposed to be able to deduce the right answer from the right area of the image. Lately, some studies have proposed to synthesize counterfactual samples to improve the robustness of VQA models. (Agarwal et al., 2019; Pan et al., 2019) apply GAN (Goodfellow et al., 2014) to generate images. CSS algorithm proposed by (Chen et al., 2020) generates counterfactual samples by masking the critical objects in images or words in questions, as shown in Figure 1. The critical objects or words can be obtained from CSS as by-products. Nevertheless, the counterfactual samples are simply added to the training data for augmentation, ignoring that the relationship between original samples

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3285–3292,
November 16–20, 2020. ©2020 Association for Computational Linguistics

and counterfactual samples are vital for the reasoning of VQA models. Specifically, the model should be able to learn why the correct answer cannot be inferred after changing the original sample to the counterfactual sample. We posit that modeling the relationship between original samples, factual samples and counterfactual samples can bring more self-supervised signals to improve the reasoning ability of the model.

In order to enable the VQA model to understand the impact of the samples changing from original to counterfactual, we introduce a novel contrastive learning mechanism into the training with counterfactual samples, which is first proposed in the field of learning with counterfactual samples. The auxiliary contrastive training objective model the relationship between original samples, factual samples and counterfactual samples in the cross-modal joint embedding space. With the better cross-modal representations, both the reasoning ability and robustness of the VQA model are improved efficiently.

Overall, the contributions of this paper are as follows:

- We are the first to introduce a self-supervised contrastive learning mechanism for counterfactual samples in VQA. Our method not only helps the VQA model learn the relationship between original samples, factual samples and counterfactual samples but also improves the generalization ability of the model significantly.
- Experiment results show that our method brings significant improvements and achieves state of the art on VQA-CP dataset. Furthermore, the effectiveness of contrastive mechanism in counterfactual sample learning is not limited to the form of contrastive loss.

2 Related Work

2.1 Language Bias in VQA

As the issue of language bias in VQA models is pointed out (Agrawal et al., 2016; Jabri et al., 2016; Goyal et al., 2017), creating a more balanced dataset is a simple way to alleviate it. To this end, the VQA v2 dataset (Goyal et al., 2017) rearranges the sample distribution so that it contains at least one different answer when given a same question and a similar image. Since the statistical bias problem remains, (Agrawal et al., 2018) introduce the VQA-CP dataset where the answer distributions are re-distributed in the training and test splits, making it become the standard benchmark for evaluating the robustness of VQA models.

2.2 Counterfactual Samples for VQA

Recently, employing insights from causal inference (Neuberg, 2003), some researches synthesize counterfactual samples to augment the training of VQA models (Agarwal et al., 2019; Pan et al., 2019; Chen et al., 2020). Similar to our work, (Teney et al., 2020a) have proposed a training objective named Gradient Supervision (GS) to use the relation information between original training samples and additional counterfactual samples. The GS encourages the gradient of the model to align with a "ground truth" gradient, which is the translation from original sample to counterfactual sample in the input space. In contrast, we employ a novel contrastive learning strategy to simultaneously learn the triplet relationship between the original training samples, factual samples and counterfactual samples.

2.3 Contrastive Learning

Contrastive learning techniques have achieved great success in unsupervised learning (Oord et al., 2018; He et al., 2019). The main idea of unsupervised contrastive learning is to maximize the mutual information between the input samples and positive samples so as to learn better representations. Inspired by this, we apply the contrastive mechanism to learn the self-supervision information from counterfactual samples for the first time and improve the robustness of VQA models.

3 Methodology

In this section, we introduce our technical realization. The flowchart of our proposed method is illustrated in Figure 2. Our method consists of three parts: (1) A base VQA model (2) A factual and Counterfactual Samples Synthesizing (CSS) module (3) A Contrastive Learning (CL) objective.

3.1 Baseline VQA Model

We adopt the Bottom-Up Top-Down (UpDn) (Anderson et al., 2018) model into our method, which considers the common formulation of VQA task as a multi-class classification problem. Given a set consisting of N triplets of images $I_i \in \mathcal{I}$, question $Q_i \in \mathcal{Q}$ and answer $a_i \in \mathcal{A}$, we denote as $\mathcal{D} = \{I_i, Q_i, a_i\}_{i=1}^{N}$. The task aims to learn a mapping function $f_{vqa} : \mathcal{I} \times \mathcal{Q} \rightarrow [0, 1]^{|\mathcal{A}|}$, producing

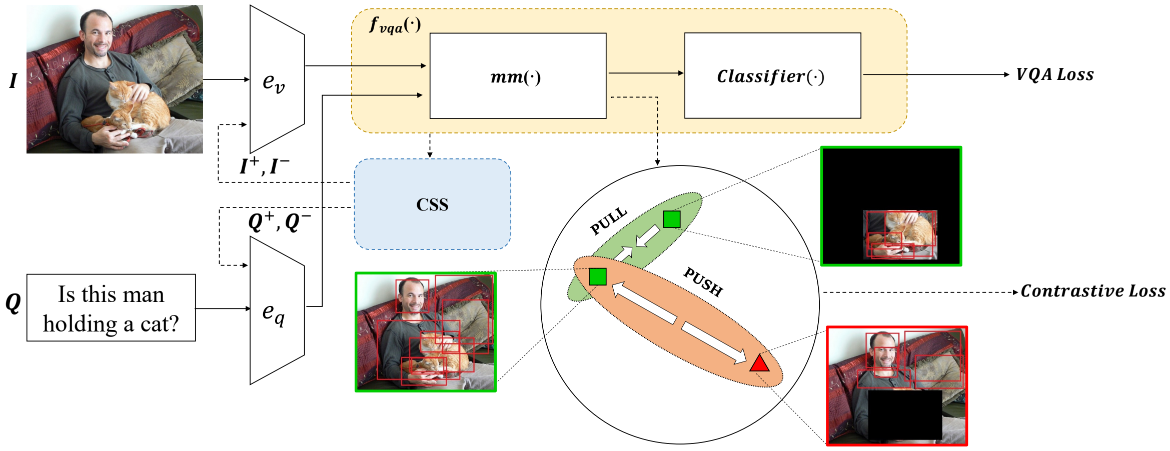

Figure 2: The flowchart of our proposed method. Optimizing the contrastive loss can pull up the original sample (I or Q) and factual sample (I^+ or Q^+) and push away the original sample and counterfactual sample (I^- or Q^-) in the joint embedding space. The example here is the case of (I, I^+, I^-).

an answer distribution of the given image and question. In the following sections, we will omit the subscript i for simplicity. For each question Q, the UpDn uses a question encoder e_q to extract a set of word embeddings $\boldsymbol{Q}$. For each image I, the UpDn uses an object detector e_v to extract a set of visual object embeddings $\boldsymbol{V}$. Then both $\boldsymbol{Q}$ and $\boldsymbol{V}$ are fed into attention and fusion modules to generate the joint embedding $mm(\boldsymbol{Q}, \boldsymbol{V})$. The joint embedding is then fed into classifier C to predict the answer:

$$P_{vqa}(\mathbf{a}|I, Q) = f_{vqa}(\boldsymbol{V}, \boldsymbol{Q}) = C(mm(\boldsymbol{Q}, \boldsymbol{V})) \tag{1}$$

3.2 Synthesizing Counterfactual Samples

There are several ways to synthesize the counterfactual samples of the given image-question pairs in our pipeline. For instance, (Teney et al., 2020a) build counterfactual samples using annotations of human attention (Das et al., 2016). Basically, they generate the counterfactual image by masking the features whose bounding boxes overlap with the human attention map past a certain threshold. In contrast to using extra manual annotations, CSS algorithm proposed by (Chen et al., 2020) calculates the critical objects (I^+) in image or words (Q^+) in question by the modified Grad-CAM (Selvaraju et al., 2017) and masks them to generate the counterfactual samples. Since the latter is more practical, we adopt the CSS algorithm into our pipeline and obtain the factual (I^+, Q^+) and counterfactual (I^-, Q^-) samples:

$$(I^+, I^-, Q^+, Q^-) = CSS(f_{vqa}, (I, Q, a)) \tag{2}$$

3.3 Contrastive Learning Objective

With the causal triplets (I, I^+, I^-) and (Q, Q^+, Q^-) obtained from CSS, we can apply the contrastive learning mechanism. We take a specific triplet (I, I^+, I^-) as an example shown in Figure 2 to illustrate the contrastive learning method. First, the I, I^+ and I^- paired with the Q are fed into the VQA model to generate the joint embeddings of them. Then, we denote the joint embedding $mm(\boldsymbol{Q}, \boldsymbol{V})$ of the original sample as the anchor a, the embedding $mm(\boldsymbol{Q}, \boldsymbol{V}^+)$ of the factual sample as the positive p and the embedding $mm(\boldsymbol{Q}, \boldsymbol{V}^-)$ of the counterfactual sample as the negative n.

Before defining the contrastive loss, we first define a scoring function s that outputs high values for the positive sample and low values for the negative sample. We take the cosine similarity of the representations in the joint embedding space as our scoring function because it implicitly normalizes the embeddings. The score between the anchor and the positive $s(a, p)$ can be described as:

$$s(a, p) = \frac{a^T \cdot p}{\|a\| \cdot \|p\|} \tag{3}$$

Similarly, the score between the anchor and the negative is defined as $s(a, n)$. Then, following recent work in unsupervised learning (Oord et al., 2018), the contrastive loss is formulated as:

$$L_c = \mathop{\mathbb{E}}_{a,p,n}\left[-\log\left(\frac{e^{s(a,p)}}{e^{s(a,p)} + e^{s(a,n)}}\right)\right] \tag{4}$$

For each synthesized triplet, minimizing this loss

can maximize a lower bound on mutual information between factual sample and original sample, enabling the model to learn the relationship between them and predict the right answer from a more causal aspect. The weighted sum of this contrastive loss and the base VQA classification loss L_{vqa} make up the overall loss:

$$L = \lambda_{vqa} L_{vqa} + \lambda_c L_c \quad (5)$$

where λ_{vqa} and λ_c are the loss weight for each loss.

4 Experiments

4.1 Datasets

The VQA-CP dataset[1] (Agrawal et al., 2018) is the standard benchmark for evaluating the robustness of VQA models, where the answer distribution of the training set differs from the test set vastly. The VQA-CP v1 *train* consists of ∼118K images, ∼245K questions and ∼2.5M answers (∼121K images, ∼438K questions and ∼4.4M answers for VQA-CP v2 *train*). The VQA-CP v1 *test* consists of ∼87K images, ∼125K questions and ∼1.3M answers (∼ 98K images, ∼220K questions and ∼2.2M answers for VQA-CP v2 *test*).

4.2 Settings and Comparisons with SoTA

We validate the effectiveness of our method in the VQA-CP (both v1 and v2) datasets (Agrawal et al., 2018). Results on the VQA v2 are also reported in appendices for completeness. We use the standard VQA evaluation metric (Antol et al., 2015) for accuracy report. All our implementation details are in appendices.

4.3 Performance on VQA-CP v2

Table 1 shows the result comparison with the state-of-the-art models on the VQA-CP v2. According to the backbone of these models, we group them into: 1) **SAN** based methods, including **GVQA**. 2) **Unshuffling** based methods, including **CF**, **CF+GS**. 3) **UpDn** based methods, including **AReg**, **GRL**, **RUBi**, **LMH**, **CSS**, **HINT** and **SCR**. The results show that our Contrastive Learning (CL) building on top of UpDn+LMH+CSS outperforms these previous results, improving the overall accuracy from 57.74% to 59.18% (+1.44%). In contrast, the Gradient Supervision (GS) for the counterfactuals brings smaller gain (+0.80%) from Unshuffling+CF. We further explore the performance of Gradient Supervision when applied with the same set of counterfactual samples (CSS). From Table 1, we can observe that our method still outperforms the LMH+CSS+GS by 1.88%, indicating that our method can bring more self supervision from the counterfactual samples than the GS.

4.3.1 Performance on VQA-CP v1

Table 2 shows performance comparisons with the existing state-of-the-art methods on the VQA-CP v1 test split. We achieves a new state-of-the-art performance on VQA-CP v1 test split, improving the UpDn+LMH+CSS method from 59.63% to 61.27% (+1.64%). Particularly, our method outperforms the Gradient Supervision(GS) by 3.22%.

4.4 Different Forms of Contrastive Loss

To explore whether different forms of contrastive loss are effective in learning the counterfactual samples in VQA, we conduct experiments on the VQA-CP v2 using the varient of Margin-based Contrastive Loss (MarginCL) proposed by (Hadsell

Table 3: Effectiveness of different supervision of counterfactual samples on different architectures on VQA-CP v2 test. *indicates the results of our reimplementation.

et al., 2006), which is formulated as:

$$L_{MC} = D(a,p) + \max\left(0, m - D(a,n)\right) \quad (6)$$

where the $D(a,p) = 1 - s(a,p)$ (cosine distance between a and p). The m is the margin between a and n, which is set to 0.3. Table 3 shows the experimental results. The improvements on two different VQA models demonstrate that our method is generic.

4.5 Performance of counterfactual samples and factual samples

To further explore whether our method improves the generalization capability of the VQA model, we conduct the experiments about the VQA performance of the counterfactual samples and factual samples on the VQA-CP v2 and report the result in Table 4. Comparing with the CSS and the CSS+GS, our method achieves the best performance, which demonstrates that the VQA model benefits from the contrastive learning mechanism and accordingly generalizes better on the counterfactual samples and factual samples.

4.6 Case Study

To validate the effects of our contrastive training objective, we visualize the joint embeddings of two examples and their synthesized samples by employing the t-SNE (Maaten and Hinton, 2008). As Figure 3 shows, compared with the LMH+CSS, our auxiliary training objective helps to not only pull up the original sample and factual sample but also push away the original sample and counterfactual sample in the embedding space, which may build a better causal VQA model.

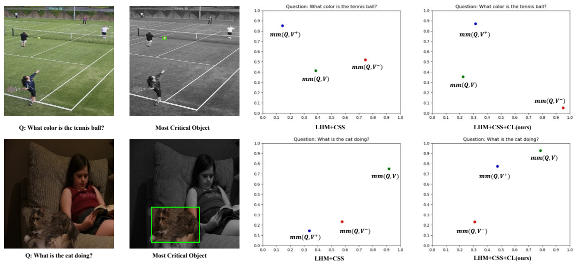

Figure 3: t-SNE visualizations of the cross-modal joint embedding space of the causal triplet generated by the CSS algorithm. $mm(\boldsymbol{Q}, \boldsymbol{V})$ is the joint embedding of original input. $mm(\boldsymbol{Q}, \boldsymbol{V}^+)$ and $mm(\boldsymbol{Q}, \boldsymbol{V}^-)$ are the embeddings of the input with only the most critical object and without the most critical object respectively.

5 Conclusion

In order to fully utilize the supervision information of synthesized counterfactual samples in robust VQA, we introduce a self-supervised contrastive learning mechanism to learn the relationship between factual samples and counterfactual samples. The experimental results demonstrate that our method improves the reasoning ability and robustness of the VQA models.

A Appendices

A.1 Implementation Details

The UpDn model uses pretrained Faster R-CNN (Ren et al., 2015) to extract top K object feature embeddings. We set $K = 36$ in our implementation, and the dimension of each object features is 2048. For question embeddings, we preprocess the questions to a maximum of 14 words. The word embeddings are initialized with pretrained GloVe (Pennington et al., 2014) vectors with dimension of 300. A single-layer GRU (Cho et al., 2014) is used to obtain question embedding vectors with the dimension of 512. The dimension of the joint embedding is 2048. The initial learning rate of Adamax optimizer and learning rate decay schedule are followed to the public reimplementation[2]. The entire system is trained end-to-end with both L_{vqa} and L_c. The parameters are initialized from scratch and the random seed is set to 0. The loss weight λ_{vqa} and λ_c are respectively set to 1 and 2. We set batch size to 512. The model developed on the official public Pytorch codebase[3] takes about 5 hours ($\sim$30 epochs) to train on a Nvidia RTX 2080Ti. Both Q-CSS and V-CSS are used to generate (Q, Q^+, Q^-) and (I, I^+, I^-).

Abstract

Physical common sense plays an essential role in the cognition abilities of robots for human-robot interaction. Machine learning methods have shown promising results on physical commonsense learning in natural language processing but still suffer from model generalization. In this paper, we formulate physical commonsense learning as a knowledge graph completion problem to better use the latent relationships among training samples. Compared with completing general knowledge graphs, completing a physical commonsense knowledge graph has three unique characteristics: training data are scarce, not all facts can be mined from existing texts, and the number of relationships is small. To deal with these problems, we first use a pre-training language model BERT to augment training data, and then employ constrained tucker factorization to model complex relationships by constraining types and adding negative relationships. We compare our method with existing state-of-the-art knowledge graph embedding methods and show its superior performance.

1 Introduction

Physical common sense means understanding the physical properties of objects and how they can be manipulated (Forbes et al., 2019). Empowering natural language processing (NLP) methods with physical common sense is important when dealing with tasks that are related to the physical world, such as physical commonsense reasoning (Bisk et al., 2020), grounded verb semantics (She and Chai, 2017), and the more general human-robot interaction problem.

Generally, there are currently three methods of learning physical common sense: manual annotation, text mining, and machine learning. Manual annotation is difficult for human annotators due to inconsistent perceptions and the challenge of enumerating all physical facts. Mining text data is also challenging because some physical facts are not written in texts explicitly. Machine learning is a promising method to discover new physical facts using existing data. Forbes et al. (2019) formulate physical commonsense learning as three separate machine learning tasks: 1) given an object and a property, predicting whether they follow an object-property (OP) relationship, *e.g., an apple is edible*; 2) given an object and an affordance, predicting whether they follow an object-affordance (OA) relationship, *e.g., he drove the car*; and 3) given an affordance and a property, predicting whether they follow an affordance-property (AP) relationship, *e.g., if you can eat something, then it is edible*. However, it is difficult for a machine learning model to generalize through the use of the latent relationships among samples. For example, even if we have a training sample *an apple is edible*, it is hard to say that the trained model can generalize to predict a testing sample *an apple is red* correctly.

In this paper, we propose to model physical commonsense learning as a knowledge graph completion problem to better use the latent relationships among samples. An knowledge graph can be represented as a 3-way binary tensor, and each entry is in triple form (e_h, r, e_t) (Nickel et al., 2016; Wang et al., 2017), where e_h denotes the head entity, e_t denotes the tail entity, r denotes the relationship between e_h and e_t, $(e_h, r, e_t) = 1$ denotes the fact is true in the training data, and $(e_h, r, e_t) = 0$ denotes the fact does not exist or is false in the training data. The goal of knowledge graph completion is to predict the real value of (e_h, r, e_t) when it is missing or its label is wrong in the training data. In terms of physical common sense, entities come from the set of all objects, properties, and affordances, and relationships come from the set of OP, OA, and AP.

Compared with general knowledge graphs such

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3293–3298,
November 16–20, 2020.

as DBpedia (Auer et al., 2007) and Freebase (Bollacker et al., 2008), a physical commonsense knowledge graph has at least three characteristics: 1) Training facts are scarce. For example, when labeling the properties of an object, people usually name the ones that are easiest to think of but cannot enumerate all properties. 2) Not all facts can be mined from existing texts. For example, the relationships between affordances and properties usually do not appear in texts explicitly and need to be reasoned. 3) The number of relationships is small and all are n-to-n relationships, which makes modeling relationships between entities more complicated.

Forbes et al. (2019) show that with supervised fine-tuning, Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) can learn the relationships OP and OA well but not AP. In this paper, we first use BERT to augment training data of OP and OA and then employ constrained Tucker factorization (Balazevic et al., 2019) to complete the knowledge graph of physical common sense. More specially, we use typed constraints to reduce the solution space and add negative relationships to leverage negative training samples. We evaluate this method on triple classification and link prediction tasks using a physical commonsense dataset (Forbes et al., 2019), and show that it can model physical common sense more effectively compared with state-of-the-art knowledge graph embedding methods.

The contributions of this paper are: 1) we formulate physical commonsense learning as a knowledge graph completion problem, 2) we propose a novel pipeline that combines pre-training models and knowledge graph embedding to learn physical common sense, and experiment results show its superior performance.

2 Related Work

2.1 Common Sense and Physical Common Sense

Common sense learning is one of the main challenges in NLP (Cambria and White, 2014). Although existing works have made significant progress on reading comprehension and question answering (Rajpurkar et al., 2016), they are still text-based and challenging to use for commonsense reasoning (Ostermann et al., 2018). In general, commonsense modeling can be classified into two categories: 1) explicitly encoding via knowledge graphs (Auer et al., 2007; Bollacker et al., 2008) and 2) implicitly encoding via language models (Bosselut et al., 2019). Building high-quality knowledge graphs usually requires expensive human annotation. There is some research on extracting facts from unstructured text (Clancy et al., 2019), but it is not flexible to build domain-specific knowledge graphs. Recent research works show that pre-training models can be good at encoding commonsense knowledge due to a large number of model parameters and text corpora, and they can be used to complete knowledge graphs (Bosselut et al., 2019).

Physical commonsense learning is a recently-proposed task (Forbes et al., 2019) that is related to language understanding with a physical world context, which is a sub-category of commonsense learning. Forbes et al. (2019) formulate physical commonsense learning as a machine learning problem, and show that a pre-training BERT model can learn the OP and OA tasks well but cannot generalize well on the AP task. In this paper, to deal with the generalization problem of BERT, we explore using knowledge graph embedding that is commonly used in commonsense modeling to deal with the issue of physical commonsense learning.

2.2 Knowledge Graph Embedding

Knowledge graphs have been shown to be useful for many NLP tasks, such as contextual word embedding (Peters et al., 2019), text classification (K M et al., 2018), and language generation (Zhou et al., 2018). In general, knowledge graph embedding can be classified into two categories: translational distance models and semantic matching models (Wang et al., 2017). Translational distance models model the score function of a factual triple (e_h, r, e_t) as the distance between e_h and e_t through the relationship r. Typical methods include TransE (Bordes et al., 2013) and its variants, such as TransD (Ji et al., 2015). Semantic matching models model the score function of a factual triple by exploiting the latent semantics between e_h and e_t, and they are usually modeled as a 3-way tensor. Typical methods include RESCAL (Nickel et al., 2011), DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2016), SimplE (Kazemi and Poole, 2018), and Tucker factorization (Balazevic et al., 2019). Compared with other methods, the Tucker factorization method learns a basis of relationship embeddings and can model more complex relationships, so it is used in this paper.

3 Method

Our method consists of two components: 1) we first augment all pairs of OP and OA tasks using BERT; 2) with the training data of OP, OA, and AP as input, we use constrained Tucker factorization to de-noise and complete the knowledge graph. In particular, we use typed constraints to reduce the solution space and add negative relationships to leverage negative training samples.

3.1 Data Augmentation

Because BERT can only do well on the OP and OA tasks (Forbes et al., 2019), we only augment data of these two tasks. In particular, for each pair (o, p) of OP, where $o \in O$ is an instance of objects and $p \in P$ is an instance of properties, we compose a sentence: "A/An o is p.", and use fine-tuned BERT on OP to predict its label l_{op}. Similarly, for each pair (o, a) of OA, where $o \in O$ is an instance of objects and $a \in A$ is an instance of affordances, we compose a sentence: "He a the o.", and use fine-tuned BERT on OA to predict its label l_{oa}. We use the augmented data $\mathcal{D}_{OP}$, $\mathcal{D}_{OA}$, together with the original AP data $\mathcal{D}_{AP}$ as input to the constrained Tucker factorization model.

3.2 Constrained Tucker Factorization

All (e_h, r, e_t) tuples compose a 3-way binary tensor $\mathcal{X} \in \{0,1\}^{n_e \times n_e \times n_r}$, where each entry $\mathcal{X}(i,j,k)$ denotes whether the i-th head entity and j-th tail entity follow the k-th relationship, n_e is the number of entities, and n_r is the number of relationships. Each slice of $\mathcal{X}$ is a $n_e \times n_e$ matrix of the relationship k. The Tucker factorization model proposed by Balazevic et al. (2019) approximates $\mathcal{X}$ as:

$$\hat{\mathcal{X}} = W \times_1 E \times_2 E \times_3 R, \quad (1)$$

where $\times_i$ denotes the i-mode product, $E \in \mathbb{R}^{d_e \times n_e}$ is entity embeddings, $R \in \mathbb{R}^{d_r \times n_r}$ is relation embeddings, $W \in \mathbb{R}^{d_e \times d_e \times d_r}$ is a core tensor, d_e is the latent dimension of entities, and d_r is the latent dimension of relationships.

3.2.1 Typed Constraints

Similar to the typed tensor decomposition method in (Chang et al., 2014), because we know that only objects and properties can potentially have the relationship OP, we can constrain the remaining entries of the OP matrix as 0. We can also constrain the OA and AP relationships in a similar way. Therefore, we optimize the following objective jointly for the three tasks:

$$\min_{E,R,W} ||\mathcal{X} - \hat{\mathcal{X}}||_F^2 + \lambda ||\hat{\mathcal{X}} \odot \mathcal{M}||_F^2 + \beta f(\hat{\mathcal{X}}), \quad (2)$$

where $||\cdot||_F$ denotes the Frobenius norm, $\odot$ denotes element-wise production, $\mathcal{M}$ is the mask tensor for the typed constraint, and $f(\hat{\mathcal{X}}) = ||E||_F^2 + ||R||_F^2 + ||W||_F^2$ is the regularization term. λ and β are coefficient weights of constraints. Because all entities are categorized and we consider the type constraint, there is only one possible relationship for a single head and tail.

3.2.2 Negative Samples

One unique challenge of a physical commonsense knowledge graph is that we have to use the open-world assumption. Namely, for unknown facts, we cannot assume that they are negative samples. In this paper, we propose encoding negative samples by adding corresponding negative relationships explicitly. For each OP, OA and AP relationship, we add a corresponding negative relationship, *i.e.*, NOT-OP, NOT-OA and NOT-AP. For example, *(person, NOT-OP, a_tool)*, *(cup, NOT-OA, twist)*, *(walk, NOT-AP, used_for_eating)*. Similar to (Balazevic et al., 2019), we also use reverse relationships. Namely, for each tuple *(h, r, t)*, we add *(t, r-reverse, h)*. Therefore, there are six negative relationships in total. For the OP and OA tasks, the negative samples are added through the data augmentation module in subsection 3.1, *i.e.*, the labels are predicted by BERT, and for the AP task, we use the negative samples from the dataset. In this way, we can not only increase the number of relationships but also leverage labeled negative samples more effectively.

4 Experiments

To evaluate the method, we conducted experiments with a physical commonsense dataset (Forbes et al., 2019) on triple classification and link prediction. To simplify the problem, we only used the situated OP, OA, and AP data, which contains 80 objects, 50 properties, and 504 affordances. The statistics are shown in Table 2. With the data augmentation component, we generated 4000 OP samples and 40320 OA samples. We compared the method with state-of-the-art knowledge graph embedding methods, including TransE, TransD, RESCAL, Dist-

Mult, ComplEx, SimplE, and Tucker [1]. We optimized equation 2 with Adam in PyTorch and did not optimize the regularization explicitly. λ was set to 0.1 through a 5-fold cross validation. d_e and d_r were set to 200 by default.

4.1 Triple Classification

Triple classification needs to predict whether a fact (e_h, r, e_t) is correct or not. With the learned E, R, and W, we calculated the probability that two entities e_h, e_t follow a relationship r as:

$$\sigma(W \times_1 e_h \times_2 e_t \times_3 r), \tag{3}$$

where σ is the sigmoid function. With the typed constraint, we then selected the relationship with the maximal probability. The results are shown in Table 1. For other methods, we only input the original training data without data augmentation.

With the data augmentation (**DA**) and typed constraints (**CSTR**), we achieved the best classification accuracy. In particular, we achieved relatively high micro and macro F1 scores for the three tasks, indicating that our method can predict positive samples more accurately.

4.2 Link Prediction

Link prediction predicts the tail entity with one head and one relationship, *i.e.*, $(e_h, r, ?)$. With the learned E, R, and W, we calculated probabilities of all candidate entities as:

Method	MRR	Hits@10	Hits@3	Hits@1
TransE	0.629	0.691	0.636	0.596
TransD	0.631	0.701	0.637	0.596
RESCAL	0.019	0.036	0.017	0.006
DistMult	0.598	0.619	0.605	0.582
ComplEx	0.605	0.615	0.603	0.597
SimpleIE	0.603	0.619	0.606	0.591
Tucker	0.650	0.723	0.648	0.620
Ours (w/o DA)	0.733	0.815	0.764	0.687
Ours (w/o CSTR)	0.514	0.727	0.549	0.416
Ours	**0.826**	**0.931**	**0.863**	**0.768**

Table 3: Link prediction results, where MRR denotes Mean Reciprocal Rank.

$$\sigma(W \times_1 e_h \times_3 r). \tag{4}$$

Similarly, we compared our results with typical knowledge graph embedding methods. For the Tucker method, we trained 2000 epochs, and for our method, we trained 50 epochs. The results are shown in Table 3. Compared with other methods, our method usually had relatively higher performance, indicating its potential in discovering new physical commonsense facts.

4.3 Discussion

To evaluate the effectiveness of the data augmentation (**DA**) and typed constraint (**CSTR**) components, we also conducted ablation studies on triple classification and link prediction separately, and the results are shown in Tables 1 and 3, from which we can see that **DA** and **CSTR** can help improve the performance of Tucker factorization.

Compared with knowledge graph embedding methods, the pre-training BERT model can perform better on OP and OA, but it is more difficult to generalize well on AP because such facts are not written in existing texts explicitly and BERT does not encode them as well as the OP and OA tasks (Forbes et al., 2019). For example, in terms of AP triple classification, the results of BERT are: a mi-

---

[1] The implementations of TransE, TransD, RESCAL, DistMult, ComplEx and SimplE are from OpenKE (Han et al., 2018). The implementation of Tucker is from Balazevic et al. (2019). Without any explicit statement, we used their default parameters.

cro F1 score of 0.37, an affordance macro F1 score of 0.36, and a property macro F1 score of 0.25. Our results for triple classification outperform them by a large margin, although our results are still worse in terms of OP and OA classification.

From the perspective of multi-task learning, one explanation of the improvement on the AP task is that the core tensor W can be viewed as parameter sharing among the three tasks and through the parameter sharing, the OP and OA tasks help improve the performance of AP. In a separate experiment, we used a multi-task BERT model (Stickland and Murray, 2019), and got a micro F1 score of 0.46, an affordance macro F1 score of 0.37, and a property macro F1 score of 0.48 for the AP task, which was similar to the result with our model.

5 Conclusion

In this paper, we formulate physical commonsense learning as a knowledge graph completion problem. We first use BERT to augment training data of OP and OA, and then employ constrained Tucker factorization to complete the knowledge graph. We constrain types to reduce the solution space and add negative relationships to leverage negative training samples. Compared with typical knowledge graph embedding methods, our results show good performance on triple classification and link prediction. Our method also has the potential to be a generic approach to benefit performance on the knowledge graph completion problem.

Abstract

In real-world dialogue, first-person visual information about where the other speakers are and what they are paying attention to is crucial to understand their intentions. Non-verbal responses also play an important role in social interactions. In this paper, we propose a visually-grounded first-person dialogue (VFD) dataset with verbal and non-verbal responses. The VFD dataset provides manually annotated (1) first-person images of agents, (2) utterances of human speakers, (3) eye-gaze locations of the speakers, and (4) the agents' verbal and non-verbal responses. We present experimental results obtained using the proposed VFD dataset and recent neural network models (e.g., BERT, ResNet). The results demonstrate that first-person vision helps neural network models correctly understand human intentions, and the production of non-verbal responses is a challenging task like that of verbal responses. Our dataset is publicly available[1].

U: これのＬはないのかしら
V: 同じ服がたくさんあるからどれかはLじゃないかな
N: 同じ服のサイズをチェックする

U: I wonder if there is an L for this.
V: We have a lot of the same clothes, so I'm guessing one of them is an L.
N: Check out the same clothing size.

Figure 1: Example of proposed VFD dataset. "U", "V", and "N" denote a human utterance, the agent's *verbal* response, and the agent's *non-verbal* response (i.e., action), respectively. All utterances and responses are represented in Japanese. English translations are added below for easier understanding. The red line links the eyes to the gaze location.

1 Introduction

In recent years, visually-grounded dialogue systems have attracted increasing attention (Zhu et al., 2016; Ben-Youssef et al., 2017; Liao et al., 2018; Kottur et al., 2018). For example, Huber et al. (2018) developed an image-grounded conversational agent that uses visual sentiment, facial expression, and scene features, and Mostafazadeh et al. (2017) constructed the publicly available IGC dataset, which comprises image-grounded conversations.

Although these studies and resources have been shown to be useful, there are currently two limitations. First, in image-grounded dialogue tasks, human speakers do not appear in the agents' vision because images are used as the topic of conversation, and the speakers are required to discuss the input image. However, in real-world dialogue scenarios, first-person visual information about where the human speaker is and what they are paying attention to is crucial for agents to understand human intentions. To understand this, we show an example in Figure 1. Without the first-person image, it is difficult for the agent to recognize that the pronoun "this" in the human utterance (U) refers to the article of yellow clothing rather than any other products (e.g., brown clothes).

Another important limitation is that, although

IGC (Mostafazadeh et al., 2017)	Task & Non-task oriented	Third-person	Verbal	4K
SDG (Hu et al., 2016)	Non-task oriented	Third-person	Verbal & Non-verbal	50
VFD (ours)	Task & Non-task oriented	First-person	Verbal & Non-verbal	308K

Table 1: Comparison of existing visually-grounded dialogue datasets in terms of dialogue types (task-oriented or non-task-oriented), visual perspectives, response types, and the dataset size.

previous studies considered non-verbal input information (e.g., human facial expressions), they did not consider the agents' non-verbal responses (i.e., actions). Non-verbal responses often play an important role in dialogue systems. For example, a museum tour-guide robot should use non-verbal gestures to explain things to the audience better. Even in ordinary conversation, non-verbal responses such as "making a smile" or "helping to lift luggage" are often crucial for social interactions in conjunction with verbal responses.

Thus, we propose a visually-grounded first-person dialogue (VFD) dataset with verbal and non-verbal responses. As shown in Figure 1, the VFD dataset comprises (1) *first-person images* of agents, (2) *utterances* of human speakers, (3) *eye-gaze locations* of the speakers, and (4) the agents' *verbal and non-verbal responses* to the utterances. Here, human utterances and agents' verbal and non-verbal responses were manually annotated for first-person images (with eye-gaze locations) in the GazeFollow dataset (Recasens et al., 2015) using crowdsourcing with carefully-designed settings, resulting in 308K verbal and 81K non-verbal dialogues. This paper also presents experimental results obtained using the VFD dataset and recent neural network models, e.g., BERT (Devlin et al., 2019) and ResNet (He et al., 2016).

Our primary contributions are summarized as follows. (1) We present a new multimodal dialogue dataset that contains visually-grounded first-person dialogues with human speakers' eye-gaze locations. (2) We provide the manually-annotated non-verbal responses of agents, which are often crucial for social communication in the real world. (3) Our experimental results demonstrate that first-person vision helps recent neural network models understand human intentions accurately and that the production of non-verbal responses is a challenging task like that of verbal responses.

2 Related Work

Table 1 summarizes the related visually-grounded dialogue datasets.

Several multimodal dialogue datasets have investigated task-oriented situations. For example, MMD dataset (Saha et al., 2018) contains dialogues between shoppers of fashion products and sales agents. TalkTheWalk dataset (de Vries et al., 2018) aims to guide tourists to their destinations. In VisDial dataset (Das et al., 2017) and AVSD dataset (Alamri et al., 2019), an agent must answer questions about an input image (or video) given dialogue history. Unlike these datasets, which can only work in some limited scenarios, we aim to cover both task-oriented and non-task-oriented dialogue systems.

As shown in Table 1, IGC dataset (Mostafazadeh et al., 2016), like our VFD dataset, assumes both task-oriented and non-task oriented situations. However, in IGC, images are used as a conversation topic, and the human speakers do not appear in the agents' vision. In contrast, VFD dataset contains dialogues based on "first-person" images (and eye-gaze information), which are useful for figuring where the human speaker is and what he or she is focusing on.

Like our VFD dataset, SDG dataset (Hu et al., 2016) contains dialogues with non-verbal actions. However, SDG focuses on gestures (or body languages), e.g., "making a cup shape with the right hand", which are categorized into 271 gesture classes. In contrast, VFD dataset represents non-verbal responses as text (typically sentences) to cover a wider range of gestures, e.g., "Check out the same clothing size", "Buy one of the pumpkins a girl has", etc.

In addition, our VFD dataset is large in comparison to other datasets. It is twice the size of the MMD dataset and approximately 75 times the size of the IGC dataset. IGC dataset is small because it provides only validation and test sets.

3 VFD Dataset

3.1 Task Definition

In this paper, we define the visually-grounded first-person dialogue as to produce an utterance or take action given a human utterance and the agent's first-person vision.

Formally, the input to the system can be represented as a tuple of a human utterance u and the agent's first-person vision v. The first-person vision v is assumed to be used to understand human intentions. Thus, v can be factorized into first-person image i and more explicit visual hints for the human intentions g, i.e., $v = (i, g)$. We use eye-gaze locations for the explicit hints g. For the input triplet (u, i, g), an agent is assumed to produce a verbal response r_v and non-verbal response (i.e., actions) r_n. Here, we use textual descriptions to represent non-verbal responses, as shown in Figure 1.

The VFD dataset can be interpreted as a collection of quintuples, i.e., $\{(u, i, g, r_v, r_n)\}$. We describe how we collected these five elements in the following.

3.2 Dataset Construction

First-person Images & Eye-gaze Locations. We used the 34,775 first-person images with eye-gaze annotations in the GazeFollow dataset (Recasens et al., 2015). Here, eye-gaze locations are represented as coordinates $(x, y)_{\text{eye}}$ and $(x, y)_{\text{gaze}}$. In Figure 1, the eye location and the gaze location are linked by a red line.

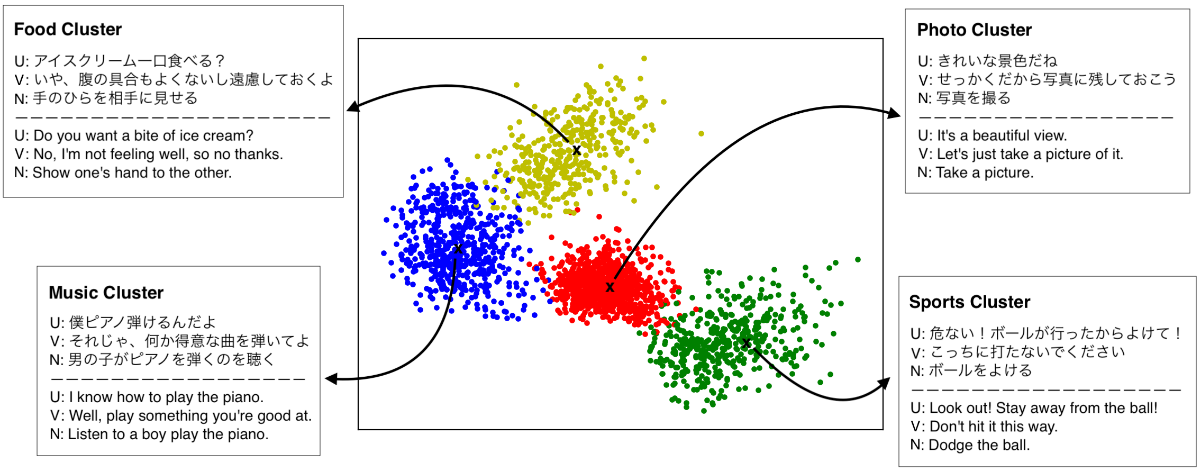
Human Utterances. Following Le Minh et al. (2018), who collected English utterances for first-person images using Amazon Mechanical Turk (AMT), we first translated their English instructions into Japanese. Then, we used a crowdsourcing platform similar to AMT called Yahoo! Crowdsourcing, operated by Yahoo Japan Corporation. It can be safely assumed that Yahoo! Crowdsourcing participants will be proficient in Japanese because such proficiency is required to sign up, navigate the user interface, and participate in the microtask market. In the annotation instructions, we showed an image with a single person marked with a red dot and asked the participants to imagine this person is speaking. We then asked the participants to submit what they think the speaker is likely saying.

The following notes were included in the instructions to avoid unexpected or trivial annotations. Note 1: "Never use the same lines again. Please write a different sentence every time." Note 2: "Do not put a commentary from a third-party perspective." Note 3: "Please do not write something people would not usually say in this situation. Please avoid lines that contain abuse and prejudice, words likely to cause a quarrel, and over-familiar tone. Please do not assume that the talking person has an extreme personality. As it is not a comedy, you do not have to write a funny line."

Verbal and Non-verbal Responses. The participants were shown the images and the utterances collected in the previous step. Then, they were asked to enter what to say (i.e., a verbal response) and what to do (i.e., a corresponding non-verbal action). To focus on dialogues requiring visual grounding, we also asked the participants the following question: "Whenever possible, please try to use some additional information found in the image to frame your response, so that your response is not entirely predictable from the utterance." We also asked the participants to enter a special dummy response "x" if it is inappropriate to respond. For a single utterance, five participants were asked to enter a response and an action.

After conducting this pilot task, we examined the results and selected promising participants (comprising a whitelist) for future task requests. Only participants on the whitelist could perform the next task. We also used the whitelist from our previous study for text entry tasks. We repeated this selection process until the final whitelist included approximately 1,600 participants. Here, approximately 200-250 of these participants regularly participated in the actual VQA collection task. Note that we allocated tasks in small batches over the course of a few months to prevent participants from working long hours.

Despite the above measures, however, the resulting 327,884 data instances contained noisy or trivial responses. To eliminate such undesirable responses automatically, we created a list of erroneous patterns manually via visual inspection, and responses matching the patterns were removed. The dummy responses "x" were also removed. Finally, the total number of verbal and non-verbal responses were 308,793 and 81,867, respectively. The gap between the number of verbal and non-verbal responses is due to the fact that non-verbal responses contained more dummy responses than verbal responses.



U: アイスクリーム一口食べる？
V: いや、腹の具合もよくないし遠慮しておくよ
N: 手のひらを相手に見せる

U: Do you want a bite of ice cream?
V: No, I'm not feeling well, so no thanks.
N: Show one's hand to the other.

U: きれいな景色だね
V: せっかくだから写真に残しておこう
N: 写真を撮る

U: It's a beautiful view.
V: Let's just take a picture of it.
N: Take a picture.

U: 僕ピアノ弾けるんだよ
V: それじゃ、何か得意な曲を弾いてよ
N: 男の子がピアノを弾くのを聴く

U: I know how to play the piano.
V: Well, play something you're good at.
N: Listen to a boy play the piano.

U: 危ない！ボールが行ったからよけて！
V: こっちに打たないでください
N: ボールをよける

U: Look out! Stay away from the ball!
V: Don't hit it this way.
N: Dodge the ball.

Figure 2: Dialogue topics in VFD dataset. Each dialogue is represented using BERT-based vectors and colored according to the associated cluster, i.e., *food*, *photo*, *music*, or *sports*. The dialogue topics are widely distributed.

Quality Evaluation. To assess the quality of the resulting dataset, we qualitatively inspected 1,000 randomly-sampled data instances. Of those 1,000 samples, there was only one sample that was clearly as bad as spam. In addition, the percentage of slightly inappropriate samples was only 2% of the total. Therefore, we considered the quality of the VFD dataset to be sufficient for our purposes.

Among those 2% noisy samples, we found the following erroneous patterns: For utterances, some were for the person who took the photo rather than the person appearing in the photo. One utterance was very comedic. For the images, there were two images without people, e.g., a mannequin or food. In addition, there was one image that did not show the speaker's face and one image that shows many people. These errors mainly stem from the original GazeFollow dataset (Recasens et al., 2015). For verbal or non-verbal responses, one response ignored the human utterance. In addition, some responses ignored the images or were not from the robot's perspective, and some responses were offensive to the speakers. Some non-verbal responses were not actionable, e.g., "Nice Shot!" and "That's tough."

We did not remove these noisy samples in the current version because it was difficult to remove them all automatically, and the noisy samples represent only 2% of the total.

3.3 Dataset Analysis

We perform a more detailed analysis of the VFD dataset.

	Utterance	Response	
		Verbal	Non-verbal
Text length	7.6	6.8	3.5
Unique words	13,352	23,880	7,711

Table 2: Linguistic statistics of utterances, and verbal and non-verbal responses in VFD dataset. Verbal responses tend to be diverse, and non-verbal responses tend to be much simpler.

We explore the topical diversity of the dataset. Specifically, we use a Japanese BERT model pre-trained on Japanese Wikipedia from HuggingFace's Transformers library (Wolf et al., 2019) and project each word in dialogue text (i.e., utterance, verbal response, and non-verbal response) to 768-dimensional vectors. Then, we average the word embeddings to obtain a vector representation of the dialogue text (utterance + two responses). Finally, we use agglomerative clustering (Karypis et al., 2000) to obtain 70 clusters for the dialogues. We select 4 of the 70 clusters and visualize them by principal component analysis (PCA), as shown in Figure 2. These 4 clusters, i.e., *food*, *photo*, *music*, and *sports*, represent typical dialogue topics in the VFD dataset. Figure 2 shows that the dialogue topics are widely distributed in the VFD dataset.

We also calculate the linguistic statistics of the texts. Here, we use MeCab morphological analyzer (Kudo et al., 2004) to tokenize the dialogue text into tokens. Table 2 summarizes the results. The average numbers of tokens (or text length) in the utterances and verbal and non-verbal responses are 7.6, 6.8, and 3.5, respectively. The number of uniques words (i.e., vocabulary size) in the ut-

U: 大きいね
V: 一つ買っていこうか？
N: 女の子が持っているかぼちゃを一つ買う

U: It’s a big one.
V: Do you want me to buy you one?
N: Buy one of the pumpkins a girl has.

U1: Place near my house is getting ready for Halloween a little early.
V1: Don’t you think Halloween should be year-round, though?
U2: That’d be fun since it’s my favorite holiday!
V2: It’s my favorite holiday as well!
U3: I never got around to carving a pumpkin last year even though I bought one.
V3: Well, it’s a good thing that they are starting to sell them early this year!

