Preface by the General Chair

Like my colleague, Dan Jurafsky, General Chair of ACL-2020, the first ACL conference to be hit by the virus that has up-ended our world, I am sitting at my laptop, in the same chair I have sat in since March 2020, to welcome you to EMNLP-2020. It is also where I am likely to be sitting for EMNLP-2020 itself.

As in previous years, the purpose of the General Chair's preface to express thanks — first, to the obvious people whose heroic efforts brought such a large conference to fruition, including:

- the three Programme Co-Chairs — Trevor Cohn, Yulan He and Yang Liu — who oversaw a process in which 3677 papers were submitted for review from 57 countries;
- the Senior Area Chairs, Area Chairs and reviewers whose expertise enabled authors to learn from their reviews and to deliver papers that improved on their original submissions;
- the Publication Co-Chairs — Yang Gao, Veronika Laippala and Philippe Muller — and the experience they gained from the General Publication Chair, Fei Liu, who met the challenge of identifying and correcting the myriad ways in which papers could be mis-formatted and assembled the result into our conference proceedings
- the Co-Chairs of *Findings of the ACL* – Jing Li and Lemao Liu – ACL's new publication venue, and Kushal Arora, who implemented a new process for matching Findings papers to workshops where they might be presented;
- the Tutorial Co-Chairs — Aline Villavicencio and Benjamin Van Durme — who selected the seven tutorials to be presented at the conference;
- the Demonstration Co-Chairs — Qun Liu and David Schlangen — who did the same for the 35 demos that we will see over the course of the conference;
- the new Ethics Co-Chairs — Dirk Hovy and Karën Fort — who undertook the delicate task of checking papers that had been flagged for potential ethics issues;
- our website chair, Andy MacKinlay, who ensured that the EMNLP-2020 website stayed fit for purpose.

But, in addition, we must also thank others whose support has been critical to both virtualizing EMNLP-2020 and keeping the community engaged with it —

- the members of the Virtual Infra-structure Committee, co-chaired by Jan-Christoph Klie and Zhongyu Wei — Eduardo Blanco, Yang Feng and Yansong Feng — helped by advisors from the ACL-2020 Virtual Infra-structure Committee — Hao Fang, Sudha Rao and Xiruo Ding;
- the Volunteer Coordinator — Kellie Webster — who managed to attract over 200 student and early career volunteers willing to help make EMNLP a success;
- of those student and early career volunteers, those who shouldered responsibility for important parts of the infra-structure, including Luciana Benotti and Cyril Weerasooriya (RocketChat), Ed Howard-Jones (HelpDesk), and Gisela Vallejo (Zoom);
- also of those student and early career volunteers, those who undertook to build booths for our sponsors — Kaushal Kumar Maurya, Francisco Xavier Sumba Toral, Saichethan M. Reddy, Shirley Anugrah Hayati, Manan Dey, Eraldo R. Fernandes, Arshiya Aggarwal, Alfredo Lozano, Jiaxin Pei, Junheng Hao, Reem Al-Yami, Anish Mohan, Christian Kavouras, Tornike Tsereteli, Emily Chen, Wiem Ben Rim and Chandrahas;

- the Publicity Co-chairs — Anna Rogers and Ruifeng Xu — who have served as both the voice of EMNLP in communicating with the community and as its ears, reporting on community concerns as soon as they were expressed;
- the Workshop Co-chairs — Jackie Chi Kit Cheung and Lonneke van der Plas — whose work in selecting the 24 workshops for EMNLP-2020 turned out to be only the start of ensuring that the workshops could successfully run virtually;
- the Diversity & Inclusion Chairs – Isabelle Augenstein and Chris Brew — and the D&I Student Chairs – Murathan Kurfali and Prathyusha Jwalapuram — who have worked tirelessly to make EMNLP as welcoming and inclusive as possible for all participants. The activities that they have worked with community members to create (Birds of a Feather sessions, Affinity Group sessions, student panels, Mentoring sessions and Coffee Socials) should contribute to reinforcing us as a community (and as sub-groups within the community), despite not being together physically.

We also want to express special thanks to Priscilla Rasmussen, the ACL Business Manager, first for booking EMNLP 2020 into a beautiful resort in the Dominican Republic, and then for getting the booking postponed until EMNLP 2021.

Last but not least, I would like to express gratitude to our sponsors, whose generous support has been invaluable in building up EMNLP to what it is now. These include our Diamond-level sponsors — Bloomberg Engineering, Google Research, Apple and Amazon Science; our Platinum-level sponsors — Baidu, Megagon Labs, Facebook and DeepMind; our Gold-level sponsors — Grammarly, ByteDance and Zeta Alpha; our Silver-level sponsors — Babelscape, Naver, Adobe, Hitachi and Salesforce; and our Bronze-level sponsor — USC ISI. DeepMind has also generously contributed to supporting our Diversity & Inclusion activities.

EMNLP 2020 General Chair

Bonnie Webber, University of Edinburgh, UK

Preface by the Program Committee Co-Chairs

Welcome to EMNLP 2020!

Due to the unprecedented situation with the Covid-19 pandemic, EMNLP 2020 will be held completely online this year. We decided to move EMNLP to a virtual format early on, when the pandemic just started, and postponed the paper submission deadlines by three weeks such that authors affected by the pandemic could have more time for their paper submissions. This resulted in a much tighter schedule for paper review and decisions, as well as publications, workshop programs, virtual infrastructure, etc. However, thanks to everyone's hard work, we made it.

We received a record number of 3,677 submissions. This is a significant increase of 26% over EMNLP 2019, making it the largest NLP conference to date in terms of paper submissions. After removing withdrawals and desk rejecting papers which violated our formatting requirements, the anonymity policy, or double submission policy, 3,359 submissions were sent out for review. Despite the sharp increase in submissions, we kept the acceptance rates at a similar level as past years. The acceptance statistics are shown below:

	Long	Short	Total
Reviewed	2,455	904	3,359
Accepted	602	150	752
Acceptance Rate	24.6%	16.6%	22.4%

It is important to have a well-organized review structure to handle a large number of submissions. We first set up a total of 21 tracks (including a special Multidisciplinary and Area Chair Conflict of Interest track) based on the track information in past conferences such as ACL 2020, EMNLP 2019 and NAACL 2019. We used the submission numbers per track from past conferences to estimate the number of Senior Area Chairs (SACs) and Area Chairs (ACs) required for each track. We eventually recruited 33 SACs and 196 ACs.

For reviewer recruitment, we started with the reviewer lists from NAACL 2019, EMNLP 2019 and ACL 2020 and sent out initial invitations asking reviewers to express their track preferences. In addition, we introduced a new policy that in order to submit paper(s) to EMNLP, at least one author must be nominated to serve as a reviewer (usually the most senior author) and for that author to take on a full load of up to 6 reviews. We filtered out some reviewers who were less experienced in paper review or did not hold a PhD degree (except those final-year PhD students). We then passed the reviewer list to SACs and asked them to select from these candidate reviewers based on their expertise and semantic scholar profiles. Overall, this resulted in a total of 2,633 reviewers.

For AC assignments, we matched papers with ACs automatically based on comparing submissions' abstracts with ACs' past papers in ACL* venues, using semantic scholar to harvest this data. For reviewer assignment, we generated a "seniority score" for each reviewer based on their past publication record and recent ACL* papers. Where possible, we have ensured every paper has at least one "senior" reviewer and not more than one "junior" reviewer.

As a result of ever increasing paper submissions, review quality is a pressing issue in our community. To help improve review quality, this year we prepared review guidelines with explicit dos and don'ts. We observed many cases where authors called out problems in reviews for these papers based on these guidelines, ACs took action, and reviewers revised their reviews. Overall the review guidelines seem to be well received by authors and reviewers, and we feel they lead to improved reviews in aggregate. Having said this, we emphasize that the guidelines are only a partial solution, and more work is needed from the entire community to manage the increasing submissions and continue to maintain or improve review quality.

Authors resubmitting papers that were previously rejected from another publication venue were given the option of providing these previous reviews and a rejoinder as part of their submission. This was designed to accommodate authors who have improved their paper based on previous feedback, and feel they have addressed the key issues raised, and would benefit from having this considered as part of the EMNLP review process. Roughly, this is designed to mimic the "revise-and-resubmit" procedure in a journal. These "sticky reviews" were made available to the AC, SACs and PCs, but not the reviewers, lest it bias their assessments. A total of 349 submissions used this facility. While we do not have firm numbers confirming the utility of sticky reviews, we feel that it was useful for making decisions for borderline submissions, where the past reviews and quality of the rejoinder could be used to justify paper acceptance.

This year we experimented with "*Findings*", a new publication model based on an idea floated in the ACL reviewing committee, designed to allow more papers to be accepted for publication beyond those accepted to the main conference. Please see the Preface to the *Findings of ACL: EMNLP 2020* for a detailed description of this new initiative, including the acceptance rate and processes specific to this publication.

Another "first" was the formation of an ethics committee, which was assembled to provide input on submissions which were flagged by reviewers, ACs or SACs as needing further consideration on ethical grounds during the review process. This might relate to potential misuse of the work, the legality of use of data, ethics approvals for work involving human subjects, suspected plagiarism and more. The committee provided careful assessment to ensure these papers were treated uniformly and fairly, and these ethics assessments were considered alongside the reviews when making acceptance decisions. Ideally, authors would be given a chance to respond to the ethical assessments, however this was not possible given the reviewing timeline. We recommend this is something that should be factored into future conference planning.

Finally this year we introduced a Reproducibility Checklist in order to encourage reporting information necessary for reproducible research (thanks to Jesse Dodge and Noah Smith for initiating this). Many papers have included more details relating to code, data, and their experimental setup. 78% of reviewers felt the reproduciblity checklist is useful or somewhat useful. In addition, EMNLP will join several major AI conferences in the upcoming ML Reproducibility Challenge (https://paperswithcode.com/rc2020). We hope you can participate in or contribute to the challenge. The current reproducibility checklist may not be a norm yet for our scientific community, but it is a step forward, and we expect it will lead to more reproducible published work in the future.

From the accepted papers, 5 papers were selected for awards, include a best long paper and 4 outstanding papers. Best paper candidates were initially selected based on recommendations from SACs and ACs, and then evaluated by the best paper committee. The award winners will be announced at the closing session.

In addition, EMNLP 2020 will feature 25 papers from Transactions of Association for Computational Linguistics (TACL), and 5 papers from the journal of Computational Linguistics.

We are excited to have three keynote talks, by Professor Claire Cardie (Cornell University) on information extraction, Dr. Rich Caruana (Microsoft) on interpretability in machine learning, and Professor Janet Pierrehumbert (University of Oxford) on linguistic behaviour and the realistic testing of NLP systems. We thank them for accepting our invitation to give the keynote speeches.

Another highlight of the program is the two panel sessions, one industry panel discussing NLP practice in industry and future directions, and another one on Ethics statements for future NLP paper submissions.

We thank all the panelists for joining the live discussions.

Putting together a virtual program is challenging. Based on the feedback on the ACL 2020 program, one of our goals is to provide more opportunities for authors and attendees to interact with each other and create an experience similar to in-person conferences. We have grouped papers into Zoom QA sessions (each session with 4-5 papers in similar areas) and Gather.towns (analogous to poster sessions where attendees can walk around and interact with paper authors). Doing this with timezone constraints is a hard optimization problem. We tried our best to make the program timezone friendly such that everyone is able to attend as many sessions as possible. However, the solutions are not perfect, and we appreciate everyone's understanding and cooperation.

We are grateful for many people's contributions in the past year. Without their help, EMNLP 2020 would not be possible. We thank:

- First our general chair, Bonnie Webber, who has provided us all the guidance we need and helped with many of our decision processes;
- Past ACL* PCs, including Jing Jiang, Vincent Ng, and Xiaojun Wan (EMNLP 2019), and Joyce Chai, Natalie Schluter, and Joel Tetreault (ACL 2020) for all the useful tips and suggestions about organizing NLP conferences;
- Amanda Stent and Graham Neubig for providing the code for reviewer COI detection and paper assignment, and their time in helping to get it running;
- 33 SACs who have helped us tremendously through the entire review process, from recruiting ACs and reviewers, paper assignment, to making final paper recommendation decisions and selection of best paper candidates;
- 196 ACs who led paper discussions, wrote meta reviews, and ensured review quality;
- 2,633 reviewers, 565 secondary reviewers for reviewing papers and actively participating in paper discussions;
- 8,682 authors for submitting their work to EMNLP;
- Our Publicity chairs Anna Rogers and Ruifeng Xu who keep us connected with the community, announce conference news on social media, follow EMNLP related online discussions, and collect feedback from the community;
- Publication chairs Fei Liu, Philippe Muller, Yang Gao, Veronika Laippala, Jing Li, and Lemao Liu for completing the proceedings within a shortened work period, including additional Findings proceedings;
- Best paper committee, Mirella Lapata (Chair), Kyunghyun Cho, Vera Demberg, Matt Gardner, Nizar Habash, Xuanjing Huang, Haizhou Li, Kathleen McKeown, Barbara Plank, Alexander Rush, for selecting the best papers and outstanding papers;
- The Ethics committee, chaired by Dirk Hovy and Karën Fort, and members: Emily Bender, Ryan Georgi, Alvin Grissom II, Margot Mieskes, Aurelie Nevol, and Amanda Stent, who graciously accepted our invitation towards the end of the review period and assessed papers with ethical concerns in a very tight schedule;
- Infrastructure chairs Eduardo Blanco, Jan-Christoph Klie, Yang Feng, Yansong Feng, Zhongyu Wei, Hao Fang, Sudha Rao who have made the virtual conference possible;
- Webmaster Andy Mckinlay for keeping the conference website updated;

- TACL editors-in-chief Mark Johnson, Ani Nenkova, and Brian Roark, TACL Editorial Assistant Cindy Robinson, and CL Editor-in-Chief Hwee Tou Ng for coordinating TACL and CL presentations with us;
- Jesse Dodge and Noah Smith for initiating the Reproducibility Checklist, helping the NLP community with more reproducible results;
- SIGDAT board members that have provided guidance regarding various decisions;
- Rich Gerber from Softconf who set up the EMNLP conference site, has always answered our questions in a timely manner, and helped us with different new requests such as handling Findings papers and sharing reviews between EMNLP and workshops;
- Priscilla Rasmussen for various discussions on organizing EMNLP;
- The entire EMNLP organizing committee who have worked together to make EMNLP a success.

We hope you will enjoy the virtual conference, and can participate in as many sessions as possible!

EMNLP 2020 Program Co-Chairs

Trevor Cohn, University of Melbourne, Australia
Yulan He, University of Warwick, UK
Yang Liu, Amazon – Alexa AI, USA

Organizing Committee

General Chair
Bonnie Webber, University of Edinburgh, UK

Program Committee Co-chairs
Trevor Cohn, University of Melbourne, Australia
Yulan He, University of Warwick, UK
Yang Liu, Amazon – Alexa AI, USA

Workshop Co-chairs
Jackie Chi Kit Cheung, McGill University, Canada
Lonneke van der Plas, University of Malta, Malta

Tutorial Co-chairs
Benjamin van Durme, Johns Hopkins University, USA
Aline Villavicencio, University of Sheffield, UK

Demonstration Co-chairs
Qun Liu, Huawei Noah's Ark Lab, Hong Kong
David Schlangen, University of Potsdam, Germany

General Publication Chair
Fei Liu, University of Central Florida, USA

Publication Chairs
Yang Gao, Royal Holloway, University of London, UK
Veronika Laippala, University of Turku, Finland
Philippe Muller, University of Toulouse, France

Findings Chairs
Jing Li, The Hong Kong Polytechnic University, Hong Kong
Lemao Liu, Tencent AI Lab, China

Publicity Chairs
Anna Rogers, University of Copenhagen, Denmark
Ruifeng Xu, Harbin Institute of Technology, China

Website Chair
Andy MacKinlay, Culture Amp, Australia

Student Volunteer Coordinator and Student Scholarship Chair
Kellie Webster, Google, USA

Diversity and Inclusion Chairs
Isabelle Augenstein, University of Copenhagen
Chris Brew, LivePerson

Diversity and Inclusion Student Chairs
Prathyusha Jwalapuram, Nanyang Technological University, Singapore
Murathan Kurfali, University of Stockholm, Sweden

Virtual Infrastructure Chairs
Eduardo Blanco, University of North Texas, USA
Yang Feng, Chinese Academy of Sciences, China
Yansong Feng, Peking University, China
Jan-Christoph Klie, Technical University of Darmstadt, Germany
Zhongyu Wei, Fudan University, China

Advisors, Virtual Infrastructure Committee
Hao Fang, Microsoft Semantic Machines, USA
Sudha Rao, Microsoft Research, USA

Ethics Committee Chairs
Karën Fort, Sorbonne University, France
Dirk Hovy, Bocconi University, Italy

ACL Business Manager & Local Arrangements Chair
Priscilla Rasmussen, Association for Computational Linguistics, USA

Program Committee

Program Committee Co-chairs
Trevor Cohn, University of Melbourne, Australia
Yulan He, University of Warwick, UK
Yang Liu, Amazon – Alexa AI, USA

Senior Area Chairs
Computational Social Science and Social Media
Jacob Eisenstein, Google, USA
Dong Nguyen, Utrecht University, Netherlands

Dialog and Interactive Systems
Srinivas Bangalore, Interactions Corp, USA
Xiaodong He, JD AI Research, China

Discourse and Pragmatics
Vincent Ng, University of Texas at Dallas, USA

Information Extraction
Maggie Li, The Hong Kong Polytechnic University, China
Alan Ritter, Georgia Institute of Technology, USA

Information Retrieval and Text Mining
Alessandro Moschitti, Amazon, USA

Interpretability and Analysis of Models for NLP
Sameer Singh, University of California, Irvine, USA
William Wang, University of California, Santa Barbara, USA

Language Generation
Chenghua Lin, University of Sheffield, UK
Lu Wang, University of Michigan, USA

Language Grounding to Vision, Robotics and Beyond
Lucia Specia, Imperial College London, UK

Linguistic Theories, Cognitive Modeling and Psycholinguistics
Roger Levy, Massachusetts Institute of Technology, USA

Machine Learning for NLP
Mohit Bansal, University of North Carolina at Chapel Hill, USA
Reza Haffari, Monash University, Australia
Yulia Tsvetkov, Carnegie Mellon University, USA

Machine Translation and Multilinguality
Stefan Riezler, Heidelberg University, Germany
Yang Liu, Tsinghua University, China

NLP Applications

Thamar Solorio, University of Houston, USA
Deyu Zhou, Southeast University, China

Phonology, Morphology and Word Segmentation

Hinrich Schutze, University of Munich, Germany

Question Answering

Markus Dreyer, Amazon, USA
Anh Tuan Luu, Massachusetts Institute of Technology, USA

Semantics: Lexical Semantics

Mona Diab, Facebook AI, USA

Semantics: Sentence-level Semantics, Textual Inference and Other areas

Ivan Titov, University of Edinburgh / University of Amsterdam, UK
Yue Zhang, Westlake University, China

Sentiment Analysis, Stylistic Analysis, and Argument Mining

Saif Mohammad, National Research Council, Canada
Bing Qin, Harbin Institute of Technology, China

Speech and Multimodality

Geoffrey Zweig, Facebook, USA

Summarization

Xiaojun Wan, Peking University, China

Syntax: Tagging, Chunking, and Parsing

Mark Johnson, Oracle Corporation, Australia

Multidisciplinary and AC COI

Heng Ji, University of Illinois at Urbana-Champaign, USA

Area Chairs

Computational Social Science and Social Media

David Bamman, Cristian Danescu-Niculescu-Mizil, Lucie Flek, Jing Jiang, David Jurgens, Brendan O'Connor, Chenhao Tan, Sara Tonelli, Andreas Vlachos

Dialog and Interactive Systems

Yun-Nung Chen, Alborz Geramifard, Minlie Huang, Jing Huang, Seokhwan Kim, Mahnoosh Mehrabani, Helen Meng, Aasish Pappu, Xiaojun Quan, Sakriani Sakti, Ethan Selfridge, Ruihua Song, Rui Yan, Zhou Yu

Discourse and Pragmatics

Invited Speaker: Claire Cardie, Cornell University

Information Extraction Through the Years: How Did We Get Here?

Abstract: In this talk, I'll examine the state of the NLP subfield of information extraction from its inception almost 30 years ago to its current realization in neural network models. Which aspects of the original formulation of the task are more or less solved? In what ways are current state-of-the-art methods still falling short? What's up next for information extraction?

Bio: Claire Cardie is the John C. Ford Professor of Engineering in the Departments of Computer Science and Information Science at Cornell University. She has worked since the early 1990's on application of machine learning methods to problems in Natural Language Processing — on topics ranging from information extraction, noun phrase coreference resolution, text summarization and question answering to the automatic analysis of opinions, argumentation, and deception in text. She has served on the executive committees of the ACL and AAAI and twice as secretary of NAACL. She has been Program Chair for ACL/COLING, EMNLP and CoNLL, and General Chair for ACL in 2018. Cardie was named a Fellow of the ACL in 2015 and a Fellow of the Association for Computing Machinery (ACM) in 2019. At Cornell, she led the development of the university's academic programs in Information Science and was the founding Chair of its Information Science Department.

Invited Speaker: Rich Caruana, Microsoft

Friends Don't Let Friends Deploy Black-Box Models: The Importance of Intelligibility in Machine Learning

Abstract: In machine learning sometimes tradeoffs must be made between accuracy and intelligibility: the most accurate models usually are not very intelligible, and the most intelligible models usually are less accurate. This can limit the accuracy of models that can safely be deployed in mission-critical applications where being able to understand, validate, edit, and ultimately trust a model is important. We have been working on a learning method to escape this tradeoff that is as accurate as full complexity models such as boosted trees and random forests, but more intelligible than linear models. This makes it easy to understand what the model has learned and to edit the model when it learns inappropriate things. Making it possible for humans to understand and repair a model is critical because most training data has unexpected problems. I'll present several case studies where these high-accuracy GAMs discover surprising patterns in the data that would have made deploying a black-box model inappropriate. I'll also show how these models can be used to detect and correct bias. And if there's time, I'll briefly discuss using intelligible GAM models to predict COVID-19 mortality.

Bio: Rich Caruana is a Senior Principal Researcher at Microsoft. His focus is on intelligible/transparent modeling, machine learning for medical decision making, deep learning, and computational ecology. Before joining Microsoft, Rich was on the faculty in Computer Science at Cornell, at UCLA's Medical School, and at CMU's Center for Learning and Discovery. Rich's Ph.D. is from CMU. His work on Multitask Learning helped create interest in a subfield of machine learning called Transfer Learning. Rich received an NSF CAREER Award in 2004 (for Meta Clustering), best paper awards in 2005 (with Alex Niculescu-Mizil), 2007 (with Daria Sorokina), and 2014 (with Todd Kulesza, Saleema Amershi, Danyel Fisher, and Denis Charles), and co-chaired KDD in 2007 with Xindong Wu.

Invited Speaker: Janet B. Pierrehumbert, University of Oxford

Linguistic Behaviour and the Realistic Testing of NLP Systems

Abstract: To evaluate the performance of NLP systems, the standard is to use held-out test data. When the systems are deployed in real-world applications, they will only be successful if they perform well on examples that their architects never saw before. Many of these will be examples that nobody ever saw before; the central observation of generative linguistics, going back to Von Humboldt, is that human language involves "The infinite use of finite means".

Predicting the real-world success of NLP systems thus comes down to predicting future human linguistic behaviour. In this talk, I will discuss some general characteristics of human linguistic behaviour, and the extent to which they are, or are not addressed in current NLP methodology. The topics I will address include: look-ahead and prediction; the role of categorization in building abstractions; effects of context; and variability across individuals.

Bio: Janet B. Pierrehumbert is the Professor of Language Modelling in the Department of Engineering Science at the University of Oxford. She received her BA in Linguistics and Mathematics at Harvard in 1975, and her Ph.D in Linguistics from MIT in 1980. Much of her Ph.D dissertation research on English prosody and intonation was carried out at AT&T Bell Laboratories, where she was also a Member of Technical Staff from 1982 to 1989. After she moved to Northwestern University in1989, her research program used a wide variety of experimental and computational methods to explore how lexical systems emerge in speech communities. She showed that the mental representations of words are at once abstract and phonetically detailed, and that social factors interact with cognitive factors as lexical patterns are learned, remembered, and generalized. Pierrehumbert joined the faculty at the University of Oxford in 2015 as a member of the interdisciplinary Oxford e-Research Centre. Her current research uses machine-learning methods to model the dynamics of on-line language. Her latest project, funded by the UK EPSRC, seeks to develop new NLP methods to characterize exaggeration, cohesion, and fragmentation in on-line forums.

Pierrehumbert is a Fellow of the Linguistic Society of America, the Cognitive Science Society, and the American Academy of Arts and Sciences. She was elected to the National Academy of Sciences in 2019. She is the recipient of the 2020 Medal for Scientific Achievement from the International Speech Communication Association.

Table of Contents

Conference Program

Monday, November 16, 2020

10:45–11:00 *Opening Remarks*

11:00–12:00 *Keynote I: Claire Cardie*

12:00–13:00 *Zoom Q&A Session 1*

12:00–13:00 *Zoom Q&A Session 1i: Sentiment Analysis, Stylistic Analysis, and Argument Mining*

Detecting Attackable Sentences in Arguments
Yohan Jo, Seojin Bang, Emaad Manzoor, Eduard Hovy and Chris Reed

Extracting Implicitly Asserted Propositions in Argumentation
Yohan Jo, Jacky Visser, Chris Reed and Eduard Hovy

Quantitative Argument Summarization and Beyond: Cross-Domain Key Point Analysis
Roy Bar-Haim, Yoav Kantor, Lilach Eden, Roni Friedman, Dan Lahav and Noam Slonim

Unsupervised Stance Detection for Arguments from Consequences
Jonathan Kobbe, Ioana Hulpuș and Heiner Stuckenschmidt

12:00–13:00 *Zoom Q&A Session 1ii: Machine Translation and Multilinguality*

BLEU might be Guilty but References are not Innocent
Markus Freitag, David Grangier and Isaac Caswell

Statistical Power and Translationese in Machine Translation Evaluation
Yvette Graham, Barry Haddow and Philipp Koehn

Simulated Multiple Reference Training Improves Low-Resource Machine Translation
Huda Khayrallah, Brian Thompson, Matt Post and Philipp Koehn

Monday, November 16, 2020 (continued)

Automatic Machine Translation Evaluation in Many Languages via Zero-Shot Paraphrasing
Brian Thompson and Matt Post

12:00–13:00 *Zoom Q&A Session 1iii: Question Answering*

PRover: Proof Generation for Interpretable Reasoning over Rules
Swarnadeep Saha, Sayan Ghosh, Shashank Srivastava and Mohit Bansal

Learning to Explain: Datasets and Models for Identifying Valid Reasoning Chains in Multihop Question-Answering
Harsh Jhamtani and Peter Clark

Self-Supervised Knowledge Triplet Learning for Zero-Shot Question Answering
Pratyay Banerjee and Chitta Baral

More Bang for Your Buck: Natural Perturbation for Robust Question Answering
Daniel Khashabi, Tushar Khot and Ashish Sabharwal

12:00–13:00 *Zoom Q&A Session 1iv: Interpretability and Analysis of Models for NLP*

A Matter of Framing: The Impact of Linguistic Formalism on Probing Results
Ilia Kuznetsov and Iryna Gurevych

Information-Theoretic Probing with Minimum Description Length
Elena Voita and Ivan Titov

Intrinsic Probing through Dimension Selection
Lucas Torroba Hennigen, Adina Williams and Ryan Cotterell

Learning Which Features Matter: RoBERTa Acquires a Preference for Linguistic Generalizations (Eventually)
Alex Warstadt, Yian Zhang, Xiaocheng Li, Haokun Liu and Samuel R. Bowman

13:00–14:00 *Zoom Q&A Session 2*

13:00–14:00 *Zoom Q&A Session 2i: Machine Learning for NLP*

Repulsive Attention: Rethinking Multi-head Attention as Bayesian Inference
Bang An, Jie Lyu, Zhenyi Wang, Chunyuan Li, Changwei Hu, Fei Tan, Ruiyi Zhang, Yifan Hu and Changyou Chen

KERMIT: Complementing Transformer Architectures with Encoders of Explicit Syntactic Interpretations
Fabio Massimo Zanzotto, Andrea Santilli, Leonardo Ranaldi, Dario Onorati, Pierfrancesco Tommasino and Francesca Fallucchi

ETC: Encoding Long and Structured Inputs in Transformers
Joshua Ainslie, Santiago Ontanon, Chris Alberti, Vaclav Cvicek, Zachary Fisher, Philip Pham, Anirudh Ravula, Sumit Sanghai, Qifan Wang and Li Yang

Pre-Training Transformers as Energy-Based Cloze Models
Kevin Clark, Minh-Thang Luong, Quoc Le and Christopher D. Manning

Calibration of Pre-trained Transformers
Shrey Desai and Greg Durrett

13:00–14:00 *Zoom Q&A Session 2ii: NLP Applications*

Near-imperceptible Neural Linguistic Steganography via Self-Adjusting Arithmetic Coding
Jiaming Shen, Heng Ji and Jiawei Han

Multi-Dimensional Gender Bias Classification
Emily Dinan, Angela Fan, Ledell Wu, Jason Weston, Douwe Kiela and Adina Williams

FIND: Human-in-the-Loop Debugging Deep Text Classifiers
Piyawat Lertvittayakumjorn, Lucia Specia and Francesca Toni

Conversational Document Prediction to Assist Customer Care Agents
Jatin Ganhotra, Haggai Roitman, Doron Cohen, Nathaniel Mills, Chulaka Gunasekara, Yosi Mass, Sachindra Joshi, Luis Lastras and David Konopnicki

13:00–14:00 *Zoom Q&A Session 2iii: Dialog and Interactive Systems*

Monday, November 16, 2020 (continued)

Incremental Processing in the Age of Non-Incremental Encoders: An Empirical Assessment of Bidirectional Models for Incremental NLU
Brielen Madureira and David Schlangen

Augmented Natural Language for Generative Sequence Labeling
Ben Athiwaratkun, Cicero Nogueira dos Santos, Jason Krone and Bing Xiang

Dialogue Response Ranking Training with Large-Scale Human Feedback Data
Xiang Gao, Yizhe Zhang, Michel Galley, Chris Brockett and Bill Dolan

13:00–14:00 *Zoom Q&A Session 2iv: Semantics: Sentence-level Semantics, Textual Inference and Other areas*

Semantic Evaluation for Text-to-SQL with Distilled Test Suites
Ruiqi Zhong, Tao Yu and Dan Klein

Cross-Thought for Sentence Encoder Pre-training
Shuohang Wang, Yuwei Fang, Siqi Sun, Zhe Gan, Yu Cheng, Jingjing Liu and Jing Jiang

AutoQA: From Databases To QA Semantic Parsers With Only Synthetic Training Data
Silei Xu, Sina Semnani, Giovanni Campagna and Monica Lam

19:00–20:00 *Industry Panel*

20:00–21:00 *Zoom Q&A Session 3*

20:00–21:00 *Zoom Q&A Session 3i: Summarization*

A Spectral Method for Unsupervised Multi-Document Summarization
Kexiang Wang, Baobao Chang and Zhifang Sui

What Have We Achieved on Text Summarization?
Dandan Huang, Leyang Cui, Sen Yang, Guangsheng Bao, Kun Wang, Jun Xie and Yue Zhang

Q-learning with Language Model for Edit-based Unsupervised Summarization
Ryosuke Kohita, Akifumi Wachi, Yang Zhao and Ryuki Tachibana

Monday, November 16, 2020 (continued)

Friendly Topic Assistant for Transformer Based Abstractive Summarization
Zhengjue Wang, Zhibin Duan, Hao Zhang, chaojie wang, long tian, Bo Chen and Mingyuan Zhou

20:00–21:00 *Zoom Q&A Session 3ii: Machine Learning for NLP*

Contrastive Distillation on Intermediate Representations for Language Model Compression
Siqi Sun, Zhe Gan, Yuwei Fang, Yu Cheng, Shuohang Wang and Jingjing Liu

TernaryBERT: Distillation-aware Ultra-low Bit BERT
Wei Zhang, Lu Hou, Yichun Yin, Lifeng Shang, Xiao Chen, Xin Jiang and Qun Liu

Self-Supervised Meta-Learning for Few-Shot Natural Language Classification Tasks
Trapit Bansal, Rishikesh Jha, Tsendsuren Munkhdalai and Andrew McCallum

Efficient Meta Lifelong-Learning with Limited Memory
Zirui Wang, Sanket Vaibhav Mehta, Barnabas Poczos and Jaime Carbonell

20:00–21:00 *Zoom Q&A Session 3iii: Machine Translation and Multilinguality*

Don't Use English Dev: On the Zero-Shot Cross-Lingual Evaluation of Contextual Embeddings
Phillip Keung, Yichao Lu, Julian Salazar and Vikas Bhardwaj

A Supervised Word Alignment Method based on Cross-Language Span Prediction using Multilingual BERT
Masaaki Nagata, Katsuki Chousa and Masaaki Nishino

Accurate Word Alignment Induction from Neural Machine Translation
Yun Chen, Yang Liu, Guanhua Chen, Xin Jiang and Qun Liu

ChrEn: Cherokee-English Machine Translation for Endangered Language Revitalization
Shiyue Zhang, Benjamin Frey and Mohit Bansal

20:00–21:00 *Zoom Q&A Session 3iv: Computational Social Science and Social Media*

Unsupervised Discovery of Implicit Gender Bias
Anjalie Field and Yulia Tsvetkov

Condolence and Empathy in Online Communities
Naitian Zhou and David Jurgens

An Embedding Model for Estimating Legislative Preferences from the Frequency and Sentiment of Tweets
Gregory Spell, Brian Guay, Sunshine Hillygus and Lawrence Carin

Measuring Information Propagation in Literary Social Networks
Matthew Sims and David Bamman

Social Chemistry 101: Learning to Reason about Social and Moral Norms
Maxwell Forbes, Jena D. Hwang, Vered Shwartz, Maarten Sap and Yejin Choi

21:00–22:00 *Zoom Q&A Session 4*

21:00–22:00 *Zoom Q&A Session 4i: Information Extraction*

Event Extraction by Answering (Almost) Natural Questions
Xinya Du and Claire Cardie

Connecting the Dots: Event Graph Schema Induction with Path Language Modeling
Manling Li, Qi Zeng, Ying Lin, Kyunghyun Cho, Heng Ji, Jonathan May, Nathanael Chambers and Clare Voss

Joint Constrained Learning for Event-Event Relation Extraction
Haoyu Wang, Muhao Chen, Hongming Zhang and Dan Roth

Incremental Event Detection via Knowledge Consolidation Networks
Pengfei Cao, Yubo Chen, Jun Zhao and Taifeng Wang

Semi-supervised New Event Type Induction and Event Detection
Lifu Huang and Heng Ji

21:00–22:00 *Zoom Q&A Session 4ii: Language Generation*

Language Generation with Multi-Hop Reasoning on Commonsense Knowledge Graph
Haozhe Ji, Pei Ke, Shaohan Huang, Furu Wei, Xiaoyan Zhu and Minlie Huang

Reformulating Unsupervised Style Transfer as Paraphrase Generation
Kalpesh Krishna, John Wieting and Mohit Iyyer

De-Biased Court's View Generation with Causality
Yiquan Wu, Kun Kuang, Yating Zhang, Xiaozhong Liu, Changlong Sun, Jun Xiao, Yueting Zhuang, Luo Si and Fei Wu

PAIR: Planning and Iterative Refinement in Pre-trained Transformers for Long Text Generation
Xinyu Hua and Lu Wang

Back to the Future: Unsupervised Backprop-based Decoding for Counterfactual and Abductive Commonsense Reasoning
Lianhui Qin, Vered Shwartz, Peter West, Chandra Bhagavatula, Jena D. Hwang, Ronan Le Bras, Antoine Bosselut and Yejin Choi

21:00–22:00 *Zoom Q&A Session 4iii: Language Grounding to Vision, Robotics and Beyond*

Where Are You? Localization from Embodied Dialog
Meera Hahn, Jacob Krantz, Dhruv Batra, Devi Parikh, James Rehg, Stefan Lee and Peter Anderson

Learning to Represent Image and Text with Denotation Graph
Bowen Zhang, Hexiang Hu, Vihan Jain, Eugene Ie and Fei Sha

Video2Commonsense: Generating Commonsense Descriptions to Enrich Video Captioning
Zhiyuan Fang, Tejas Gokhale, Pratyay Banerjee, Chitta Baral and Yezhou Yang

Does my multimodal model learn cross-modal interactions? It's harder to tell than you might think!
Jack Hessel and Lillian Lee

MUTANT: A Training Paradigm for Out-of-Distribution Generalization in Visual Question Answering
Tejas Gokhale, Pratyay Banerjee, Chitta Baral and Yezhou Yang

21:00–22:00 *Zoom Q&A Session 4iv: Dialog and Interactive Systems*

Mitigating Gender Bias for Neural Dialogue Generation with Adversarial Learning
Haochen Liu, Wentao Wang, Yiqi Wang, Hui Liu, Zitao Liu and Jiliang Tang

Will I Sound Like Me? Improving Persona Consistency in Dialogues through Pragmatic Self-Consciousness
Hyunwoo Kim, Byeongchang Kim and Gunhee Kim

TOD-BERT: Pre-trained Natural Language Understanding for Task-Oriented Dialogue
Chien-Sheng Wu, Steven C.H. Hoi, Richard Socher and Caiming Xiong

RiSAWOZ: A Large-Scale Multi-Domain Wizard-of-Oz Dataset with Rich Semantic Annotations for Task-Oriented Dialogue Modeling
Jun Quan, Shian Zhang, Qian Cao, Zizhong Li and Deyi Xiong

Filtering Noisy Dialogue Corpora by Connectivity and Content Relatedness
Reina Akama, Sho Yokoi, Jun Suzuki and Kentaro Inui

22:00–00:00 *Gather Session 1i: Linguistic Theories, Cognitive Modeling and Psycholinguistics; Machine Translation and Multilinguality; Question Answering*

Latent Geographical Factors for Analyzing the Evolution of Dialects in Contact
Yugo Murawaki

Predicting Reference: What do Language Models Learn about Discourse Models?
Shiva Upadhye, Leon Bergen and Andrew Kehler

Word class flexibility: A deep contextualized approach
Bai Li, Guillaume Thomas, Yang Xu and Frank Rudzicz

Shallow-to-Deep Training for Neural Machine Translation
Bei Li, Ziyang Wang, Hui Liu, Yufan Jiang, Quan Du, Tong Xiao, Huizhen Wang and Jingbo Zhu

Iterative Refinement in the Continuous Space for Non-Autoregressive Neural Machine Translation
Jason Lee, Raphael Shu and Kyunghyun Cho

Why Skip If You Can Combine: A Simple Knowledge Distillation Technique for Intermediate Layers
Yimeng Wu, Peyman Passban, Mehdi Rezagholizadeh and Qun Liu

Multi-task Learning for Multilingual Neural Machine Translation
Yiren Wang, ChengXiang Zhai and Hany Hassan

Token-level Adaptive Training for Neural Machine Translation
Shuhao Gu, Jinchao Zhang, Fandong Meng, Yang Feng, Wanying Xie, Jie Zhou and Dong Yu

Multi-Unit Transformers for Neural Machine Translation
Jianhao Yan, Fandong Meng and Jie Zhou

On the Sparsity of Neural Machine Translation Models
Yong Wang, Longyue Wang, Victor Li and Zhaopeng Tu

Incorporating a Local Translation Mechanism into Non-autoregressive Translation
Xiang Kong, Zhisong Zhang and Eduard Hovy

Self-Paced Learning for Neural Machine Translation
Yu Wan, Baosong Yang, Derek F. Wong, Yikai Zhou, Lidia S. Chao, Haibo Zhang and Boxing Chen

Long-Short Term Masking Transformer: A Simple but Effective Baseline for Document-level Neural Machine Translation
Pei Zhang, Boxing Chen, Niyu Ge and Kai Fan

Generating Diverse Translation from Model Distribution with Dropout
Xuanfu Wu, Yang Feng and Chenze Shao

Non-Autoregressive Machine Translation with Latent Alignments
Chitwan Saharia, William Chan, Saurabh Saxena and Mohammad Norouzi

Look at the First Sentence: Position Bias in Question Answering
Miyoung Ko, Jinhyuk Lee, Hyunjae Kim, Gangwoo Kim and Jaewoo Kang

ProtoQA: A Question Answering Dataset for Prototypical Common-Sense Reasoning
Michael Boratko, Xiang Li, Tim O'Gorman, Rajarshi Das, Dan Le and Andrew McCallum

IIRC: A Dataset of Incomplete Information Reading Comprehension Questions
James Ferguson, Matt Gardner, Hannaneh Hajishirzi, Tushar Khot and Pradeep Dasigi

Unsupervised Adaptation of Question Answering Systems via Generative Self-training
Steven Rennie, Etienne Marcheret, Neil Mallinar, David Nahamoo and Vaibhava Goel

TORQUE: A Reading Comprehension Dataset of Temporal Ordering Questions
Qiang Ning, Hao Wu, Rujun Han, Nanyun Peng, Matt Gardner and Dan Roth

22:00–00:00 *Gather Session 1ii: Language Generation; Machine Learning for NLP*

ToTTo: A Controlled Table-To-Text Generation Dataset
Ankur Parikh, Xuezhi Wang, Sebastian Gehrmann, Manaal Faruqui, Bhuwan Dhingra, Diyi Yang and Dipanjan Das

ENT-DESC: Entity Description Generation by Exploring Knowledge Graph
Liying Cheng, Dekun Wu, Lidong Bing, Yan Zhang, Zhanming Jie, Wei Lu and Luo Si

Small but Mighty: New Benchmarks for Split and Rephrase
Li Zhang, Huaiyu Zhu, Siddhartha Brahma and Yunyao Li

Online Back-Parsing for AMR-to-Text Generation
Xuefeng Bai, Linfeng Song and Yue Zhang

Reading Between the Lines: Exploring Infilling in Visual Narratives
Khyathi Raghavi Chandu, Ruo-Ping Dong and Alan W Black

Acrostic Poem Generation
Rajat Agarwal and Katharina Kann

Local Additivity Based Data Augmentation for Semi-supervised NER
Jiaao Chen, Zhenghui Wang, Ran Tian, Zichao Yang and Diyi Yang

Grounded Compositional Outputs for Adaptive Language Modeling
Nikolaos Pappas, Phoebe Mulcaire and Noah A. Smith