Figure 3: Comparison of VFD dataset (left) and IGC dataset (Mostafazadeh et al., 2017) (right). U, V, and N denote an utterance, a verbal response, and a non-verbal response, respectively.

terances and verbal and non-verbal responses are 13,352, 23,880, and 7,711, respectively. These facts imply that verbal responses tend to be diverse, which is desirable for training well-generalized machine learning models. In contrast, the textual description of the non-verbal responses is much simpler than the utterances and verbal responses, which is desirable when building a model to perform actual actions from a textual description of a given non-verbal response.

3.4 Comparison

Here, we emphasize the characteristics of the VFD dataset by comparing it to the IGC dataset (Mostafazadeh et al., 2016), which is most similar to the VFD dataset. Figure 3 compares two examples each from the VFD dataset (left) and IGC dataset (right). In the IGC dataset, an image is used as a topic of conversation, and the human speaker does not appear in the agent’s vision. In contrast, our VFD dataset uses an image as taken from the agent’s first-person camera as a dynamic visual environment. In addition, the VFD dataset contains manually-annotated non-verbal responses and human eye-gaze locations.

4 Experiments

4.1 Task Setting

In this section, we perform experiments with the task of selecting a verbal response and a non-verbal response from candidate response sets given a human utterance, a first-person image, and eye-gaze locations. Although it is possible to train a response generator using VFD dataset, the selection task was chosen for ease of evaluation and simplicity. It is worth noting that, in our experiments, the eye-gaze locations are given to the input as an oracle during validation and testing. In the real world, this information can be given by automatic gaze-estimation techniques (Chong et al., 2018; Wei et al., 2018) developed in computer vision.

4.2 Data

For the verbal response selection task, VFD dataset is split into training, validation, and test sets each containing 569K, 12K, and 12K dialogues. For the non-verbal response selection task, the training, validation, and test sets consist of 151K, 3K, and 3K dialogues. The images are completely separated across the training/validation/test sets. For the training data, we sample negative responses randomly from the training set and fix them throughout the epochs. For the validation and test data, we perform the same negative sampling across the models for a fair comparison. The data splits and the negative samples used for validation and testing will be provided along with the VFD dataset.

4.3 Metrics

Following Lowe et al. (2015), we use Recall@k (denoted $R_n@k$) for response-selection evaluation. Here, the model selects the k most likely responses from n available candidates. Note that only one response among the n candidates is true, and the others are sampled randomly from the same set. The prediction is correct if the true response is among the top k list. We report $R_{10}@1$, $R_{10}@2$, $R_{10}@5$, and $R_2@1$.

4.4 Baseline Models

Figure 4 shows the architecture of the baseline models. We follow the same ranking strategy of Lowe et al. (2015) to develop the baseline neural network models for our selection-based dialogue task. That is, the response-selection problem in our experiments is to find a verbal (or non-verbal) response with the highest score for an input triplet $x = (u, i, g)$, i.e.,

$$r^* = \operatorname*{argmax}_{r \in \mathcal{C}} \text{Score}(x, r), \tag{1}$$

where $\text{Score}(x, r) \in \mathbb{R}$ denotes a real-valued score of the response r for the input utterance u, input image i, and input eye-gaze locations g.

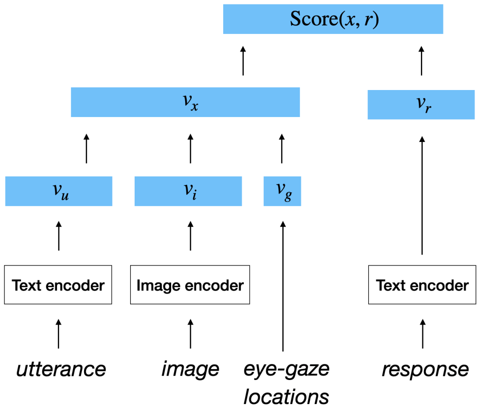


Figure 4: Overview of the baseline architecture for the response scoring. Given an input triplet of (utterance u, image i, eye-gaze locations g) and a candidate response r, the baseline model calculates the matching score between the input and the response.

We define the scoring function in Eq.(1) as follows:

$$\mathrm{Score}(x, r) = \boldsymbol{v}_x^\top \boldsymbol{W} \boldsymbol{v}_r + \boldsymbol{b}, \tag{2}$$

where $\boldsymbol{v}_x$ and $\boldsymbol{v}_r$ denote the feature vectors for $x = (u, i, g)$ and r. $\boldsymbol{W}$ and $\boldsymbol{b}$ are a weight matrix and a bias vector, respectively.

We first apply two neural encoders, f_u and f_i, to extract feature vectors from the input utterance u and the input image i:

$$\boldsymbol{v}_u = f_u(u),\ \boldsymbol{v}_i = f_i(i). \tag{3}$$

We also represent the coordinates of eye-gaze locations as a four-dimensional vector, $\boldsymbol{v}_g \in \mathbb{R}^4$. We concatenate these feature vectors to get $\boldsymbol{v}_x$:

$$\boldsymbol{v}_x = [\boldsymbol{v}_u;\ \boldsymbol{v}_i;\ \boldsymbol{v}_g], \tag{4}$$

where $[\ \cdot\ ;\ \cdot\ ]$ denotes concatenation of vectors. The feature vector of a candidate response r is also calculated using a different text encoder f_r:

$$\boldsymbol{v}_r = f_r(r). \tag{5}$$

For training, we minimize the binary cross-entropy loss by applying a sigmoid function to the predicted scores.

In the following subsection, we describe the text encoders (i.e., f_u and f_r) and the image encoder (i.e., f_i) we used in our experiments.

Text Encoder: We employ two neural network variants for encoding utterances and responses: Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019). With the LSTM model, we use the last hidden state as the utterance or response features. With the BERT model, we insert a [CLS] token before and a [SEP] token after the utterance (or response) and use the hidden state of [CLS] tokens in the last layer of BERT as the feature vector. It is worth noting that we develop two different text encoders for f_u and f_r, which are optimized during the training.

Image Encoder: We employ two neural network models for image encoding: VGGNet (Simonyan and Zisserman, 2015) and ResNet (He et al., 2016), which are used widely for image classification and have proven to be effective methods. We use the 16-layer VGGNet and replace the last linear layer named `fc6` with a learnable linear layer whose output dimensionality is 4096. We use the 4096-dimensional vector as the image features. We also use the 50-layer ResNet. We use the last fully connected layer as the image features.

4.5 Other Settings

We used the Adam (Kingma and Ba, 2015) optimizer for training. The learning rate was fixed at 0.0001, and the mini-batch size was fixed at 64. The training was terminated when validation accuracy drops more than 1.5 points compared to the highest validation accuracy. The training typically converged in approximately 3 days for the verbal response selection task and 1 day for the non-verbal response selection task on an Nvidia GeForce GTX 1080 GPU. For the LSTM-based text encoding, we used MeCab (Kudo et al., 2004) for tokenization and used fastText (Bojanowski et al., 2017) for word embeddings, which were pre-trained on Japanese Common-Crawl and Wikipedia articles. The word-embedding and LSTM dimensions were set to 300 and 100, respectively. For the BERT-based encoding, we used a BERT model named “bert-base-japanese-whole-word-masking” from Hugging Face’s (Wolf et al., 2019) library, which was pre-trained on Japanese Wikipedia using Whole-Word-Masking. For data augmentation, we applied random cropping, random horizontal flipping, and normalization transformations to the original images during training. The baseline models were trained separately for verbal and non-verbal response selection tasks.

	Encoders		Verbal Response				Non-verbal Response			
Input	Text	Image	R_{10}@1	R_{10}@2	R_{10}@5	R_2@1	R_{10}@1	R_{10}@2	R_{10}@5	R_2@1
U	LSTM	-	50.0	**69.2**	**91.1**	**84.8**	35.6	56.3	84.9	78.6
U	BERT	-	**50.1**	67.4	89.7	84.3	**42.3**	**60.1**	**86.2**	**80.6**
U+I	LSTM	VGGNet	49.1	68.9	92.1	85.1	41.5	61.5	89.7	82.0
U+I	LSTM	ResNet	49.4	69.9	**92.4**	85.3	40.0	61.4	89.7	81.6
U+I	BERT	VGGNet	**52.7**	**71.1**	91.9	**86.1**	**44.8**	**65.7**	**89.7**	**82.6**
U+I	BERT	ResNet	52.5	71.1	91.9	86.0	43.4	64.5	89.1	82.1
U+I+G	LSTM	VGGNet	50.2	69.5	92.0	85.2	39.6	61.2	89.1	81.8
U+I+G	LSTM	ResNet	49.1	69.3	92.1	85.1	39.6	61.0	89.8	81.7
U+I+G	BERT	VGGNet	**53.6**	**72.1**	92.5	**86.6**	**46.2**	**66.3**	**90.7**	**82.9**
U+I+G	BERT	ResNet	53.2	71.8	**92.6**	86.5	43.7	65.7	89.7	82.2

Table 3: Comparison results of the baseline models in verbal and non-verbal response selection tasks. U, I, and G denote that we use utterances, images, and eye-gaze locations for inputs, respectively. First-person images and eye-gaze locations improve the performance for almost all encoder combinations.

4.6 Quantitative Results

We report the evaluation scores of the baseline models in the verbal and non-verbal response selection tasks. We summarize the results in Table 3. U, I, and G denote that we use utterances, images, and eye-gaze locations for inputs, respectively.

For almost all encoder combinations (e.g., BERT × VGGNet), first-person images improve the verbal and non-verbal response-selection performance by up to 5.6 points (See U vs. U+I). In addition, especially when using BERT, eye-gaze locations always improve the performance further by up to 1.4 points (See U+I vs. U+I+G). These results indicate that the eye-gaze information from the agents' first-person perspective is effective in understanding the human intentions.

Overall, the BERT scores are higher than the LSTM scores for all input variations: U, U+I, U+I+G. This is consistent with results in other NLP tasks. As for image encoders, VGGNet achieves higher scores than ResNet, which is often observed in multimodal tasks (Wang et al., 2017; Ouyang et al., 2017; Yudistira and Kurita, 2017). BERT × VGGNet using all the input modalities achieves the highest R_{10}@1 score of 53.6%.

Interestingly, the best R_{10}@1 score for non-verbal response selection is about 7 points worse than the score for verbal-response selection. This fact indicates that producing non-verbal responses is more difficult than producing conventional verbal responses and there is room for improvement.

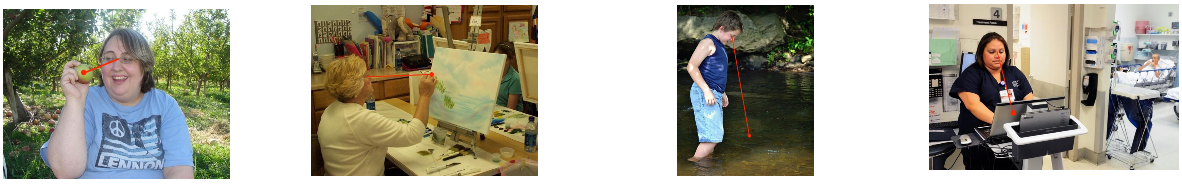
4.7 Qualitative Analysis

Here, we inspect the verbal and non-verbal responses selected by the baseline model, BERT × VGGNet. Figure 5 (a) shows the selected verbal responses. The selected non-verbal responses are shown in Figure 5 (b). The other examples can also be found in the supplemental material.

In the leftmost example of Figure 5 (a), the model cannot understand what the pronoun "this" in the human utterance refers to without the image. By using the image information (U+I), the model wrongly focuses on the human face in the image and responds, "You have a funny face." By using the eye-gaze locations (U+I+G), the model understands that the person is paying attention to the green apple and succeeds in finding the correct response.

In the second example from the left in Figure 5 (a), the human utterance, "What do you think?", is too ambiguous. By using the image information (U+I), we can see that the model wrongly focuses on the speaker, as in the previous example. The eye-gaze locations (U+I+G) allow the model to understand that the speaker asks about the painting and finds the correct response.

The right two examples in Figure 5 (a) show the failure cases. In the third example from the left, it is difficult for the model to select the correct response, "You can't do that with your bare hands", because it requires the world knowledge that fish are hard to catch without tools. In the rightmost example, the woman's gaze is on the computer, which wrongly lets the model focus on the computer instead of the next "hospital room."



U: これを見て!
V(U): それは望遠鏡だよ ✗
V(U+I): 面白い顔だね ✗
V(U+I+G): まだ青いけど旨そうだね ✓
V*: まだ青いけど旨そうだね

U: Look at this!
V(U): It's a telescope. ✗
V(U+I): You have a funny face. ✗
V(U+I+G): It's still green, but it looks delicious. ✓
V*: It's still green, but it looks delicious.

U: どうかしら?
V(U): 画面に映っているのは何でしょう ✗
V(U+I): おばあちゃんに似ているわ ✗
V(U+I+G): 雲のもくもくとした自然な感じとか良く描けてますね ✓
V*: 雲のもくもくとした自然な感じとか良く描けてますね

U: What do you think?
V(U): What's that on the screen? ✗
V(U+I): It looks just like my grandma. ✗
V(U+I+G): You drew the cloudy, natural feeling well. ✓
V*: You drew the cloudy, natural feeling well.

U: これから魚を捕まえます
V(U): 中華料理ですか ✗
V(U+I): いい波が来るといいね ✗
V(U+I+G): いい波が来るといいね ✗
V*: 素手で無理じゃない

U: I'm going to catch some fish.
V(U): Will you cook Chinese food? ✗
V(U+I): I hope we get some good waves. ✗
V(U+I+G): I hope we get some good waves. ✗
V*: You can't do that with your bare hands.

U: ここで管理してるのよ
V(U): どんな野菜やハーブを植えているんですか? ✗
V(U+I): 病室のすぐ横なんですね ✓
V(U+I+G): パソコンならもう少し大きい画面なんだけどね ✗
V*: 病室のすぐ横なんですね

U: I manage it here.
V(U): What vegetables and herbs are you planting? ✗
V(U+I): So it's right next to the hospital room. ✓
V(U+I+G): If it was a computer, it would have a bit bigger screen. ✗
V*: So it's right next to the hospital room.

(a) Verbal Response

U: 誰が作ったんだろう?
N(U): 料理を食べてみる ✗
N(U+I): 見る ✗
N(U+I+G): 正面から雪だるまを見る ✓
N*: 正面から雪だるまを見る

U: I wonder who made it.
N(U): Try the food. ✗
N(U+I): Look at it. ✗
N(U+I+G): Looking at the snowman from the front. ✓
N*: Looking at the snowman from the front.

U: 今できるからね
N(U): 子供がジャンプするのを見守る ✗
N(U+I): 男性が掃除の作業をしているのを見る ✗
N(U+I+G): 皿を出す ✓
N*: 皿を出す

U: It's almost done.
N(U): Watch a child jump ✗
N(U+I): See a man cleaning. ✗
N(U+I+G): Put out a plate. ✓
N*: Put out a plate.

U: ちょっと外行ってくるわ
N(U): 玄関へいく ✗
N(U+I): テントの下に行く ✗
N(U+I+G): テントの下に行く ✗
N*: 上着を渡す

U: I'm going to go out for a minute.
N(U): Go to the front door. ✗
N(U+I): Go under the tent. ✗
N(U+I+G): Go under the tent. ✗
N*: Give you the jacket.

U: 作業してるあいだ犬がいたずらしないか見張っていてくれ
N(U): 犬を見張る ✓
N(U+I): 犬を見張る ✓
N(U+I+G): ペンキ塗りしているところを眺める ✗
N*: 犬を見張る

U: While I'm working, keep an eye out for any mischief from the dogs.
N(U): Keep an eye on the dog. ✓
N(U+I): Keep an eye on the dog. ✓
N(U+I+G): Watch the paint job. ✗
N*: Keep an eye on the dog.

(b) Non-verbal Response

Figure 5: Verbal and non-verbal responses selected by the baseline model, BERT × VGGNet. U, V, N denote the human utterance and the selected verbal and non-verbal response, respectively. V* and N* indicates the gold-standard responses. We show the input modalities (U, I, G) used to produce the response in parentheses. We mark the correct responses by ✓, while the incorrect responses are marked ✗.

Similar phenomena can be observed for non-verbal response selection. In the left two examples in Figure 5 (b), it is hard to identify the human intentions from the utterances alone. The images (U+I) provide important contextual information, but it is still not sufficient for properly understanding the intentions of the utterances. The eye-gaze locations (U+I+G) enable the models to identify the human intentions and respond more accurately. For instance, in the second example from the left, it is hard to understand what the man is doing due to the mess in the room; however, if you look at the tip of the man's gaze, you can see that he is cutting vegetables with a kitchen knife. In such cases, eye-gaze information works particularly well when many objects are present.

We also show the failure examples for non-verbal response selection. We consider that the third example from the left is difficult because the agent has to be thoughtful just like preparing a jacket. In the rightmost example, the man is asking someone to keep an eye on the dog; however, he is not looking at it, so it appears that his gaze has a negative effect.

In summary, we found that first-person images and eye-gaze information are effective in the following cases: (1) when the utterance is ambiguous, e.g., when it contains indicative pronouns like ”this”, and (2) when there are many objects in the image, and it is difficult to identify what the speaker is talking about. These are very common in everyday conversation. Thus, we consider that it would be effective and beneficial to develop social robots that interact with first-person visual information, including gaze, in real-world applications.

5 Conclusion

In this paper, we have presented the VFD dataset with verbal and non-verbal responses. We manually annotated 308K human utterances and 308K verbal and 81K non-verbal responses of agents, which are grounded in the agents' first-person images with human eye-gaze locations. We confirmed the validity of the first-person view in the experiments for the response selection tasks; however, this task (especially, non-verbal response production) remains challenging, and improvements are required.

(b) Non-verbal Response

Figure 6: Additional verbal and non-verbal responses selected by the baseline model, BERT × VGGNet. U, V, N denote the human utterance and the selected verbal and non-verbal response, respectively. V^* and N^* indicates the gold-standard responses. We show the input modalities (U, I, G) used to produce the response in parentheses. We mark the correct responses by ✓, while the incorrect responses are marked ✗.

A Supplemental Material

Here, we show additional examples for verbal and non-verbal responses selected by the baseline model, BERT × VGGNet.

What these examples have in common is that the intentions of the utterances are ambiguous in isolation, which is common in everyday conversation. For instance, in the leftmost example of Figure 6 (a), it is hard for machines to identify what the pronoun "this" refers to.

We show four successful examples on the left side of Figure 6 (a), (b). By using first-person perspective visual information (U+I or U+I+G), the models can understand the intentions correctly. For instance, in the leftmost example of Figure 6 (a), the model correctly understands that the speaker is asking about his playing. In the second example from the left in Figure 6 (a), the visual information allows the model to understand that the speaker is talking about the golf game. Also, in the left two examples in Figure 6 (b), the models successfully utilize the visual information to understand the human intentions.

We also show four failure examples on the right side of Figure 6 (a), (b). In the third example from the left in Figure 6 (a), it is difficult to choose the ground truth response (V^*) because the human speaker is watching TV and talking about it, while the ground truth one is talking about the laptop on the desk. In the rightmost example in Figure 6 (a), the visual information is not useful because the utterance is not sufficiently related to the given image. The third example from the left in Figure 6 (b) is also difficult because the agent has to have the common knowledge that we must put away the used trays before we leave in a cafe. In the rightmost example in Figure 6 (b), we consider that the visual information wrongly lets the models take actions related to more specific information about players or shoes rather than the more general action of suggesting to buy the shoes.

Cross-Media Keyphrase Prediction: A Unified Framework with Multi-Modality Multi-Head Attention and Image Wordings

Abstract

Social media produces large amounts of contents every day. To help users quickly capture what they need, keyphrase prediction is receiving a growing attention. Nevertheless, most prior efforts focus on text modeling, largely ignoring the rich features embedded in the matching images. In this work, we explore the joint effects of texts and images in predicting the keyphrases for a multimedia post. To better align social media style texts and images, we propose: (1) a novel *Multi-Modality Multi-Head Attention* (M^{3}H-Att) to capture the intricate cross-media interactions; (2) *image wordings*, in forms of optical characters and image attributes, to bridge the two modalities. Moreover, we design a novel *unified* framework to leverage the outputs of keyphrase classification and generation and couple their advantages. Extensive experiments on a large-scale dataset[1] newly collected from Twitter show that our model significantly outperforms the previous state of the art based on traditional co-attentions. Further analyses show that our multi-head attention is able to attend information from various aspects and boost classification or generation in diverse scenarios.

1 Introduction

The prominent use of social media platforms (such as Twitter) exposes individuals with an abundance of fresh information in a wide variety of forms such as texts, images, videos, etc. Meanwhile, the explosive growth of multimedia data has far outpaced individuals' capability to understand them, presenting a concrete challenge to digest the massive amount of data, distill the salient contents therein, and provide users with a quick access to the information they need when navigating noisy online data.

Post (a): Contemplating the mysteries of life from inside my egg carton...☺
#cat #cats #CatsOfTwitter

Post (b): The <*mention*> have the slight lead at halftime!
#NBAFinals

Figure 1: Two multimedia posts from Twitter, where texts offer limited help in identifying their keyphrases while images provide essential clues.

To that end, extensive efforts have been made to **social media keyphrase prediction**[2] — aiming to produce a sequence of words that reflect a post's key concern. Nevertheless, previous work mostly focuses on the use of textual signals (Zhang et al., 2018; Wang et al., 2019a,b), which sometimes provide limited features as social media language is essentially informal and fragmented. To enrich the contexts, here we resort to exploiting the matching images, which are widely used in social media posts to deliver auxiliary information from authors (e.g., opinions, feelings, topics, etc.), primarily due to the flourish of mobile Internet.

To illustrate our motivation, Figure 1 shows the texts and images of two Twitter posts (tweets). The left is tagged with a keyphrase "cat", which can be clearly signaled with its image while the paired text is an anthropomorphic description and hardly unveils its real semantics. For the right, the image depicts a basketball game scene with optical characters "2019 NBA FINALS", directly indicating its keyphrase, which is difficult to identify from

[2] We consider a hashtag as a post's keyphrase annotation following the common practice (Zhang et al., 2016, 2018).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3311–3324,
November 16–20, 2020. ©2020 Association for Computational Linguistics

the texts. In both examples, images play a more vital role in reflecting the key information. These points motivate our cross-media keyphrase prediction study that examines how the salient contents can be indicated by the coupled effects of post texts and their matching images.

Previous work (Zhang et al., 2017, 2019) employs co-attention networks (Lu et al., 2016; Xu and Saenko, 2016) to encode multimedia posts, where a single attention function is concurrently performed to infer either visual or textual distributions. We argue that they might be suboptimal to model intricate text-image associations, as a recent finding (Vempala and Preotiuc-Pietro, 2019) points out there can be four diverse semantic relations held by images and texts on Twitter. To allow for better modeling, in this work, we take advantage of the recent advance of multi-head attention (Vaswani et al., 2017) capable of learning from different representation subspaces and extend it to capture diverse cross-media interactions, named as *Multi-Modality Multi-Head Attention* (M^3H-Att). Moreover, to well align the images' semantics to texts', we adopt *image wordings* and define two forms for that — explicit *optical characters* (such as "NBA Finals" in post (b)) detected from the optical character reader (OCR) and implicit *image attributes* (Wu et al., 2006), high-level text labels predicted to summarize the image's semantic concepts (such as a "cat" label for post (a)).

Furthermore, unlike prior work employing either classification (Gong and Zhang, 2016) or generation models (Wang et al., 2019a), we propose a *unified* framework to couple the advantages of keyphrase classification and generation. Specifically, in addition to the joint training of both modules, we further extend the copy mechanism (See et al., 2017) to explicitly aggregate classification outputs together with tokens from the source input. Empirical results show that integrating classification outputs not only keeps classification's superiority to predict common keyphrases (Figure 5(c)) while enables keyphrase creation beyond a predefined candidate list, but also largely benefits the keyphrase generation with better absent keyphrase prediction (Figure 5(b)).

For experiments, we collect a large-scale tweet dataset with texts and images, which is presented as part of our work. The empirical results show that our model significantly outperforms the state-of-the-art (SOTA) methods using traditional attention. For example, we obtain 47.06% F1@1 compared with 43.17% by Wang et al. (2019a) (keyphrase generation from texts only) and 42.12% by Zhang et al. (2017) (multi-modal keyphrase classification). We then examine how we perform to handle absent and present keyphrases, and varying keyphrase frequency and post length. The results indicate the consistent performance boost brought by our M^3H-Att design and unified framework in diverse scenarios (§5.3). We further quantify the effects of different settings of multi-head attention and image wordings to see when and how they work the best (§5.4). Lastly, we provide qualitative analysis to interpret why our model results in superior multimedia understanding (§5.5).

2 Related Work

Social Media Keyphrase Prediction. Traditional keyphrase prediction studies focus on using two-step pipeline methods: candidates are first extracted with handcrafted features (e.g. part-of-speech tags (Witten et al., 1999)) and then ranked by unsupervised (Wan and Xiao, 2008) or supervised algorithms (Medelyan et al., 2009). These methods undergo labor-intensive feature engineering and hence lead to the growing popularity of adopting data-driven neural networks. Specifically for social media keyphrase prediction, most efforts are based on sequence tagging style extraction (Zhang et al., 2016, 2018) or classification from a predefined candidate list (Gong and Zhang, 2016; Zhang et al., 2017), which are however unable to produce keyphrases absent in the post or the fixed list. Inspired by the recent success of keyphrase generation for scientific articles (Meng et al., 2017; Chan et al., 2019), Wang et al. (2019a,b) employ sequence-to-sequence (seq2seq) models to allow unseen keyphrases to be flexibly created for social media posts. Unlike them, we propose a novel unified framework to combine the benefits of keyphrase classification and generation. Similar to this, Chen et al. (2019) also exploits the power of classification for keyphrase generation but in a separated retrieval manner, where we elegantly integrate them with a tailored copy mechanism and allow for the end-to-end joint training. While most of prior work focuses on the modeling of texts, we additionally exploit their matching images and study the coupled effects for indicating keyphrases.

Cross-media Research. We are also related to cross-media research, where texts and images are jointly exploited for a variety of applications, such as personalized image captioning (Park et al., 2019), event extraction (Li et al., 2020), sarcasm detection (Cai et al., 2019), and text-image relation classification (Vempala and Preotiuc-Pietro, 2019). Some of them have pointed out the usefulness of OCR texts (Chen et al., 2016) and image attributes (Wu et al., 2016) to endow images with higher-level semantics beyond visual features, where we are the first to study how OCR texts and image attributes work together to indicate keyphrases. Closest to our work, Zhang et al. (2017, 2019) study multimedia hashtag classification and employ co-attention (Lu et al., 2016; Xu and Saenko, 2016) to model the text-image associations, while we extend the multi-head attention (Vaswani et al., 2017) to better capture diverse styles of cross-modal interactions in social media.

While multi-head attention has been widely exploited in many vision-language (VL) tasks, such as image captioning (Zhou et al., 2020), visual question answering (Tan and Bansal, 2019; Lu et al., 2019), and visual dialog (Kang et al., 2019; Wang et al., 2020), its potential benefit to model flexible cross-media posts has been previously ignored. Due to the informal style in social media, cross-media keyphrase prediction brings unique difficulties mainly in two aspects: first, its text-image relationship is rather complicated (Vempala and Preotiuc-Pietro, 2019) while in conventional VL tasks the two modalities have most semantics shared; second, social media images usually exhibit a more diverse distribution and a much higher probability of containing OCR tokens (§4), thereby posing a hurdle for effectively processing.

3 Our Unified Cross-Media Keyphrase Prediction Framework

Given a collection $\mathcal{C}$ with $|C|$ text-image post pairs $\{(\mathbf{x}^n, I^n)\}_{n=1}^{|C|}$ as input, we aim to predict a keyphrase set $\mathcal{Y} = \{\mathbf{y}^i\}_{i=1}^{|\mathcal{Y}|}$ for each of them. Following Meng et al. (2017), we copy the source input pair multiple times to allow each paired to have one keyphrase. We represent each input as a triplet $(\mathbf{x}, I, \mathbf{y})$, where $\mathbf{x}$ and $\mathbf{y}$ are formulated as word sequences $\mathbf{x} = \langle x_1, ..., x_{l_x} \rangle$ and $\mathbf{y} = \langle y_1, ..., y_{l_y} \rangle$ (l_x and l_y denote the number of words).

We show the overview of our proposed cross-media keyphrase prediction model in Figure 2. We first encode a text-image tweet into three modalities: *text*, *attribute*, and *vision* (§3.1), and propose a Multi-Modality Multi-Head Attention (M^{3}H-Att) to capture their intricate interactions (§3.2). Then, we feed the learned multi-modality representations for either keyphrase classification or generation, followed with a tailored aggregator to combine their outputs (§3.3). Lastly, the entire framework can be jointly trained via multi-task learning (§3.4).

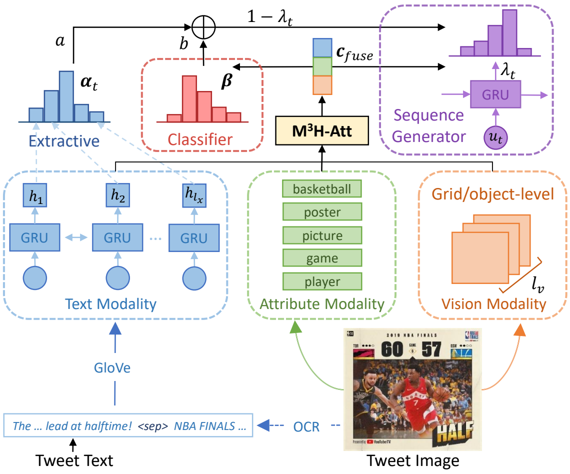

Figure 2: The overview of our unified cross-media keyphrase prediction model.

3.1 Multi-modality Encoder

Learning Text Representation. We first embed each token x_i from the input sequence into a high-dimensional vector via a pre-trained lookup table, and then employ bidirectional gated recurrent unit (Bi-GRU) (Cho et al., 2014) to encode the embedded input token $e(x_i)$:

$$\overrightarrow{\mathbf{h}_i} = GRU(e(x_i), \ \overrightarrow{\mathbf{h}_{i-1}}), \quad (1)$$

$$\overleftarrow{\mathbf{h}_i} = GRU(e(x_i), \ \overleftarrow{\mathbf{h}_{i+1}}). \quad (2)$$

Forward hidden state $\overrightarrow{\mathbf{h}_i}$ and backward one $\overleftarrow{\mathbf{h}_i}$ are later concatenated into $\mathbf{h}_i = [\overrightarrow{\mathbf{h}_i}; \overleftarrow{\mathbf{h}_i}]$. We employ it as the context-aware representation of x_i and pack all of them in the input sequence into a textual memory bank $\mathbf{M}_{text} = \{\mathbf{h}_i, ..., \mathbf{h}_{l_x}\} \in \mathbb{R}^{l_x \times d}$, where d denotes the hidden state dimension.

Encoding OCR Text. To detect optical characters from images, we use an open-source toolkit (Smith, 2007) to extract OCR texts in form of a word sequence. It is then appended into the post text with a delimited token $\langle sep \rangle$ to notify the change of text genres, which is shown to be a simple yet effective design to combine OCR features.

Learning Image Representation. We consider two types of image representations: *grid-level* or *object-level* visual features. For the former, we apply a pre-trained VGG-16 Net (Simonyan and Zisserman, 2015) to extract 7×7 convolutional feature maps for each image I. For the latter, inspired by bottom-up attention (Anderson et al., 2018), we use the Faster-RCNN (Ren et al., 2015) pre-trained on Visual Genome (Krishna et al., 2017) to detect the objects and extract their features. Each feature map is further transformed into a new vector $\mathbf{v}_i$ through a linear projection layer. As such, we construct a visual memory bank as $\mathbf{M}_{vis} = \{\mathbf{v}_1, ..., \mathbf{v}_{l_v}\} \in \mathbb{R}^{l_v \times d}$, where l_v denotes the number of image regions or objects.

Encoding Image Attribute. Following Cai et al. (2019), we first train an attribute predictor based on the Resnet-152 (He et al., 2016) features on MS-COCO 2014 caption dataset (Lin et al., 2014). Specifically, we extract noun and adjective tokens from the image captions as the attribute labels. Afterward, the top five predicted attributes of each image are transformed with another linear layer to an attribute memory bank $\mathbf{M}_{attr} = \{\mathbf{a}_1, ..., \mathbf{a}_5\} \in \mathbb{R}^{5 \times d}$, which aims to capture images' high-level semantic concepts.

3.2 Multi-modality Multi-Head Attention

Our design of multi-head attention is inspired by its prototype in Transformer (Vaswani et al., 2017). We extend it to capture multiple forms of cross-modality interactions for a multimedia post, which is therefore named as M^{3}H-Att, short for Multi-Modality Multi-Head Attention. Compared to its original use as a self-attention over texts only, we instead operate on three modalities (text, attribute, and vision) in a *pairwise* co-attention manner.

For each co-attention, we perform scaled dot attention $\mathcal{A}$ on a set of $\{Query, Key, Value\}$:

$$\mathcal{A}(Q, K, V) = \texttt{softmax}(\frac{QK^T}{\sqrt{d_K}})V, \quad (3)$$

$$\mathcal{A}^M(Q, K, V) = [head_1; ...; head_H]W^O, \quad (4)$$

$$\text{where} \quad head_h = \mathcal{A}(QW_h^Q, KW_h^K, VW_h^V), \quad (5)$$

where $W_h^Q, W_h^K, W_h^V \in \mathbb{R}^{d \times d_H}$ are learnable weights to project the query, key, and value from dimension d to a lower space of d_H-dimension and H is the head number. Outputs from all the heads are concatenated (in $\mathcal{A}^M$) and passed to a feedforward network with residual connections (He et al., 2016) and layer normalization (Ba et al., 2016).

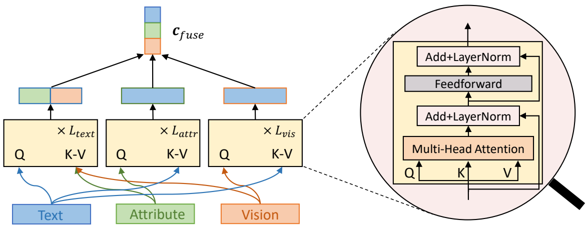

Figure 3: Overview of M^{3}H-Att to fuse multi-modal features from text, attribute, and vision modalities.

Specifically, we employ the text features as a query to attend to the vision/attribute modality and vice versa.[3] Here max/average-pooling is adopted to obtain one holistic query vector for each modality instead of token-level queries considering the noisy nature of social media data. Moreover, we stack multiple co-attention layers to empower its modeling capability, where $L_{text}, L_{attr}, L_{vis}$ denote the number of stacked layers for text, attribute, and vision queries, respectively. After that, the outputs from all co-attention layers are summed up with a linear multi-modal fusion layer to produce a context vector $\mathbf{c}_{fuse} \in \mathbb{R}^d$. It will be fed into a keyphrase classifier and generator for the unified prediction. Notably, this indicates that our M^{3}H-Att's great potential to serve as a generic module for benefiting other cross-media applications.

3.3 Unified Keyphrase Prediction

We describe how we combine the keyphrase classification and generation into a unified prediction for coupling their advantages below.

Keyphrase Classification. As each keyphrase $\mathbf{y}$ usually consists of only several tokens, it can be considered as a discrete integral label and predicted it with a keyphrase classifier. Here we directly pass the multi-modal context vector $\mathbf{c}_{fuse}$ into a two-layer of multi-layer perceptron (MLP) and map it to the distribution over the label vocabulary V_{cls}:

$$P_{cls}(\mathbf{y}) = \texttt{softmax}(\texttt{MLP}_{cls}(\mathbf{c}_{fuse})). \quad (6)$$

Keyphrase Generation with Pointer. For keyphrase generation, we base on a sequence-to-sequence framework to predict the keyphrase word sequence $\mathbf{y} = \langle y_1, ..., y_{l_y} \rangle$, where the generation probability is defined as $\prod_{t=1}^{l_y} P(y_t \,|\, \mathbf{y}_{<t})$.

Concretely, we use an unidirectional GRU decoder to model the generation process, which emits the hidden state $\mathbf{s}_t = GRU(\mathbf{s}_{t-1}, \mathbf{u}_t) \in \mathbb{R}^d$ based

---

[3] We also try other combinations, e.g., M^{3}H-Att between the vision and attribute, but the improvements are negligible.

on the previous hidden state $\mathbf{s}_{t-1}$ and the embedded decoder input $\mathbf{u}_t$. The decoder state is initialized by the last hidden state $\mathbf{h}_{l_x}$ of the text encoder. Here an attention mechanism (Bahdanau et al., 2015) is adopted to obtain a textual context $\mathbf{c}_{text}$:

$$\mathbf{c}_{text} = \sum_{i=1}^{l_x} \alpha_{t,i} \mathbf{h}_i, \tag{7}$$

$$\alpha_{t,i} = \texttt{softmax}(S(\mathbf{s}_t, \mathbf{h}_i)), \tag{8}$$

$$S(\mathbf{s}_t, \mathbf{h}_i) = \mathbf{v}_\alpha^T \tanh(\mathbf{W}_\alpha[\mathbf{s}_t; \mathbf{h}_i] + \mathbf{b}_\alpha), \tag{9}$$

where $S(\mathbf{s}_t, \mathbf{h}_i)$ is a score function to measure the compatibility between the t-th word to be decoded and the i-th word from the text encoder. $\mathbf{W}_\alpha \in \mathbb{R}^{d\times 2d}$, $\mathbf{b}_\alpha, \mathbf{v} \in \mathbb{R}^d$ are trainable weights.

Next, we incorporate the static multi-modal vector $\mathbf{c}_{fuse}$ (produced by M^{3}H-Att and independent of the decoding step t) to construct a context-rich representation $\mathbf{c}_t = [\mathbf{u}_t; \mathbf{s}_t; \mathbf{c}_{text} + \mathbf{c}_{fuse}]$. Based on it, we apply another MLP with softmax to produce a word distribution over vocabulary V_{gen}:

$$P_{gen}(y_t) = \texttt{softmax}(\texttt{MLP}_{gen}(\mathbf{c}_t)). \tag{10}$$

To further allow the decoder to explicitly extract words from the source post, we apply the copy mechanism (See et al., 2017) by calculating a soft switch $\lambda_t \in [0, 1]$ with a sigmoid-activated MLP on $\mathbf{c}_t$. It indicates whether to generate the word from the vocabulary V_{gen} or copy it from the input sequence, where the extractive distribution is decided by the text attention weights $\alpha_{t,i}$ in Eq. (8).

Classification Output Aggregation. We further extend the copy mechanism to aggregate the classification's outputs to benefit keyphrase generation. First, we retrieve the top-K predictions from the classifier and convert each into the word sequence $\mathbf{w} = \langle w_1, ..., w_{l_w}\rangle$, where l_w is the sequence length of the combined predictions. Then, we normalize their classification logits using softmax into a word-level distribution $\beta \in \mathbb{R}^{l_w}$, which represents the extractive probability from the classification output. Finally, we obtain the unified prediction via:

$$\begin{aligned} P_{unf}(y_t) = \lambda_t \cdot P_{gen}(y_t) \ + \\ (1-\lambda_t)\cdot(a \cdot \sum_{i:x_i=y_t}^{l_x} \alpha_{t,i} + b \cdot \sum_{j:w_j=y_t}^{l_w} \beta_j), \end{aligned} \tag{11}$$

where a, b ($a + b = 1$) are hyper-parameters to decide whether to copy from the input sequence or the classification outputs. To stabilize the aggregation of classification outputs, we warm up the classifier for several epochs first by setting a to 1 and b to 0 and then both to 0.5 for further training.

3.4 Joint Training Objective

We employ the standard negative log-likelihood loss and define the entire framework's training objective with the linear combination of the label classification loss and the token-level sequence generation loss for multitask learning:

$$\mathcal{L}(\theta) = -\sum_{n=1}^{N} [\underbrace{\log P_{cls}(\mathbf{y}^n)}_{\text{Classification}} + \gamma \cdot \sum_{t=1}^{l_y^n} \underbrace{\log P_{unf}(y_t^n)}_{\text{Unified}}], \tag{12}$$

where N is size of the training text-image pairs and γ is a hyper-parameter to balance the two losses (empirically set to 1) and θ denotes the trainable parameters shared for the whole framework. Intuitively, jointly training keyphrase classification would benefit the unified prediction by not only implicitly better parameter learning, but also explicitly providing more precise outputs to be copied by the aggregation module.

4 Multi-modal Tweet Dataset

Data Collection and Statistics. Since there are no publicly available datasets for multi-modal keyphrase annotation, we contribute a new dataset with social media posts from **Twitter**. Specifically, we employ the Twitter advanced search API[4] to query English tweets that contain both images and hashtags from January to June 2019. For keyphrases, we consider to use user-generated hashtags following common practice (Zhang et al., 2016, 2018). We further clean the raw data in the following ways: 1) we only retain tweets with one color image in JPG form; 2) we remove tweets with less than 4 tokens or more than 5 hashtags to filter out noise data; 3) rare hashtags (occurring less than 10 times) and their corresponding tweets are removed to alleviate sparsity issue; 4) we remove the duplicate tweets (e.g., retweets) and images and obtain 53,701 tweets with each containing a distinct tweet text-image pair. We randomly split the data into 80%, 10%, 10% corresponding to training, validation, and test set. The data split statistics of tweet texts are displayed in Table 1.

---

[4] `https://twitter.com/search-advanced`

Split	#Post	Post Len	#KP /Post	|KP|	KP Len	% of occ. KP	Vocab
Train	42,959	27.26	1.33	4,261	1.85	37.14	48,019
Val	5,370	26.81	1.34	2,544	1.85	36.01	16,892
Test	5,372	27.05	1.32	2,534	1.86	37.45	17,021

Table 1: Data split statistics. KP: keyphrase; |KP|: the size of unique keyphrase; % of occ. KP: percentage of keyphrases occurring in the source post.

Preprocessing. We employ an open-source Twitter preprocessing tool (Baziotis et al., 2017) to tokenize the tweets, segment the hashtags, and apply common spelling corrections. To reduce the errors introduced by the automatic hashtag segmentation, we manually check them and construct a complete mapping list. Following Wang et al. (2019a), we retain tokens in hashtags (without # prefix) for those occurring in the middle of the posts due to their inseparable semantic roles. We further remove all the non-alphabetic tokens and replace links, mentions (@username), digits into special tokens as $\langle$*url*$\rangle$, $\langle$*mention*$\rangle$, and $\langle$*number*$\rangle$ respectively.

Tweet Image Analysis. To further analyze the Twitter image characteristics, we sample 200 text-image tweets and analyze their distributions over varying types in Figure 4. We observe a diverse set of categories and only around half of the images (54%) are natural photos, which is rather different from other standard image data such as MS-COCO. Moreover, we conduct a pilot study to categorize the text-image relations following Vempala and Preotiuc-Pietro (2019) and find 52% of them have either texts or images useless to represent semantics (see Figure 9 for some examples in the Appendix). Such diverse category and complex text-image relationship pose unique challenges compared to traditional vision-language tasks like image captioning and visual question answering, where they focus on more natural images, and more importantly, their two modalities have most semantics shared. To deal with this, we propose M^{3}H-Att and image wordings to better capture essential information from noisy cross-media data.

Image Wording Analysis. Here we shed light on some interesting statistics on image wordings. We first analyze the top 5 attributes predicted from the images in our dataset: {*man, shirt, woman, sign, white*}, which shows that *most of the images on Twitter are about people and daily life*. For OCR texts, we employ a widely used OCR engine Tesserocr[5] to extract optical characters. From all matching images, there are around 35% of them contain characters, significantly larger than the corresponding number in COCO images (4%), indicating *social media users' preference to post images containing optical characters*. To mitigate the effects of OCR errors, we only consider tokens present in the vocabulary of tweet texts and find about 17% left with a median length of 16 tokens. Besides, 32% of the remaining data have words appearing in their corresponding keyphrases and 13% contain the entire keyphrases, suggesting its potential help in keyphrase prediction.

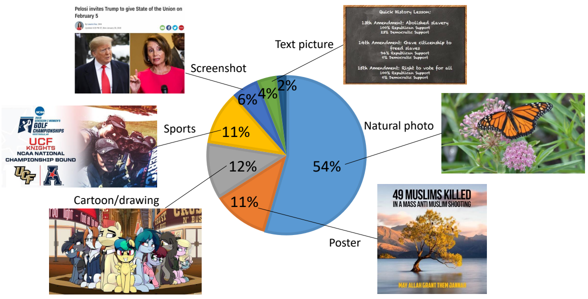

Figure 4: Image type distribution of 200 sampled text-image tweets in our collected dataset.

5 Experiments and Analyses

5.1 Experimental Setup

Evaluation Metrics. We mainly evaluate our model with popular information retrieval metrics macro-average F1@K, where K is 1 or 3 as there are 1.33 keyphrases on average per tweet (Table 1). To further measure the keyphrase orders (as we can generate a keyphrase ranking list with beam search), we employ mean average precision (MAP) for the top five predictions following Chen et al. (2019). The higher scores from all the metrics indicate better performance. For word matchings in evaluation, we consider the results after processed with Porter Stemmer following Meng et al. (2017).

Comparison Models. We first consider the upper-bound performance of extractive methods, denoted as EXT-ORACLE. Then, the following baselines are compared. (1) **Image-only** models: we apply max/average pooling on the grid-level VGG features or object-level BUTD (Anderson et al., 2018) and aggregate them for classification. (2) **Text-only** models: we consider classification-based (CLS) or sequence generation-based (GEN)

---

[5] `https://pypi.org/project/tesserocr/`

methods. For CLS models, we consider simple max/average pooling on the text features learned from Bi-GRU encoder and the Topic Memory Network (TMN) (Zeng et al., 2018) (a SOTA short text classification model). For GEN models, we employ the seq2seq with attention (Bahdanau et al., 2015), copy mechanism (See et al., 2017), and latent topics (Wang et al., 2019a) (the SOTA topic-aware model for social media keyphrase generation). (3) **Text-image** models: we consider the SOTA CLS model for multi-modal hashtag recommendation (Zhang et al., 2017) using co-attention and its variant with image-attention (Yang et al., 2016), as well as Bilinear Attention Networks (BAN) (Kim et al., 2018) (a SOTA variant for Visual Question Answering (Antol et al., 2015)). For our models, we first adopt the basic variants with M^{3}H-Att separately applying to either CLS or GEN. Then we additionally combine image wordings and the joint training strategy (Eq. (12)). Our full model is obtained by further aggregating the CLS and GEN outputs (Eq. (11)).

Parameter Settings. We maintain a generation vocabulary V_{gen} of $45K$ tokens and the keyphrase classification vocabulary V_{cls} with 4,262 labels. We apply 200-d Twitter GloVe embedding (Pennington et al., 2014) for encoding inputs. We employ two layers of Bi-GRU for the encoder and a single layer GRU for the decoder with hidden size set to 300. For visual signals, we extract either 49 grid-level VGG 512-d features or 36 object-level BUTD 2048-d features. For the M^{3}H-Att, we employ 4 heads with 64-d subspace, where 4 layers are stacked for attention to text modality, and 1 layer for vision or attribute modality. In training, we set the loss coefficient $\gamma = 1$ and employ Adam optimizer (Kingma and Ba, 2015) with a learning rate as 0.001. We decay it by 0.5 if validation loss does not drop and apply gradient clipping with the max gradient norm as 5. Early stop (Caruana et al., 2000) is adopted via monitoring the change of validation loss. For inference, we employ beam search with beam size set to 10 to generate a ranking list of keyphrases. For the baselines, we re-implement CLS-IMG-ATT and CLS-CO-ATT, and employ the released codes to produce results for CLS-TMN[6], GEN-TOPIC[7], and CLS-BAN[8].

	Models	**F1@1**	**F1@3**	**MAP@5**

	GEN-CLS-M^{3}H-ATT (ours)	$\mathbf{47.06}_{04}$	$\mathbf{33.11}_{01}$	$\mathbf{52.07}_{03}$

Table 2: Comparison results (in %) displayed with average scores from 5 random seeds. Our GEN-CLS-M^{3}H-ATT significantly outperforms all the comparison models (paired t-test $p < 0.05$). Subscripts denote the standard deviation (e.g., $47.06_{04} \Rightarrow 47.06 \pm 0.04$).

5.2 Main Comparison Results

We first report the main comparison results in Table 2 and draw the following observations:

• *Textual features are more important than visual signals.* It is seen from the text-only models' better performance compared with their counterparts relying solely on images. For image-only models, we find that object-level BUTD outperforms grid-level VGG, while for pooling methods, average pooling works better for visual signals while max pooling is more suitable for texts.[9]

• *Vision modality can provide complementary information to the text.* Most models considering cross-media signals perform better than text-only and image-only baselines. An exception is observed on CLS-CO-ATT, which indicates the limitation of traditional co-attention to well exploit multi-modality representations from social media.

• *Both M^{3}H-Att and image wordings are helpful to encode social media features.* We find that both M^{3}H-Att and image wordings contribute to the performance boost of keyphrase classification or generation or their joint training results, which showcase their ability to handle multi-modality data from social media. We will discuss more in §5.4.

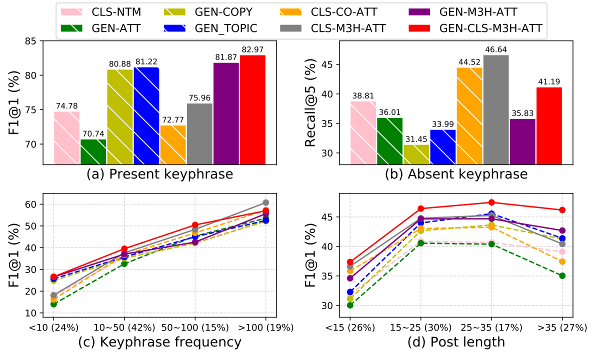
[7] `https://github.com/yuewang-cuhk/TAKG`

[8] `https://github.com/jnhwkim/ban-vqa`

[9] In experiments, we find that VGG works better than BUTD features for M^{3}H-Att in our variants. We show results with the better setting without otherwise specified.



(a) Present keyphrase

(b) Absent keyphrase

(c) Keyphrase frequency

(d) Post length

Figure 5: Model comparison over: (a) present keyphrases, (b) absent keyphrases, (c) varying keyphrase frequency, and (d) varying post length. Striped bars or dashed lines denote previous models while solid ones denote ours.

- *Our output aggregation strategy is effective.* Seq2seq-based keyphrase generation models (especially armed with the copy mechanism to enable better extraction capability) perform better than most classification models and even upper bound results of extraction models. It is probably because of the high absent keyphrase rate and the large size of keyphrase tags (Table 1) exhibited in the noisy social media data. Nevertheless, GEN-CLS-M^{3}H-ATT, coupling advantages of classification and generation, obtains the best results (47.06 F1@1), drastically outperforms the SOTA text-only model (43.17) and text-image one (42.12).

5.3 Quantitative Analyses

We examine how our models perform in diverse scenarios: present vs. absent keyphrases and varying keyphrase frequency and post length in Figure 5.

Present vs. Absent Keyphrases. As shown in Figure 5 (a-b), generation models with copy mechanism consistently outperform classification models for present keyphrases, while the latter works better for absent keyphrases. Nonetheless, our output aggregation strategy is able to cover generation models' inferiority for absent keyphrases and exhibits better results from GEN-CLS-M^{3}H-ATT than GEN-M^{3}H-ATT. Besides, visual signals are helpful to both generation and classification to yield either present or absent keyphrases, where a larger boost is observed for the latter, probably owing to the inadequate clues available from texts.

Keyphrase Frequency. From Figure 5 (c), we observe better F1@1 from all models to produce more frequent keyphrases, because common keyphrases allow better representation learning from more training instances. For extremely rare keyphrases (occur <10 times in training), generation models with copy mechanisms exhibit better capability to handle them than classification ones.

# Layer	2 Head			4 Head			8 Head			12 Head		
	64-d	128-d	256-d	64-d	128-d	256-d	64-d	128-d	256-d	64-d	128-d	256-d
1	42.06	43.32	43.01	43.11	43.98	43.63	43.75	44.18	43.43	43.48	43.81	43.53
2	43.22	44.36	44.26	44.27	44.38	44.27	44.58	44.59	43.12	45.05	38.16	39.97

Table 3: Analysis of M^{3}H-Att with various stacked layer number, head number, and subspace dimension.

Models	No Image Wording			Add OCR				Add Attribute			
	Full	OCR	Attr	Full	Δ (%)	OCR	Δ (%)	Full	Δ (%)	Attr	Δ (%)
CLS-MAX	38.31	36.11	32.04	38.75	+1.1	40.67	+12.6	41.09	+7.3	37.87	+18.2
GEN-COPY	42.01	40.81	35.55	42.86	+2.0	43.58	+6.8	43.11	+2.6	38.10	+7.2
CLS-M^{3}H-ATT	44.19	42.93	36.93	44.27	+0.2	46.53	+8.4	44.38	+0.4	38.73	+4.9
GEN-M^{3}H-ATT	44.33	43.26	35.93	44.48	+0.3	46.31	+7.1	44.77	+1.0	39.90	+11.0

Table 4: F1@1 over three test sets with various settings: no image wording, adding either OCR or attribute. Δ: the relative improvements over no image wording.

Post Length. From Figure 5 (d), we observe that longer post length does not guarantee better performance and the best results are obtained for posts with $15 \sim 35$ tokens. It might be attributed to the noisy nature of social media data — longer posts provide both richer contents and more noise. For the posts with <15 tokens, all multi-modal methods perform better than the text-only ones, as the image modality enriches the context for short texts.

5.4 Analyses of M^{3}H-Att and Image Wording

We proceed to quantify the effects of different settings in M^{3}H-Att and image wording.

M^{3}H-Att Analysis. We investigate how various configurations ($L_{vis} \in \{1,2,3,4\}$, $H \in \{2,4,8,12\}$, $d_H \in \{64,128,256\}$) of our M^{3}H-Att affect the prediction results in Table 3. Here we only show the classification results (and similar trends are observed from generation). We notice that more complex models do not always present better results and even render performance deteriorate in some cases due to the overfitting issue. The best performance is attained by 4 stacked layers of 4 heads with a 64-d subspace.

Image Wording Analysis. To examine image wording effects, we compare four models in three settings: no image wording, OCR (only), and image attributes (only) in Table 4. The results are shown in three test sets: the entire test set (Full), the 889 subset instances with OCR tokens (OCR), and the 266 ones containing keyphrases from ImageNet labels (Attr) (Russakovsky et al., 2015). For the CLS-MAX and GEN-COPY, we add at-

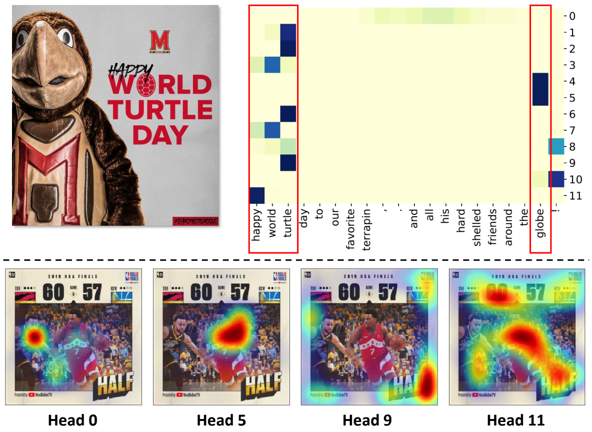

Figure 6: Attention weight visualization of M^{3}H-Att for two example posts with image-to-text (top) and text-to-image attention (bottom). Best viewed in color.

Post (a): Contemplating the mysteries of life from inside my egg carton...☺	**Post (b)**: Epic Texas *#sunset* from NNE Bastrop County TX. @TxStormChasers	**Post (c)**: Your plastic bag ends up somewhere, and sometimes, it goes to the ocean. *#WorldOceansDay*

GEN-COPY: star wars	GEN-COPY: storm hour	GEN-COPY: plastic fandom
CLS-CO-ATT: **cats of twitter**	CLS-CO-ATT: storm hour	CLS-CO-ATT: plastic
Our: **cats of twitter**	Our: **sunset**	Our: **world oceans day**

Figure 7: Tweet image's effects for keyphrase prediction. Blue tokens are the top 4 attributes and purple ones are OCR tokens. Correct predictions are in **bold**.

tributes by using its max-pooled features to attend the text memory, which is later used for prediction.

We observe that either OCR texts or image attributes contribute to better F1@1 on the entire test set for all chosen models, while much more performance gain can be observed on their subsets with OCR texts or ImageNet keyphrases, indicating that images with optical characters and natural styles can benefit more from image wordings.[10]

5.5 Qualitative Analysis

To explore whether M^{3}H-Att is able to attend different aspects from the image, we probe into its attention weights via heatmap visualization in Figure 6. Here CLS-M^{3}H-ATT is employed with a single layer of 12 heads, whose image-to-text and text-to-image attention are examined. The top figure shows that all its heads attend to the text based on the visual cues, where some attend to "turtle" while others attend to "world" and "globe" with various emphasis. Interestingly, Head 11 highlights the "happy" token, which also appears in the image. For the text-to-image attentions (bottom), we find some heads tend to highlight the specific local objects, such as the two players by Head 0 and 5 and the textual regions by Head 9, while some capture a more global view of the image like Head 11. More examples are shown in Figure 8.

We further illustrate how images (visual signals, image attributes, and OCR tokens) help cross-media keyphrase prediction by analyzing their predictions in Figure 7. In post (a), visual features help both CLS-CO-ATT and our model correctly predict its keyphrase, where our model precisely attends the cat's face (key region reflecting the image's semantics). Without such context, GEN-COPY wrongly predicts *"star wars"*, which might be caused by the misleading token *"mysterious"* in the texts. Besides, the keyphrase is also revealed in the top predicted attribute. In post (b-c), only our model with image wordings makes correct predictions, where we observe that the ground-truth keyphrases directly appear in the attributes or OCR texts. See Figure 10 and 11 for more examples.

6 Conclusion

This paper studies cross-media keyphrase prediction on social media and presents a unified framework to couple the advantages of generation and classification models for this task. Moreover, we propose a novel *Multi-Modality Multi-Head Attention* to capture the dense interactions between texts and images, where image wordings explicit in optical characters and implicit in image attributes are further exploited to bridge their semantic gap. Experimental results on a large-scale newly-collected Twitter corpus show that our model significantly outperforms SOTA either generation or classification models with traditional attention.

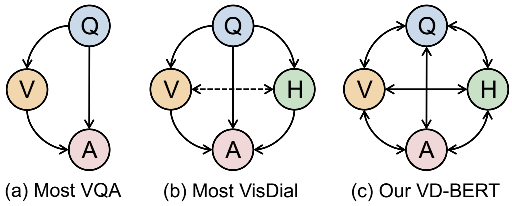
Abstract

Visual dialog is a challenging vision-language task, where a dialog agent needs to answer a series of questions through reasoning on the image content and dialog history. Prior work has mostly focused on various attention mechanisms to model such intricate interactions. By contrast, in this work, we propose VD-BERT, a simple yet effective framework of unified vision-dialog Transformer that leverages the pretrained BERT language models for Visual Dialog tasks. The model is *unified* in that (1) it captures all the interactions between the image and the multi-turn dialog using a single-stream Transformer encoder, and (2) it supports both answer ranking and answer generation seamlessly through the same architecture. More crucially, we adapt BERT for the effective fusion of vision and dialog contents via *visually grounded* training. Without the need of pretraining on external vision-language data, our model yields new state of the art, achieving the top position in both single-model and ensemble settings (74.54 and 75.35 NDCG scores) on the visual dialog leaderboard. Our code and pretrained models are released at `https://github.com/salesforce/VD-BERT`.

1 Introduction

Visual Dialog (or VisDial) aims to build an AI agent that can answer a human's questions about visual content in a natural conversational setting (Das et al., 2017). Unlike the traditional single-turn Visual Question Answering (VQA) (Antol et al., 2015), the agent in VisDial requires to answer questions through multiple rounds of interactions together with visual content understanding.



(a) Most VQA (b) Most VisDial (c) Our VD-BERT

Figure 1: Attention flow direction illustration. V: vision, H: dialog history, Q: question, A: answer. The arrow denotes the attention flow direction and the dashed line represents an optional connection.

The primary research direction in VisDial has been mostly focusing on developing various attention mechanisms (Bahdanau et al., 2015) for a better fusion of vision and dialog contents. Compared to VQA that predicts an answer based only on the question about the image (Figure 1(a)), VisDial needs to additionally consider the dialog history. Typically, most of previous work (Niu et al., 2019; Gan et al., 2019; Kang et al., 2019) uses the question as a query to attend to relevant image regions and dialog history, where their interactions are usually exploited to obtain better visual-historical cues for predicting the answer. In other words, the attention flow in these methods is *unidirectional* – from question to the other components (Figure 1(b)).

By contrast, in this work, we allow for *bidirectional* attention flow between all the entities using a unified Transformer (Vaswani et al., 2017) encoder, as shown in Figure 1(c). In this way, all the entities simultaneously play the role of an "information seeker" (query) and an "information provider" (key-value), thereby fully unleashing the potential of attention similar to Schwartz et al. (2019). We employ the Transformer as the encoding backbone due to its powerful representation learning capability exhibited in pretrained language models like BERT (Devlin et al., 2019). Inspired by its recent success in vision-language pretraining, we further extend BERT to achieve simple yet effective fusion of vision and dialog contents in VisDial tasks.

Recently several emerging works have attempted to adapt BERT for multimodal tasks (Sun et al.,

2019; Lu et al., 2019; Tan and Bansal, 2019; Zhou et al., 2020). They often use self-supervised objectives to pretrain BERT-like models on large-scale external vision-language data and then fine-tune on downstream tasks. This has led to compelling results in tasks such as VQA, image captioning, image retrieval (Young et al., 2014), and visual reasoning (Suhr et al., 2019). However, it is still unclear how visual dialog may benefit from such vision-language pretraining due to its unique multi-turn conversational structure. Specifically, each image in the VisDial dataset is associated with up to 10 dialog turns, which contain much longer contexts than either VQA or image captioning.

In this paper, we present VD-BERT, a novel unified vision-dialog Transformer framework for VisDial tasks. Specifically, we first encode the image into a series of detected objects and feed them into a Transformer encoder together with the image caption and multi-turn dialog. We initialize the encoder with BERT for better leveraging the pre-trained language representations. To effectively fuse features from the two modalities, we make use of two *visually grounded* training objectives – Masked Language Modeling (MLM) and Next Sentence Prediction (NSP). Different from the original MLM and NSP in BERT, we additionally take the visual information into account when predicting the masked tokens or the next answer.

VisDial models have been trained in one of two settings: discriminative or generative. In the discriminative setting, the model ranks a pool of answer candidates, whereas the generative setting additionally allows the model to generate the answers. Instead of employing two types of decoders like prior work, we rely on a unified Transformer architecture with two different self-attention masks (Dong et al., 2019) to seamlessly support both settings. During inference, our VD-BERT either ranks the answer candidates according to their NSP scores or generates the answer sequence by recursively applying the MLM operations. We further fine-tune our model on dense annotations that specify the relevance score for each answer candidate with a ranking optimization module. In summary, we make the following contributions:

- To the best of our knowledge, our work serves as one of the first attempts to explore pretrained language models for visual dialog. We showcase that BERT can be effectively adapted to this task with simple visually grounded training for capturing the intricate vision-dialog interactions. Besides, our VD-BERT is the first unified model that supports both discriminative and generative training settings without explicit decoders.
- We conduct extensive experiments not only to analyze how our model performs with various training aspects (§5.2) and fine-tuning on dense annotations (§5.3), but also to interpret it via attention visualization (§5.4), shedding light on future transfer learning research for VisDial tasks.
- Without the need to pretrain on external vision-language data, our model yields new state-of-the-art results in discriminative setting and promising results in generative setting on the visual dialog benchmarks (§5.1).

2 Related Work

Visual Dialog. The Visual Dialog task has been recently proposed by Das et al. (2017), where a dialog agent needs to answer a series of questions grounded by an image. It is one of the most challenging vision-language tasks that require not only to understand the image content according to texts, but also to reason through the dialog history. Previous work (Lu et al., 2017; Seo et al., 2017; Wu et al., 2018; Kottur et al., 2018; Jiang et al., 2020; Yang et al., 2019; Guo et al., 2019a; Niu et al., 2019) focuses on developing a variety of attention mechanisms to model the interactions among entities including image, question, and dialog history. For example, Kang et al. (2019) proposed DAN, a dual attention module to first refer to relevant contexts in the dialog history, and then find indicative image regions. ReDAN, proposed by Gan et al. (2019), further explores the interactions between image and dialog history via multi-step reasoning.

Different from them, we rely on the self-attention mechanism within a single-stream Transformer encoder to capture such interactions in a unified manner and derive a “holistic” contextualized representation for all the entities. Similar to this, Schwartz et al. (2019) proposed FGA, a general factor graph attention that can model interactions between any two entities but in a pairwise manner. There are recent works (Nguyen et al., 2019; Agarwal et al., 2020) also applying the Transformer to model the interactions among many entities. However, their models neglect the important early interaction of the answer entity and cannot naturally leverage the pretrained language representations from BERT like ours.

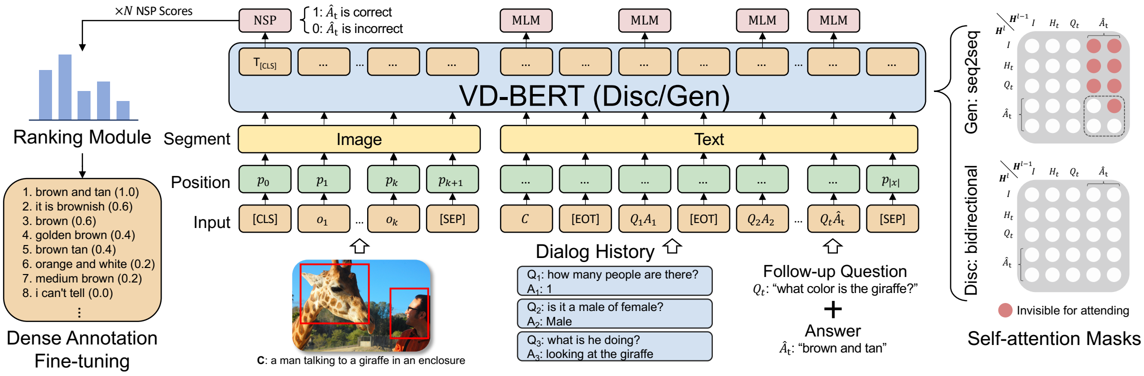

Figure 2: The model architecture of our unified VD-BERT for both discriminative and generative settings.

Regarding the architecture, our model mainly differs from previous work in two facets: first, unlike most prior work that considers answer candidates only at the final similarity computation layer, our VD-BERT integrates each answer candidate at the input layer to enable its early and deep fusion with other entities, similar to Schwartz et al. (2019); second, existing models adopt an encoder-decoder framework (Sutskever et al., 2014) with two types of decoder for the discriminative and generative settings separately, while we instead adopt a unified Transformer encoder with two different self-attention masks (Dong et al., 2019) to seamlessly support both settings without extra decoders.

Pretraining in Vision and Language. Pretrained language models like BERT (Devlin et al., 2019) have boosted performance greatly in a broad set of NLP tasks. In order to benefit from the pretraining, there are many recent works on extending BERT for vision and language pretraining. They typically employ the Transformer encoder as the backbone with either a two-stream architecture to encode text and image independently such as ViLBERT (Lu et al., 2019) and LXMERT (Tan and Bansal, 2019), or a single-stream architecture to encode both text and image together, such as B2T2 (Alberti et al., 2019), Unicoder-VL (Li et al., 2020), VisualBERT (Li et al., 2019), VL-BERT (Su et al., 2020), and UNITER (Chen et al., 2019). Our VD-BERT belongs to the second group. These models yield prominent improvements mainly on vision-language understanding tasks like VQA, image retrieval (Young et al., 2014), and visual reasoning (Suhr et al., 2019; Zellers et al., 2019).

More recently, Zhou et al. (2020) proposed VLP which also allows generation using a unified Transformer with various self-attention masks (Dong et al., 2019). Their model was proposed for VQA and image captioning. Our model is inspired by VLP and specifically tailored for the visual dialog task. Most closely related to this paper is the concurrent work VisDial-BERT by Murahari et al. (2019), who also employ pretrained models (i.e., ViLBERT) for visual dialog. Our work has two major advantages over VisDial-BERT: first, VD-BERT supports both discriminative and generative settings while theirs is restricted to only the discriminative setting; second, we do not require to pretrain on large-scale external vision-language datasets like theirs and still yield better performance (§5.1).

3 The VD-BERT Model

We first formally describe the visual dialog task. Given a question Q_t grounded on an image I at t-th turn, as well as its dialog history formulated as $H_t = \{C, (Q_1, A_1), ..., (Q_{t-1}, A_{t-1})\}$ (where C denotes the image caption), the agent is asked to predict its answer A_t by ranking a list of 100 answer candidates $\{\hat{A}_t^1, \hat{A}_t^2, ..., \hat{A}_t^{100}\}$. In general, there are two types of decoder to predict the answer: a *discriminative* decoder that *ranks* the answer candidates and is trained with a cross entropy loss, or a *generative* decoder that *synthesizes* an answer and is trained with a maximum log-likelihood loss.

Figure 2 shows the overview of our approach. First, we employ a unified vision-dialog Transformer to encode both the image and dialog history, where we append an answer candidate $\hat{A}_t$ in the input to model their interactions in an early fusion manner (§3.1). Next, we adopt visually grounded MLM and NSP objectives to train the model for effective vision and dialog fusion using two types of self-attention masks – bidirectional and seq2seq. This allows our unified model to work in both discriminative and generative settings (§3.2). Lastly, we devise a ranking optimization module to further fine-tune on the dense annotations (§3.3).

3.1 Vision-Dialog Transformer Encoder

Vision Features. Following previous work, we employ Faster R-CNN (Ren et al., 2015) pre-trained on Visual Genome (Krishna et al., 2017) to extract the object-level vision features. Let $O_I = \{o_1, ..., o_k\}$ denote the vision features for an image I, where each object feature o_i is a 2048-d Region-of-Interest (RoI) feature and k is the number of the detected objects (fixed to 36 in our setting). As there is no natural orders among these objects, we adopt normalized bounding box coordinates as the spatial location. Specifically, let (x_1, y_1) and (x_2, y_2) be the coordinates of the bottom-left and top-right corner of the i-th object, its location information is encoded into a 5-d vector: $p_i = (\frac{x_1}{W}, \frac{y_1}{H}, \frac{x_2}{W}, \frac{y_2}{H}, \frac{(x_2-x_1)(y_2-y_1)}{WH})$, where W and H respectively denote the width and height of the input image, and the last element is the relative area of the object. We extend p_i with its class id and confidence score for a richer representation.

Language Features. We pack all the textual elements (caption and multi-turn dialog) into a long sequence. We employ WordPiece tokenizer (Wu et al., 2016) to split it into a word sequence $\mathbf{w}$, where each word is embedded with an absolute positional code following Devlin et al. (2019).

Cross-Modality Encoding. To feed both image and text into the Transformer encoder, we integrate the image objects with language elements into a whole input sequence. Similar to BERT, we use special tokens like `[CLS]` to denote the beginning of the sequence, and `[SEP]` to separate the two modalities. Moreover, to inject the multi-turn dialog structure into the model, we utilize a special token `[EOT]` to denote *end of turn* (Whang et al., 2019), which informs the model when the dialog turn ends. As such, we prepare the input sequence into the format as $\mathbf{x} = ($`[CLS]`$, o_1, ..., o_k,$ `[SEP]`, C, `[EOT]`$, Q_1A_1,$ `[EOT]`, ..., $Q_t\hat{A}_t$, `[SEP]`$)$. To notify the model for the answer prediction, we further insert a `[PRED]` token between the $Q_t\hat{A}_t$ pair. Finally, each input token embedding is combined with its position embedding and segment embedding (0 or 1, indicating whether it is image or text) with layer normalization (Ba et al., 2016).

Transformer Backbone. We denote the embedded vision-language inputs as $\mathbf{H}^0 = [\mathbf{e}_1, ..., \mathbf{e}_{|\mathbf{x}|}]$ and then encode them into multiple levels of contextual representations $\mathbf{H}^l = [\mathbf{h}_1^l, ..., \mathbf{h}_{|\mathbf{x}|}^l]$ using L-stacked Transformer blocks, where the l-th Transformer block is denoted as $\mathbf{H}^l = \text{Transformer}(\mathbf{H}^{l-1}), l \in [1, L]$. Inside each Transformer block, the previous layer's output $\mathbf{H}^{l-1} \in \mathbb{R}^{|\mathbf{x}| \times d_h}$ is aggregated using the multi-head self-attention (Vaswani et al., 2017):

$$\mathbf{Q} = \mathbf{H}^{l-1}\mathbf{W}_l^Q, \mathbf{K} = \mathbf{H}^{l-1}\mathbf{W}_l^K, \mathbf{V} = \mathbf{H}^{l-1}\mathbf{W}_l^V, \tag{1}$$

$$\mathbf{M}_{ij} = \begin{cases} 0, & \text{allow to attend,} \\ -\infty, & \text{prevent from attending,} \end{cases} \tag{2}$$

$$\mathbf{A}_l = \text{softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d_k}} + \mathbf{M})\mathbf{V}, \tag{3}$$

where $\mathbf{W}_l^Q, \mathbf{W}_l^K, \mathbf{W}_l^V \in \mathbb{R}^{d_h \times d_k}$ are learnable weights for computing the queries, keys, and values respectively, and $\mathbf{M} \in \mathbb{R}^{|\mathbf{x}| \times |\mathbf{x}|}$ is the self-attention mask that determines whether tokens from two layers can attend each other. Then $\mathbf{A}_l$ is passed into a feedforward layer to compute $\mathbf{H}^l$ for the next layer.

3.2 Visually Grounded Training Objectives

We use two *visually grounded* training objectives—masked language modeling (MLM) and next sentence prediction (NSP) to train our VD-BERT. Particularly, we aim to capture dense interactions among both inter-modality (i.e., image-dialog) and intra-modality (i.e., image-image, dialog-dialog).

Similar to MLM in BERT, 15% tokens in the text segment (including special tokens like `[EOT]` and `[SEP]`) are randomly masked out and replaced with a special token `[MASK]`. The model is then required to recover them based not only on the surrounding tokens $\mathbf{w}_{\backslash m}$ but also on the image I:

$$\mathcal{L}_{MLM} = -E_{(I,\mathbf{w})\sim D} \log P(w_m | \mathbf{w}_{\backslash m}, I), \tag{4}$$

where w_m refers to the masked token and D denotes the training set. Following Zhou et al. (2020), we do not conduct similar masked object/region modeling in the image segment.

As for NSP, instead of modeling the relationship between two sentences (as in BERT) or the matching of an image-text pair (as in other vision-language pretraining models like ViLBERT), VD-BERT aims to predict whether the appended answer candidate $\hat{A}_t$ is correct or not based on the joint understanding of the image and dialog history:

$$\mathcal{L}_{NSP} = -E_{(I,\mathbf{w})\sim D} \log P(y | S(I, \mathbf{w})), \tag{5}$$

where $y \in \{0, 1\}$ indicates whether $\hat{A}_t$ is correct, and $S(\cdot)$ is a binary classifier to predict the probability based on the `[CLS]` representation $\mathbf{T}_{\texttt{[CLS]}}$ at the final layer. Below we introduce the discriminative and generative settings of VD-BERT.

Discriminative Setting. For training in the discriminative setting, we transform the task of selecting an answer into a point-wise binary classification problem. Specifically, we sample an answer $\hat{A}_t$ from the candidate pool and append it to the input sequence, and ask the NSP head to distinguish whether the sampled answer is correct or not. We employ the *bidirectional* self-attention mask to allow all the tokens to attend to each other by setting the mask matrix $\mathbf{M}$ in Eq. (2) to all 0s. To avoid imbalanced class distribution, we keep the ratio of positive and negative instances to 1:1 in each epoch. To encourage the model to penalize more on negative instances, we randomly resample a negative example from the pool of 99 negatives w.r.t. every positive one at different epochs. During inference, we rank the answer candidates according to the positive class score of their NSP heads.

Generative Setting. In order to autoregressively generate an answer, we also train VD-BERT with the *sequence-to-sequence* (seq2seq) self-attention mask (Dong et al., 2019). For this, we divide the input sequence to each Transformer block into two subsequences, *context* and *answer*:

$$\mathbf{x} \triangleq (I, \mathbf{w}) = (\underbrace{I, H_t, Q_t,}_{\text{context}} \hat{A}_t). \tag{6}$$

We allow tokens in the context to be fully visible for attending by setting the left part of $\mathbf{M}$ to all 0s. For the answer sequence, we mask out (by setting $-\infty$ in $\mathbf{M}$) the "future" tokens to get autoregressive attentions (see the red dots in Figure 2).

During inference, we rely on the same unified Transformer encoder with sequential MLM operations without an explicit decoder. Specifically, we recursively append a `[MASK]` token to the end of the sequence to trigger a one-step prediction and then replace it with the predicted token for the next token prediction. The decoding process is based on greedy sampling and terminated when a `[SEP]` is emitted, and the resulting log-likelihood scores will be used for ranking the answer candidates.

3.3 Fine-tuning with Rank Optimization

As some answer candidates may be semantically similar (e.g., "brown and tan" vs "brown" in Figure 2), VisDial v1.0 additionally provides dense annotations that specify real-valued relevance scores for the 100 answer candidates, $[s_1, ..., s_{100}]$ with $s_i \in [0, 1]$. To fine-tune on this, we combine the NSP scores from the model for all answer candidates together into a vector $[p_1, ..., p_{100}]$.

As dense annotation fine-tuning is typically a Learning to Rank (LTR) problem, we can make use of some ranking optimization methods (see the Appendix B.1 for more details). We adopt ListNet (Cao et al., 2007) with the top-1 approximation as the ranking module for VD-BERT:

$$\mathcal{L}_{ListNet} = -\sum_{i=1}^{N} f(s_i) \log(f(p_i)), \tag{7}$$

$$f(x_i) = \frac{\exp(x_i)}{\sum_{j=1}^{N} \exp(x_j)}, \quad i = 1, ..., N. \tag{8}$$

Here N is the number of answer candidates. For training efficiency, we sub-sample the candidate list and use only $N = 30$ answers (out of 100) for each instance. To better leverage the contrastive signals from the dense annotations, the sub-sampling method first picks randomly the candidates with non-zero relevance scores, and then it picks the ones from zero scores (about 12% of candidates are non-zero on average).

4 Experimental Setup

Datasets. We evaluate our model on the VisDial v0.9 and v1.0 datasets (Das et al., 2017). Specifically, v0.9 contains a training set of 82,783 images and a validation set of 40,504 images. The v1.0 dataset combines the training and validation sets of v0.9 into one training set and adds another 2,064 images for validation and 8,000 images for testing (hosted blindly in the task organizers' server). Each image is associated with one caption and 10 question-answer pairs. For each question, it is paired with a list of 100 answer candidates, one of which is regarded as the correct answer.

For the v1.0 validation split and a part of v1.0 train split (2,000 images), extra dense annotations for the answer candidates are provided to make the evaluation more reasonable. The dense annotation specifies a relevance score for each answer candidate based on the fact that some candidates with similar semantics to the ground truth answer can also be considered as correct or partially correct, e.g., "brown and tan" and "brown" in Figure 2.

Evaluation Metric. Following Das et al. (2017), we evaluate our model using the ranking metrics like Recall@K (K $\in \{1, 5, 10\}$), Mean Reciprocal Rank (MRR), and Mean Rank, where only one answer is considered as correct. Since the 2018 VisDial challenge (after the acquisition of dense annotations), NDCG metric that considers the relevance degree of each answer candidate, has been adopted as the main metric to determine the winner.

Configurations. We use $\text{BERT}_{\text{BASE}}$ as the backbone, which consists of 12 Transformer blocks, each with 12 attention heads and a hidden state dimensions of 768. We keep the max input sequence length (including 36 visual objects) to 250. We use Adam (Kingma and Ba, 2015) with an initial learning rate of $3e-5$ and a batch size of 32 to train our model. A linear learning rate decay schedule with a warmup of 0.1 is employed. We first train VD-BERT for 30 epochs on a cluster of 4 V100 GPUs with 16G memory using MLM and NSP losses (with equal coefficients). Here we only utilize one previous dialog turn for training efficiency. For instances where the appended answer candidate is incorrect, we do not conduct MLM on the answer sequence to reduce the noise introduced by the negative samples. After that, we train for another 10 epochs with full dialog history using either NSP in the discriminative setting or MLM on the answer sequence in the generative setting. For dense annotation fine-tuning in the discriminative setting, we train with the ListNet loss for 5 epochs.

5 Results and Analysis

We first compare VD-BERT with state-of-the-art models on VisDial datasets (§5.1). Then we conduct ablation studies to examine various aspects of our model (§5.2), followed by an in-depth analysis of fine-tuning on dense annotations (§5.3). Lastly, we interpret how it attains the effective fusion of vision and dialog via attention visualization (§5.4).

5.1 Main Results

Comparison. We consider state-of-the-art published baselines, including NMN (Hu et al., 2017), CorefNMN (Kottur et al., 2018), GNN (Zheng et al., 2019), FGA (Schwartz et al., 2019), DVAN (Guo et al., 2019b), RvA (Niu et al., 2019), DualVD (Jiang et al., 2020), HACAN (Yang et al., 2019), Synergistic (Guo et al., 2019a), DAN (Kang et al., 2019), ReDAN (Gan et al., 2019), CAG (Guo et al., 2020), Square (Kim et al., 2020), MCA (Agarwal et al., 2020), MReal-BDAI and P1_P2 (Qi et al., 2020). We further report results from the leaderboard[1] for a more up-to-date comparison, where some can be found in the arXiv, such as MVAN (Park et al., 2020), SGLNs (Kang et al., 2020), VisDial-BERT (Murahari et al., 2019), and Tohoku-CV (Nguyen et al., 2019).

Table 1: Summary of results on the test-std split of VisDial v1.0 dataset. The results are reported by the test server. "†" denotes ensemble model and "$*$" indicates fine-tuning on dense annotations. The "↑" denotes higher value for better performance and "↓" is the opposite. The best and second-best results in each column are in bold and underlined respectively.

Results on VisDial v1.0 test-std. We report the comparison results on VisDial v1.0 test-std split in Table 1 and make the following observations.

• *New state of the art for both single-model and ensemble settings.* Our single-model VD-BERT significantly outperforms all of its single-model counterparts across various metrics, even including some ensemble variants such as Synergistic, DAN (except R@10), and ReDAN (except NDCG). With further fine-tuning on dense annotations, the NDCG score increases quite sharply, from 59.96 to 74.54 with nearly 15% absolute improvement, setting a new state of the art in the single-model setting. This indicates that dense annotation fine-tuning plays a crucial role in boosting the NDCG

Table 2: Discriminative and generative results of various models on the val split of VisDial v0.9 dataset.

scores. Moreover, our designed ensemble version yields new state of the art (**75.35** NDCG), outperforming the 2019 VisDial challenge winner MReal-BDAI (74.02 NDCG) by over 1.3 absolute points.

• *Inconsistency between NDCG and other metrics.* While dense annotation fine-tuning yields huge improvements on NDCG, we also notice that it has a severe countereffect on other metrics, e.g., reducing the MRR score from 65.44 to 46.72 for VD-BERT. Such a phenomenon has also been observed in other recent models, such as MReal-BDAI, VisDial-BERT, Tohoku-CV Lab, and P1_P2, whose NDCG scores surpass others without dense annotation fine-tuning by at least around 10% absolute points while other metrics drop dramatically. We provide a detailed analysis of this phenomenon in §5.3.

• *Our VD-BERT is simpler and more effective than VisDial-BERT.* VisDial-BERT is a concurrent work to ours that also exploits vision-language pretrained models for visual dialog. It only reports the single-model performance of 74.47 NDCG. Compare to that, our VD-BERT achieves slightly better results (74.54 NDCG), however, note that we did not pretrain on large-scale external vision-language datasets like Conceptual Captions (Sharma et al., 2018) and VQA (Antol et al., 2015) as VisDial-BERT does. Besides, while VisDial-BERT does not observe improvements by ensembling, we endeavor to design an effective ensemble strategy to increase the NDCG score to 75.35 for VD-BERT.

Results on VisDial v0.9 val. We further show both discriminative and generative results on v0.9 val split in Table 2. For comparison, we choose LF, HRE, HREA, MN (Das et al., 2017), HCIAE (Lu et al., 2017), CoAtt (Wu et al., 2018), RvA, and DVAN as they contain results in both settings on the v0.9 val split. These models employ dual decoders for each setting separately. Our model continues to yield much better results in the discriminative setting (e.g., 70.04 MRR compared to DVAN's 66.67) and comparable results with the state of the art in the generative setting (e.g., 55.95 MRR score vs. DVAN's 55.94). This validates the effectiveness of our VD-BERT in both settings using a unified Transformer encoder. By contrast, VisDial-BERT can only support the discriminative setting.

Table 3: Extensive ablation studies: training with (a) various settings and (b) contexts on v1.0 val; dense annotation fine-tuning with (c) varying ranking methods and (d) various ensemble strategies on v1.0 test-std.

5.2 Ablation Study

We first study how different training settings influence the results in Table 3(a). We observe that initializing the model with weights from BERT indeed benefits the visual dialog task a lot, increasing the NDCG score by about 7% absolute over the model trained from scratch. Surprisingly, the model initialized with the weights from VLP that was pretrained on Conceptual Captions (Sharma et al., 2018), does not work better than the one initialized from BERT. It might be due to the domain discrepancy between image captions and multi-turn dialogs, as well as the slightly different experiment settings (e.g., we extract 36 objects from image compared to their 100 objects). Another possible reason might be that the VisDial data with more than one million image-dialog turn pairs can provide adequate contexts to adapt BERT for effective vision and dialog fusion. We also find that the visually grounded MLM is crucial for transferring BERT into the multimodal setting, indicated by a large performance drop when using only NSP.

We then examine the impact of varying the dialog context used for training in Table 3(b). With longer dialog history ("Full history"), our model indeed yields better results in most of the ranking metrics, while the one without using any dialog history obtains the highest NDCG score. This in-

Figure 3: The effects of dense annotation fine-tuning in our VD-BERT for two examples. GT: ground truth.

dicates that dense relevance scores might be annotated with less consideration of dialog history. If we remove the visual cues from the "Full history" model, we see a drop in all metrics, especially, on NDCG. However, this version still obtains comparable results to the "No history" variant, revealing that textual information dominates the VisDial task.

In Table 3(c), we compare Cross Entropy (CE) training with a bunch of other listwise ranking optimization methods: ListNet (Cao et al., 2007), ListMLE (Xia et al., 2008), and approxNDCG (Qin et al., 2010). Among these methods, ListNet yields the best NDCG and Mean Rank, while the approxNDCG achieves the best MRR and Recall on VisDial v1.0 test-std. Therefore, we employ the ListNet as our ranking module.

We also explore ways to achieve the best ensemble performance with various model selection criteria in Table 3(d). We consider three criteria, EPOCH, LENGTH, and RANK that respectively refer to predictions from different epochs of a single model, from different models trained with varying context lengths and with different ranking methods in Table 3(b)-(c). We use four predictions from each criterion and combine their diverse predictions (DIVERSE) by summing up their normalized ranking scores. We observe that EPOCH contributes the least to the ensemble performance while RANK models are more helpful than LENGTH models. The diverse set of them leads to the best performance.

5.3 Fine-tuning on Dense Annotations

In this section, we focus on the effect of dense annotation fine-tuning and try to analyze the reason of the inconsistency issue between NDCG and other ranking metrics (see Table 1) in the following.

Case Study. We provide two examples to qualitatively demonstrate how dense annotation fine-tuning results in better NDCG scores in Figure 3. For the example at the top, fine-tuning helps our model to assign higher ranks to the answers that share similar semantics with the ground truth answer and should also be regarded as correct ("yes, it is" and "yep" vs. "yes"). In the example at the bottom, we spot a mismatch between the sparse and dense annotations: the ground truth answer "no, it's empty" is only given a 0.4 relevance score, while uncertain answers like "i don't know" are considered to be more relevant. In this case, fine-tuning instead makes our model fail to predict the correct answer despite the increase of NDCG score.

Relevance Score and Question Type Analysis. We first show how various metrics change for fine-tuning in Figure 4. For this experiment, we randomly sample 200 instances from VisDial v1.0 val as the test data and use the rest for fine-tuning with the ListNet ranking method. We observe that NDCG keeps increasing with more epochs of fine-tuning, while other metrics such as Recall@K and MRR) drop. For further analysis, we classify the $2,064$ instances in VisDial v1.0 val set based on the ground-truth's relevance score and question type (Table 4). We consider four bins $\{0.0, 0.2 \sim 0.4, 0.6 \sim 0.8, 1.0\}$ for the relevance score and four question types: *Yes/no*, *Number*, *Color*, and *Others*. We then analyze the NDCG scores assigned by DAN (Kang et al., 2019) and our VD-BERT with and without dense annotation fine-tuning. We choose DAN as it achieves good NDCG scores (Table 1) and provides the source code to reproduce their predictions.

By examining the distribution of the relevance scores, we find that only 31% of them are aligned well with the sparse annotations and 9% are totally misaligned. As the degree of such mismatch increases (relevance score changes $1.0 \rightarrow 0.0$), both DAN and our model witness a plunge in NDCG ($63.29 \rightarrow 43.86$ and $70.25 \rightarrow 48.07$), while dense annotation fine-tuning significantly boosts NDCG scores for all groups, especially for the most misaligned one ($48.07 \rightarrow 82.84$ for our model). These results validate that the misalignment of the sparse and dense annotations is the key reason for the inconsistency between NDCG and other metrics.

For question types, we observe that *Yes/no* is the major type (76%) and also the easiest one, while *Number* is the most challenging and least frequent one (3%). Our model outperforms DAN by over 10% in most of the question types except *Color*. Fine-tuning on dense annotations gives our model huge improvements across all the question types, especially for *Others* with over 30% absolute gain.

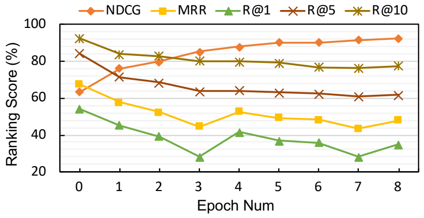

Figure 4: Dense annotation fine-tuning on various metrics with the ListNet method.

Models	All	**Relevance Score**				**Question Type**			
		1.0 (31%)	0.6∼0.8 (35%)	0.2∼0.4 (25%)	0.0 (9%)	Yes/no (76%)	Number (3%)	Color (11%)	Others (10%)
DAN	58.28	63.29	61.02	53.29	43.86	59.86	41.03	57.55	51.89
Ours	63.55	70.25	65.18	58.40	48.07	65.45	48.98	58.51	58.75
Ours (w/ ft)	89.62	95.38	89.76	84.63	82.84	91.05	74.41	84.00	89.12

Table 4: NDCG scores in VisDial v1.0 val split broken down into 4 groups based on relevance score and the question type. The % value in the parentheses denotes the corresponding data proportion.