SSMBA: Self-Supervised Manifold Based Data Augmentation for Improving Out-of-Domain Robustness
Nathan Ng, Kyunghyun Cho and Marzyeh Ghassemi

SetConv: A New Approach for Learning from Imbalanced Data
Yang Gao, Yi-Fan Li, Yu Lin, Charu Aggarwal and Latifur Khan

Scalable Multi-Hop Relational Reasoning for Knowledge-Aware Question Answering
Yanlin Feng, Xinyue Chen, Bill Yuchen Lin, Peifeng Wang, Jun Yan and Xiang Ren

Improving Bilingual Lexicon Induction for Low Frequency Words
Jiaji Huang, Xingyu Cai and Kenneth Church

Learning VAE-LDA Models with Rounded Reparameterization Trick
Runzhi Tian, Yongyi Mao and Richong Zhang

Calibrated Language Model Fine-Tuning for In- and Out-of-Distribution Data
Lingkai Kong, Haoming Jiang, Yuchen Zhuang, Jie Lyu, Tuo Zhao and Chao Zhang

Scaling Hidden Markov Language Models
Justin Chiu and Alexander Rush

Coding Textual Inputs Boosts the Accuracy of Neural Networks
Abdul Rafae Khan, Jia Xu and Weiwei Sun

Learning from Task Descriptions
Orion Weller, Nicholas Lourie, Matt Gardner and Matthew Peters

22:00–00:00 *Gather Session 1iii: Computational Social Science and Social Media; NLP Applications; Semantics: Sentence-level Semantics, Textual Inference and Other areas*

Hashtags, Emotions, and Comments: A Large-Scale Dataset to Understand Fine-Grained Social Emotions to Online Topics
Keyang Ding, Jing Li and Yuji Zhang

Named Entity Recognition for Social Media Texts with Semantic Augmentation
Yuyang Nie, Yuanhe Tian, Xiang Wan, Yan Song and Bo Dai

Coupled Hierarchical Transformer for Stance-Aware Rumor Verification in Social Media Conversations
Jianfei Yu, Jing Jiang, Ling Min Serena Khoo, Hai Leong Chieu and Rui Xia

Social Media Attributions in the Context of Water Crisis
Rupak Sarkar, Sayantan Mahinder, Hirak Sarkar and Ashiqur KhudaBukhsh

On the Reliability and Validity of Detecting Approval of Political Actors in Tweets
Indira Sen, Fabian Flöck and Claudia Wagner

Towards Medical Machine Reading Comprehension with Structural Knowledge and Plain Text
Dongfang Li, Baotian Hu, Qingcai Chen, Weihua Peng and Anqi Wang

Generating Radiology Reports via Memory-driven Transformer
Zhihong Chen, Yan Song, Tsung-Hui Chang and Xiang Wan

Planning and Generating Natural and Diverse Disfluent Texts as Augmentation for Disfluency Detection
Jingfeng Yang, Diyi Yang and Zhaoran Ma

Predicting Clinical Trial Results by Implicit Evidence Integration
Qiao Jin, Chuanqi Tan, Mosha Chen, Xiaozhong Liu and Songfang Huang

Explainable Clinical Decision Support from Text
Jinyue Feng, Chantal Shaib and Frank Rudzicz

A Knowledge-driven Generative Model for Multi-implication Chinese Medical Procedure Entity Normalization
Jinghui Yan, Yining Wang, Lu Xiang, Yu Zhou and Chengqing Zong

Combining Automatic Labelers and Expert Annotations for Accurate Radiology Report Labeling Using BERT
Akshay Smit, Saahil Jain, Pranav Rajpurkar, Anuj Pareek, Andrew Ng and Matthew Lungren

Benchmarking Meaning Representations in Neural Semantic Parsing
Jiaqi Guo, Qian Liu, Jian-Guang LOU, Zhenwen Li, Xueqing Liu, Tao Xie and Ting Liu

Analogous Process Structure Induction for Sub-event Sequence Prediction
Hongming Zhang, Muhao Chen, Haoyu Wang, Yangqiu Song and Dan Roth

Monday, November 16, 2020 (continued)

SLM: Learning a Discourse Language Representation with Sentence Unshuffling
Haejun Lee, Drew A. Hudson, Kangwook Lee and Christopher D. Manning

Detecting Fine-Grained Cross-Lingual Semantic Divergences without Supervision by Learning to Rank
Eleftheria Briakou and Marine Carpuat

A Bilingual Generative Transformer for Semantic Sentence Embedding
John Wieting, Graham Neubig and Taylor Berg-Kirkpatrick

Semantically Inspired AMR Alignment for the Portuguese Language
Rafael Anchiêta and Thiago Pardo

An Unsupervised Sentence Embedding Method by Mutual Information Maximization
Yan Zhang, Ruidan He, ZUOZHU LIU, Kwan Hui Lim and Lidong Bing

Compositional Phrase Alignment and Beyond
Yuki Arase and Jun'ichi Tsujii

22:00–00:00 *Gather Session 1iv: Information Extraction; Information Retrieval and Text Mining; Speech and Multimodality*

Table Fact Verification with Structure-Aware Transformer
Hongzhi Zhang, Yingyao Wang, Sirui Wang, Xuezhi Cao, Fuzheng Zhang and Zhongyuan Wang

Double Graph Based Reasoning for Document-level Relation Extraction
Shuang Zeng, Runxin Xu, Baobao Chang and Lei Li

Event Extraction as Machine Reading Comprehension
Jian Liu, Yubo Chen, Kang Liu, Wei Bi and Xiaojiang Liu

MAVEN: A Massive General Domain Event Detection Dataset
Xiaozhi Wang, Ziqi Wang, Xu Han, Wangyi Jiang, Rong Han, Zhiyuan Liu, Juanzi Li, Peng Li, Yankai Lin and Jie Zhou

Knowledge Graph Alignment with Entity-Pair Embedding
Zhichun Wang, Jinjian Yang and Xiaoju Ye

Adaptive Attentional Network for Few-Shot Knowledge Graph Completion
Jiawei Sheng, Shu Guo, Zhenyu Chen, Juwei Yue, Lihong Wang, Tingwen Liu and Hongbo Xu

Pre-training Entity Relation Encoder with Intra-span and Inter-span Information
Yijun Wang, Changzhi Sun, Yuanbin Wu, Junchi Yan, Peng Gao and Guotong Xie

Two are Better than One: Joint Entity and Relation Extraction with Table-Sequence Encoders
Jue WANG and Wei Lu

Beyond [CLS] through Ranking by Generation
Cicero Nogueira dos Santos, Xiaofei Ma, Ramesh Nallapati, zhiheng huang and Bing Xiang

Tired of Topic Models? Clusters of Pretrained Word Embeddings Make for Fast and Good Topics too!
Suzanna Sia, Ayush Dalmia and Sabrina J. Mielke

Multi-document Summarization with Maximal Marginal Relevance-guided Reinforcement Learning
Yuning Mao, Yanru Qu, Yiqing Xie, Xiang Ren and Jiawei Han

Improving Neural Topic Models using Knowledge Distillation
Alexander Miserlis Hoyle, Pranav Goel and Philip Resnik

Short Text Topic Modeling with Topic Distribution Quantization and Negative Sampling Decoder
Xiaobao Wu, Chunping Li, Yan Zhu and Yishu Miao

Querying Across Genres for Medical Claims in News
Chaoyuan Zuo, Narayan Acharya and Ritwik Banerjee

Incorporating Multimodal Information in Open-Domain Web Keyphrase Extraction
Yansen Wang, Zhen Fan and Carolyn Rose

CMU-MOSEAS: A Multimodal Language Dataset for Spanish, Portuguese, German and French
AmirAli Bagher Zadeh, Yansheng Cao, Simon Hessner, Paul Pu Liang, Soujanya Poria and Louis-Philippe Morency

Combining Self-Training and Self-Supervised Learning for Unsupervised Disfluency Detection
Shaolei Wang, Zhongyuan Wang, Wanxiang Che and Ting Liu

Multimodal Routing: Improving Local and Global Interpretability of Multimodal Language Analysis
Yao-Hung Hubert Tsai, Martin Ma, Muqiao Yang, Ruslan Salakhutdinov and Louis-Philippe Morency

Multistage Fusion with Forget Gate for Multimodal Summarization in Open-Domain Videos
Nayu Liu, Xian Sun, Hongfeng Yu, Wenkai Zhang and Guangluan Xu

22:00–00:00 *Gather Session 1v: Dialog and Interactive Systems; Interpretability and Analysis of Models for NLP; Language Grounding to Vision, Robotics and Beyond*

BiST: Bi-directional Spatio-Temporal Reasoning for Video-Grounded Dialogues
Hung Le, Doyen Sahoo, Nancy Chen and Steven C.H. Hoi

UniConv: A Unified Conversational Neural Architecture for Multi-domain Task-oriented Dialogues
Hung Le, Doyen Sahoo, Chenghao Liu, Nancy Chen and Steven C.H. Hoi

GraphDialog: Integrating Graph Knowledge into End-to-End Task-Oriented Dialogue Systems
Shiquan Yang, Rui Zhang and Sarah Erfani

Structured Attention for Unsupervised Dialogue Structure Induction
Liang Qiu, Yizhou Zhao, Weiyan Shi, Yuan Liang, Feng Shi, Tao Yuan, Zhou Yu and Song-Chun Zhu

Cross Copy Network for Dialogue Generation
Changzhen Ji, Xin Zhou, Yating Zhang, Xiaozhong Liu, Changlong Sun, Conghui Zhu and Tiejun Zhao

Multi-turn Response Selection using Dialogue Dependency Relations
Qi Jia, Yizhu Liu, Siyu Ren, Kenny Zhu and Haifeng Tang

Parallel Interactive Networks for Multi-Domain Dialogue State Generation
Junfan Chen, Richong Zhang, Yongyi Mao and Jie Xu

SlotRefine: A Fast Non-Autoregressive Model for Joint Intent Detection and Slot Filling
Di Wu, Liang Ding, Fan Lu and Jian Xie

An Information Bottleneck Approach for Controlling Conciseness in Rationale Extraction
Bhargavi Paranjape, Mandar Joshi, John Thickstun, Hannaneh Hajishirzi and Luke Zettlemoyer

CrowS-Pairs: A Challenge Dataset for Measuring Social Biases in Masked Language Models
Nikita Nangia, Clara Vania, Rasika Bhalerao and Samuel R. Bowman

LOGAN: Local Group Bias Detection by Clustering
Jieyu Zhao and Kai-Wei Chang

RNNs can generate bounded hierarchical languages with optimal memory
John Hewitt, Michael Hahn, Surya Ganguli, Percy Liang and Christopher D. Manning

Detecting Independent Pronoun Bias with Partially-Synthetic Data Generation
Robert Munro and Alex (Carmen) Morrison

Visually Grounded Continual Learning of Compositional Phrases
Xisen Jin, Junyi Du, Arka Sadhu, Ram Nevatia and Xiang Ren

MAF: Multimodal Alignment Framework for Weakly-Supervised Phrase Grounding
Qinxin Wang, Hao Tan, Sheng Shen, Michael Mahoney and Zhewei Yao

Domain-Specific Lexical Grounding in Noisy Visual-Textual Documents
Gregory Yauney, Jack Hessel and David Mimno

HERO: Hierarchical Encoder for Video+Language Omni-representation Pre-training
Linjie Li, Yen-Chun Chen, Yu Cheng, Zhe Gan, Licheng Yu and Jingjing Liu

Vokenization: Improving Language Understanding with Contextualized, Visual-Grounded Supervision
Hao Tan and Mohit Bansal

Detecting Cross-Modal Inconsistency to Defend Against Neural Fake News
Reuben Tan, Bryan Plummer and Kate Saenko

Tuesday, November 17, 2020

04:00–05:00 *Zoom Q&A Session 5*

04:00–05:00 *Zoom Q&A Session 5i: Information Extraction*

Enhancing Aspect Term Extraction with Soft Prototypes
Zhuang Chen and Tieyun Qian

FedED: Federated Learning via Ensemble Distillation for Medical Relation Extraction
Dianbo Sui, Yubo Chen, Jun Zhao, Yantao Jia, Yuantao Xie and Weijian Sun

Multimodal Joint Attribute Prediction and Value Extraction for E-commerce Product
Tiangang Zhu, Yue Wang, Haoran Li, Youzheng Wu, Xiaodong He and Bowen Zhou

A Predicate-Function-Argument Annotation of Natural Language for Open-Domain Information eXpression
Mingming Sun, Wenyue Hua, Zoey Liu, Xin Wang, Kangjie Zheng and Ping Li

04:00–05:00 *Zoom Q&A Session 5ii: Language Generation*

Retrofitting Structure-aware Transformer Language Model for End Tasks
Hao Fei, Yafeng Ren and Donghong Ji

Lightweight, Dynamic Graph Convolutional Networks for AMR-to-Text Generation
Yan Zhang, Zhijiang Guo, Zhiyang Teng, Wei Lu, Shay B. Cohen, ZUOZHU LIU and Lidong Bing

If beam search is the answer, what was the question?
Clara Meister, Ryan Cotterell and Tim Vieira

04:00–05:00 *Zoom Q&A Session 5iii: Machine Learning for NLP*

Understanding the Mechanics of SPIGOT: Surrogate Gradients for Latent Structure Learning
Tsvetomila Mihaylova, Vlad Niculae and André F. T. Martins

Is the Best Better? Bayesian Statistical Model Comparison for Natural Language Processing
Piotr Szymański and Kyle Gorman

Exploring Logically Dependent Multi-task Learning with Causal Inference
Wenqing Chen, Jidong Tian, Liqiang Xiao, Hao He and Yaohui Jin

Masking as an Efficient Alternative to Finetuning for Pretrained Language Models
Mengjie Zhao, Tao Lin, Fei Mi, Martin Jaggi and Hinrich Schütze

04:00–05:00 *Zoom Q&A Session 5iv: Machine Translation and Multilinguality*

Dynamic Context Selection for Document-level Neural Machine Translation via Reinforcement Learning
Xiaomian Kang, Yang Zhao, Jiajun Zhang and Chengqing Zong

Data Rejuvenation: Exploiting Inactive Training Examples for Neural Machine Translation
Wenxiang Jiao, Xing Wang, Shilin He, Irwin King, Michael Lyu and Zhaopeng Tu

Pronoun-Targeted Fine-tuning for NMT with Hybrid Losses
Prathyusha Jwalapuram, Shafiq Joty and Youlin Shen

Learning Adaptive Segmentation Policy for Simultaneous Translation
Ruiqing Zhang, Chuanqiang Zhang, Zhongjun He, Hua Wu and Haifeng Wang

Learn to Cross-lingual Transfer with Meta Graph Learning Across Heterogeneous Languages
Zheng Li, Mukul Kumar, William Headden, Bing Yin, Ying Wei, Yu Zhang and Qiang Yang

05:00–06:00 *Zoom Q&A Session 6*

05:00–06:00 *Zoom Q&A Session 6i: Syntax: Tagging, Chunking, and Parsing*

UDapter: Language Adaptation for Truly Universal Dependency Parsing
Ahmet Üstün, Arianna Bisazza, Gosse Bouma and Gertjan van Noord

Uncertainty-Aware Label Refinement for Sequence Labeling
Tao Gui, Jiacheng Ye, Qi Zhang, Zhengyan Li, Zichu Fei, Yeyun Gong and Xuanjing Huang

Adversarial Attack and Defense of Structured Prediction Models
Wenjuan Han, Liwen Zhang, Yong Jiang and Kewei Tu

Position-Aware Tagging for Aspect Sentiment Triplet Extraction
Lu Xu, Hao Li, Wei Lu and Lidong Bing

05:00–06:00 *Zoom Q&A Session 6ii: Machine Translation and Multilinguality*

Simultaneous Machine Translation with Visual Context
Ozan Caglayan, Julia Ive, Veneta Haralampieva, Pranava Madhyastha, Loïc Barrault and Lucia Specia

XCOPA: A Multilingual Dataset for Causal Commonsense Reasoning
Edoardo Maria Ponti, Goran Glavaš, Olga Majewska, Qianchu Liu, Ivan Vulić and Anna Korhonen

The Secret is in the Spectra: Predicting Cross-lingual Task Performance with Spectral Similarity Measures
Haim Dubossarsky, Ivan Vulić, Roi Reichart and Anna Korhonen

Bridging Linguistic Typology and Multilingual Machine Translation with Multi-View Language Representations
Arturo Oncevay, Barry Haddow and Alexandra Birch

05:00–06:00 *Zoom Q&A Session 6iii: Question Answering*

AnswerFact: Fact Checking in Product Question Answering
Wenxuan Zhang, Yang Deng, Jing Ma and Wai Lam

Context-Aware Answer Extraction in Question Answering
Yeon Seonwoo, Ji-Hoon Kim, Jung-Woo Ha and Alice Oh

What do Models Learn from Question Answering Datasets?
Priyanka Sen and Amir Saffari

Discern: Discourse-Aware Entailment Reasoning Network for Conversational Machine Reading
Yifan Gao, Chien-Sheng Wu, Jingjing Li, Shafiq Joty, Steven C.H. Hoi, Caiming Xiong, Irwin King and Michael Lyu

05:00–06:00 *Zoom Q&A Session 6iv: Semantics: Sentence-level Semantics, Textual Inference and Other areas*

A Method for Building a Commonsense Inference Dataset based on Basic Events
Kazumasa Omura, Daisuke Kawahara and Sadao Kurohashi

Neural Deepfake Detection with Factual Structure of Text
Wanjun Zhong, Duyu Tang, Zenan Xu, Ruize Wang, Nan Duan, Ming Zhou, Jiahai Wang and Jian Yin

MultiCQA: Zero-Shot Transfer of Self-Supervised Text Matching Models on a Massive Scale
Andreas Rücklé, Jonas Pfeiffer and Iryna Gurevych

XL-AMR: Enabling Cross-Lingual AMR Parsing with Transfer Learning Techniques
Rexhina Blloshmi, Rocco Tripodi and Roberto Navigli

Improving AMR Parsing with Sequence-to-Sequence Pre-training
Dongqin Xu, Junhui Li, Muhua Zhu, Min Zhang and Guodong Zhou

06:00–08:00 *Gather Session 2i: Computational Social Science and Social Media; Machine Translation and Multilinguality; Syntax: Tagging, Chunking, and Parsing*

Hate-Speech and Offensive Language Detection in Roman Urdu
Hammad Rizwan, Muhammad Haroon Shakeel and Asim Karim

Suicidal Risk Detection for Military Personnel
Sungjoon Park, Kiwoong Park, Jaimeen Ahn and Alice Oh

Comparative Evaluation of Label-Agnostic Selection Bias in Multilingual Hate Speech Datasets
Nedjma Ousidhoum, Yangqiu Song and Dit-Yan Yeung

HENIN: Learning Heterogeneous Neural Interaction Networks for Explainable Cyberbullying Detection on Social Media
Hsin-Yu Chen and Cheng-Te Li

Reactive Supervision: A New Method for Collecting Sarcasm Data
Boaz Shmueli, Lun-Wei Ku and Soumya Ray

Self-Induced Curriculum Learning in Self-Supervised Neural Machine Translation
Dana Ruiter, Josef van Genabith and Cristina España-Bonet

Towards Reasonably-Sized Character-Level Transformer NMT by Finetuning Subword Systems
Jindřich Libovický and Alexander Fraser

Transfer Learning and Distant Supervision for Multilingual Transformer Models: A Study on African Languages
Michael A. Hedderich, David Adelani, Dawei Zhu, Jesujoba Alabi, Udia Markus and Dietrich Klakow

Translation Quality Estimation by Jointly Learning to Score and Rank
Jingyi Zhang and Josef van Genabith

Direct Segmentation Models for Streaming Speech Translation
Javier Iranzo-Sánchez, Adrià Giménez Pastor, Joan Albert Silvestre-Cerdà, Pau Baquero-Arnal, Jorge Civera Saiz and Alfons Juan

Not Low-Resource Anymore: Aligner Ensembling, Batch Filtering, and New Datasets for Bengali-English Machine Translation
Tahmid Hasan, Abhik Bhattacharjee, Kazi Samin, Masum Hasan, Madhusudan Basak, M. Sohel Rahman and Rifat Shahriyar

CSP:Code-Switching Pre-training for Neural Machine Translation
Zhen Yang, Bojie Hu, ambyera han, shen huang and Qi Ju

Type B Reflexivization as an Unambiguous Testbed for Multilingual Multi-Task Gender Bias
Ana Valeria González, Maria Barrett, Rasmus Hvingelby, Kellie Webster and Anders Søgaard

Pre-training Multilingual Neural Machine Translation by Leveraging Alignment Information
Zehui Lin, Xiao Pan, Mingxuan Wang, Xipeng Qiu, Jiangtao Feng, Hao Zhou and Lei Li

Losing Heads in the Lottery: Pruning Transformer Attention in Neural Machine Translation
Maximiliana Behnke and Kenneth Heafield

Towards Enhancing Faithfulness for Neural Machine Translation
Rongxiang Weng, Heng Yu, Xiangpeng Wei and Weihua Luo

COMET: A Neural Framework for MT Evaluation
Ricardo Rei, Craig Stewart, Ana C Farinha and Alon Lavie

Reusing a Pretrained Language Model on Languages with Limited Corpora for Unsupervised NMT
Alexandra Chronopoulou, Dario Stojanovski and Alexander Fraser

LNMap: Departures from Isomorphic Assumption in Bilingual Lexicon Induction Through Non-Linear Mapping in Latent Space
Tasnim Mohiuddin, M Saiful Bari and Shafiq Joty

Uncertainty-Aware Semantic Augmentation for Neural Machine Translation
Xiangpeng Wei, Heng Yu, Yue Hu, Rongxiang Weng, Luxi Xing and Weihua Luo

Can Automatic Post-Editing Improve NMT?
Shamil Chollampatt, Raymond Hendy Susanto, Liling Tan and Ewa Szymanska

Parsing Gapping Constructions Based on Grammatical and Semantic Roles
Yoshihide Kato and Shigeki Matsubara

Span-based discontinuous constituency parsing: a family of exact chart-based algorithms with time complexities from O(nˆ6) down to O(nˆ3)
Caio Corro

Some Languages Seem Easier to Parse Because Their Treebanks Leak
Anders Søgaard

Discontinuous Constituent Parsing as Sequence Labeling
David Vilares and Carlos Gómez-Rodríguez

Modularized Syntactic Neural Networks for Sentence Classification
Haiyan Wu, Ying Liu and Shaoyun Shi

06:00–08:00 *Gather Session 2ii: Discourse and Pragmatics; Language Generation; Machine Learning for NLP; Question Answering*

TED-CDB: A Large-Scale Chinese Discourse Relation Dataset on TED Talks
Wanqiu Long, Bonnie Webber and Deyi Xiong

QADiscourse - Discourse Relations as QA Pairs: Representation, Crowdsourcing and Baselines
Valentina Pyatkin, Ayal Klein, Reut Tsarfaty and Ido Dagan

Discourse Self-Attention for Discourse Element Identification in Argumentative Student Essays
Wei Song, Ziyao Song, Ruiji Fu, Lizhen Liu, Miaomiao Cheng and Ting Liu

MEGATRON-CNTRL: Controllable Story Generation with External Knowledge Using Large-Scale Language Models
Peng Xu, Mostofa Patwary, Mohammad Shoeybi, Raul Puri, Pascale Fung, Anima Anandkumar and Bryan Catanzaro

Incomplete Utterance Rewriting as Semantic Segmentation
Qian Liu, Bei Chen, Jian-Guang LOU, Bin Zhou and Dongmei Zhang

Improving Grammatical Error Correction Models with Purpose-Built Adversarial Examples
Lihao Wang and Xiaoqing Zheng

Homophonic Pun Generation with Lexically Constrained Rewriting
Zhiwei Yu, Hongyu Zang and Xiaojun Wan

How to Make Neural Natural Language Generation as Reliable as Templates in Task-Oriented Dialogue
Henry Elder, Alexander O'Connor and Jennifer Foster

Multilingual AMR-to-Text Generation
Angela Fan and Claire Gardent

Exploring the Linear Subspace Hypothesis in Gender Bias Mitigation
Francisco Vargas and Ryan Cotterell

Lifelong Language Knowledge Distillation
Yung-Sung Chuang, Shang-Yu Su and Yun-Nung Chen

Sparse Parallel Training of Hierarchical Dirichlet Process Topic Models
Alexander Terenin, Måns Magnusson and Leif Jonsson

Multi-label Few/Zero-shot Learning with Knowledge Aggregated from Multiple Label Graphs
Jueqing Lu, Lan Du, Ming Liu and Joanna Dipnall

Word Rotator's Distance
Sho Yokoi, Ryo Takahashi, Reina Akama, Jun Suzuki and Kentaro Inui

Disentangle-based Continual Graph Representation Learning
Xiaoyu Kou, Yankai Lin, Shaobo Liu, Peng Li, Jie Zhou and Yan Zhang

Semi-Supervised Bilingual Lexicon Induction with Two-way Interaction
Xu Zhao, Zihao Wang, Hao Wu and Yong Zhang

Wasserstein Distance Regularized Sequence Representation for Text Matching in Asymmetrical Domains
Weijie Yu, Chen Xu, Jun Xu, Liang Pang, Xiaopeng Gao, Xiaozhao Wang and Ji-Rong Wen

A Simple Approach to Learning Unsupervised Multilingual Embeddings
Pratik Jawanpuria, Mayank Meghwanshi and Bamdev Mishra

Bootstrapped Q-learning with Context Relevant Observation Pruning to Generalize in Text-based Games
Subhajit Chaudhury, Daiki Kimura, Kartik Talamadupula, Michiaki Tatsubori, Asim Munawar and Ryuki Tachibana

BERT-EMD: Many-to-Many Layer Mapping for BERT Compression with Earth Mover's Distance
jianquan li, Xiaokang Liu, Honghong Zhao, Ruifeng Xu, Min Yang and yaohong jin

Slot Attention with Value Normalization for Multi-Domain Dialogue State Tracking
Yexiang Wang, Yi Guo and Siqi Zhu

Don't Read Too Much Into It: Adaptive Computation for Open-Domain Question Answering
Yuxiang Wu, Sebastian Riedel, Pasquale Minervini and Pontus Stenetorp

Multi-Step Inference for Reasoning Over Paragraphs
Jiangming Liu, Matt Gardner, Shay B. Cohen and Mirella Lapata

Learning a Cost-Effective Annotation Policy for Question Answering
Bernhard Kratzwald, Stefan Feuerriegel and Huan Sun

Scene Restoring for Narrative Machine Reading Comprehension
Zhixing Tian, Yuanzhe Zhang, Kang Liu, Jun Zhao, Yantao Jia and Zhicheng Sheng

A Simple and Effective Model for Answering Multi-span Questions
Elad Segal, Avia Efrat, Mor Shoham, Amir Globerson and Jonathan Berant

06:00–08:00 *Gather Session 2iii: Information Retrieval and Text Mining; Interpretability and Analysis of Models for NLP; Language Grounding to Vision, Robotics and Beyond*

Top-Rank-Focused Adaptive Vote Collection for the Evaluation of Domain-Specific Semantic Models
Pierangelo Lombardo, Alessio Boiardi, Luca Colombo, Angelo Schiavone and Nicolò Tamagnone

Meta Fine-Tuning Neural Language Models for Multi-Domain Text Mining
Chengyu Wang, Minghui Qiu, jun huang and XIAOFENG HE

Incorporating Behavioral Hypotheses for Query Generation
Ruey-Cheng Chen and Chia-Jung Lee

Conditional Causal Relationships between Emotions and Causes in Texts
Xinhong Chen, Qing Li and Jianping Wang

COMETA: A Corpus for Medical Entity Linking in the Social Media
Marco Basaldella, Fangyu Liu, Ehsan Shareghi and Nigel Collier

Pareto Probing: Trading Off Accuracy for Complexity
Tiago Pimentel, Naomi Saphra, Adina Williams and Ryan Cotterell

Interpretation of NLP models through input marginalization
Siwon Kim, Jihun Yi, Eunji Kim and Sungroh Yoon

Generating Label Cohesive and Well-Formed Adversarial Claims
Pepa Atanasova, Dustin Wright and Isabelle Augenstein

Are All Good Word Vector Spaces Isomorphic?
Ivan Vulić, Sebastian Ruder and Anders Søgaard

Cold-Start and Interpretability: Turning Regular Expressions into Trainable Recurrent Neural Networks
Chengyue Jiang, Yinggong Zhao, Shanbo Chu, Libin Shen and Kewei Tu

When BERT Plays the Lottery, All Tickets Are Winning
Sai Prasanna, Anna Rogers and Anna Rumshisky

On the weak link between importance and prunability of attention heads
Aakriti Budhraja, Madhura Pande, Preksha Nema, Pratyush Kumar and Mitesh M. Khapra

Towards Interpreting BERT for Reading Comprehension Based QA
Sahana Ramnath, Preksha Nema, Deep Sahni and Mitesh M. Khapra

How do Decisions Emerge across Layers in Neural Models? Interpretation with Differentiable Masking
Nicola De Cao, Michael Sejr Schlichtkrull, Wilker Aziz and Ivan Titov

A Diagnostic Study of Explainability Techniques for Text Classification
Pepa Atanasova, Jakob Grue Simonsen, Christina Lioma and Isabelle Augenstein

STL-CQA: Structure-based Transformers with Localization and Encoding for Chart Question Answering
Hrituraj Singh and Sumit Shekhar

Learning to Contrast the Counterfactual Samples for Robust Visual Question Answering
Zujie Liang, Weitao Jiang, Haifeng Hu and Jiaying Zhu

Learning Physical Common Sense as Knowledge Graph Completion via BERT Data Augmentation and Constrained Tucker Factorization
Zhenjie Zhao, Evangelos Papalexakis and Xiaojuan Ma

A Visually-grounded First-person Dialogue Dataset with Verbal and Non-verbal Responses
Hisashi Kamezawa, Noriki Nishida, Nobuyuki Shimizu, Takashi Miyazaki and Hideki Nakayama

Cross-Media Keyphrase Prediction: A Unified Framework with Multi-Modality Multi-Head Attention and Image Wordings
Yue Wang, Jing Li, Michael Lyu and Irwin King

VD-BERT: A Unified Vision and Dialog Transformer with BERT
Yue Wang, Shafiq Joty, Michael Lyu, Irwin King, Caiming Xiong and Steven C.H. Hoi

The Grammar of Emergent Languages
Oskar van der Wal, Silvan de Boer, Elia Bruni and Dieuwke Hupkes

Sub-Instruction Aware Vision-and-Language Navigation
Yicong Hong, Cristian Rodriguez, Qi Wu and Stephen Gould

06:00–08:00 *Gather Session 2iv: Dialog and Interactive Systems; Semantics: Lexical Semantics; Sentiment Analysis, Stylistic Analysis, and Argument Mining; Summarization*

Knowledge-Grounded Dialogue Generation with Pre-trained Language Models
Xueliang Zhao, wei wu, Can Xu, Chongyang Tao, Dongyan Zhao and Rui Yan

MinTL: Minimalist Transfer Learning for Task-Oriented Dialogue Systems
Zhaojiang Lin, Andrea Madotto, Genta Indra Winata and Pascale Fung

Variational Hierarchical Dialog Autoencoder for Dialog State Tracking Data Augmentation
Kang Min Yoo, Hanbit Lee, Franck Dernoncourt, Trung Bui, Walter Chang and Sang-goo Lee

Bridging the Gap between Prior and Posterior Knowledge Selection for Knowledge-Grounded Dialogue Generation
Xiuyi Chen, Fandong Meng, Peng Li, Feilong Chen, Shuang Xu, Bo Xu and Jie Zhou

Counterfactual Off-Policy Training for Neural Dialogue Generation
Qingfu Zhu, Wei-Nan Zhang, Ting Liu and William Yang Wang

Dialogue Distillation: Open-Domain Dialogue Augmentation Using Unpaired Data
Rongsheng Zhang, Yinhe Zheng, Jianzhi Shao, Xiaoxi Mao, Yadong Xi and Minlie Huang

Task-Completion Dialogue Policy Learning via Monte Carlo Tree Search with Dueling Network
Sihan Wang, kaijie zhou, Kunfeng Lai and Jianping Shen

Learning a Simple and Effective Model for Multi-turn Response Generation with Auxiliary Tasks
YUFAN ZHAO, Can Xu and wei wu

AttnIO: Knowledge Graph Exploration with In-and-Out Attention Flow for Knowledge-Grounded Dialogue
Jaehun Jung, Bokyung Son and Sungwon Lyu

Amalgamating Knowledge from Two Teachers for Task-oriented Dialogue System with Adversarial Training
Wanwei He, Min Yang, Rui Yan, Chengming Li, Ying Shen and Ruifeng Xu

Task-oriented Domain-specific Meta-Embedding for Text Classification
Xin Wu, Yi Cai, Yang Kai, Tao Wang and Qing Li

Don't Neglect the Obvious: On the Role of Unambiguous Words in Word Sense Disambiguation
Daniel Loureiro and Jose Camacho-Collados

Within-Between Lexical Relation Classification
Oren Barkan, Avi Caciularu and Ido Dagan

With More Contexts Comes Better Performance: Contextualized Sense Embeddings for All-Round Word Sense Disambiguation
Bianca Scarlini, Tommaso Pasini and Roberto Navigli

Convolution over Hierarchical Syntactic and Lexical Graphs for Aspect Level Sentiment Analysis
Mi Zhang and Tieyun Qian

Multi-Instance Multi-Label Learning Networks for Aspect-Category Sentiment Analysis
Yuncong Li, Cunxiang Yin, Sheng-hua Zhong and Xu Pan

Aspect Sentiment Classification with Aspect-Specific Opinion Spans
Lu Xu, Lidong Bing, Wei Lu and Fei Huang

Emotion-Cause Pair Extraction as Sequence Labeling Based on A Novel Tagging Scheme
Chaofa Yuan, Chuang Fan, Jianzhu Bao and Ruifeng Xu

End-to-End Emotion-Cause Pair Extraction based on Sliding Window Multi-Label Learning
Zixiang Ding, Rui Xia and Jianfei Yu

Multi-modal Multi-label Emotion Detection with Modality and Label Dependence
Dong Zhang, Xincheng Ju, Junhui Li, Shoushan Li, Qiaoming Zhu and Guodong Zhou

Tasty Burgers, Soggy Fries: Probing Aspect Robustness in Aspect-Based Sentiment Analysis
Xiaoyu Xing, Zhijing Jin, Di Jin, Bingning Wang, Qi Zhang and Xuanjing Huang

Modeling Content Importance for Summarization with Pre-trained Language Models
Liqiang Xiao, Lu Wang, Hao He and Yaohui Jin

Unsupervised Reference-Free Summary Quality Evaluation via Contrastive Learning
Hanlu Wu, Tengfei Ma, Lingfei Wu, Tariro Manyumwa and Shouling Ji

Neural Extractive Summarization with Hierarchical Attentive Heterogeneous Graph Network
Ruipeng Jia, Yanan Cao, Hengzhu Tang, Fang Fang, Cong Cao and Shi Wang

Coarse-to-Fine Query Focused Multi-Document Summarization
Yumo Xu and Mirella Lapata

Pre-training for Abstractive Document Summarization by Reinstating Source Text
Yanyan Zou, Xingxing Zhang, Wei Lu, Furu Wei and Ming Zhou

06:00–08:00 *Gather Session 2v: Information Extraction; NLP Applications; Phonology, Morphology and Word Segmentation; Semantics: Sentence-level Semantics, Textual Inference and Other areas*

Learning from Context or Names? An Empirical Study on Neural Relation Extraction
Hao Peng, Tianyu Gao, Xu Han, Yankai Lin, Peng Li, Zhiyuan Liu, Maosong Sun and Jie Zhou

SelfORE: Self-supervised Relational Feature Learning for Open Relation Extraction
Xuming Hu, Lijie Wen, Yusong Xu, Chenwei Zhang and Philip Yu

Denoising Relation Extraction from Document-level Distant Supervision
Chaojun Xiao, Yuan Yao, Ruobing Xie, Xu Han, Zhiyuan Liu, Maosong Sun, Fen Lin and Leyu Lin

Let's Stop Incorrect Comparisons in End-to-end Relation Extraction!
Bruno Taillé, Vincent Guigue, Geoffrey Scoutheeten and patrick Gallinari

Exposing Shallow Heuristics of Relation Extraction Models with Challenge Data
Shachar Rosenman, Alon Jacovi and Yoav Goldberg

Global-to-Local Neural Networks for Document-Level Relation Extraction
Difeng Wang, Wei Hu, Ermei Cao and Weijian Sun

Recurrent Interaction Network for Jointly Extracting Entities and Classifying Relations
Kai Sun, Richong Zhang, Samuel Mensah, Yongyi Mao and xudong Liu

Temporal Knowledge Base Completion: New Algorithms and Evaluation Protocols
Prachi Jain, Sushant Rathi, Mausam and Soumen Chakrabarti

OpenIE6: Iterative Grid Labeling and Coordination Analysis for Open Information Extraction
Keshav Kolluru, Vaibhav Adlakha, Samarth Aggarwal, Mausam and Soumen Chakrabarti

Public Sentiment Drift Analysis Based on Hierarchical Variational Auto-encoder
Wenyue Zhang, Xiaoli Li, Yang Li, Suge Wang, Deyu Li, Jian Liao and Jianxing Zheng

Point to the Expression: Solving Algebraic Word Problems using the Expression-Pointer Transformer Model
Bugeun Kim, Kyung Seo Ki, Donggeon Lee and Gahgene Gweon

Semantically-Aligned Universal Tree-Structured Solver for Math Word Problems
Jinghui Qin, Lihui Lin, Xiaodan Liang, Rumin Zhang and Liang Lin

Neural Topic Modeling by Incorporating Document Relationship Graph
Deyu Zhou, Xuemeng Hu and Rui Wang

Routing Enforced Generative Model for Recipe Generation
Zhiwei Yu, Hongyu Zang and Xiaojun Wan

Assessing the Helpfulness of Learning Materials with Inference-Based Learner-Like Agent
Yun-Hsuan Jen, Chieh-Yang Huang, MeiHua Chen, Ting-Hao Huang and Lun-Wei Ku

Selection and Generation: Learning towards Multi-Product Advertisement Post Generation
Zhangming Chan, Yuchi Zhang, Xiuying Chen, Shen Gao, Zhiqiang Zhang, Dongyan Zhao and Rui Yan

Form2Seq : A Framework for Higher-Order Form Structure Extraction
Milan Aggarwal, Hiresh Gupta, Mausoom Sarkar and Balaji Krishnamurthy

Domain Adaptation of Thai Word Segmentation Models using Stacked Ensemble
Peerat Limkonchotiwat, Wannaphong Phatthiyaphaibun, Raheem Sarwar, Ekapol Chuangsuwanich and Sarana Nutanong

DagoBERT: Generating Derivational Morphology with a Pretrained Language Model
Valentin Hofmann, Janet Pierrehumbert and Hinrich Schütze

Attention Is All You Need for Chinese Word Segmentation
Sufeng Duan and Hai Zhao

A Joint Multiple Criteria Model in Transfer Learning for Cross-domain Chinese Word Segmentation
Kaiyu Huang, Degen Huang, Zhuang Liu and Fengran Mo

Alignment-free Cross-lingual Semantic Role Labeling
Rui Cai and Mirella Lapata

Leveraging Declarative Knowledge in Text and First-Order Logic for Fine-Grained Propaganda Detection
Ruize Wang, Duyu Tang, Nan Duan, Wanjun Zhong, Zhongyu Wei, Xuanjing Huang, Daxin Jiang and Ming Zhou

X-SRL: A Parallel Cross-Lingual Semantic Role Labeling Dataset
Angel Daza and Anette Frank

Graph Convolutions over Constituent Trees for Syntax-Aware Semantic Role Labeling
Diego Marcheggiani and Ivan Titov

Fast semantic parsing with well-typedness guarantees
Matthias Lindemann, Jonas Groschwitz and Alexander Koller

11:00–12:00 *Ethics Panel Discussion*

12:00–13:00 *Zoom Q&A Session 7*

12:00–13:00 *Zoom Q&A Session 7i: Dialog and Interactive Systems*

Improving Out-of-Scope Detection in Intent Classification by Using Embeddings of the Word Graph Space of the Classes
Paulo Cavalin, Victor Henrique Alves Ribeiro, Ana Appel and Claudio Pinhanez

Supervised Seeded Iterated Learning for Interactive Language Learning
Yuchen Lu, Soumye Singhal, Florian Strub, Olivier Pietquin and Aaron Courville

Spot The Bot: A Robust and Efficient Framework for the Evaluation of Conversational Dialogue Systems
Jan Deriu, Don Tuggener, Pius von Däniken, Jon Ander Campos, Alvaro Rodrigo, Thiziri Belkacem, Aitor Soroa, Eneko Agirre and Mark Cieliebak

Human-centric dialog training via offline reinforcement learning
Natasha Jaques, Judy Hanwen Shen, Asma Ghandeharioun, Craig Ferguson, Agata Lapedriza, Noah Jones, Shixiang Gu and Rosalind Picard

12:00–13:00 *Zoom Q&A Session 7ii: Linguistic Theories, Cognitive Modeling and Psycholinguistics*

Speakers Fill Lexical Semantic Gaps with Context
Tiago Pimentel, Rowan Hall Maudslay, Damian Blasi and Ryan Cotterell

Investigating Cross-Linguistic Adjective Ordering Tendencies with a Latent-Variable Model
Jun Yen Leung, Guy Emerson and Ryan Cotterell

Surprisal Predicts Code-Switching in Chinese-English Bilingual Text
Jesús Calvillo, Le Fang, Jeremy Cole and David Reitter

Word Frequency Does Not Predict Grammatical Knowledge in Language Models
Charles Yu, Ryan Sie, Nicolas Tedeschi and Leon Bergen

12:00–13:00 *Zoom Q&A Session 7iii: Semantics: Lexical Semantics*

Improving Word Sense Disambiguation with Translations
Yixing Luan, Bradley Hauer, Lili Mou and Grzegorz Kondrak

Towards Better Context-aware Lexical Semantics:Adjusting Contextualized Representations through Static Anchors
Qianchu Liu, Diana McCarthy and Anna Korhonen

Compositional Demographic Word Embeddings
Charles Welch, Jonathan K. Kummerfeld, Verónica Pérez-Rosas and Rada Mihalcea

Do “Undocumented Workers" == “Illegal Aliens"? Differentiating Denotation and Connotation in Vector Spaces
Albert Webson, Zhizhong Chen, Carsten Eickhoff and Ellie Pavlick