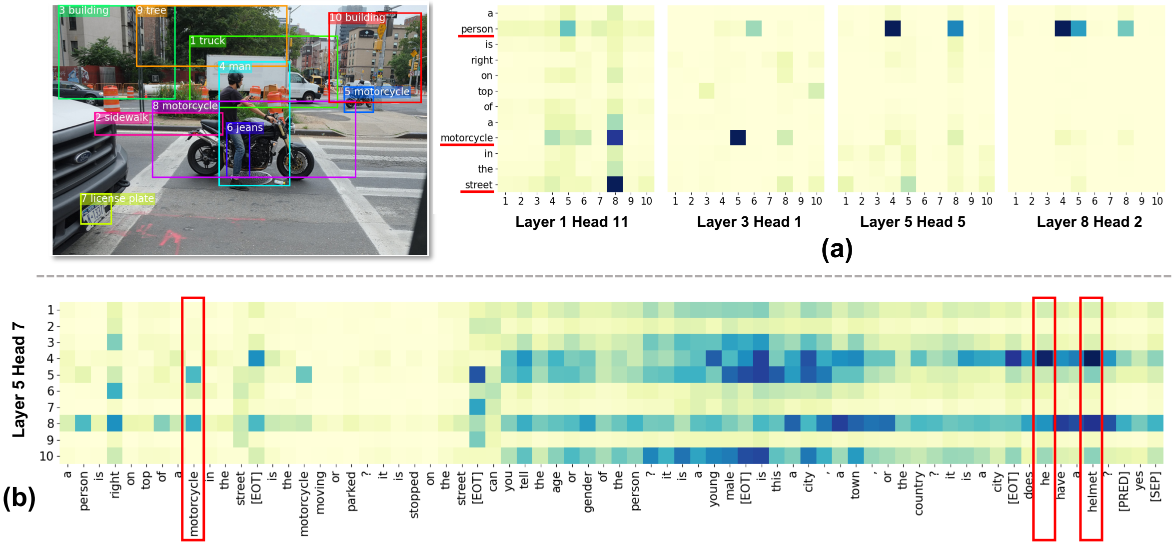

Figure 5: Attention weight visualization in our VD-BERT for a sampled image-dialog example.

5.4 Attention Visualization

To interpret our VD-BERT, we visualize the attention weights on the top 10 detected objects from its caption in Figure 5(a). We observe that many heads at different layers can correctly ground some entities like `person` and `motorcycle` in the image, and even reveal some high-level semantic correlations such as `person`↔`motorcycle` (at L8H2) and `motorcycle`↔`street` (at L1H11). Besides, heads at higher layers tend to have a sharper focus on specific objects like the man and the motorcycles in the image.

Next, we examine how our VD-BERT captures the interactions between image and multi-turn dialog. In contrast to other vision-language tasks, visual dialog has a more complex multi-turn structure, thereby posing a hurdle for effective fusion. As shown in Figure 5(b), VD-BERT can ground entities and discover some object relations, e.g., `helmet` is precisely related to the man and the motorcycle in the image (see the rightmost red box). More interestingly, it can even resolve visual pronoun coreference of `he` in the question to the man in the image (see the middle red box). We provide more qualitative examples in Figure 6 and 7.

6 Conclusion

We have presented VD-BERT, a unified vision-dialog Transformer model that exploits the pre-trained BERT language models for visual dialog. VD-BERT is capable of modeling all the interactions between an image and a multi-turn dialog within a single-stream Transformer encoder and enables the effective fusion of features from both modalities via simple visually grounded training. Besides, it can either rank or generate answers seamlessly. Without pretraining on external vision-language datasets, our model establishes new state-of-the-art performance in the discriminative setting and shows promising results in the generative setting on the visual dialog benchmarks.

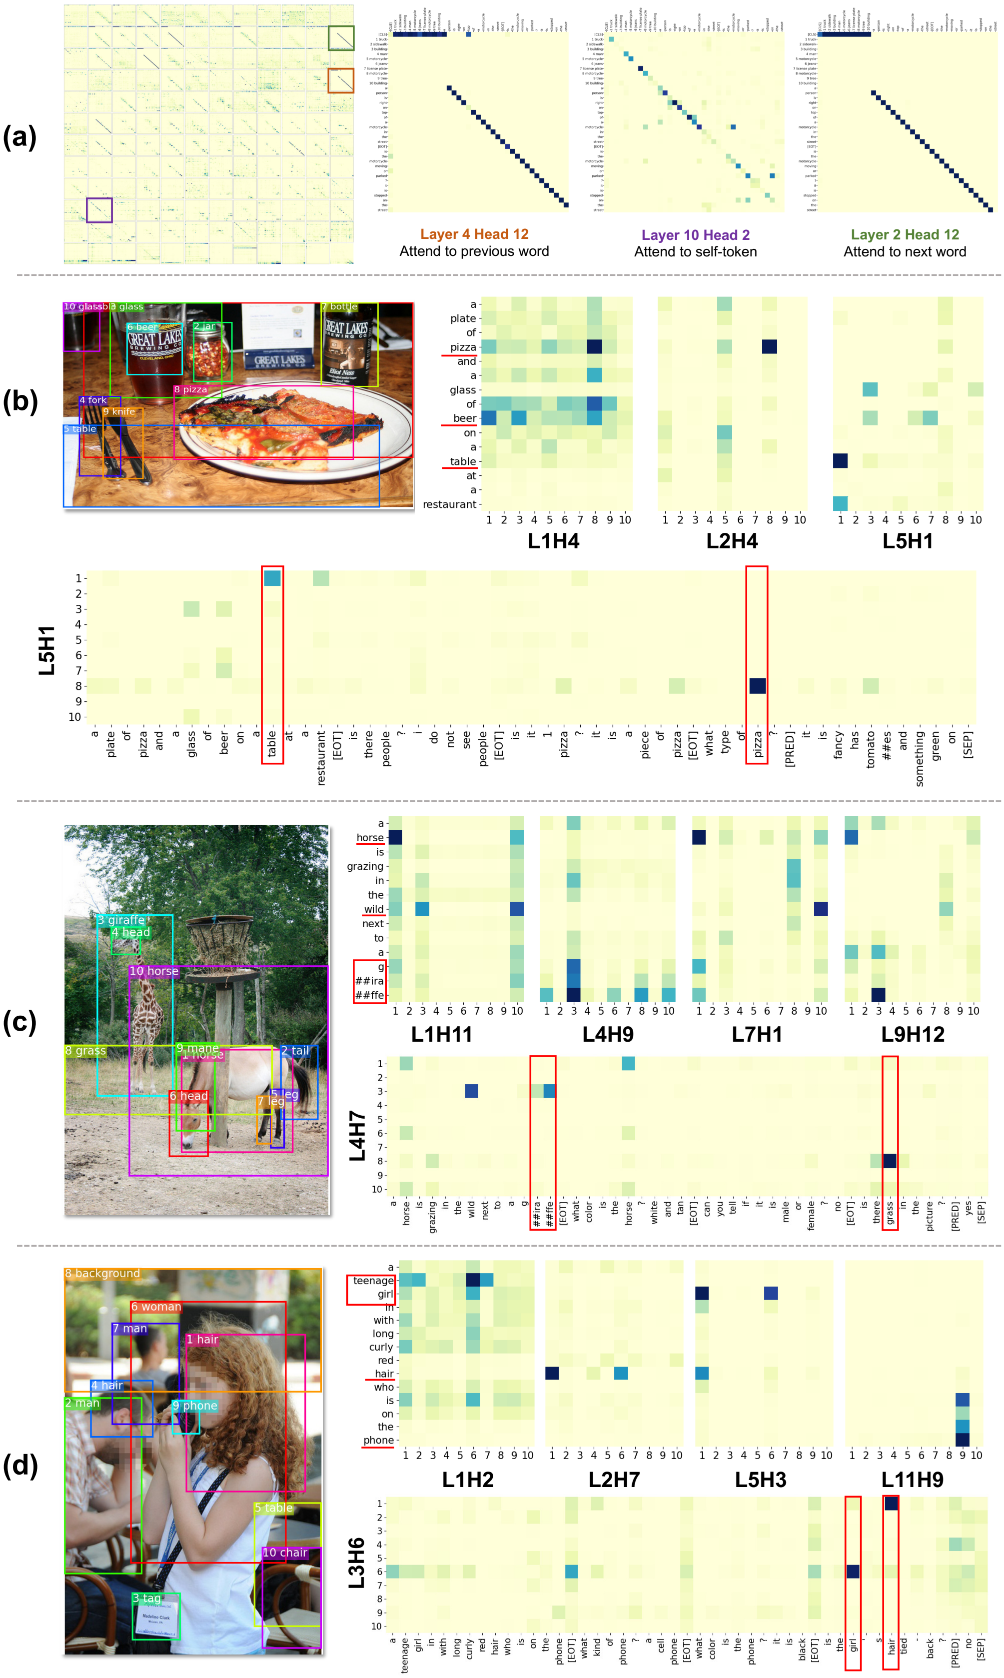

Figure 6: More attention visualization examples showing that VD-BERT achieves the effective fusion of vision and dialog contents. LxHy: Layer x Head y ($1 \leq x, y \leq 12$). (a) It learns three apparent attention patterns for the example in Figure 5: attentions that a token puts to its previous token, to itself, and to the next token. Besides, some of its attention heads can precisely ground some entities between image and caption/multi-turn dialog: (b) `pizza`, `beer`, and `table`; (c) `horse`, `wild`, and `giraffe`; (d) `teenage girl`, `hair`, and `phone`.

Image + Caption	GT Dialog	DAN	VD-BERT	VD-BERT (w/ft)
 a brown building stands at the corner of a street on a sunny day	Q1: is there any people in the photo? A1: yes far away Q2: are there any streets visible in the photo? A2: yes Q3: are there cars parked along the streets? A3: no Q4: what kind of buildings appear in the photo? A4: older architectural building like a library Q5: is there any signs visible in the photo? A5: there is a no entry sign Q6: are there traffic lights visible? A6: no Q7: can you see the sidewalk? A7: yes Q8: are the sidewalks clean? A8: immaculate Q9: are there any trees planted near the building? A9: there is a tree next to the building Q10: is the tree short or tall? A10: tall	Q1: is there any people in the photo? A1: yes Q2: are there any streets visible in the photo? A2: no on the street Q3: are there cars parked along the streets? A3: no Q4: what kind of buildings appear in the photo? A4: yes shops Q5: is there any signs visible in the photo? A5: yes Q6: are there traffic lights visible? A6: 1 light pole Q7: can you see the sidewalk? A7: yes Q8: are the sidewalks clean? A8: yes very clean Q9: are there any trees planted near the building? A9: yes Q10: is the tree short or tall? A10: tall	Q1: is there any people in the photo? A1: yes Q2: are there any streets visible in the photo? A2: yes Q3: are there cars parked along the streets? A3: no Q4: what kind of buildings appear in the photo? A4: older architectural building like a library Q5: is there any signs visible in the photo? A5: yes Q6: are there traffic lights visible? A6: no Q7: can you see the sidewalk? A7: yes Q8: are the sidewalks clean? A8: yes Q9: are there any trees planted near the building? A9: there is a tree next to the building Q10: is the tree short or tall? A10: tall	Q1: is there any people in the photo? A1: yes Q2: are there any streets visible in the photo? A2: yes Q3: are there cars parked along the streets? A3: no Q4: what kind of buildings appear in the photo? A4: not sure Q5: is there any signs visible in the photo? A5: yes Q6: are there traffic lights visible? A6: no Q7: can you see the sidewalk? A7: yes Q8: are the sidewalks clean? A8: yes, they are clean Q9: are there any trees planted near the building? A9: no there isn't Q10: is the tree short or tall? A10: tall
 man pointing at tv display in a store	Q1: is the picture in color? A1: yes Q2: how many people are in the picture? A2: i see 2 people Q3: how many tv's are in the picture? A3: 18 screens on the display but there are some in boxes as well Q4: is 1 of the people a worker in the store? A4: no it doesn't look like it Q5: is there an image on the tv that he is pointing at? A5: yes it is an cartoon Q6: is the man standing or sitting? A6: standing Q7: what is the brand of tv? A7: i am unable to tell Q8: can you tell what store it is? A8: no Q9: are there any other products in view? A9: i just see tv's and boxes Q10: what color is the floor? A10: blue	Q1: is the picture in color? A1: yes Q2: how many people are in the picture? A2: 2 Q3: how many tv's are in the picture? A3: 2 Q4: is 1 of the people a worker in the store? A4: yes, but they are taking a break Q5: is there an image on the tv that he is pointing at? A5: yes it is an cartoon Q6: is the man standing or sitting? A6: standing Q7: what is the brand of tv? A7: it's in japanese Q8: can you tell what store it is? A8: yes it is a list of rules Q9: are there any other products in view? A9: there is papers all over the desk so i would say yes Q10: what color is the floor? A10: blue	Q1: is the picture in color? A1: yes Q2: how many people are in the picture? A2: 2 Q3: how many tv's are in the picture? A3: 18 screens on the display but there are some in boxes as well Q4: is 1 of the people a worker in the store? A4: there are no visible workers Q5: is there an image on the tv that he is pointing at? A5: yes it is an cartoon Q6: is the man standing or sitting? A6: standing Q7: what is the brand of tv? A7: it's in japanese Q8: can you tell what store it is? A8: no Q9: are there any other products in view? A9: i just see tv's and boxes Q10: what color is the floor? A10: blue	Q1: is the picture in color? A1: yes it is Q2: how many people are in the picture? A2: 1 Q3: how many tv's are in the picture? A3: 18 screens on the display but there are some in boxes as well Q4: is 1 of the people a worker in the store? A4: there are no visible workers Q5: is there an image on the tv that he is pointing at? A5: yes Q6: is the man standing or sitting? A6: standing Q7: what is the brand of tv? A7: i can't tell Q8: can you tell what store it is? A8: no Q9: are there any other products in view? A9: yes Q10: what color is the floor? A10: blue
 a woman is smiling next to a decorated microwave	Q1: is there anyone in the room with the woman? A1: no Q2: is she young? A2: no Q3: what color is her hair? A3: black Q4: is it a big microwave? A4: yes Q5: is it sunny? A5: no Q6: is there any other appliances in the room? A6: no Q7: what is the woman wearing? A7: a shirt Q8: is her hair long? A8: no Q9: what color is the microwave? A9: white Q10: is she wearing glasses? A10: no	Q1: is there anyone in the room with the woman? A1: no, she is alone Q2: is she young? A2: no about 18 Q3: what color is her hair? A3: brown Q4: is it a big microwave? A4: normal size Q5: is it sunny? A5: no Q6: is there any other appliances in the room? A6: no Q7: what is the woman wearing? A7: brown jacket Q8: is her hair long? A8: yes Q9: what color is the microwave? A9: silver Q10: is she wearing glasses? A10: no	Q1: is there anyone in the room with the woman? A1: no Q2: is she young? A2: yes Q3: what color is her hair? A3: brown Q4: is it a big microwave? A4: yes Q5: is it sunny? A5: no Q6: is there any other appliances in the room? A6: no Q7: what is the woman wearing? A7: black jeans and a t shirt Q8: is her hair long? A8: no Q9: what color is the microwave? A9: white Q10: is she wearing glasses? A10: no	Q1: is there anyone in the room with the woman? A1: no Q2: is she young? A2: yes Q3: what color is her hair? A3: brown Q4: is it a big microwave? A4: yes Q5: is it sunny? A5: i can't tell Q6: is there any other appliances in the room? A6: not that i can see Q7: what is the woman wearing? A7: a black jacket Q8: is her hair long? A8: no Q9: what color is the microwave? A9: white Q10: is she wearing glasses? A10: no
 an elephant sprays the person on its back	Q1: is the elephant large? A1: yes, but doesn't look full grown Q2: how many people are on the elephant? A2: i can only see 1 Q3: are there more elephants in the picture? A3: no Q4: what is the person wearing? A4: i think it's shorts, hard to tell with the spray from the elephant Q5: where is the elephant getting the water from? A5: it's either a large puddle or maybe a river bank, not sure Q6: is the water clean or dirty? A6: it looks pretty muddy, so i would say dirty Q7: is there grass anywhere near the water or mainly mud? A7: mainly mud Q8: can you see the sky? A8: no Q9: are there any trees in the photo? A9: yes Q10: can you tell what type of trees? A10: no	Q1: is the elephant large? A1: yes Q2: how many people are on the elephant? A2: four, 1 in each photo Q3: are there more elephants in the picture? A3: no, just the 2 birds Q4: what is the person wearing? A4: a green button up Q5: where is the elephant getting the water from? A5: it's either a large puddle or maybe a river bank, not sure Q6: is the water clean or dirty? A6: it looks pretty muddy, so i would say dirty Q7: is there grass anywhere near the water or mainly mud? A7: there's a bit of grass, and a green reflection on the water Q8: can you see the sky? A8: a very little part of if through the trees Q9: are there any trees in the photo? A9: yes, but there's hardly any leaves Q10: can you tell what type of trees? A10: i would think late spring or summer cause all the trees are nice and green	Q1: is the elephant large? A1: yes Q2: how many people are on the elephant? A2: 2 Q3: are there more elephants in the picture? A3: no Q4: what is the person wearing? A4: a waterproof swimsuit thing Q5: where is the elephant getting the water from? A5: it's either a large puddle or maybe a river bank, not sure Q6: is the water clean or dirty? A6: it looks pretty muddy, so i would say dirty Q7: is there grass anywhere near the water or mainly mud? A7: mainly mud Q8: can you see the sky? A8: no Q9: are there any trees in the photo? A9: yes Q10: can you tell what type of trees? A10: no	Q1: is the elephant large? A1: yes Q2: how many people are on the elephant? A2: 1 Q3: are there more elephants in the picture? A3: no Q4: what is the person wearing? A4: he is wearing a jacket Q5: where is the elephant getting the water from? A5: cannot tell from the picture Q6: is the water clean or dirty? A6: it looks pretty muddy, so i would say dirty Q7: is there grass anywhere near the water or mainly mud? A7: no, there is 0 Q8: can you see the sky? A8: no Q9: are there any trees in the photo? A9: yes Q10: can you tell what type of trees? A10: no i can't
 a man wearing a hat holds a small white dog	Q1: age of man? A1: maybe 20s Q2: type of dog? A2: a white fluffy dog Q3: is it small? A3: yes Q4: can you see the head? A4: i can see the dogs head and the man's head Q5: is the mouth open on the dog? A5: no Q6: what else is the man wearing? A6: eyeglasses Q7: what color hat is it? A7: tan hat Q8: what color is his shirt? A8: hard to tell, possibly a grey vest Q9: what color is his pants? A9: they are not shown Q10: is the man outside? A10: no, he is inside	Q1: age of man? A1: 40s Q2: type of dog? A2: a white fluffy dog Q3: is it small? A3: average size Q4: can you see the head? A4: yes Q5: is the mouth open on the dog? A5: yes Q6: what else is the man wearing? A6: a jacket and a hat Q7: what color hat is it? A7: brown Q8: what color is his shirt? A8: black Q9: what color is his pants? A9: black Q10: is the man outside? A10: no, he is inside	Q1: age of man? A1: 40s Q2: type of dog? A2: a white fluffy dog Q3: is it small? A3: yes Q4: can you see the head? A4: i can see the dogs head and the man's head Q5: is the mouth open on the dog? A5: no Q6: what else is the man wearing? A6: a jacket and a hat Q7: what color hat is it? A7: tan hat Q8: what color is his shirt? A8: white Q9: what color is his pants? A9: they are not shown Q10: is the man outside? A10: no, he is inside	Q1: age of man? A1: 40s Q2: type of dog? A2: i can't tell Q3: is it small? A3: yes Q4: can you see the head? A4: yes Q5: is the mouth open on the dog? A5: nope Q6: what else is the man wearing? A6: eyeglasses Q7: what color hat is it? A7: it's brown Q8: what color is his shirt? A8: his shirt is white Q9: what color is his pants? A9: i can't see it Q10: is the man outside? A10: no
 a small bedroom with a hall with laundry in the background	Q1: do you see any people? A1: no Q2: is there a bed in the bedroom? A2: yes Q3: is it a big pile of laundry? A3: no Q4: what color is the bedspread? A4: white and light gray Q5: is it dirty laundry or clean? A5: clean Q6: is the hall carpeted or hard floor? A6: hard floor Q7: is the laundry hanging or piled or folded? A7: hanging Q8: is it a light or dark wood floor? A8: dark Q9: is the bedroom a child's room, guest room, or adult bedroom? A9: adult Q10: is there any other furniture in the bedroom? A10: yes	Q1: do you see any people? A1: no Q2: is there a bed in the bedroom? A2: no Q3: is it a big pile of laundry? Abstract

In this paper, we consider the syntactic properties of languages emerged in referential games, using unsupervised grammar induction (UGI) techniques originally designed to analyse natural language. We show that the considered UGI techniques are appropriate to analyse emergent languages and we then study if the languages that emerge in a typical referential game setup exhibit syntactic structure, and to what extent this depends on the maximum message length and number of symbols that the agents are allowed to use. Our experiments demonstrate that a certain message length and vocabulary size are required for structure to emerge, but they also illustrate that more sophisticated game scenarios are required to obtain syntactic properties more akin to those observed in human language. We argue that UGI techniques should be part of the standard toolkit for analysing emergent languages and release a comprehensive library to facilitate such analysis for future researchers.

1 Introduction

Artificial agents parameterised by deep neural networks can learn to communicate using discrete symbols to solve collaborative tasks (Foerster et al., 2016; Lazaridou et al., 2017; Havrylov and Titov, 2017). A prime reason to conduct such studies, which constitute a new generation of experiments with referential games, is that they may provide insight in the factors that shaped the evolution of human languages (Kirby, 2002).

However, the *emergent languages* developed by neural agents are not human-interpretable, and little is known about their semantic and syntactic nature. More specifically, we do not know to what extent the structure of emergent languages resembles the structure of human languages, what the languages encode, and how these two things depend on choices that need to be made by the modeller.

A substantial obstacle to better understanding emergent languages is the lack of tools to analyse their properties. Previous work has concentrated primarily on understanding languages through their *semantics*, by studying the alignment of messages and symbolic representations of the meaning space (e.g. Lazaridou et al., 2018). A substantial downside of such approaches is that they are restricted to scenarios for which a symbolic representation of the meaning space is available. Furthermore, they ignore a second important aspect of language: syntax, which is relevant not just for syntactically-oriented researchers, but also for those that are interested in semantics from a compositional perspective. In this work, we aim to address this gap in the literature by presenting an analysis of the syntax of emergent languages.

We take inspiration from unsupervised grammar induction (UGI) techniques originally proposed for natural language. In particular, we use them to investigate if the languages that emerge in the typical setup of referential games exhibit interesting syntactic structure, and to what extent this depends on the maximum message length and number of symbols that the agents are allowed to use.

We first establish that UGI techniques are suitable also for our artificial scenario, by testing them on several artificial structured languages that are distributionally similar to our emergent languages. We then use them to analyse a variety of languages emerging from a typical referential game, with various message lengths and vocabulary sizes. We

show that short messages of up to length five do not give rise to any interesting structure, while longer messages are significantly more structured than *random* languages, but yet far away from the type of syntactic structure observed in even simple human language sentences.

As such, our results thus suggest that more interesting games scenarios may be required to trigger properties more similar to human syntax and – importantly – confirm that UGI techniques are a useful tool to analyse such more complex scenarios. Their results are informative not only for those interested in the evolution of *structure* of human languages, but can also fuel further semantic analysis of emergent languages.

2 Related work

Previous work that focused on the analysis of emergent languages has primarily concentrated on semantics-based analysis. In particular, they considered whether agents transmit information about categories or objects, or instead communicate using low-level feature information (Steels, 2010; Lazaridou et al., 2017; Bouchacourt and Baroni, 2018; Lazaridou et al., 2018; Mihai and Hare, 2019, i.a.).

2.1 Qualitative inspection

Many previous studies have relied on qualitative, manual inspection. For instance, Lazaridou et al. (2018) and Havrylov and Titov (2017) showed that emergent languages can encode category-specific information through prefixing as well as word-order and hierarchical coding, respectively. Others instead have used qualitative inspection to support the claim that messages focus on pixel information instead of concepts (Bouchacourt and Baroni, 2018), that agents consistently use certain words for specific situations (Mul et al., 2019) or re-use the same words for different property values (Lu et al., 2020), or that languages represent distinct properties of the objects (e.g. colour and shape) under specific circumstances (Kottur et al., 2017; Choi et al., 2018; Słowik et al., 2020).

2.2 RSA

Another popular approach to analyse the semantics of emergent languages relies on *representational similarity analysis* (RSA, Kriegeskorte et al., 2008). RSA is used to analyse the similarity between the language space and the meaning space, in which case it is also called *topographic similarity* (Brighton et al., 2005; Brighton and Kirby, 2006; Lazaridou et al., 2018; Andreas, 2019; Li and Bowling, 2019; Keresztury and Bruni, 2020; Słowik et al., 2020; Ren et al., 2020), It has also been used to directly compare the continuous hidden representations of a neural agent with the input space (Bouchacourt and Baroni, 2018).

2.3 Diagnostic Classification

A last technique used to analyse emergent languages is *diagnostic classification* (Hupkes et al., 2018), which is used to examine which concepts are captured by the visual representations of the playing agents (Lazaridou et al., 2018), whether the agents communicate their hidden states (Cao et al., 2018), which input properties are best retained by the agent's messages (Luna et al., 2020) and whether the agents communicate about their own objects and possibly ask questions (Bouchacourt and Baroni, 2019).

3 Method

We analyse the syntactic structure of languages emerging in referential games with UGI techniques. In this section, we describe the game setup that we consider (§3.1), the resulting languages that are the subject of our analysis (§3.2) and the UGI techniques that we use (§3.3). Lastly, we discuss our main methods of evaluating our UGI setups and the resulting grammars (§3.4) as well as several baselines that we use for comparison (§3.5).

3.1 Game

We consider a game setup similar to the one presented by Havrylov and Titov (2017), in which we vary the message length and vocabulary size. In this game, two agents develop a language in which they speak about 30×30 pixel images that represent objects of different shapes, colours and sizes ($3 \times 3 \times 2$), placed in different locations. In the first step of the game, the *sender* agent observes an image and produces a discrete message to describe it. The *receiver* agent then uses this message to select an image from a set containing the correct image and three distractor images. Following Luna et al. (2020), we generate the target and distractor images from a symbolic description with a degree of non-determinism, resulting in $75k$, $8k$, and $40k$ samples for the train, validation, and test set.

Both the sender and receiver agent are modelled by an LSTM and CNN as language and visual units, respectively. We pretrain the visual unit of the agents by playing the game once, after which it is kept fixed throughout all experiment. All trained agents thus have the same visual unit, during training only the LSTM's parameters are updated. We use Gumbel-Softmax with a temperature of 1.2 for optimising the agents' parameters, with batch size 128 and initial learning rate 0.0001 for the Adam optimiser (Kingma and Ba, 2015). In addition to that, we use early stopping with a patience of 30 to avoid overfitting. We refer to Appendix A for more details about the architectures and a mathematical definition of the game that we used.

3.2 Languages

From the described game, we obtain several different languages by varying the maximum message length L and vocabulary size V throughout experiments. For each combination of $L \in \{3, 5, 10\}$ and $V \in \{6, 13, 27\}$, we train the agents three times. In all these runs, the agents develop successful communication protocols, as indicated by their high test accuracies (between 0.95 and 1.0). Furthermore, all agents can generalise to unseen scenarios.

For our analysis, we then extract the sender messages for all $40K$ images from the game's test set. From this set of messages, we construct a disjoint induction set (90%) and validation set (10%). Because the sender may use the same messages for several different input images, messages can occur multiple times. In our experiments, we consider only the set of unique messages, which us this smaller than the total number of images. Table 1 provides an overview of the number of messages in the induction and evaluation set for each language with maximum message length L and vocabulary size V.

		seed 0		seed 1		seed 2	
L	V	induct.	eval.	induct.	eval.	induct.	eval.

	27	9538	1060	8308	924	9112	1013

Table 1: The number of messages per language for the induction and evaluation set, for all three seeds for playing the referential game.

In the rest of this paper we refer to the three sets by denoting the message length and vocabulary size of the game they come from. For instance, $V6L10$ refers to the set of languages trained with a vocabulary size of 6 and a maximum message length of 10. Note that while the sender agent of the game may choose to use shorter messages and fewer symbols than these limits, they typically do not.

3.3 Grammar induction

For natural language, there are several approaches to unsupervised parsing and grammar induction. Some of these approaches induce the syntactic structure (in the form of a bracketing) and the constituent labels simultaneously, but most do only one of those. We follow this common practice and use a two-stage induction process (see Figure 1), in which we first infer unlabelled constituency structures and then label them. From these labelled structures, we then read out a probabilistic context free grammar (PCFG).

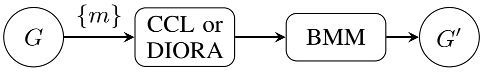

Figure 1: Our two-stage grammar induction setup. We try to reconstruct the grammar G that is hypothesised to have generated our set of messages M, using first CCL and DIORA to infer unlabeled constituency trees for all $m \in M$ and then BMM to label these trees.

3.3.1 Constituency structure induction

To induce constituency structures, we compare two different techniques: the pre-neural statistical *common cover link* parser (CCL, Seginer, 2007) and the neural parser *Deep Inside-Outside Recursive Auto-encoder* (DIORA, Drozdov et al., 2019).[1]

CCL While proposed in 2007, CCL[2] is still considered a state-of-the-art unsupervised parser. Contrary to other popular parsers from the 2000s (e.g. Klein and Manning, 2004, 2005; Ponvert et al., 2011; Reichart and Rappoport, 2010), it does not require POS-annotation of the words in the corpus, making it appropriate for our setup.

CCL is an incremental and greedy parser, that aims to incrementally add *cover links* to all words

---

[1] Another recent and state-of-the-art unsupervised neural parser is the *Unsupervised Recurrent Neural Network Grammar* (URNNG Kim et al., 2019). For our languages, URNNG generated exclusively right-branching trees, which is why we disregarded it in an initial stage of our experiments.

[2] `http://www.seggu.net/ccl/`

in a sentence. From these sets of cover links, constituency trees can be constructed. To limit the search space, CCL incorporates a few assumptions based on knowledge about natural language, such as the fact that constituency trees are generally skewed and the word distribution zipfian. In our experiments, we use the default settings for CCL.

DIORA In addition to CCL, we also experiment with the more recent *neural* unsupervised parser DIORA[3]. As the name suggests, DIORA is built on the application of recursive auto-encoders.

In our experiments with DIORA, we use a *tree-LSTM* with a hidden dimension of 50, and train for a maximum of 5 epochs with a batch size of 128. We use the GloVe framework[4] (Pennington et al., 2014) to pretrain word-embeddings for our corpus; using an embedding size of 16.

3.3.2 Constituency labelling

To label the constituency structures returned by CCL and DIORA, we use *Bayesian Model Merging* (BMM, Stolcke and Omohundro, 1994). BMM was originally approached to induce *grammars* for natural language corpora, but proved to be infeasible for that purpose. However, BMM has been successfully used to infer labels for unlabelled constituency trees (Borensztajn and Zuidema, 2007). It can therefore complement techniques such as CCL and DIORA.

The BMM algorithm starts from a set of constituency trees in which each constituent is given its own unique label. It defines an iterative search procedure that merges labels to reduce the joint description length of the data (DDL) and the grammar that can be inferred from the labelling (GDL). To find the next best merge step, the algorithm computes the effect of merging two labels on the sum of the GDL and DDL after doing the merge, where the GDL is defined as the number of bits to encode the grammar that can be inferred from the current labelled treebank with relative frequency estimation, and the DDL as the negative log-likelihood of the corpus given this grammar. To facilitate the search and avoid local minima, several heuristics and a look-ahead procedure are used to improve the performance of the algorithm. We use the BMM implementation provided by Borensztajn and Zuidema (2007)[5].

We refer to our complete setups with the names CCL-BMM and DIORA-BMM, respectively, depending on which constituency inducer was used in the first step.

3.4 Evaluation

As we do not know the true structure of the emergent languages, we have to resort to different measures than the traditional *precision*, *recall* and *F1 scores* that are typically used to evaluate parses and grammars. We consider three different aspects, which we explain below.

3.4.1 Grammar aptitude

To quantitatively measure how well the grammar describes the data, we compute its *coverage* on a disjoint evaluation set. Coverage is defined as the ratio of messages that the grammar can parse and thus indicates how well a grammar generalises to unseen messages of the same language. We also provide an estimate of how many messages *outside* of the language the grammar can parse – i.e. to what extent the grammar *overgenerates* – by computing its coverage on a subset of 500 randomly sampled messages.

3.4.2 Language compressibility

To evaluate the extent to which the grammar can compress a language, we consider the grammar and data description lengths (*GDL* and *DDL*), as defined by Borensztajn and Zuidema (2007). To allow comparison between languages that have a different number of messages, we consider the average message DDL.

3.4.3 Grammar nature

Lastly, to get a more qualitative perspective in the nature of the induced grammar, we consider a few statistics expressing the number of *non-terminals* and *pre-terminals* in the grammar, as well as the number of *recursive production rules*, defined as a production rule where the symbol from the left-hand side also appears on the right-hand side. Additionally, we consider the distribution of *depths* of the most probable parses of all messages in the evaluation sets.

3.5 Baselines

To ground our interpretation, we compare our induced grammars with three different language baselines that express different levels of structure. We provide a basic description here, more details can be found in Appendix D.1.

---

[3] `https://github.com/iesl/diora`

[4] `https://nlp.stanford.edu/software/GloVe-1.2.zip`

[5] `https://github.com/pld/BMM_labels/`

3.5.1 Random baseline

We compare all induced grammars with a grammar induced on a random language that has the same vocabulary and length distribution as the original language, but whose messages are sampled completely randomly from the vocabulary.

3.5.2 Shuffled baseline

We also compare the induced grammars with a grammar induced on languages that are constructed by *shuffling* the symbols of the emergent languages. The symbol distribution in these languages are thus identical to the symbol distribution in the languages they are created from, but the symbol *order* is entirely random.

3.5.3 Structured baseline

Aside from (semi)random baselines, we also consider a *structured baseline*, consisting of a grammar induced on languages that are similar in length and vocabulary size, but that are generated from a context-free grammar defining a basic hierarchy and terminal-class structure.[6] These structured baseline grammars indicate what we should expect if a relatively simple but yet hierarchical grammar would explain the emergent languages.

4 Suitability of induction techniques

As the grammar induction techniques we apply are defined for natural language, they are not trivially also suitable for emergent languages. In our first series of experiments, we therefore assess the suitability of the grammar induction techniques for our artificial scenario, evaluate to what extent the techniques are dependent on the exact sample taken from the training set, and we determine what is a suitable data set size for the induction techniques. The findings of these experiments inform and validate the setup for analysing the emergent languages in §5.

4.1 Grammars for structured baselines

We first qualitatively assess the extent to which CCL-BMM and DIORA-BMM are able to infer the correct grammars for the structured baseline languages described in the previous section. In particular, we consider if the induced grammars reflect the correct *word classes* defined by the preterminals, and if they capture the simple hierarchy defined on top of these word-classes.

Results We conclude that CCL-BMM is able to correctly identify all the unique word classes for the examined languages, as well as the simple hierarchy (for some examples of induced grammars, we refer to Appendix B). DIORA-BMM performs well for the smallest languages, but for the most complex grammar ($V = 27$, $L = 10$) it is only able to find half of the word classes and some of the word class combinations. We also observe that DIORA-BMM appears to have a bias for binary trees, which results in larger and less interpretable grammars for the longer fully structured languages. Overall, we conclude that both CCL-BMM and DIORA-BMM should be able to infer interesting grammars for our artificial setup; CCL-BMM appears to be slightly more adequate.

4.2 Grammar consistency and data size

As a next step, we study the impact of the induction set sample on the resulting grammars. We do so by measuring the *consistency* of grammars induced on different sections of the training data as well as grammars induced on differently-sized sections of the training data. We consider incrementally larger message pools of size $N = \{500, 1000, 2000, 4000, 8000\}$ by sampling from the $V27L10$ language with replacement according to the original message frequencies. From each pool we take the unique messages to induce the grammar. More details on this procedure and the resulting data sets can be found in Appendix C.

We express the consistency between two grammars as the F1-score between their parses on the same test data. We furthermore consider the GDL of the induced grammars, which we compare with a baseline grammar that contains exactly one prediction rule for each message. If the GDL of the induced grammar is not smaller than the GDL of this baseline grammar, then the grammar was not more efficient than simply enumerating all messages.

The experiments described above provide information about the sensitivity of the grammar induction techniques on the exact section of the training data as well as the size of the training data that is required to obtain a consistent result. We use the results to find a suitable data set size for the rest of our experiments.

Results Overall, the experiments show that CCL-BMM has higher consistency scores than DIORA-BMM, but also more variation between different

---

Figure 2: The consistencies for CCL-BMM (left) and DIORA-BMM (right) for language set $V27L10$. The axes show the message pool sizes (N) for inducing the compared grammars.

induction set sizes (see Figure 2). From the changing consistencies of CCL-BMM with increasing the number of messages, we conclude that differences in data-set size influence its grammar induction considerably. We believe that the low consistency scores of DIORA-BMM are due to the strongly stochastic nature of the neural parser.

For both CCL-BMM and DIORA-BMM, the evaluation set coverage increases with the induction set-size, although CCL-BMM reaches a near perfect coverage much faster than DIORA-BMM. Furthermore, the GDL implies a lower bound for the required induction set size, since the GDL is only smaller than its baseline for $N > 2000$ with CCL-BMM, while the crossover point is even larger for DIORA-BMM. More details on the progressions of the coverage and GDL can be found in the appendix in Figures C.1 and C.2 respectively.

To conclude, while a small induction set would suffice for CCL, we decide to use all messages of the induction set, because DIORA requires more data for good results, and we see no evidence that this impairs the performance of CCL-BMM.

5 Analysing emergent languages

Having verified the applicability of both CCL-BMM and DIORA-BMM, we use them to induce grammars for all languages described in §3.2. We analyse the induced grammars and parses, comparing with the structured, shuffled, and random baselines introduced in §3.5.

5.1 Grammar aptitude and compressibility

We first quantitatively evaluate the grammars, considering the description lengths and their evaluation and overgeneration coverage, as described in §3.4. As a general observation, we note that the GDL increases with the vocabulary size. This is not surprising, as larger vocabularies require a larger number of lexical rules and allow for more combinations of symbols, but indicates that comparisons across different types of languages should be taken with care.

5.1.1 L3 and L5

As a first finding, we see that little to no structure appears to be present in the shorter languages with messages of length 3 and 5: there are no significant differences between the emergent languages and the random and shuffled baseline (full plots can be found in the appendix, Figures D.1 and D.2). Some of the grammars for the emergent $L3$ languages and random baselines, however, have a surprisingly low GDL. Visual inspection of the trees suggests that this is due to the fact that the grammars approach a trivial form, in which there is only one pre-terminal X that expands to every lexical item in the corpus, and one production rule $S \rightarrow XXX$.[7] This result is further confirmed by the *coverages* presented in Table 2, which illustrates that the grammars for the $L3$ and $L5$ languages can parse not only all sentences in these languages, but also all other possible messages with the same length and vocabulary.

Interestingly, for DIORA-BMM, there are also no significant differences for the *structured* baselines. We hypothesise that this may stem from DIORA's inductive bias and conclude that for the analysis of shorter languages, CCL-BMM might be more suitable.

5.1.2 L10

In the $L10$ languages, we find more indication of structure. As can be seen in Figure 3, the emergent grammars differ all significantly from all baselines grammars ($p < .05$) and most strongly from the *random baseline* ($p < .001$). The GDL of the shuffled baseline grammar is in-between the language and random baseline grammar, suggesting that some regularity may be encoded simply in the frequency distribution of the symbols.

The average DDL of the $L10$ languages, however, also differs considerably from the baselines, but in the other direction: both the structured and the completely random baseline are much smaller than the emergent language DDL. An explanation for this discrepancy is suggested when looking at

---

[7] In the case of DIORA-BMM, it is a trivial *binary* tree $S \rightarrow AX$ and $A \rightarrow XX$.

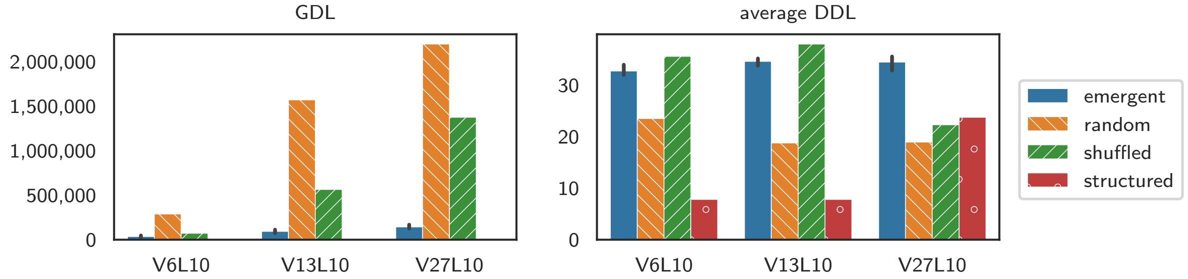

Figure 3: The grammar description lengths (GDL) and average data description lengths (DDL) for the CCL-BMM induced grammars with $L = 10$. The languages with $L = \{3, 5\}$ and the DIORA-BMM induced grammars are left out and can be found in Figures D.1 and D.2. The GDL of the *structured baseline* is too small to be seen.

their *coverages*. A good grammar has a high coverage on an independent evaluation set with messages from the same language, but a low coverage on a random sample of messages outside of the language (which we measure with *overgeneration coverage*, see §3.4). A perfect example of such a grammar is the CCL-BMM grammar inferred for the structured baseline, which has a coverage of 100% for the evaluation set but approximately 0% outside of it (see Table 2). For the $V13L10$ and $V27L10$ languages, we observe a similar pattern.

Coming back to the random languages, we can see that their grammars do not generalise to *any* message outside of their induction set. This result suggests that for these languages, the induction method resulted in a large grammar that keeps the DDL low at the expense of a larger GDL, by simply overfitting to exactly the induction set.

Concerning the coverage, another interesting finding is that the shuffled baseline often has a higher coverage than the random baseline. Combined with the generally higher average DDL, this suggests that the induction methods are less inclined to overfit the shuffled baselines. This might be explained by the regularities present in the shuffled messages through the frequencies of the symbols, as well as their co-occurrences within messages.

5.2 Nature of syntactic structure

The description lengths and coverage give an indication of whether there is *any* structure present in the languages, we finish with an explorative analysis of the *nature* of this structure. We focus our analysis on the $V13L10$ and $V27L10$ languages, which we previously found most likely to contain interesting structure.

		evaluation (%)		overgeneration (%)			
L	V	emerg.	struct.	emerg.	rand.	shuf.	struct.
3	6	100	100	100	100	100	0
	13	100	100	100	100	100	0
	27	100	100	100	100	100	0
5	6	100	100	100	100	100	0
	13	100	100	100	100	100	0
	27	100	100	100	100	100	0
10	6	100	100	78±2	0	94	0
	13	**98±1**	100	**3±1**	0	13	0
	27	**96±1**	100	**1±1**	0	0	0

Table 2: The average evaluation and overgeneration coverage for the CCL-BMM induced grammars. In bold we emphasise where we recognise a pattern of high evaluation coverage, but low overgeneration coverage. Standard deviations of < 0.5 for the emergent languages are left out.

5.2.1 Word class structure

We first examine if there is any structure at the lexical level, in the form of *word classes*. We consider the number of terminals per pre-terminal and vice versa. We will discuss the most important results here, the complete results can be found in the appendix, in Figure D.3.

A first observation is that in all grammars each symbol is unambiguously associated with only one pre-terminal symbol, indicating that there is no ambiguity with respect to the word class it belongs to. The number of terminals per pre-terminal suggests that our grammar induction algorithms also do not find many word classes: with some notable exceptions, every pre-terminal symbols expand only to a single terminal symbol. Interestingly, some of these exceptions overlap between CCL-BMM and DIORA-BMM (see Table 3), suggesting that they in fact are indicative of some form of lexical structure.

seed	CCL-BMM	DIORA-BMM
0	$\{14, \mathbf{16}, \mathbf{24}\}$	$\{\mathbf{16}, 19, \mathbf{24}\}$
1	$\{0, \mathbf{10}\}$	$\{\mathbf{10}, 22\}$
2	none	$\{0, 18\}$

Table 3: An overview of the captured word classes found in language $V27L10$ by CCL-BMM and DIORA-BMM. The overlap between the word-classes found by both setups is indicated in bold.

L	V	emergent	random	shuffled	structured
10	6	34.7 ±0.9	36.0	36.0	2.0*
	13	78.7 ±6.0	169*	137*	2.0*
	27	192 ±65	441*	262	2.0

Table 4: The number of unique *pre-terminal groups* in the CCL-BMM induced grammars for $L = 10$. A pre-terminal group constitutes the right-hand side of a production rule leading only to pre-terminals or symbols. An asterisk (*) indicates a significant difference with the baseline value (p < .05).

5.2.2 Higher level structure

We next check if the trees contain structure one level above the pre-terminals, by computing if pre-terminals can be grouped based on the non-terminal that generates them (e.g. if there is a rule $K \rightarrow A\ B$ we say that *K* generates the group *A B*). Specifically, we count the unique number of *pre-terminal groups*, defined by each right-hand side consisting solely of pre-terminals and symbols. If there is an underlying linguistic structure that prescribes which pre-terminals belong together (and in which order), it is expected that fewer groups are required to explain the messages than if no such hierarchy were present. Indeed, the number of *pre-terminal groups* (see Table 4) shows this pattern, as we discover a significantly smaller number of groups than the random baseline. These results thus further confirm the presence of structure in the $V13L10$ and $V27L10$ languages.

As a tentative explanation, we would like to suggest that perhaps the symbols in the emergent languages are more akin to characters than to words. In that case, the pre-terminal groups would represent the words, and the generating non-terminals the word-classes. For both CCL-BMM and DIORA-BMM, the average number of pre-terminal groups generated by these non-terminals is $2.4\pm < 0.01$ for the emergent languages, while it is 1.0 for the shuffled and random baselines. This suggests that the pre-terminal groups share in syntactic function. Such observations could form a fruitful basis for further semantic analysis of the languages.

5.2.3 Recursion

Lastly, we would like to note the lack of recursive production rules in nearly all induced grammars. While this is not surprising given both the previous results as well as the simplicity of the meaning space, it does suggest that perhaps more interesting input scenarios are required for referential games.

5.3 CCL vs DIORA

We ran all our experiments with both CCL-BMM and DIORA-BMM. There were similarities, but also some notable differences. Based on the GDL, CCL-BMM seems more suitable to analyse shorter languages, but earlier tests with reconstructing the structured baseline grammars (see §4.1) suggest that DIORA-BMM also performs worse on languages with a *larger* message length and vocabulary size; leading us to believe that CCL-BMM is more appropriate for our setup.