12:00–13:00 *Zoom Q&A Session 7iv: Summarization*

Multi-View Sequence-to-Sequence Models with Conversational Structure for Abstractive Dialogue Summarization
Jiaao Chen and Diyi Yang

Few-Shot Learning for Opinion Summarization
Arthur Bražinskas, Mirella Lapata and Ivan Titov

Learning to Fuse Sentences with Transformers for Summarization
Logan Lebanoff, Franck Dernoncourt, Doo Soon Kim, Lidan Wang, Walter Chang and Fei Liu

Stepwise Extractive Summarization and Planning with Structured Transformers
Shashi Narayan, Joshua Maynez, Jakub Adamek, Daniele Pighin, Blaz Bratanic and Ryan McDonald

13:00–14:00 *Zoom Q&A Session 8*

13:00–14:00 *Zoom Q&A Session 8i: Information Retrieval and Text Mining*

CLIRMatrix: A massively large collection of bilingual and multilingual datasets for Cross-Lingual Information Retrieval
Shuo Sun and Kevin Duh

SLEDGE-Z: A Zero-Shot Baseline for COVID-19 Literature Search
Sean MacAvaney, Arman Cohan and Nazli Goharian

Modularized Transfomer-based Ranking Framework
Luyu Gao, Zhuyun Dai and Jamie Callan

Ad-hoc Document Retrieval using Weak-Supervision with BERT and GPT2
Yosi Mass and Haggai Roitman

13:00–14:00 *Zoom Q&A Session 8ii: Interpretability and Analysis of Models for NLP*

Adversarial Semantic Collisions
Congzheng Song, Alexander Rush and Vitaly Shmatikov

Learning Explainable Linguistic Expressions with Neural Inductive Logic Programming for Sentence Classification
Prithviraj Sen, Marina Danilevsky, Yunyao Li, Siddhartha Brahma, Matthias Boehm, Laura Chiticariu and Rajasekar Krishnamurthy

AutoPrompt: Eliciting Knowledge from Language Models with Automatically Generated Prompts
Taylor Shin, Yasaman Razeghi, Robert L Logan IV, Eric Wallace and Sameer Singh

Learning Variational Word Masks to Improve the Interpretability of Neural Text Classifiers
Hanjie Chen and Yangfeng Ji

13:00–14:00 *Zoom Q&A Session 8iii: Language Generation*

Sparse Text Generation
Pedro Henrique Martins, Zita Marinho and André F. T. Martins

PlotMachines: Outline-Conditioned Generation with Dynamic Plot State Tracking
Hannah Rashkin, Asli Celikyilmaz, Yejin Choi and Jianfeng Gao

Do sequence-to-sequence VAEs learn global features of sentences?
Tom Bosc and Pascal Vincent

Content Planning for Neural Story Generation with Aristotelian Rescoring
Seraphina Goldfarb-Tarrant, Tuhin Chakrabarty, Ralph Weischedel and Nanyun Peng

Generating Dialogue Responses from a Semantic Latent Space
Wei-Jen Ko, Avik Ray, Yilin Shen and Hongxia Jin

13:00–14:00 *Zoom Q&A Session 8iv: Language Grounding to Vision, Robotics and Beyond*

Refer, Reuse, Reduce: Generating Subsequent References in Visual and Conversational Contexts
Ece Takmaz, Mario Giulianelli, Sandro Pezzelle, Arabella Sinclair and Raquel Fernández

Visually Grounded Compound PCFGs
Yanpeng Zhao and Ivan Titov

ALICE: Active Learning with Contrastive Natural Language Explanations
Weixin Liang, James Zou and Zhou Yu

Room-Across-Room: Multilingual Vision-and-Language Navigation with Dense Spatiotemporal Grounding
Alexander Ku, Peter Anderson, Roma Patel, Eugene Ie and Jason Baldridge

SSCR: Iterative Language-Based Image Editing via Self-Supervised Counterfactual Reasoning
Tsu-Jui Fu, Xin Wang, Scott Grafton, Miguel Eckstein and William Yang Wang

14:00–16:00 *Gather Session 3i: Machine Translation and Multilinguality; Semantics: Sentence-level Semantics, Textual Inference and Other areas*

Identifying Elements Essential for BERT's Multilinguality
Philipp Dufter and Hinrich Schütze

On Negative Interference in Multilingual Models: Findings and A Meta-Learning Treatment
Zirui Wang, Zachary C. Lipton and Yulia Tsvetkov

Pre-tokenization of Multi-word Expressions in Cross-lingual Word Embeddings
Naoki Otani, Satoru Ozaki, Xingyuan Zhao, Yucen Li, Micaelah St Johns and Lori Levin

Monolingual Adapters for Zero-Shot Neural Machine Translation
Jerin Philip, Alexandre Berard, Matthias Gallé and Laurent Besacier

Do Explicit Alignments Robustly Improve Multilingual Encoders?
Shijie Wu and Mark Dredze

From Zero to Hero: On the Limitations of Zero-Shot Language Transfer with Multilingual Transformers
Anne Lauscher, Vinit Ravishankar, Ivan Vulić and Goran Glavaš

Distilling Multiple Domains for Neural Machine Translation
Anna Currey, Prashant Mathur and Georgiana Dinu

Making Monolingual Sentence Embeddings Multilingual using Knowledge Distillation
Nils Reimers and Iryna Gurevych

A Streaming Approach For Efficient Batched Beam Search
Kevin Yang, Violet Yao, John DeNero and Dan Klein

Improving Multilingual Models with Language-Clustered Vocabularies
Hyung Won Chung, Dan Garrette, Kiat Chuan Tan and Jason Riesa

Zero-Shot Cross-Lingual Transfer with Meta Learning
Farhad Nooralahzadeh, Giannis Bekoulis, Johannes Bjerva and Isabelle Augenstein

The Multilingual Amazon Reviews Corpus
Phillip Keung, Yichao Lu, György Szarvas and Noah A. Smith

GLUCOSE: GeneraLized and COntextualized Story Explanations
Nasrin Mostafazadeh, Aditya Kalyanpur, Lori Moon, David Buchanan, Lauren Berkowitz, Or Biran and Jennifer Chu-Carroll

Character-level Representations Improve DRS-based Semantic Parsing Even in the Age of BERT
Rik van Noord, Antonio Toral and Johan Bos

Infusing Disease Knowledge into BERT for Health Question Answering, Medical Inference and Disease Name Recognition
Yun He, Ziwei Zhu, Yin Zhang, Qin Chen and James Caverlee

Unsupervised Commonsense Question Answering with Self-Talk
Vered Shwartz, Peter West, Ronan Le Bras, Chandra Bhagavatula and Yejin Choi

Reasoning about Goals, Steps, and Temporal Ordering with WikiHow
Li Zhang, Qing Lyu and Chris Callison-Burch

14:00–16:00 *Gather Session 3ii: Linguistic Theories, Cognitive Modeling and Psycholinguistics; NLP Applications; Syntax: Tagging, Chunking, and Parsing*

Structural Supervision Improves Few-Shot Learning and Syntactic Generalization in Neural Language Models
Ethan Wilcox, Peng Qian, Richard Futrell, Ryosuke Kohita, Roger Levy and Miguel Ballesteros

Investigating representations of verb bias in neural language models
Robert Hawkins, Takateru Yamakoshi, Thomas Griffiths and Adele Goldberg

Generating Image Descriptions via Sequential Cross-Modal Alignment Guided by Human Gaze
Ece Takmaz, Sandro Pezzelle, Lisa Beinborn and Raquel Fernández

Optimus: Organizing Sentences via Pre-trained Modeling of a Latent Space
Chunyuan Li, Xiang Gao, Yuan Li, Baolin Peng, Xiujun Li, Yizhe Zhang and Jianfeng Gao

BioMegatron: Larger Biomedical Domain Language Model
Hoo-Chang Shin, Yang Zhang, Evelina Bakhturina, Raul Puri, Mostofa Patwary, Mohammad Shoeybi and Raghav Mani

Text Segmentation by Cross Segment Attention
Michal Lukasik, Boris Dadachev, Kishore Papineni and Goncalo Simoes

RussianSuperGLUE: A Russian Language Understanding Evaluation Benchmark
Tatiana Shavrina, Alena Fenogenova, Emelyanov Anton, Denis Shevelev, Ekaterina Artemova, Valentin Malykh, Vladislav Mikhailov, Maria Tikhonova, Andrey Chertok and Andrey Evlampiev

An Empirical Study of Pre-trained Transformers for Arabic Information Extraction
Wuwei Lan, Yang Chen, Wei Xu and Alan Ritter

TNT: Text Normalization based Pre-training of Transformers for Content Moderation
Fei Tan, Yifan Hu, Changwei Hu, Keqian Li and Kevin Yen

Methods for Numeracy-Preserving Word Embeddings
Dhanasekar Sundararaman, Shijing Si, Vivek Subramanian, Guoyin Wang, Devamanyu Hazarika and Lawrence Carin

An Empirical Investigation of Contextualized Number Prediction
Taylor Berg-Kirkpatrick and Daniel Spokoyny

Modeling the Music Genre Perception across Language-Bound Cultures
Elena V. Epure, Guillaume Salha, Manuel Moussallam and Romain Hennequin

Joint Estimation and Analysis of Risk Behavior Ratings in Movie Scripts
Victor Martinez, Krishna Somandepalli, Yalda Tehranian-Uhls and Shrikanth Narayanan

Keep it Surprisingly Simple: A Simple First Order Graph Based Parsing Model for Joint Morphosyntactic Parsing in Sanskrit
Amrith Krishna, Ashim Gupta, Deepak Garasangi, Pavankumar Satuluri and Pawan Goyal

Unsupervised Parsing via Constituency Tests
Steven Cao, Nikita Kitaev and Dan Klein

Please Mind the Root: Decoding Arborescences for Dependency Parsing
Ran Zmigrod, Tim Vieira and Ryan Cotterell

Unsupervised Cross-Lingual Part-of-Speech Tagging for Truly Low-Resource Scenarios
Ramy Eskander, Smaranda Muresan and Michael Collins

Unsupervised Parsing with S-DIORA: Single Tree Encoding for Deep Inside-Outside Recursive Autoencoders
Andrew Drozdov, Subendhu Rongali, Yi-Pei Chen, Tim O'Gorman, Mohit Iyyer and Andrew McCallum

14:00–16:00 *Gather Session 3iii: Interpretability and Analysis of Models for NLP; Machine Learning for NLP*

Utility is in the Eye of the User: A Critique of NLP Leaderboards
Kawin Ethayarajh and Dan Jurafsky

An Empirical Investigation Towards Efficient Multi-Domain Language Model Pre-training
Kristjan Arumae, Qing Sun and Parminder Bhatia

Analyzing Individual Neurons in Pre-trained Language Models
Nadir Durrani, Hassan Sajjad, Fahim Dalvi and Yonatan Belinkov

Dissecting Span Identification Tasks with Performance Prediction
Sean Papay, Roman Klinger and Sebastian Padó

Assessing Phrasal Representation and Composition in Transformers
Lang Yu and Allyson Ettinger

Analyzing Redundancy in Pretrained Transformer Models
Fahim Dalvi, Hassan Sajjad, Nadir Durrani and Yonatan Belinkov

Be More with Less: Hypergraph Attention Networks for Inductive Text Classification
Kaize Ding, Jianling Wang, Jundong Li, Dingcheng Li and Huan Liu

Tuesday, November 17, 2020 (continued)

Entities as Experts: Sparse Memory Access with Entity Supervision
Thibault Févry, Livio Baldini Soares, Nicholas FitzGerald, Eunsol Choi and Tom Kwiatkowski

H2KGAT: Hierarchical Hyperbolic Knowledge Graph Attention Network
Shen Wang, Xiaokai Wei, Cicero Nogueira dos Santos, Zhiguo Wang, Ramesh Nallapati, Andrew Arnold, Bing Xiang and Philip S. Yu

Does the Objective Matter? Comparing Training Objectives for Pronoun Resolution
Yordan Yordanov, Oana-Maria Camburu, Vid Kocijan and Thomas Lukasiewicz

On Losses for Modern Language Models
Stéphane Aroca-Ouellette and Frank Rudzicz

We Can Detect Your Bias: Predicting the Political Ideology of News Articles
Ramy Baly, Giovanni Da San Martino, James Glass and Preslav Nakov

Semantic Label Smoothing for Sequence to Sequence Problems
Michal Lukasik, Himanshu Jain, Aditya Menon, Seungyeon Kim, Srinadh Bhojanapalli, Felix Yu and Sanjiv Kumar

Training for Gibbs Sampling on Conditional Random Fields with Neural Scoring Factors
Sida Gao and Matthew R. Gormley

Multilevel Text Alignment with Cross-Document Attention
Xuhui Zhou, Nikolaos Pappas and Noah A. Smith

14:00–16:00 *Gather Session 3iv: Dialog and Interactive Systems; Language Generation; Phonology, Morphology and Word Segmentation*

Conversational Semantic Parsing
Armen Aghajanyan, Jean Maillard, Akshat Shrivastava, Keith Diedrick, Michael Haeger, Haoran Li, Yashar Mehdad, Veselin Stoyanov, Anuj Kumar, Mike Lewis and Sonal Gupta

Probing Task-Oriented Dialogue Representation from Language Models
Chien-Sheng Wu and Caiming Xiong

End-to-End Slot Alignment and Recognition for Cross-Lingual NLU
Weijia Xu, Batool Haider and Saab Mansour

Discriminative Nearest Neighbor Few-Shot Intent Detection by Transferring Natural Language Inference
Jianguo Zhang, Kazuma Hashimoto, Wenhao Liu, Chien-Sheng Wu, Yao Wan, Philip Yu, Richard Socher and Caiming Xiong

Simple Data Augmentation with the Mask Token Improves Domain Adaptation for Dialog Act Tagging
Semih Yavuz, Kazuma Hashimoto, Wenhao Liu, Nitish Shirish Keskar, Richard Socher and Caiming Xiong

Low-Resource Domain Adaptation for Compositional Task-Oriented Semantic Parsing
Xilun Chen, Asish Ghoshal, Yashar Mehdad, Luke Zettlemoyer and Sonal Gupta

Sound Natural: Content Rephrasing in Dialog Systems
Arash Einolghozati, Anchit Gupta, Keith Diedrick and Sonal Gupta

Zero-Shot Crosslingual Sentence Simplification
Jonathan Mallinson, Rico Sennrich and Mirella Lapata

Facilitating the Communication of Politeness through Fine-Grained Paraphrasing
Liye Fu, Susan Fussell and Cristian Danescu-Niculescu-Mizil

CAT-Gen: Improving Robustness in NLP Models via Controlled Adversarial Text Generation
Tianlu Wang, Xuezhi Wang, Yao Qin, Ben Packer, Kang Li, Jilin Chen, Alex Beutel and Ed Chi

Seq2Edits: Sequence Transduction Using Span-level Edit Operations
Felix Stahlberg and Shankar Kumar

Controllable Meaning Representation to Text Generation: Linearization and Data Augmentation Strategies
Chris Kedzie and Kathleen McKeown

Blank Language Models
Tianxiao Shen, Victor Quach, Regina Barzilay and Tommi Jaakkola

COD3S: Diverse Generation with Discrete Semantic Signatures
Nathaniel Weir, João Sedoc and Benjamin Van Durme

Automatic Extraction of Rules Governing Morphological Agreement
Aditi Chaudhary, Antonios Anastasopoulos, Adithya Pratapa, David R. Mortensen, Zaid Sheikh, Yulia Tsvetkov and Graham Neubig

Tackling the Low-resource Challenge for Canonical Segmentation
Manuel Mager, Özlem Çetinoğlu and Katharina Kann

IGT2P: From Interlinear Glossed Texts to Paradigms
Sarah Moeller, Ling Liu, Changbing Yang, Katharina Kann and Mans Hulden

14:00–16:00 *Gather Session 3v: Computational Social Science and Social Media; Information Extraction; Question Answering*

A Computational Approach to Understanding Empathy Expressed in Text-Based Mental Health Support
Ashish Sharma, Adam Miner, David Atkins and Tim Althoff

Modeling Protagonist Emotions for Emotion-Aware Storytelling
Faeze Brahman and Snigdha Chaturvedi

Help! Need Advice on Identifying Advice
Venkata Subrahmanyan Govindarajan, Benjamin Chen, Rebecca Warholic, Katrin Erk and Junyi Jessy Li

Quantifying Intimacy in Language
Jiaxin Pei and David Jurgens

Writing Strategies for Science Communication: Data and Computational Analysis
Tal August, Lauren Kim, Katharina Reinecke and Noah A. Smith

Weakly Supervised Subevent Knowledge Acquisition
Wenlin Yao, Zeyu Dai, Maitreyi Ramaswamy, Bonan Min and Ruihong Huang

Biomedical Event Extraction as Sequence Labeling
Alan Ramponi, Rob van der Goot, Rosario Lombardo and Barbara Plank

Annotating Temporal Dependency Graphs via Crowdsourcing
Jiarui Yao, Haoling Qiu, Bonan Min and Nianwen Xue

Introducing a New Dataset for Event Detection in Cybersecurity Texts
Hieu Man Duc Trong, Duc Trong Le, Amir Pouran Ben Veyseh, Thuat Nguyen and Thien Huu Nguyen

CHARM: Inferring Personal Attributes from Conversations
Anna Tigunova, Andrew Yates, Paramita Mirza and Gerhard Weikum

Event Detection: Gate Diversity and Syntactic Importance Scores for Graph Convolution Neural Networks
Viet Dac Lai, Tuan Ngo Nguyen and Thien Huu Nguyen

Severing the Edge Between Before and After: Neural Architectures for Temporal Ordering of Events
Miguel Ballesteros, Rishita Anubhai, Shuai Wang, Nima Pourdamghani, Yogarshi Vyas, Jie Ma, Parminder Bhatia, Kathleen McKeown and Yaser Al-Onaizan

How Much Knowledge Can You Pack Into the Parameters of a Language Model?
Adam Roberts, Colin Raffel and Noam Shazeer

EXAMS: A Multi-subject High School Examinations Dataset for Cross-lingual and Multilingual Question Answering
Momchil Hardalov, Todor Mihaylov, Dimitrina Zlatkova, Yoan Dinkov, Ivan Koychev and Preslav Nakov

End-to-End Synthetic Data Generation for Domain Adaptation of Question Answering Systems
Siamak Shakeri, Cicero Nogueira dos Santos, Henghui Zhu, Patrick Ng, Feng Nan, Zhiguo Wang, Ramesh Nallapati and Bing Xiang

Multi-Stage Pre-training for Low-Resource Domain Adaptation
Rong Zhang, Revanth Gangi Reddy, Md Arafat Sultan, Vittorio Castelli, Anthony Ferritto, Radu Florian, Efsun Sarioglu Kayi, Salim Roukos, Avi Sil and Todd Ward

ISAAQ - Mastering Textbook Questions with Pre-trained Transformers and Bottom-Up and Top-Down Attention
Jose Manuel Gomez-Perez and Raúl Ortega

SubjQA: A Dataset for Subjectivity and Review Comprehension
Johannes Bjerva, Nikita Bhutani, Behzad Golshan, Wang-Chiew Tan and Isabelle Augenstein

19:00–20:00 *Keynote II: Rich Caruana*

20:00–21:00 *Zoom Q&A Session 9*

20:00–21:00 *Zoom Q&A Session 9i: Speech and Multimodality*

Widget Captioning: Generating Natural Language Description for Mobile User Interface Elements
Yang Li, Gang Li, Luheng He, Jingjie Zheng, Hong Li and Zhiwei Guan

Unsupervised Natural Language Inference via Decoupled Multimodal Contrastive Learning
Wanyun Cui, Guangyu Zheng and Wei Wang

Digital Voicing of Silent Speech
David Gaddy and Dan Klein

20:00–21:00 *Zoom Q&A Session 9ii: Machine Learning for NLP*

Imitation Attacks and Defenses for Black-box Machine Translation Systems
Eric Wallace, Mitchell Stern and Dawn Song

Sequence-Level Mixed Sample Data Augmentation
Demi Guo, Yoon Kim and Alexander Rush

Consistency of a Recurrent Language Model With Respect to Incomplete Decoding
Sean Welleck, Ilia Kulikov, Jaedeok Kim, Richard Yuanzhe Pang and Kyunghyun Cho

An Exploration of Arbitrary-Order Sequence Labeling via Energy-Based Inference Networks
Lifu Tu, Tianyu Liu and Kevin Gimpel

Ensemble Distillation for Structured Prediction: Calibrated, Accurate, Fast—Choose Three
Steven Reich, David Mueller and Nicholas Andrews

20:00–21:00 *Zoom Q&A Session 9iii: Sentiment Analysis, Stylistic Analysis, and Argument Mining*

Inducing Target-Specific Latent Structures for Aspect Sentiment Classification
Chenhua Chen, Zhiyang Teng and Yue Zhang

Affective Event Classification with Discourse-enhanced Self-training
Yuan Zhuang, Tianyu Jiang and Ellen Riloff

Deep Weighted MaxSAT for Aspect-based Opinion Extraction
Meixi Wu, Wenya Wang and Sinno Jialin Pan

Multi-view Story Characterization from Movie Plot Synopses and Reviews
Sudipta Kar, Gustavo Aguilar, Mirella Lapata and Thamar Solorio

21:00–22:00 *Zoom Q&A Session 10*

21:00–22:00 *Zoom Q&A Session 10i: Phonology, Morphology and Word Segmentation*

Mind Your Inflections! Improving NLP for Non-Standard Englishes with Base-Inflection Encoding
Samson Tan, Shafiq Joty, Lav Varshney and Min-Yen Kan

Measuring the Similarity of Grammatical Gender Systems by Comparing Partitions
Arya D. McCarthy, Adina Williams, Shijia Liu, David Yarowsky and Ryan Cotterell

RethinkCWS: Is Chinese Word Segmentation a Solved Task?
Jinlan Fu, Pengfei Liu, Qi Zhang and Xuanjing Huang

Learning to Pronounce Chinese Without a Pronunciation Dictionary
Christopher Chu, Scot Fang and Kevin Knight

21:00–22:00 *Zoom Q&A Session 10ii: Information Extraction*

Dynamic Anticipation and Completion for Multi-Hop Reasoning over Sparse Knowledge Graph
Xin Lv, Xu Han, Lei Hou, Juanzi Li, Zhiyuan Liu, Wei Zhang, YICHI ZHANG, Hao Kong and Suhui Wu

Knowledge Association with Hyperbolic Knowledge Graph Embeddings
Zequn Sun, Muhao Chen, Wei Hu, Chengming Wang, Jian Dai and Wei Zhang

Domain Knowledge Empowered Structured Neural Net for End-to-End Event Temporal Relation Extraction
Rujun Han, Yichao Zhou and Nanyun Peng

Tuesday, November 17, 2020 (continued)

TeMP: Temporal Message Passing for Temporal Knowledge Graph Completion
Jiapeng Wu, Meng Cao, Jackie Chi Kit Cheung and William L. Hamilton

21:00–22:00 *Zoom Q&A Session 10iii: Machine Translation and Multilinguality*

Understanding the Difficulty of Training Transformers
Liyuan Liu, Xiaodong Liu, Jianfeng Gao, Weizhu Chen and Jiawei Han

An Empirical Study of Generation Order for Machine Translation
William Chan, Mitchell Stern, Jamie Kiros and Jakob Uszkoreit

Inference Strategies for Machine Translation with Conditional Masking
Julia Kreutzer, George Foster and Colin Cherry

21:00–22:00 *Zoom Q&A Session 10iv: Question Answering*

AmbigQA: Answering Ambiguous Open-domain Questions
Sewon Min, Julian Michael, Hannaneh Hajishirzi and Luke Zettlemoyer

Tell Me How to Ask Again: Question Data Augmentation with Controllable Rewriting in Continuous Space
Dayiheng Liu, Yeyun Gong, Jie Fu, Yu Yan, Jiusheng Chen, Jiancheng Lv, Nan Duan and Ming Zhou

Training Question Answering Models From Synthetic Data
Raul Puri, Ryan Spring, Mohammad Shoeybi, Mostofa Patwary and Bryan Catanzaro

Few-Shot Complex Knowledge Base Question Answering via Meta Reinforcement Learning
Yuncheng Hua, Yuan-Fang Li, Gholamreza Haffari, Guilin Qi and Tongtong Wu

22:00–00:00 *Gather Session 4i: Computational Social Science and Social Media; Machine Translation and Multilinguality; Syntax: Tagging, Chunking, and Parsing*

Multilingual Offensive Language Identification with Cross-lingual Embeddings
Tharindu Ranasinghe and Marcos Zampieri

Solving Historical Dictionary Codes with a Neural Language Model
Christopher Chu, Raphael Valenti and Kevin Knight

Toward Micro-Dialect Identification in Diaglossic and Code-Switched Environments
Muhammad Abdul-Mageed, Chiyu Zhang, AbdelRahim Elmadany and Lyle Ungar

Investigating African-American Vernacular English in Transformer-Based Text Generation
Sophie Groenwold, Lily Ou, Aesha Parekh, Samhita Honnavalli, Sharon Levy, Diba Mirza and William Yang Wang

Iterative Domain-Repaired Back-Translation
Hao-Ran Wei, Zhirui Zhang, Boxing Chen and Weihua Luo

Dynamic Data Selection and Weighting for Iterative Back-Translation
Zi-Yi Dou, Antonios Anastasopoulos and Graham Neubig

Revisiting Modularized Multilingual NMT to Meet Industrial Demands
Sungwon Lyu, Bokyung Son, Kichang Yang and Jaekyoung Bae

LAReQA: Language-Agnostic Answer Retrieval from a Multilingual Pool
Uma Roy, Noah Constant, Rami Al-Rfou, Aditya Barua, Aaron Phillips and Yinfei Yang

OCR Post Correction for Endangered Language Texts
Shruti Rijhwani, Antonios Anastasopoulos and Graham Neubig

X-FACTR: Multilingual Factual Knowledge Retrieval from Pretrained Language Models
Zhengbao Jiang, Antonios Anastasopoulos, Jun Araki, Haibo Ding and Graham Neubig

CCAligned: A Massive Collection of Cross-Lingual Web-Document Pairs
Ahmed El-Kishky, Vishrav Chaudhary, Francisco Guzmán and Philipp Koehn

Localizing Open-Ontology QA Semantic Parsers in a Day Using Machine Translation
Mehrad Moradshahi, Giovanni Campagna, Sina Semnani, Silei Xu and Monica Lam

Interactive Refinement of Cross-Lingual Word Embeddings
Michelle Yuan, Mozhi Zhang, Benjamin Van Durme, Leah Findlater and Jordan Boyd-Graber

Exploiting Sentence Order in Document Alignment
Brian Thompson and Philipp Koehn

XGLUE: A New Benchmark Datasetfor Cross-lingual Pre-training, Understanding and Generation
Yaobo Liang, Nan Duan, Yeyun Gong, Ning Wu, Fenfei Guo, Weizhen Qi, Ming Gong, Linjun Shou, Daxin Jiang, Guihong Cao, Xiaodong Fan, Ruofei Zhang, Rahul Agrawal, Edward Cui, Sining Wei, Taroon Bharti, Ying Qiao, Jiun-Hung Chen, Winnie Wu, Shuguang Liu, Fan Yang, Daniel Campos, Rangan Majumder and Ming Zhou

AIN: Fast and Accurate Sequence Labeling with Approximate Inference Network
Xinyu Wang, Yong Jiang, Nguyen Bach, Tao Wang, Zhongqiang Huang, Fei Huang and Kewei Tu

HIT: Nested Named Entity Recognition via Head-Tail Pair and Token Interaction
Yu Wang, Yun Li, Hanghang Tong and Ziye Zhu

Supertagging Combinatory Categorial Grammar with Attentive Graph Convolutional Networks
Yuanhe Tian, Yan Song and Fei Xia

DAGA: Data Augmentation with a Generation Approach forLow-resource Tagging Tasks
BOSHENG DING, Linlin Liu, Lidong Bing, Canasai Kruengkrai, Thien Hai Nguyen, Shafiq Joty, Luo Si and Chunyan Miao

Interpretable Multi-dataset Evaluation for Named Entity Recognition
Jinlan Fu, Pengfei Liu and Graham Neubig

Adversarial Semantic Decoupling for Recognizing Open-Vocabulary Slots
Yuanmeng Yan, Keqing He, Hong Xu, Sihong Liu, Fanyu Meng, Min Hu and Weiran XU

22:00–00:00 *Gather Session 4ii: Machine Learning for NLP; Semantics: Lexical Semantics; Summarization*

Plug and Play Autoencoders for Conditional Text Generation
Florian Mai, Nikolaos Pappas, Ivan Montero, Noah A. Smith and James Henderson

Structure Aware Negative Sampling in Knowledge Graphs
Kian Ahrabian, Aarash Feizi, Yasmin Salehi, William L. Hamilton and Avishek Joey Bose

Neural Mask Generator: Learning to Generate Adaptive Word Maskings for Language Model Adaptation
Minki Kang, Moonsu Han and Sung Ju Hwang

Autoregressive Knowledge Distillation through Imitation Learning
Alexander Lin, Jeremy Wohlwend, Howard Chen and Tao Lei

T3: Tree-Autoencoder Constrained Adversarial Text Generation for Targeted Attack
Boxin Wang, Hengzhi Pei, Boyuan Pan, Qian Chen, Shuohang Wang and Bo Li

Structured Pruning of Large Language Models
Ziheng Wang, Jeremy Wohlwend and Tao Lei

Effective Unsupervised Domain Adaptation with Adversarially Trained Language Models
Thuy-Trang Vu, Dinh Phung and Gholamreza Haffari

BAE: BERT-based Adversarial Examples for Text Classification
Siddhant Garg and Goutham Ramakrishnan

Adversarial Self-Supervised Data-Free Distillation for Text Classification
Xinyin Ma, Yongliang Shen, Gongfan Fang, Chen Chen, Chenghao Jia and Weiming Lu

BERT-ATTACK: Adversarial Attack Against BERT Using BERT
Linyang Li, Ruotian Ma, Qipeng Guo, Xiangyang Xue and Xipeng Qiu

The Thieves on Sesame Street are Polyglots - Extracting Multilingual Models from Monolingual APIs
Nitish Shirish Keskar, Bryan McCann, Caiming Xiong and Richard Socher

When Hearst Is not Enough: Improving Hypernymy Detection from Corpus with Distributional Models
Changlong Yu, Jialong Han, Peifeng Wang, Yangqiu Song, Hongming Zhang, Wilfred Ng and Shuming Shi

Interpreting Open-Domain Modifiers: Decomposition of Wikipedia Categories into Disambiguated Property-Value Pairs
Marius Pasca

A Synset Relation-enhanced Framework with a Try-again Mechanism for Word Sense Disambiguation
Ming Wang and Yinglin Wang

Diverse, Controllable, and Keyphrase-Aware: A Corpus and Method for News Multi-Headline Generation
Dayiheng Liu, Yeyun Gong, Yu Yan, Jie Fu, Bo Shao, Daxin Jiang, Jiancheng Lv and Nan Duan

Factual Error Correction for Abstractive Summarization Models
Meng Cao, Yue Dong, Jiapeng Wu and Jackie Chi Kit Cheung

Compressive Summarization with Plausibility and Salience Modeling
Shrey Desai, Jiacheng Xu and Greg Durrett

Understanding Neural Abstractive Summarization Models via Uncertainty
Jiacheng Xu, Shrey Desai and Greg Durrett

Better Highlighting: Creating Sub-Sentence Summary Highlights
Sangwoo Cho, Kaiqiang Song, Chen Li, Dong Yu, Hassan Foroosh and Fei Liu

Summarizing Text on Any Aspects: A Knowledge-Informed Weakly-Supervised Approach
Bowen Tan, Lianhui Qin, Eric Xing and Zhiting Hu

22:00–00:00 *Gather Session 4iii: Discourse and Pragmatics; Information Extraction; Language Generation*

BERT-enhanced Relational Sentence Ordering Network
Baiyun Cui, Yingming Li and Zhongfei Zhang

Online Conversation Disentanglement with Pointer Networks
Tao Yu and Shafiq Joty

VCDM: Leveraging Variational Bi-encoding and Deep Contextualized Word Representations for Improved Definition Modeling
Machel Reid, Edison Marrese-Taylor and Yutaka Matsuo

Coarse-to-Fine Pre-training for Named Entity Recognition
Xue Mengge, Bowen Yu, Zhenyu Zhang, Tingwen Liu, Yue Zhang and Bin Wang

Exploring and Evaluating Attributes, Values, and Structures for Entity Alignment
Zhiyuan Liu, Yixin Cao, Liangming Pan, Juanzi Li, Zhiyuan Liu and Tat-Seng Chua

Simple and Effective Few-Shot Named Entity Recognition with Structured Nearest Neighbor Learning
Yi Yang and Arzoo Katiyar

Learning Structured Representations of Entity Names using ActiveLearning and Weak Supervision
Kun Qian, Poornima Chozhiyath Raman, Yunyao Li and Lucian Popa

Entity Enhanced BERT Pre-training for Chinese NER
Chen Jia, Yuefeng Shi, Qinrong Yang and Yue Zhang

Scalable Zero-shot Entity Linking with Dense Entity Retrieval
Ledell Wu, Fabio Petroni, Martin Josifoski, Sebastian Riedel and Luke Zettlemoyer

A Dataset for Tracking Entities in Open Domain Procedural Text
Niket Tandon, Keisuke Sakaguchi, Bhavana Dalvi, Dheeraj Rajagopal, Peter Clark, Michal Guerquin, Kyle Richardson and Eduard Hovy

Design Challenges in Low-resource Cross-lingual Entity Linking
Xingyu Fu, Weijia Shi, Xiaodong Yu, Zian Zhao and Dan Roth

Efficient One-Pass End-to-End Entity Linking for Questions
Belinda Z. Li, Sewon Min, Srinivasan Iyer, Yashar Mehdad and Wen-tau Yih

LUKE: Deep Contextualized Entity Representations with Entity-aware Self-attention
Ikuya Yamada, Akari Asai, Hiroyuki Shindo, Hideaki Takeda and Yuji Matsumoto

Generating similes effortlessly like a Pro: A Style Transfer Approach for Simile Generation
Tuhin Chakrabarty, Smaranda Muresan and Nanyun Peng

STORIUM: A Dataset and Evaluation Platform for Machine-in-the-Loop Story Generation
Nader Akoury, Shufan Wang, Josh Whiting, Stephen Hood, Nanyun Peng and Mohit Iyyer

Substance over Style: Document-Level Targeted Content Transfer
Allison Hegel, Sudha Rao, Asli Celikyilmaz and Bill Dolan

Template Guided Text Generation for Task-Oriented Dialogue
Mihir Kale and Abhinav Rastogi

MOCHA: A Dataset for Training and Evaluating Generative Reading Comprehension Metrics
Anthony Chen, Gabriel Stanovsky, Sameer Singh and Matt Gardner

Plan ahead: Self-Supervised Text Planning for Paragraph Completion Task
Dongyeop Kang and Eduard Hovy

Inquisitive Question Generation for High Level Text Comprehension
Wei-Jen Ko, TE-YUAN CHEN, Yiyan Huang, Greg Durrett and Junyi Jessy Li

22:00–00:00 *Gather Session 4iv: Dialog and Interactive Systems; NLP Applications; Question Answering*

Towards Persona-Based Empathetic Conversational Models
Peixiang Zhong, Chen Zhang, Hao Wang, Yong Liu and Chunyan Miao

Personal Information Leakage Detection in Conversations
Qiongkai Xu, Lizhen Qu, Zeyu Gao and Gholamreza Haffari

Response Selection for Multi-Party Conversations with Dynamic Topic Tracking
Weishi Wang, Steven C.H. Hoi and Shafiq Joty

Regularizing Dialogue Generation by Imitating Implicit Scenarios
Shaoxiong Feng, Xuancheng Ren, Hongshen Chen, Bin Sun, Kan Li and Xu SUN

MovieChats: Chat like Humans in a Closed Domain
Hui Su, Xiaoyu Shen, Zhou Xiao, Zheng Zhang, Ernie Chang, Cheng Zhang, Cheng Niu and Jie Zhou

Conundrums in Entity Coreference Resolution: Making Sense of the State of the Art
Jing Lu and Vincent Ng

Semantic Role Labeling Guided Multi-turn Dialogue ReWriter
Kun Xu, Haochen Tan, Linfeng Song, Han Wu, Haisong Zhang, Linqi Song and Dong Yu

Continuity of Topic, Interaction, and Query: Learning to Quote in Online Conversations
Lingzhi Wang, Jing Li, Xingshan Zeng, Haisong Zhang and Kam-Fai Wong

Profile Consistency Identification for Open-domain Dialogue Agents
Haoyu Song, Yan Wang, Wei-Nan Zhang, Zhengyu Zhao, Ting Liu and Xiaojiang Liu

An Element-aware Multi-representation Model for Law Article Prediction
Huilin Zhong, Junsheng Zhou, Weiguang QU, Yunfei Long and Yanhui Gu

Recurrent Event Network: Autoregressive Structure Inferenceover Temporal Knowledge Graphs
Woojeong Jin, Meng Qu, Xisen Jin and Xiang Ren

Multi-resolution Annotations for Emoji Prediction
Weicheng Ma, Ruibo Liu, Lili Wang and Soroush Vosoughi

Less is More: Attention Supervision with Counterfactuals for Text Classification
Seungtaek Choi, Haeju Park, Jinyoung Yeo and Seung-won Hwang

MODE-LSTM: A Parameter-efficient Recurrent Network with Multi-Scale for Sentence Classification
Qianli Ma, Zhenxi Lin, Jiangyue Yan, Zipeng Chen and Liuhong Yu

HSCNN: A Hybrid-Siamese Convolutional Neural Network for Extremely Imbalanced Multi-label Text Classification
Wenshuo Yang, Jiyi Li, Fumiyo Fukumoto and Yanming Ye

Multi-Stage Pre-training for Automated Chinese Essay Scoring
Wei Song, Kai Zhang, Ruiji Fu, Lizhen Liu, Ting Liu and Miaomiao Cheng

Multi-hop Inference for Question-driven Summarization
Yang Deng, Wenxuan Zhang and Wai Lam

Towards Interpretable Reasoning over Paragraph Effects in Situation
Mucheng Ren, Xiubo Geng, Tao QIN, Heyan Huang and Daxin Jiang

Question Directed Graph Attention Network for Numerical Reasoning over Text
Kunlong Chen, Weidi Xu, Xingyi Cheng, Zou Xiaochuan, Yuyu Zhang, Le Song, Taifeng Wang, Yuan Qi and Wei Chu

Dense Passage Retrieval for Open-Domain Question Answering
Vladimir Karpukhin, Barlas Oguz, Sewon Min, Patrick Lewis, Ledell Wu, Sergey Edunov, Danqi Chen and Wen-tau Yih

Distilling Structured Knowledge for Text-Based Relational Reasoning
Jin Dong, Marc-Antoine Rondeau and William L. Hamilton

22:00–00:00 *Gather Session 4v: Interpretability and Analysis of Models for NLP; Semantics: Sentence-level Semantics, Textual Inference and Other areas; Sentiment Analysis, Stylistic Analysis, and Argument Mining*

Asking without Telling: Exploring Latent Ontologies in Contextual Representations
Julian Michael, Jan A. Botha and Ian Tenney

Pretrained Language Model Embryology: The Birth of ALBERT
Cheng-Han Chiang, Sung-Feng Huang and Hung-yi Lee

Learning Music Helps You Read: Using Transfer to Study Linguistic Structure in Language Models
Isabel Papadimitriou and Dan Jurafsky

What Do Position Embeddings Learn? An Empirical Study of Pre-Trained Language Model Positional Encoding
Yu-An Wang and Yun-Nung Chen

“You are grounded!”: Latent Name Artifacts in Pre-trained Language Models
Vered Shwartz, Rachel Rudinger and Oyvind Tafjord

Birds have four legs?! NumerSense: Probing Numerical Commonsense Knowledge of Pre-Trained Language Models
Bill Yuchen Lin, Seyeon Lee, Rahul Khanna and Xiang Ren

Grounded Adaptation for Zero-shot Executable Semantic Parsing
Victor Zhong, Mike Lewis, Sida I. Wang and Luke Zettlemoyer

An Imitation Game for Learning Semantic Parsers from User Interaction
Ziyu Yao, Yiqi Tang, Wen-tau Yih, Huan Sun and Yu Su

IGSQL: Database Schema Interaction Graph Based Neural Model for Context-Dependent Text-to-SQL Generation
Yitao Cai and Xiaojun Wan

"What Do You Mean by That?" A Parser-Independent Interactive Approach for Enhancing Text-to-SQL
Yuntao Li, Bei Chen, Qian Liu, Yan Gao, Jian-Guang LOU, Yan Zhang and Dongmei Zhang

DuSQL: A Large-Scale and Pragmatic Chinese Text-to-SQL Dataset
Lijie Wang, Ao Zhang, Kun Wu, Ke Sun, Zhenghua Li, Hua Wu, Min Zhang and Haifeng Wang

Mention Extraction and Linking for SQL Query Generation
Jianqiang Ma, ZEYU YAN, Shuai Pang, Yang Zhang and Jianping Shen

Re-examining the Role of Schema Linking in Text-to-SQL
Wenqiang Lei, Weixin Wang, Zhixin MA, Tian Gan, Wei Lu, Min-Yen Kan and Tat-Seng Chua

A Multi-Task Incremental Learning Framework with Category Name Embedding for Aspect-Category Sentiment Analysis
Zehui Dai, Cheng Peng, Huajie Chen and Yadong Ding

Train No Evil: Selective Masking for Task-Guided Pre-Training
Yuxian Gu, Zhengyan Zhang, Xiaozhi Wang, Zhiyuan Liu and Maosong Sun

SentiLARE: Sentiment-Aware Language Representation Learning with Linguistic Knowledge
Pei Ke, Haozhe Ji, Siyang Liu, Xiaoyan Zhu and Minlie Huang

Weakly-Supervised Aspect-Based Sentiment Analysis via Joint Aspect-Sentiment Topic Embedding
Jiaxin Huang, Yu Meng, Fang Guo, Heng Ji and Jiawei Han

APE: Argument Pair Extraction from Peer Review and Rebuttal via Multi-task Learning
Liying Cheng, Lidong Bing, Qian Yu, Wei Lu and Luo Si

Diversified Multiple Instance Learning for Document-Level Multi-Aspect Sentiment Classification
Yunjie Ji, Hao Liu, Bolei He, Xinyan Xiao, Hua Wu and Yanhua Yu