Another difference concerns the distribution of the tree depths, which reflects mostly skewed and binary trees for CCL-BMM for $L = 10$, but more evenly distributed depths for DIORA-BMM (for a plot of the depth distributions, we refer to D.4). An example of this difference is shown in Figure 4. A possible explanation is that CCL-BMM is more biased towards fully right-branching syntax trees, since these are a good baseline for natural language. Alternatively, these trees might actually reflect the emergent languages best, perhaps because of the left-to-right nature of the agents' LSTMs. Additional work is required to establish which type of trees better reflect the true structure of the emergent languages.

6 Conclusion

While studying language and communication through *referential games* with *artificial agents* has recently regained popularity, there is still a very limited amount of tools available to facilitate the analysis of the resulting emergent languages. As a consequence, we still have very little understanding of what kind of information these languages encode. In this paper, for the first time, we focus on *syntactic* analysis of emergent languages.

We test two different unsupervised grammar induction (UGI) algorithms that have been successful for natural language: a pre-neural statistical one, CCL, and a neural one, DIORA. We use them to

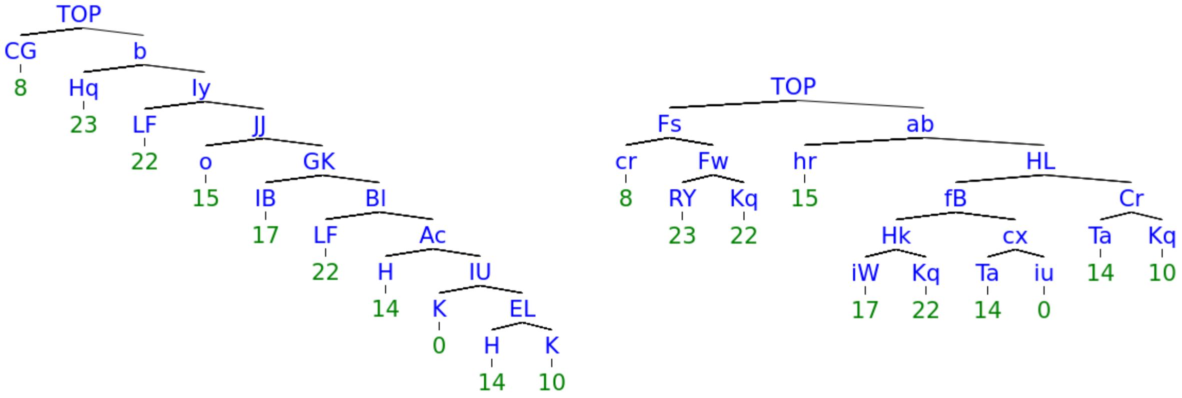

Figure 4: Example parse trees from the same $V27L10$ evaluation set by a CCL-BMM (left) and DIORA-BMM (right) induced grammar. It should be noted that this is one of the few exceptions for $L = 10$ where some symbols share a pre-terminal.

infer grammars for a variety of languages emerging from a simple referential game and then label those trees with BMM, considering in particular the effect of the message length and vocabulary size on the extent to which structure emerges.

We first confirm that the techniques are capable of inferring interesting grammars for our artificial setup and demonstrate that CCL appears to be a more suitable constituency parser than DIORA. We then find that the shorter languages, with messages up to 5 symbols, do not contain any interesting structure, while languages with longer messages appear to be substantially more structured than the two random baselines we compare them with. Interestingly, our analysis shows that even these languages do not appear to have a notion of *word classes*, suggesting that their symbols may in fact be more akin to *letters* than to words. In light of these results, it would be interesting to explore the use of unsupervised tokenisers that work well for languages without spaces (e.g. SentencePiece Kudo and Richardson, 2018) prior to our approach and to try other word embedding models for DIORA, such as the *character*-based ELMo embeddings[8] (Peters et al., 2018) or the more recent BERT (Devlin et al., 2019).

Our results also suggest that more sophisticated game scenarios may be required to obtain more interesting structure. UGI could provide an integral part in analysing the languages emerging in such games, especially since it – contrary to most techniques previously used for the analysis of emergent languages – does not require a description of the hypothesised semantic content of the messages. Examples of more sophisticated game scenarios are bidirectional conversations where multi-symbol messages are challenging to analyse (Kottur et al., 2017; Bouchacourt and Baroni, 2019) or games with image sequences as input (Santamaría-Pang et al., 2019).

We argue that while the extent to which syntax develops in different types of referential games is an interesting question in its own right, a better understanding of the syntactic structure of emergent languages could also provide pivotal in better understanding their *semantics*, especially if this is considered from a compositional point of view. To facilitate such analysis, we bundled our tests in a comprehensive and easily usable evaluation framework.[9] We hope to have inspired other researchers to apply syntactic analysis techniques and encourage them to use our code to evaluate new emergent languages trained in other scenarios.

A Definition of the referential game

The languages emerge from two agents playing a referential game with a setup similar to Havrylov and Titov (2017). In each round of the game, the sender samples a message m describing the target image t to the receiver. m consists of up to L symbols sampled from a vocabulary with size V.[10] The receiver has to identify the described image from a set with t and three other distracting images in random order. The images are created by generating a shape with a certain colour and size, on a logical grid. In the game, two images are the same if they have the same colour, shape, and size, even when differently positioned. Table A.1 provides an overview of the agents' architectures used in this game.

LSTM	Embedding size	256
	Hidden layer size	512
CNN	# of convolutional layers	5
	# of filters	20
	Kernel size	3
	Stride	2
	No padding	
	Activation function	ReLU

Table A.1: Parameters for the sender and receiver architecture. The convolutional layers are followed by batch normalisation.

B Fully structured languages

For all the configurations of L and V of our emergent languages (see §3.2), we create a simple grammar containing word classes, each with a disjoint set of symbols. Furthermore, two pre-terminals form a group that can be placed either at the beginning or the end of the message or both, while the other pre-terminals occupy the remaining spots in fixed order. The smaller grammars repeat word classes to ensure enough messages for the induction and evaluation.

All the possible messages are randomly divided over a induction and evaluation set (80% and 20% respectively). Table B.1 provides more details on the data sets used for each language configuration.

L	V	total	induction	evaluation
3	6	16	12	4
	13	160	128	32
	27	1458	1166	292
5	6	24	19	5
	13	378	302	76
	27	15480	2000	500
10	6	24	19	5
	13	32	25	7
	27	52488	2000	500

Table B.1: An overview of the total number of possible messages that can be generated for each L and V configuration, as well as the sizes of the induction and evaluation sets. The size of the induction set is capped at 2000 to keep the grammar induction computationally feasible. When evaluating the grammars a maximum number of 500 messages of either set is used.

B.1 Example grammars

In the following examples, `TOP` denotes the start symbol, `NP` the pre-terminal group, and the numbers the terminals that represent the symbols in the generated messages.

The structured baseline grammar for $V = 13$ and $L = 5$ is represented as:

```
TOP -> NP AP
TOP -> AP NP
TOP -> NP VP NP
NP  -> A B
AP  -> E C D
VP  -> E
A   -> 0 | 1 | 2
B   -> 3 | 4 | 5
C   -> 6 | 7 | 8
D   -> 9 | 10
E   -> 11 | 12
```

The resulting CCL-BMM induced grammar is:

```
TOP -> H E A
TOP -> A G
G   -> H A | H E
E   -> B F
A   -> C D
C   -> 0 | 1 | 2
D   -> 3 | 4 | 5
B   -> 6 | 7 | 8
F   -> 9 | 10
H   -> 11 | 12
```

and DIORA-BMM finds:

```
TOP -> K A
TOP -> L D
TOP -> B J
TOP -> N H
TOP -> J B
E -> C K
A -> O D | F H | D J
G -> B C | K F
O -> F K | D E
F -> D C
H -> M I
L -> J K | B E | G K | K O
B -> K D
J -> E D | C B | C H
```

---

[10] Technically, the vocabulary also contains a *stop character* and the sender is allowed to generate messages shorter than L. However, typically the messages have a length of L. For the analyses in this paper we have removed all stop characters in a pre-processing step and we do not count it as part of L and V.

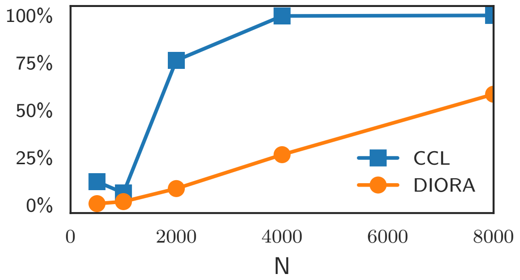

Figure C.1: Average evaluation coverage of the CCL-BMM and DIORA-BMM induced grammars ($V27L10$) against the induction pool size N.

```
N -> K F
K -> 0 | 1 | 2
D -> 3 | 4 | 5
M -> 6 | 7 | 8
I -> 9 | 10
C -> 11 | 12
```

C Consistency and suitable data set size

The number of messages in the induction set might influence the properties of the grammars induced from it. To investigate these effects, we perform induction experiments on different sub-samples of the language $V27L10$. We compare the induced grammars on their consistency and study the progression of the evaluation coverage and GDL.

The consistency of a setup is computed on different samples of a data set to study the effect of the data set size as well as to show how dependent the algorithm is on the exact selection of induction messages. We create incrementally larger pools by sampling a fixed number of randomly selected messages from the data-set, resulting in pool sizes $N = \{500, 1000, 2000, 4000, 8000\}$. The messages are sampled with replacement according to the frequency in the original language. From these pools we then only consider the unique messages. The procedure is repeated three times for each N to obtain an average consistency.

Subsequently, we study the average evaluation coverage and GDL for these grammars. The resulting progression of the evaluation coverage is shown in Figure C.1. The coverage is evaluated with respect to the disjoint set consisting of 10% of the language's messages. We study the GDL against the number of messages compared to the baseline grammar of one production rule for each message in the induction set in Figure C.2.

L	V	shuffled	random
3	6	147	150
	13	358	396

	27	9112	8986

Table D.1: Number of messages per language for the shuffled and random baseline.

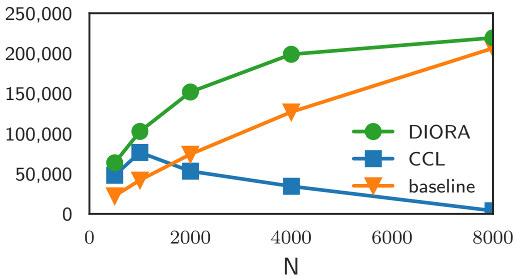

Figure C.2: Progression of the average GDL of the induced grammars ($V27L10$) compared to the baseline grammar of one production rule for each message.

D Analysing emergent languages

Here we present a complete overview of the results from analysing the languages in §5. To aid in interpreting the different metrics, we compare these with several baselines. To test for significance, we report the p-values from a *one-sample t-test*, where the baseline value is assumed to be the population mean.

D.1 Baselines

The *shuffled baselines* are constructed by randomly shuffling the messages of the *induction set* for a randomly selected seed, such that they are unique in the shuffled set. We create the *random baselines* by randomly sampling the same number of unique messages as the *induction set*, also for one seed. See Table D.1 for the number of messages used for each baseline per language.

D.2 Description lengths

Tables D.2, D.3, and D.4 give an overview of the description lengths for the induction sets, the evaluation sets, and their ratios, respectively. The description lengths are also visualised in Figures D.1 and D.2.

D.3 Coverage

We show the evaluation and overgeneration coverage in Table D.5.

D.4 Nature of syntactic structure

Table D.6 gives an overview of the total number of unique pre-terminals and terminals in the induced grammars. We show the average number of preterminals per terminal in Table D.8 and Figure D.3. The average number of pre-terminals per terminal is one for every language and baseline, and is therefore omitted. The number of pre-terminal groups and the number of non-terminals generating these groups are presented in Table D.7.

D.5 Parse tree distributions

In Figure D.4 we show the parse tree distributions. For the CCL induced $L3$ grammars, we see all depths are 1, while for DIORA all depths are 2. A parse depth of 1 indicates a flat grammar, without hierarchical structure. The depth of 2 reflects the bias of DIORA towards binary trees.

The $L5$, and especially $L10$, grammars show deeper trees, often the maximum tree depth, which would mean binary skewed trees. DIORA shows more variation in the tree depth distributions.

Abstract

Vision-and-language navigation requires an agent to navigate through a real 3D environment following natural language instructions. Despite significant advances, few previous works are able to fully utilize the strong correspondence between the visual and textual sequences. Meanwhile, due to the lack of intermediate supervision, the agent's performance at following each part of the instruction cannot be assessed during navigation. In this work, we focus on the granularity of the visual and language sequences as well as the traceability of agents through the completion of an instruction. We provide agents with fine-grained annotations during training and find that they are able to follow the instruction better and have a higher chance of reaching the target at test time. We enrich the benchmark dataset Room-to-Room (R2R) with sub-instructions and their corresponding paths. To make use of this data, we propose effective sub-instruction attention and shifting modules that select and attend to a single sub-instruction at each time-step. We implement our sub-instruction modules in four state-of-the-art agents, compare with their baseline models, and show that our proposed method improves the performance of all four agents.

We release the Fine-Grained R2R dataset (FGR2R) and the code at `https://github.com/YicongHong/Fine-Grained-R2R`.

1 Introduction

Creating an agent that can navigate through an unknown environment following natural language instructions has been a dream of human-beings for many years. Such an agent needs to possess the ability to perceive its environment, understand the instructions and learn the relationship between these two streams of information. Recently, Anderson et al. (2018b) proposed the vision-and-language navigation (VLN) task that formalized such requirements through an evaluation of an agent's ability to follow natural language instructions in photo-realistic environments.

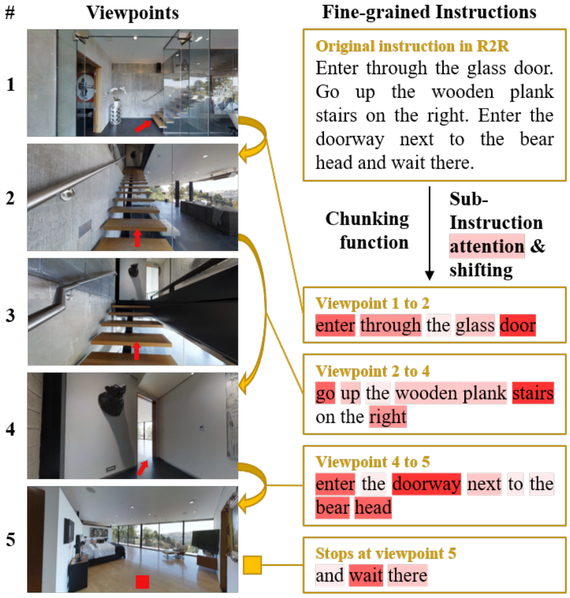

Figure 1: Visual navigation with sub-instruction and sub-path pairs. We enrich the R2R dataset by providing fine-grained matching between sub-instructions and viewpoints along the ground-truth path.

Despite the significant progress made by recent approaches, there is little evidence that agents learn the correspondence between observations and instructions. Hu et al. (2019) found that a modified self-monitoring agent (Ma et al., 2019a), could achieve similar performance with (success rate 40.5%) and without (success rate 39.7%) visual information. Among other reasons, such as dataset bias, the result suggests that this agent gains little from having the two streams of information.

We argue that one of the main reasons be-

hind this is that current methods are not adequately teaching agents the relationship between perception—things that the robot is observing—and parts of the instructions. Since datasets do not provide such information agents can only use the ground-truth trajectory as a learning signal. Moreover, given the lack of fine-grained annotation, current methods cannot evaluate the (perceptual or linguistic) grounding process at each step as there is no ground truth signal to indicate which part of the instruction has been completed.

To address this problem, we enhance the R2R dataset (Anderson et al., 2018a) to acquire intermediate supervision for the agents, providing a fine-grained matching between sub-instructions and the agent's visual perception, as illustrated in Figure 1, to produce our Fine-Grained Room-to-Room dataset (FGR2R). We argue that the granularity of the navigation task should be at the level of these sub-instructions, rather than attempting to ground a specific part of the original long and complex instruction without any direct supervision or measure navigation progress at word level.

Our work aims to make the navigation process traceable and encourage the agent to run precisely on the described path rather than just focusing on reaching the target. We hypothesize that the agent should reach the target with higher success rate by following a detailed instruction with richer information, and in practice, the agent could complete some additional tasks on its way to the target.

In light of this, we propose a novel sub-instruction attention mechanism to better learn the correspondence between visual features and language features. Our agent first segments the long and complicated instruction into short and easier-to-understand sub-instructions using a heuristic method based on the grammatical relations provided by the Stanford NLP Parser (Qi et al., 2018). Moreover, we propose a shifting module that infers whether the current sub-instruction has been completed. Hence, only one sub-instruction is available to the agent at each time step for textual grounding. These modules can be easily applied to previous VLN models.

We conduct experiments to compare the performance of four state-of-the-art agents to evaluate with or without our sub-instruction module, for agents based on imitation learning (Anderson et al., 2018b; Fried et al., 2018; Ma et al., 2019a) and reinforcement learning (Tan et al., 2019). Analyzing the results we find that the intermediate supervision and our proposed modules help the agents to better follow the instructions. Furthermore, we demonstrate the traceability of the navigation process through qualitative and quantitative analysis.

2 Related Work

Visual and textual grounding. Visual grounding aims to infer the relationship between a text description and a spatial or temporal region in an image or video, respectively. It is an essential component for a variety of tasks in vision-and-language research such as visual question answering (VQA) (Schwartz et al., 2017; Anderson et al., 2018a; Hudson and Manning, 2019), image captioning (Xu et al., 2015; Anderson et al., 2018a; Cornia et al., 2019; Ma et al., 2020), video understanding (Gao et al., 2017; Ma et al., 2018; Rodriguez et al., 2020) and phrase localization (Engilberge et al., 2018; Yu et al., 2018). In the case of vision-and-language navigation, at each navigational step, the agent attends to the relevant part of the instruction according to visual clues to direct the future action. Meanwhile, the agent attends the visual inputs at different directions as described by text to perceive the environment (Fried et al., 2018; Ma et al., 2019a).

Vision and language navigation. Anderson et al. (2018b) formalized the vision-and-language navigation task in a photo-realistic environment, and proposed a benchmark Room-to-Room (R2R) dataset and a sequence-to-sequence agent as a baseline model. Other datasets in real environments, such as R4R (Jain et al., 2019), which is an extended version of R2R with longer instruction-path pairs, and Touchdown (Chen et al., 2019) for navigation on streets have also been proposed for study.

Researchers have addressed the R2R task through a great variety of approaches. Wang et al. (2018) propose a look-ahead model that combines model-based and model-free reinforcement learning, predicts the agent's next state and reward during navigation. Fried et al. (2018) proposed the Speaker-Follower model which generates augmented samples for training and makes use of the panoramic action space to ground and navigate efficiently. Later, Ma et al. (2019a) introduced the Self-Monitoring agent which includes a vision and language co-grounding network and a progress monitor. The progress monitor estimates a normalized distance to the target and guides the transition of the textual attention. Wang et al. (2019) applied the REINFORCE algorithm (Williams, 1992) to improve the agent's generalizability and proposed a Self-Supervised Imitation Learning (SIL) method to facilitate lifelong learning in a new environment. The Back Translation agent (Tan et al., 2019) applied the A2C algorithm (Mnih et al., 2016) and made use of a speaker module with environmental dropout for data augmentation. Landi et al. (2019) applied dynamic convolutional filters for image feature extraction for low-level grounding of visual inputs and Hu et al. (2019) grounded multiple modalities using a mixture-of-experts approach and applied joint training strategy. Besides, the Regretful agent (Ma et al., 2019b) and the Tactical Rewind agent (Ke et al., 2019) are models which focus on path-scoring and backtracking methods. Very recently, Zhu et al. (2020a) introduces multiple auxiliary losses in training to help exploring the semantic meaning of visual features, Huang et al. (2019) and Hao et al. (2020) apply pre-trained encoders to generate generic visual and textual representations for the agent.

In contrast to all previously mentioned methods that ground the complete instruction, we propose to divide the instruction into meaningful semantic sub-instructions, and teach the agent to complete each one at a time before reading the next sub-instruction. In that spirit, our method is similar to the image captioning work by Cornia et al. (2019). They design a shifting gate over the image regions to control the visual features that feed into each time step of the caption module. We differ from their work in the modality that is attended. Our method works in the language domain, and the shifting depends only on local context rather than looking over all the sub-instructions. BabyWalk (Zhu et al., 2020b) is a concurrent work to ours, it uses sub-instructions for curriculum learning which trains the agent to complete shorter navigation tasks before trying to solve the longer ones. Comparing the sub-instruction and sub-path pairs in FGR2R and BabyWalk, BabyWalk aligns the textual and visual sequences by solving a dynamic programming problem, whereas FGR2R employs human annotation, which is more fine-grained and accurate.

3 Sub-instruction Aware VLN

In this section, we first introduce the VLN problem and the general architecture of the agent. Then, we discuss about the proposed chunking function for producing the sub-instructions and the novel sub-instruction module for enabling sub-instruction attention and transition.

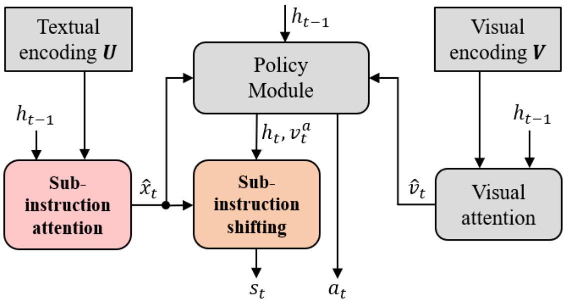

Figure 2: Our sub-instruction attention and shifting modules built into the self-monitoring agent pipeline. We replace the original textual attention module with our sub-instruction modules that select and attend a single sub-instruction at each time-step.

The VLN task requires the agent to navigate through a real environment to a target location following a natural language instruction. Formally, an instruction $\boldsymbol{w}$ is a sequence of words $\langle w_1, w_2, \ldots, w_l \rangle$ provided to the agent at the beginning of its navigation, where w_i denotes the i-th word in the sequence. The environment is defined as set of viewpoints $\{p_j\}$ denoting all the navigable locations. At time step t, the agent at viewpoint p_t receives a panoramic view $\boldsymbol{V}_t$ composed of n single view images $\langle \boldsymbol{v}_{t,1}, \boldsymbol{v}_{t,2}, \ldots, \boldsymbol{v}_{t,n} \rangle$. Using the given instruction $\boldsymbol{w}$ and the current observation $\boldsymbol{V}_t$, the agent needs to infer an action a_t which triggers a transition signal from p_t to p_{t+1}. The episode ends when the agent output a $STOP$ action or the maximum number of steps allowed is reached.

3.1 Base Agent Model

We build our sub-instruction module based on the current state-of-the-art VLN agents, as shown in Figure 2. Those agents share a similar pipeline, a sequence-to-sequence architecture with textual and visual attentions. In this section, we refer to the Self-Monitoring Agent (Ma et al., 2019a) to present the flow of information in the network.

Visual and textual encoding. Before the start of navigation, the agent first encodes the given instruction, using an LSTM with a learned embedding as $\hat{\boldsymbol{w}}_j$= Embed(w_j) and $\boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_l$= LSTM$(\hat{\boldsymbol{w}}_1, \hat{\boldsymbol{w}}_2, \ldots, \hat{\boldsymbol{w}}_l)$, where $\boldsymbol{u}_j$ is the hidden state of word w_j in the instruction. In the case of the panoramic view, the agent encodes the images using a ResNet-152 model (He et al., 2016) pre-trained on ImageNet (Russakovsky et al., 2015) for each navigable direction. A 4-dimensional vector $[\sin\psi, \cos\psi, \sin\theta, \cos\theta]$ is concatenated with the image encoding to represent the direction of visual features, where ψ and θ are the heading and elevation angles, respectively.

Policy module and co-grounding. We define the agent's state at time t as a combination of the attended textual representation $\hat{\boldsymbol{u}}_t$, the attended visual representation $\hat{\boldsymbol{v}}_t$ and the previous selected action $\boldsymbol{a}_{t-1}$, encoded by an LSTM as

$$\boldsymbol{h}_t, \boldsymbol{m}_t = \text{LSTM}([\hat{\boldsymbol{v}}_t; \boldsymbol{a}_{t-1}], (\hat{\boldsymbol{u}}_t, \boldsymbol{m}_{t-1})). \quad (1)$$

We refer to $\boldsymbol{h}$ and $\boldsymbol{m}$ as the agent's state and memory, respectively.

The attended textual representation is obtained by performing soft-attention over the language features $\boldsymbol{U}$=$\langle \boldsymbol{u}_1, \boldsymbol{u}_2, \ldots, \boldsymbol{u}_l \rangle$ with the agent's state at the previous time step. The attention weights over all the words are calculated as $z^{\text{text}}_{t,j}$=$(\boldsymbol{W}_u \boldsymbol{h}_{t-1})^T \boldsymbol{u}_j$ and $\boldsymbol{\alpha}_t$= Softmax($\boldsymbol{z}^{\text{text}}_t$), obtaining the attended textual representation by $\hat{\boldsymbol{u}}_t$=$\boldsymbol{\alpha}_t{}^T \boldsymbol{U}$. Similarly, we perform soft-attention over the single-view visual features $\boldsymbol{V_t}$ as $z^{\text{vis}}_{t,i}$=$(\boldsymbol{W}_v \boldsymbol{h}_{t-1})^T g(\boldsymbol{v}_{t,i})$ where $g(\cdot)$ is a multi-layer perceptron (MLP), and the attention weight $\boldsymbol{\beta}_t$= Softmax($\boldsymbol{z}^{\text{vis}}_t$). The attended visual representation is $\hat{\boldsymbol{v}}_t$=$\boldsymbol{\beta}_t{}^T \boldsymbol{V_t}$. The previous selected action $\boldsymbol{a}_{t-1}$ is represented by the visual features at the previously selected action direction. Finally, the agent decides an action by finding the visual features at a navigable direction with the highest correspondence to the attended language features $\hat{\boldsymbol{u}}$ and the agent's current state $\boldsymbol{h}_t$. The probability at each navigable direction is computed as:

$$o_{t,i} = (\boldsymbol{W}_a [\boldsymbol{h}_t, \hat{\boldsymbol{u}}_t])^T g(\boldsymbol{v}_{t,i}) \qquad (2)$$

and

$$\boldsymbol{p}_t = \text{Softmax}(\boldsymbol{o}_t) \qquad (3)$$

where $g(\cdot)$ is the same MLP as in visual attention for feature projection. Then, the agent moves in a panoramic action space (Fried et al., 2018), so that it jumps directly to an adjacent viewpoint in the selected direction.

All baseline agents in our experiments are variants of this pipeline. For instance, the Speaker-Follower agent (Fried et al., 2018) encodes the agent's state with only the previous action and the attended visual features. In the case of the Back-Translation agent (Tan et al., 2019), it attends the language features by the agent's current state.

3.2 Chunking

To encourage the learning of vision and language correspondences, we provide short and easier-to-learn sub-instructions to the agent at each time step. Formally, for each instruction $\boldsymbol{w}$, there exists a set of sub-instructions $\boldsymbol{X}$=$\langle \boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_L \rangle$, where $\boldsymbol{x}_i$=$\langle w_j \rangle$ and L is the total number of sub-instructions. The sub-instructions are ordered, mutually exclusive and cover the entire $\boldsymbol{w}$.

We propose a chunking function to break the original instruction into several sub-instructions, where each sub-instruction is an independent navigation task and usually requires the agent to perform one or two actions to complete. To achieve this automatically, we design chunking rules based on the grammatical relations between words in the instruction, where the relations are produced by the Stanford NLP Parser (Qi et al., 2018), a pre-trained natural language analysis tool. First, we pass the entire instruction into the StanfordNLP Parser for extracting the *dependency* and the *governor* of each word, denoted as $\eta(w_j)$ and $\rho(w_j)$, respectively. Then, using the two attributes, we formulate a heuristic as shown in Algorithm 1.

Algorithm 1 Chunking Function

```
Initialize empty lists $l_{conj}$, $l_x$, $l_\eta$, $l_{\boldsymbol{X}}$. Count $k = 0$.
# Find index of the word that satisfies condition (2)
for $w_j$ in $\boldsymbol{w}$ do
    if $\eta(w_j)$ is conj && $\rho(w_j)$ is 1 then
        Save word index $j$ into $l_{conj}$
    end if
end for
for $w_j$ in $\boldsymbol{w}$ do
    # Condition (1)
    if $\eta(w_j)$ is root && (root in $l_\eta$ or parataxis in $l_\eta$) then
        $l_{\boldsymbol{X}} \leftarrow$ Check($l_x$)
        # Condition (2)
    else if $k \leq$ len($l_{conj}$) $- 1$ && $\rho(w_j)$ is $l_{conj}[k]$ then
        $l_{\boldsymbol{X}} \leftarrow$ Check($l_x$), $k = k + 1$
        # Condition (3)
    else if $\eta(w_j)$ is parataxis && (root in $l_\eta$ or parataxis in $l_\eta$) then
        $l_{\boldsymbol{X}} \leftarrow$ Check($l_x$)
        # Save the word into temporary chunk
    else if $\eta(w_j)$ is not punct then
        Save $w_j$ into $l_x$, save $\eta(w_j)$ into $l_\eta$
    end if
end for
```

The chunking function considers words in the instruction that meet one of the following three conditions as the beginning of a new sub-instruction: (1) its dependency is `root` and all the words before belong to the previous chunk, (2) its dependency is `conj` and its governor is the previous `root`, (3) its dependency is `parataxis` and all the words before belong to the previous chunk. If any one of the three conditions is met, a **Check**$(\cdot)$ function will be performed on the temporary chunk to decide whether to save the temporary chunk into the final sub-instruction list $l_{\boldsymbol{X}}$. Here, the **Check**$(\cdot)$ function examines if the temporary chunk meets two conditions: (1) the chunk length should exceed the minimum length of two words, and (2) the temporary chunk should not only contains a single action-related phrase which is following the previous chunk or is leading the next chunk (e.g. "*go straight then ...*"), if it happens, then the temporary chunk should be appended to the previous chunk or added to the next chunk respectively.

We provide an illustrative example here. Our chunking function breaks the given instruction "*Enter through the glass door. Go up the wooden plank stairs on the right. Enter the doorway next to the bear head and wait there.*" into $\boxed{1}$ "*Enter through the glass door*", $\boxed{2}$ "*Go up the wooden plank stair on the right*", $\boxed{3}$ "*Enter the doorway next to the bear head*" and $\boxed{4}$ "*And wait there*", as shown in Figure 1. In the third and the fourth sub-instructions, the words "Enter" and "Wait" satisfy the conditions (1) and (2), respectively. Notice that the *governor* of conjunction word "And" is "Wait", so it has been assigned to the fourth sub-instruction.

3.3 Sub-Instruction Module

To encourage the agent to learn the correspondence between visual and language features in a sub-instruction, we modify the base agents to include a sub-instruction module, which enables the agent to focus on a particular sub-instruction at each time step, as shown in Figure 2. It contains two main components: the sub-instruction attention and the sub-instruction shifting module.

Sub-instruction attention. The module attends the words inside the selected sub-instruction $\boldsymbol{x}_i$ through a soft-attention mechanism. Formally, at each time step, we calculate the distribution of weights over each word in $\boldsymbol{x}_i$ as:

$$\begin{aligned} z_{t,j}^{\text{text}} &= (\boldsymbol{W}_u \boldsymbol{h}_{t-1})^T \boldsymbol{x}_{i,j}, \\ \boldsymbol{\alpha}_t &= \text{Softmax}(\boldsymbol{z}_t^{\text{text}}) \end{aligned} \tag{4}$$

where $\boldsymbol{h}_{t-1}$ is the previous state of the agent and $\boldsymbol{W}_u$ is the learned weights. The grounded representation of the sub-instruction is hence $\hat{\boldsymbol{x}}_i = {\boldsymbol{\alpha}_t}^T \boldsymbol{x}_i$.

With the sub-instruction attention, the agent is forced to attend the most relevant part of the instruction and prevent the agent from "getting distracted" by the other part of the instruction that has been completed or to be completed in the further steps.

Sub-instruction shifting. At each time step, the agent needs to decide whether the current sub-instruction will be completed by the next action or not. We enable this functionality by designing a shifting module that estimates the probability of proceeding to the next sub-instruction.

The module uses a recurrent neural architecture to encode a representation that reflect the vision and language co-grounded features:

$$\boldsymbol{h}_t^c = \sigma(\boldsymbol{W}_{c1}[\boldsymbol{W}_{c0}(\boldsymbol{h}_t), \boldsymbol{v}_t^a, \hat{\boldsymbol{x}}_i]) \odot \tanh(\boldsymbol{m}_t) \tag{5}$$

where $\boldsymbol{h}_t$ and $\boldsymbol{m}_t$ is the agent's current state and memory, $\boldsymbol{v}_t^a$ is the visual feature at the selected action direction, σ represents a sigmoid function, $\boldsymbol{W}_{c1}$ and $\boldsymbol{W}_{c0}$ are the learned weights and $\odot$ denotes the Hadamard product.

The module then computes the shifting probability from $\boldsymbol{h}_t^c$ and a one-hot encoding $\boldsymbol{e}_t$ of the number of sub-instructions left to be completed, as:

$$p_t^s = \sigma(\boldsymbol{W}_{c2}[\boldsymbol{W}_{c3}(\boldsymbol{e}_t), \boldsymbol{h}_t^c]) \tag{6}$$

where $\boldsymbol{W}_{c2}$ and $\boldsymbol{W}_{c3}$ are the learned parameters. Here, $\boldsymbol{e}_t$ introduces a learnable prior on when to shift before viewing the scene. This prior is then modified by taking into account the visual evidence, which is essential for efficient navigation. If the shifting probability exceed a certain threshold, a shift signal $s_t{=}1$ ($s_t{\in}\{0,1\}$) of reading the next sub-instruction will be produced. We only enable the module to do a single step uni-directional shifting, which agrees with the fact that instructions and trajectory in the R2R dataset are monotonically aligned.

3.4 Training

In the training stage, for each instruction $\boldsymbol{w}$, there exists a corresponding ground-truth path $\boldsymbol{p}_g = \langle p_{g(1)}, p_{g(2)}, ..., p_{g(M)} \rangle$. In the case of sub-instructions, we partition the path into sub-paths, one for each sub-instruction.

The binary cross-entropy loss compares the estimated shifting probabilities p_t^s to the target shifting signals y_t^s, where the target is either 1 or 0 depending on the distance between the agent's current position and the ending viewpoint of the current sub-path. In summary, the agent's parameters are learned to optimized

$$\mathcal{L} = -\sum_t y_t^a \log p_t^a - \sum_t y_t^s \log p_t^s + (1 - y_t^s) \log(1 - p_t^s) \quad (7)$$

where p_t^a is the predicted action, y_t^a and y_t^s are the ground-truth action and shifting signal respectively at time step t.

During training, we apply student-forcing supervision to the action to encourage exploration, but use teacher-forcing for the sub-instruction shifting (Williams and Zipser, 1989; Anderson et al., 2018b). In early stages of training, the ground-truth shifting signal will have a large number of zeros since the agent has a high probability of deviating from the desired path. We prevent the sub-instruction shifting module from converging to an undesirable local minimum by forcing the shifting loss to consider an equal number of randomly selected shift and do-not-shift samples in each time step.

4 The FGR2R Dataset

To acquire the matching between vision and language sub-sequences, we introduce a Fine-Grained Room-to-Room (FGR2R) dataset which enriches the benchmark Room-to-Room dataset by dividing the instructions into sub-instructions and pairing each of those with their corresponding viewpoints in the path.

Dataset collection. We first apply the chunking function introduced in Section 3.2 to generate the sub-instructions automatically from the original R2R data. We demonstrate the quality of the generated sub-instructions by comparing the output sub-instructions against a manually annotated subset of 300 samples, obtaining a smoothed BLEU-4 score of 0.84. Then, we add annotations of sub-path corresponding to each sub-instruction using the Amazon Mechanical Turk (AMT)[2]. We refer the readers to Appendix A.1 for more information about the data collection interface and the qualification process of the annotators that we designed to ensure the quality of the collected data.

Dataset statistics. The original R2R possesses 21,567 navigation instructions and 7,189 paths in 91 real-world environments, where 3 or 4 different natural language instructions describe each path. The R2R data has been split for learning proposes, with 4,675 paths for training and 340 paths for seen validation in 61 scenes, 783 paths in 11 scenes for unseen validation and the remaining 1,391 paths in 18 scenes for testing[3]. Based on the original R2R data, FGR2R divides the instructions for the training and validation set in an average of 3.6 sub-instructions. Each sub-instruction has 7.2 words on average. Sub-instructions are paired on average 2.4 viewpoints, and with a minimum and maximum of 1 and 7 viewpoints, respectively. We refer the readers to Appendix A.1 for more dataset statistics.

5 Experiments

5.1 Experiment Setup

We experiment with four state-of-the-art VLN agents with and without our sub-instruction module and compare their performance on the original R2R validation unseen split.

The agents are chosen to include the most common network architectures, training strategies and inference methods among the previous VLN agents. They include the Sequence-to-Sequence (Seq2Seq) (Anderson et al., 2018b) model which does not apply panoramic action space, two visual-textual co-grounding models, the Speaker-Follower (Fried et al., 2018) and the Self-Monitoring agent (Ma et al., 2019a), as well as the Back-Translation model (Tan et al., 2019) which applies reinforcement learning. For all agents, we implement our sub-instruction module in their network based on their officially released code. For the self-monitoring agent, we remove the progress monitor since it requires the attention weight over the entire instruction for estimating the navigation progress.

Implementation details. To obtain the word representations in each sub-instruction, the entire instruction is first passed to a unidirectional LSTM, then we implement chunking on the language hidden states to obtain the word representations of the selected sub-instructions. The ground-truth shifting signal at each time-step is dependent on the distance between the agent's current position and the end viewpoint of the selected sub-instruction. If the distance is smaller than or equal to 0.5 meters, the ground-truth shift signal s_t will be 1, and 0 otherwise. For the Back-Translation model (Tan et al., 2019), we only apply chunk shifting loss to the

teacher-forcing imitation learning branch, so that the agent navigates on the ground-truth path and learns the chunk-shifting with less noise. We train all agents on a single NVIDIA Tesla K80 GPU, using the same hyperparameters as the baselines.

Evaluation metrics. We follow the standard metrics that previous work employed for evaluating the agent's performance on the R2R dataset (Anderson et al., 2018b), which include Path Length (PL) of the agent's trajectory, average Navigation Error (NE) for the distance between agent's final position and the target, Oracle Success Rate (OSR) for the ratio of agents which the shortest distance between the target and the trajectory is within $3m$, Success Rate (SR) for the ratio of agents which the distance between agent's final position and the target is within $3m$, and Success Rate Weighted by Path Length (SPL). Furthermore, we also consider the normalized Dynamic Time Warping (nDTW) score (Magalhaes et al., 2019), which is a metric that measure the overall performance of the agent with a focus on the similarity between the ground-truth and the actual trajectories.

6 Results and Analysis

We compare the performance of the four agents on the R2R unseen validation set. We also present the traceability of the navigation process resulting from our FGR2R data.

6.1 Comparisons

Quantitative results. Table 1 shows the results of the four agents in unseen environments. The performance of the imitation learning agents (Row 1–3) with our sub-instruction attention module outperforms the base agents. In terms of the success rate, the Seq2Seq, Speaker-Follower and the Self-Monitoring agents achieve an absolute increase of 1.1%, 4.9% and 1.7% respectively. The improvement is consistent in most of the other metrics, e.g. for the Self-Monitoring agent, its SPL improves from 0.30 to 0.32 and its nDTW score grows from 0.58 to 0.61. The overall improvement on Path Length and nDTW score for the first three agents indicates that using sub-instructions improves the agent's ability to navigate on the described path. As for the Back-Translation agent (Row 4), the performance with sub-instruction attention is very similar to the baseline, one possible reason could be that the introduction of sub-instruction shifting perturbs

#	Model with sub-instructions	SR	TP	TN	FP	FN	Accuracy	Precision	Recall	F1-Score
1	Seq2Seq (Anderson et al., 2018b)	22.9	608	36344	1602	4796	0.852	0.275	0.113	0.160
2	Speaker-Follower (Fried et al., 2018)	34.7	963	9966	452	4878	0.672	0.681	0.165	0.265
3	Self-Monitoring (Ma et al., 2019a)	42.4	1130	10619	363	4686	0.699	0.757	0.194	0.309
4	Back-Translation (Tan et al., 2019)	46.7	1256	8086	303	4765	0.648	0.806	0.209	0.331

Table 2: Statistics of the shifting signal on the unseeen validation set.

the learning of action during for the reinforcement learning scheme which the agent could deviate far from the ground-truth path.

Learning when the agent needs to read a new sub-instruction is a difficult task, the same viewpoint in a specific environment can be considered as a shifting point or not depending on the sub-instruction that the agent follows. In Table 2, we show the confusion matrix of the shifting signals and we compute accuracy, precision, recall and F1-score to evaluate the performance of our proposed shifting module. Results show that all the agents have huge room for improvement for shifting, since the best F1-Score obtained is only 0.331. But we can see from the four agents that, as the success rate increases, the precision, recall and F1-score also improve. We propose to consider these results to be useful baselines for future methods that apply sub-instructions. Notice that agents visit a different number of viewpoints due to the maximum number of steps allowed, the use of panoramic action space and the ability to stop. In the case of Seq2Seq model, since the agent is not using a panoramic view, it performs many actions to change the camera orientation.

Qualitative performance. We illustrate a qualitative example in Figure 3 to show how the sub-instruction module works in the agent. In the example, both the baseline model and the model with the sub-instruction module completes the task successfully. However, unlike the baseline model which fails to follow the instruction and stops within 3 meters of the target by chance, our model correctly identifies the completeness of each sub-instruction, guides the agent to walk on the described path and eventually stops right at the target position. We refer the readers to Supplementary Materials for visualization of more trajectories.

6.2 Traceability

With the FGR2R data, we reveal the navigation process of the agent working on specific sub-instructions. For each sub-instruction, we measure the similarity between the ground-truth path and the actual trajectory using nDTW as well as the distance between the end viewpoint of the sub-instruction and the predicted shift viewpoint. As a result, we can estimate the performance of the agent in each sub-task.

rank	$\overline{d}$	$\overline{nDTW}$	f	$\overline{s}$	Representative sub-instruction
1	2.22	0.72	7	2.8	head down the stair
2	2.52	0.57	5	4.6	wait near the first open door
3	2.58	0.73	8	2.5	go into the bedroom
4	2.66	0.73	21	2.6	exit the bedroom
5	2.77	0.65	10	2.1	turn right at the entry
⋮	⋮	⋮	⋮	⋮	⋮
96	6.33	0.55	35	3.8	stop behind the table at the far end
97	6.56	0.43	8	2.0	walk past the sink, fridge, oven
98	6.86	0.46	11	3.2	go through the wooden archway
99	6.88	0.51	20	3.0	walk along the grass until you reach ...
100	7.36	0.52	38	3.4	walk into the room which have a ...

Table 3: Performance on different sub-instruction clusters in validation unseen split. $\overline{d}$, f and $\overline{s}$ denote the mean distance, the frequency and the mean number of viewpoints of a cluster.

We cluster the sub-instructions into 100 clusters using complete-linkage hierarchical agglomerative clustering algorithm. Instead of using a standard metric of distance such as the Euclidean distance, we compute a similarity matrix of sub-instructions using the BLEU-4 metric. We experiment with the Self-Monitoring agent on validation unseen split and present a summary of the top five and the bottom five clusters ranked by the mean distance, as shown in Table 3.

We can see from the table that the clusters which the agent performs better consist of simple and direct sub-instructions which refer to a single action, such as "*head down the stair*" and "*exit the bedroom*". On the other hand, with sub-instructions that refer to specific objects such as "*walk past the sink, fridge, oven*" or express an action which is conditioned on the completion of another action, such as "*walk along the grass until you reach* ...", the agent deviates far from the described path. Moreover, the ranking does not show a strong correlation with the frequency or the number of viewpoints of each sub-instruction. These results suggest that agent is incapable of understanding complex natural language instructions or ground to specific objects with a high accuracy.

7 Conclusion

In this paper we introduce a novel sub-instruction module and the Fine-Grained R2R Dataset to encourage the learning of correspondences between vision and language. The sub-instruction module enables the agent to attend to one particular sub-instruction at each time-step and decides whether the agent needs to proceed to the next sub-instruction. Our experiments show that by implementing the sub-instruction module in state-of-the-art agents, most of the agents are able to follow the given instruction more closely and achieve better performance. We also show that, with the sub-instruction annotations, the entire navigation trajectory is trackable. We believe that the idea of sub-instruction module and a sub-instruction annotated dataset can benefit future studies in the VLN task as well as other vision-and-language problems.

A Appendices

A.1 FGR2R Dataset

Data collection. We build a web interface to collect FGR2R data using Amazon Mechanical Turk (AMT), as shown in Figure 5. In the interactive window, each viewpoint on the ground-truth path is highlighted with a large cylinder and an index of the viewpoint. Besides each sub-instruction, there is a drop-down list for assigning the start and end viewpoints of the corresponding sub-path. The annotators can click in the interactive window to freely move on the ground-truth path and freely rotate the camera to observe its surroundings. Before the start of labelling, we first ask the annotators to watch the automatic trajectory run-through to get familiar with the environment. Then, we ask them to partition the ground-truth path and assign a sub-instruction to those partitions. Once the labelling is completed, a function will automatically check if the annotation disobeys any rules (e.g., the start viewpoint of a sub-path should be the same as the end viewpoint of the previous sub-path) before approval for submission.

Annotator qualification. To ensure the quality of the annotation returned by the annotators, we annotated a subset of 300 samples as ground-truths and we exam each annotator with 15 ground-truth samples before approval for labelling. In total, there are 126 participants. We reject workers with a low agreement to the ground-truth. The qualification process leaves us 58 qualified annotators to complete the annotation task.

Dataset statistics. Apart from the FGR2R statistics mentioned in the paper, we present the distribution of sub-instructions in an instruction and the distribution of viewpoints for a sub-instruction in Figure 4. As we can see, most of the instructions are broken down into more than one sub-instruction and the frequency of more than seven sub-instructions is very low. Also, notice that about 15% of the sub-instructions are paired with only one viewpoint, as a result of the sub-instructions that only refer to camera rotation such as “*rotate slightly to the left*” or stopping command such as “*wait by the sink*”.

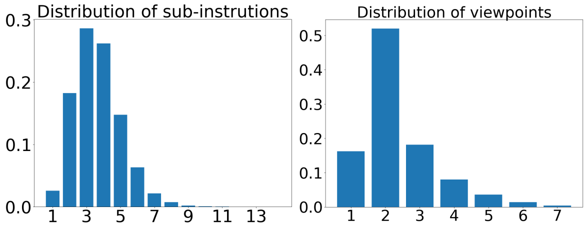

Figure 4: Distribution of sub-instructions in an instruction and distribution of viewpoints for a sub-instruction in the FGR2R dataset.

Training with FGR2R. During training, consider that more coherent motion could be beneficial for the agent to learn the textual-visual correspondence. We combine the sub-instructions which are only paired with one viewpoint to the next sub-instruction (and combine with the previous sub-instruction if it is the last one). The sub-instructions in validation sets remain in their original format so that the ground-truth trajectories are kept unknown. In this work, we only enable the sub-instruction module with a single step uni-directional shifting, which agrees with the observation that instructions and trajectory in the R2R dataset are monotonically aligned. However, different rules could be designed. For example, one can allow the agent to shift for more than one step or enable the agent to read the previous sub-instructions once it backtracks to the visited viewpoint. Our proposed FGR2R make all these research directions possible. We leave these ideas to future research.

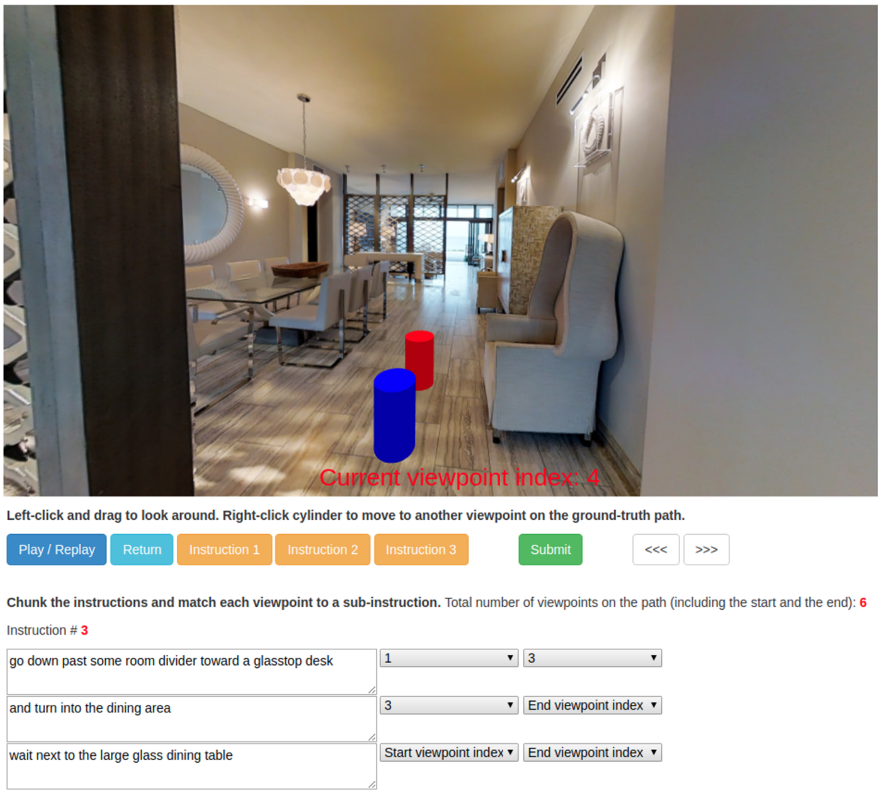
A.2 Extension to Fine-Grained R4R

R2R to R4R The R4R dataset is created by concatenating two trajectories in R2R, which the first path ends within three meters from the start of the second path (Jain et al., 2019). We enrich the R4R data with sub-instructions annotations by joining two sequences of sub-instructions corresponding to the two trajectories. However, for some trajectories in R4R, there exist several additional viewpoints for connecting the two paths, which has no sub-instruction annotation. Therefore, we assign those additional viewpoints to the first sub-instruction of the second path.

Evaluation We further experimented the four agents on the R4R dataset, with and without sub-instruction modules. As shown in Table 4, the performance of the first three agents are very similar. For agents with sub-instruction modules, the SR of Seq2Seq and Speaker-Follower are slightly lower, whereas the SR of Self-Monitoring agent

		R4R Validation Unseen					
#	Model	PL	NE $\downarrow$	OSR $\uparrow$	SR $\uparrow$	SPL $\uparrow$	nDTW $\uparrow$
1	Seq2Seq (Anderson et al., 2018b)	9.40 (10.85)	9.35 (**9.20**)	32.8 (**35.5**)	21.2 (**22.3**)	**0.11** (**0.11**)	0.42 (**0.43**)
2	Speaker-Follower (Fried et al., 2018)	26.64 (25.68)	8.46 (**8.09**)	**42.1** (40.7)	26.4 (**27.4**)	0.12 (**0.13**)	**0.41** (**0.41**)
3	Self-Monitoring (Ma et al., 2019a)	28.01 (23.41)	**8.07** (8.46)	**46.2** (40.6)	**27.4** (25.8)	**0.10** (0.09)	**0.42** (0.41)
4	Back-Translation (Tan et al., 2019)	7.78 (39.66)	9.33 (**7.90**)	38.1 (**53.5**)	21.5 (**31.2**)	**0.17** (0.14)	**0.48** (0.39)

Table 4: Comparison on the R4R validation unseen split with and without the sub-instruction module. Values not in brackets are with sub-instructions, values in brackets are without sub-instructions.



Left-click and drag to look around. Right-click cylinder to move to another viewpoint on the ground-truth path.

Chunk the instructions and match each viewpoint to a sub-instruction. Total number of viewpoints on the path (including the start and the end): 6

Instruction # 3

go down past some room divider toward a glasstop desk	1	3
and turn into the dining area	3	End viewpoint index
wait next to the large glass dining table	Start viewpoint index	End viewpoint index

Figure 5: The web interface for FGR2R data collection. The displayed photo of the environment is an interactive window, cylinders are the viewpoints on the ground-truth path. “*Play / Replay*” shows an automatic run-through of the entire trajectory. “*Return*” brings the agent back to the first viewpoint. “*Instruction #*” switches among the three instructions that described the same path. “*Submit*” checks and submits the annotations.

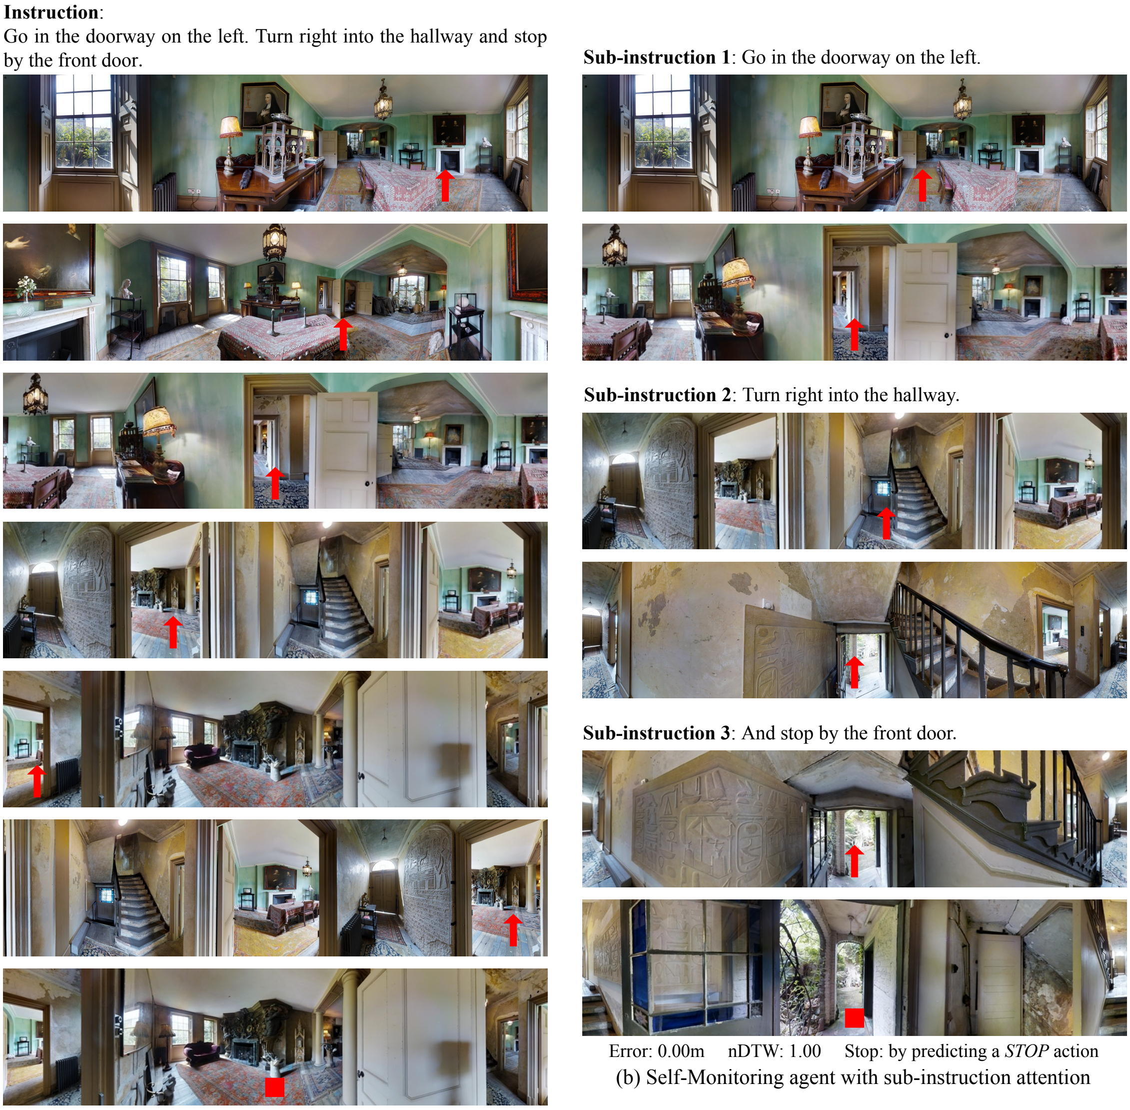
is 1.6% higher. As for the Back-Translation, the agent experiences a large OSR and SR drop after applying sub-instructions, but the SPL and nDTW are increased by 3% and 9%. This result indicates that although the agent with sub-instruction modules has a lower chance to reach the target (stop within 3m), it follows the instruction much better.

However, we argue that a large performance gain has not been obtained in R4R mainly for two reasons: (1) The additional viewpoints created for linking the two trajectories have no corresponding sub-instructions. Hence, agents trained to follow each sub-instructions strictly have no guidance for those steps. (2) The last sub-instruction of the first trajectory is very confusing to the agent, as it usually refers to the $STOP$ action, but the navigation does not end. This prevents the agent from learning a good stopping policy since the ground-truth action requires the agent to keep moving.

In conclusion, we believe that it is inappropriate to apply FGR2R data directly for FGR4R task. To obtain FGR4R data, our suggestion is to remove the final sub-instruction about the $STOP$ action from the first trajectory, and use a Speaker module (Fried et al., 2018) to generate a new sub-instruction for the additional viewpoints for linking the two trajectories. We will leave this idea for future work.

A.3 Visualization of Navigation

We visualize the navigation trajectories of the Self-Monitoring agent with and without our proposed sub-instruction module in the following pages.



(a) Self-Monitoring agent without sub-instruction attention

(b) Self-Monitoring agent with sub-instruction attention

Figure 6: A positive example of sub-instruction aware navigation. Without sub-instruction module, the agent wanders between rooms and decides to stop at a wrong location. With sub-instruction module, the agent successfully leaves the room, finds the way to the target and stops at the right location.

Error: 2.81m nDTW: 0.68 Stop: by reaching the maximum steps

(a) Self-Monitoring agent without sub-instruction module

Error: 0.00m nDTW: 1.00 Stop: by predicting a *STOP* action

(b) Self-Monitoring agent with sub-instruction module

Figure 7: A positive example of sub-instruction aware navigation. Without sub-instruction module, the agent fails to follow the instruction and stops next to the target by chance. With sub-instruction module, the agent navigates on the described path and eventually stops right at the target location.

Instruction:
With the door leading outside behind you, walk forward and turn left to go down the corridor with the eye chart towards your right. Continue past the half bath on your left and the kitchen on your right, then turn left. Enter the bedroom ahead of your through the leftmost door on the opposite wall.

Error: 1.40m nDTW: 0.85 Stop: by reaching the maximum steps

(a) Self-Monitoring agent without sub-instruction attention

Sub-instruction 1: With the door lead outside behind you, walk forward.

Sub-instruction 2: And turn left to go down the corridor with the eye chart towards your right.

Sub-instruction 3: Continue past the half bath on your left and the kitchen on your right.

Sub-instruction 4: Then turn left.

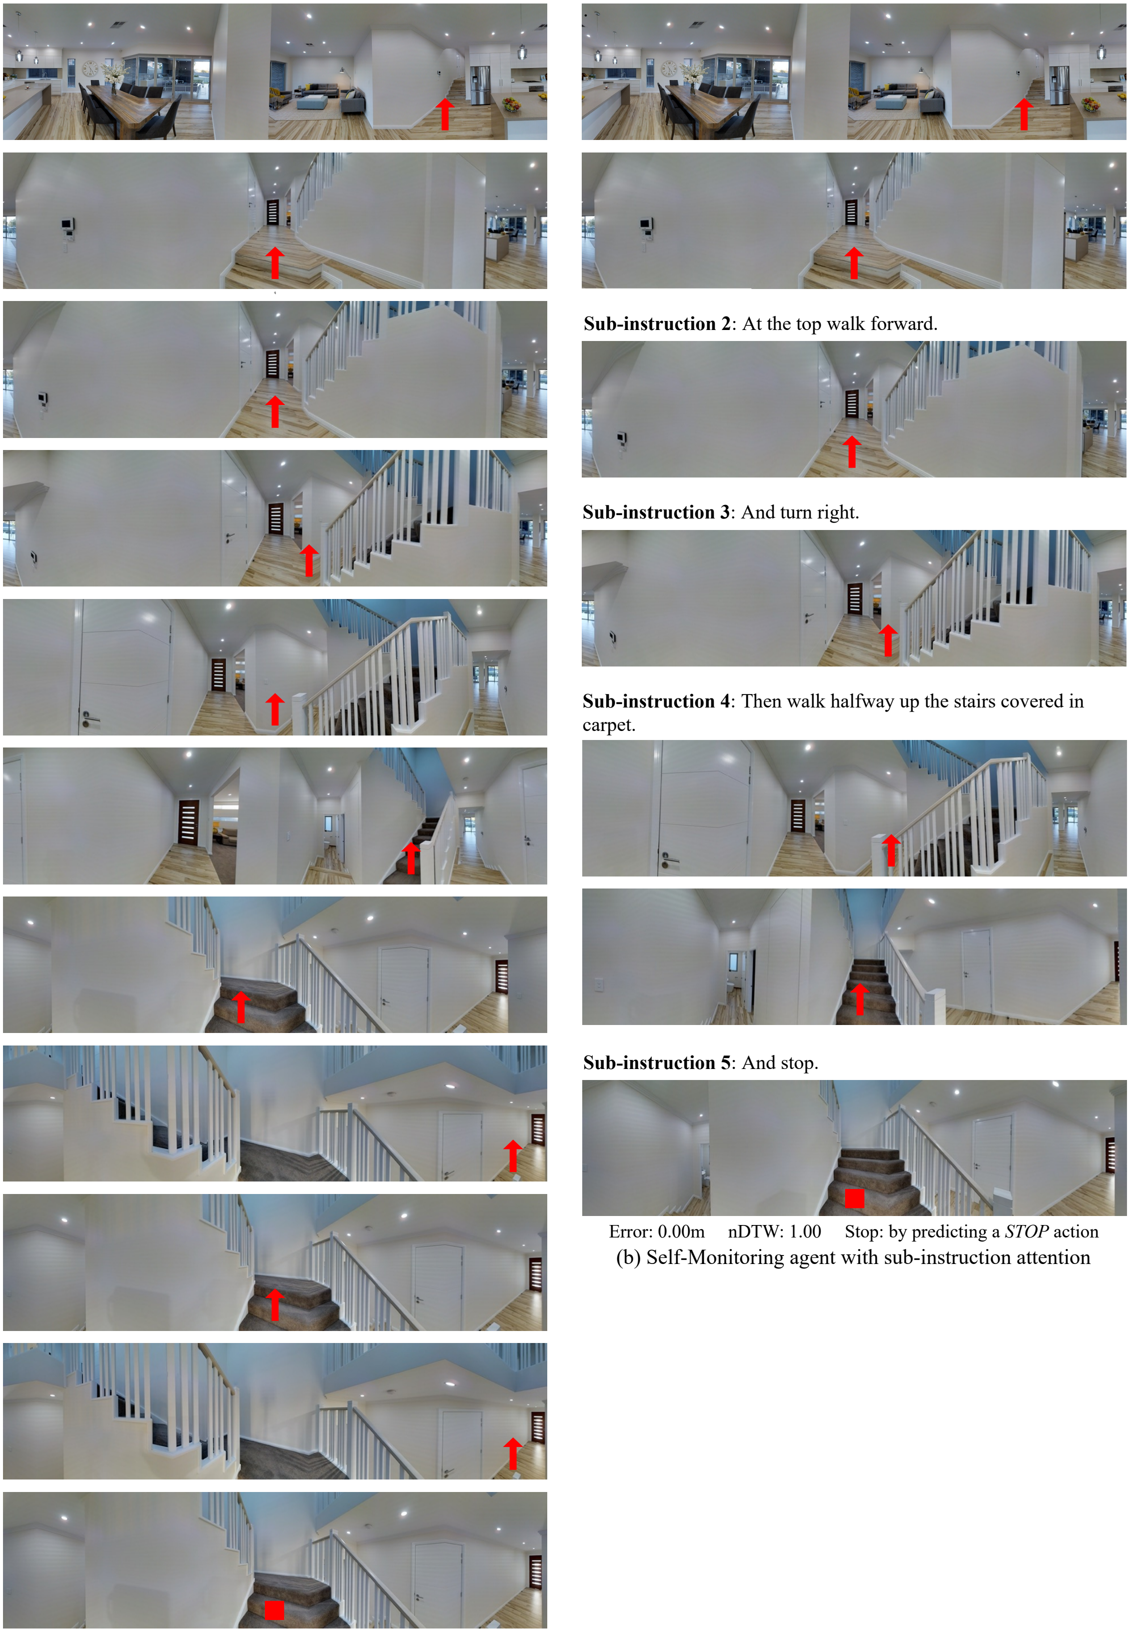
Sub-instruction 5: Enter the bedroom ahead of you through the leftmost door on the opposite wall.

Error: 0.00m nDTW: 0.95 Stop: by predicting a *STOP* action

(b) Self-Monitoring agent with sub-instruction attention

Figure 8: A positive example of sub-instruction aware navigation. Without sub-instruction module, the agent loops around the target and doesn't know how to stop. With sub-instruction module, the agent falls into the same loop but quickly escapes from it and stops at the correct location.

Instruction:
Turn right and go up the wood stairs. At the top walk forward and turn right. Then walk halfway up the stairs covered in carpet and stop.



Sub-instruction 1: Turn right and go up the wood stair.

Sub-instruction 2: At the top walk forward.

Sub-instruction 3: And turn right.

Sub-instruction 4: Then walk halfway up the stairs covered in carpet.

Sub-instruction 5: And stop.

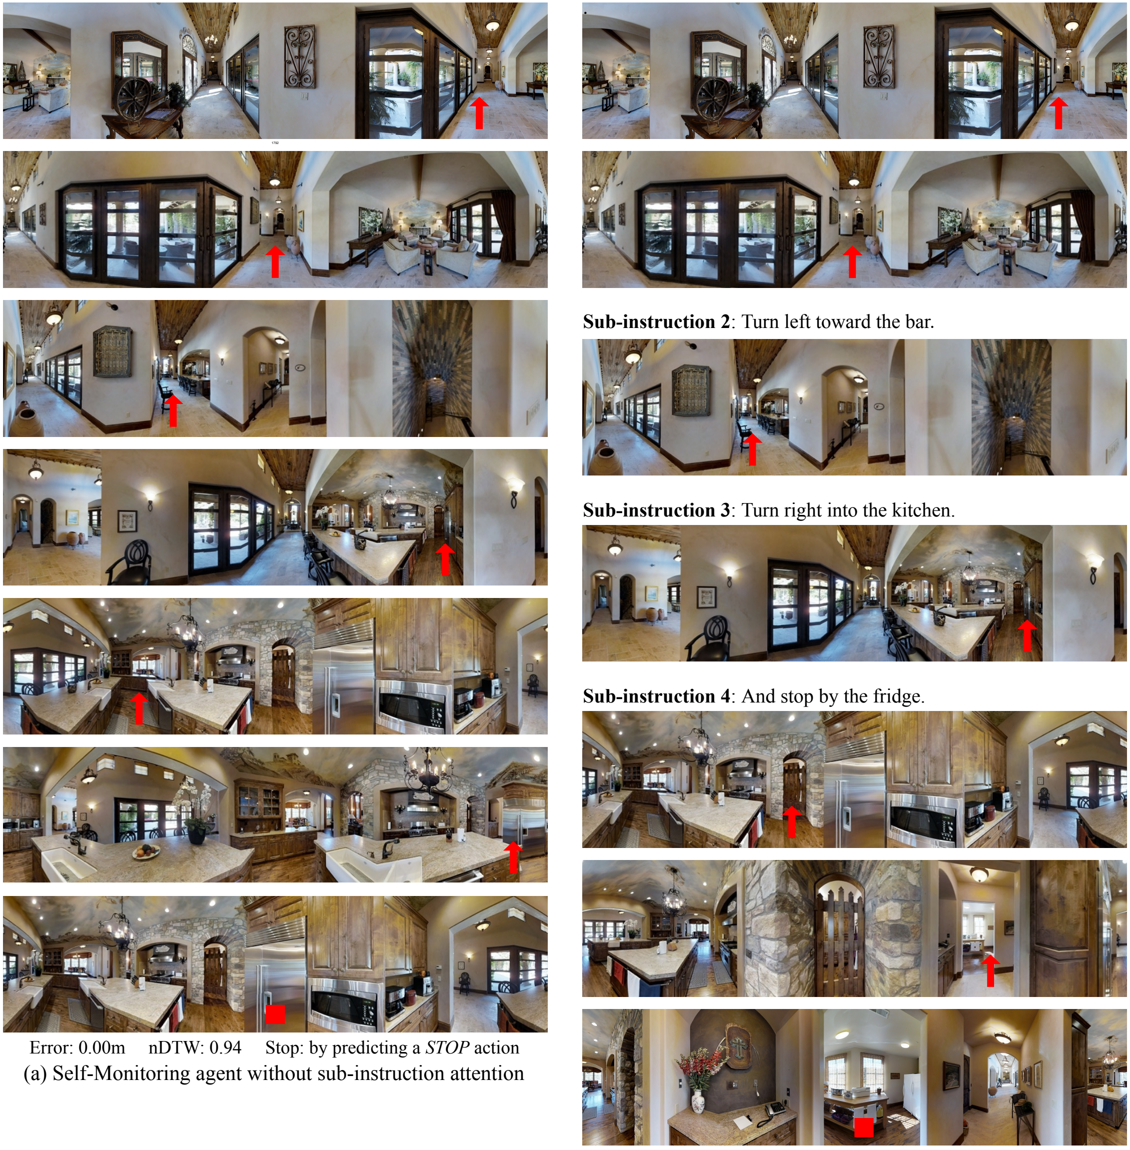
Error: 0.61m nDTW: 0.68 Stop: by reaching the maximum steps

(a) Self-Monitoring agent without sub-instruction attention

Error: 0.00m nDTW: 1.00 Stop: by predicting a *STOP* action

(b) Self-Monitoring agent with sub-instruction attention

Figure 9: A positive example of sub-instruction aware navigation. Without sub-instruction module, the agent loops around the target and doesn't know how to stop. With sub-instruction module, the agent navigates on the described path and eventually stops right at the target location.



Instruction:
Turn right and go down the long hall. Turn left toward the bar. Turn right into the kitchen and stop by the fridge.

Error: 0.00m nDTW: 0.94 Stop: by predicting a *STOP* action

(a) Self-Monitoring agent without sub-instruction attention

Sub-instruction 1: Turn right and go down the long hall.

Sub-instruction 2: Turn left toward the bar.

Sub-instruction 3: Turn right into the kitchen.

Sub-instruction 4: And stop by the fridge.

Error: 3.95m nDTW: 0.82 Stop: by predicting a *STOP* action

(b) Self-Monitoring agent with sub-instruction attention

Figure 10: A negative example of sub-instruction aware navigation. Without sub-instruction module, the agent completes the navigation task without making any mistake. With sub-instruction module, although the agent performs sub-instruction shifting perfectly, it overlooks the target object and walks away from the target, eventually decides to stop at a wrong location.

Knowledge-Grounded Dialogue Generation with Pre-trained Language Models

Abstract

We study knowledge-grounded dialogue generation with pre-trained language models. To leverage the redundant external knowledge under capacity constraint, we propose equipping response generation defined by a pre-trained language model with a knowledge selection module, and an unsupervised approach to jointly optimizing knowledge selection and response generation with unlabeled dialogues. Empirical results on two benchmarks indicate that our model can significantly outperform state-of-the-art methods in both automatic evaluation and human judgment.

1 Introduction

With advances in neural machine learning (Sutskever et al., 2014; Gehring et al., 2017; Vaswani et al., 2017) and availability of the huge amount of human conversations on social media (Adiwardana et al., 2020), building an open domain dialogue system with data-driven approaches has attracted increasing attention from the community of artificial intelligence and natural language processing. In this work, we are interested in generative approaches. Generative models for open domain dialogues are notorious for replying with generic and bland responses, resulting in meaningless and boring conversations (Li et al., 2015). Such deficiency is particularly severe when human participants attempt to dive into specific topics in conversation (Dinan et al., 2019). As a result, there is still a big gap between conversation with existing systems and conversation with humans.

Very recently, there emerge two lines of research that seem promising to bridge the gap. One is to apply large-scale pre-trained language models, such as GPT-2 (Radford et al., 2019), to the task of open domain dialogue generation. Prototypes such as DialoGPT (Zhang et al., 2019c) have exhibited compelling performance on generating responses that make sense under conversation contexts and at the same time carry specific content for keeping the conversation going. While the giant language models can memorize enough patterns in language during pre-training, they only capture "average" semantics of the data (Zhang et al., 2019c). As a result, responses could still be bland or inappropriate when specific knowledge is required, as illustrated by the example in Table 1. The other line is to ground dialogue generation by extra knowledge such as unstructured documents (Zhao et al., 2020). By the means, the documents (e.g., wiki articles) serve as content sources, and make a dialogue system knowledgeable regarding to a variety of concepts in discussion. However, collecting enough dialogues that are naturally grounded on documents for model training is not trivial. Although some benchmarks built upon crowd-sourcing have been released by recent papers (Zhou et al., 2018b; Dinan et al., 2019; Gopalakrishnan et al., 2019), the small training size

Context	
A	I just discovered star trek and I really like watching star trek .
B	Gene Roddenberry created it based upon science fiction and it is American media.
	...
A	If I remember Captain Kirk was not the original captain .
B	The Star Trek Canon of the series an animated had 5 spin offs.
A	I watched a little of the next generation but could not get into it like i did with the original show .
Response	
Human	These adventures went on but were short lived and six feature films.
DialoGPT	I think it's worth it.

makes the generation models generalize badly on unseen topics (Dinan et al., 2019) and the cost of building such data also prevents from transferring the techniques proved on the benchmarks to new domains and new languages.

Encouraged by the results on pre-training for dialogue generation and knowledge-grounded dialogue generation, and motivated by the problems in both sides, we consider bringing the two together in this work. Specifically, we propose knowledge-grounded dialogue generation with pre-trained language models in order to endow a generative model with both rich knowledge and good generalization ability[1]. The challenge is that pre-trained language models often set constraints on the maximum number of tokens they can handle (e.g., the maximum number for GPT-2 (Radford et al., 2019) is 1024), and thus hinders exploitation of the knowledge text which could be rather long and redundant (e.g., in Wizard of Wikipedia (Dinan et al., 2019), on average each conversation context is associated with 61.2 sentences retrieved from wiki articles, and the average number of tokens in the extra knowledge is 1625.6). Indeed, the conflict between model capacity and the ability required for processing long knowledge input represents an essential obstacle for applying pre-trained language models to knowledge-grounded dialogue generation, since on the one hand we always have to set up an upper bound to the capacity of pre-trained models in order to handle massive text corpus, and on the other hand we need to keep sufficient candidates with rich enough content in the procedure of response generation in order to guarantee the recall of relevant knowledge.

To overcome the challenge, we consider equipping the pre-trained response generation model with a knowledge selection module whereby the redundant knowledge input is slimmed with relevant information (regarding to conversation contexts) kept to meet the capacity constraint. While some recent papers on knowledge-grounded dialogues have paid attention to the problem of knowledge selection (Lian et al., 2019; Kim et al., 2020; Ren et al., 2019), the knowledge selection module is either deeply coupled with the specially configured models (Lian et al., 2019; Ren et al., 2019) and thus is incompatible with the pre-trained language models, or it is learned with human annotations (Dinan et al., 2019; Kim et al., 2018) which are difficult to obtain in practice (e.g., the dataset in (Zhou et al., 2018b) does not contain annotations for knowledge selection). Therefore, we propose an unsupervised approach where learning of knowledge selection and fine-tuning of response generation are jointly conducted with unlabeled dialogues. Specifically, we build the knowledge selection module on the basis of BERT, and formalize knowledge selection as a sequence prediction process, by which the model can take advantage of the pre-training techniques and dynamically determine the relevant knowledge for a given context. The learning algorithm starts from training with pseudo ground-truth that is constructed by making full use of responses as an alternation of human annotations, and then alternatively updates the knowledge selection model and the response generation model through a reinforcement learning approach and a curriculum learning approach respectively. Thus, knowledge selection is further optimized with the feedback from response generation, and the knowledge used for fine-tuning the response generation model gradually moves from the pseudo ground-truth to the prediction of the knowledge selection module.

We test the proposed method on two benchmarks of knowledge-grounded dialogue generation: Wizard of Wikipedia (Dinan et al., 2019) and CMU Document Grounded Conversations (Zhou et al., 2018b). Evaluation results indicate that our model can significantly outperform state-of-the-art methods as well as a few pre-trained models used in heuristic ways, and thus achieves new state-of-the-art on the benchmarks. Moreover, as a byproduct, the knowledge selection module also outperforms the state-of-the-art model in terms of accuracy of knowledge selection on Wizard of Wikipedia, implying that other models could also benefit from the component.

Our contributions in this paper are three-fold: (1) proposal of a knowledge selection module for applying pre-trained language models to the task of knowledge-grounded dialogue generation; (2) proposal of an unsupervised approach in which learning of knowledge selection and fine-tuning of the pre-trained model are conducted in a joint manner; and (3) empirical verification of the effectiveness of the proposed method on benchmarks of knowledge-grounded dialogue generation.

---

[1] In this paper, we assume that knowledge is retrieved from documents.

2 Related Work

Early work on end-to-end open domain dialogue generation is inspired by the research of machine translation (Ritter et al., 2011; Shang et al., 2015; Vinyals and Le, 2015). Later, the vanilla encoder-decoder architecture is widely extended to improve diversity of responses (Li et al., 2015; Xing et al., 2017a; Zhao et al., 2017; Tao et al., 2018); to model the structure of conversation contexts (Serban et al., 2016, 2017; Xing et al., 2017b; Zhang et al., 2019a); to control attributes of responses (Xu et al., 2019; Zhou et al., 2017; Zhang et al., 2018a; Wang et al., 2018; See et al., 2019); and to bias responses to some specific personas (Li et al., 2016; Zhang et al., 2018b). Recently, grounding dialogue generation by extra knowledge is emerging as an important step towards human-like conversational AI, where the knowledge could be obtained from knowledge graphs (Zhou et al., 2018a; Moon et al., 2019; Tuan et al., 2019), retrieved from unstructured documents (Dinan et al., 2019; Lian et al., 2019; Zhao et al., 2020; Kim et al., 2020), or extracted from visual background (Mostafazadeh et al., 2017; Shuster et al., 2018; Huber et al., 2018). In this work, we study document-grounded dialogue generation. Rather than learning from scratch like most existing work, we take advantage of the pre-trained language models and achieve new state-of-the-art on the benchmarks of the task.

Big, deep neural language models pre-trained on huge unlabeled text corpus have led to strong improvements on numerous natural language understanding and natural language generation benchmarks (Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019; Radford et al., 2019; Song et al., 2019; Dong et al., 2019; Lewis et al., 2019), and therefore are revolutionizing almost the full spectrum of NLP applications (Raffel et al., 2019; Sun et al., 2019b; Qiao et al., 2019; Zhang et al., 2019b; Lample and Conneau, 2019) and some interdisciplinary applications in NLP and computer vision (Lu et al., 2019; Su et al., 2019; Sun et al., 2019a). In the context of dialogue generation, by fine-tuning GPT-2 (Radford et al., 2019) in different sizes on social media data, recent work has (Zhang et al., 2019c; Wolf et al., 2019) shown promising progress on conversation engagement and commonsense question-answering. In this work, we further explore the application of pre-training to the task of open domain dialogue generation by equipping the pre-trained language models with external knowledge. Different from a very recent paper on pre-training for low-resource knowledge-grounded dialogue generation (Zhao et al., 2020), the work presents an in-depth investigation on how to release the power of the existing pre-trained language models on the task when input exceeds the capacity of the models.

3 Preliminary

3.1 Problem Formalization

Suppose that we have a dataset $\mathcal{D} = \{(U_i, D_i, r_i)\}_{i=1}^N$, where $\forall i \in \{1, \ldots, N\}$, U_i is a dialogue context, D_i is a document that contains relevant knowledge regarding to U_i, and r_i is a response to U_i based on D_i. The goal is to learn a generation model $P(r|U, D; \theta)$ (θ denotes the parameters of the model) from $\mathcal{D}$, and thus given a new dialogue context U associated with a document D, one can generate a response r following $P(r|U, D; \theta)$.

3.2 Pre-trained Language Models

We define $P(r|U, D; \theta)$ on the basis of GPT-2 from OpenAI (Radford et al., 2019). GPT-2 are transformer language models with a stack of masked multi-head self-attention layers, and are learned from large scale web text. To apply GPT-2 to the task of knowledge-grounded dialogue generation, we formulate the generation problem as

$$\begin{aligned} P(r|U, D; \theta) &= P(r|g(U, D); \theta) \\ &= \prod_{t=1}^{l_r} P(r_t|g(U, D), r_{1:t-1}; \theta), \end{aligned} \tag{1}$$

where $g(U, D)$ tailors $U \cup D$ to meet the length constraint of a GPT-2 model as the input of generation, and r_t refers to the t-th token of r whose length is supposed to be l_r. The problem then boils down to (1) how to define $g(U, D)$; and (2) how to fine-tune θ (and probably learn $g(U, D)$) with $\mathcal{D}$.

In this work, we assume that labels that indicate the ground-truth knowledge are not available, which is practical but makes the problem even more challenging. Since D could be rather redundant with a lot of information irrelevant with the topic or the context of the conversation, simply truncating the concatenation of sentences of U and D as $g(U, D)$ may cut the relevant knowledge and introduce noise into response generation, which hurts the performance of the GPT-2 model, as will be demonstrated in the experiments. Therefore, we consider learning a $g(U, D)$ that can distill useful

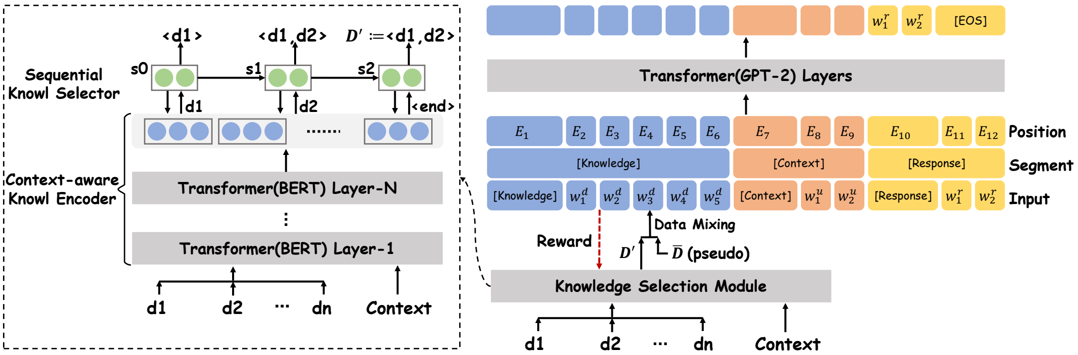

Figure 1: Architecture of the proposed model.

information from D for the GPT-2 model, as will be elaborated in the next section.

4 Approach

Heading for learning a $g(U, D)$ for applying GPT-2 to the task of knowledge-grounded dialogue generation, we need to deal with several challenges: (1) how to model the correlation between a context and the external knowledge; (2) how to learn $g(U, D)$ when labels of ground-truth knowledge are absent; and (3) how to jointly optimize $g(U, D)$ and the GPT-2 model with $\mathcal{D}$, and thus the two can boost each other. Figure 1 illustrates the architecture of the model. On the basis of the transformer architecture, the knowledge selection module is made up of a context-aware knowledge encoder and a sequential knowledge selector. The former captures interaction patterns between a context U and each sentence in D through a stack of self-attention layers, and the patterns are then fed to the latter to decode useful knowledge one sentence per step. Since human annotations are not accessible, the learning method begins with pseudo ground-truth constructed by making full use of responses, and optimization of $g(U, D)$ and optimization of the GPT-2 generation model are alternatively conducted with a reinforcement learning approach and a curriculum learning approach respectively.

4.1 Context-Aware Knowledge Encoder

We choose BERT (Devlin et al., 2018) as the backbone of the encoder. Thus, the encoder can take advantage of pre-training, and the multi-layer bidirectional attention mechanism in BERT allows a dialogue context and the associated knowledge to sufficiently interact with each other, resulting in context-aware knowledge representations. Specifically, let $U = (u_1, \ldots, u_n)$ and $D = (d_1, \ldots, d_m)$ be the context and the knowledge respectively, then we concatenate $\{u_i\}_{i=1}^n$ as $(w_1^u, \cdots, w_{l_u}^u)$ with w_i^u the i-th word and l_u the length of the sequence, and define the input of the encoder as $\mathcal{S} = (S_1, \ldots, S_m)$ with S_i formulated as

$$S_i = [\mathrm{CLS}] w_1^u \ldots w_{l_u}^u [\mathrm{SEP}] w_{i,1}^d \ldots w_{i,j}^d \ldots w_{i,l_d}^d [\mathrm{SEP}], \tag{2}$$

where $w_{i,j}^d$ refers to the j-th word of $d_i \in D$, and l_d is the length of d_i. Each $S_i \in \mathcal{S}$ passes through the stacked self-attention layers, and is finally represented as $e_i = \mathrm{CLS}(\mathrm{BERT}(S_i))$ where $\mathrm{BERT}(S_i)$ refers to the sequence of vectors from the last layer of the encoder and $\mathrm{CLS}(\cdot)$ is a function that returns the first vector of the sequence (i.e., the vector corresponding to the $[\mathrm{CLS}]$ token). The output of the encoder is given by $E = (e_1, \ldots, e_m)$.

4.2 Sequential Knowledge Selector

With E as input, the sequential knowledge selector determines a subset of D (denoted as D') as the relevant knowledge and exploits D' to construct $g(U, D)$. Since there may exist one-to-many relations between a context and the relevant knowledge (Kim et al., 2020), the size of D' could vary from context to context. Therefore, we regard the construction of D' as a sequence prediction process in which D' starts from an empty set and gradually expands by adding one sentence from D per step. By this means, the size of D' can also be viewed as a parameter and is dynamically determined according to the given context. Formally, we maintain a sequence of hidden states $\{s_t\}_{t=0}^{T_{U,D}}$ with the initial state s_0 a trainable parameter, and weight $\{d_i\}_{i=1}^m$ by an attention mechanism which can be formulated as

$$P(d_i|U, d_{j_{1:t-1}}) = \exp(\alpha_{t,i}) / \sum_i \exp(\alpha_{t,i})$$
$$\alpha_{t,i} = v^\top \tanh(W_e e_i + W_s s_t + b), \tag{3}$$

where W_e, W_s, b and v are trainable parameters. Then d_{j_t} will be added to D' if $j_t = \text{argmax}_{i \in \{1,\ldots,m\}} P(d_i|U, d_{j_{1:t-1}})$. After that, s_{t+1} is calculated by

$$s_{t+1} = \text{LSTM}(e_{j_t}, s_t) \tag{4}$$

To determine $T_{U,D}$, we introduce a special embedding e_{spe} into E, and terminate the prediction process if e_{spe} is selected or an upper bound T_{max} is reached. Finally, $g(U, D)$ is defined as the concatenation of the sentences in $U \cup D'$.

4.3 Learning Method

Learning a $g(U, D)$ without human annotations is not trivial. For example, in a recent paper (Kim et al., 2020), when human labels are removed, the accuracy of knowledge selection drops from 27% to 0.3%. Moreover, since knowledge selection and response generation are entangled, ideally we hope $g(U, D)$ and the GPT-2 model can enhance each other in learning. However, as the parameters of $g(U, D)$ are far from optimal at the early stage, it is very possible that noise from $g(U, D)$ will be fed to the GPT-2 model and then flows back to the learning procedure of $g(U, D)$, resulting in inferior models on both sides. To cope with the challenges, we propose a joint optimization strategy with weak supervision as follows. The learning algorithm is summarized in Algorithm 1.

Pseudo Ground-Truth Construction. To alleviate error accumulation in joint optimization, we consider constructing weak supervision and utilize the signals to warm up the learning of $g(U, D)$ and the fine-tuning of GPT-2 beforehand. The intuition is that responses from humans carry clues to relevance of the knowledge candidates, and thus can be used to construct pseudo ground-truth. To be specific, we first sort $D = \{d_t\}_{t=1}^m$ in a descending order as $\{d_{j_t}\}_{t=1}^m$ according to $\{\text{Sim}(d_t, r)\}_{t=1}^m$ where $\text{Sim}(\cdot, \cdot)$ denotes a similarity function, and then build a subset of D by

$$\bar{D} = \{d_{j_1}, \ldots, d_{j_{\bar{m}}}\},$$
$$\bar{m} = \text{argmax}_t(\text{Sim}(d_{j_{1:t}}, r)), \tag{5}$$

where $d_{j_{1:t}}$ refers to the concatenation of $\{d_{j_i}\}_{i=1}^t$. With $\bar{D}$, $g(U, D)$ and the GPT-2 model are optimized via maximum likelihood estimation (MLE) on $\mathcal{D}_K = \{(U_i, D_i, \bar{D}_i)\}_{i=1}^N$ and $\mathcal{D}_G = \{(U_i, \bar{D}_i, r_i)\}_{i=1}^N$ respectively.

Joint Optimization: the Reinforcement Step. We exploit the policy-gradient method (Sutton et al., 2000) to continue-train $g(U, D)$ by which $g(U, D)$ is further "supervised" by the GPT-2 model and is directly optimized for a target metric (e.g., F1 in the experiments). Specifically, we sample a $\tilde{D}$ according to $P(d_i|U, d_{j_{1:t-1}})$ (in Eq.3.) under a termination criterion similar to $\bar{D}$ at each time step, and define the loss function as

$$\mathcal{L}_K = -\frac{1}{N} \sum_{i=1}^N \left(\tilde{R}_i \sum_{t=1}^{|\tilde{D}_i|} \log P(d_{i,j_t}|U_i, d_{i,j_{1:t-1}}) \right),$$
$$\tilde{R}_i = R(\tilde{D}_i) - b, \tag{6}$$

where $R(\tilde{D}_i) = \text{Sim}(r'_i, r_i)$ with r'_i the response generated by the GPT-2 model given U_i and $\tilde{D}_i$, and $b = \sum_{i=1}^N R(\tilde{D}_i)/N$ is the baseline that is used to reduce the variance of gradient estimation(Clark and Manning, 2016). We can see that minimizing $\mathcal{L}_K$ is equivalent to maximizing the conditional likelihood of $\tilde{D}_i$ if it obtains a higher reward than the baseline.

Joint Optimization: the Curriculum Step. Though $g(U, D)$ has been pre-trained with the pseudo ground-truth $\bar{D}$, the relevant knowledge provided by the model (i.e., D') may still be worse than $\bar{D}$ at the beginning of fine-tuning. Therefore, we mix D' and $\bar{D}$ and exploit a curriculum learning strategy to fine-tune the GPT-2 model where D' and $\bar{D}$ are regarded as hard materials and easy materials respectively and fine-tuning gradually moves from $\bar{D}$ to D'. Formally, the loss function for fine-tuning the GPT-2 model is defined by

$$\mathcal{L}_G = -\frac{1}{N} \sum_{i=1}^N \left(z_i \sum_{t=1}^{l_r} \log P(r_{i,t}|U_i, \bar{D}_i, r_{i,1:t-1}) + (1 - z_i) \sum_{t=1}^{l_r} \log P(r_{i,t}|U_i, D'_i, r_{i,1:t-1}) \right), \tag{7}$$

where $\{z_i\}$ are sampled from a Bernoulli distribution parameterized by p. By gradually shrinking p, the generation model will be exposed to more hard materials with the learning procedure going on.