Identifying Exaggerated Language
Li Kong, Chuanyi Li, Jidong Ge, Bin Luo and Vincent Ng

Unified Feature and Instance Based Domain Adaptation for Aspect-Based Sentiment Analysis
Chenggong Gong, Jianfei Yu and Rui Xia

Wednesday, November 18, 2020

04:00–05:00 *Zoom Q&A Session 11*

04:00–05:00 *Zoom Q&A Session 11i: Interpretability and Analysis of Models for NLP*

Compositional and Lexical Semantics in RoBERTa, BERT and DistilBERT: A Case Study on CoQA
Ieva Staliūnaitė and Ignacio Iacobacci

Attention is Not Only a Weight: Analyzing Transformers with Vector Norms
Goro Kobayashi, Tatsuki Kuribayashi, Sho Yokoi and Kentaro Inui

F1 is Not Enough! Models and Evaluation Towards User-Centered Explainable Question Answering
Hendrik Schuff, Heike Adel and Ngoc Thang Vu

On the Ability and Limitations of Transformers to Recognize Formal Languages
Satwik Bhattamishra, Kabir Ahuja and Navin Goyal

04:00–05:00 *Zoom Q&A Session 11ii: NLP Applications*

An Unsupervised Joint System for Text Generation from Knowledge Graphs and Semantic Parsing
Martin Schmitt, Sahand Sharifzadeh, Volker Tresp and Hinrich Schütze

DGST: a Dual-Generator Network for Text Style Transfer
Xiao Li, Guanyi Chen, Chenghua Lin and Ruizhe Li

A Knowledge-Aware Sequence-to-Tree Network for Math Word Problem Solving
Qinzhuo Wu, Qi Zhang, Jinlan Fu and Xuanjing Huang

Generating Fact Checking Briefs
Angela Fan, Aleksandra Piktus, Fabio Petroni, Guillaume Wenzek, Marzieh Saeidi, Andreas Vlachos, Antoine Bordes and Sebastian Riedel

Improving the Efficiency of Grammatical Error Correction with Erroneous Span Detection and Correction
Mengyun Chen, Tao Ge, Xingxing Zhang, Furu Wei and Ming Zhou

04:00–05:00 *Zoom Q&A Session 11iii: Question Answering*

Coreferential Reasoning Learning for Language Representation
Deming Ye, Yankai Lin, Jiaju Du, Zhenghao Liu, Peng Li, Maosong Sun and Zhiyuan Liu

Is Graph Structure Necessary for Multi-hop Question Answering?
Nan Shao, Yiming Cui, Ting Liu, Shijin Wang and Guoping Hu

04:00–05:00 *Zoom Q&A Session 11iv: Semantics: Lexical Semantics*

XL-WiC: A Multilingual Benchmark for Evaluating Semantic Contextualization
Alessandro Raganato, Tommaso Pasini, Jose Camacho-Collados and Mohammad Taher Pilehvar

Generationary or "How We Went beyond Word Sense Inventories and Learned to Gloss”
Michele Bevilacqua, Marco Maru and Roberto Navigli

Probing Pretrained Language Models for Lexical Semantics
Ivan Vulić, Edoardo Maria Ponti, Robert Litschko, Goran Glavaš and Anna Korhonen

05:00–06:00 *Zoom Q&A Session 12*

05:00–06:00 *Zoom Q&A Session 12i: Dialog and Interactive Systems*

Cross-lingual Spoken Language Understanding with Regularized Representation Alignment
Zihan Liu, Genta Indra Winata, Peng Xu, Zhaojiang Lin and Pascale Fung

SLURP: A Spoken Language Understanding Resource Package
Emanuele Bastianelli, Andrea Vanzo, Pawel Swietojanski and Verena Rieser

Neural Conversational QA: Learning to Reason vs Exploiting Patterns
Nikhil Verma, Abhishek Sharma, Dhiraj Madan, Danish Contractor, Harshit Kumar and Sachindra Joshi

05:00–06:00 *Zoom Q&A Session 12ii: Information Extraction*

Counterfactual Generator: A Weakly-Supervised Method for Named Entity Recognition
Xiangji Zeng, Yunliang Li, Yuchen Zhai and Yin Zhang

Understanding Procedural Text using Interactive Entity Networks
Jizhi Tang, Yansong Feng and Dongyan Zhao

A Rigorous Study on Named Entity Recognition: Can Fine-tuning Pretrained Model Lead to the Promised Land?
Hongyu Lin, Yaojie Lu, Jialong Tang, Xianpei Han, Le Sun, Zhicheng Wei and Nicholas Jing Yuan

05:00–06:00 *Zoom Q&A Session 12iii: Machine Learning for NLP*

DyERNIE: Dynamic Evolution of Riemannian Manifold Embeddings for Temporal Knowledge Graph Completion
Zhen Han, Peng Chen, Yunpu Ma and Volker Tresp

Embedding Words in Non-Vector Space with Unsupervised Graph Learning
Max Ryabinin, Sergei Popov, Liudmila Prokhorenkova and Elena Voita

Debiasing knowledge graph embeddings
Joseph Fisher, Arpit Mittal, Dave Palfrey and Christos Christodoulopoulos

Message Passing for Hyper-Relational Knowledge Graphs
Mikhail Galkin, Priyansh Trivedi, Gaurav Maheshwari, Ricardo Usbeck and Jens Lehmann

05:00–06:00 *Zoom Q&A Session 12iv: Sentiment Analysis, Stylistic Analysis, and Argument Mining*

Relation-aware Graph Attention Networks with Relational Position Encodings for Emotion Recognition in Conversations
Taichi Ishiwatari, Yuki Yasuda, Taro Miyazaki and Jun Goto

BERT Knows Punta Cana is not just beautiful, it's gorgeous: Ranking Scalar Adjectives with Contextualised Representations
Aina Garí Soler and Marianna Apidianaki

Feature Adaptation of Pre-Trained Language Models across Languages and Domains with Robust Self-Training
Hai Ye, Qingyu Tan, Ruidan He, Juntao Li, Hwee Tou Ng and Lidong Bing

Textual Data Augmentation for Efficient Active Learning on Tiny Datasets
Husam Quteineh, Spyridon Samothrakis and Richard Sutcliffe

11:00–12:00 *Keynote III: Janet B. Pierrehumbert*

12:00–13:00 *Zoom Q&A Session 13*

12:00–13:00 *Zoom Q&A Session 13i: Discourse and Pragmatics*

"I'd rather just go to bed": Understanding Indirect Answers
Annie Louis, Dan Roth and Filip Radlinski

PowerTransformer: Unsupervised Controllable Revision for Biased Language Correction
Xinyao Ma, Maarten Sap, Hannah Rashkin and Yejin Choi

MEGA RST Discourse Treebanks with Structure and Nuclearity from Scalable Distant Sentiment Supervision
Patrick Huber and Giuseppe Carenini

Centering-based Neural Coherence Modeling with Hierarchical Discourse Segments
Sungho Jeon and Michael Strube

Keeping Up Appearances: Computational Modeling of Face Acts in Persuasion Oriented Discussions
Ritam Dutt, Rishabh Joshi and Carolyn Rose

12:00–13:00 *Zoom Q&A Session 13ii: NLP Applications*

HABERTOR: An Efficient and Effective Deep Hatespeech Detector
Thanh Tran, Yifan Hu, Changwei Hu, Kevin Yen, Fei Tan, Kyumin Lee and Se Rim Park

An Empirical Study on Large-Scale Multi-Label Text Classification Including Few and Zero-Shot Labels
Ilias Chalkidis, Manos Fergadiotis, Sotiris Kotitsas, Prodromos Malakasiotis, Nikolaos Aletras and Ion Androutsopoulos

*Which *BERT? A Survey Organizing Contextualized Encoders*
Patrick Xia, Shijie Wu and Benjamin Van Durme

Fact or Fiction: Verifying Scientific Claims
David Wadden, Shanchuan Lin, Kyle Lo, Lucy Lu Wang, Madeleine van Zuylen, Arman Cohan and Hannaneh Hajishirzi

12:00–13:00 *Zoom Q&A Session 13iii: Semantics: Sentence-level Semantics, Textual Inference and Other areas*

Semantic Role Labeling as Syntactic Dependency Parsing
Tianze Shi, Igor Malioutov and Ozan Irsoy

PARADE: A New Dataset for Paraphrase Identification Requiring Computer Science Domain Knowledge
Yun He, Zhuoer Wang, Yin Zhang, Ruihong Huang and James Caverlee

Causal Inference of Script Knowledge
Noah Weber, Rachel Rudinger and Benjamin Van Durme

Towards Debiasing NLU Models from Unknown Biases
Prasetya Ajie Utama, Nafise Sadat Moosavi and Iryna Gurevych

12:00–13:00 *Zoom Q&A Session 13iv: Syntax: Tagging, Chunking, and Parsing*

On the Role of Supervision in Unsupervised Constituency Parsing
Haoyue Shi, Karen Livescu and Kevin Gimpel

13:00–14:00 *Zoom Q&A Session 14*

13:00–14:00 *Zoom Q&A Session 14i: Machine Translation and Multilinguality*

Language Model Prior for Low-Resource Neural Machine Translation
Christos Baziotis, Barry Haddow and Alexandra Birch

Detecting Word Sense Disambiguation Biases in Machine Translation for Model-Agnostic Adversarial Attacks
Denis Emelin, Ivan Titov and Rico Sennrich

MAD-X: An Adapter-Based Framework for Multi-Task Cross-Lingual Transfer

Detecting Attackable Sentences in Arguments

Yohan Jo[1] **Seojin Bang**[1] **Emaad Manzoor**[2] **Eduard Hovy**[1] **Chris Reed**[3]

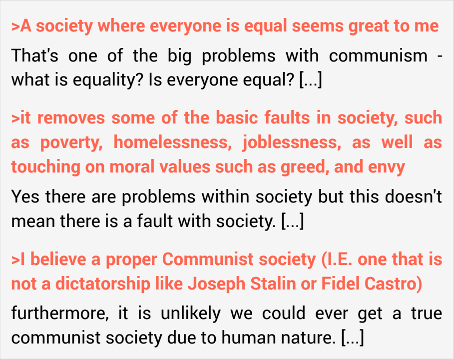
`c.a.reed@dundee.ac.uk`

Abstract

Finding attackable sentences in an argument is the first step toward successful refutation in argumentation. We present a first large-scale analysis of sentence attackability in online arguments. We analyze driving reasons for attacks in argumentation and identify relevant characteristics of sentences. We demonstrate that a sentence's attackability is associated with many of these characteristics regarding the sentence's content, proposition types, and tone, and that an external knowledge source can provide useful information about attackability. Building on these findings, we demonstrate that machine learning models can automatically detect attackable sentences in arguments, significantly better than several baselines and comparably well to laypeople.[1]

1 Introduction

Effectively refuting an argument is an important skill in persuasion dialogue, and the first step is to find appropriate points to attack in the argument. Prior work in NLP has studied argument quality (Wachsmuth et al., 2017a; Habernal and Gurevych, 2016a) and counterargument generation (Hua et al., 2019; Wachsmuth et al., 2018). But these studies mainly concern an argument's overall quality and making counterarguments toward the main claim, without investigating what parts of an argument are attackable for successful persuasion. Nevertheless, attacking specific points of an argument is common and effective; in our data of online discussions, challengers who successfully change the original poster's view are 1.5 times more likely to quote specific sentences of the argument for attacks than unsuccessful challengers (Figure 1). In this paper, we examine how to computationally detect attackable sentences in arguments. This attackability information would help people make persuasive refutations and strengthen an argument by solidifying potentially attackable points.



>A society where everyone is equal seems great to me

That's one of the big problems with communism - what is equality? Is everyone equal? [...]

>it removes some of the basic faults in society, such as poverty, homelessness, joblessness, as well as touching on moral values such as greed, and envy

Yes there are problems within society but this doesn't mean there is a fault with society. [...]

>I believe a proper Communist society (I.E. one that is not a dictatorship like Joseph Stalin or Fidel Castro)

furthermore, it is unlikely we could ever get a true communist society due to human nature. [...]

Figure 1: A comment to a post entitled "I believe that Communism is not as bad as everyone says". It quotes and attacks some sentences in the post (red with ">")

To examine the characteristics of attackable sentences in an argument, we first conduct a qualitative analysis of reasons for attacks in online arguments. Our data comes from discussions in the ChangeMyView (CMV) forum on Reddit. In CMV, users challenge the viewpoints of original posters (OPs), and those who succeed receive a Δ from the OPs. In this setting, sentences that are attacked and lead to the OP's view change are considered "attackable", i.e., targets that are worth attacking. Admittedly, persuasion has to do with "how" to attack as well, but this is beyond the scope of this paper. We only focus on choosing proper sentences to attack, which is a prerequisite for effective persuasion.

This analysis of reasons for attacks, along with argumentation theory and discourse studies, provide insights into what characteristics of sentences are relevant to attackability. Informed by these insights, we extract features that represent relevant sentence characteristics, clustered into four categories: content, external knowledge, proposition

---

[1] Our data and source code are available at: `github.com/yohanjo/emnlp20_arg_attack`

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1–23,
November 16–20, 2020. ©2020 Association for Computational Linguistics

types, and tone. We demonstrate the effects of individual features on sentence attackability, in regard to whether a sentence would be *attacked* and whether a sentence would be attacked *successfully*.

Building on these findings, we examine the efficacy of machine learning models in detecting attackable sentences in arguments. We demonstrate that their decisions match the gold standard significantly better than several baselines and comparably well to laypeople.

To the best of our knowledge, this work is the first large-scale analysis of sentence attackability in arguments. Our contributions are as follows:

- We introduce the problem of detecting attackable sentences in arguments and release the processed data from online discussions and the external knowledge source we used.
- We analyze driving reasons for attacks in arguments and the effects of sentence characteristics on a sentence's attackability.
- We demonstrate the performance of machine learning models for detecting attackable sentences, setting a baseline for this challenging task and suggesting future directions.

2 Background

The strength of an argument is a long-studied topic, dating back to Aristotle (2007), who suggested three aspects of argument persuasiveness: ethos (the arguer's credibility), logos (logic), and pathos (appeal to the hearer's emotion). More recently, Wachsmuth et al. (2017b) summarized various aspects of argument quality studied in argumentation theory and NLP, such as clarity, relevance, and arrangement. Some research took empirical approaches and collected argument evaluation criteria from human evaluators (Habernal and Gurevych, 2016a; Wachsmuth et al., 2017a). By adopting some of these aspects, computational models have been proposed to automatically evaluate argument quality in various settings, such as essays (Ke et al., 2019), online comments (Gu et al., 2018), and pairwise ranking (Habernal and Gurevych, 2016b). While these taxonomies help understand and evaluate the quality of an argument as a whole, little empirical analysis has been done in terms of what to attack in an argument to persuade the arguer.

What can be attacked in an argument has been studied more in argumentation theory. Particularly, Walton et al. (2008) present argumentation schemes and critical questions (CQs). Argument schemes are reasoning types commonly used in daily argumentation. For instance, the scheme of *argument from cause to effect* has the conclusion "*B* will occur" supported by the premise "if *A* occurs, *B* will occur. In this case, A occurs". Each scheme is associated with a set of CQs for judging the argument to be good or fallacious. CQs for the above scheme include "How strong is the causal generalization?" and "Are there other factors that interfere with the causal effect?" Unlike the general argument quality described in the previous paragraph, CQs serve as an evaluation tool that specify local attackable points in an argument. They have been adopted for grading essays (Song et al., 2017) and teaching argumentation skills (Nussbaum et al., 2018). Some of the sentence characteristics in our work are informed by argumentation schemes and CQs.

NLP researchers have widely studied the effectiveness of counterarguments on persuasion (Tan et al., 2016; Cano-Basave and He, 2016; Wei et al., 2016; Wang et al., 2017; Morio et al., 2019) and how to generate counterarguments (Hua et al., 2019; Wachsmuth et al., 2018). Most of the work focuses on the characteristics of counterarguments with respect to topics and styles, without consideration of what points to attack. On the other hand, some studies aimed to model the salience of individual sentences in attacked arguments by paying different degrees of attention to sentences using attention mechanism (Jo et al., 2018; Ji et al., 2018). While their approaches helped to predict the success of persuasion, it was difficult to interpret what constitute the salience or attackability of sentences. To address this limitation, we quantify and analyze the characteristics of sentences that are attacked and lead to the arguer's view change.

3 Data

Here we describe how we collected and labeled our data.

3.1 Data Collection

We use online discussions from the ChangeMyView (CMV) subreddit[2]. In this forum, users post their views on various issues and invite other users to challenge their views. If a comment changes the original poster (OP)'s view, the OP acknowledges it by replying to the comment with a Δ symbol. The high quality of the discussions in this forum is maintained through several mod-

---

[2] `https://www.reddit.com/r/changemyview`

eration rules, such as the minimum length of an original post and the maximum response time of OPs. As a result, CMV discussions have been used in many NLP studies (Chakrabarty et al., 2019; Morio et al., 2019; Jo et al., 2018; Musi, 2017; Wei et al., 2016; Tan et al., 2016).

We scraped CMV posts and comments written between January 1, 2014 and September 30, 2019, using the Pushshift API. We split them into a dev set (Jan 2014–Jan 2018 for training and Feb 2018–Nov 2018 for validation) and a test set (Dec 2018–Sep 2019), with the ratio of 6:2:2. We split the data by time to measure our models' generality to unseen subjects.

As the characteristics of arguments vary across different issues, we categorized the posts into domains using LDA. For each post, we chose as its domain the topic that has the highest standard score; topics comprising common words were excluded. We tried different numbers of topics (25, 30, 35, 40) and finalized on 40, as it achieves the lowest perplexity. This process resulted in 30 domains (excluding common-word topics): media, abortion, sex, election, Reddit, human economy, gender, race, family, life, crime, relationship, movie, world, game, tax, law, money, drug, war, religion, job, food, power, school, college, music, gun, and Jewish (from most frequent to least, ranging 5%–2%).

3.2 Labeling Attackability

Since we are interested in which parts of a post are attacked by comments and whether the attacks lead to successful view changes, our goal here is to label each sentence in a post as *successfully attacked*, *unsuccessfully attacked*, or *unattacked*. We only consider comments directly replying to each post (top-level comments), as lower-level comments usually address the same points as their parent comments (as will be validated at the end of the section).

Attacked vs. Unattacked: Some comments use direct quotes with the > symbol to address specific sentences of the post (Figure 1). Each quote is matched with the longest sequence of sentences in the post using the Levenshtein edit distance (allowing a distance of 2 characters for typos). A matched text span should contain at least one word and four characters, and cover at least 80% of the quote to exclude cases where the > symbol is used to quote external content. As a result, 98% of the matched spans cover the corresponding quotes entirely. Additionally, a sentence in the post is considered to be quoted if at least four non-stopwords appear in a comment's sentence. For example:

> Post: ... *If you do something, you should be prepared to accept the consequences. ...*
>
> Comment: ... *I guess my point is, even if you do believe that "**If you do something, you should be prepared to accept the consequences**," you can still feel bad for the victims. ...*

We considered manually annotating attacked sentences too, but it turned out to be extremely time-consuming and subjective (Appendix A). We tried to automate it using heuristics (word overlap and vector embeddings), but precision severely deteriorated. As we value the precision of labels over recall, we only use the method described in the previous paragraph. Chakrabarty et al. (2019) used the same method to collect attack relations in CMV.

Successfully vs. Unsuccessfully Attacked: After each sentence in a post is labeled as attacked or not, each attacked sentence is further labeled as *successfully attacked* if any of the comments that attack it, or their lower-level comments win a Δ.

We post-process the resulting labels to increase their validity. First, as a challenger and the OP have discussion down the comment thread, the challenger might attack different sentences than the originally attacked ones and change the OP's view. In this case, it is ambiguous which sentences contribute to the view change. Hence, we extract quotes from all lower-level comments of Δ-winning challengers, and if any of the quotes attack new sentences, this challenger's attacks are excluded from the labeling of *successfully attacked*. This case is not common, however (0.2%).

Second, if a comment attacks many sentences in the post and change the OP's view, some of them may not contribute to the view change but are still labeled as *successfully attacked*. To reduce this noise, comments that have more than three quotes are excluded from the labeling of *successfully attacked*[3]. This amounts to 12% of top-level comments (63% of comments have only one quote, 17% two quotes, and 8% three quotes).

Lastly, we verified if quoted sentences are actually attacked. We randomly selected 500 comments and checked if each quoted sentence is purely agreed with without any opposition, challenge, or question. This case was rare (0.4%)[4], so we do

---

[3] This allows our subsequent analyses to capture stronger signals for successful attacks than without this process.

[4] Further, this case happened in only one out of the 500 comments (0.2%), where the author agreed with 4 quoted sentences. In CMV, challengers do use concessions but hardly

Dataset		Train	Val	Test

not further process this case. Table 1 shows some statistics of the final data.

4 Quantifying Sentence Characteristics

As the first step for analyzing the characteristics of attackable sentences, we examine driving reasons for attacks and quantify relevant characteristics.

4.1 Rationales and Motivation for Attacks

To analyze rationales for attacks, two authors examined quotes and rebuttals in the training data (one successful and one unsuccessful comment for each post). From 156 attacks, we identified 10 main rationales (Table 2a), which are finer-grained than the refutation reasons in prior work (Wei et al., 2016). The most common rationale is that the sentence is factually correct but is irrelevant to the main claim (19%). Counterexample-related rationales are also common: the sentence misses an example suggesting the opposite judgment to the sentence's own (18%) and the sentence has exceptions (17%).

This analysis is based on polished rebuttals, which mostly emphasize logical aspects, and cannot fully capture other factors that motivate attacks. Hence, we conducted a complementary analysis, where an undergraduate student chose three sentences to attack for each of 50 posts and specified the reasons in their own terms (Table 2b). The most common factor is that the sentence is only a personal opinion (28%). Invalid hypotheticals are also a common factor (26%). The tone of a sentence motivates attacks as well, such as generalization (13%), absoluteness (7%), and concession (5%).

4.2 Feature Extraction

Based on these analyses, we cluster various sentence characteristics into four categories—content, external knowledge, proposition types, and tone.[5]

4.2.1 Content

Content and logic play the most important role in CMV discussions. We extract the content of each sentence at two levels: TFIDF-weighted **n-grams** ($n = 1, 2, 3$) and sentence-level **topics**. Each sentence is assigned one topic using Sentence LDA (Jo and Oh, 2011). We train a model on posts in the training set and apply it to all posts, exploring the number of topics $\in \{10, 50, 100\}$.[6]

4.2.2 External Knowledge

External knowledge sources may provide information as to how truthful or convincing a sentence is (e.g., Table 2a-R2, R3, R4, R7 and Table 2b-F4). As our knowledge source, we use kialo.com—a collaborative argument platform over more than 1.4K issues. Each issue has a main statement, and users can respond to any existing statement with pro/con statements (1-2 sentences), building an argumentation tree. Kialo has advantages over structured knowledge bases and Wikipedia in that it includes many debatable statements; many attacked sentences are subjective judgments (§4.1), so fact-based knowledge sources may have limited utility. In addition, each statement in Kialo has pro/con counts, which may reflect the convincingness of the statement. We scraped 1,417 argumentation trees and 130K statements (written until Oct 2019).

---

quote the OP's sentences just to agree.

[5] Some rationales in Table 2a (e.g., R1 and R9) are difficult to operationalize reliably using the current NLP technology and thus are not included in our features.

[6] We also tried features based on semantic frames using SLING (Ringgaard et al., 2017), but they were not helpful.

For each sentence in CMV, we retrieve similar statements in Kialo that have at least 5 common words[7] and compute the following three features. **Frequency** is the number of retrieved statements; sentences that are not suitable for argumentation are unlikely to appear in Kialo. This feature is computed as $\log_2(N+1)$, where N is the number of retrieved statements. **Attractiveness** is the average number of responses for the matched statements, reflecting how debatable the sentence is. It is computed as $\log_2(M+1)$, where $M = \frac{1}{N}\sum_{i=1}^{N} R_i$ and R_i is the number of responses for the ith retrieved statement. Lastly, **extremeness** is $\frac{1}{N}\sum_{i=1}^{N} |P_i - N_i|$, where P_i and N_i are the proportions (between 0 and 1) of pro responses and con responses for the ith retrieved statement. A sentence that most people would see flawed would have a high extremeness value.

4.2.3 Proposition Types

Sentences convey different types of propositions, such as predictions and hypotheticals. No proposition types are fallacious by nature, but some of them may make it harder to generate a sound argument. They also communicate different moods, causing the hearer to react differently. We extract 13 binary features for proposition types. They are all based on lexicons and regular expressions, which are available in Appendix C.

Questions express the intent of information seeking. Depending on the form, we define three features: **confusion** (e.g., *I don't understand*), **why/how** (e.g., *why ...?*), and **other**.

Normative sentences suggest that an action be carried out. Due to their imperative mood, they can sound face-threatening and thus attract attacks.

Prediction sentences predict a future event. They can be attacked with reasons why the prediction is unlikely (Table 2a-R6), as in critical questions for *argument from cause to effect* (Walton et al., 2008).

Hypothetical sentences may make implausible assumptions (Table 2a-R8 and Table 2b-F2) or restrict the applicability of the argument too much (Table 2b-F7).

Citation often strengthens a claim using authority, but the credibility of the source could be attacked (Walton et al., 2008).

Comparison may reflect personal preferences that are vulnerable to attacks (Table 2b-F1).

Examples in a sentence may be attacked for their invalidity (Walton et al., 2008) or counterexamples (Table 2a-R3).

Definitions form a ground for arguments, and challengers could undermine an argument by attacking this basis (e.g., Table 2a-R5).

Personal stories are the arguer's experiences, whose validity is difficult to refute. A sentence with a personal story has subject *I* and a non-epistemic verb; or it has *my* modifying non-epistemic nouns.

Inclusive sentences that mention ***you*** and ***we*** engage the hearer into the discourse (Hyland, 2005), making the argument more vulnerable to attacks.

4.2.4 Tone

Challengers are influenced by the tone of an argument, e.g., subjectiveness, absoluteness, or confidence (Table 2b). We extract 8 features for the tone of sentences.

Subjectivity comprises judgments, which are often attacked due to counterexamples (Table 2a-R2) or their arbitrariness (Table 2b-F1, Walton et al. (2008)). The subjectivity of a sentence is the average subjectivity score of words based on the Subjectivity Lexicon (Wilson et al., 2005) (non-neutral words of "weaksubj" = 0.5 and "strongsubj" = 1).

Concreteness is the inverse of abstract diction, whose meaning depends on subjective perceptions and experiences. The concreteness of a sentence is the sum of the standardized word scores based on Brysbaert et al. (2014)'s concreteness lexicon.

Qualification expresses the level of generality of a claim, where absolute statements can motivate attacks (Table 2b-R3). The qualification score of a sentence is the average word score based on our lexicon of qualifiers and generality words.

Hedging can sound unconvincing (Durik et al., 2008) and motivate attacks. A sentence's hedging score is the sum of word scores based on our lexicon of downtoners and boosters.

Sentiment represents the valence of a sentence. Polar judgments may attract more attacks than neutral statements. We calculate the sentiment of each sentence with BERT (Devlin et al., 2018) trained on the data of SemEval 2017 Task 4 (Rosenthal et al., 2017). **Sentiment score** is a continuous value ranging between -1 (negative) and +1 (positive), and **sentiment categories** are nominal (positive, neutral, and negative)[8]. In addition, we compute the

---

[7] Similarity measures based on word embeddings and knowledge representation did not help (Appendix B).

[8] We achieved an average recall of 0.705, which is higher than the winner team's performance of 0.681.

scores of **arousal** (intensity) and **dominance** (control) as the sum of the standardized word scores based on Warriner et al. (2013)'s lexicon.

5 Task 1: Attackability Characteristics

One of our goals in this paper is to analyze what characteristics of sentences are associated with a sentence's attackability. Hence, in this section, we measure the effect size and statistical significance of each feature toward two labels: (i) whether a sentence is attacked or not, using the dev set of the "Attacked" dataset (N=553,635), (ii) whether a sentence is attacked successfully or unsuccessfully, using all attacked sentences (N=159,417).[9] Since the effects of characteristics may depend on the issue being discussed, the effect of each feature is estimated conditioned on the domain of each post using a logistic regression, and the statistical significance of the effect is assessed using the Wald test. For interpretation purposes, we use *odds ratio* (OR)—the exponent of the effect size.[10]

5.1 Content

Attacked sentences tend to mention big issues like gender, race, and health as revealed in topics 47, 8, and 6 (Table 3) and n-grams *life*, *weapons*, *women*, *society*, and *men* (Table 7 in Appendix E). These issues are also positively correlated with successful attacks. On the other hand, mentioning relatively personal issues (*tv*, *friends*, topic 38) seems negatively correlated with successful attacks. So do forum-specific messages (*cmv*, *thank*, topic 4).

Attacking seemingly evidenced sentences appears to be effective for persuasion when properly done. Successfully attacked sentences are likely to mention specific data (*data*, *%*) and be the OP's specific reasons under bullet points (*2.* and *3.*).

n-grams capture various characteristics that are vulnerable to attacks, such as uncertainty and absoluteness (*i believe*, *never*), hypotheticals (*if i*), questions (*?*, *why*), and norms (*should*).

5.2 External Knowledge

The Kialo-based knowledge features provide significant information about whether a sentence would be attacked successfully (Table 3). As the frequency of matched statements in Kialo increases twice, the odds for successful attack increase by 7%. As an example, the following attacked sentence has 18 matched statements in Kialo.

> *I feel like it is a parents right and responsibility to make important decisions for their child.*

The attractiveness feature has a stronger effect; as matched statements have twice more responses, the odds for successful attack increase by 18%, probably due to higher debatability.

A sentence being completely extreme (i.e., the matched sentences have only pro or con responses) increases the odds for successful attack by 19%.

As expected, the argumentative nature of Kialo

---

[9] Simply measuring the predictive power of features in a prediction setting provides an incomplete picture of the roles of the characteristics. Some features may not have drastic contribution to prediction due to their infrequency, although they may have significant effects on attackability.

[10] Odds are the ratio of the probability of a sentence being (successfully) attacked to the probability of being not (successfully) attacked; OR is the ratio of odds when the value of the characteristic increases by one unit (Appendix D).

allows its statements to match many subjective sentences in CMV and serves as an effective information source for a sentence's attackability.

5.3 Proposition Types

Questions, especially why/how, are effective targets for successful attack (Table 3). Although challengers do not pay special attention to expressions of confusion (see column "Attacked"), they are positively correlated with successful attack (OR=1.29).

Citations are often used to back up an argument and have a low chance of being attacked, reducing the odds by half. However, properly attacking citations significantly increases the odds for successful attack by 17%. Similarly, personal stories have a low chance of being attacked and definitions do not attract challengers' attacks, but attacking them is found to be effective for successful persuasion.

All other features for proposition types have significantly positive effects on being attacked (OR=1.18–1.29), but only normative and example sentences are correlated with successful attack.

5.4 Tone

Successfully attacked sentences tend to have lower subjectivity and arousal (Table 3), in line with the previous observation that they are more data- and reference-based than unsuccessfully attacked sentences. In contrast, sentences about concrete concepts are found to be less attackable.

Uncertainty (high hedging) and absoluteness (low qualification) both increase the chance of attacks, which aligns with the motivating factors for attacks (Table 2b), while only hedges are positively correlated with successful attacks, implying the importance of addressing the arguer's uncertainty.

Negative sentences with high arousal and dominance have a high chance of being attacked, but most of these characteristics have either no or negative effects on successful attacks.

5.5 Discussion

We have found some evidence that, somewhat counter-intuitively, seemingly evidenced sentences are more effective to attack. Such sentences use specific data (*data*, %), citations, and definitions. Although attacking these sentences may require even stronger evidence and deeper knowledge, arguers seem to change their viewpoints when a fact they believe with evidence is undermined. In addition, it seems very important and effective to identify and address what the arguer is confused (confusion) or uncertain (hedges) about.

Our analysis also reveals some discrepancies between the characteristics of sentences that challengers commonly think are attackable and those that are indeed attackable. Challengers are often attracted to subjective and negative sentences with high arousal, but successfully attacked sentences have rather lower subjectivity and arousal, and have no difference in negativity compared to unsuccessfully attacked sentences. Furthermore, challengers pay less attention to personal stories, while successful attacks address personal stories more often.

6 Task 2: Attackability Prediction

Now we examine how well computational models can detect attackable sentences in arguments.

6.1 Problem Formulation

This task is cast as ranking sentences in each post by their attackability scores predicted by a regression model. We consider two types of attackability: (i) whether a sentence will be attacked or not, (ii) whether a sentence will be successfully attacked or not (attacked unsuccessfully + unattacked). For both settings, we consider posts that have at least one sentence with the positive label (Table 1).

We use three evaluation metrics. **P@1** is the precision of the first ranked sentence, measuring the model's accuracy when choosing one sentence to attack for each post. Less strictly, **A@3** gives a score of 1 if any of the top 3 sentences is a positive instance and 0 otherwise. **AUC** measures individual sentence-level accuracy—how likely positive sentences are assigned higher probabilities.

6.2 Comparison Models

For machine learning models, we explore two logistic regression models to compute the probability of the positive label for each sentence, which becomes the sentence's *attackability score*. **LR** is a basic logistic regression with our features[11] (Section 4) and binary variables for domains. We explored feature selection using L1-norm and regularization using L2-norm.[12] **BERT** is logistic regression where our features are replaced with the BERT embedding of the input sentence (Devlin et al., 2018). Contextualized BERT embeddings have achieved

---

[11] We tried the number of topics $\in \{10, 50, 100\}$, and 50 has the best AUC on the val set for both prediction settings.

[12] We also tried a multilayer perceptron to model feature interactions, but it consistently performed worse than LR.

	Attacked			Successful		
	P@1	A@3	AUC	P@1	A@3	AUC
Random	35.9	66.0	50.1	18.9	45.0	50.1
Length	42.9	73.7	54.5	22.3	52.1	55.7
LR	47.1	76.2	61.7	24.2	54.5	59.3
(×) Content	45.2	74.4	58.1	24.0	52.6	57.0
(×) Knowledge	47.0	76.0	61.7	24.1	54.3	59.0
(×) Prop Type	46.7	75.9	61.5	24.4	53.6	59.0
(×) Tone	47.0	76.0	61.9	25.2	56.2	59.4
BERT	49.6	77.8	64.4	28.3	57.2	62.0
Humans†	51.7	80.1	–	27.8	54.2	–

Table 4: Prediction accuracy. All LR/BERT scores (rows 3–8) have standard deviations between 0.1 and 1.1, significantly outperforming "Length". †The average bootstrap accuracy after resampling 100K times with sample size 200—the standard deviations of P@1 and A@3 range between 2.1 and 3.5.

state-of-the-art performance in many NLP tasks. We use the pretrained, uncased base model from Hugging Face (Wolf et al., 2019) and fine-tune it during training.[13]

We explore two baseline models. **Random** is to rank sentences randomly. **Length** is to rank sentences from longest to shortest, with the intuition that longer sentences may contain more information and thus more content to attack as well.

Lastly, we estimate laypeople's performance on this task. Three undergraduate students each read 100 posts and rank three sentences to attack for each post. Posts that have at least one positive instance are randomly selected from the test set.[14]

6.3 Results

All computational models were run 10 times, and their average accuracy is reported in Table 4. Both the LR and BERT models significantly outperform the baselines, while the BERT model performs best. For predicting attacked sentences, the BERT model's top 1 decisions match the gold standard 50% of the time; its decisions match 78% of the time when three sentences are chosen. Predicting successfully attacked sentences is harder, but the performance gap between our models and the baselines gets larger. The BERT model's top 1 decisions match the gold standard 28% of the time—a 27% and 10% boost from random and length-based performance, respectively.

To examine the contribution of each feature category, we did ablation tests based on the best performing LR model (Table 4 rows 4–7). The two prediction settings show similar tendencies. Regarding P@1 for successful attack, content has the highest contribution, followed by knowledge, proposition types, and tone. This result reaffirms the importance of content for a sentence's attackability. But the other features still have significant contribution, yielding higher P@1 and AUC (Table 4 row 4) than the baselines.

It is worth noting that our features, despite the lower accuracy than the BERT model, are clearly informative of attackability prediction as Table 4 row 3 shows. Moreover, since they directly operationalize the sentence characteristics we compiled, it is pretty transparent that they capture relevant information that contributes to sentence attackability and help us better understand what characteristics have positive and negative signals for sentence attackability. We speculate that transformer models like BERT are capable of encoding these characteristics more sophisticatedly and may include some additional information, e.g., lexical patterns, leading to higher accuracy. But at the same time, it is less clear exactly what they capture and whether they capture relevant information or irrelevant statistics, as is often the case in computational argumentation (Niven and Kao, 2019).

Figure 2 illustrates how LR allows us to interpret the contribution of different features to attackability, by visualizing a post with important features highlighted. For instance, external knowledge plays a crucial role in this post; all successfully attacked sentences match substantially more Kialo statements than other sentences. The attackability scores of these sentences are also increased by the use of hypotheticals and certain n-grams like *could*. These features align well with the actual attacks by successful challengers. For instance, they pointed out that the expulsion of Russian diplomats (sentence 2) is not an aggressive reaction because the diplomats can be simply replaced with new ones. Kialo has a discussion on the relationship between the U.S. and Russia, and one statement puts forward exactly the same point that the expulsion was a forceful-looking but indeed a nice gesture. Similarly, a successful challenger pointed out the consistent attitude of the U.S. toward regime change in North Korea (sentence 3), and the North Korean regime is a controversial topic in Kialo. Lastly,

one successful challenger attacked the hypothetical outcomes in sentences 4 and 5, pointing out that those outcomes are not plausible, and the LR model also captures the use of hypothetical and the word *could* as highly indicative of attackability. More successful and erroneous cases are in Appendix H.

Laypeople perform significantly better than the BERT model for predicting attacked sentences, but only comparably well for successfully attacked sentences (Table 4 row 9). Persuasive argumentation in CMV requires substantial domain knowledge, but laypeople do not have such expertise for many domains. The BERT model, however, seems to take advantage of the large data and encodes useful linguistic patterns that are predictive of attackability. A similar tendency has been observed in predicting persuasive refutation (Guo et al., 2020), where a machine-learned model outperformed laypeople. Nevertheless, in our task, the humans and the BERT model seem to make similar decisions; the association between their choices of sentences is high, with odds ratios ranging between 3.43 (top 1) and 3.33 (top 3). Interestingly, the LR model has a low association with the human decisions for top 1 (OR=2.65), but the association exceeds the BERT model for top 3 (OR=3.69). It would be interesting to further examine the similarities and differences in how humans and machines choose sentences to attack.

7 Conclusion

We studied how to detect attackable sentences in arguments for successful persuasion. Using online arguments, we demonstrated that a sentence's attackability is associated with many of its characteristics regarding its content, proposition types, and tone, and that Kialo provides useful information about attackability. Based on these findings we demonstrated that machine learning models can automatically detect attackable sentences, comparably well to laypeople.

Our work contributes a new application to the growing literature on causal inference from text (Egami et al., 2018), in the setting of "text as a treatment". Specifically, our findings in Section 5 pave the way towards answering the causal question: would attacking a certain type of sentence (e.g., questions or expressions of confusion) in an argument increase the probability of persuading the opinion holder? While our findings suggest initial hypotheses about the characteristics of sentences that can be successfully attacked, establishing causality in a credible manner would require addressing confounders, such as the challenger's reputation (Manzoor et al., 2020) and persuasive skill reflected in their attack (Tan et al., 2014). We leave this analysis to future work.

Our work could be improved also by including discourse properties (coherence, cohesiveness). Further, argumentation structure (support relations between sentences or lack thereof) might provide useful information about each sentence's attackability.

Appendices

A Annotating Attacked Sentences

We tried capturing sentences in posts that are addressed by comments but not directly quoted. To see its feasibility, we randomly sampled 100 post-comment pairs that do not contain direct quotes and then asked an undergraduate native speaker of English (who has no knowledge about this work) to mark attacked sentences in each post, if any. This revealed two challenges. First, human annotation is subjective when compared to a co-author's result and very time-consuming (2.5 min/comment). Second, we tried several methods to automatically identify attacked sentences. We compared the similarity between each post sentence with the comment (first sentence of the comment, first sentence of each paragraph, or all comment text) based on word overlap with/without synonym expansion and the GloVe embeddings. But it turned out to be difficult to get similar results to human annotations. Therefore, we decided to use only those sentences that are direct quoted or have at least 4 common words with a comment's sentence as the most reliable labels.

B External Knowledge

In this section, we describe the methods that we explored to use Kialo as a knowledge base but that were not successful.

B.1 UKP Sentence Embedding-Based Retrieval

We measured the similarity between CMV sentences and Kialo statements using the UKP sentence embedding—BERT embeddings fine-tuned to measure argument similarity (Reimers et al., 2019). Specifically, the authors provide pretrained embeddings constructed by appending a final softmax layer to BERT to predict a numerical *dissimilarity* score between 0 and 1 for each sentence pair in the UKP ASPECT corpus. The 3,595 sentence pairs in this corpus were drawn from 28 controversial topics and annotated via crowd workers to be "unrelated" or of "no", "some" or "high" similarity. They report a mean F1-score of 65.39% on a held-out subset of this corpus, which was closest to human performance (F1=78.34%) among all competing methods that were not provided with additional information about the argument topic.

We used this fine-tuned model to measure the dissimilarity between each CMV sentence and Kialo statements. Based on this information, we extracted the feature **UKP Avg Distance 10**, which is the average dissimilarity score of the 10 Kialo statements that are closest to the sentence. This score is expected to be low if a sentence has many similar statements in Kialo. In addition, we extracted the same **frequency**, **attractiveness**, and **extremeness** features as in §4.2.2. Here, we determine whether a CMV sentence and a Kialo statement are "matched" based on several dissimilarity thresholds (0.1, 0.2, 0.3, 0.4); A Kialo statement is considered matched with a CMV sentence if the dissimilarity is below the selected threshold.