Algorithm 1 Optimization Algorithm

```
Input: Training data $\mathcal{D}$, pre-trained GPT-2, initial curriculum rate $p_0$, exponential decay constant $\lambda$, maximum step $M$.
Construct $\mathcal{D}_K$ and $\mathcal{D}_G$.
Optimize $g(U, D)$ and GPT-2 using MLE on $\mathcal{D}_K$ and $\mathcal{D}_G$ respectively.
for $m \leftarrow 1$ to $M$ do
    Sample a mini-batch $\{(U_i, D_i, r_i)\}$ from $\mathcal{D}$.
    Update the parameters of $g(U, D)$ based on Eq.6.                          ▷ the Reinforcement Step.
    Sample $\{z_i\}$ from a Bernoulli distribution parameterized by $p$, where $p = p_0 e^{-\lambda m}$.
    Update the parameters of the GPT-2 model based on Eq.7.                    ▷ the Curriculum Step.
end for
return $g(U, D)$ and GPT-2.
```

5 Experiments

We conduct experiments on Wizard of Wikipedia (Wizard) and CMU Document Grounded Conversations (CMU_DoG) (Zhou et al., 2018b).

5.1 Datasets and Evaluation Metrics

Both datasets are built with crowd-sourcing on Amazon Mechanical Turk, employ Wikipedia as the knowledge base, and are split into training sets, validation sets, and test sets by the data owners. Topics in Wizard cover a wide range ($1,365$ in total), and each conversation happens between a wizard who has access to the knowledge about a specific topic and an apprentice who is just eager to learn from the wizard about the topic. The test set is split into two subsets: Test Seen and Test Unseen. Test Seen contains new dialogues with topics appearing in the training set, while topics in Test Unseen never appear in the training set and the validation set. We follow (Dinan et al., 2019) and conduct the pre-processing with the code published on ParlAI[2]. Different from Wizard, CMU_DoG focuses on movie domain, and besides wizard-apprentice conversations, the data also contain conversations between two workers who know the document and try to discuss the content in depth. To better compare with the baselines, we adopt the version shared at `https://github.com/lizekang/ITDD`. In both data, only the turns where knowledge is accessible are considered in response generation. More details are described in supplementary material.

We choose perplexity (PPL) of the ground-truth responses, BOW Embedding (Liu et al., 2016), and unigram F1 (Dinan et al., 2019) as metrics, where Embedding-based metrics are computed with an NLG evaluation open source available at `https://github.com/Maluuba/nlg-eval`, and F1 is calculated with the code published at `https://github.com/facebookresearch/ParlAI/blob/master/parlai/core/metrics.py`.

Besides automatic evaluation, we randomly sample 300 examples from Test Seen, Test Unseen, and the test set of CMU_DoG respectively, and recruit 3 well-educated native speakers as annotators for human evaluation. To each annotator, an example is presented with a context, the associated external knowledge[3], and model responses (top 1 in greedy search) that are randomly shuffled to hide their sources. The annotators then judge the quality of the responses from three aspects, including *fluency*, *context coherence* and *knowledge relevance*, and assign a score in $\{0, 1, 2\}$ (representing "bad", "fair", and "good") to each response for each aspect. Each response receives 3 scores per aspect, and the agreement among the annotators is measured via Fleiss' kappa (Fleiss, 1971).

5.2 Baselines

The following models are selected as baselines:

Transformer Memory Network (TMN): the model proposed in (Dinan et al., 2019) along with the release of the Wizard data. We implement it using the code shared at `https://github.com/facebookresearch/ParlAI/blob/master/projects/wizard_of_wikipedia`.

Incremental Transformer with Deliberation Decoder (ITDD): a transformer-based model (Li et al., 2019) that incrementally encodes multi-turn dialogues and knowledge and decodes responses with a deliberation technique. We implement it using the code shared at `https://github.com/lizekang/ITDD`.

Sequential Knowledge Transformer (SKT): a sequential latent variable model with state-of-the-art performance on knowledge selection published in a very recent paper (Kim et al., 2020). Since human labels that indicate ground-truth knowl-

edge are crucial to the performance of the model, we only involve it as a baseline on the Wizard data. The model is implemented with the code shared at https://github.com/bckim92/sequential-knowledge-transformer.

Disentangled Response Decoder (DRD): a model that tackles the low-resource challenge with pre-training techniques (Zhao et al., 2020). We choose the one in which all parameters are fine-tuned with the full training data after pre-training as the baseline, since such a configuration results in state-of-the-art performance on Wizard, as reported in (Zhao et al., 2020).

We name our model **KnowledGPT**. Besides the baselines described above, the following pre-trained models are also included in comparison in order to have a thorough understanding towards the proposed method: (1) **GPT-2$_{trunc}$**. We concatenate a context and the associated knowledge as a long document, and then truncate the document to meet the length constraint of the GPT-2 model. This is to check if the simple heuristics work for the task. Note that in Wizard, we randomly mix the ground-truth knowledge with others and repeat the procedure 8 times. The means with standard deviation (i.e., numbers in "( )") are reported to remove randomness; and (2) **SKT+GPT-2**. We feed the candidate selected by SKT to GPT-2 for response generation. This is to examine if we can simply replace the proposed knowledge selection module as well as the learning approach with an off-the-shelf knowledge selection model. Similar to SKT, the comparison is only conducted on Wizard.

5.3 Implementation Details

In both Wizard and CMU_DoG, we set the hidden size and the number of layers of the sequential knowledge selector as 256 and 1 respectively. T_{max} for D' is set as 1 in Wizard, and 2 in CMU_DoG. We choose BERT (110M) and GPT-2 (117M) as the pre-trained language models in KnowledGPT, and implement the models with the code in https://github.com/huggingface/transformers. We employ greedy search in response decoding. All models are learned with Adam (Kingma and Ba, 2015) optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. In warming up, we define $\mathrm{Sim}(\cdot, \cdot)$ as unigram F1, and optimize $g(U, D)$ and the GPT-2 model with the pseudo ground-truth for 1000 steps with a batch size of 64. In joint optimization, the batch size is set as 128, and the learning rates for $g(U, D)$ and GPT-2 are set as $5e-6$ and $5e-5$ respectively. The learning rate will be halved if there is no improvement in terms of PPL on the validation sets. The parameter p of the Bernoulli distribution in the curriculum step is initially set as 1.0 and anneals with a rate of $1e-5$. Early stopping on validation is adopted as a regularization strategy.

5.4 Evaluation Results

Table 2 and Table 3 report evaluation results on Wizard and CMU_DoG respectively. KnowledGPT achieves new state-of-the-art on most metrics in both datasets, which demonstrates the effectiveness of large-scale pre-trained language models on the task of knowledge-grounded dialogue generation. GPT-2$_{trunc}$ is worse than KnowledGPT, due to (1) knowledge loss: we find that in 53% test examples (Test Seen+Test Unseen), the ground-truth knowledge is cut. In this case, GPT-2$_{trunc}$ only relies on the context, the related knowledge in other candidates (thanks to the one-to-many relations between a context and knowledge), and the knowledge packed in the parameters of GPT-2 for responding, which explains the comparable per-

Table 5: Ablation study on Wizard and CMU_DoG

formance with SKT and DRD; and (2) noisy input: even though the ground-truth knowledge is kept, the redundant and irrelevant information in the knowledge candidates are still harmful. Evidence is that GPT-2$_{trunc}$ is worse than KnowledGPT on CMU_DoG even though we do not cut anything on the knowledge (the maximum length of the knowledge input is 502, and thus is within the constraint of GPT-2). KnowledGPT also outperforms SKT+GPT-2 on Wizard, because (1) KnowledGPT is more accurate than SKT on knowledge selection, even though it does not leverage any human annotations in learning. In fact, the accuracy scores of knowledge selection for SKT are 26.8 and 18.3 on Test Seen and Test Unseen respectively, while the two numbers are 28.0 and 25.4 respectively for KnowledGPT; and (2) in KnowledGPT, knowledge selection and response generation are jointly optimized.

Table 4 shows human evaluation results. While the three models are comparable on *fluency*, KnowledGPT is superior to the others on both *context coherence* and *knowledge relevance*, which is consistent with the results on automatic metrics. All kappa values are no less than 0.6, indicating substantial agreement among the annotators. We present a case study in supplementary material.

5.5 Discussions

Ablation study. To understand the impact of the learning strategies on model performance, we compare the full KnowledGPT with the following variants: (1) *-pseudo*: the warming up stage is removed; (2) *-joint*: the joint optimization stage is removed; (3) *-reinforcement*: $g(U, D)$ is fixed after it is optimized with MLE on $\mathcal{D}_K$; and (4) *-curriculum*: GPT-2 is fixed after it is optimized with MLE on $\mathcal{D}_G$. Table 5 reports the evaluation results. We can conclude that (1) the pseudo ground-truth plays a crucial role in Wizard, as removing the step causes dramatic performance drop. This is because in Wizard, there is a strong correlation between the knowledge and human responses. The results indicate that though the pseudo ground-truth is constructed with heuristics, it still contains valuable information and thus allows the following joint optimization to start from a good point. On the other hand, in CMU_DoG, the crowd-workers do not refer to the external knowledge as much as those workers do in Wizard when they form the responses; (2) the reinforcement step and curriculum step are useful because the reinforcement step allows the knowledge selection module to make better use of GPT-2's feedback, and through the curriculum step GPT-2 can take advantage of the output of knowledge selection module progressively; (3) joint optimization is meaningful, as removing this stage results in performance drop.

Models	Wizard				CMU_DoG	
	Test Seen		Test Unseen			
	PPL	F1	PPL	F1	PPL	F1
T$_{max}$=1	19.2	22.0	22.3	20.5	20.6	12.6
T$_{max}$=2	18.2	21.3	21.0	20.3	20.6	13.5
T$_{max}$=3	17.2	21.1	20.2	20.3	19.7	11.2

Table 6: Performance of KnowledGPT under different T_{max}s.

Impact of T_{max} (i.e., the upper bound in knowledge selection). Besides the learning strategies, we are also curious about how T_{max}, as part of the termination criterion in knowledge selection described at the end of Section 4.2, influences the performance of KnowledGPT. To this end, we vary the value of T_{max} in $\{1, 2, 3\}$ and report the evaluation results in Table 6. The larger T_{max} is, the more chances KnowledGPT has to involve the ground-truth candidate into generation, and the lower PPL is. This also explains why the PPL of GPT-2_{trunc} is lower than that of KnowledGPT in Table 2 and Table 3. On the other hand, a larger T_{max} also means more noise in generation. That is why when T_{max} exceeds a value, F1 begins to drop.

6 Conclusions

We apply large-scaled pre-trained language models to the task of knowledge-grounded dialogue generation. To this end, we devise a knowledge selection module, and propose an unsupervised approach to jointly optimizing knowledge selection and response generation. Evaluation results on two benchmarks indicate that our model can significantly outperform state-of-the-art methods.

A Details of Datasets

Table 7 reports the statistics of the Wizard data and the CMU_DoG data.

	Wizard of Wikipedia				CMU_DoG		
	Train	Valid	Test Seen	Test Unseen	Train	Valid	Test
# Utterances	166,787	17,715	8,715	8,782	74,717	4,993	13,646
# Conversations	18,430	1,948	965	968	3,373	229	619
# Topics/Documents	1,247	599	533	58	30	30	30
Avg. # of Turns	9.0	9.1	9.0	9.1	22.2	21.8	22.0

Table 7: Statistics of the two datasets.

B Comparison with DialoGPT

We compare KnowledGPT and with DialoGPT in order to learn if a pre-trained generation model with state-of-the-art performance on open domain dialogues is already good enough when it is fine-tuned with knowledge-grounded dialogues. We discard the associated knowledge and fine-tune DialoGPT on the knowledge-grounded dialogues. We choose the model trained from OpenAI GPT-2 with 345M parameters, as it shows the best performance in the evaluation in the original paper. The model is implemented based on the code shared at `https://github.com/microsoft/DialoGPT`.

Table 8 shows the results, indicating that external knowledge is necessary even though one has exploited a powerful pre-trained language model for dialogue generation. In CMU_DoG the gap between DialoGPT and KnowledGPT is narrowed because about 35% of the conversation has a weak correlation with the document (e.g. BLEU < 0.1).

Models	Wizard				CMU_DoG	
	Test Seen		Test Unseen			
	PPL	F1	PPL	F1	PPL	F1
DialoGPT	16.0	17.9	20.0	16.8	16.9	12.3
KnowledGPT	19.2	22.0	22.3	20.5	20.6	13.5

Table 8: Comparison with DialoGPT on Wizard and CMU_DoG

C Impact of Maximum Tokens of GPT-2

To further justify our claims on why GPT-2_{trunc} is worse than KnowledGPT, we keep the ground-truth knowledge in the input sequence of GPT-2 and gradually increase the constraint of the maximum number of tokens on Wizard. As the maximum token limit increases, more irrelevant knowledge is introduced. Note that in practice, one has no way to perfectly locate the ground-truth, and this experiment is only to provide more insights to GPT-2_{trunc}. Table 9 shows the performance of GPT-2_{trunc} with the increase of the maximum number of tokens where Ground-truth Percentage indicates the percentage of ground-truth in the input knowledge. First, when the ground-truth is forced to be kept, GPT-2_{trunc} is always better than the one where the ground-truth is randomly mixed with other candidates and bears the risk to be cut. This echoes our claim that knowledge loss is one of the reasons for the poor performance of GPT-2_{trunc} used with the practical setting. Second, even if ground-truth is retained, once more noise is introduced, the performance of GPT-2_{trunc} will become worse. When the length is limited to 128 tokens, the PPL of the model is not good, mainly because under this limitation, the input sequence of some cases only contains the dialogue context and response.

Maximum Tokens	Test Seen		Test Unseen		Ground-truth Percentage
	PPL	F1	PPL	F1	
128	10.8	30.9	11.6	30.4	62.3%
256	9.3	25.6	10.0	24.6	20.3%
512	9.7	21.8	10.5	21.2	8.5%
768	10.1	20.6	10.7	20.2	5.5%
1024	10.7	19.7	11.3	19.4	4.1%

Table 9: Performance of GPT-2_{trunc} under different maximum tokens with ground-truth knowledge involved.

Models	Wizard of Wikipedia				CMUDoG	
	Test Seen		Test Unseen			
	PPL	F1	PPL	F1	PPL	F1
KnowledGPT (117M)	19.2	22.0	22.3	20.5	20.6	13.5
KnowledGPT (345M)	16.1	22.0	17.9	20.6	18.1	13.4

Table 10: Performance of KnowledGPT under different sizes of GPT-2.

D Impact of the Size of GPT-2

We further check if the performance of KnowledGPT can be further improved when the GPT-2 model is replaced with a larger one. Table 10 shows the results. Though GPT-2 (345M) can further reduce PPL, it does not bring significant improvement to F1 over GPT-2 (117M), probably because the larger model can not provide more accurate feedback to the knowledge selection module in learning. Therefore, to balance efficacy and cost, GPT-2 (117M) is still favored in practice.

E Case Study

Table 11 and Table 12 show the examples from Test Seen and Test Unseen of Wizard, each example contains the dialogue context and the background knowledge which is retrieved from Wikipedia given the last two turns of dialogue and the original topic. We can see that KnowledGPT can locate the knowledge more accurately due to its knowledge selection module and reinforcement learning, and make better use of the associated knowledge with the help of curriculum learning.

<tr><th colspan="2">Knowledge (Topic: Cinematography)</th></tr>
<tr><td colspan="2">...
Cinematography (also called ”direction of photography”) is the science or art of motion-picture photography by recording light or other electromagnetic radiation, either electronically by means of an image sensor, or chemically by means of a light-sensitive material such as film stock.
Typically, a lens is used to repeatedly focus the light reflected from objects into real images on the light-sensitive surface inside a camera during a questioned exposure, creating multiple images.
With an electronic image sensor, this produces an electrical charge at each pixel, which is electronically processed and stored in a video file for subsequent display or processing.
The result with photographic emulsion is a series of invisible latent images on the film stock, which are later chemically ”developed” into a visible image.
The images on the film stock are played back at a rapid speed and projected onto a screen, creating the illusion of motion.
Cinematography finds uses in many fields of science and business as well as for entertainment purposes and mass communication.
The word ”cinematography” was created from the greek words (”kinema”), meaning ”movement, motion” and (”graphein”) meaning ”to record”, together meaning ”recording motion.”

MinTL: Minimalist Transfer Learning for Task-Oriented Dialogue Systems

Zhaojiang Lin, Andrea Madotto, Genta Indra Winata, Pascale Fung
Center for Artificial Intelligence Research (CAiRE)
Department of Electronic and Computer Engineering
The Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong
`zlinao@connect.ust.hk`

Abstract

In this paper, we propose Minimalist Transfer Learning (*MinTL*) to simplify the system design process of task-oriented dialogue systems and alleviate the over-dependency on annotated data. *MinTL* is a simple yet effective transfer learning framework, which allows us to plug-and-play pre-trained seq2seq models, and jointly learn dialogue state tracking and dialogue response generation. Unlike previous approaches, which use a copy mechanism to "carryover" the old dialogue states to the new one, we introduce *Levenshtein belief spans* (*Lev*), that allows efficient dialogue state tracking with a minimal generation length. We instantiate our learning framework with two pre-trained backbones: T5 (Raffel et al., 2019) and BART (Lewis et al., 2019), and evaluate them on MultiWOZ. Extensive experiments demonstrate that: 1) our systems establish new state-of-the-art results on end-to-end response generation, 2) *MinTL*-based systems are more robust than baseline methods in the low resource setting, and they achieve competitive results with only 20% training data, and 3) *Lev* greatly improves the inference efficiency[1].

1 Introduction

Building robust task-oriented dialogue systems is challenging due to complex system design and limited availability of human-annotated data (Wen et al., 2017; Wu et al., 2019b). A dialogue agent is expected to learn dialogue reasoning, decision making, and language generation, which require a large amount of training data. However, collecting and annotating data for training a dialogue system is time-intensive and not transferable among domains (Young et al., 2013). One possible workaround is to leverage the pre-trained language model to reduce human supervision (Budzianowski and Vulić, 2019).

Recent progress in pre-training language models has been shown to be promising in alleviating the data scarcity problem (Budzianowski and Vulić, 2019; Wu et al., 2020). Such models are typically pre-trained on large-scale plain text with self-supervised objectives, e.g., language modeling (Radford et al., 2019) and language denoising (Devlin et al., 2019). Fine tuning pre-trained language models improves a wide range of natural language processing applications (Lewis et al., 2019; Raffel et al., 2019), notably machine translation (Conneau and Lample, 2019), and personalized dialogue response generation (Wolf et al., 2019b). However, adapting pre-trained language models to task-oriented dialogue systems is not trivial. Current state-of-the-art (SOTA) approaches in task-oriented dialogue rely on several tasks-specific modules, such as State Operation Predictor (Kim et al., 2019) for dialogue state tracking, and CopyNet (Gu et al., 2016) for end-to-end dialogue task completion (Lei et al., 2018; Zhang et al., 2019b). Such modules are usually absent in the pre-training stage. Therefore, tasks-specific architecture modifications are required in order to adapt pre-trained language models to different dialogue tasks.

In this work, we aim to simplify the process of transferring the prior knowledge of pre-trained language models for improving task-oriented dialogue systems. We propose Minimalist Transfer Learning (*MinTL*), a simple yet effective transfer learning framework that allows to plug-and-play pre-trained sequence-to-sequence (Seq2Seq) models and jointly learn dialogue state tracking (DST) and dialogue response generation. Unlike previous approaches (Lei et al., 2018; Zhang et al., 2019b), which use a copy mechanism to "carryover" the previous dialogue states and generate new dialogue states, we introduce *Levenshtein belief spans* (*Lev*)

---

[1] Code available in `https://github.com/zlinao/MinTL`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3391–3405,
November 16–20, 2020.

which models the difference between old states and new states. In practice, *MinTL* first decodes the Lev for updating the previous dialogue state; then, the updated state is used to search the external knowledge base; and finally, a response decoder decodes response by conditioning on the dialogue context and knowledge base match result.

MinTL is easy to set up by using different pre-trained seq2seq backbones. We conduct extensive experiments on both DST and end-to-end dialogue response generation tasks with two pre-trained seq2seq models, such as T5 (Raffel et al., 2019) and BART (Lewis et al., 2019). The experimental result on a large-scale task-oriented dialogue benchmark MultiWOZ (Budzianowski et al., 2018; Eric et al., 2019) suggests that our proposed method significantly improves SOTA performance in both the full data and simulated low resource setting. Our contributions are summarized as follows:

- We propose the *MinTL* framework that efficiently leverages pre-trained language models for task-oriented dialogue without any ad hoc module.
- We propose the novel Lev for efficiently tracking the dialogue state with the minimal length of generation, which greatly reduces the inference latency.
- We instantiate our framework with two different pre-trained backbones, and both of them improve the SOTA results by a large margin.
- We demonstrate the robustness of our approach in the low-resource setting. By only using 20% training data, *MinTL*-based systems achieve competitive results compared to the SOTA.

2 Related Work

Pre-trained Language Models. Language model (LM) pre-training (Radford et al., 2019; Devlin et al., 2019; Yang et al., 2019), has been shown to be beneficial in NLP downstream tasks. Generative pre-trained unidirectional LMs (e.g., GPT2) are effective in language generation tasks (Radford et al., 2019; Hosseini-Asl et al., 2020; Peng et al., 2020; Lin et al., 2020). Several works have applied a generative pre-training approach in open domain chitchat tasks (Wolf et al., 2019b; Zhang et al., 2019c), and achieved promising results. On the other hand, bidirectional pre-trained LMs (Devlin et al., 2019; Liu et al., 2019) significantly improve the performance of natural language understanding tasks. These models are usually evaluated on classification tasks such as the GLUE benchmark (Wang et al., 2018), extractive question answering tasks (Rajpurkar et al., 2016), and dialogue context understanding (Wu et al., 2020). However, their bidirectionality nature makes them difficult to be applied to natural language generation tasks (Dong et al., 2019). Recent works (Dong et al., 2019; Raffel et al., 2019; Lewis et al., 2019) unified unidirectional LM and bidirectional LM pre-training approaches, and proposed a Seq2Seq LM, which are pre-trained with language denoising objectives. A systematic study conducted by Raffel et al. (2019) suggests that the combination of an encoder-decoder architecture and language denoising pre-training objectives yields the best result in both language understanding and generation tasks. Notably, the two latest pre-trained chatbots, Meena (Adiwardana et al., 2020) and BST (Roller et al., 2020), are also built on an encoder-decoder architecture. In this work, we transfer the prior knowledge of Seq2Seq LMs to task-oriented dialogues, and successfully improve the SOTA (Zhang et al., 2019b) result with less human annotation.

Task-Oriented Dialogue. Task-oriented dialogue systems are designed to accomplish a goal described by a user in natural language. Such systems are usually built with a pipeline approach. The pipeline often requires natural language understanding (NLU) for belief state tracking, dialogue management (DM) for deciding which actions to take, and natural language generation (NLG) for generating responses (Williams and Young, 2007). To simplify the system design and reduce human supervision, several end-to-end trainable systems have been proposed (Bordes et al., 2016; Wen et al., 2017; Lei et al., 2018; Neelakantan et al., 2019; Eric and Manning, 2017; Eric et al., 2017; Madotto et al., 2018). These methods have been shown to achieve promising results in single-domain tasks. However, the recently proposed multi-domain task-oriented dialogue datasets (Budzianowski et al., 2018; Eric et al., 2019) bring new challenges for multi-domain dialogue state tracking and response generation. Several follow up works (Wu et al., 2019a; Chen et al., 2019; Budzianowski and Vulić,

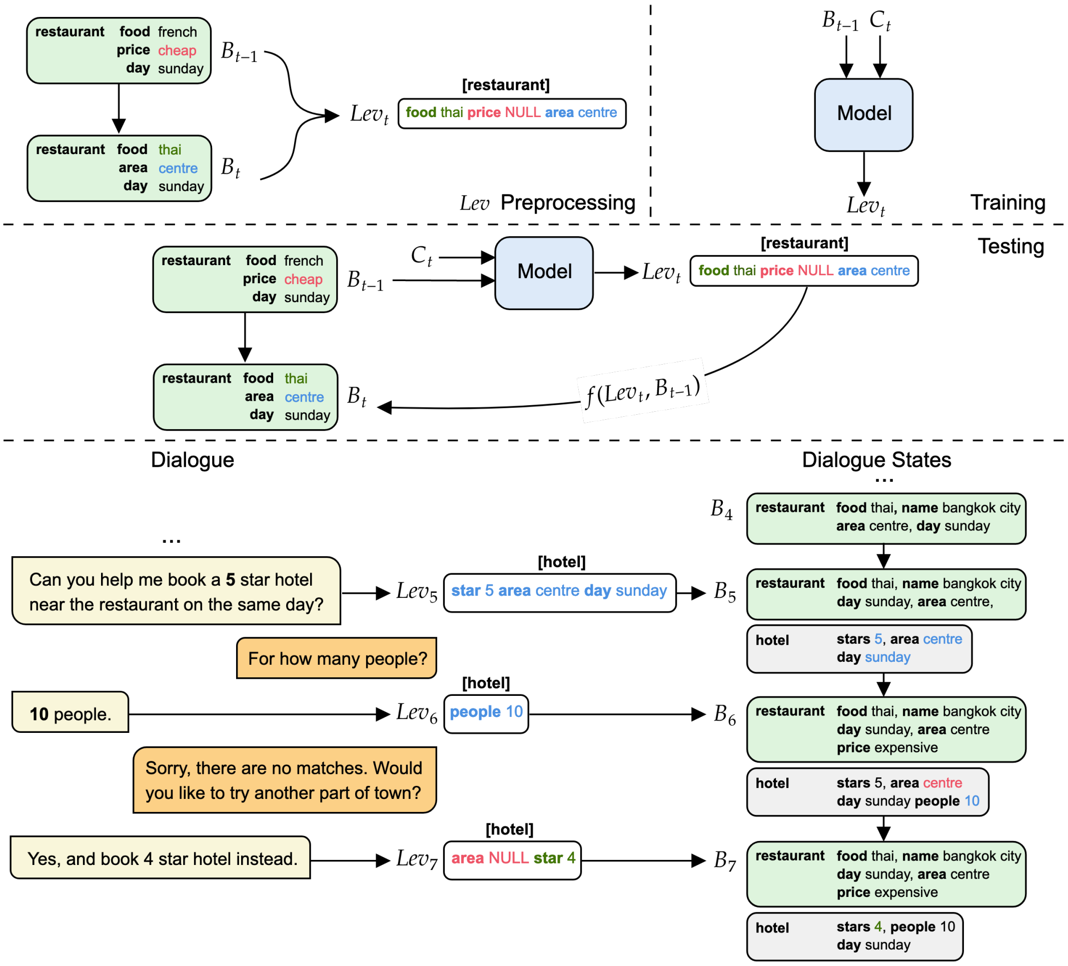

Figure 1: Dialogue state tracking with Lev. The model first generates Lev, then updates the dialogue state with new generated slot-values. The updating operations are insertion (blue), deletion (red), and substitution (green).

2019; Mehri et al., 2019; Madotto et al., 2020b) improved on the initial baselines with various methodologies. Zhang et al. (2019b) proposed the domain aware multi-decoder network and augmented the system act labels by leveraging the user act annotation, achieving the SOTA results in MultiWoz. However, the aforementioned works rely on task-specific design and extensive human annotations. To reduce the human effort and simplify the system design, we propose a simple transfer learning framework that can be easily set up with pre-trained Seq2Seq models and obtain decent performance with a small fraction of the training data.

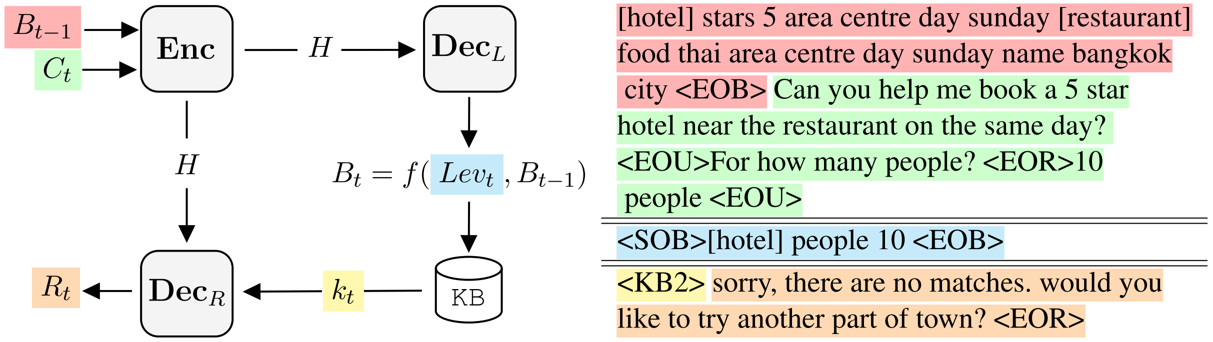
3 Methodology

In this section, we first provide the notations that are used throughout the paper, then we introduce the Lev for efficient DST, and finally, describe the *MinTL* framework and two backbone models.

Notations. Let us define a dialogue $\mathcal{C} = \{U_1, R_1, \dots, U_T, R_T\}$ as an alternating set of utterances from two speakers, where U and R represent the user utterance and the system response, respectively. At turn t, we denote a dialogue context as $C_t = \{U_{t-w}, R_{t-w}, \dots, R_{t-1}, U_t\}$ and system response as R_t, where w is the context window size. $\mathcal{B} = \{B_1, \dots, B_T\}$ is the dialogue states for each turn. We define B_t, the dialogue state at turn t, as a dictionary that maps (domain: d_i, slot: s_j) a pair into values v, where $\mathcal{D} = \{d_1, \dots, d_N\}$ are the domains, and $\mathcal{S} = \{s_1, \dots, s_M\}$ are slots to track. Thoughtout the paper, we denote the value of a pair (d_i, s_j) in B_t as $B_t(d_i, s_j) = v$, and $B_t(d_i, s_j) = \varepsilon$ when key (d_i, s_j) is not in B_t, where ε denotes an empty string, and $|\varepsilon| = 0$.

3.1 Levenshtein Belief Spans

The goal of DST is to track the slot values for each domain mentioned in dialogue. Existing works either perform classifications for each slot over a



[hotel] stars 5 area centre day sunday [restaurant] food thai area centre day sunday name bangkok city <EOB> Can you help me book a 5 star hotel near the restaurant on the same day? <EOU>For how many people? <EOR>10 people <EOU>

<SOB>[hotel] people 10 <EOB>

<KB2> sorry, there are no matches. would you like to try another part of town? <EOR>

Figure 2: Overview of the *MinTL* framework. The left figure shows the information flow among all modules. The explicit inputs and outputs of each module are described on the right. *MinTL* first encodes previous dialogue state B_t and dialogue context C_t, and decodes Lev_t. Then Lev_t is used to update B_{t-1} to B_t via function f. The updated B_t is used to query the KB and booking API and return KB state k_t. Finally, the R_t is generated by conditioning on B_{t-1}, C_t and k_t.

candidate-value list (Zhang et al., 2019a) or directly generate slot values with a generative model (Lei et al., 2018; Wu et al., 2019a; Kim et al., 2019; Le et al., 2020). Notably, Lei et al. (2018) introduce the concept of *Belief span* that reformats the dialogue states into a text span for allowing models to generate slot values dynamically. Compared to classification based DST, generative DST models can predict the slot values without full access to predefined ontology. However, the aforementioned generative methods either generate the belief span from scratch (Lei et al., 2018) or classify the state operations over all the combinations of domain slot pairs for decoding necessary slot values (Kim et al., 2019; Le et al., 2020), which is not scalable when interfacing to a large number of services and APIs spanning multiple domains (Rastogi et al., 2019).

The idea of Lev is to generate minimal belief spans at each turn for editing the previous dialogue states. As illustrated in Figure 1, Lev is constructed at training time as the DST training target. Given B_{t-1}, B_t, and a pair of (d_i, s_j), we define the three slot level edit operation conditions, i.e., insertion (`INS`), deletion (`DEL`) and substitution (`SUB`), as:

$$\texttt{INS} \rightarrow B_t(d_i, s_j) \neq \varepsilon \wedge B_{t-1}(d_i, s_j) = \varepsilon \quad (1)$$

$$\texttt{DEL} \rightarrow B_t(d_i, s_j) = \varepsilon \wedge B_{t-1}(d_i, s_j) \neq \varepsilon \quad (2)$$

$$\texttt{SUB} \rightarrow B_t(d_i, s_j) \neq B_{t-1}(d_i, s_j). \quad (3)$$

In domain d_i, to update the $B_{t-1}(d_i, s_j)$ to $B_t(d_i, s_j)$, the minimal slot-value pair needed to be generated is $E(d_i, s_j)$, defined as

$$E(d_i, s_j) = \begin{cases} s_j \oplus B_t(d_i, s_j) & \text{if } \texttt{INS} \\ s_j \oplus \texttt{NULL} & \text{if } \texttt{DEL} \\ s_j \oplus B_t(d_i, s_j) & \text{if } \texttt{SUB} \\ \varepsilon & \text{otherwise,} \end{cases} \quad (4)$$

where $\oplus$ denotes string concatenation. `NULL` is the symbol denoting to delete the slot (d_i, s_j) from B_{t-1}. Then, we aggregate all the $E(d_i, s_j)$ for domain d_i as follows:

$$L(d_i) = E(d_i, s_1) \oplus \cdots \oplus E(d_i, s_M). \quad (5)$$

When the dialogue state of domain d_i needs to be updated, i.e., $L(d_i) \neq \varepsilon$, we append the domain information $[d_i]$ at the beginning of $L(d_i)$ to construct Lev of domain d_i:

$$\delta(L, d_i) = \begin{cases} [d_i] \oplus L(d_i) & \text{if } L(d_i) \neq \varepsilon \\ \varepsilon & \text{otherwise.} \end{cases} \quad (6)$$

Finally, we formally define Lev as the following:

$$Lev = \delta(L, d_1) \oplus \cdots \oplus \delta(L, d_N). \quad (7)$$

At inference time, the model first generates Lev_t at turn t, then edits the B_{t-1} by using a deterministic function f, defined as:

$$B_t = f(Lev_t, B_{t-1}). \quad (8)$$

This function simply update the B_{t-1} when new slot-value pairs appear in Lev_t, and it delete the corresponding slot-value when the `NULL` symbol is generated.

Figure 1 shows an example of editing the dialogue state editing process using Lev. In the 6-th turn, the generated Lev_6 inserts the value 10 into the slot *people*. In the 7-th turn, the `NULL` in Lev_7 triggers the `DEL` operation, and thus the slot $(hotel, area)$ is deleted in B_6, which is equivalent to $B_7(hotel, area) = \varepsilon$.

3.2 *MinTL* Framework

Figure 2 describes the flow of the *MinTL* framework with a general encoder-decoder architecture. The input of our framework is a dialogue context C_t and a previous dialogue state B_{t-1}. All sub-sequences are concatenated with special segment tokens, i.e., B_{t-1}<EOB>…R_{t-1}<EOR>U_t<EOU>, as input to the encoder.

$$H = Encoder(\mathcal{C}_t, B_{t-1}), \tag{9}$$

where the $H \in \mathbb{R}^{I \times d_{model}}$ is the hidden states of the encoder, and I is the input sequence length. Then, the Lev decoder attends to the encoder hidden states H and decodes Lev_t sequentially:

$$Lev_t = Decoder_L(H). \tag{10}$$

The learning objective of this generation process is minimizing the negative log-likelihood of Lev_t given $\mathcal{C}_t$ and B_{t-1}, that is

$$\mathcal{L}_L = -\log p(Lev_t|\mathcal{C}_t, B_{t-1}). \tag{11}$$

The generated Lev_t is used for editing the B_{t-1} with the deterministic function f described in Equation 8.

The updated B_t is used to query the external knowledge (KB) and booking APIs. We first categorize the query result k_t according to the number of matching entities and the booking availability (a detailed list of k_t values is provided in the Appendix A). According to the result, we look up one embedding $e_k \in \mathbb{R}^{d_{model}}$ from the set of learnable KB state embeddings $E_k \in \mathbb{R}^{K \times d_{model}}$ [2], where K is the number of possible KB states. Then, the looked up embedding e_k is used as the starting token embedding of the response decoder for generating the delexicalized response R_t:

$$R_t = Decoder_R(H, e_k). \tag{12}$$

The learning objective of response generation is minimizing the negative log-likelihood of R_t given $B_{t-1}, \mathcal{C}_t$ and k_t,

$$\mathcal{L}_R = -\log p(R_t|\mathcal{C}_t, B_{t-1}, k_t). \tag{13}$$

Different from previous works (Lei et al., 2018; Zhang et al., 2019b), our response generation process is not condition on B_t because the dialogue context C_t already includes the information of B_t.

During training, all parameters are jointly optimized by minimizing the sum of the Lev generation and response generation losses:

$$\mathcal{L} = \mathcal{L}_L + \mathcal{L}_R. \tag{14}$$

3.3 Backbone Models

Our framework can be easily set up with pre-trained language models by initializing the encoder and decoders with pre-trained weights. We briefly introduce the two pre-trained backbones used in this paper: BART (Lewis et al., 2019) and Text-To-Text Transfer Transformer (T5) (Raffel et al., 2019).

BART is implemented as a standard encoder-decoder Transformer with a bidirectional encoder and an autoregressive decoder. It is pre-trained as denoising autoencoders which corrupt documents, and then optimize a reconstruction loss—the cross-entropy between the decoder's output and the original document. BART applies five different document corruption methods in the pre-training, including Token Masking (Devlin et al., 2019), Token Deletion, Text Infilling (Joshi et al., 2020), Sentence Permutation, and Document Rotation.

T5 is an encoder-decoder Transformer with relative position embeddings (Shaw et al., 2018). The model is pre-trained on the Colossal Clean Crawled Corpus (C4) (Raffel et al., 2019) that contains about 750GB of clean and natural English text. The pre-training objective is spans prediction, i.e., masking out 15% of input spans, then predicting the missing spans using the decoder.

4 Experiments

4.1 Datasets

We evaluate the proposed framework on the MultiWOZ dataset. It is a large-scale multi-domain task-oriented dialogue benchmark collected via the Wizard-of-Oz setting. The dataset contains 8438/1000/1000 dialogues for training/validation/testing, respectively. The dialogues

in the corpus span over seven domains (restaurant, train, attraction, hotel, taxi, hospital, and police), and each dialogue session contains one to three domains. There are two existing dataset versions: MultiWOZ 2.0 (Budzianowski et al., 2018) and MultiWOZ 2.1 (Eric et al., 2019). We test the dialogue state tracking module of our framework on both datasets, and end-to-end models on MultiWOZ 2.0.

4.2 Implementation Details

We set up our framework with three pre-trained models: 1) T5-small (60M parameters) has 6 encoder-decoder layers and each layer has 8-headed attention with hidden size $d_{model} = 512$; 2) T5-base (220M parameters) has 12 encoder-decoder layers, and each of them has 12-headed attention with hidden size $d_{model} = 768$; 3) BART-large (400M parameters) has 12 encoder-decoder layers, each layer has 16-headed attention with hidden size $d_{model} = 1024$. We add special segment token embeddings and KB state embeddings to pre-trained models by extending the token embeddings. For a fair comparison, we use the pre-processing script released by Zhang et al. (2019b) [3]. All the models are fine-tuned with a batch size of 64 and early stop according to the performance on the validation set. Our implementation is based on HuggingFace Transformers library (Wolf et al., 2019a). We report the training hyper-parameters of each model in Appendix B.

4.3 Evaluation Metrics

For the end-to-end dialogue modeling task, there are three automatic metrics to evaluate the response quality: 1) **Inform** rate: if the system provides a correct entity, 2) **Success** rate: if the system provides the correct entity and answers all the requested information, 3) **BLEU** (Papineni et al., 2002) for measuring the fluency of the generated response. Following previous work (Mehri et al., 2019), we also report the combined score, i.e., **Combined** = (Inform + Success)×0.5 + BLEU, as an overall quality measure. Joint goal accuracy (**Joint Acc.**) is used to evaluate the performance of the DST. The model outputs are only counted as correct when all of the predicted values exactly match the oracle values.

4.4 Baselines

4.4.1 End-to-end Modeling

Oracle DST: **Seq2Seq**, fine-tuned **GPT2-small**, and **GPT2-medium** (Radford et al., 2019) with oracle dialogue state as input (Budzianowski et al., 2018).

HRED-TS: a teacher-student framework with a hierarchical recurrent encoder-decoder backbone (Peng et al., 2019).

SFN + RL: a seq2seq network comprised of several pre-trained dialogue modules that are connected through hidden states. Reinforcement fine tuning is used additionally to train the model (Mehri et al., 2019).

Table 3: Ablation study on different variants of *MinTL* on MultiWOZ 2.0 in the end-to-end evaluation setting.

MD-Sequicity: an extension of the *Sequicity* (Lei et al., 2018) framework for multi-domain task-oriented dialogue by Zhang et al. (2019b).

DAMD: the domain-aware multi-decoder network proposed by Zhang et al. (2019b). The author also proposed the multi-action data augmentation method by leveraging system act and user act annotations. We denote the method as **DAMD + multi-action**.

Sequicity + T5: The *Sequicity* (Lei et al., 2018) framework with the T5 backbone model (Raffel et al., 2019). There are two main differences between *Sequicity* and our framework: 1) *Sequicity* generates dialogue states from scratch at each turn, 2) *MinTL* generates responses by conditioning on dialogue context C_t instead of new generated dialogue state B_t.

4.4.2 Dialogue State Tracking

We compare our DST module with both the classification-based DST and generation-based DST baselines. The former includes MDBT (Ramadan et al., 2018), GLAD (Zhong et al., 2018), GCE (Nouri and Hosseini, 2018), FJST (Eric et al., 2019), HyST (Goel et al., 2019), SUMBT (Lee et al., 2019), SST (Chen et al., 2020), TOD-BERT (Wu et al., 2020), and DST-Picklist (Zhang et al., 2019a); the latter includes Neural Reading (Gao et al., 2019), TRADE (Wu et al., 2019a), COMER (Ren et al., 2019), SOM-DST (Kim et al., 2019), DSTQA (Zhou and Small, 2019), and NADST (Le et al., 2020).

4.5 Results

4.5.1 End-to-end Modeling

We first compare our systems with baselines in the end-to-end dialogue learning setting, where the generated dialogue states are used for the knowledge base search and response generation. The results are shown in Table 1. *MinTL*-based systems achieve the best performance in terms of inform rate, success rate, and BLEU. With fewer human annotations, our models improve the previous SOTA model (Zhang et al., 2019b) by around a 10% success rate. Using T5-small as the backbone barely improves the overall performance of *Sequicity* (Lei et al., 2018), because the copy mechanism (Gu et al., 2016) is absent in this pre-trained model. Compared to the *Sequicity* framework, our approach achieves an around 11% higher success rate with the same backbone model, which suggests that *MinTL* is able to effectively leverage pre-trained language models.

Low Resource Settings. We evaluate our models in the simulated low resource setting to test if transferring a pre-trained language model to task-oriented dialogue can alleviate the data scarcity problem. Specifically, we use 5%, 10%, and 20% of the training set data to train our models and baselines. The result is reported in Table 2. *MinTL*-based systems consistently outperform the DAMD (Zhang et al., 2019b), MD-Sequicity (Lei et al., 2018) baselines by a large margin, which demonstrates the effectiveness of transfer learning. It is worth noting that the performance gap between *MinTL* and baselines decreases with respect to the increase in the training data size. This indicates that prior knowledge from the pre-trained language model is more important in the extremely low-resource scenarios. With only 20% of training

data, our models can achieve competitive results compared to the full data trained DAMD model.

Ablation Study. We conduct a simple ablation study with the T5-small backbone to understand the different variants of *MinTL*. We test our framework with: 1) the belief span proposed by Lei et al. (2018), and 2) sharing the decoder parameter for both Lev generation and response generation. The result is reported in Table 3. Replacing Lev with *belief span* hurts the overall performance, which shows the effectiveness of Lev. In section 4.5.2, we also show that Lev greatly reduces the inference latency. On the other hand, although the Lev generation and response generation are conditioned on different starting tokens, sharing the parameters of the two decoders decreases both inform and success rate. It is important to decouple the two decoders because the distributions between the Lev decoder and response decoder are different.

4.5.2 Dialogue State Tracking

Table 4 reports the DST results on MultiWOZ 2.0 and MultiWOZ 2.1. *MinTL*-based BART model achieves the highest joint goal accuracy among the generation-based DST models on both datasets. Compared to the SOTA classification-based DST model SST (Chen et al., 2020), our model obtains a 1.62% lower joint goal accuracy on MultiWOZ 2.1. This is because classification-based models have the advantage of predicting slot values from valid candidates. However, having one classifier per domain-slot pair is not scalable when the number of slots and values grow (Lei et al., 2018). In contrast, our model only generates minimal slot-value pairs when necessary. In our error analysis, we found that our model sometimes generates invalid slot values (e.g., *the cambridge punte* instead of *the cambridge punter* for the *taxi-destination* slot), which can be avoided with a full ontology constraint.

Table 5: Latency analysis on MultiWOZ 2.1. **Latency** denotes the average inference time (ms) per turn and **NoT** denotes the average number of generated tokens per turn. ⋆: results borrowed from Le et al. (2020)

Latency Analysis. Table 5 reports the average inference time (ms) of each model on the test set of MultiWOZ 2.1. Following Le et al. (2020), we compute the latency of each model on Nvidia V100 with a batch size of 1. Our model is 15 times faster than TSCP (Lei et al., 2018) and around 7 times faster than TRADE (Wu et al., 2019a). On the other hand, our model is slower than NADST (Le et al., 2020), which is explicitly optimized for inference speed using the non-autoregressive decoding strategy. However, it is hard to incorporate NADST into end-to-end response generation models due to its task-specific architecture design (e.g., fertility decoder). Finally, we compare the generative DST modules of two end-to-end models. By using same backbone model, *MinTL* is around 4 times faster than Sequicity by generating only 6 tokens per turn, which suggests that Lev significantly improves the inference efficiency.

5 Conclusion

In this paper, we proposed *MinTL*, a simple and general transfer learning framework that effectively leverages pre-trained language models to jointly learn DST and dialogue response generation. The Lev is proposed for reducing the DST complexity and improving inference efficiency. In addition, two pre-trained Seq2Seq language models: T5 (Raffel et al., 2019) and BART (Lewis et al., 2019) are incorporated in our framework. Experimental results on MultiWOZ shows that, by using *MinTL*, our systems not only achieve new SOTA result on both dialogue state tracking and end-to-end response generation but also improves the inference efficiency. In future work, we plan to explore task-oriented dialogues domain-adaptive pre-training methods (Wu et al., 2020; Peng et al., 2020) to enhance our language model backbones, and extend the framework for mixed chit-chat and task-oriented dialogue agents (Madotto et al., 2020a).