B.2 Semantic Frame-Based Knowledge

We extracted semantic frames from CMV sentences and Kialo statements, using Google SLING (Ringgaard et al., 2017). For each frame in a sentence or statement, a "knowledge piece" is defined as the concatenation of the predicate and arguments (except negation); the predicate is lemmatized and the arguments are stemmed to remove differences in verb/noun forms. We also mark each knowledge piece as negated if the frame contains negation. Example knowledge pieces include:

- ARG0:peopl-ARG1:right-ARGM-MOD:should-PRED:have (Negation: true)
- ARG1:person-ARG2:abl-ARGM-MOD:should-PRED:be (Negation: false)

For each CMV sentence, we extracted two features: the count of knowledge pieces in Kialo that are **consistent** with those in the sentence, and the count of knowledge pieces in Kialo that are **conflicting** with those in the sentence. Two knowledge pieces are considered consistent if they are identical, and conflicting if they are identical but negated. Attackable sentences are expected to have many consistent and conflicting knowledge pieces in Kialo. If we assume that most statements in Kialo are truthful, attackable sentences may have more conflicting knowledge pieces than consistent knowledge pieces.

B.3 Word Sequence-Based Knowledge

Treating each frame as a separate knowledge piece does not capture the dependencies between multiple predicates within a sentence. Hence, we tried a simple method to capture this information, where a knowledge pieces is defined as the concatenation of

Knowledge Feature	Attacked	Successful
Word Overlap Frequency (log2)	1.18 (***)	1.07 (***)
Word Overlap Attractiveness (log2)	1.30 (***)	1.18 (***)
Word Overlap Extremeness	1.51 (***)	1.19 (***)
UKP Avg Distance 10‡	0.93 (***)	0.98 (*)
UKP 0.1 Frequency†	1.08 (*)	0.99 ( )
UKP 0.1 Attractiveness†	1.11 (*)	1.08 ( )
UKP 0.1 Extremeness	3.49 (*)	6.77 ( )
UKP 0.2 Frequency†	1.02 (**)	1.01 ( )
UKP 0.2 Attractiveness†	1.05 (***)	1.06 ( )
UKP 0.2 Extremeness	1.69 (***)	1.76 ( )
UKP 0.3 Frequency†	1.04 (***)	1.01 ( )
UKP 0.3 Attractiveness†	1.09 (***)	1.02 ( )
UKP 0.3 Extremeness	2.44 (***)	1.40 ( )
UKP 0.4 Frequency†	1.04 (***)	1.01 (**)
UKP 0.4 Attractiveness†	1.12 (***)	1.01 ( )
UKP 0.4 Extremeness	2.35 (***)	1.02 ( )
Frame Knowledge Consistent	1.28 (***)	1.01 ( )
Frame Knowledge Conflict	1.37 (***)	1.08 ( )
Word Sequence Knowledge Consistent	1.05 ( )	0.98 ( )
Word Sequence Knowledge Conflict	1.18 ( )	1.49 ( )

Table 5: Odds ratio (OR) and statistical significance of features. An effect is positive (blue) if OR > 1 and negative (red) if OR < 1. (†: log2, ‡: standardized / *: $p < 0.05$, **: $p < 0.01$, ***: $p < 0.001$)

verbs, nouns, adjectives, modal, prepositions, subordinating conjunctions, numbers, and existential *there* within a sentence; but independent clauses (e.g., a *because* clause) were separated off. All words were lemmatized. Each knowledge piece is negated if the source text has negation words. Example knowledge pieces include:

- gender-be-social-construct (Negation: true)
- congress-shall-make-law-respect-establishment-of-religion-prohibit-free-exercise (Negation: false)

For each CMV sentence, we extracted the same two features as in semantic frame-based knowledge pieces: the count of knowledge pieces in Kialo that are **consistent** with those in the sentence, and the count of knowledge pieces in Kialo that are **conflicting** with those in the sentence.

B.4 Effects and Statistical Significance

The effects and statistical significance of the above features were estimated in the same way as §5 and are shown in Table 5. Word sequence-based knowledge has no effect, probably because not many knowledge pieces are matched. Most of the other features have significant effects only for “Attacked”. We speculate that a difficulty comes from the fact that both vector embedding-based matching and frame-based matching are inaccurate in many cases. UKP sentence embeddings often retrieve Kialo statements that are only topically related to a CMV sentence. Similarly, frame-based knowledge pieces often cannot capture complex information conveyed in a CMV sentence. In contrast, word overlap-based matching seems to be more reliable and better retrieve Kialo statements that have similar content to a CMV sentence.

C Lexicons

Table 6 shows the lexicons and regular expressions used in feature extraction. `r"pattern"` represents a regular expression.

</table>

Table 6: Lexicons and regular expressions used in feature extraction.

D Statistical Model for Feature Effects

For each feature, we use the following logistic regression model:

$$\log \frac{\mathbb{P}(\mathbf{Y}=1)}{1-\mathbb{P}(\mathbf{Y}=1)} = \beta_0 + \beta_X \mathbf{X} + \alpha_1 \mathbf{D}_1 + \cdots + \alpha_{|D|} \mathbf{D}_{|D|},$$

where $\mathbf{X}$ is a continuous or binary explanatory variable that takes the value of a characteristic that we are interested in. $\mathbf{D}_d$ ($d = 1, \cdots, |D|$) is a binary variable that takes 1 if the sentence belongs to the d-th domain. $\mathbf{Y}$ is a binary response variable that takes 1 if the sentence is attacked or if the sentence is attacked successfully. β_X is the regression coefficient of the characteristic $\mathbf{X}$, which is the main value of our interest for examining the association between the characteristic and the response; $\exp(\beta_X)$ is the *odds ratio* (OR) that is interpreted as the change of odds (i.e., the ratio of the probability that a sentence is (successfully) attacked to the probability that a sentence is not (successfully) attacked) when the value of the characteristic increases by one unit. If β_X is significant, we can infer that $\mathbf{X}$ has an effect on $\mathbf{Y}$. If β_X is positive (and significant), we can infer that the characteristic and the response have positive association, and vice versa.

E Important n-gram Features

Table 7 shows the top 100 n-grams that have the highest or lowest weights for attacked sentences (vs. unattacked sentences) and for successfully attacked sentences (vs. unsuccessfully attacked).

	Attacked (vs. Unattacked)	Attacked Successfully (vs. Unsuccessfully)

Table 9: Prediction accuracy.

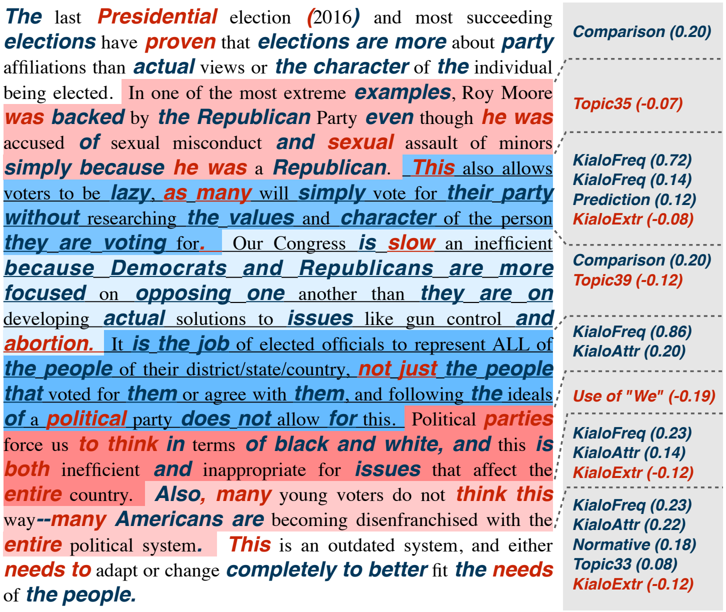
H Visualization Examples

For the successful example in Figure 3a, the model finds evidence for the successfully attacked sentences 3 and 5 from the external knowledge source (Kialo). Although some of the other sentences (7–8) also match Kialo statements, the degree of match is relatively low, and the model determines that their n-grams reduce attackability (*many*, *think*, *needs*). Sentence 4 is properly found to have high attackability, since it makes a comparison and contains many n-grams predictive of attackability (*because*, *Democrats*, *Republicans*, *opposing*).

For the successful example in Figure 3b, topics play important roles for determining attackability. The topics of the successfully attacked sentences 2–4 all increase attackability, whereas the topics of other sentences 5–9 reduce attackability.

For the erroneous example in Figure 4a, all sentences have relatively little evidence for attackability/unattackability. The model determines sentence 5 to have relatively high attackability because of many n-grams that increase attackability (*know*, *absolutely*, *nothing*). On the other hand, the successfully attacked sentence 6 is assigned a low attackability score despite its match with Kialo statements, because its use of *we*, personal stories, and certain n-grams (*many*, *times*, and *friends*).

For the erroneous example in Figure 4b, the model finds sentence 4 to have high attackability because it matches with Kialo statements, makes a comparison and prediction, and certain n-grams (*believe*, *presence*, *society*, *market*). Sentence 5 is also assigned a relatively high attackability score due to its use of examples and certain n-grams (*know*, *committed*, *weapons*). However, these sentences were not successfully attacked. In contrast, the successfully attacked sentences 2–4 do not have strong enough evidence for attackability compared to their negatively signals, such as personal stories and n-grams *own* and *I*.



The last Presidential election (2016) and most succeeding elections have proven that elections are more about party affiliations than actual views or the character of the individual being elected. In one of the most extreme examples, Roy Moore was backed by the Republican Party even though he was accused of sexual misconduct and sexual assault of minors simply because he was a Republican. This also allows voters to be lazy, as many will simply vote for their party without researching the values and character of the person they are voting for. Our Congress is slow an inefficient because Democrats and Republicans are more focused on opposing one another than they are on developing actual solutions to issues like gun control and abortion. It is the job of elected officials to represent ALL of the people of their district/state/country, not just the people that voted for them or agree with them, and following the ideals of a political party does not allow for this. Political parties force us to think in terms of black and white, and this is both inefficient and inappropriate for issues that affect the entire country. Also, many young voters do not think this way--many Americans are becoming disenfranchised with the entire political system. This is an outdated system, and either needs to adapt or change completely to better fit the needs of the people.

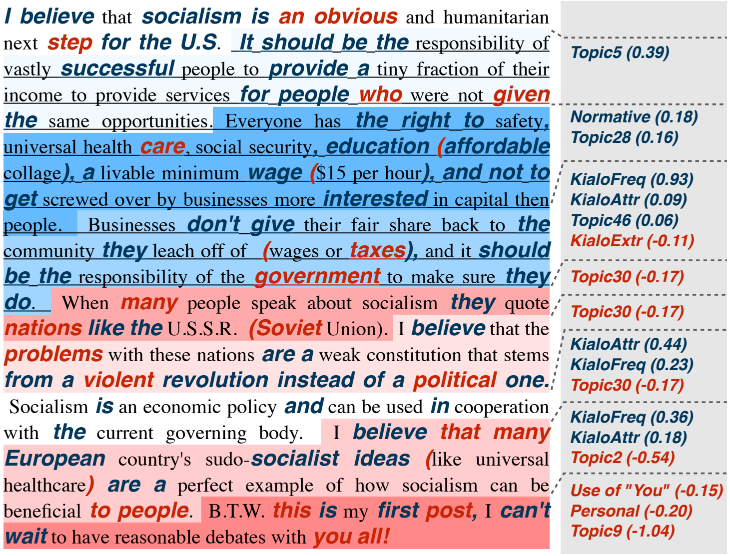
(a) Successful example 2.



I believe that socialism is an obvious and humanitarian next step for the U.S. It should be the responsibility of vastly successful people to provide a tiny fraction of their income to provide services for people who were not given the same opportunities. Everyone has the right to safety, universal health care, social security, education (affordable collage), a livable minimum wage ($15 per hour), and not to get screwed over by businesses more interested in capital then people. Businesses don't give their fair share back to the community they leach off of (wages or taxes), and it should be the responsibility of the government to make sure they do. When many people speak about socialism they quote nations like the U.S.S.R. (Soviet Union). I believe that the problems with these nations are a weak constitution that stems from a violent revolution instead of a political one. Socialism is an economic policy and can be used in cooperation with the current governing body. I believe that many European country's sudo-socialist ideas (like universal healthcare) are a perfect example of how socialism can be beneficial to people. B.T.W. this is my first post, I can't wait to have reasonable debates with you all!

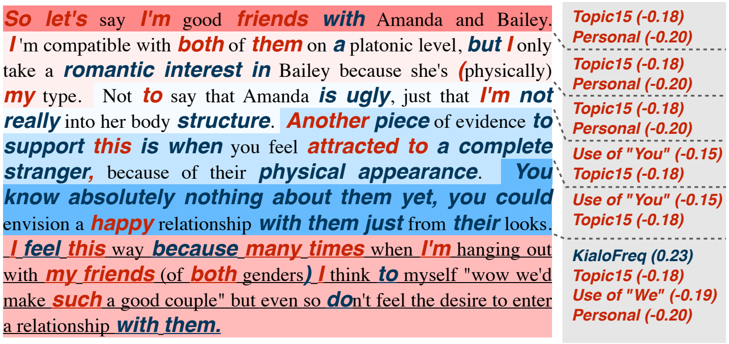
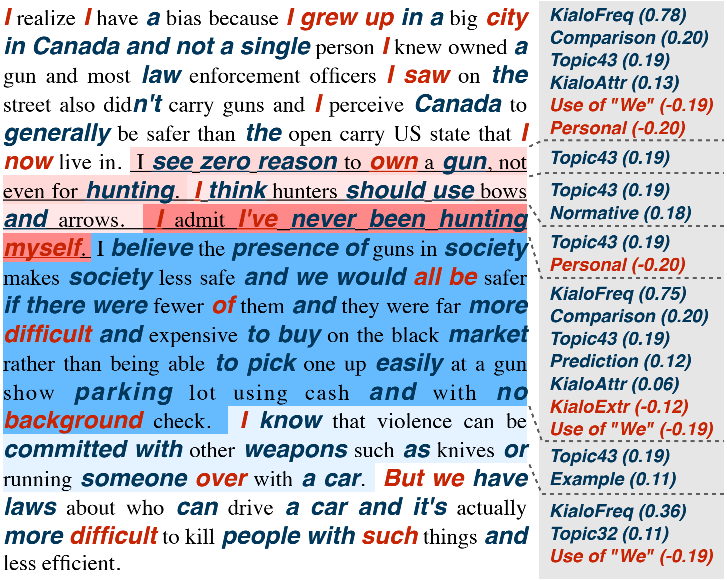
(b) Successful example 3.

Figure 3: Successful examples.



So let's say I'm good friends with Amanda and Bailey. I'm compatible with both of them on a platonic level, but I only take a romantic interest in Bailey because she's (physically) my type. Not to say that Amanda is ugly, just that I'm not really into her body structure. Another piece of evidence to support this is when you feel attracted to a complete stranger, because of their physical appearance. You know absolutely nothing about them yet, you could envision a happy relationship with them just from their looks. I feel this way because many times when I'm hanging out with my friends (of both genders) I think to myself "wow we'd make such a good couple" but even so don't feel the desire to enter a relationship with them.

(a) Erroneous example 1.



I realize I have a bias because I grew up in a big city in Canada and not a single person I knew owned a gun and most law enforcement officers I saw on the street also didn't carry guns and I perceive Canada to generally be safer than the open carry US state that I now live in. I see zero reason to own a gun, not even for hunting. I think hunters should use bows and arrows. I admit I've never been hunting myself. I believe the presence of guns in society makes society less safe and we would all be safer if there were fewer of them and they were far more difficult and expensive to buy on the black market rather than being able to pick one up easily at a gun show parking lot using cash and with no background check. I know that violence can be committed with other weapons such as knives or running someone over with a car. But we have laws about who can drive a car and it's actually more difficult to kill people with such things and less efficient.

(b) Erroneous example 2.

Extracting Implicitly Asserted Propositions in Argumentation

Abstract

Argumentation accommodates various rhetorical devices, such as questions, reported speech, and imperatives. These rhetorical tools usually assert argumentatively relevant propositions rather implicitly, so understanding their true meaning is key to understanding certain arguments properly. However, most argument mining systems and computational linguistics research have paid little attention to implicitly asserted propositions in argumentation. In this paper, we examine a wide range of computational methods for extracting propositions that are implicitly asserted in questions, reported speech, and imperatives in argumentation. By evaluating the models on a corpus of 2016 U.S. presidential debates and online commentary, we demonstrate the effectiveness and limitations of the computational models. Our study may inform future research on argument mining and the semantics of these rhetorical devices in argumentation.[1]

1 Introduction

Argument mining is a growing research field in computational linguistics. One of its main goals is to automatically identify pro- and counter-arguments underlying argumentative discourse. The foundational step for argument mining is to extract the elementary units of arguments in the discourse, after which the support or attack relations between these units are identified. According to argumentation theory, the elementary units in argumentation are *asserted propositions* (Eemeren and Grootendorst, 1984). However, the dominant approach to extracting elementary units from text—often called *argumentative discourse unit segmentation* (Ajjour et al., 2017; Persing and Ng, 2016; Jo et al., 2019)—is rather simplistic and may even seem inconsistent with the theory. This approach segments text into smaller pieces (e.g., clauses) and treats each segment as an elementary unit of arguments. But these segments include locutions that are seemingly not assertives, such as questions and imperatives used as rhetorical devices. In fact, questions, imperatives, and reported speech in argumentation often assert propositions implicitly. Therefore, in order to understand certain argumentation and identify pro-/counter-arguments properly, locutions in argumentation should not be taken literally in their surface forms; instead, we need to go further and understand what propositions are implicitly asserted and argumentatively relevant in those locutions. Our work provides some computational solutions to this problem, namely, extracting implicitly asserted propositions in argumentation.

The following example dialogue illustrates how questions, reported speech, and imperatives assert propositions implicitly in argumentation.

A : *All human should be vegan.* (1)
Look at how unethical the meat production industry is. (2)
Environmental scientists proved that vegan diets reduce meat production by 73%. (3)
B : *Well, don't vegan diets lack essential nutrients, though?* (4)

In this dialogue, speaker A is supporting conclusion 1 using sentences 2 and 3, whereas speaker B is attacking the conclusion using sentence 4. Sentence 2 is an imperative, but in this argumentation, it is *asserting* that the meat production industry *is* unethical. In sentence 3, the primary proposition asserted in support of the conclusion is the content of this reported speech—"vegan diets reduce meat production by 73%"; the "environmental scientists" is presented as the source of this content in order to strengthen the main proposition in this

November 16–20, 2020.

sentence. Lastly, sentence 4 is in question form, but it is in fact *asserting* that vegan diets *lack* essential nutrients. These examples suggest that properly understanding arguments requires comprehension of what is meant by questions, reported speech, and imperatives, that is, what they assert implicitly.

In this paper, we test various computational methods to extract propositions that are implicitly asserted in questions, reported speech, and imperatives. Across the tasks, we explore a wide range of computational methods. For questions, we develop neural and rule-based methods for transforming questions into asserted propositions. For reported speech, we present feature-based and neural models to identify speech content (the primary proposition asserted) and speech source. Lastly, for imperatives, we test a simple transformation rule manually and analyze the patterns of how they assert propositions. By evaluating our models on a corpus of the 2016 U.S. presidential debates and online commentary, we demonstrate their effectiveness and limitations.

Our contributions are as follows:

- Our work is a first computational study of extracting propositions asserted in questions, reported speech, and imperatives in argumentation. We demonstrate the effectiveness and limitations of various computational models. This problem is fundamental in argument mining, albeit understudied.
- We find the evidence of strong syntactic regularities in how propositions are asserted in question form.
- We show the robust performance of a state-of-the-art language model for identifying speech content and source in reported speech.
- Our case study of how imperatives implicitly assert propositions is novel in computational linguistics and argumentation theory. This study may inform future research on the semantics of imperatives in argumentation.

2 Background

Argumentation is an illocutionary act of supporting or attacking an expressed opinion by *asserting* propositions, according to Pragma-Dialectics (Eemeren and Grootendorst, 1984). This definition might seem counterintuitive, as argumentation often accommodates locutions that are not assertives, such as questions and imperatives. We will draw upon theory and discuss how propositions are asserted implicitly in questions, reported speech, and imperatives in argumentation. But for the sake of the readability of the paper, we will defer this discussion to the respective sections of questions (§4), reported speech (§5), and imperatives (§6).

On the other hand, one of the main goals of argument mining is to identify pro- and counter-relations between asserted propositions. In most argument mining systems, asserted propositions are approximated and substituted by argumentative discourse units (ADUs). An ADU is the minimal locution that performs an argumentative function. Given an utterance, ADUs may be identified based on syntactic rules, such as phrases (Stede et al., 2016), clauses (Peldszus and Stede, 2015), or a series of clauses (Al Khatib et al., 2016), or by machine learning models, such as neural networks (Ajjour et al., 2017) or retrieval (Persing and Ng, 2016). None of these methods go further to understand what propositions are asserted in each ADU.

More recently, a computational framework has been proposed to extract asserted propositions from ADUs (Jo et al., 2019). This cascade model proposes how to detect reported speech, questions, and imperatives, reconstruct any missing subjects, and make final revisions for grammar correction. While this model was built upon the same goal of extracting asserted propositions from locutions, it does not present computational models to extract implicit propositions in questions, reported speech, and imperatives. Hence, our work fills this gap in the cascade model.

3 Domain

The domain we focus on is 2016 U.S. presidential debates and online commentary on Reddit (Visser et al., 2019). This corpus includes the first Republican candidates debate for the primaries, the first Democratic candidates debate for the primaries, and the first general election debate. The corpus also includes Reddit discussions on these debates.

Each utterance has been segmented into ADUs, and each ADU has been further annotated with an asserted proposition. The inter-annotator agreement is Cohen's κ of 0.61 (substantial agreement). These debates are ideal for our analysis, since they accommodate questions, reported speech, and imperatives from various speakers and in both formal and informal debate settings.

Our work uses the data pre-processed by Jo et al. (2019). This dataset has resolved anaphors in ADUs and paired ADUs with asserted propositions in a readily-available format[2]. While most of our work is based on this dataset, individual tasks need additional processing or additional data. They will be described in the respective section.

4 Questions

In this section, we extract implicit propositions from questions in argumentation. The task is formulated as transforming a question into its asserted proposition.

4.1 Theoretical Background

Questions in argumentation may be categorized into rhetorical questions and pure questions. Rhetorical questions are not intended to require an answer; instead, they often make an implicit assertive (as in sentence 4). Zhang et al. (2017) identified finer-grained types of rhetorical questions, such as sharing concerns, agreeing, and conceding. Our work is not aiming to classify these types, but instead focuses on extracting implicit assertives in rhetorical questions.

Pure questions, on the other hand, are intended to seek information. According to the speech act theory, non-binary questions have incomplete propositions (Searle, 1969). For instance, the question "*How many people were arrested?*" has the proposition "*X people were arrested*", with the questioned part underspecified and denoted by *X*. Although the proposition is semantically underspecified, subsequent arguments may build on this, making this proposition an important argumentative component. Hence, our work covers extracting semantically underspecified propositions from pure questions as well. (See Bhattasali et al. (2015) for computational methods to distinguish between rhetorical questions and pure questions.)

4.2 Models

We explore two neural seq2seq models and one rule-based model. For all these models, both input and output are a sequence of words.

4.2.1 Neural Models

We test two RNN-based seq2seq models. First, the **basic** model encodes a question using BiLSTM and decodes a proposition using LSTM and the standard attention mechanism (Luong et al., 2015). Figure 1 illustrates the snapshot of the model for the jth output word.

Formally, the input is a sequence of words $w_1^E, \cdots, w_N^E$, and the embedding of w_i^E is denoted by $\boldsymbol{w}_i^E$. BiLSTM encodes each word $\boldsymbol{w}_i^E$ and outputs forward/backward hidden states $\overrightarrow{\boldsymbol{h}}_i^E$ and $\overleftarrow{\boldsymbol{h}}_i^E$:

$$\overrightarrow{\boldsymbol{h}}_i^E, \overleftarrow{\boldsymbol{h}}_i^E = \text{BiLSTM}(\boldsymbol{w}_i^E, \overrightarrow{\boldsymbol{h}}_{i-1}^E, \overleftarrow{\boldsymbol{h}}_{i+1}^E),$$
$$\overrightarrow{\boldsymbol{h}}_0^E = \overleftarrow{\boldsymbol{h}}_{N+1}^E = \mathbf{0}.$$

For the jth word to be generated, an LSTM decoder encodes the concatenation of the previously generated word $\boldsymbol{w}_{j-1}^D$ and context vector $\bar{\boldsymbol{h}}_{j-1}^E$ (explained below), and the previous hidden state:

$$\boldsymbol{h}_j^D = \text{LSTM}([\boldsymbol{w}_{j-1}^D; \bar{\boldsymbol{h}}_{j-1}^E], \boldsymbol{h}_{j-1}^D),$$
$$\boldsymbol{h}_0^D = [\overleftarrow{\boldsymbol{h}}_1^E; \overrightarrow{\boldsymbol{h}}_N^E].$$

Next, the decoder attends to the encoder's hidden states using an attention mechanism. The attention weight of the ith hidden state is the dot product of the hidden states from the encoder and the decoder:

$$a_{ji} = \boldsymbol{h}_j^D \cdot [\overleftarrow{\boldsymbol{h}}_i^E; \overrightarrow{\boldsymbol{h}}_i^E], \quad \hat{a}_{ji} = \frac{\exp(a_{ji})}{\sum_{i'} \exp(a_{ji'})},$$
$$\bar{\boldsymbol{h}}_j^E = \sum_i \hat{a}_{ji}[\overrightarrow{\boldsymbol{h}}_i^E; \overleftarrow{\boldsymbol{h}}_i^E].$$

The probability of the vth word in the vocabulary being generated is calculated as in the standard attention decoder mechanism:

$$P_G(w_v) = \text{softmax}(W_G[\boldsymbol{h}_j^D; \bar{\boldsymbol{h}}_j^E] + \boldsymbol{b}_G)_v,$$

where W_G and $\boldsymbol{b}_G$ are trainable weight matrix and bias vector.

The basic seq2seq model requires a lot of training data, whereas according to our observation, question transformation is often formulaic, consisting largely of word reordering. Hence, our **copy** model uses a copying mechanism to learn to re-use input words. A prior model (Gu et al., 2016) does not perform well in our task, so we modified it as follows (Figure 1).

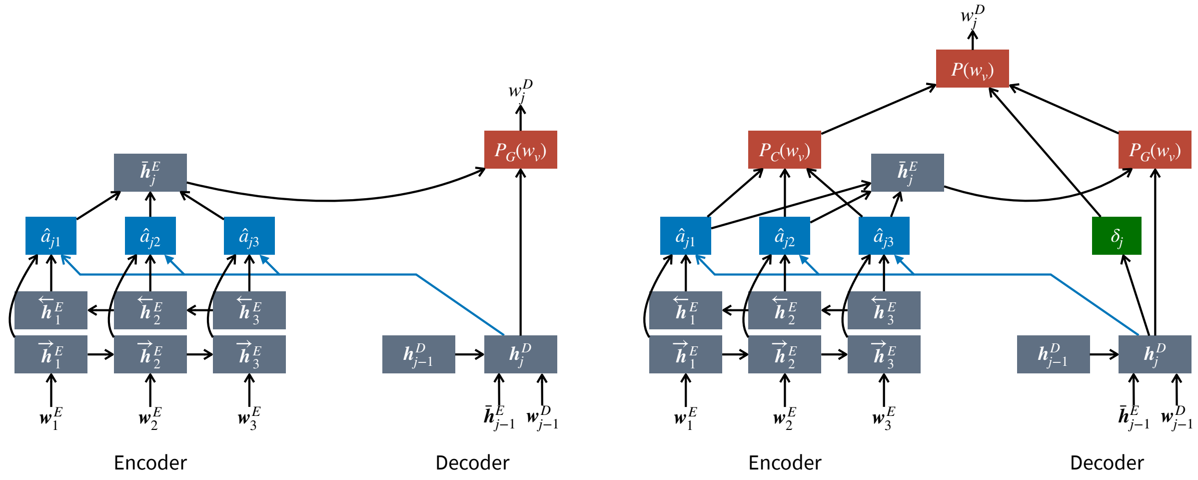
Our copy model is based on the basic model and has the same process for the generating part. When an output word is copied from the input text, instead of being generated, the probability of the ith input word being copied is proportional to the attention weight of the ith hidden state. That is, the probability of the vth word in the vocabulary being copied is:

$$P_C(w_v) = \sum_{i=1}^{N} \hat{a}_{ji} I(w_i^E = w_v).$$

The final probability of w_v being output is a weighted sum of $P_C(w_v)$ and $P_G(w_v)$, where the

---

[2] `https://github.com/yohanjo/amw19`



Basic Model **Copy Model**

Figure 1: Basic model and copy model for question transformation. The snapshots for the jth output word.

weight δ is calculated as

$$\delta_j = \sigma(W_\delta \boldsymbol{h}_j^D + \boldsymbol{b}_\delta),$$

$$P(w_v) = \delta P_C(w_v) + (1-\delta) P_G(w_v),$$

where W_δ and $\boldsymbol{b}_\delta$ are trainable weight matrix and bias vector. The main difference of our model from existing ones is that we compute the mixture weight δ_j for P_C and P_G using a separate neural network. In contrast, existing models do not explicitly compute this weight (Gu et al., 2016) or do not use attentional hidden states (Allamanis et al., 2016).

We try the following hyperparameter values:

- Encoder/decoder hidden dim: 96, 128, 160, 192 (basic model) / 128, 192 (copy model)
- Beam size: 4
- Optimizer: Adam
- Learning rate: 0.001
- Gradient clipping: 1
- Word embedding: GloVe 840B

4.2.2 Rule-Based Model

As question transformation is often formulaic, a rule-based method may be effective for small data. For each question, the most relevant parts for transformation are the first word (wh-adverb or auxiliary verb), subject, auxiliary verb, negation, and main verb (i.e., *be*+adjective, *be*+gerund, or else). For instance, the question "*Why would you not pay the tax?*" might be rearranged to "*You would pay the tax*", where *why* and *not* are removed. We compile rules that match combinations of these components, starting with a rule that has a high coverage and breaking it down to more specific ones if the rule makes many errors. An example rule is "*Why* [MODAL] [SUBJECT] *not*" → "[SUBJECT] [MODAL]", which applies to the above example. As a result, we compiled total 94 rules for 21 first words (4.5 rules per first word on average) based on the US2016 dataset (see Table 7 in Appendix B for a summary of these rules).

4.3 Data

US2016: Our main data is Jo et al. (2019)'s dataset of the 2016 U.S. presidential debates and commentary. We filtered 565 pairs of an ADU and its asserted proposition that are annotated with the following question types:

- **Pure:** e.g., *"Who is Chafee?"* → *"Chafee is xxx"*; *"Do lives matter?"* → *"Lives do / do not matter"* (Semantically underspecified parts are denoted by *xxx* and the slash /.)
- **Assertive:** e.g., *"What does that say about your ability to handle challenging crises as president?"* → *"Clinton does not have the ability to handle challenging crises as president"*
- **Challenge:** e.g., *"What has he not answered?"* → *"He has answered questions"*
- **Directive:** e.g., *"Any specific examples?"* → *"Provide any specific examples"*

Note that only pure questions are semantically underspecified (indicated by *xxx* and /); the other types contain concrete propositions to be asserted. Our models are trained on all question types.

MoralMaze: This dataset consists of 8 episodes of the BBC Moral Maze Radio 4 program from the 2012 summer season[3] (Lawrence et al., 2015). The

---

Rules	54.5	64%	51.9	48%
Rules (well-formed)	56.7	85%	54.5	69%

Table 1: Accuracy of extracting implicitly asserted propositions from questions. "%M" is the percentage of questions matched with any hand-crafted rules.

episodes deal with various issues, such as the banking system, welfare state, and British empire. In each episode, the BBC Radio presenter moderates argumentation among four regular panelists and three guest participants. This dataset has been annotated in the same way as US2016, and we filtered 314 pairs of a question and its asserted proposition. This dataset is not used for training or compiling rules; instead, it is only used as a test set to examine the domain-generality of the models.

4.4 Experiment Settings

For the neural models, we conduct two sets of experiments. First, we train and test the models on US2016 using 5-fold cross validation. Second, to examine domain generality, we train the models on the entire US2016 dataset and test on MoralMaze.

For the rule-based model, we compile the rules based on US2016 and test them on US2016 (previously seen) and MoralMaze (unseen).

The accuracy of the models is measured in terms of the BLEU score, where the references are asserted propositions annotated in the dataset.

4.5 Result

As shown in Table 1, the basic seq2seq model (row 2) performs poorly, because of the small size of the training data. On the other hand, the copy model (row 3) significantly improves the BLEU scores by 36.2–37.6 points, by learning to re-use words in input texts[4]. However, it still suffers the small data size, and its outputs are worse than the original questions without any transformation (row 1).

In contrast, the hand-crafted rules (rows 4–5) significantly improve performance and outperform the original questions. The effectiveness of the rule-based method on MoralMaze, which was not used for compiling the rules, indicates that these rules generalize across argumentative dialogue[5]. The effectiveness of the rule-based method also suggests that there exist a high degree of syntactic regularities in how propositions are asserted implicitly in question form, and the hand-crafted rules provide interpretable insights into these regularities (see Table 7 in Appendix B for the rules).

Taking a closer look at the rule-based method, we find that many questions are subordinated or ill-formed, and thus the rules match only 64% of questions for US2016 and 48% of questions for MoralMaze. When we focus only on well-formed questions (that begin with a wh-adverb or auxiliary verb), the rules match 85% and 69% of questions for the respective dataset, and the BLEU scores improve by 2.2–2.6 points (row 4 vs. row 5). When analyzed by the first word of a question, questions beginning with *have*, *do*, and modal verbs achieve the highest BLEU scores. Why-questions achieve the lowest, probably due to many variants possible; for example, "*why isn't* [SUBJECT] [ADJECTIVE]*?*" is most likely to be transformed to "[SUBJECT] *is* [ADJECTIVE]", whereas "*why isn't* [SUBJECT] [VERB]*?*" is to "[SUBJECT] *should be* [VERB]".

One limitation of the rule-based method, however, is that it cannot distinguish between questions that have the same syntactic structure but assert opposite propositions. For example, "*Would you ...?*" can mean both "*You would ...*" and "*You would not ...*" depending on the context. In order to separate these cases properly, we may need to take into account more nuanced features and context, and machine learning with large data would be the most promising direction eventually.

5 Reported Speech

In this section, we extract speech content (i.e., propositions that are often asserted as the primary contribution to the argumentation) and speech source in reported speech. This task is formulated as sequence tagging: words that constitute speech content or source are tagged with B followed by I, and all other words are tagged with O.

5.1 Theoretical Background

Reported speech consists of *speech content* that is borrowed from a *speech source* external to the

---

[4] Our model also outperforms a prior copy model (Gu et al., 2016) by more than 20 BLEU scores.

[5] Yet, we do not believe these rules would be effective beyond argumentation if the distribution of rhetorical questions and pure questions is significantly different from argumentative dialogue.

speaker. Speech content can be a direct quote of the original utterance or an indirect, possibly paraphrased utterance. Reported speech is a common rhetorical device in argumentation and performs various functions, including:

- Appeals to authority by referencing experts or rules (Walton et al., 2008) (e.g., "*Environmental scientists proved that vegan diets reduce meat production by 73%.*")
- Sets a stage for dis/agreeing with the position (Janier and Reed, 2017) (e.g., "*You say that you want attention, but, at the same time, you don't want me to bring attention to you.*")
- Commits straw man fallacies by distorting the original representation or selecting part of the original utterance (Talisse and Aikin, 2006)

While reported speech as a whole is an assertion, its primary contribution to the argumentation usually comes from the speech content (e.g., "vegan diets reduce meat production by 73%"), and the speech source (e.g., "environmental scientists") is used to support the speech content.

Due to the important roles of speech content and source, computational models have been proposed to identify them, based on rules (Krestel et al., 2008), conditional random fields (Pareti et al., 2013), and a semi-Markov model (Scheible et al., 2016). Our work is different from these studies in two ways. First, they are based on news articles, whereas our work is on argumentative dialogue. Second, they use rules or features that reflect typical words and structures used in reported speech, whereas our work explores a neural method that does not require feature engineering. We aim to show how well a state-of-the-art neural technique performs on extraction of speech content and source. A slightly different but related strain of work is to identify authority claims in Wikipedia discussions (Bender et al., 2011), but this work does not identify speech content and source.

5.2 Models

We explore three models: a conditional random field (CRF) with hand-crafted features, the BERT token classifier with a pretrained language model, and a semi-Markov model as the baseline. For all models, the input is a sequence of words and the output is a BIO tag for each word. We conduct separate experiments for content and source, because we do not assume that they are mutually exclusive (although they are in most cases).

5.2.1 Conditional Random Field (CRF)

Our CRF uses the following features:

- Current word.
- Named entity type of the word.
- POS tag of the word.
- Unigram and bigram preceding the word.
- Unigram and bigram following the word.
- Indicator of if the word is a subject ("nsubj*" on the dependency parse tree).
- Indicator of if the current word is the beginning/end of a clause ("S" on the parse tree).

The features were extracted using Stanford CoreNLP 0.9.2 (Manning et al., 2014).

For model parameters, we explore two optimization functions: (i) L-BFGS with the combinations of L1/L2 regularization coefficients $\{0, .05, .1, .2\}$; (ii) Passive Aggressive with aggressiveness parameter values $\{.5, 1, 2, 4\}$. The model was implemented using sklearn_crfsuite 0.3.6.

5.2.2 BERT

The second model is the BERT token classifier (Devlin et al., 2018), which classifies the tag of each word. BERT has shown significant performance boosts in many NLP tasks and does not require hand-crafted features. We use the pretrained, uncased base model with the implementation provided by Hugging Face (Wolf et al., 2019). The model is fine-tuned during training.

5.2.3 Baseline

The baseline is the state-of-the-art semi-Markov model for speech content identification (Scheible et al., 2016). This model first identifies cue words (e.g., reporting verbs) and iteratively identifies the boundaries of speech content using a set of hand-crafted features. This model does not identify speech sources and thus is compared with other models only for content identification.

For a methodological note, the original source code was hard-coded to work for the PARC3.0 dataset, and we could not replicate the model to train on other data. Therefore, all accuracies of this model in the next section result from training it on the training set of the PARC3.0 dataset (Section 5.3). We will show its performance on both PARC3.0 and US2016.

5.3 Data

PARC3.0: The first dataset is 18,201 instances of reported speech in news data (Pareti, 2016). The original dataset was built upon the Wall Street

Journal articles in the Penn Discourse TreeBank (PDTB) (Prasad et al., 2008), where each instance of reported speech has been annotated with the content, source, and cue word (e.g., reporting verbs). The reliability of the annotations were measured by the overlap of annotated text spans between annotators. The overlap for speech content is 94% and that for speech source is 91%, suggesting the high reliability of the annotations.

This dataset consists of 24 sections corresponding to the PDTB sections. The original paper suggests using sections 00-22 for training (16,370 instances), section 23 for testing (667 instances), and section 24 for validation (1,164 instances).

US2016: The second dataset is the instances of reported speech in the corpus of the 2016 U.S. presidential debates and commentary, prepared by Jo et al. (2020)[6]. This dataset includes 242 instances of reported speech annotated with speech content and source. The reliability of the annotations was measured by the number non-overlapping words between annotators. The average number of words that are outside of the overlapping text span was 0.2 for speech content and 0.5 for speech sources, suggesting the high reliability of the annotations.

5.3.1 Experiment Settings

The CRF and BERT models are trained and tested on both PARC3.0 and US2016, separately. For PARC3.0, we use the split of train, validation, and test as suggested by the original paper. For US2016, we use 5-fold cross validation; for each iteration, three folds are used for training, one for testing, and the other for choosing the optimal hyperparameters (CRF) or the optimal number of epochs (BERT).

The baseline model is trained and tested on PARC3.0 using the same training, validation, and test split. US2016 is used only for testing after it is trained on the training set of PARC3.0 (as mentioned in 5.2.3).

We use various evaluation metrics. For speech content, the **F1-score** is calculated based on the true and predicted BIO tags of individual words, as well as the **BLEU** score of the predicted text span against the true text span. For speech sources, the F1-score is calculated based on the match between the true source's text and the predicted text. Two texts are considered matched if they are identical (**Strict**) or if their words overlap (**Relaxed**). We do not measure the F1-score based on BIO tags for speech sources, because the source may be mentioned multiple times in reported speech and we do not want to penalize the model when the mention identified by the model is the true source but different from the annotated mention.

	PARC3.0		US2016	
	F1	BLEU	F1	BLEU
Scheible (All)	64.4	57.1	*37.9*	*23.4*
Scheible (Matched)	75.8	72.7	*79.3*	*76.5*
CRF	71.3	66.3	72.5	68.7
BERT	82.6	82.0	87.1	89.3

(a) Accuracy of identifying speech content. The accuracies of Scheible for US2016 (italic) result from training it on the training data of PARC3.0.

	PARC3.0		US2016	
	Strict F1	Relaxed F1	Strict F1	Relaxed F1
CRF	52.4	59.8	62.4	71.6
BERT	71.0	78.6	70.3	84.8

(b) Accuracy of identifying speech source.

Table 2: Accuracy of identifying speech content and source.

5.4 Result

Content Identification: The accuracies of all models are summarized in Table 2a. The baseline model (Scheible) has two rows: row 1 is its accuracy on all test instances, and row 2 is on test instances where the model was able to identify cue words. We find that the BERT model (row 4) outperforms the feature-based CRF and the baseline model for both corpora, achieving a macro F1-score of 82.6% at tag levels and a BLEU score of 82.0% for PARC3.0 and an F1-score of 87.1% and a BLEU score of 89.3% for US2016. These scores show the high reliability of the BERT model for extracting main propositions asserted in reported speech. In addition, the high accuracy on US2016 despite its small size suggests that the pretrained language model effectively encodes important semantic information, such as reporting verbs and dependencies among subject, verb, and object.

The baseline model, which was trained on PARC3.0, performs poorly on US2016 (row 1). The main obstacle is that it fails to detect cue words (e.g., reporting verbs) in 168 out of 242 instances (69%). This shows one weakness of the baseline model: since this model works at two steps—detect cue words and find content boundaries—identifying speech content is strongly subject to

---

[6] `https://github.com/yohanjo/lrec20`

cue word detection. When the baseline is evaluated only on the instances where a cue word was detected, its accuracy boosts significantly (row 2), outperforming the CRF but still worse than BERT.

A qualitative analysis of the BERT model reveals that most instances are tagged accurately, and errors are concentrated on a few instances. One of the main issues is whether a reporting verb should be included or not as speech content. In the annotation process for US2016, a reporting verb was included as speech content only if the verb has meaning other than merely "to report" (e.g., ***blamed*** *his idea*, ***declared*** *their candidacy*). As a result, the model often has difficulty judging a reporting verb to be part of the speech content or not.