A Appendices

A.1 KB States

Table 6 shows KB states that are categorized by the number of matching entities and booking availability. T_1, T_2 are thresholds of the number of match entities. We define $T_1 = 1$ and $T_2 = 3$ for train domain, $T_1 = 5$ and $T_2 = 10$ for other domains.

KB States	Entity Match	Book Availability
KB1	-	-
KB2	0	-
KB3	$\leq T_1$	-
KB4	$\leq T_2$	-
KB5	$> T_2$	-
KB6	-	fail
KB7	0	fail
KB8	$\leq T_1$	fail
KB9	$\leq T_2$	fail
KB10	$> T_2$	fail
KB11	-	success
KB12	0	success
KB13	$\leq T_1$	success
KB14	$\leq T_2$	success
KB15	$> T_2$	success

Table 6: KB states categorized by the number of matching entities and booking availability. T_1 and T_2 are thresholds. We define $T_1 = 1$ and $T_2 = 3$ for train domain, $T_1 = 5$ and $T_2 = 10$ for other domains.

A.2 Hyper-parameters

We report our training hyper-parameters on each task, which includes context window size `w`, learning rate `lr`, and learning rate decay rate `lr-decay`. We decay the learning rate when the performance in validation set does not improve. All of models are trained on Nvidia V100.

Task	Model	w	lr	lr-decay
End-to-End Response Generation	T5-small	2	6e-4	0.8
	T5-base	2	6e-4	0.8
	BART-large	2	3e-5	0.8
DST	T5-small	3	6e-4	0.8
	T5-base	3	6e-4	0.8
	BART-large	3	1e-5	0.8

Table 7: This table reports the hyper-parameters used by each model. w: window size, `lr`: learning rate, `lr-decay`: learning rate decay rate per epoch.

A.3 Generated Examples

Table 8 - 10 shows the end-to-end response generation examples by *MinTL* with T5-small, T5-base, and BART-large backbones.

MUL0113		**Dialogue**
Turn 1	User	i am in need of an expensive indian restaurant for dinner .
	Dialogue State	[restaurant] food indian pricerange expensive
	Delex. Response	there are [value_choice] [value_price] [value_food] restaurants . do you have a preference for area ?
	Lex. Response	There are 14 expensive indian restaurants . Do you have a preference for area ?
	Gold Response	there are 14 such restaurants . do you want to be in a specific part of town ?
Turn 2	User	i don't care what part of town it is in , i would like a phone number please .
	Dialogue State	[restaurant] food indian pricerange expensive
	Delex. Response	[value_name] is in the [value_area] and is in the [value_price] price range . their phone number is [value_phone] .
	Lex. Response	Curry Garden is in the centre and is in the expensive price range . Their phone number is 01223302330 .
	Gold response	sure , i am sorry . i have curry garden their phone number is 01223302330 . would you like me to reserve a table for you ?
Turn 3	User	not at this time . i am looking for a 3-star hotel , though . no guest house .
	Dialogue State	[restaurant] food indian pricerange expensive [hotel] stars 3 type hotel
	Delex. Response	there are [value_choice] [value_type] that meet your criteria . [value_name] and [value_name] . would you like me to book 1 of these for you ?
	Lex. Response	There are 2 hotel that meet your criteria . Gonville Hotel and the Lensfield Hotel . Would you like me to book 1 of these for you ?
	Gold response	i have found the gonville hotel . it is a 3 star hotel . would you like me to book it for you ?
Turn 4	User	not yet . is the gonville hotel in the same price range as the curry garden ?
	Dialogue State	[restaurant] food indian pricerange expensive [hotel] stars 3 type hotel
	Delex. Response	yes , it is in the [value_price] price range . would you like me to book it for you ?
	Lex. Response	yes , it is in the expensive price range . would you like me to book it for you ?
	Gold response	yes , it is an expensive hotel .
Turn 5	User	can you book a room for 2 people for 2 nights starting on sunday ?
	Dialogue State	[restaurant] food indian pricerange expensive [hotel] stars 3 type hotel people 2 day sunday stay 2
	Delex. Response	I am sorry , but the booking was unsuccessful . Would you like to try another day or a shorter stay ?
	Lex. Response	I am sorry , but the booking was unsuccessful . Would you like to try another day or a shorter stay ?
	Gold response	the booking was unsuccessful . would you like to try for another day or a shorter stay ?
Turn 6	User	could you try it for 1 night ? if that works , please book it and get the reference number .
	Dialogue State	[restaurant] food indian pricerange expensive [hotel] stars 3 type hotel people 2 day sunday stay 1
	Delex. Response	booking was successful . reference number is : [value_reference] .
	Lex. Response	Booking was successful . Reference number is : 5VRJSMSE .
	Gold response	you are all set for 1 night (sunday) , reference number is 6wvv053q . would you like to try another location for monday night ?
Turn 7	User	no . that is all i need , thank you .
	Dialogue State	[restaurant] food indian pricerange expensive [hotel] stars 3 type hotel people 2 day sunday stay 1
	Delex. Response	You are welcome . Have a great day .
	Lex. Response	You are welcome . Have a great day .
	Gold response	thank you , and goodbye .

Table 8: *MinTL* (T5-small) end-to-end response generation on the test set of MultiWOZ. We show the dialogue states, delexicalized responses, lexicalized responses generated by our model.

PMUL2000		**Dialogue**
Turn 1	User	i am looking for information on a hotel called hobsons house .
	Dialogue State	[hotel] name hobsons house
	Delex. Response	[value_name] is a [value_type] in the [value_area] . it is [value_price] and has a [value_stars] star rating . would you like to book a room ?
	Lex. Response	Hobsons House is a guest house in the west . It is moderate and has a 3 star rating . Would you like to book a room ?
	Gold response	hobsons house is a guest house found in the west side of town . it is in the moderate price range and is rated 3 stars .
Turn 2	User	do they have free parking ?
	Dialogue State	[hotel] name hobsons house
	Delex. Response	yes , they do have free parking .
	Lex. Response	Yes , they do have free parking .
	Gold response	yes hobsons house has both free internet and parking . would you like to book a room ?
Turn 3	User	can i please get their postcode ?
	Dialogue State	[hotel] name hobsons house
	Delex. Response	the postcode is [value_postcode] . is there anything else i can help you with today?
	Lex. Response	The postcode is CB39LH . Is there anything else i can help you with today ?
	Gold response	yes , of course ! it is cb39lh .
Turn 4	User	i also need a train that should depart from kings lynn and should go to cambridge .
	Dialogue State	[hotel] name hobsons house [train] destination cambridge departure kings lynn
	Delex. Response	there are [value_choice] trains that leave from [value_departure] to [value_destination] . what day would you like to travel ?
	Lex. Response	There are 133 trains that leave from kings lynn to cambridge . What day would you like to travel ?
	Gold response	what day will you travel ?
Turn 5	User	i 'll be traveling on monday and need to arrive by 10 :00 .
	Dialogue State	[hotel] name hobsons house [train] destination cambridge departure kings lynn day monday arrive 10 :00
	Delex. Response	the [value_id] leaves at [value_leave] and arrives at [value_arrive] . would you like me to book that for you ?
	Lex. Response	The TR4943 leaves at 05:11 and arrives at 05:58 . Would you like me to book that for you ?
	Gold response	the tr0942 leaves kings lynn at 09 :11 and arrives in cambridge at 09 :58 . would you like to book a reservation ?
Turn 6	User	yes can i book it for 8 people ?
	Dialogue State	[hotel] name hobsons house [train] destination cambridge departure kings lynn day monday arrive 10 :00 people 8
	Delex. Response	booking was successful , the total fee is [value_price] payable at the station . reference number is : [value_reference] .
	Lex. Response	Booking was successful , the total fee is 9.80 pounds payable at the station . Reference number is : I4AFI8ET .
	Gold response	you are all set ! your reference # is 2pffj67j . total cost is 78 .40 gbp , payable at the station . can i help you with anything else today ?
Turn 7	User	no , thank you . i have everything i need .
	Dialogue State	[hotel] name hobsons house [train] destination cambridge departure kings lynn day monday arrive 10 :00 people 8
	Delex. Response	you are welcome . have a great day .
	Lex. Response	You are welcome . Have a great day .
	Gold response	you have a wonderful day . goodbye .

Table 9: *MinTL* (T5-base) end-to-end response generation on the test set of MultiWOZ. We show the dialogue states, delexicalized responses, lexicalized responses generated by our model.

MUL0570		**Dialogue**
Turn 1	User	hello , do you know of any points of interest in the centre of cambridge ?
	Dialogue state:	[attraction] area centre
	Delexicalized	there are [value_choice] attractions in the [value_area] . what type of attraction are you interested in ?
	lexicalized	There are 44 attractions in the centre . What type of attraction are you interested in ?
	Gold response	there are 44 attractions in the center of town . what types are you interested in ?
Turn 2	User	i am not sure . what types of attractions are there ?
	Dialogue state:	[attraction] area centre
	Delexicalized	there are [value_type] , [value_type] , and [value_type] .
	Lexicalized	There are theatre , architecture , and nightclub .
	Gold response	you could visit a church or college . there are also 8 museums that are free of charge to enter .
Turn 3	User	i would like to visit a college . may i have the entrance fee and postcard ?
	Dialogue state:	[attraction] area centre type college
	Delexicalized	there are [value_choice] [value_type] in the [value_area] . [value_name] is [value_price] to enter .
	Lexicalized	There are 13 college in the centre . Christ 's College is free to enter .
	Gold response	there is christ 's college , which has a free entrance fee . their postcode is cb23bu .
Turn 4	User	can i have information for a train departing from ely ? i am looking to arrive in cambridge by about 15 :15 on tuesday .
	Dialogue state:	[attraction] area centre type college [train] destination cambridge day tuesday arrive 15 :15 departure ely
	Delexicalized	there are [value_choice] trains that fit your needs . what time would you like to leave ?
	Lexicalized	There are 5 trains that fit your needs . What time would you like to leave ?
	Gold response	tr3412 will arrive around 11 :52 on tuesday if you are interested in that .
Turn 5	User	i 'll take it for just me what is the travel time , and the price please ?
	Dialogue state:	[attraction] area centre type college [train] destination cambridge day tuesday arrive 15 :15 departure ely
	Delexicalized	the travel time is [value_time] and the price is [value_price] .
	Lexicalized	The travel time is 17 minutes and the price is 4.40 pounds .
	Gold response	the travel time is 17 minutes and the price is 4 .40 gbp .
Turn 6	User	great thank you i think i have all the information i need
	Dialogue state:	[attraction] area centre type college [train] destination cambridge day tuesday arrive 15 :15 departure ely
	Delexicalized	Thank you for using our service today !
	Lexicalized	Thank you for using our service today !
	Gold response	would you like me to book that train for you ?
Turn 7	User	no thank you . appreciate the help !
	Dialogue state:	[attraction] area centre type college [train] destination cambridge day tuesday arrive 15 :15 departure ely
	Delexicalized	thank you for using our service . have a great day . goodbye .
	Lexicalized	thank you for using our service . have a great day . goodbye .
	Gold response	you are welcome . have a good day !

Abstract

Recent works have shown that generative data augmentation, where synthetic samples generated from deep generative models complement the training dataset, benefit NLP tasks. In this work, we extend this approach to the task of dialog state tracking for goal-oriented dialogs. Due to the inherent hierarchical structure of goal-oriented dialogs over utterances and related annotations, the deep generative model must be capable of capturing the coherence among different hierarchies and types of dialog features. We propose the Variational Hierarchical Dialog Autoencoder (VHDA) for modeling the complete aspects of goal-oriented dialogs, including linguistic features and underlying structured annotations, namely speaker information, dialog acts, and goals. The proposed architecture is designed to model each aspect of goal-oriented dialogs using inter-connected latent variables and learns to generate coherent goal-oriented dialogs from the latent spaces. To overcome training issues that arise from training complex variational models, we propose appropriate training strategies. Experiments on various dialog datasets show that our model improves the downstream dialog trackers' robustness via generative data augmentation. We also discover additional benefits of our unified approach to modeling goal-oriented dialogs – dialog response generation and user simulation, where our model outperforms previous strong baselines.

1 Introduction

Data augmentation, a technique that augments the training set with label-preserving synthetic samples, is commonly employed in modern machine learning approaches. It has been used extensively in visual learning pipelines (Shorten and Khoshgoftaar, 2019) but less frequently for NLP tasks due to the lack of well-established techniques in the area. While some notable work exists in text classification (Zhang et al., 2015), spoken language understanding (Yoo et al., 2019), and machine translation (Fadaee et al., 2017), we still lack the full understanding of utilizing generative models for text augmentation.

Ideally, a data augmentation technique for supervised tasks must synthesize *distribution-preserving* and *sufficiently realistic* samples. Current approaches for data augmentation in NLP tasks mostly revolve around thesaurus data augmentation (Zhang et al., 2015), in which words that belong to the same semantic role are substituted with one another using a preconstructed lexicon, and noisy data augmentation (Wei and Zou, 2019) where random editing operations create perturbations in the language space. Thesaurus data augmentation requires a set of handcrafted semantic dictionaries, which are costly to build and maintain, whereas noisy data augmentation does not synthesize sufficiently realistic samples. The recent trend (Hu et al., 2017; Yoo et al., 2019; Shin et al., 2019) gravitates towards *generative data augmentation* (GDA), a class of techniques that leverage deep generative models such as VAEs to delegate the automatic discovery of novel class-preserving samples to machine learning. In this work, we explore GDA in the context of dialog modeling and contextual understanding.

Goal-oriented dialogs occur between a user and a system that communicates verbally to accomplish the user's goals (Table 6). However, because the user's goals and the system's possible actions are not transparent to each other, both parties must rely on verbal communications to infer and take appropriate actions to resolve the goals. Dialog state tracker is a core component of such systems, enabling it to track the dialog's latest status (Henderson et al., 2014). A dialog state typically consists of `inform` and `request` types of slot values.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3406–3425,
November 16–20, 2020.

For example, a user may verbally refer to a previously mentioned food type as the preferred one - e.g., Asian (`inform(food=asian)`). Given the user utterance and historical turns, the state tracker must infer the user's current goals. As such, we can view dialog state tracking as a sparse sequential multi-class classification problem. Modeling goal-oriented dialogs for GDA requires a novel approach that simultaneously solves state tracking, user simulation (Schatzmann et al., 2007), and utterance generation.

Various deep models exist for modeling dialogs. The Markov approach (Serban et al., 2017) employs a sequence-to-sequence variational autoencoder (VAE) (Kingma and Welling, 2013) structure to predict the next utterance given a deterministic context representation, while the holistic approach (Park et al., 2018) utilizes a set of global latent variables to encode the entire dialog, improving the awareness in general dialog structures. However, current approaches are limited to linguistic features. Recently, Bak and Oh (2019) proposed a hierarchical VAE structure that incorporates the speaker's information, but we have yet to explore a universal approach for encompassing fundamental aspects of goal-oriented dialogs. Such a unified model capable of disentangling latents into specific dialog aspects can increase the modeling efficiency and enable interesting extensions based on the fine-grained controllability.

This paper proposes a novel multi-level hierarchical and recurrent VAE structure called Variational Hierarchical Dialog Autoencoder (VHDA). Our model enables modeling all aspects (speaker information, goals, dialog acts, utterances, and general dialog flow) of goal-oriented dialogs in a disentangled manner by assigning latents to each aspect. However, complex and autoregressive VAEs are known to suffer from the risk of *inference collapse* (Cremer et al., 2018), in which the model converges to a local optimum where the generator network neglects the latents, reducing the generation controllability. To mitigate the issue, we devise two simple but effective training strategies.

Our contributions are summarized as follows.

1. We propose a novel deep latent model for modeling dialog utterances and their relationships with the goal-oriented annotations. We show that the strong level of coherence and accuracy displayed by the model allows it to be used for augmenting dialog state tracking datasets.
2. Leveraging the model's generation capabilities, we show that generative data augmentation is attainable even for the complex dialog-related tasks that pertain to both hierarchical and sequential annotations.
3. We propose simple but effective training policies for our VAE-based model, which have applications in other similar VAE structures.

The code for reproducing this paper is available at github [1].

2 Background and Related Work

Dialog State Tracking. Dialog state tracking (DST) predicts the user's current goals and dialog acts, given the dialog context. Historically, DST models have gradually evolved from hand-crafted finite-state automata and multi-stage models (Dybkjær and Minker, 2008; Thomson and Young, 2010; Wang and Lemon, 2013) to end-to-end models that directly predict dialog states from dialog features (Zilka and Jurcicek, 2015; Mrkšić et al., 2017; Zhong et al., 2018; Nouri and Hosseini-Asl, 2018).

Among the proposed models, Neural Belief Tracker (NBT) (Mrkšić et al., 2017) decreases reliance on handcrafted semantic dictionaries by reformulating the classification problem. Global-locally Self-attentive Dialog tracker (GLAD) (Zhong et al., 2018) introduces global modules for sharing parameters across slots and local modules, allowing the learning of slot-specific feature representations. Globally-Conditioned Encoder (GCE) (Nouri and Hosseini-Asl, 2018) improves further by forgoing the separation of global and local modules, allowing the unified module to take slot embeddings for distinction. Recently, dialog state trackers based on pre-trained language models have demonstrated their strong performance in many DST tasks (Wu et al., 2019; Kim et al., 2019; Hosseini-Asl et al., 2020). While the utilization of large-scale pre-trained language models is not within our scope, we wish to explore further concerning the recent advances in the area.

Conversation Modeling. While the previous approaches for hierarchical dialog modeling relate to the Markov assumption (Serban et al., 2017), recent approaches have geared towards utilizing

---

[1] `https://github.com/kaniblu/vhda`

global latent variables for representing the holistic dialog structure (Park et al., 2018; Gu et al., 2018; Bak and Oh, 2019), which helps in preserving long-term dependencies and total semantics. In this work, we employ global latent variables to maximize the effectiveness in preserving dialog semantics for data augmentation.

Data Augmentation. Transformation-based data augmentation is popular in vision learning (Shorten and Khoshgoftaar, 2019) and speech signal processing (Ko et al., 2015), while thesaurus and noisy data augmentation techniques are more common for text. (Zhang et al., 2015; Wei and Zou, 2019). Recently, generative data augmentation (GDA), augmenting data gather from samples generated from fine-tuned deep generative models, have gained traction in several NLP tasks (Hu et al., 2017; Hou et al., 2018; Yoo et al., 2019; Shin et al., 2019). GDA can be seen as a form of unsupervised data augmentation, delegating the automatic discovery of novel data to machine learning without injecting external knowledge or data sources. While most works utilize VAE for the generative model, some works achieved a similar effect without employing variational inference (Kurata et al., 2016; Hou et al., 2018). In contrast to unsupervised data augmentation, another line of work has explored self-supervision mechanisms to fine-tune the generators for specific tasks (Tran et al., 2017; Antoniou et al., 2017; Cubuk et al., 2018). Recent work proposed a reinforcement learning-based noisy data augmentation framework for state tracking (Yin et al., 2019). Our work belongs to the family of unsupervised GDA, which can incorporate self-supervision mechanisms. We wish to explore further in this regard.

3 Proposed Model

This section describes VHDA, our latent variable model for generating goal-oriented dialog datasets. We first introduce a set of notations for describing core concepts.

3.1 Notations

A dialog dataset $\mathbb{D}$ is a set of N i.i.d samples $\{\mathbf{c}_1, \dots, \mathbf{c}_N\}$, where each $\mathbf{c}$ is a sequence of turns $(\mathbf{v}_1, \dots, \mathbf{v}_T)$. Each goal-oriented dialog turn $\mathbf{v}$ is a tuple of speaker information $\mathbf{r}$, the speaker's goals $\mathbf{g}$, dialog state $\mathbf{s}$, and the speaker's utterance $\mathbf{u}$: $\mathbf{v} = (\mathbf{r}, \mathbf{g}, \mathbf{s}, \mathbf{u})$. Each utterance $\mathbf{u}$ is a sequence of words $(w_1, \dots, w_{|\mathbf{u}|})$. Goals $\mathbf{g}$ or a dialog state $\mathbf{s}$ is defined as a set of the smallest unit of dialog act specification a (Henderson et al., 2014), which is a tuple of dialog act, slot and value defined over the space of $\mathcal{T}$, $\mathcal{S}$, and $\mathcal{V}$: $\mathbf{g} = \{a_1, \dots, a_{|\mathbf{g}|}\}$, $\mathbf{s} = \{a_1, \dots, a_{|\mathbf{s}|}\}$, where $a_i \in \mathcal{A} = (\mathcal{T}, \mathcal{S}, \mathcal{V})$. A dialog act specification is represented as `<act>(<slot>=<value>)`.

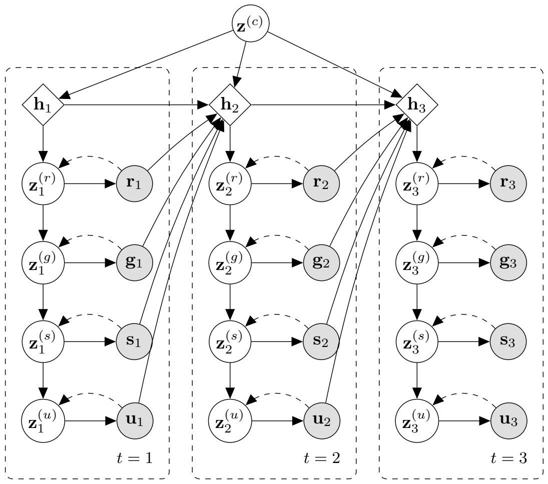

Figure 1: Graphical representation of VHDA. Solid and dashed arrows represent generation and recognition respectively.

3.2 VHCR

Given a conversation $\mathbf{c}$, Variational Hierarchical Conversational RNN (VHCR) (Park et al., 2018) models the holistic features of the conversation and the individual utterances $\mathbf{u}$ using a hierarchical and recurrent VAE model. The model introduces global-level latent variables $\mathbf{z}^{(c)}$ for encoding the high-level dialog structure and, at each turn t, local-level latent variables $\mathbf{z}_t^{(u)}$ responsible for encoding and generating the utterance at turn t. The local latent variables $\mathbf{z}^{(u)}$ conditionally depends on $\mathbf{z}^{(c)}$ and previous observations, forming a hierarchical structure with the global latents. Furthermore, hidden variables $\mathbf{h}_t$, which are conditionally dependent on the global information and the hidden variables from the previous step $\mathbf{h}_{t-1}$, facilitate the latent inference.

3.3 VHDA

We propose Variational Hierarchical Dialog Autoencoder (VHDA) to generate dialogs and their underlying dialog annotations simultaneously (Figure 1). Like VHCR, we employ a hierarchical VAE structure to capture holistic dialog semantics using the conversation latent variables $\mathbf{z}^{(c)}$. Our model incorporates full dialog features using turn-level latents $\mathbf{z}^{(r)}$ (speaker), $\mathbf{z}^{(g)}$ (goal), $\mathbf{z}^{(s)}$ (dialog state), and $\mathbf{z}^{(u)}$ (utterance), motivated by speech act theory (Searle et al., 1980). Specifically, at a given dialog turn, the information about the speaker, the speaker's goals, the speaker's turn-level dialog acts, and the utterance all cumulatively determine one after the other in that order.

VHDA consists of multiple encoder and decoder modules, each responsible for encoding or generating a particular dialog feature. The encoders share the identical sequence-encoding architecture described as follows.

Sequence Encoder Architecture. Given a sequence of variable number of elements $\mathbf{X} = [\mathbf{x}_1; \dots; \mathbf{x}_n]^\intercal \in \mathbb{R}^{n \times d}$, where n is the number of elements, the goal of a sequence encoder is to extract a fixed-size representation $\mathbf{h} \in \mathbb{R}^d$, where d is the dimensionality of the hidden representation. For our implementation, we employ the self-attention mechanism over hidden outputs of bidirectional LSTM (Hochreiter and Schmidhuber, 1997) cells produced from the input sequence. We also allow the attention mechanism to be optionally queried by $\mathbf{Q}$, enabling the sequence to depend on external conditions, such as using the dialog context to attend over an utterance:

$$
\begin{aligned}
\mathbf{H} &= [\overrightarrow{\mathrm{LSTM}}(\mathbf{X}); \overleftarrow{\mathrm{LSTM}}(\mathbf{X})] \in \mathbb{R}^{n \times d} \\
\mathbf{a} &= \mathrm{softmax}([\mathbf{H}; \mathbf{Q}]\mathbf{w} + b) \in \mathbb{R}^n \\
\mathbf{h} &= \mathbf{H}^\intercal \mathbf{a} \in \mathbb{R}^d.
\end{aligned}
$$

Here, $\mathbf{Q} \in \mathbb{R}^{n \times d_q}$ is a collection of query vectors of size d_q where each vector corresponds to one element in the sequence; $\mathbf{w} \in \mathbb{R}^{d+d_q}$ and $b \in \mathbb{R}$ are learnable parameters. We encapsulate the above operations with the following notation:

$$
\mathcal{E} : \mathbb{R}^{n \times d}(\times \mathbb{R}^{n \times d_q}) \to \mathbb{R}^d.
$$

Our model utilizes the $\mathcal{E}$ structure for encoding dialog features of variable lengths.

Encoder Networks. Based on the $\mathcal{E}$ architecture, feature encoders are responsible for encoding dialog features from their respective raw feature spaces to hidden representations. For goals and turn states, the encoding consists of two steps. Initially, the multi-purpose dialog act encoder $\mathcal{E}^{(a)}$ processes each dialog act triple of the goals $a^{(g)} \in \mathbf{g}$ and turn states $a^{(s)} \in \mathbf{s}$ into a fixed-size representation $\mathbf{h}^{(a)} \in \mathbb{R}^{d^{(a)}}$. The encoder treats the dialog act triples as sequences of tokens. Subsequently, the goal encoder and the turn state encoder process those dialog act representations to produce goal representations and turn state representations, respectively:

$$
\begin{aligned}
\mathbf{h}^{(g)} &= \mathcal{E}^{(g)}([\mathcal{E}^{(a)}(a_1^{(g)}); \dots; \mathcal{E}^{(a)}(a_{|\mathbf{g}|}^{(g)})]) \\
\mathbf{h}^{(s)} &= \mathcal{E}^{(s)}([\mathcal{E}^{(a)}(a_1^{(s)}); \dots; \mathcal{E}^{(a)}(a_{|\mathbf{s}|}^{(s)})]).
\end{aligned}
$$

Note that, as the model is sensitive to the order of the dialog acts, we randomize the order during training to prevent overfitting. The utterances are encoded using the utterance encoder from the word embeddings space: $\mathbf{h}^{(u)} = \mathcal{E}^{(u)}([\mathbf{w}_1; \dots; \mathbf{w}_{|u|}])$, while the entire conversation is encoded by the conversation encoder from the encoded utterance vectors: $\mathbf{h}^{(c)} = \mathcal{E}^{(c)}([\mathbf{h}_1^{(u)}; \dots; \mathbf{h}_T^{(u)}])$. All sequence encoders mentioned above depend on the global latent variables $\mathbf{z}^{(c)}$ via the query vector. For the speaker information, we use the speaker embedding matrix $\mathbf{W}^{(r)} \in \mathbb{R}^{n^{(r)} \times d^{(r)}}$ to encode the speaker vectors $\mathbf{h}^{(r)}$, where $n^{(r)}$ is the number of participants and $d^{(r)}$ is the embedding size.

Main Architecture. At the top level, our architecture consists of five $\mathcal{E}$ encoders, a context encoder $\mathcal{C}$, and four types of decoder $\mathcal{D}$. The context encoder $\mathcal{C}$ is different from the other encoders, as it does *not* utilize the bidirectional $\mathcal{E}$ architecture but a uni-directional LSTM cell. The four decoders $\mathcal{D}^{(r)}$, $\mathcal{D}^{(g)}$, $\mathcal{D}^{(s)}$, and $\mathcal{D}^{(u)}$ generate respective dialog features.

$\mathcal{C}$ is responsible for keeping track of the dialog context by encoding all features generated so far. The context vector at t ($\mathbf{h}_t$) is updated using the historical information from the previous step:

$$
\begin{aligned}
\mathbf{v}_{t-1} &= [\mathbf{h}_{t-1}^{(r)}; \mathbf{h}_{t-1}^{(g)}; \mathbf{h}_{t-1}^{(s)}; \mathbf{h}_{t-1}^{(u)}] \\
\mathbf{h}_t &= \mathcal{C}(\mathbf{h}_{t-1}, \mathbf{v}_{t-1})
\end{aligned}
$$

where $\mathbf{v}_t$ is represents all features at the step t.

VHDA uses the context information to successively generate turn-level latent variables using a series of generator networks:

$$
\begin{aligned}
p_\theta(\mathbf{z}_t^{(r)} | \mathbf{h}_t, \mathbf{z}^{(c)}) &= \mathcal{N}(\mu_t^{(r)}, \sigma_t^{(r)} \mathbf{I}) \\
p_\theta(\mathbf{z}_t^{(g)} | \mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{z}_t^{(r)}) &= \mathcal{N}(\mu_t^{(g)}, \sigma_t^{(g)} \mathbf{I}) \\
p_\theta(\mathbf{z}_t^{(s)} | \mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{z}_t^{(r)}, \mathbf{z}_t^{(g)}) &= \mathcal{N}(\mu_t^{(s)}, \sigma_t^{(s)} \mathbf{I}) \\
p_\theta(\mathbf{z}_t^{(u)} | \mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{z}_t^{(r)}, \mathbf{z}_t^{(g)}, \mathbf{z}_t^{(s)}) &= \mathcal{N}(\mu_t^{(u)}, \sigma_t^{(u)} \mathbf{I})
\end{aligned}
$$

where all latents are assumed to be Gaussian. In addition, we assume the standard Gaussian for the global latents: $p(\mathbf{z}^{(c)}) = \mathcal{N}(0, \mathbf{I})$. We implemented the Gaussian distribution encoders (μ and σ) using fully-connected networks f. We also apply $\mathrm{softplus}$ on the output of the networks to infer the variance of the distributions. Employing the reparameterization trick (Kingma and Welling, 2013) allows standard backpropagation during training of our model.

Approximate Posterior Networks. We use a separate set of parameters ϕ and encoders to approximate the posterior distributions of latent variables from the evidence. In particular, the model infers the global latents $\mathbf{z}^{(c)}$ using the conversation encoder $\mathcal{E}^{(c)}$ solely from the linguistic features:

$$q_\phi(\mathbf{z}^{(c)}|\mathbf{h}_1^{(u)}, \ldots, \mathbf{h}_T^{(u)}) = \mathcal{N}(\mu^{(c)}, \sigma^{(c)}\mathbf{I}).$$

Similarly, the approximate posterior distributions of all turn-level latent variables are estimated from the evidence in cascade, while maintaining the global conditioning:

$$\begin{aligned} q_\phi(\mathbf{z}_t^{(r)}|\mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{h}_t^{(r)}) &= \mathcal{N}(\mu_t^{(r')}, \sigma_t^{(r')}\mathbf{I}) \\ q_\phi(\mathbf{z}_t^{(g)}|\mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{z}_t^{(r)}, \mathbf{h}_t^{(g)}) &= \mathcal{N}(\mu_t^{(g')}, \sigma_t^{(g')}\mathbf{I}) \\ q_\phi(\mathbf{z}_t^{(s)}|\mathbf{h}_t, \ldots, \mathbf{z}_t^{(g)}, \mathbf{h}_t^{(s)}) &= \mathcal{N}(\mu_t^{(s')}, \sigma_t^{(s')}\mathbf{I}) \\ q_\phi(\mathbf{z}_t^{(u)}|\mathbf{h}_t, \ldots, \mathbf{z}_t^{(s)}, \mathbf{h}_t^{(u)}) &= \mathcal{N}(\mu_t^{(u')}, \sigma_t^{(u')}\mathbf{I}), \end{aligned}$$

where all Gaussian parameters are estimated using fully-connected layers, parameterized by ϕ.

Realization Networks. A series of generator networks successively decodes dialog features from their respective latent spaces to realize the surface forms:

$$\begin{aligned} p_\theta(\mathbf{r}_t|\mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{z}_t^{(r)}) &= \mathcal{D}_\theta^{(r)}(\mathbf{h}_t, \mathbf{z}^{(c)}, \mathbf{z}_t^{(r)}) \\ p_\theta(\mathbf{g}_t|\mathbf{h}_t, \ldots, \mathbf{z}_t^{(g)}) &= \mathcal{D}_\theta^{(g)}(\mathbf{h}_t, \ldots, \mathbf{z}_t^{(g)}) \\ p_\theta(\mathbf{s}_t|\mathbf{h}_t, \ldots, \mathbf{z}_t^{(s)}) &= \mathcal{D}_\theta^{(s)}(\mathbf{h}_t, \ldots, \mathbf{z}_t^{(s)}) \\ p_\theta(\mathbf{u}_t|\mathbf{h}_t, \ldots, \mathbf{z}_t^{(u)}) &= \mathcal{D}_\theta^{(u)}(\mathbf{h}_t, \ldots, \mathbf{z}_t^{(u)}). \end{aligned}$$

The utterance decoder $\mathcal{D}^{(u)}$ is implemented using the LSTM cell. To alleviate sparseness in goals and turn-level dialog acts, we formulate the classification problem as a set of binary classification problems (Mrkšić et al., 2017). Specifically, given a candidate dialog act a,

$$p_\theta(a \in \mathbf{s}_t|\mathbf{v}_{<t}, \ldots) = \sigma(\mathbf{o}_t^{(s)} \cdot \mathcal{E}^{(a)}(a))$$

where σ is the sigmoid function and $\mathbf{o}_t^{(s)} \in \mathbb{R}^{d^{(a)}}$ is the output of a feedforward network parameterized by θ that predicts the dialog act specification embeddings. Goals are predicted analogously.

3.4 Training Objective

Given all the latent variables $\mathbf{z}$ in our model, we optimize the evidence lower-bound (ELBO) of the goal-oriented dialog samples $\mathbf{c}$:

$$\begin{aligned} \mathcal{L}_{\text{VHDA}} =& \mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{c} \mid \mathbf{z})] \\ & - D_{\text{KL}}(q_\phi(\mathbf{z} \mid \mathbf{c}) \| p(\mathbf{z})). \end{aligned} \tag{1}$$

The reconstruction term of Equation 5 can be factorized into posterior probabilities in the realization networks. Similarly, the KL-divergence term can be factorized and reformulated in approximate posterior networks and conditional priors based on the graphical structure.

3.5 Minimizing Inference Collapse

Inference collapse is a relatively common phenomenon among autoregressive VAE structures (Zhao et al., 2017). The hierarchical and recurrent nature of our model makes it especially vulnerable. The standard treatment for alleviating the inference collapse problem include (1) annealing the KL-divergence term weight during the initial training stage and (2) employing word dropouts on the decoder inputs (Bowman et al., 2016). For our model, we observe that the basic techniques are insufficient (Table 3). While more recent treatments exist (Kim et al., 2018; He et al., 2019), they incur high computational costs that prohibit practical deployment in our cases. We introduce two simpler but effective methods to prevent encoder degeneration.

Mutual Information Maximization. The KL-divergence term in the standard VAE ELBO can be decomposed to reveal the mutual information term (Hoffman and Johnson, 2016):

$$\begin{aligned} & \mathbb{E}_{p_d}[D_{\text{KL}}(q_\phi(\mathbf{z} \mid \mathbf{x}) \| p(\mathbf{z}))] = \\ & \qquad D_{\text{KL}}(q_\phi(\mathbf{z}) \| p(\mathbf{z})) + I_{q_\phi}(\mathbf{x}; \mathbf{z}) \end{aligned}$$

where p_d is the empirical distribution of the data. Re-weighting the decomposed terms for optimizing the VAE behaviors has been explored previously (Chen et al., 2018; Zhao et al., 2017; Tolstikhin et al., 2018). In this work, we propose simply canceling out the mutual information term by performing mutual information estimation as a post-procedure. Since the preservation of the conversation encoder $\mathcal{E}^{(c)}$ and global latents is vital for generation controlability, we specifically maximize mutual information between the global latents and the evidence:

$$\begin{aligned}\mathcal{L}_{\text{VHDA}} =& \mathbb{E}_{q_\phi}[\log p_\theta(\mathbf{c} \mid \mathbf{z})] \\ &- D_{\text{KL}}(q_\phi(\mathbf{z} \mid \mathbf{c}) \| p(\mathbf{z})) + I_{q_\phi}(\mathbf{c}; \mathbf{z}^{(c)}).\end{aligned} \quad (2)$$

In our work, the mutual information term is computed empirically using the Monte-Carlo estimator for each mini-batch. The details are provided in the supplementary material.

Hierarchically-scaled Dropout. Extending word dropouts and utterance dropouts Park et al. (2018), we apply dropouts discriminatively to all dialog features (goals and dialog acts) according to the feature hierarchy level. We hypothesize that employing dropouts could be detrimental to the learning of lower-level latent variables, as information dropouts stack multiplicatively along the hierarchy. However, it is also necessary in order to encourage meaningful encoding of latent variables. Specifically, we propose a novel dropout scheme that scales exponentially along with the hierarchical depth, allowing higher-level information to flow towards lower levels easily. For our implementation, we set the dropout ratio between two adjacent levels to 1.5, resulting in the dropout probabilities of [0.1, 0.15, 0.23, 0.34, 0.51] for speaker information to utterances. We confirm our hypothesis in § 4.2.

4 Experiments

4.1 Experimental Settings

Following the protocol in (Yoo et al., 2019), we generate three independent sets of synthetic dialog samples, and, for each augmented dataset, we repeatedly train the same dialog state tracker three times with different seeds. We compare the aggregated results from all nine trials with the baseline results. Ultimately, we repeat this procedure for all combinations of state trackers and datasets. For non-augmented baselines, we repeat the experiments ten times.

Implementation Details. The hidden size of dialog vectors is 1000, and the hidden size of utterance, dialog act specification, turn state, and turn goal representations is 500. The dimensionality for latent variables is between 100 and 200. We use GloVe (Pennington et al., 2014) and character (Hashimoto et al., 2017) embeddings as pre-trained word emebddings (400 dimensions total) for word and dialog act tokens. All models used Adam optimizer (Kingma and Ba, 2014) with the initial learning rate of 1e-3, We annealed the KL-divergence weights over 250,000 training steps. For data synthesis, we employ ancestral sampling to generate samples from the empirical posterior distribution. We fixed the ratio of synthetic to original data samples to 1.

Datasets. We conduct experiments on four state tracking corpora: *WoZ2.0* (Wen et al., 2017), *DSTC2* (Henderson et al., 2014), *MultiWoZ* (Budzianowski et al., 2018), and *DialEdit* (Manuvinakurike et al., 2018). These corpora cover a variety of domains (restaurant booking, hotel reservation, and image editing). Note that, because the MultiWoZ dataset is a multi-domain corpus, we extract single-domain dialog samples from the two most prominent domains (hotel and restaurant, denoted by *MultiWoZ-H* and *MultiWoZ-R*, respectively).

Dialog State Trackers. We use GLAD and GCE as the two competitive baselines for state tracking. Besides, modifications are applied to these trackers to stabilize the performance on random seeds (denoted as GLAD$^+$ and GCE$^+$). Specifically, we enrich the word embeddings with subword information (Bojanowski et al., 2017) and apply dropout on word embeddings (dropout rate of 0.2). Furthermore, we also conduct experiments on a simpler architecture that shares a similar structure with GCE but does not employ self-attention for the sequence encoders (denoted as RNN).

Evaluation Measures. *Joint goal accuracy* (*goal* for short) measures the ratio of the number of turns whose goals a tracker has correctly identified over the total number of turns. Similarly, *request accuracy*, or *request*, measures the turn-level accuracy of request-type dialog acts, while *inform accuracy* (*inform*) measures the turn-level accuracy of inform-type dialog acts. Turn-level goals accumulate from inform-type dialog acts starting from the beginning of the dialog until respective dialog turns, and thus they can be inferred from historical inform-type dialog acts (Table 6).

4.2 Data Augmentation Results

Main Results. We present the data augmentation results in Table 1. The results strongly suggest that generative data augmentation for dialog state tracking is a viable strategy for improving existing DST models without modifying them, as improvements were observed at statistically significant levels regardless of the tracker and dataset.

The margin of improvements was more signifi-

cant for less expressive state trackers (RNN) than the more expressive ones (GLAD$^+$ and GCE$^+$). Even so, we observed varying degrees of improvements (zero to two percent in joint goal accuracy) even for the more expressive trackers, suggesting that GDA is effective regardless of downstream model expressiveness.

We observe larger improvement margins for inform-type dialog acts (or subsequently goals) from comparing performances between the dialog act types. This observation is because request-type dialog acts are generally more dependent on the user utterance in the same turn rather than requiring resolution of long-term dependencies, as illustrated in the dialog sample (Table 6). The observation supports our hypothesis that more diverse synthetic dialogs can benefit data augmentation by exploring unseen dialog dynamics.

Note that the goal tracking performances have relatively high variances due to the accumulative effect of tracking dialogs. However, as an additional benefit of employing GDA, we observe that synthetic dialogs help stabilize downstream tracking performances on DSTC2 and MultiWoZ-R datasets.

Effects of Joint Goal Tracking. Since user goals can be inferred from turn-level inform-type dialog acts, it may seem redundant to incorporate goal modeling into our model. To verify its effectiveness, we train a variant of VHDA, where the model does not explicitly track goals. The results (Table 2) show that VDHA without explicit goal tracking suffers in joint goal accuracy but performs better in turn request accuracy for some instances. We conjecture that explicit goal tracking helps the model reinforce long-term dialog goals; however, the model does so in the minor expense of short-term state tracking (as evident from lower state tracking accuracy).

Effects of Employing Training Techniques. To demonstrate the effectiveness of the two proposed training techniques, we compare (1) the data augmentation results and (2) the KL-divergence between the posterior and prior of the dialog latents $\mathbf{z}^{(c)}$ (Table 3). The results support our hypothesis that the proposed measures reduce the risk of inference collapse. We also confirm that exponentially-scaled dropouts are more or comparably effective at preventing posterior collapse than uniform

Model	WoZ2.0		DSTC2	
	rouge	Ent	rouge	Ent
VHCR[a]	0.476	0.193	0.680	0.153
VHDA[b] w/o goal	0.473	**0.195**	0.743	**0.162**
VHDA[B]	**0.499**	0.193	**0.781**	0.154

dropouts while generating more coherent samples (evident from higher data augmentation results).

4.3 Language Evaluation

To understand the effect of joint learning of various dialog features on language generation, we compare our model with a model that only learns linguistic features. Following the evaluation protocol from prior work (Wen et al., 2017; Bak and Oh, 2019), we use ROUGE-L F1-score (Lin, 2004) to evaluate the linguistic quality and utterance-level unigram cross-entropy (Serban et al., 2017) (regarding the training corpus distribution) to evaluate diversity. Table 4 shows that our model generates better and more diverse utterances than the previous strong baseline on conversation modeling. These results supports the idea that joint learning of dialog annotations improves utterance generation, thereby increasing the chance of generating novel samples that improve the downstream trackers.

4.4 User Simulation Evaluation

Simulating human participants has become a crucial feature for training dialog policy models using reinforcement learning and automatic evaluation of dialog systems (Asri et al., 2016). Although our model does not specialize in user simulation, our experiments show that the model outperforms the previous model (VHUS[2]) (Gür et al., 2018) in terms of accuracy and creativeness (diversity). We evaluate the user simulation quality using the prediction accuracy on the test sets and the diversity using the entropy[3] of predicted dialog act specifications (`act-slot-value` triples). We present the results in Table 5.

Spkr.		Utterance	Goal	Turn Act
1	User	i want to find a cheap restaurant in the north part of town .	inform(area=north) inform(price range=cheap)	inform(area=north) inform(price range=cheap)
2	Wizard	what food type are you looking for ?		request(slot=food)
3	User	any type of restaurant will be fine .	inform(area=north) inform(food=dontcare) inform(price range=cheap)	inform(food=dontcare)
4	Wizard	the `<place>` is a cheap indian restaurant in the north . would you like more information ?		
5	User	what is the number ?	inform(area=north) inform(food=dontcare) inform(price range=cheap)	request(slot=phone)
6	Wizard	`<place>` 's phone number is `<number>` . is there anything else i can help you with ?		
7	User	no thank you . goodbye .	inform(area=north) inform(food=dontcare) inform(price range=cheap)	

Table 6: A sample generated from the midpoint between two latent variables in the $\mathbf{z}^{(c)}$ space encoded from two anchor data points.

4.5 $\mathbf{z}^{(c)}$-interpolation

We conduct $\mathbf{z}^{(c)}$-interpolation experiments to demonstrate that our model can generalize the dataset space and learn to decode plausible samples from unseen latent space. The generated sample (Table 6) shows that our model can maintain coherence while generalizing key dialog features, such as the user goal and the dialog length. As a specific example, given both anchors' user goals (`food=mediterranean` and `food=indian`, respectively) [4], the generated midpoint between the two data points is a novel dialog with no specific food type (`food=dontcare`).

5 Conclusion

We proposed a novel hierarchical and recurrent VAE-based architecture to capture accurately the semantics of fully annotated goal-oriented dialog

---

[2] The previous model employs variational inference for contextualized sequence-to-sequence dialog act prediction.

corpora. To reduce the risk of inference collapse while maximizing the generation quality, we directly modified the training objective and devised a technique to scale dropouts along the hierarchy. We showed that our proposed model VHDA was able to achieve significant improvements for various competitive dialog state trackers in diverse corpora through extensive experiments. With recent trends in goal-oriented dialog systems gravitating towards end-to-end approaches (Lei et al., 2018), we wish to explore a self-supervised model, which discriminatively generates samples that directly benefit the downstream models for the target task. We would also like to explore different implementations in line with recent advances in dialog models, especially using large-scale pre-trained language models.

Acknowledgement

We thank Hyunsoo Cho for his help with implementations and Jihun Choi for the thoughtful feedback. We also gratefully acknowledge support from Adobe Inc. in the form of a generous gift to Seoul National University.