In some cases, the exact boundary of speech content is ambiguous. For instance, in the sentence

> "*Bush has promised* ***four percent economic growth and 19 million new jobs*** *if Bush is fortunate enough to serve two terms as president.*"

the annotated speech content is in bold, while the model included the if-clause as the content (underlined). However, it may seem more appropriate to include the if-clause as part of the promise.

Source Identification: The accuracies of all models are summarized in Table 2b. The BERT model (row 2) again significantly outperforms the CRF (row 1), achieving F1-scores of 75.7% for strict evaluation (exact match) and 85.1% for relaxed evaluation (overlap allowed). It is usually when a source is a long noun phrase that a predicted source and the true source overlap without exact match (e.g., *President Obama* vs. *Obama*).

Our qualitative analysis of the BERT model reveals two common error cases. First, the model tends to capture subjects and person names as a speech source, which is not correct in some cases:

> "*We have been told through investigative reporting that he owes about $650 million to Wall Street and foreign banks*"

where the model identifies *we* as the speech source, while the true source is the *investigative reporting*. The model also sometimes fails to detect any source candidate if reported speech has an uncommon structure, such as "*The record shows that ...*" and "*No one is arguing ... except for racists*", where the speech sources are underlined. These problems may be rectified with larger training data that include more diverse forms of reported speech.

6 Imperatives

In this section, we collect imperatives in argumentative dialogue and examine a simple method for extracting propositions asserted in them. We do not build automated models for transformation (as in questions), because US2016 had no clear guidelines on how to annotate asserted propositions in imperatives when the dataset was built.

6.1 Theoretical Background

Imperatives are common in argumentation as in "*Stop raising the sales tax*" and "*Look how bad the system is*". However, to our knowledge, there is little theoretical work on what propositional content is asserted by imperatives in argumentation. There have been theories about the semantics of imperatives in general context; for example, the *you-should* theory suggests that an imperative of the form "*Do X*" may imply "*X should be done*" (Hamblin, 1987; Schwager, 2005). While applicable in many general cases, this mechanism is not satisfactory in argumentation. For instance, while this transformation preserves the literal meaning of both the first and second examples above, it does not capture the main proposition asserted in the second example. This example is unlikely arguing for "looking" per se; it rather asserts that the system is bad, which is the main content that contributes to the argumentation. No simple transformation rules apply here, and such irregularities call for more case studies. Our work aims to make an initial contribution in that direction.

6.2 Model

No automated model is used in this section, but instead, we examine the applicability of the *you-should* theory in argumentation. Specifically, we analyze whether each imperative preserves the original intent when it is transformed to an assertive by adding "*should*", along with appropriate changes in the verb form, (implicit) subject, and object. We additionally analyze the argumentative relevancy of the transformed verb, that is, whether the imperative is mainly asserting that it should happen.

6.3 Data

We use imperatives in US2016 (Jo et al., 2019). We assume that a sentence is an imperative if its root is a verb in the bare infinitive form and has no explicit subject. Using Stanford CoreNLP, we chose locutions that are not questions and whose

Top 1-8	Top 9-16	Top 17-24	Top 25-32
let (39)	fuck (5)	say (3)	bring (2)
look (7)	stop (5)	ask (2)	love (2)
have (7)	do (4)	vote (2)	drink (2)
wait (6)	check (3)	help (2)	pay (2)
thank (6)	give (3)	keep (2)	are (2)
please (6)	make (3)	find (2)	believe (2)
go (5)	get (3)	think (2)	talk (2)
take (5)	use (3)	forget (2)	screw (2)

Table 3: Root verbs and counts in imperatives.

root is a verb with base form or second-person present case (VB/VBP), neither marked (e.g., *to go*) nor modified by an auxiliary modal verb (e.g., *would go*). We found total 191 imperatives, and the most common root verbs are listed in Table 3.

6.4 Result

We found that 74% of the imperatives can be transformed to an assertion by adding *should* while preserving their original meaning[7]. And 80% of the transformed assertions were found to be argumentatively relevant content. For example, the imperative "*Take away some of the pressure placed on it*" can be transformed to (and at the same time asserts that) "*some of the pressure placed on it should be taken away*". This result suggests that we can apply the *you-should* theory to many imperatives and extract implicitly asserted propositions in consistent ways.

Some imperatives were found to be rather rhetorical, and the propositions they assert cannot be obtained simply by adding *should*. Those imperatives commonly include such verbs as *let*, *fuck*, *look*, *wait*, and *have*. The verb *let* can assert different things. For instance, "*Let's talk about the real issues facing america*" asserts that "*there are real issues facing america*", while "*Let's solve this problem in an international way*" asserts that "*we should solve this problem in an international way*". The words *fuck* and *screw* are used to show strong disagreement and often assert that something should go away or be ignored.

We cannot apply the same transformation rule to the same verb blindly, as a verb can be argumentatively relevant sometimes and only rhetorical at other times depending on the context. For instance, the verb *take* in the above example is argumentatively relevant, but it can also be used only rhetorically as in "*Take clean energy (as an example)*".

Based on our analyses, we propose rough two-step guidelines for annotating propositions that are implicitly asserted in imperatives. First, we may group imperatives by their semantics based on theories, such as *you-should* and *you-will* (Schwager, 2005). Second, for these imperatives, we may annotate whether the root verb is argumentatively relevant. For instance, if the *you-should* theory is applicable to an imperative, we may annotate whether its verb is at the core of the main argumentative content that the speaker asserts should happen; the assertive form of this imperative is likely to be a statement that proposes a policy or action (Park and Cardie, 2018). Argumentatively relevant imperatives may be annotated with asserted propositions using predefined transformation templates appropriate for their semantics. On the other hand, argumentatively irrelevant verbs may simply be rhetorical and need to be replaced properly. Annotation of these imperatives should handle many irregular cases, relying on the domain of the argumentation and the annotator's expertise.

7 Conclusion

Identifying implicitly asserted propositions in argumentation is key to understanding arguments properly. We presented and tested computational methods for extracting implicit propositions from questions and reported speech in argumentation. For transforming questions to propositions, handcrafted rules were significantly more effective than neural models and provided insights into the regularities in how propositions are implicitly asserted in question form. Since rule-based methods do not take context into account, however, more annotated data would be needed for better question transformation based on machine learning. For reported speech, BERT-based models demonstrated high effectiveness in identifying speech content and source by utilizing the rich semantic information in the pretrained model. Lastly, for imperatives, we demonstrated some regularities and irregularities in how propositions are asserted in imperatives. We find evidence that some verbs may need to be treated specially, while many other verbs could be treated in consistent ways.

Acknowledgments

This research was supported by the Kwanjeong Educational Foundation and by UK EPSRC grant EP/N014871/1.

---

[7] Many of the other cases are attributed to subject drop (e.g., "*Thank you*", "*Doesn't work*") and CoreNLP errors (e.g., "*Please nothing on abortion*", "*So do police jobs*").

Abstract

When summarizing a collection of views, arguments or opinions on some topic, it is often desirable not only to extract the most salient points, but also to quantify their prevalence. Work on multi-document summarization has traditionally focused on creating textual summaries, which lack this quantitative aspect. Recent work has proposed to summarize arguments by mapping them to a small set of expert-generated *key points*, where the salience of each key point corresponds to the number of its matching arguments. The current work advances *key point analysis* in two important respects: first, we develop a method for automatic extraction of key points, which enables fully automatic analysis, and is shown to achieve performance comparable to a human expert. Second, we demonstrate that the applicability of key point analysis goes well beyond argumentation data. Using models trained on publicly available argumentation datasets, we achieve promising results in two additional domains: municipal surveys and user reviews. An additional contribution is an in-depth evaluation of argument-to-key point matching models, where we substantially outperform previous results.

1 Introduction

The need for summarizing views, arguments and opinions on a given topic is common to many text analytics applications, across a variety of domains. Some prominent examples for this type of data are responses to open-ended questions in surveys, user reviews on products and services, and posts in online discussion forums. We will hereafter refer to such utterances that express an opinion, view, argument, ask, or suggestion, collectively as *comments*.

Compressing such textual collections into short summaries relies on their inherent *redundancy*. The goal of Multi-Document Summarization (MDS) algorithms is to create short textual summaries from document clusters sharing the same topic. These summaries aim to capture most of the relevant information in the input clusters, while removing redundancies. However, in many cases we would also like to *quantify* the prevalence of each of the points included in the summary. For example, when analyzing the responses of a municipal survey, it would be desirable to let the policy makers know that the point *"The city needs better public transportation"* in the summary matches 8% of the comments, while the points *"Please consider increasing the number of parks, walking and biking trails."* and *"electric rates are too high"* match 4% and 2% of the comments, respectively. The users may also want to drill down to view the comments that were mapped to a specific point in the summary.

Recently, Bar-Haim et al. (2020) proposed *key point analysis* as a summarization framework that meets the above desiderata, in the context of argument summarization. Given a collection of arguments on some topic, their approach aims to match each argument to a short list of *key points*, defined as high-level arguments. In their work, key points were manually composed by an expert, while the matching of arguments to key points was done automatically.

The current work promotes this line of research in two important respects. First, we develop a method for automatic key point extraction (Section 3), allowing fully automatic key point analysis. Our method first selects short, high quality comments as *key point candidates*. It then leverages previous work on argument-to-key-point matching to select a subset of the candidates that achieve high coverage of the data. We show that this relatively simple approach for key point extraction achieves

results on argumentation data that are on par with human experts.

The second major contribution of this work is demonstrating the applicability of key point analysis in additional domains beyond argumentation. We report promising results on two datasets: municipal surveys and user reviews. Remarkably, the results are achieved using the same argument matching and argument quality models that were trained on argumentation data, and require only minimal parameter tuning, but no domain-specific labeled data.

An additional contribution is an extensive comparison of pre-trained Transformer models for argument matching, in terms of both accuracy and run time, which results in substantial improvement over the best results reported by Bar-Haim et al. (Section 2).

2 Matching Comments to Key Points

The goal of key point analysis is to extract key points and to match comments to these key points. As mentioned in the previous section (and will be further detailed in the next section), our key point selection algorithm is also based on matching comments to key points, making it a critical component in our system.

We build on the work of Bar-Haim et al. (2020), who developed a large-scale labeled dataset for the task of matching arguments to key points. The dataset, termed *ArgKP*, contains about 24K *(argument, key point)* pairs, for 28 controversial topics. Each of the pairs is labeled as matching/non-matching. Given a set of key points for a topic, an argument could be matched to one or more key points, or to none of them. The arguments in this dataset are a subset of a larger dataset, the *IBM-ArgQ-Rank-30kArgs* dataset, which contains 71 topics, with stance and argument quality annotations for each argument (Gretz et al., 2020).

Bar-Haim et al. only experimented with BERT (Devlin et al., 2019) as a supervised model for argument matching, which they trained on the ArgKP dataset. We aimed to improve their results by testing several more recent transformer-based pre-trained models that were shown to substantially outperform BERT on various tasks (Wang et al., 2018), and in particular on the related task of Recognising Textual Entailment (RTE). We used the HuggingFace transformers framework and fine-tuned four different models: bert-large-uncased (Devlin et al., 2019) (BERT), xlnet-large-cased (Yang et al., 2019) (XLNet), roberta-large (Liu et al., 2019) (RoBERTa) and albert-xxlarge-v1 (Lan et al., 2020) (ALBERT).[1]

We ran 4-fold cross-validation on the ArgKP dataset, where each fold had a train set of 17 topics, development set (dev-set) of 4 topics and test set of 7 topics. The learning rate for each model was tuned based on the final training loss in one of the splits. This learning rate was then used in all four splits. The selected learning rates were 2e-5 for BERT, 7e-6 for XLNet, 5e-6 for RoBERTa and 1e-5 for ALBERT. For choosing the number of epochs, we trained each model with 3 epochs and 9 epochs and selected the one that performed better on the dev-set. All models were better when trained for 9 epochs, except BERT that was better when trained for 3 epochs.

The evaluation results for these models with the above parameters are shown in Table 1. First, we ran inference with each model over all the (argument, key point) pairs in the dev-set and test-set. We then evaluated the following *selection policies* defined by Bar-Haim et al. A selection policy defines how to match an argument to one or more key points, based on the classifier's match score for each key point (kp), and a given threshold t:

- The *threshold (TH)* policy matches the argument to all the kps with match score $> t$.
- The *best match (BM)* policy matches the argument to the kp with the highest match score.
- The *best match+threshold (BM+TH)* policy matches the argument to the kp with the highest match score, if the match score $> t$.

For each fold, we selected the threshold t that maximizes the F1 score over the dev-set.

The model that achieves the best F1 score is ALBERT with an F1 score of 0.809. RoBERTa is second best with an F1 score of 0.773. However, inference time of RoBERTA is about 6 times faster than ALBERT (run times for each model are detailed in Appendix A). Taking run time into account, we decided, for practical reasons, to use the RoBERTa model in the rest of the experiments. We apply this model to arguments, as well as other types of comments in different domains. Notably, both ALBERT and RoBERTa substantially outperform BERT, which only reaches F1 score of 0.721

Table 1: Argument-to-Key Point matching results on the ArgKP dataset.

(similar to the F1 of 0.713, reported for BERT by Bar-Haim et al.).

3 Key Point Extraction

In addition to the matching of comments to given key points, we wish to extract the key points automatically from the set of comments, to enable fully-automatic key point analysis. Extraction is performed in two steps: first, a set of key point candidates is selected from the comments and second, the most salient candidates are selected as key points.

3.1 Candidate Extraction

Our approach assumes that the desired key points can be found among the given comments. We start by collecting concise, high quality candidates. We consider only single sentences, and filter out sentences whose length exceed a certain number of tokens. In order to ensure the high quality and argumentative nature of the selected comments, we use the publicly available *IBM-ArgQ-Rank-30kArgs* dataset of Gretz et al. (2020), which consists of around 30k arguments annotated for point-wise quality to train an argument quality ranking model.

We then use this model to compute the argument quality score of each comment, and include only high quality candidates. In addition, we filter out sentences starting with pronouns in order to keep the key points self-contained.

3.2 Key Point Selection

After the set of candidates is extracted, we use the matching model described in Section 2 to obtain a match score between each comment and candidate, and between each pair of candidates.

First, to achieve high coverage of the selected key points, we match comments to candidates by applying the BM+TH selection policy using the matching model and a threshold t, and sort the candidates in descending order according to their coverage, i.e., the number of matched comments. Second, in order to avoid redundancy among the selected key points, we traverse the candidates and remove from the list each candidate whose matching score with a higher-ranked candidate exceeded the threshold.[2] The removed candidates and their matched comments are then matched to the remaining candidates. Finally, the candidates are resorted to form a ranked list of top key points.

The pseudo-code of the algorithm can be found in Appendix B.

4 Experiments

4.1 Evaluaton Method

Let D be a dataset, T the set of topics[3] in D, C_t the set of comments for a topic $t \in T$, and K_t the set of key points extracted for t. Key point analysis finds for each $t \in T$ a set of key points K_t and a mapping from a subset of C_t to K_t. We define *precision* as the fraction of mapped comments for which the mapping was correct, and *coverage* as the fraction of mapped comments out of all the comments.

Our goal is to achieve both high precision and high coverage, however there is typically a tradeoff between the two. This tradeoff can be controlled by setting a threshold on the match score, and applying the BM+TH selection policy to match only a subset of the comments to the key points.

We explore this tradeoff by measuring the precision for different levels of coverage. The precision

---

[2] As the match scoring function is not symmetric, we compute the match score in both directions and take the average.

[3] Topics may be debate motions in argumentation data, products in user reviews, etc.

at coverage c is defined as the maximal precision such that the coverage is at least c (which can be found by searching over possible threshold values). We measure precision at coverage levels of $0.2, 0.4..., 1.0$.

All the configurations in the following experiments use the matching model that was selected as described in Section 2, and differ only in the set of key points K_t generated for each of the topics $t \in T$ in the dataset D.

The evaluation of each configuration is performed as follows:

1. For each $t \in T, c \in C_t$ we map c to its best matching key point k in K_t, with matching score s.
2. We randomly select from the dataset 500 comments with uniform distribution over the topics. For each sampled comment, we add the tuple $[(c, k), s]$ to our sample.
3. The (c, k) pairs are manually labeled as matched/unmatched (cf. Section 4.4).
4. Based on the manual labeling of the sample, we measure precision at coverage levels of $0.2, 0.4..., 1.0$.

4.2 Datasets

We test our key point analysis method on three datasets: *Arguments*, *Survey* and *Reviews*.

Arguments Dataset. The *IBM-ArgQ-Rank-30kArgs* dataset (Gretz et al., 2020) contains 30k arguments actively collected for and against 71 debatable topics, such as *"Homeopathy brings more harm than good"*[4]. Arguments in the dataset have strict length limitations. Each argument is annotated for its stance towards the topic it discusses and for its quality. As previously mentioned, *ArgKP* was created based on part of this dataset (28/71 topics).

Survey Dataset. Open-ended comments provided by respondents to the *Austin Community Survey*, which took place in 2016 and 2017[5]. Comments were written in response to the following question: *"If there was ONE thing you could share with the Mayor regarding the City of Austin (any comment, suggestion, etc.), what would it be?"*. These comments are raw and unedited, and sometimes contain a few sentences each. The dataset contains $3, 188$ comments. Since over 90% of the arguments in our training data are single sentences, and in order to avoid sentences with missing context, only the first sentence of each comment was included in our set.[6]

Reviews Dataset. The *Opinosis* dataset (Ganesan et al., 2010) contains sentences extracted from user reviews on a given topic[7]. Each topic is a combination of product name and review aspect, such as *sound quality of ipod nano*. The dataset contains 51 topics and $7, 086$ review sentences, obtained from Tripadvisor (hotels), Edmunds.com (cars) and Amazon.com (various electronics).

4.3 Experimental Setup

Data Splits and Model Training. We used the 28 topics of the ArgKP dataset as training set (24 topics) and development set (4 topics) for the comment matching classifier, which used the selected model as described in Section 2. This model was applied to all three datasets. The remaining 43 topics in the Arguments dataset were used as the test set. Following Bar-Haim et al., we perform key point analysis per topic+stance, 86 pairs in total.

We trained two versions of the argument quality classifier[8]. One was applied to the Arguments test set, so it was only trained on the 24 training topics, with the 4 development topics serving as a development (dev) set. For the Survey and Reviews datasets, we trained a second model on all the available 71 topics.

We did not have training data for the Survey and Reviews datasets. However, we split each of them into test/dev sets, and used the dev set for experimentation and manual parameter tuning. The Survey dataset was split into 314 dev and 2,840 test comments (after comments filtering, as described below). The Reviews dataset was split into 10 dev and 41 test topics.

Filtering and Parameter Tuning. We applied the following filters to each of the datasets. First, comments with non-ascii characters, less than 10

---

[4] `https://www.research.ibm.com/haifa/dept/vst/debating_data.shtml`

[5] `https://data.world/cityofaustin/mf9f-kvkk`

[6] About 50% of the comments contain a single sentence, and in many of the multi-sentence comments, the first sentence captures the main point of the comment.

[7] `https://github.com/kavgan/opinosis-summarization/blob/master/OpinosisDataset1.0_0.zip`

[8] Replicating the $BERT\_FT_{topic}$ model of Gretz et al. (2020).

characters, under 4 or over 30 tokens (excluding punctuation marks) were removed. In the Arguments dataset, we also removed 10% of the comments that had the lowest quality, as predicted by the argument quality classifier. We did not apply this filter to the other datasets, as we found the quality predictions to be less indicative for their comments. Table 2 lists the number of topics and comments in the three datasets, before and after filtering.

When selecting key point candidates, we aimed to extract about 20% of the shorter, higher quality comments. Since the datasets vary in their characteristics, we adjusted the thresholds for each of them using the respective dev-set. We selected candidates of up to 12 tokens in Arguments and Reviews, and 10 for Survey. The argument quality thresholds were 0.7, 0.4 and 0.35 for Arguments, Survey and Reviews, respectively.

Finally, the key point selection algorithm requires a matching threshold (parameter t in Section 3.2). We tuned this parameter on the dev set of the Arguments dataset, and selected the threshold that maximized the F1, using the BM+TH selection policy. The best threshold (0.856), was used for both the Arguments and Surveys datasets, where key points were extracted for broad topics. The Reviews dataset, however, required finer granularity, as topics were specific aspects of products[9]. Therefore, its threshold was manually set to 0.999 after a few iterations of running the algorithm on the dev set and reviewing the results.

4.4 Human Evaluation

Annotation Process. Using the Appen crowd labeling platform[10], we annotated pairs of comments and key points for match. The instructions stated that *"A key point matches a comment if it captures the gist of the comment, or is directly supported by a point made in the comment"*. In addition to this binary choice, there was also an option to indicate that either key point or comment were not clear (which we considered as *no match* in our assessment). Each comment and key point pair was annotated by 7 crowd annotators. There were three variants of this task:

- Argumentative data - which presented the topic as the context for each comment and key point pair. It also included an additional question regarding the stance of the comment towards the topic, which we used for quality control.
- Survey data - which mentioned the general context in which the comments were written (a community survey about the city of Austin).
- Product review data - which presented product and review aspect as the context for each comment and key point pair.

For each variant, examples matching the type of data labeled were offered in the guidelines.

We employed the following measures to ensure the annotations quality:

- Annotator-κ score - a score measuring inter annotator agreement, averaging all pair-wise Cohen's Kappa for a given annotator, for any annotator sharing at least 50 judgements with at least 5 other annotators, as introduced in Toledo et al. (2019). Judgements of annotators with annotator-$\kappa < 0.1$ were ignored.
- Selected group of trusted annotators - access to the task was limited to a group of annotators with trusted quality, based on previous tasks that were performed for our team, as in Gretz et al. (2020).
- Hidden test questions - for the tasks on argumentative data, stance questions functioned as hidden test questions. As they are based on the *IBM-ArgQ-Rank-30kArgs* dataset, their stance was known. Annotators choosing the wrong stance in more than 15% of their annotations, were ignored.

We consider a pair as a match if it was labeled as a match by more than 50% of the annotators.

Annotations Consistency. Fleiss' Kappa for the match question on this task was 0.38. In the Arguments dataset, where stance was also labeled, stance Fleiss' Kappa was 0.86. Both were calculated prior to any filtering performed on the results.

Previous work has shown for a variety of NLP annotation tasks that while individual crowd annotations have lower quality than expert annotations, expert-level annotation quality can be achieved by aggregating over sufficient number of crowd annotations (Snow et al., 2008). Therefore, crowd annotation quality should be assessed primarily by considering the final, aggregated label.

To this end, we tested the consistency of the la-

---

[9] When using threshold 0.856, around 90% of the comments for most topics were clustered under a single key point.

[10] `https://appen.com/`

	Train		Dev		Test

Arguments	24	10,324/10,324	4	1,775/1,599	43	18,398/16,488
Survey	-	-	1	314/272	1	2,840/2,425
Reviews	-	-	10	1,208/1,094	41	5,878/4,845

Table 2: Number of topics and comments per dataset

beled results over different sets of annotators as follows: 300 random comment-key point pairs were selected from the Arguments dataset[11]. Each pair was annotated by 14 different annotators. Annotations for each pair were randomly split to two sets, such that each pair in each set had 7 annotations. After processing each set to produce majority labels, Cohen's Kappa obtained between the pair labels of each set was 0.63.

4.5 Results and Discussion

The results for the three datasets are summarized in Table 3. Fully automatic key point analysis is shown to perform well on the Arguments test set: precision of 0.752 and 0.792 when matching all the comments to 5 and 10 key points, respectively. When matching 60% of the comments, we achieve precision above 90%. Table 4 shows an example for key points generated for one of the topic+stance pairs in the Arguments datasets, and their distribution over the comments for that topic and stance.

We also compared our automatic key point extraction to the approach taken by (Bar-Haim et al., 2020), where key points were manually created by a debate expert. Following Bar-Haim et al., the expert composed 7 key points per topic+stance, based on his domain knowledge, and without being exposed to the comments. A total of 70 key points were composed, for 10 randomly-sampled topic+stance pairs from the test set. Comparing the results for these key points with our automatic results for the same number of key points shows that we were able to achieve similar precision (0.696 vs. 0.708) over all the comments (coverage of 100%). The precision for coverage of 80% is also comparable (0.8 vs. 0808). For lower coverage rates, the precision for the manual key points is higher.

To evaluate the similarity between our automatically extracted key points and the ones generated by the human expert, we attempted to match each automatic key point to an associated manually composed key point. Out of the 70 KPs, 10 were classified as *Matching* - the key points are essentially the same; 32 were *Related* - the key points reflect a similar point or one key point is entailed by the other; 16 were *Remote* - the key points are connected but there exists a distinct change that makes them different in essence, and only 12 were unrelated. These results suggest that the automatic process was able, to a large extent, to mimic the analysis of a human expert. We also found that manually composed key points tend to be more abstract, and in some cases a single manual point matched several more specific automatically extracted points.

Remarkably, our method, which makes use of models trained on argumentation data, performs reasonably well also when applied to survey and user reviews data. Presumably, the comments in these datasets also contain argumentation, which allows to transfer the knowledge learned from the argumentation dataset to these domains. The argumentation in the Arguments dataset is more explicit, though, as the contributors to this dataset were asked to provide pro and con arguments for the given controversial topics.

For the Survey dataset, we achieve precision of 0.763 when matching 60% of the comments in the labeled sample to 20 key points[12]. Table 5 shows KP analysis results for this coverage rate, including the extracted key points, their distribution, comment matching precision per key point, and the top two matching comments for each key point. While the extracted key points are largely concise and to the point, the results could be further improved with some manual post-processing. For example, the first KP can be rephrased as *"Reduce traffic congestion"*, removing the extra part about a monorail system, which is not mentioned in the top comments. We can then re-match the comments to the revised KPs, and the process can iterate, until both

---

[11] This dataset had the lowest Fleiss kappa of the three - 0.34. Survey dataset kappa was 0.41 and Reviews dataset kappa was 0.37

[12] We used here a larger number of key points since, unlike the other two datasets, the Survey test set contains a single topic with more than 2, 400 comments.

Table 3: Results for the Arguments, Survey, and Reviews datasets.

Key Point	**%**
People who have three minor offences are unfairly punished.	30%
The three strike law has not proved effective in reducing criminality	15%
The three strike law prohibits reform of offenders.	12%
Many people could pay long sentences for nonviolent crimes	12%
The three-strikes law has resulted in overcrowded prisons	8%
The 3 strikes law doesn't allow judicial discretion in sentencing	7%
The three-strikes law costs tax payers too much money.	6%
The three-strikes law is inequitable and targets men of color.	5%
The three strike law is too strict for some offenders	5%

Table 4: Top key points and their coverage for the topic *"We should abolish the three-strikes laws"* and *Pro* stance from the Arguments dataset, when generating up to 10 key points using the selection algorithm. After generating the key points list, each of the 267 comments is matched to a key point using the BM selection policy.

coverage and precision are satisfactory.

The precision over all the comments was 0.514. We note that key point analysis can be effectively applied even if the matching precision is not very high. For example, suppose that 10% of the comments were matched to a certain key point with precision of only 50%. This means that in practice, 5% of the comments do match this key point, so it is an important point nonetheless.

For the Reviews dataset, we selected two key points per topic, since this was the length of summaries in the experiments conducted by Ganesan et al. on this data. We compared our results to a configuration where the key point candidates are the union of the sentences in the human-generated gold summaries that were released as part of this dataset.

We obtained precision of 0.731 for coverage of 60%, and 0.568 for 100% coverage, better than the results for the key points that were based on the gold summaries (0.642 and 0.454, respectively). The precision differences in coverage levels of 0.6 and above are statistically significant[13]. Table 6 shows both the automatically extracted key points and the key points selected from human summaries, along with their coverage, for several selected topics.

Error Analysis. The dominant types of matching errors differed amongst the datasets. The most common type in Reviews data was the comment and KP having opposite polarity. This was expected, since in the ArgKP training data, the argument and the key point always have the same polarity. The highest proportion of comments that were not related to the key point was in the Survey dataset. This is likely an outcome of analyzing all the comments in this dataset under a single topic. The dominant issue in the Arguments dataset was key points that were related to the comment but had slight changes that altered their meaning. For example: *"if people have been committing crimes anyway, they deserve to be caught through whatever means necessary, including the use of entrapment."* was matched to *"sometimes the only way police can catch a criminal is by entrapment."*, where the phrase *"the only way"* was crucial for capturing the right meaning of the key point.

Table 6: Top two key points extracted from gold summaries and from original reviews, on selected topics from the Reviews dataset. For each key point we show the percentage of matching comments, with match threshold 0.999.

lenge for applying supervised learning to MDS has been the limited amount of available training data. Most of the approaches applied to the task were extractive, operating over graph-based representations of sentences or passages (Erkan and Radev, 2004; Christensen et al., 2013). Recently, Liu et al. (2018) proposed a method for creating a large-scale dataset from Wikipedia (WikiSum), which allowed training an abstractive neural model for this task. Key point analysis adds a quantitative dimension that is not addressed by MDS, by measuring the prevalence of each point in the summary.

Many of the works on Opinion Summarization take an alternative, sentiment-based approach. These works aim to identify the main aspects discussed in user reviews, and quantify the sentiment towards each of these aspects (Hu and Liu, 2004; Snyder and Barzilay, 2007; Titov and McDonald, 2008). However, as noted by Ganesan et al. (2010), it is still hard for a user to understand why an aspect received a particular rating. As demonstrated in Table 6, key points can address this limitation by providing a more informative summary of user reviews. However, the detection of the stance (or sentiment) of each key point with respect to the topic was left out of the scope of the current work, and we plan to address it in future work.

In computational argumentation, several works have focused on pairwise argument similarity and clustering (Ajjour et al., 2019; Reimers et al., 2019; Misra et al., 2016). These works, however, did not attempt to create textual summaries from the resulting clusters. Egan et al. (2016) summarized argumentative discussions through the extraction of salient "points", where each point is a verb and its syntactic arguments. The current work also extracts points from argumentative data, but our goal is to go beyond textual summaries, by matching each key point to its corresponding sentences in the input data. Similar to Egan et al., we also experimented with extracting syntactic subtrees as key points, but found that this often results in incomplete sentences or omission of important information. Selecting short, high quality sentences as key points was found to perform better in our experiments.

The line of research that is most relevant to the current work deals with matching argumentative texts to predefined, short lists of manually-composed arguments or points (Hasan and Ng, 2014; Boltužić and Šnajder, 2014; Naderi, 2016). Bar-Haim et al. (2020) matched crowd-contributed arguments, taken from the dataset of Gretz et al. (2020), to key points composed by a debate expert. We used the labeled dataset developed by Bar-Haim et al. to train our comment matching model.

As previously discussed, the main contributions we make to this line of work are (i) Fully-automatic key point analysis, enabled by automatic key point extraction, and (ii) Demonstrating the applicability of key point analysis to additional domains besides argumentation, including surveys and user reviews. Furthermore, we were able to achieve promising results on these domains using models that were only trained on argumentation data.

6 Conclusion

Key Point Analysis is a novel framework for summarizing arguments, opinions and views. It provides both textual and quantitative view of the main points in the summarized data, and allows the user to interactively drill down from points to the actual sentences they cover. Previous work only applied key point analysis in the context of argumentation data, and required a domain expert for writing the key points.

The current work addresses both of the above limitations. First, we present an automatic method for key point extraction, which is shown to perform on par with a human expert. Second, our work demonstrates the potential of key point analysis in multiple domains besides argumentation. Furthermore, we show that the necessary knowledge for key point analysis, once acquired by supervised learning from argumentation data, can be successfully applied cross-domain, making it unnecessary to collect domain specific labeled data for each target domain.

In future work, we would like to improve comment matching, e.g., by making it stance-aware. We also plan to experiment with sequence-to-sequence neural models for generating key point candidates from comments.

Unsupervised Stance Detection for Arguments from Consequences

Jonathan Kobbe, Ioana Hulpuş, Heiner Stuckenschmidt
University of Mannheim
`{jonathan,ioana,heiner}@informatik.uni-mannheim.de`

Abstract

Social media platforms have become an essential venue for online deliberation where users discuss arguments, debate, and form opinions. In this paper, we propose an unsupervised method to detect the stance of argumentative claims with respect to a topic. Most related work focuses on topic-specific supervised models that need to be trained for every emergent debate topic. To address this limitation, we propose a topic independent approach that focuses on a frequently encountered class of arguments, specifically, on arguments from consequences. We do this by extracting the effects that claims refer to, and proposing a means for inferring if the effect is a *good* or *bad* consequence. Our experiments provide promising results that are comparable to, and in particular regards even outperform BERT. Furthermore, we publish a novel dataset of arguments relating to consequences, annotated with Amazon Mechanical Turk.

1 Introduction

In the context of decision making it is crucial to compare positive and negative effects that result from a potential decision. Indeed, arguing for or against something because of its possible consequences is a frequent form of argumentation (Reisert et al., 2018; Al-Khatib et al., 2020). In this paper, we address the classical stance detection problem paying special attention to such arguments.

Stance detection, also called stance classification, is the task to decide whether a text is in favor of, against, or unrelated to a given topic. This problem is related to opinion mining, but while opinion mining focuses on the sentiment polarity explicitly expressed by a text, stance detection aims to determine the position that the text holds with respect to a topic that is generally more abstract and might not be mentioned in the text. As such, in stance detection, texts can transmit a negative sentiment or opinion, but be in favor of the targeted topic. For example, the text *Holocaust denial psychologically harms Holocaust survivors* expresses a negative opinion, but its stance towards *Criminalization of Holocaust denial* is positive.[1]

Recently, the problem of stance detection has received growing attention from the scientific community, as shown by the recent survey of Küçük and Can (2020). Most approaches tackle this problem by learning stance classification models for each topic. While this can achieve good results, new models need to be trained for each new topic of interest, generally entailing large annotation studies.

While we admit that a one-size-fits-all approach to stance detection is currently unfeasible, we take a different perspective. Rather than targeting topic-dependent models, we target a subclass of arguments. Specifically, we focus on arguments that have been classified by Walton et al. (2008) under the *argument from consequences* scheme. They contain a premise of the form *If A is brought about, then good (bad) consequences will (may plausibly) occur*, and a conclusion *A should (not) be brought about*. In most real-life arguments of this type, the consequences are expressed, but the interpretation that they are *good* or *bad*, as well as the conclusion, are most often implicit. The task of stance detection is then to determine if the argument is against or in favor of *A*. Our solution to find the stance of such arguments revolves around extracting and analyzing cause-effect relations in order to infer if the consequences are *good* or *bad*.

We conducted an Amazon Mechanical Turk (AMT) study, in which we crowdsourced annotations for 1894 arguments extracted from Debatepedia. We compared our system's performance

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 50–60,
November 16–20, 2020.

to a sentiment analysis baseline and a fine-tuned BERT model. The results show that our results are comparable and, in some settings, even better than BERT's.[2] Aside from not needing annotated training data, we stress the advantage of our approach for providing human-understandable explanations to the results, and to provide, as a by-product, cause-effect relations between concepts brought up in arguments.

The paper is structured as follows. Section 2 positions our contributions with respect to related literature. Section 3 presents our proposed approach. Section 4 describes our crowdsourced dataset, which we use in Section 5 to evaluate our approach. Lastly, Section 6 concludes the paper.

2 Related Work

Stance detection has been studied on various types of formal texts such as congressional debates (Thomas et al., 2006) and company-internal discussions (Murakami and Raymond, 2010). However, like most recent related work on the topic, we are particularly interested in informal texts from online social media.

The vast majority of previous approaches proposes supervised methods, using traditional machine learning algorithms (Somasundaran and Wiebe, 2010; Anand et al., 2011; Hasan and Ng, 2013; Faulkner, 2014; Sobhani et al., 2016; Addawood et al., 2017) and more recently, various deep neural networks architectures (Sun et al., 2018; Du et al., 2017; Dey et al., 2018; Ghosh et al., 2019). These approaches, most of which have been triggered by a recent SemEval shared task[3] (Mohammad et al., 2016), learn topic-specific models. Thus, new topics require new models whose training entails large user annotation studies. In contrast, we propose a fully unsupervised, topic-independent method, and rather target a particular but frequent class of claims, those that refer to consequences.

Among the unsupervised approaches, the most prominent one is this of Somasundaran and Wiebe (2009), which got extended by Konjengbam et al. (2018) and Ghosh et al. (2018). However, they focus on non-ideological topics (usually products, e.g., *iPhone vs. Galaxy*). In contrast, we target ideological topics (e.g., *Gay Marriage, Abortion*) whose stance is harder to detect due to less frequent use of sentiment words and a wider variety of brought up issues and arguments (Rajendran et al., 2016; Wang et al., 2019). On the one hand, these works extract topic aspects (e.g., *screen resolution, battery*) and polarities towards these aspects, a step that is unfeasible for ideological topics. On the other hand, like these works, we also use syntactic rules, but not for pairing aspects to opinions, but for extracting triples that correspond to statements about effects over opinion words.

Another class of stance detection approaches uses the context of the post, such as its relations to other posts in the debate, the network of authors, or the author's identity (Hasan and Ng, 2013; Sridhar et al., 2014; Addawood et al., 2017; Bar-Haim et al., 2017b). By contrast, we target claim-topic pairs in isolation.

Another aspect that sets our work apart from most related work is that, except for the approaches that target tweets, most focus on longer texts while we consider short, one-sentence claims. In this regard, but not only, the stance detection work that is closest to ours is the partly supervised system of Bar-Haim et al. (2017a). They also propose a topic-independent solution to stance detection for short claims without considering context, but they do not specifically address arguments from consequences. While they follow a similar sequence of steps as we do, they propose different approaches for each step. For instance, they propose a supervised approach to detect the target of a claim's opinion, while we do it in an unsupervised manner. They focus primarily on detecting contrastive relations between phrases, while our focus is on detecting effects. In this last regard, the works can be considered complementary.

Regarding the analysis of arguments from consequences, Reisert et al. (2018) provide and use scheme dependent templates to analyze the structure of arguments. Their work is rather conceptual and focuses on annotations. Very recently, Al-Khatib et al. (2020) built, on similar intuitions as ours, an approach for creating argumentation knowledge graphs based on cause-effect relations. Their work comes to reinforce the usefulness of addressing arguments from consequences.

To sum up, our contribution is three-fold: (i) we propose a fully unsupervised approach for stance detection, focusing on arguments that refer to consequences; (ii) we define rules over grammatical dependencies that exploit sentiment as well as ef-

---

[3] `http://alt.qcri.org/semeval2016/task6`

fect words in order to determine *good* and *bad* consequences; (iii) we publish a new stance detection dataset that labels claims that refer to consequences, and which was crowdsourced on AMT.

3 Our Approach

Given an argumentative claim and a topic, our task is to detect the stance that the claim has with respect to the topic. Statements such as the claim or topic usually express a positive (favorable) or negative (unfavorable) position to a concept that we call the **target**. As such, the target is a phrase that belongs to the statement. In the example shown in Table 1, the target of both topic and claim is *medical marijuana*. Our solution starts by first determining the stance of the claim and of the topic towards their respective targets T_c and T_t. We then use these stances and the semantic relation between the targets to determine the claim's stance towards the topic.

Topic:	Medical marijuana dispensaries
Claim:	Legalizing medical marijuana does not increase use and abuse

Table 1: Example of topic-claim pair

The overarching intuition behind our approach is that when the stance of a statement towards its target is favorable, the text either highlights the desirable consequences of the target being brought about (e.g., *Electing an EU president directly will increase accountability*), or it highlights the negative consequences if the target is not brought about (e.g., *Sinking organic blooms can render the deep sea anoxic*).

At the core of our approach resides what we call the **effect triple**. The effect triple is a triple of the form $< (T, dir), (P, \mathit{eff}), (O, sent) >$. The (T, dir) pair represents the target T of the statement and if the statement refers to a magnification ($dir = 1$) (e.g. *legalizing medical marijuana*), or a reduction ($dir = -1$) of the target (e.g. *banning medical marijuana*). The (P, eff) pair represents the predicate P that has T as the subject, together with the effect eff that it has over the object O. The effect can be positive ($\mathit{eff} = +1$) or negative ($\mathit{eff} = -1$). Lastly, the $(O, sent)$ pair represents the object over which T has the effect P. We expect the *sentiment* of an object to reflect whether it is generally regarded as *a good thing* ($sent = +1$) or *a bad thing* ($sent = -1$).

Our approach's core idea is to distill such an effect triple from the claim and use it to infer the claim's stance towards T_c. We further determine (T_t, dir) to infer the topic's stance towards T_t. Using these stances, together with the relation between the claim's and the topic's target, we finally decide the claim's stance with respect to the topic. We now describe the lexicons we use as well as each of these steps in more detail.

3.1 Lexicons

For determining dir, eff, and $sent$, we use an effect verb lexicon and a sentiment lexicon that we describe in the following.

The ECF Effect Lexicon To identify verbs and nominalized verbs that indicate effects on their direct objects, we extend the connotation frames (Rashkin et al., 2016). The connotation frames lexicon consists of a list of 947 verbs, manually annotated with values in the $[-1, 1]$ range, indicating if the verb implies a positive or negative effect over its object. We consider the entries with scores in the range $[-0.1, 0.1]$ as a neutral effect (e.g., *use, say, seem*), and we filter them out. We call the 845 remaining words in the lexicon **effect words**. We extend the list of effect words by adding all words in the same WordNet (Fellbaum, 2010) synset as the effect words, as long as there is no contradiction. A contradiction occurs when a new candidate effect word shares a synset with both a negative and a positive effect word. This way, we obtain 2508 effect words. We call this lexicon the extended connotation frames lexicon (ECF). As ECF only contains verbs, we use it via the stems of the words, mainly to also get the effects of nominalized verbs. In our experiments, we compare the performance of this lexicon with +/-EffectWordNet (Choi and Wiebe, 2014)(EWN).

The Sentiment Lexicon In order to determine if the object of the effect is something *good* or *bad*, we combine several commonly used sentiment lexicons: (i) the MPQA lexicon[4] (Wilson et al., 2005), (ii) the opinion lexicon of Hu and Liu (2004), and (iii) the sentiment lexicon of Toledo-Ronen et al. (2018) (uni- and bigrams, using a threshold of ±0.2). The composed lexicon contains sentiment values in the range $[-1, 1]$.

---

[4] We used an American English dictionary to correct orthographic mistakes resp. to add American English versions of British English words.

For many words, the polarities of their sentiment and of their effect are the same (e.g., *kill, love*). Still, there are important exceptions, such as *reduce*, which has neutral sentiment but indicates a negative effect, or *conquer*, which has a slightly positive sentiment but indicates a negative effect.

3.2 Effect Triple Extraction

Target Identification To detect the targets of the claim (T_c) and topic (T_t), we assume that T_c is semantically related to the topic, or more specifically, to T_t. Thus, we identify T_c and T_t simultaneously by following three strategies. The use of the second and third strategies is conditioned on the previous strategies to have failed to identify a pair of targets. First, we look for a pair of nouns that are identical or have the same lemma. We use Stanford Core NLP (Manning et al., 2014) for POS tagging and lemmatizing. Second, we look for a pair consisting of an acronym (e.g., *ICC*) and a word sequence whose first letters form the acronym (e.g., *International Criminal Court*). Third, we look for pairs of nouns that are synonyms or antonyms according to *Thesaurus.plus*[5].

Besides returning T_c and T_t, we also return a value $r = +1$ if the two targets have been found to be synonyms and $r = -1$ if they are antonyms. Thus, first and second strategies only return $r = 1$ while the third strategy returns 1 or -1.

Target Direction Determination As described earlier, each target is accompanied by a dir value which indicates if the statement refers to a phenomenon of amplification or reduction of the target. We detect this by searching for a word whose object is the target by using Patterns 1 and 2 shown in Table 2. The word is then looked-up in the effect lexicon. If a negative effect is found, then $dir = -1$, otherwise $dir = 1$. We call the word the *target effector*, or just *effector*. In the claim in Table 1, the effector is *legalizing* and expresses an amplification of the target ($dir = 1$).

Detecting Predicates and Their Effects Effect words are commonly used in arguments from consequences to express a (potential) effect that the target has or might have over another object. For example, in the claim in Table 1, the effect word *increase* expresses a positive effect that the (amplified) target has over the objects *use, abuse*.

We detect this effect of the target by using Pattern 3 to find a predicate whose subject is either the target or its effector, and by looking up this predicate in the effect lexicon. We thereby set *eff* to 1 or -1, depending on if the effect is positive or negative. In our running example, the $(P, \textit{eff})$ pair becomes $(\textit{increase}, -1)$ because of the negation, as we explain below.

Telling *good* from *bad* The last effect triple component we detect is $(O, sent)$. To this end, we search the dependency graph for instantiations of Patterns 1 or 2, where P is the predicate that has been detected to express the target's effect. If such an object is found, we use the sentiment lexicon by first searching for the exact word and, if not available, for the word's lemma. We set $sent$ to -1 if the word bears a negative sentiment or to 1 otherwise. In our example, the $(O, sent)$ pair becomes $(abuse, -1)$ because the word *use* is neutral per se.

The sentiment of a word is overwritten by the sentiment of its modifiers, as shown in Pattern 4 in Table 2. In the provided example in the table, one can see that the modifier *terrorist* dominates the sentiment of the positive word *haven*. Consequently, both *terrorist haven* and *terrorist attack* are considered generally bad.

Negation We deal with negations for each effect triple component. We identify negations by looking for Patterns 5, 6, and 7, as shown in Table 2. Patterns 5 and 6 make use of a manually created list of all negative English prepositions[6]. The existence of a negation affecting the target, predicate, or object toggles the sign of the corresponding value - dir, *eff* or $sent$, respectively.

3.3 Inferring the Stance Towards the Target

To infer the stance that a statement expresses towards its target, we use the intuition that the stance is unfavorable when the text expresses negative consequences of the target, and positive otherwise. Thus, we define that the stance towards the target is positive in exactly the following four cases: (i) the target's amplification implies a positive effect over something good (dir = *eff* = $sent$ = $+1$); (ii) the target's amplification implies a negative effect over something bad (dir = $+1$, *eff* = $sent$ = -1); (iii) the target's reduction implies a negative effect over something

---

[5] We use only the synonyms and antonyms shown at `https://thesaurus.plus/thesaurus/xxx` where `xxx` is a placeholder for concrete words

[6] Those are *except, less, minus, opposite, sans, unlike, versus, without, w/o, vice, instead (of), lack.*

	Pattern	*Interpretation*	*Example*
1	$P \overset{*}{\to} O$	P has object O	Insurance mandates violate the rights of employers. dobj
2	$P \xrightarrow{prep} ? \xrightarrow{pobj} O$	P has object O	The military industrial complex profits from escalation in Afg. prep pobj
3	$P \overset{\diamond}{\to} S$	P has subject S	Holocaust denial is inherently descriminatory and damaging. nsubj
4	$X \overset{\dagger}{\to} M, \mathit{sent}(M) \neq 0$	$\mathit{sent}(X) := \mathit{sent}(M)$	W/o more troops, Afgh will become terrorist haven amod
5	$NegP \xrightarrow{pobj} X$	X is negated	Free speech without Fairness Doctrine can harm policy-making pobj
6	$X \to NegP, \nexists NegP \xrightarrow{pobj}$	X is negated	W/o more troops, Afgh will become terrorist haven nn
7	$X \xrightarrow{neg}$	X is negated	Solar energy does not damage air quality. neg

Table 2: Dependency graph patterns. $* \in \{dobj, nsubjpass, cobj, csubjpass, nmod, xcomp\}$; $\diamond \in \{nsubj, csubj\}$; $\dagger \in \{amod, nn, advmod\}$; *NegP* stands for *negative preposition*

good (*dir* = *eff* = -1, *sent* = $+1$); (iv) the target's reduction implies a positive effect over something bad (*dir* = $+1$, *eff* = -1, *sent* = $+1$). Hence, the stance is favorable towards the target if the multiplication of the three components' values is $+1$. Consequently, we define the stance of a statement towards the target as $s = dir \cdot \mathit{eff} \cdot val$ and interpret $s = 1$ as *In favor* and $s = -1$ as *Against*.

3.4 Inferring the Stance of the Claim Towards the Topic

The steps above can be executed analogously for the claim and the topic. However, due to the nature of the text expressing the topic, we only aim to extract an effect triple from the claim. For the topic, we detect its target and set the stance to its corresponding dir value. We denote the stances of the claim and topic towards their respective targets as s_c and s_t. To infer the claim's stance towards the topic, we need to consider the relation between T_c and T_t, i.e., the value of r as described in Section 3.2. We then define the final result of the analysis as $\Pi = s_c \cdot s_t \cdot r$.

Table 3 presents further examples of how our approach detects the stance of the claim towards the topic. As illustrated in the examples, the straightforward interpretability of the stance detection process can be easily used for producing human-readable explanations for the returned results. This is particularly relevant for helping users get more control over the process, particularly in light of subsequent applications on top of stance detection.

	Porn watching may actually reduce rape rates	**Pornography**
T, *dir* P, *eff* O, *sent*	*Porn*, $+1$ *reduce*, -1 *rape rates*, -1	*Pornography*, $+1$
s	1	1
r	1	
Π	1 (In favor)	

	Holocaust denial psychologically harms Holocaust survivors	**Criminalization of Holocaust denial**
T, *dir* P, *eff* O, *sent*	*Holocaust denial*, 1 *harms*, -1 *survivors*, $+1$	*Hol. denial*, -1
s	-1	-1
r	1	
Π	1 (In favor)	

Table 3: Worked out Examples

3.5 Alternative Strategies

We denote the process in which all the previous steps are fulfilled and an effect triple is extracted as **TPO**. However, due to a variety of reasons that we analyze in Section 5.4, we might fail to extract a complete effect triple. One such case is when an adjective expresses an effect, for instance, *Holocaust denial is discriminatory*. For that reason, if we identify T and P, but not O, we set *eff* to the sentiment polarity of P, and *sent* to $+1$ by default. We refer to this strategy as **TP**.

Another potential situation is that the system detects (P, eff) and (O, sent), but it can not relate them to T. One cause can be that we fail to identify T. If so, $dir = +1$ by default. Another cause can be that T is found, but we can not infer its relation to P. In this case, we consider that the identified target is the subject of P and set (T, dir) accordingly. We refer to this strategy as **PO**.

Lastly, if all above strategies fail to create an effect triple, we use a heuristic: if T was found, dir is set accordingly. Otherwise $dir = 1$ by default. For the remaining words in the statement, we check their sentiment score, still using Pattern 4, toggling the sign if it is negated. The sum of the sentiment scores is then multiplied with dir. The stance is considered favorable or not depending on the sign of the result. We refer to this strategy as **Heuristic**.

4 Dataset Generation

To evaluate our approach, we need stance annotated topic-claim pairs, as well as annotations if the topic-claim pair refers to a consequence or not.

4.1 Data Collection

To create such a corpus, we run an AMT crowdsourcing study, where we annotate claims and topics extracted from Debatepedia[7]. We only use the 236 *Featured Debate Digest articles* as they are of higher quality. They contain more than 10,000 arguments labeled by their author as either pro or con the debate's topic. Usually, the arguments start with a bolded, one-sentence summary, which serves as the argument's claim. We exclusively use these claims and pair them to the debate's topic. We exclude 16 debates whose topics contain *vs* or *or* (e.g. *Democrats vs. Republicans*), and 30 debates without a title question. To create a balanced dataset that covers a large variety of topics, we randomly selected 5 pro and 5 con arguments of each debate. If a debate contains less than 5 pro and 5 con arguments, we select the maximum equal number of pro and con arguments. We obtain 190 different topics and 1894 arguments.

4.2 Crowdsourcing Study

The annotation task consisted of the debate's topic, one of its claims, and two questions. The first question was to select the stance of the claim towards the topic, out of the following choices: *in favor, against, neither* and *I don't know*. Although we have the original arguments' stances, this question helps us check how clear the claim is when taken out of the debate's context. The second question was whether the claim refers to a consequence related to the topic, with possible answers *yes, no* and *I don't know*. Each topic-claim pair was annotated by 10 annotators living in the US with a HIT approval rate greater than 98% and more than 10,000 approved HITs in total. Overall, 277 annotators worked on the task.

Valid Annotations	*Stance* rate	κ	κ'	*Consequence* rate	κ	κ'
6	.002	-.10	-.20	.001	-.17	-1
7	.013	.11	.15	.008	.04	.10
8	.051	.24	.32	.036	.06	.24
9	.183	.34	.58	.207	.23	.44
10	.751	.52	.74	.748	.25	.58
Weight. Avg		.47	.68		.24	.53

Table 4: Fleiss' Kappa dependent on the number of valid annotations

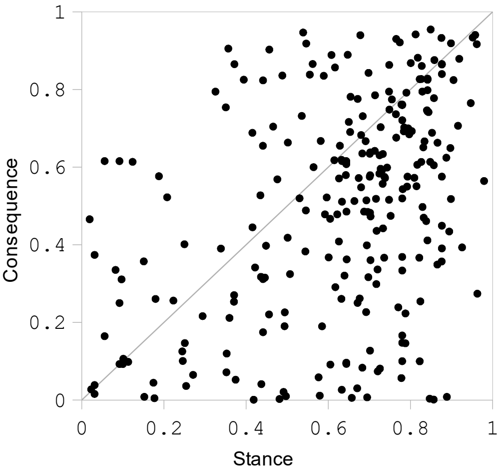

Figure 1: Reliability of annotators according to MACE: The higher the score, the more reliable the annotator is.

4.3 Agreement and Reliability

Table 4 shows the inter-annotator agreement per number of valid annotations, i.e., annotations that are not *I don't know*. Since we have many annotators, Fleiss κ is particularly low on consequence annotation, but still indicates higher agreement than random. To give an agreement estimate less sensitive to individual outliers, we also compute κ' as the Fleiss kappa between two "experts", where each expert brings together half of the number of annotators and its annotation is decided with MACE (Hovy et al., 2013).

Figure 1 shows the reliability of individual annotators. Although there is a weak correlation among the reliability of the two tasks (Pearson .41), some annotators are quite reliable in annotating stances, but highly unreliable in annotating consequences. This indicates that the latter task was unclear to some of the annotators. To understand why the annotators usually disagree, we investigated such

---

[7] `http://www.debatepedia.org`

instances and identified several possible reasons:

Complexity In the topic-claim pair *Criminalization of Holocaust denial – Danger of public accepting holocaust denial should be fought by logic*, both topic and claim have a negative stance towards *holocaust denial*, which suggests the label *in favor*. Still, by proposing a different solution than *criminalization*, the claim is *against* the topic.

Missing Background Knowledge Many arguments involve non-trivial background knowledge: *Israeli military assault in Gaza – Hamas was first to escalate conflict following end of ceasefire*.

Ambiguity According to the pair *2009 US economic stimulus – Stimulus risks being too small not too large*, a small stimulus is bad while an appropriate stimulus is good.

Ethical Judgement Different judgments on what is good and bad can lead to different stance labels: *Ban on human reproductive cloning – Cloning will involve the creation of children for predetermined roles*.

Lack of Conceptual Clarity Especially deciding whether the claim refers to a consequence related to the topic can be a matter of judgment. For example, in *Health insurance mandates – Insurance mandates violate the rights of employers*, the violation of rights can be seen as a consequence or as a property of insurance mandates.

4.4 Final Dataset

To account for unreliable annotators, we compute the annotation result with MACE. As such, we find that for 81.36% of the annotated arguments, the stance label obtained via MACE is the same as the original stance label. By comparison, the majority vote matches 79.30% of the original stance labels. Since disagreements between the MACE annotation and the original stance might indicate that the claim's stance is unclear outside the debate's context, we exclude from the dataset all such pairs. For example, the original label of the pair *Is Wikipedia valuable? – Wikipedia is online and interactive, unlike other encyclopedias* is *con*, because, in its context, it was discussed whether Wikipedia is an encyclopedia or not. In contrast, the result of our annotation is *pro*. Since the original labels are only *pro* or *con*, all pairs that our study determined as *neither* are removed. This filter resulted in a total of 1502 pairs, out of which 822 have been annotated to relate to consequences.

conseq		*other*		*debate*		*wiki*

Table 5: Class distributions

5 Evaluation

5.1 Data

We report results both on the 822 pairs that relate to consequences, denoted by *conseq*, and on the rest of the pairs, denoted by *other*, as well as on their union, denoted by *debate*.

For checking the performance of the systems on an independent dataset, we also use the claim stance dataset[8] published by Bar-Haim et al. (2017a). This dataset contains 55 topics of *idebate*[9] and 2394 manually collected claims from Wikipedia. We denote this dataset by *wiki*. As Bar-Haim et al. (2017a,b) do, when working with this dataset, we use only the topic's target and not the entire topic to ensure comparability.

Table 5 shows the class distribution of the datasets.

5.2 Compared systems

We evaluate our system with the effect lexicon lexicon that we describe in Section 3.1 (**ECF**), as well as with the +/-EffectWordNet (**EWN**). For comparison, we implement two other approaches:

sent As a baseline, we use a system that simply sums up all the sentiment scores in the claim. For the *wiki* dataset, the sign is switched if the topic sentiment is negative.

BERT As state of the art, we use BERT (Devlin et al., 2019), which was recently shown to outperform a series of alternative stance detection systems (Ghosh et al., 2019). We fine-tune BERT using the large, uncased pre-trained weights.[10] Just as Schiller et al. (2020), we set the number of epochs to 5 and the batch size to 16. The input are topic-claim pairs. We perform 10-fold cross-validation with a train-dev-test ratio of (70/20/10), ensuring that each topic exclusively occurs in one set.

5.3 Results and Discussion

The results that compare our system to BERT and the sentiment detection baseline are presented in

our system EWN	.70	.72	.71	.71	.66	.53	.60	.61	.68	.64	.66	.66	.64	.61	.63	.63

Table 6: Experimental results. F1 scores per stance class (*pro* and *con*), macro-F1 (*mac*), and Accuracy (*acc*). For *BERT*, we show the mean of the respective cross-validation results and their standard deviation.

Table 6. First, as expected, our system performs better on arguments related to consequences than on other arguments, with a macro-F1 difference of 10pp between *conseq* and *other*. Further, our system with both lexicon settings consistently outperforms the *sent* baseline, but its macro-F1 score is outperformed by BERT on *conseq* and *wiki*, and its accuracy is outperformed by BERT on all datasets. This is not surprising, given that we use BERT pre-trained and then fine-tuned to our data. Interestingly, our system with ECF achieves better results than BERT in terms of macro F1 score on the arguments that are *not* related to consequences (*other*), and on the complete *debate* dataset. This indicates that our method can deal reasonably well with arguments that are not from consequences.

Concerning the two stance classes, with both lexicon settings, our system is better than BERT at predicting the *pro* class in arguments from consequences, but is outperformed on the *con* class. Another interesting result is that on *conseq*, our system has a quite similar performance on the *pro* and *con* classes with both lexicon settings . In contrast, BERT's performance varies drastically, with a difference of approximately 17pp in favor of the *con* class. BERT's high variability is also indicated by the high standard deviation on the 10 folds. For comparison, we also computed the F1 macro standard deviation of our system with ECF when run on the same 10 folds, and the values lie between .03 on *debate* and .07 on *conseq*. This indicates that our unsupervised approach is more robust with more predictable performance.

Concerning the two effect lexicons, our system performs consistently better when using ECF than when using EWN. Our analysis indicates that the high coverage of the EWN lexicon comes at the expense of accuracy. Therefore, in the following, we will only refer to our system using ECF.

	conseq		**other**		**debate**		**wiki**	
	r	F1	r	F1	r	F1	r	F1

-Syn/Ant	.05	.69	.03	.50	.04	.64	.11	.66
TPO/TP/PO	.60	.76	.39	.64	.51	.72	.54	.67
-TPO	.23	.74	.05	.65	.15	.73	.07	.81
-TP	.21	.84	.18	.74	.20	.80	.10	.77
-PO	.16	.69	.16	.53	.16	.62	.36	.62
Heuristic	.40	.68	.61	.61	.49	.65	.46	.61

Table 7: Evaluation of the target identification and stance detection strategies; r denotes the rate of data instances.

Regarding the two datasets *debate* and *wiki*, BERT outperforms our system, with quite a high margin particularly on the *wiki* data. The accuracy that Bar-Haim et al. (2017a,b) report on the *wiki* data, when no context features are used, is .68 which is lower than BERT's (.70) but higher than ours (.65 for evaluating on the dedicated test set). This is not surprising given that the data contains general arguments. Nevertheless, as our approach only targets a subclass of these arguments, the results are quite promising. Unfortunately, Bar-Haim et al. (2017a,b)'s system is proprietary and we could not evaluate it on our *conseq* data.

Table 7 provides further insights into our solution. First, on all Debatepedia based datasets, we find a target in more than .75 of the data instances, and overall, the results are slightly better when a target is found. Most of the targets are found by word similarity and the fewest by the acronym. The results obtained on the instances where the target was found by synonym/antonym relations are significantly lower than those obtained when the target was found with the other two strategies. This indicates that the approach is sensitive to semantic drift in target identification.

Overall, we identify a potential consequence (*TPO/TP/PO*) for .6 of the arguments in *conseq*.

While the results are quite good on all datasets when we detect a complete effect triple (*TPO*), they are overtaken by results of the *TP* cases. Together, the instances solved with *TPO* and *TP* strategies amount to .44 of the *conseq* dataset but to much lower on the other datasets (e.g., only .17 on the *wiki*). The performance on the *PO* cases is comparable to the performance on the *Heuristic* cases, and significantly lower than when *TPO* or *TP* could be applied. Depending on the dataset, the system needed to apply the Heuristic strategy on .4 to .61 of the instances. Our efforts for future work are directed towards helping the system make sense of more of the claims so that the number of times it needs to fallback to *PO* and *Heuristic* are reduced.

5.4 Error Analysis

To better understand the limitations of our approach, we analyzed the errors on the *conseq* data and found several reasons for wrong predictions:

Incomplete list of patterns Some arguments cannot be meaningfully analyzed with our current list of patterns. We plan to extend this list with more complex patterns, while we are also working on automatically learning such patterns from data.

Conceptual errors We assume that positive effects on something negative result in something negative (e.g., *War in Iraq has helped terrorist recruitment.*). However, this is not always the case (e.g., *Privatizing social security helps the poor.*).

Finding the targets As shown in Table 7, we often fail to detect targets. For example, our target detection strategies fail on the claim-topic pair *Standardized tests ensure students learn essential information. – No Child Left Behind Act*. In this specific case, there is a hypernym relation between the topic and *Standardized tests*. Further, we found that our straightforward approach to identifying targets and the relations between them is one of the core reasons for our approach's poorer performance on the *wiki* data compared to the *debate* data. Improving the target finding strategy by leveraging additional semantic knowledge is one of the core directions for our future work.

Missing / wrong lexicon entries For many words, we are missing an entry in our lexicons, or the entry exists but is questionable. For instance, in the sentiment lexicon, *Palestinian* is annotated with a negative sentiment. Also, sometimes the effect on the object seems to be mixed up with the word's overall effect. For example, *solve* has a positive effect on the object in both ECF and EWN lexicons, but arguably when a problem is *solved*, it undergoes a reduction (e.g. *Reforestation,[...] can help solve global warming*).

Ambiguity Some words have a positive or negative effect depending on the sense with which they are used (e.g., *push* vs. *push for*). In the effect lexicon, we have only one entry per word. In the EWN, there are multiple senses, but we always use the most probable effect. Word sense disambiguation is required for these cases, which is known to be very challenging for verbs. However, a potential solution could be to annotate VerbNet frames with effects, but this is outside the scope of this work.

Text parsing errors As our method relies on the output of the dependency parser, the Lemmatizer, the POS tagger, and the Stemmer, their errors naturally propagate.

6 Conclusion and Future Work

We propose a fully unsupervised method to detect the stance of arguments from consequences in online debates. The method exploits grammatical dependencies and lexicons to identify effect words and their impact. For our evaluation, we annotated arguments from *Debatepedia* regarding their stance and whether they involve consequences or not. The results we obtained are motivating. Our method is comparable to BERT while being more robust.

Besides the future extensions of this approach that we mentioned in our results discussion and error analysis, this work opens several interesting research paths. Mainly, its good performance on the claims that refer to consequences reinforces our intuition that designing systems tailored for particular argumentation schemes might be a good alternative to topic-specific models. Therefore, we plan to complement this work with approaches for other frequently applied schemes such as *arguments by expert opinion* and *arguments by example*.

BLEU might be Guilty but References are not Innocent

Abstract

The quality of automatic metrics for machine translation has been increasingly called into question, especially for high-quality systems. This paper demonstrates that, while choice of metric is important, the nature of the references is also critical. We study different methods to collect references and compare their value in automated evaluation by reporting correlation with human evaluation for a variety of systems and metrics. Motivated by the finding that typical references exhibit poor diversity, concentrating around *translationese* language, we develop a paraphrasing task for linguists to perform on existing reference translations, which counteracts this bias. Our method yields higher correlation with human judgment not only for the submissions of WMT 2019 English→German, but also for Back-translation and APE augmented MT output, which have been shown to have low correlation with automatic metrics using standard references. We demonstrate that our methodology improves correlation with all modern evaluation metrics we look at, including embedding-based methods. To complete this picture, we reveal that multi-reference BLEU does not improve the correlation for high quality output, and present an alternative multi-reference formulation that is more effective.

1 Introduction

Machine Translation (MT) quality has greatly improved in recent years (Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017). This progress has cast doubt on the reliability of automated metrics, especially in the high accuracy regime. For instance, the WMT English→German evaluation in the last two years had a different top system when looking at automated or human evaluation (Bojar et al., 2018; Barrault et al., 2019). Such discrepancies have also been observed in the past, especially when comparing rule-based and statistical systems (Bojar et al., 2016b; Koehn and Monz, 2006; Callison-Burch et al., 2006).

Automated evaluations are however of crucial importance, especially for system development. Most decisions for architecture selection, hyperparameter search and data filtering rely on automated evaluation at a pace and scale that would not be sustainable with human evaluations. Automated evaluation (Koehn, 2010; Papineni et al., 2002) typically relies on two crucial ingredients: a metric and a reference translation. Metrics generally measure the quality of a translation by assessing the overlap between the system output and the reference translation. Different overlap metrics have been proposed, aiming to improve correlation between human and automated evaluations. Such metrics range from n-gram matching, e.g. BLEU (Papineni et al., 2002), to accounting for synonyms, e.g. METEOR (Banerjee and Lavie, 2005), to considering distributed word representation, e.g. BERTScore (Zhang et al., 2019). Orthogonal to metric quality (Ma et al., 2019), reference quality is also essential in improving correlation between human and automated evaluation.

This work studies how different reference collection methods impact the reliability of automatic evaluation. It also highlights that the reference sentences typically collected with current (human) translation methodology are biased to assign higher automatic scores to MT output that share a similar style as the reference. Human translators tend to generate translation which exhibit *translationese* language, i.e. sentences with source artifacts (Koppel and Ordan, 2011). This is problematic because collecting only a single style of references fails to reward systems that might produce alternative but equally accurate translations (Popović, 2019). Because of this lack of diversity, multi-reference evaluations like multi-reference BLEU are also bi-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 61–71,
November 16–20, 2020. ©2020 Association for Computational Linguistics

ased to prefer that specific style of translation.

As a better solution, we show that paraphrasing translations, when done carefully, can improve the quality of automated evaluations more broadly. Paraphrased translations increase diversity and steer evaluation away from rewarding translation artifacts. Experiments with the official submissions of WMT 2019 English→German for a variety of different metrics demonstrate the increased correlation with human judgement. Further, we run additional experiments for MT systems that are known to have low correlation with automatic metrics calculated with standard references. In particular, we investigated MT systems augmented with either back-translation or automatic post-editing (APE). We show that paraphrased references overcome the problems of automatic metrics and generate the same order as human ratings.

Our contributions are four-fold: (i) We collect different types of references on the same test set and show that it is possible to report strong correlation between automated evaluation with human metrics, even for high accuracy systems. (ii) We gather more natural and diverse valid translations by collecting human paraphrases of reference translations. We show that (human) paraphrases correlate well with human judgments when used as reference in automatic evaluations. (iii) We present an alternative multi-reference formulation that is more effective than multi reference BLEU for high quality output. (iv) We release[1] a rich set of diverse references to encourage research in systems producing other types of translations, and reward a wider range of generated language.

2 Related Work

Evaluation of machine translation is of crucial importance for system development and deployment decisions (Moorkens et al., 2018). Human evaluation typically reports adequacy of translations, often complemented with fluency scores (White, 1994; Graham et al., 2013). Evaluation by human raters can be conducted through system comparisons, *rankings* (Bojar et al., 2016a), or absolute judgments, *direct assessments* (Graham et al., 2013). Absolute judgments allow one to efficiently compare a large number of systems. The evaluation of translations as isolated sentences, full paragraphs or documents is also an important factor in the cost/quality trade-offs (Carpuat and Simard, 2012). Isolated sentence evaluation is generally more efficient but fails to penalize contextual mistakes (Tu et al., 2018; Hardmeier et al., 2015).

Automatic evaluation typically collects human reference translations and relies on an *automatic metric* to compare human references to system outputs. Automatic metrics typically measure the overlap between references and system outputs. A wide variety of metrics has been proposed, and automated metrics is still an active area of research. BLEU (Papineni et al., 2002) is the most common metric. It measures the geometric average of the precision over hypothesis n-grams with an additional penalty to discourage short translations. NIST (Doddington, 2002) is similar but considers up-weighting rare, informative n-grams. TER (Snover et al., 2006) measures an edit distance, as a way to estimate the amount of work to post-edit the hypothesis into the reference. METEOR (Banerjee and Lavie, 2005) suggested rewarding n-gram beyond exact matches, considering synonyms. Others are proposing to use contextualized word embeddings, like BERTscore (Zhang et al., 2019). Rewarding multiple alternative formulations is also the primary motivation behind multiple-reference based evaluation (Nießen et al., 2000). Dreyer and Marcu (2012) introduced an annotation tool and process that can be used to create meaning-equivalent networks that encode an exponential number of translations for a given sentence. Orthogonal to the number of references, the quality of the reference translations is also essential to the reliability of automated evaluation (Zbib et al., 2013). This topic itself raises the question of human translation assessment, which is beyond the scope of this paper (Moorkens et al., 2018).

Meta-evaluation studies the correlation between human assessments and automatic evaluations (Callison-Burch et al., 2006, 2008; Callison-Burch, 2009). Indeed, automatic evaluation is useful only if it rewards hypotheses perceived as fluent and adequate by a human. Interestingly, previous work (Bojar et al., 2016a) has shown that a higher correlation can be achieved when comparing similar systems than when comparing different types of systems, e.g. phrase-based vs neural vs rule-based. In particular, rule-based systems can be penalized as they produce less common translations, even when such translations are fluent and adequate. Similarly, recent benchmark results comparing neu-

---

[1] `https://github.com/google/wmt19-paraphrased-references`

ral systems on high resource languages (Bojar et al., 2018; Barrault et al., 2019) have shown mismatches between the systems with highest BLEU score and the systems faring the best in human evaluations. Freitag et al. (2019); Edunov et al. (2019) study this mismatch in the context of systems trained with back-translation (Sennrich et al., 2016) and noisy back-translation (Edunov et al., 2018). They observe that systems training with or without back-translation (BT) can reach a similar level of overlap (BLEU) with the reference, but hypotheses from BT systems are more fluent, both measured by humans and by a language model (LM). They suggest considering LM scores in addition to BLEU.

Freitag et al. (2019); Edunov et al. (2019) point at *translationese* as a major source of mismatch between BLEU and human evaluation. Translationese refers to artifacts from the source language present in the translations, i.e. human translations are often less fluent than natural target sentences due to word order and lexical choices influenced by the source language (Koppel and Ordan, 2011). The impact of translationese on evaluation has recently received attention (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2019). In the present work, we are specifically concerned that the presence of translationese in the references might cause overlap-based metrics to reward hypotheses with translationese language more than hypotheses using more natural language. The question of bias to a specific reference has also been raised in the case of monolingual *human* evaluation (Fomicheva and Specia, 2016; Ma et al., 2017). The impact of translationese in test sets is related to but different from the impact of translationese in the training data (Kurokawa et al., 2009; Lembersky et al., 2012; Bogoychev and Sennrich, 2019; Riley et al., 2019).

In this work, we explore collecting a single reference translation, using human paraphrases to steer away as much as possible from biases in the reference translation that affect the automatic metrics to prefer MT output with the same style (e.g. translationese). Automatic methods to extract paraphrase n-grams (Zhou et al., 2006) or full sentence paraphrases (Kauchak and Barzilay, 2006; Bawden et al., 2020; Thompson and Post, 2020) have been used to consider multiple references. In contrast, we generate a single unbiased reference translation generated by humans instead of trying to cover a wider space of possible translations. In contrast to human paraphrasing (our instructions asked for most diverse paraphrases), automatic paraphrasing are still far from perfect (Roy and Grangier, 2019) and mostly generate local changes that do not steer away from biases as e.g. introducing different sentence structures.

3 Collecting High Quality and Diverse References

We acquired two types of new reference translations: first, we asked a professional translation service to provide an additional reference translation. Second, we used the same service to paraphrase existing references, asking a different set of linguists.

3.1 Additional Standard References

We asked a professional translation service to create additional high quality references to measure the effect of different reference translations. The work was equally shared by 10 professional linguists. The use of CAT tools (dictionaries, translation memory, MT) was specifically disallowed, and the translation service employed a tool to disable copying from the source field and pasting anything into the target field. The translations were produced by experienced linguists who are native speakers in the target language. The original WMT English→German newstest2019 reference translations have been generated in sequence while keeping an 1-1 alignment between sentences. This should help the linguists to use some kind of document context. We instead shuffled the sentences to also get translations from different linguists within a document and avoid systematic biases within a document. The collection of additional references not only may yield better references, but also allows us to conduct various types of multi-reference evaluation. In addition of applying multi-reference BLEU, it also allows us to select the most adequate option among the alternative references for each sentence, composing a higher quality set.

3.2 Diversified Paraphrased References

The product of human translation is assumed to be ontologically different from natural texts (Koppel and Ordan, 2011) and is therefore often called translationese (Gellerstam, 1986). Translationese includes the effects of interference, the process by which the source language leaves distinct marks in the translation, e.g. word order, sentence structure (monotonic translation) or lexical choices. It also often brings simplification (Laviosa, 1997), as

Task: Paraphrase the sentence as much as possible:

To paraphrase a source, you have to rewrite a sentence without changing the meaning of the original sentence.

1. Read the sentence several times to fully understand the meaning
2. Note down key concepts
3. Write your version of the text without looking at the original
4. Compare your paraphrased text with the original and make minor adjustments to phrases that remain too similar

Please try to change as much as you can without changing the meaning of the original sentence.

Some suggestions:

1. Start your first sentence at a different point from that of the original source (if possible)
2. Use as many synonyms as possible
3. Change the sentence structure (if possible)

Figure 1: Instructions used to paraphrase an existing translation *as much as possible*.

Source	The Bells of St. Martin's Fall Silent as Churches in Harlem Struggle .
Translation	Die Glocken von St. Martin verstummen , da Kirchen in Harlem Probleme haben .
Paraphrase	Die Probleme in Harlems Kirchen lassen die Glocken von St. Martin verstummen .
Paraphrase	Die Kirchen in Harlem kämpfen mit Problemen , und so läuten die Glocken von St. Martin nicht mehr .

Table 1: Reference examples of a typical translation and two different paraphrases of this translation. The paraphrases are not only very different from the source sentence (e.g. sentence structure), but also differ a lot when compared to each other.

the translator might impoverish the message, the language, or both. The troubling implication is that a reference set of translationese sentences is biased to assign higher word overlap scores to MT outputs that produces a similar translationese style, and penalizes MT output with more natural targets (Freitag et al., 2019). Collecting a different type of reference could uncover alternative high quality systems producing different styles of outputs.

We explore collecting diverse references using paraphrasing to steer away from translationese, with the ultimate goal of generating a *natural-to-natural* test set, where neither the source sentences nor the reference sentences contain translationese artifacts. In an initial experiment on a sample of 100 sentences, we asked linguists to paraphrase (translated) sentences. The paraphrased references had only minor changes and consequently only minor impact on the automatic metrics. Therefore, we changed the instructions and asked linguists to paraphrase the sentence *as much as possible* while also suggesting using synonyms and different sentence structures. The paraphrase instructions are shown in Figure 1. These instructions satisfy not only our goal to generate an unbiased sentence, but also have the side effect that two paraphrases of the same sentence are quite different. All our paraphrase experiments in this paper are done with these instructions. One might be concerned that paraphrasing "as much as possible" might yield excessive reformulation at the expense of adequacy in some cases. To compensate for this in the present paper, we collect adequacy ratings for all produced paraphrases. These ratings allow us to select the most adequate paraphrase from among available alternatives for the same sentence, which results in a composite high paraphrase set with strong adequacy ratings (see Table 2). A paraphrase example is given in Table 1. Even without speaking any German, one can easily see that the paraphrases have a different sentence structure than the source sentence, and both paraphrases are quite different.

4 Experimental Set-up

4.1 Data and Models

We use the official submissions of the WMT 2019 English→German news translation task (Barrault et al., 2019) to measure automatic scores for different kinds of references. We then report correlations with the WMT human ratings from the same evaluation campaign. We chose English→German as this track had the most submissions and the outputs with the highest adequacy ratings.

4.2 Human Evaluation

We use the same direct assessment template as was used in the WMT 2019 evaluation campaign. Human raters are asked to assess a given translation by how adequately it expresses the meaning of the corresponding source sentence on an absolute 0-100 rating scale. We acquire 3 ratings per sentence and take the average as the final sentence score. In contrast to WMT, we do not normalize the scores, and report the average absolute ratings.

5 Experiments

We generate three additional references for the WMT 2019 English→German news translation task. In addition to acquiring an additional reference (AR), we also asked linguists to paraphrase the existing WMT reference and the AR reference (see Section 3 for details). We refer to these paraphrases as WMT.p and AR.p.

5.1 Human Evaluation of References

It is often believed that the most accurate translations should also yield the highest correlation with humans ratings when used as reference for an automatic metric. For that reason, we run a human evaluation (Section 4.2) for all reference translations to test this hypothesis (Table 2). While all reference translations yield high scores, the paraphrased references are rated as slightly less accurate. We suspect that this may at least in part be an artifact of the rating methodology. Specifically, translations whose word order matches that of the source (i.e. translationese) are easier to rate than translations that use very different sentence structures and phrasing than the source sentence. We generated our paraphrased reference translation with the instructions to modify the translations as much as possible. Therefore, the non-translationese, perhaps more natural, nature of the paraphrased translations make it more demanding to assign an accurate rating.

As a by-product of these ratings, we consider selecting the best rated references among alternatives for each sentence. Representing this method of combining reference sets with the HQ() function, we generate 3 new reference sets. These are (a) HQ(WMT, AR), abbreviated as HQ(R); (b) HQ(WMT.p, AR.p), abbreviated as HQ(P); and (c) HQ(WMT, AR, AR.p, WMT.p), abbreviated as HQ(all 4). Interestingly, the combined paraphrased reference *HQ(P)* has a higher human rating than WMT or AR alone.

	adequacy rating
WMT	85.3
WMT.p	81.8
AR	86.7
AR.p	80.8
HQ(R) [WMT+AR]	92.8
HQ(P) [WMT.p+AR.p]	89.1
HQ(all 4) [all 4]	95.3

Table 2: Human adequacy assessments for different kinds of references, over the full set of 1997 sentences.

5.2 Correlation with Human Judgement

Table 3 provides the system-level rank-correlations (Spearman's ρ and Kendall's τ)[2] of BLEU (calculated with sacreBLEU (Post, 2018)[3]) evaluating translations of newstest2019 for different references. On the full set of 22 submissions, all 3 new references (AR, WMT.p, AR.p) show higher correlation with human judgment than the original WMT reference, with the paraphrased references WMT.p coming out on top. Furthermore, each paraphrased reference set shows higher correlation when compared to the reference set that it was paraphrased from.

Full Set (22)	Reference	ρ	τ
single ref	WMT	0.88	0.72
	AR	0.89	0.76
	WMT.p	**0.91**	**0.79**
	AR.p	0.89	0.77
single ref	HQ(R)	**0.91**	0.78
	HQ(P)	**0.91**	0.78
	HQ(all 4)	**0.91**	**0.79**
multi ref	AR+WMT	0.90	0.75
	AR.p+WMT.p	0.90	**0.79**
	all 4	0.90	0.75

Table 3: Spearman's ρ and Kendall's τ for the WMT2019 English→German official submissions with human ratings conducted by the WMT organizers.

Although, the combined reference HQ(R) (Section 5.1) improves correlation when compared to the non-paraphrased reference sets (WMT and AR), not one of the three combined references HQ(R),

---

[2] We used the scipy implementation in all our experiments: `https://docs.scipy.org/doc/scipy/reference/stats.html`

[3] BLEU+case.mixed+lang.en-de+numrefs.1+smooth.exp+test.wmt19+tok.intl+version.1.4.2

HQ(P), HQ(all 4) shows higher correlation than the paraphrased reference set WMT.p. This result casts doubt on the belief that if references are rated as more adequate, it necessarily implies that such references will yield more reliable automated scores.

We further find that multi-reference BLEU (calculated with sacreBLEU) does not exhibit better correlation with human judgments either than single-reference BLEU or than the composed reference sets HQ(x). It is generally assumed that multi-reference BLEU yields higher correlation with human judgements due to the increased diversity in the reference translations. However, combining two translated reference sets that likely share the same systematic translationese biases does still prefers translationese translations. Interestingly, multi-reference BLEU with multiple paraphrases also does not show higher correlation than single-reference BLEU. Combining *all 4* references with multi reference BLEU shows the same correlation numbers as the combination of *AR+WMT*. As we will see later, the BLEU scores calculated with paraphrased references are much lower than those calculated with standard references. They have fewer n-gram matches, which are mostly only a subset of the n-gram matches of the standard references. Adding paraphrased references to a mix of standard references therefore has a small effect on the total number of n-gram matches, and as a consequence the scores are not much affected.

Note that the correlation numbers already appear relatively high for the full set of systems. This is because both Kendall's τ and Spearman's ρ rank correlation operate over all possible pairs of systems. Since the submissions to WMT2019 covered a wide range of translation qualities, any metric able to distinguish the highest-scoring and lowest-scoring systems will already have a high correlation. Therefore, small numeric increases as demonstrated in Table 3 can correspond to much larger improvements in the local ranking of systems.

As a consequence, we looked deeper into the correlation between a subset of the systems that performed best in human evaluation, where correlation for metrics calculated on the standard reference is known to break down. Kendall's τ rank correlation as a function of the top k systems can be seen in Figure 2. During the WMT 2019 Metric task (Ma et al., 2019), all official submissions (using the original WMT reference) had low correlation scores with human ratings. The paraphrased references improve especially on high quality system output, and every paraphrased reference set (dotted line) outperforms its corresponding unparaphrased set (same-color solid line).

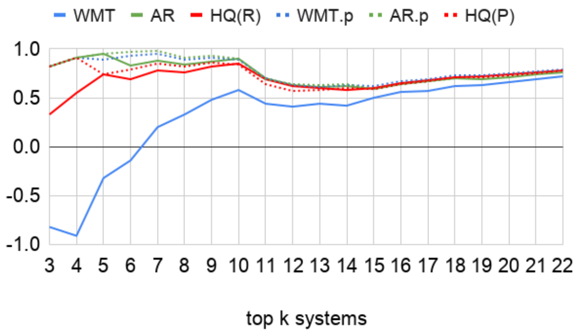

Figure 2: Kendall's τ correlation of BLEU for the best k systems (based on human ratings).

These improvements in ranking can be seen in Table 4, which reports the actual BLEU scores of the top seven submissions with four different references. Since we asked humans to paraphrase the WMT reference as much as possible (Section 3) to get very different sentences, the paraphrased BLEU scores are much lower than what one expects for a high-quality system. Nevertheless, the system outputs are better ranked and show the highest correlation of any references explored in this paper.

5.3 Alternative Metrics

Any reference-based metric can be used with our new reference translations. In addition to BLEU, we consider TER (Snover et al., 2006), METEOR (Banerjee and Lavie, 2005), chrF (Popović, 2015), the f-score variant of BERTScore (Zhang et al., 2019) and Yisi-1 (Lo, 2019) (winning system of WMT 2019 English→German metric task). Table 5 compares these metrics. As we saw in Figure 2, the paraphrased version of each reference set yields higher correlation with human evaluation across all evaluated metrics than the corresponding original references, with the only exception of TER for HQ(P). Comparing the two paraphrased references, we see that HQ(P) shows higher correlation for chrF and Yisi when compared to WMT.p. In particular Yisi (which is based on word embeddings) seems to benefit from the higher accuracy of the reference translation.

metric	WMT	HQ(R)	WMT.p	HQ(P)	HQ(all)
BLEU	0.72	0.78	**0.79**	**0.79**	**0.79**
1 - TER	0.71	**0.74**	0.71	0.67	**0.74**
chrF	0.74	0.81	0.78	**0.82**	0.78
MET	0.74	**0.81**	**0.81**	**0.81**	0.80
BERTS	0.78	**0.82**	**0.82**	**0.82**	0.81
Yisi-1	0.78	0.84	0.84	**0.86**	0.84

Table 5: WMT 2019 English→German: Correlations (Kendall's τ) of alternative metrics: BLEU, 1.0 - TER, chrF, METEOR, BERTScore, and Yisi-1.

5.4 WMT18

We acquired a paraphrased as-much-as-possible reference (WMT.p) for newstest2018 English→German with the same instruction as used before (Figure 1). The test set newstest2018 is a joint test set which means that half of the sentences have been originally written in English and translated into German, and vice versa. We paraphrased the reference sentences for the forward translated half only as we want to have a natural English source sentence. Correlation with human rankings of the WMT18 evaluation campaign are summarized in Table 6. The paraphrased reference WMT.p show higher correlations with human judgement for all metrics.

ref	BLEU	chrf	METEOR	BERTS	Yisi-1
WMT	0.75	0.76	0.75	0.80	0.82
WMT.p	0.91	0.82	0.84	0.90	0.91

Table 6: WMT 2018 English→German: Kendall's τ.

6 Why Paraphrases?

While the top WMT submissions use very similar approaches, there are some techniques in MT that are known to produce more natural (less translationese) output than others. We run experiments with a variety of models that have been shown that their actual quality scores have low correlation with automatic metrics. In particular, we focus on back-translation (Sennrich et al., 2016) and Automatic Post Editing (APE, Freitag et al. (2019)) augmented systems trained on WMT 2014 English→German. All these systems have in common that they generate less translationese output, and thus BLEU with translationese references under-estimate their quality. The experiment in this section follows the setup described in Freitag et al. (2019).

We run adequacy evaluation on WMT newstest 2019 for the 3 systems, as described in Section 4.2. Both the APE and the BT models, which use additional target-side monolingual data, are rated higher by humans than the system relying only on bitext. Table 7 summarizes the BLEU scores for our different reference translations. All references generated with human translations (WMT, HQ(R) and HQ(all 4)) show negative correlation with human ratings for these extreme cases and produce the wrong order. On the other hand, all references that rely purely on paraphrased references do produce the correct ranking of these three systems. This further suggests that reference translations based on human translations bias the metrics to generate higher scores for translationese outputs. By paraphrasing the reference translations, we undo this bias, and the metric can measure the true quality of the underlying systems with greater accuracy.

Reference	bitext	APE	BT	correct?
human	84.5	86.1	87.8	✓
WMT	39.4	34.6	37.9	✗
WMT.p	12.5	12.7	12.9	✓
HQ(R)	35.0	32.1	34.9	✗
HQ(p)	12.4	12.8	13.0	✓
HQ(all 4)	27.2	25.8	27.5	✗

Table 7: BLEU scores for WMT newstest 2019 English→German for MT systems trained on bitext, augmented with BT or using APE as text naturalizer. The *correct* column indicates if the model ranking agrees with human judgments.

This finding, that existing reference translation methodology may systematically bias against modelling techniques known to improve human-judged quality, raises the question of whether previous research has incorrectly discarded approaches that actually improved the quality of MT. Releasing all reference translations gives the community a chance to revisit some of their decisions and measure quality differences for high quality systems.

7 Characterizing Paraphrases

7.1 Alignment

One typical characteristic of translationese is that humans prefer to translate a sentence phrase-by-phrase instead of coming up with a different sentence structure, resulting in 'monotonic' translations. To measure the monotonicity of the different reference translations, we compute an alignment with fast-align (Dyer et al., 2013) on the WMT 2014 English-German parallel data and compare the alignments of all four references. Table 8 summarizes the average absolute distance of two alignment points for each reference. The paraphrased translations are less monotonic and use a different sentence structure than a pure human translation.

WMT	AR	WMT.p	AR.p
5.17	5.27	6.43	6.88

Table 8: Average absolute distance per alignment point, as a proxy for word-by-word ('monotonic') translation. Lower scores indicate more monotonic translation.

7.2 Matched n-grams

The actual BLEU scores calculated with the paraphrased references are much lower compared to BLEU scores calculated with standard references (Table 4). Nevertheless, the paraphrased references show higher correlation with human judgment, which motivates us to investigate which n-grams of the MT output are actually matching the paraphrased references during BLEU calculation. The n-grams responsible for the most overlap with standard references are generic, common n-grams. In the winning submission of the WMT 2019 English→German evaluation campaign from Facebook, the 4grams with the highest number of matches are:

- **, sagte er .** → 28 times (*, he said.*)
- **“ , sagte er** → 14 times (*” , he said*)
- **fügte hinzu , dass** → 8 times (*added that*)

These matches are crucial to reach high > 40 BLEU scores, and appear in translation when using the same sentence structure as the source sentence. On the other hand, the n-grams overlapping with the paraphrased references show a different picture. They usually reward n-grams that express the semantic meaning of the sentence. The 4-grams with the highest number of matches with the paraphrased references for the same system are:

- **Wheeling , West Virginia** → 3 times (*Wheeling , West Virginia*)
- **von Christine Blasey Ford** → 3 times (*from Christine Blasey Ford*)
- **Erdbeben der Stärke 7,5** → 3 times (*7.5 magnitude earthquake*)

8 Conclusions

This work presents a study on the impact of reference quality on the reliability of automated evaluation of machine translation. We consider collecting additional human translations as well as generating more diverse and natural references through paraphrasing. We observe that the paraphrased references result in more reliable automated evaluations, i.e. stronger correlation with human evaluation for the submissions of the WMT 2019 English→German evaluation campaign. These findings are confirmed across a wide range of automated metrics, including BLEU, chrF, METEOR, BERTScore and Yisi. We further demonstrate that the paraphrased references correlate especially well for the top submissions of WMT, and additionally are able to correctly distinguish baselines from systems known to produce more natural output (those augmented with either BT or APE), whose quality tends to be underestimated by references with translationese artifacts.

We explore two different approaches to multi-reference evaluation: (a) standard multi-reference BLEU, and (b) selecting the best-rated references for each sentence. Contrary to conventional wisdom, we find that multi-reference BLEU does not exhibit better correlation with human judgments than single-reference BLEU. Combining two standard reference translations by selecting the best rated reference, on the other hand, did increase correlation for the standard reference translations. Nevertheless, the combined paraphrasing references are of higher quality for all techniques when compared to the standard reference counter part.

We suggest using a single paraphrased reference for more reliable automatic evaluation going forward. Although a combined paraphrased reference shows slightly higher correlation for embedding based metrics, it is over twice as expensive to construct such a reference set. To drive this point home, our experiments suggest that standard reference translations may systematically bias against modelling techniques known to improve human-judged quality, raising the question of whether previous research has incorrectly discarded approaches that actually improved the quality of MT. Releasing all reference translations gives the community a chance to revisit some of their decisions and measure quality differences for high quality systems and modelling techniques that produce more natural or fluent output.

As a closing note, we would like to emphasize that it is more difficult for a human rater to rate a paraphrased translation than a translationese sentence, because the latter may share a similar structure and lexical choice to the source. We suspect that human evaluation is also less reliable for complex translations. Future work, can investigate whether finer ratings could correct the bias in favor of lower effort ratings, and how this may interact with document-level evaluation.

Abstract

The term *translationese* has been used to describe features of translated text, and in this paper, we provide detailed analysis of potential adverse effects of translationese on machine translation evaluation. Our analysis shows differences in conclusions drawn from evaluations that include translationese in test data compared to experiments that tested only with text originally composed in that language. For this reason we recommend that reverse-created test data be omitted from future machine translation test sets. In addition, we provide a re-evaluation of a past machine translation evaluation claiming human-parity of MT. One important issue not previously considered is statistical power of significance tests applied to comparison of human and machine translation. Since the very aim of past evaluations was the investigation of ties between human and MT systems, power analysis is of particular importance, to avoid, for example, claims of human parity simply corresponding to Type II error resulting from the application of a low powered test. We provide detailed analysis of tests used in such evaluations to provide an indication of a suitable minimum sample size for future studies.

1 Introduction

Human-translated text is thought to display features that deviate to some degree from those of text originally composed in that language. Baker (1993) report that translated text can: be more explicit than the original source, less ambiguous, simplified (lexical, syntactically and stylistically); display a preference for conventional grammaticality; avoid repetition; exaggerate target language features; as well as display features of the source language. The term *translationese* is often used to describe the presence of such phenomena in translated text.

Standard evaluation protocol in Machine Translation (MT) comprises system tests on a sample of human-translated text. Since creating this human-translated text is expensive, re-use of test sets for both directions of translation is commonplace, without regard to whether source or target contain features of translationese. For example, translation shared tasks at the Conference on Machine Translation (WMT) (Bojar et al., 2018) generally test translation between a given language pair with two portions of data combined to make up the overall test set. Portion (a) of the test data (accounting for approximately 50% of sentences) is made up of text that originated in Chinese that was human-translated into English, while portion (b) (i.e. the remaining 50%), was translated in the opposite direction, originating in English with manual translation into Chinese. The motivation for creating the test data in this way is to create test sets for both directions simultaneously (so at no extra cost).[1]

Although translationese has been cited as a likely confound in MT evaluation results in the past (Lambersky et al., 2012; Toral et al., 2018; Läubli et al., 2018), to the best of our knowledge, no detailed investigation into the impact of translationese on the accuracy of MT evaluation has been reported to date. With this aim, we examine the degree to which translationese phenomena may impact human and automatic evaluation results in MT. We firstly examine past results of WMT shared tasks, a main venue for MT evaluation, and reveal that although system rankings are overall very similar for human evaluation of forward and reverse test data, in a small number of cases system rankings diverge to a more serious degree. For example, for Turkish-English translation at WMT-18 forward and reverse system rankings correlate at only r = 0.703 in one case. Apart from human evaluation,

---

[1] WMT news task ceased employing reverse-created test data in 2019, motivated by the analysis provided in this current work published in an earlier archival version (Graham et al., 2019).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 72–81,
November 16–20, 2020.

much more concerning is the divergence in forward and reverse rankings when BLEU is relied upon for evaluation of systems, where the correlation can be as low as 0.106 in the worst case.

Subsequently, we provide a reassessment of a human evaluation previously criticized for including reverse-created test data that claimed human parity of Chinese to English MT. We reveal insights into additional potential sources of inaccuracy of conclusions beyond the presence of translationese with the aim of preventing future inaccuracies.

2 Related Work

Hassan et al. (2018) provide one of the earliest claims in MT of systems achieving human-parity in terms of the quality of translations. The reliability of these claims was quickly contested in follow-up studies by Läubli et al. (2018) and Toral et al. (2018), who both drew attention to the 50/50 set-up of test data creation, highlighting the inclusion of reverse-created test data as a likely confound. In their repeat of the human evaluation of the translations produced by Hassan et al. (2018), both Läubli et al. (2018) and Toral et al. (2018) used only test data that originated in the source language.

Inspired by this work, other authors considered the effect of the 50/50 set-up on evaluation using WMT data. Edunov et al. (2019) questioned whether improvements in performance due to back-translation were just an artifact of the test set construction. They found that, whilst back-translation had a disproportionately large positive effect on BLEU for reverse-created test sets, human evaluation showed that back-translation did indeed provide robust improvements to MT for forward-created text. Related to this, Freitag et al. (2019) also showed BLEU to be misleading on the reverse-created part of the test sets, when analysing why their automatic post-editing (APE) method produced improved translations according to human evaluation, but not according to BLEU. Given the concern in the community about using reverse-created test sets, the organisers of the WMT19 news translation task used only forward-created sentences in all their test sets (Barrault et al., 2019). In this current paper we provide detailed evidence to justify this decision.

We note that Zhang and Toral (2019) also provide analysis of the effect of reverse-created test sets on WMT evaluation campaigns. However they focus only on the effect of translationese with respect to human evaluation, without considering its differing effect on automatic evaluation. Also, they do not consider the problem of statistical power in human evaluation, which we raise below.

The use of reverse-created test sets was not the only concern raised by Läubli et al. (2018) and Toral et al. (2018). Both used more context than the original sentence-level evaluation in Hassan et al. (2018), Läubli et al. (2018) now asking human judges to assess entire documents, and Toral et al. (2018) involving assessment of MT output sentences in the order that they appeared in original documents. Furthermore, in contrast to the use of Direct Assessment (Graham et al., 2016) by Hassan et al. (2018), both reassessments used relative ranking, a method formerly used in WMT for evaluation (Callison-Burch et al., 2007, 2008, 2009, 2010, 2011, 2012; Bojar et al., 2013, 2014, 2015, 2016), but now abandoned, partly due to low inter-annotator agreement.

Therefore, although both re-evaluations improved the methodology employed in two respects, by eliminating reverse-created test data and including more context, both potentially include other sources of inaccuracy, such as lack of reliability of human judges when human evaluation takes the form of relative ranking.

Furthermore, Toral et al. (2018) employ Trueskill to reach the conclusion that the MT system in question has not achieved human performance, and although Trueskill has been used in past WMT evaluations to produce system rankings, its aim is to minimize the number of judgments required to produce those rankings when resources are limited. So results may not be directly comparable with results of standard statistical significance tests, now current practice at WMT evaluations.

Finally, neither Toral et al. (2018) nor Läubli et al. (2018) discuss statistical power of significance tests used to distinguish the performance of system and human, an important aspect of evaluation and one of particular importance with respect to evaluations that aim to investigate claims of human parity, where Type II error could result in false claims.

Besides criticisms already made of the human evaluation in Hassan et al. (2018), an additional aspect of importance not yet highlighted is the proportion of distinct translations that were included in the original human-parity evaluation of systems, a consideration that also relates strongly to the question of statistical power. In most MT human evaluations, it is not feasible to evaluate the full test set of sentences for all systems and it is common to instead evaluate a *sample of translations*, usually drawn at random from the test data. In current WMT evaluations, for example, translations of all test sentences produced by all participating systems are pooled and a random sample is human-evaluated. This method ensures that as great a number as possible of *distinct test sentences* are examined. Alongside system performance estimates, WMT also reports the number of distinct test sentences evaluated, n, and it is this number that they consider the *sample size* used for statistical significance tests subsequently used to draw conclusions about which competing systems outperform others. For example, all else being equal, a difference in system performance estimates for a pair of systems computed from a *larger set of distinct translations* is interpreted as *more reliable*.

Table 1: Results of Hassan et al. (2018) for forward, reverse and both test set creation directions. $N =$ number of human judgments; $n =$ number of distinct translations, Reference-HT = human translations created by (Hassan et al., 2018), Reference-PE = post-edited online MT system; Reference-WMT = original WMT reference translations; horizontal lines denote clusters according to Wilcoxon rank sum test at $p < 0.05$.

Other MT human evaluations, despite claims of following WMT human evaluation methodology, have diverged from this method of sample size computation, however, including the human-parity evaluation of Hassan et al. (2018) and Läubli et al. (2018). For example, although a large sample of human judgments is reported as $n \geq$ 1,827 per system in Hassan et al. (2018), firstly this number in fact included quality control check translations, generally removed from data before computing sample sizes. More importantly however, very high numbers of repeat evaluations of the same translations were included in the human-parity evaluation of Hassan et al. (2018). In other words, a very low number of distinct test sentences were in fact human evaluated despite reporting a large sample size. The method of computing sample size therefore diverges from that reported of WMT evaluations in a small but important way. The sample size reported instead corresponds to the total number of human ratings collected as opposed to distinct test sentences (as in WMT evaluations). In this current work, we make this important distinction explicit by referring to the number of distinct test sentences evaluated as n and the number of human judgments collected as N. We also recommend this distinction be made and adopted as common practice in future human evaluations of MT or that the number of distinct translations (as opposed to the number of human evaluations) be reported as the sample size.

Table 1 shows results reproduced from the Hassan et al. (2018) data set, where we now report both the number of human judgments collected, N, and the number of distinct test sentences included, n, in addition to adding separate results for forward and reverse-created test data. Only when tested on the less legitimate reverse direction data does MT now appear to outperform human translation. Nonetheless, when interpreting results in Table 1, it is important to remember, however, that the reliability of even the conclusions drawn from forward-created test data only is still uncertain however, due to the small n, as only 92 distinct translations were in fact included in the evaluation claiming human parity. It remains a possibility that, for example, had the number of distinct test sentences evaluated been higher, distinct conclusions would also be drawn.

We therefore rerun the evaluation using the original translation data included in Hassan et al. (2018) with entirely up-to-date WMT human evaluation methodology in addition to ensuring that a suf-

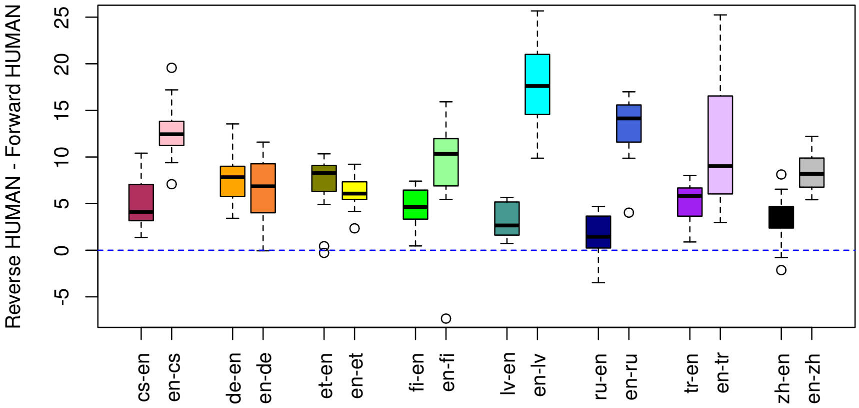

Figure 1: Differences in human evaluation Direct Assessment (DA) scores for test sentences created in the reverse direction to testing and those created in the same/forward direction to testing broken down by language pair, showing that reverse human evaluation scores higher than forward ones in almost all cases.

ficiently large sample of distinct translations are assessed by human judges. We also take into account the very legitimate criticism made by both Toral et al. (2018) and Läubli et al. (2018) and include document-level context in the human evaluation. Furthermore, since no previous evaluation has included statistical power analysis, prior to running our own human evaluation, we examine the power of significance tests to estimate a suitable sample size to decrease the likelihood of Type II error leading to conclusions of human parity due to the application of a low powered test.

Additionally, we examine potential issues for MT evaluation when test data created in the reverse direction to testing is included. Despite being identified by Toral et al. (2018) and Läubli et al. (2018) as a serious cause of concern in MT evaluations, to the best of our knowledge no previous study exists that examines in detail the degree to which reverse-created test data may have skewed past results. The sections that follow therefore include an investigation into the issue of translationese in MT evaluation, in addition to a re-evaluation of Hassan et al. (2018) data with all potential sources of criticism, in terms of test data and evaluation methodology, now taken into account and corrected.

3 Translationese

Using reverse-created test data is thought to unrealistically decrease the difficulty of MT evaluations (Toral et al., 2018; Läubli et al., 2018), because in real-world MT scenarios, input text is unlikely to very often comprise text that has already been translated from the target language. We therefore compare results of systems when test data is split according to the creation direction and examine differences in scores for systems in terms of both human and automatic metrics.

3.1 Human Evaluation

In order to examine differences in human evaluation results when translationese is in test data, we firstly examine WMT-17 and WMT-18 systems and compute two separate human evaluation scores for each system. For each individual system, we compute its *forward Direct Assessment (DA) score*, comprising the average DA score computed only for test sentences that were created in the *same direction as testing*, and a corresponding *reverse DA score* from test data created in the *opposite direction to testing*. Then, to examine the extremity to which MT human evaluation results may differ when systems are tested in the reverse as opposed to forward direction, we subtract a given system's forward DA score (expected to be lower than its reverse counterpart) from its reverse DA score (expected to be higher than its forward counterpart). This provides the difference in human DA scores for each system, with positive differences expected in general since reverse-created test data is hypothesised to be an artificially easier test for MT systems.

Figure 1 shows the distribution of DA score differences (reverse DA − forward DA) for all sys-

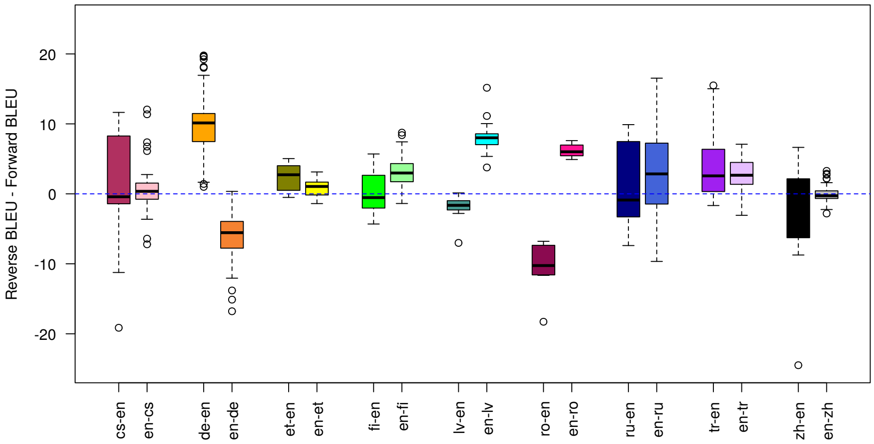

Figure 2: Differences in BLEU scores for systems participating in WMT-15–WMT-18 news translation task computed for test sentences created in the reverse direction to testing and those created in the same/forward direction to testing broken down by language pair, showing a mix of positive and negative differences in BLEU scores depending on test set creation direction.

tems participating in WMT-17 and WMT-18 news translation shared task broken down by language pair, where positive differences for systems indicate a higher human evaluation score when systems are tested in the reverse direction relative to the corresponding forward direction DA score.

As can be seen from the box plot in Figure 1 almost all reverse DA scores are higher than equivalent forward DA scores. This confirms the suspicion that absolute human evaluation results are in general higher when test data is created in the reverse direction to testing.

3.2 BLEU

Besides human evaluation, the performance of MT systems is often measured using automatic metrics, the most common of which remains to be the BLEU score (Papineni et al., 2002). Figure 2 shows a box plot of absolute differences in BLEU scores for systems (reverse BLEU − forward BLEU) participating in WMT news translation tasks from 2015 to 2018. Counter expectation there is a clear mix of positive and negative BLEU score differences for several language pairs.

Comparison of BLEU scores is not as straightforward as human evaluation however, and there are further consideration to be made before drawing conclusions from the mix of positive and negative absolute BLEU score differences described above. For example, the fact that splitting the test set into forward and reverse directions creates two test sets comprised of distinct sentences is likely to impact how each distinct BLEU score should be interpreted, as BLEU is not a simple arithmetic average of sentence scores (like human evaluation DA scores).

3.3 Relative Differences

Besides absolute differences in BLEU scores for individual systems, we also consider how differences correspond to one another for pairs of systems competing in the same competition. For example, for an individual competition, the problems associated with test data creation are more problematic if they occur differently for different systems and less severe if they affect all systems in the same way, as system scores are mainly interpreted relative to one another.

The scatter plot in Figure 3 shows relative differences in BLEU scores when we change from forward to reverse test data for all pairs of systems participating in WMT-15 to WMT-18, as well as differences in human DA scores for systems participating in WMT-17 to WMT-18. The absence of systems in the upper-left and lower-right quadrants reassuringly shows that although extreme changes in BLEU and human scores do occur when test set creation direction is altered, the changes are at least somewhat systematic in the sense that when a difference in scores occurs (a drop or increase

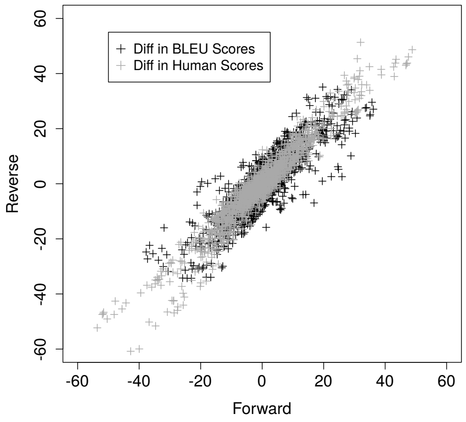

Figure 3: Differences in BLEU and human scores for pairs of systems participating in WMT-15 to WMT-18 and WMT-17 to WMT-18 respective news translation tasks for test sentences created in the reverse and forward directions.

when we change from forward to reverse test data), it occurs similarly for pairs of systems participating in the same competition. However, although there is a diagonal orientation in the plot, it still is somewhat worryingly broad and it remains possible that inclusion of reverse test data could bias BLEU and human scores in different ways for different types of systems.

3.4 System Rankings

Figure 4 shows Pearson, Spearman and Kendall's τ correlation of forward and reverse scores for systems participating individual competitions from WMT-15–WMT-18 terms of both BLEU and human evaluation. As can be seen, the correspondence between forward and reverse rank correlation of systems according to BLEU varies considerably across different evaluation test sets, from as low as a τ of 0.2 (tr-en newstest2018), where BLEU score rankings are extremely different depending on test data creation direction, up to a τ of 1.0, where rank correlation is identical (cs-en; fi-en newstest2017; fi-en; en-cs newstest2018).

In overall summary, our analysis of differences in both BLEU and human evaluation scores reveal differences in system rankings when tested on reverse and forward-created test data, differences substantial in some cases. Subsequently we have confirmed the validity of suspicions about lack of reliability of test data raised by Toral et al. (2018) and Läubli et al. (2018) caused by inclusion of reverse-created test data. However, as stated previously, neither reassessments of Hassan et al. (2018) ticked all boxes in terms of valid human evaluation methodologies and in the section that follows we therefore once again reassess the original evaluation.

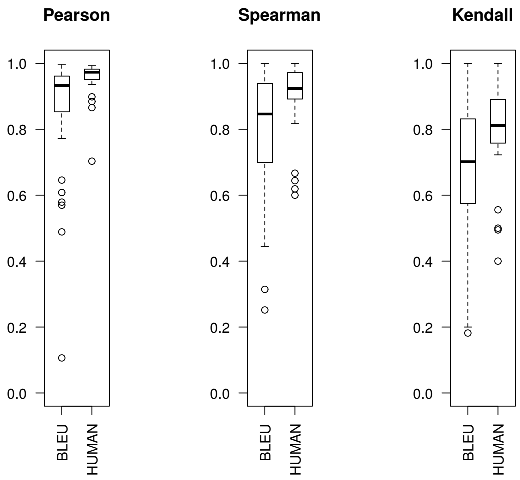

Figure 4: Pearson, Spearman and Kendall's τ correlation of forward and reverse BLEU and HUMAN scores of data for all available systems from WMT-15 – WMT-18 news translation task for BLEU and WMT-17–WMT-18 for human assessment.

4 Re-evaluation of Human Parity Claims

As described in detail in Section 2, past re-evaluations of human parity claims were hampered by sub-optimal test settings. In our re-evaluation, we firstly carry out statistical power analysis so that, in the case of encountering any ties between systems or indeed human and system, tests used to draw conclusions will have sufficient statistical power to avoid human-parity claims that in fact simply correspond to Type II error. Statistical power is of particular importance when considering document-level evaluation due to the fact that gathering ratings of documents as opposed to sentences requires substantially more annotation time and for this reason is highly likely to result in a reduction in the number of assessments collected in any evaluation. For example, Läubli et al. (2018) included as few as 55 documents in their re-evaluation of Hassan et al. (2018). Our concern about a potential substantial reduction in sample size in future document-level evaluations is well-founded therefore, especially considering standard segment-level MT human evaluations commonly include a sample of 1,500 segments. In the case of Läubli et al. (2018) this corresponds to an extreme reduction of approximately 96% to the sample size. Since the very nature of the question being investigated involves a potential tie between human and machine, such a small sample size is a serious risk to the reliability of conclusions drawn simply due to its impact in terms of statistical power.

As a rough guide to what constitutes sufficient statistical power, we borrow the five-eighty convention from the behavioural sciences that provides a balance between Type I versus Type II error, where significance and power levels are set at 0.05 and 0.8 respectively (Cohen, 1988). Table 2 shows the statistical power, the probability of identifying a significant difference when one exists, of the statistical test applied in WMT evaluations, Wilcoxon rank-sum test, for a range of effect and sample sizes (n), where for the purpose of the test the appropriate effect size is the probability of the translations of system A being scored lower than those of system B. As shown in Table 2 for the usual sample size employed in WMT evaluations, 1,500, statistical power even for closely performing systems, where the effect size, the probability of the translations of system A being scored lower than those of system B, is 0.47, statistical power remains above 0.8. For such pairs of systems, however, if we were to employ the smaller sample size of 55 documents, as in Läubli et al. (2018), the power of the test to identify a significant difference falls to as low as 0.081, approaching one tenth of acceptable statistical power levels.[2]

A good compromise between fully document-level evaluation, where only ratings of documents are collected, and fully segment-level evaluations, in which segments are presented to human judges in isolation of the document, is collection of ratings of segments with the wider document context available to the human assessor and have the segments evaluated in their original order. In this way, a sufficient sample size can still be achieved to ensure appropriate levels of statistical power with the added aim of human judges being able to take into account the quality of translations within the wider document context.[3]

We therefore plan our re-evaluation as follows: (i) collect segment ratings for documents produced by a single system within the correct document context; (ii) aim to collect direct assessments of a sufficient number of translations exceeding the minimum acceptable sample size in terms of power analysis, approximately 385 distinct translations; (iii) use n, the number of distinct translations as opposed to repeat human assessments as the sample size; (iv) employ Direct Assessment, the most up to date technology for this purpose and that employed by WMT for the official results since 2017, a method shown to produce highly repeatable results; (v) only employ forward-created test data; (vi) only draw conclusions specific to Chinese to English translation and news domain; (vii) produce clusters with a standard significance test, Wilcoxon rank-sum test.

4.1 Re-evaluation Results

Direct Assessment (DA) HITs were set up and run as in WMT human evaluations on Mechanical Turk but with the distinction of segments being evaluated in the correct order in which they appeared in a document, comprising an initial set of results, which we refer to as segment rating + document context (SR+DC). In addition to the segment rating, workers were additionally shown entire documents and asked to rate them, providing a secondary set of results for comparison purposes. We refer to these fully document-level results as document rating + document context (DR+DC) configuration. As is usual in DA evaluations, translations were rated in a 0–100 scale and quality control was applied.

131 workers participated producing a total of 13,214 assessments of translations, of which 6,606 (49.99%) were from workers who passed DA's quality control checks. Table 3 shows results of our re-evaluation[4] of the top systems originally included in Hassan et al. (2018), where REF-HT is the original set of human translations produced by Hassan et al. (2018) themselves and against which human-parity of MT was claimed, while REF-PE is machine translated outputs that have been post-edited by humans, and Combo-6 is the best-performing system in Hassan et al. (2018).

Results when segments are rated by human judges within the correct document context (Segment Rating + Document Context) show that the DA score achieved by the human reference translation, REF-HT, is significantly higher than both

---

[2] In Läubli et al. (2018) the Sign test was used as opposed to Wilcoxon rank sum and has similar statistical power for such an effect size.

[3] This approach is not that of Toral et al. (2018), where document context was only available in for the source input document as opposed to MT output document.

Table 3: Re-evaluation of human-parity-claimed Chinese to English system of Hassan et al. (2018); * denotes system that significantly outperforms all lower ranked systems according to a two-sided Wilcoxon rank-sum test $p < 0.05$

REF-PE and Combo-6, agreeing with results of both Läubli et al. (2018) and Toral et al. (2018). Since this approach has a large enough sample size to ensure sufficient statistical power, the tie between REF-PE and Combo-6 is a legitimate one however. Although this tie does indeed indicate high performance of Combo-6, since REF-PE is in fact post-edited MT output however, this tie does not provide legitimate evidence to support a human-parity claim.

Although we already know from the power analysis carried out for planning the current evaluation that fully document-level evaluations in which human assessors are required to rate documents (as opposed to segments) will encounter problems in terms of sufficient statistical power when ties occur, we nonetheless run this kind of evaluation for demonstration purposes. Document Rating + Document Context results in Table 3 do indeed produce what appears to be a statistical tie between the three sets of outputs as no "system" significantly outperforms all lower ranking ones. However, a conclusion of human parity cannot legitimately be claimed from this tie due to the low statistical power of the test caused by the small sample of documents that were rated. Ties in this case do not indicate human-parity but simply that the test is too weak to identify significant differences.

In summary, similar to Toral et al. (2018) and Läubli et al. (2018), our results show evidence that the original system, Combo-6, was outperformed by human translation. It should be noted however that from our results it cannot be inferred that machine translation in general has not yet reached human performance but simply that the system that originally claimed human-parity in fact did not achieve it, as tested on WMT-17 newstask data.

5 Conclusion

We explore issues relating to the reliability of machine translation evaluations. Firstly, we provide a detailed analysis of how the presence of translationese phenomena can adversely affect machine translation results. In terms of the legitimacy of machine translation evaluation results, our analysis provides sufficient evidence that translationese is a problem for evaluation of systems, in particular in terms of comparison of system performance with automatic metrics such as BLEU. This results in our first recommendation in future MT evaluations to *avoid the use of source side test data that was created via human translation from another language*. We provided guidance in relation to sample size and statistical power to help planning future human evaluations of MT, particularly relevant to document-level human-parity investigations. This guidance will help to avoid false conclusions due to the application of low powered statistical tests.

Simulated Multiple Reference Training Improves Low-Resource Machine Translation

Abstract

Many valid translations exist for a given sentence, yet machine translation (MT) is trained with a single reference translation, exacerbating data sparsity in low-resource settings. We introduce Simulated Multiple Reference Training (SMRT), a novel MT training method that approximates the full space of possible translations by *sampling* a paraphrase of the reference sentence from a paraphraser and training the MT model to predict the paraphraser's *distribution* over possible tokens. We demonstrate the effectiveness of SMRT in low-resource settings when translating to English, with improvements of 1.2 to 7.0 BLEU. We also find SMRT is complementary to back-translation.

1 Introduction

Variability and expressiveness are core features of language, and they extend to translation as well. Dreyer and Marcu (2012) showed that naturally occurring sentences have *billions* of valid translations. Despite this variety, machine translation (MT) models are optimized toward a single translation of each sentence in the training corpus. Training a high resource MT model on millions of sentence pairs likely exposes it to similar sentences translated different ways, but training a low-resource MT model with a single translation for each sentence (out of potentially billions) exacerbates data sparsity.

We hypothesize that the discrepancy between linguistic diversity and standard single-reference training hinders MT performance. This was previously impractical to address, since obtaining multiple human translations of training data is typically not feasible. However, recent neural sentential paraphrasers produce fluent, meaning-preserving English paraphrases. We introduce a novel method that incorporates such a paraphraser directly in the training objective, and uses it to simulate the full space of translations.

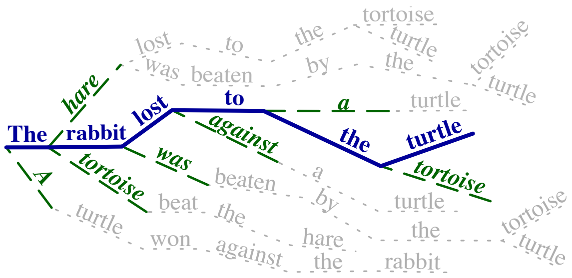

Figure 1: Some possible paraphrases of the original reference, 'The tortoise beat the hare,' for the Dutch source sentence, 'De schildpad versloeg de haas.' A **sampled path** and some of the other ***tokens also considered in the training objective*** are highlighted.

We demonstrate the effectiveness of our method on two corpora from the low-resource MATERIAL program, and on bitext from GlobalVoices. We release data & code: `data.statmt.org/smrt`

2 Method

We propose Simulated Multiple Reference Training (SMRT), which uses a paraphraser to approximate the full space of possible translations, since explicitly training on billions of possible translations per sentence is intractable.

In standard neural MT training, the reference is: (1) used in the training objective; and (2) conditioned on as the previous target token.[1] We approximate the full space of possible translations by: (1) training the MT model to predict the *distribution* over possible tokens from the paraphraser at each time step; and (2) *sampling* the previous target token from the paraphraser distribution. Figure 1 shows an example of possible paraphrases and highlights a sampled path and some of the other tokens used in the training objective distribution.

---

[1] In autoregressive NMT inference, predictions condition on the previous target tokens. In training, predictions typically condition on the previous tokens in the reference, not the model's output (teacher forcing; Williams and Zipser, 1989).

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 82–89,
November 16–20, 2020.

We review the standard NLL training objective, and then introduce our proposed objective.

NLL Objective The standard negative log likelihood (NLL) training objective in NMT, for the i^{th} target word in the reference y is:

$$\mathcal{L}_{\text{NLL}} = -\sum_{v \in \mathcal{V}} \Big[\mathbb{1}\{y_i = v\} \times \log\, p_{\text{MT}}(y_i = v \,|\, x, y_{j<i}) \Big] \tag{1}$$

where $\mathcal{V}$ is the vocabulary, $\mathbb{1}\{\cdot\}$ is the indicator function, and p_{MT} is the MT output distribution (conditioned on the source x, and on the previous tokens in the reference $y_{j<i}$). Equation 1 computes the cross-entropy between the MT model's distribution and the one-hot reference.

Proposed Objective We compute the cross entropy between the distribution of the MT model and the distribution from a paraphraser conditioned on the original reference:

$$\mathcal{L}_{\text{SMRT}} = -\sum_{v \in \mathcal{V}} \Big[p_{\text{para}}(y'_i = v \,|\, y, y'_{j<i}) \times \log\, p_{\text{MT}}(y'_i = v \,|\, x, y'_{j<i}) \Big] \tag{2}$$

where y' is a paraphrase of the original reference y. p_{para} is the output distribution from the paraphraser (conditioned on the reference y and the previous tokens in the sentence produced by the paraphraser $y'_{j<i}$). p_{MT} is the MT output distribution (conditioned on the source sentence, x and the previous tokens in the sentence produced by the paraphraser, $y'_{j<i}$). At each time step we sample a target token y'_i from the paraphraser's output distribution to cover the space of translations. We condition on the sampled y'_{i-1} as the previous target token for both the MT model and paraphraser.

For a visualization see Figure 1, which shows possible paraphrases of the reference, 'The tortoise beat the hare.' The paraphraser and MT model condition on the **paraphrase (y')** as the previous output. The **paraphrase (y')** and the rest of the ***tokens in the paraphraser's distribution*** make up p_{PARA}, which is used to compute $\mathcal{L}_{\text{SMRT}}$.

3 Experimental Setup

3.1 Paraphraser

For use as an English paraphraser, we train a Transformer model (Vaswani et al., 2017) in FAIRSEQ (Ott et al., 2019) with an 8-layer encoder and decoder, 1024 dimensional embeddings, 16 encoder and decoder attention heads, and 0.3 dropout. We optimize using Adam (Kingma and Ba, 2015). We train on PARABANK2 (Hu et al., 2019c), an English paraphrase dataset.[2] PARABANK2 was generated by training an MT system on CzEng 1.7 (a Czech−English bitext with over 50 million lines (Bojar et al., 2016)), re-translating the Czech training sentences, and pairing the English output with the original English translation.

3.2 NMT models

We train Transformer NMT models in FAIRSEQ using the FLORES low-resource benchmark parameters (Guzmán et al., 2019): 5-layer encoder and decoder, 512-dimensional embeddings, and 2 encoder and decoder attention heads. We regularize with 0.2 label smoothing and 0.4 dropout. We optimize using Adam with a learning rate of 10^{-3}. We train for 200 epochs, and select the best checkpoint based on validation set perplexity. We translate with a beam size of 5. For our method we use the proposed objective $\mathcal{L}_{\text{SMRT}}$ with probability $p = 0.5$ and standard $\mathcal{L}_{\text{NLL}}$ on the original reference with probability $1 - p$. We sample from only the 100 highest probability vocabulary items at a given time step when sampling from the paraphraser distribution to avoid very unlikely tokens (Fan et al., 2018).

Using our English paraphraser, we aim to demonstrate improvements in low-resource settings, since these remain a challenge in NMT (Koehn and Knowles, 2017; Sennrich and Zhang, 2019). We use Tagalog (tl) to English and Swahili (sw) to English bitext from the MATERIAL low-resource program (Rubino, 2018). We also report results on MT bitext from GlobalVoices, a non-profit news site that publishes in 53 languages.[3] We evaluate on the 10 lowest-resource settings that have at least 10,000 lines of parallel text with English: Hungarian (hu), Indonesian (id), Czech (cs), Serbian (sr), Catalan (ca), Swahili (sw),[4] Dutch (nl), Polish (pl), Macedonian (mk), Arabic (ar).

We use 2,000 lines each for a validation set for model selection from checkpoints and a test set for reporting results. The approximate number of lines of training data is in the top of Table 1. We train an English SentencePiece model (Kudo and Richard-

---

[2] Hu et al. released a trained SOCKEYE paraphraser but we implement our method in FAIRSEQ.

[3] We use v2017q3 released on Opus (Tiedemann, 2012, `opus.nlpl.eu/GlobalVoices.php`).

[4] Swahili is in both. MATERIAL data is not widely available, so we separate them to keep GlobalVoices reproducible.

son, 2018) on the paraphraser data, and apply it to the target (English) side of the MT bitext, so that the paraphraser and MT models have the same output vocabulary. We also train SentencePiece models on the source-side of the bitexts. We use a subword vocabulary size of 4,000 for each.

4 Results

Results are shown in Table 1. Our method improves over the baseline in all settings, by between 1.2 and 7.0 BLEU (all statistically significant at the 95% confidence level (Koehn, 2004)).[5] We see larger improvements for lower-resource corpora.

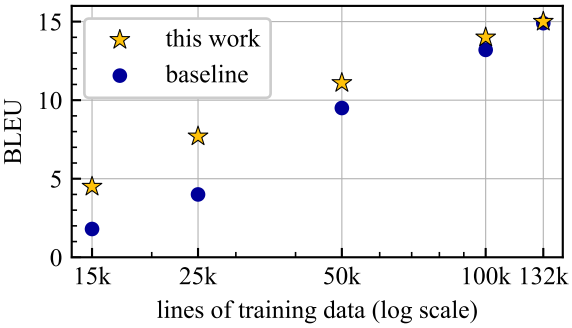

Figure 2: Bengali-English data ablation. Improvements of 2.7, 3.7, 1.6, and 0.8 BLEU at the 15k, 25k, 50k, and 100k subsets are statistically significant.

5 Analysis

We analyze our method to explore: (1) how it performs at a various resource levels; (2) how it combines with back-translation; (3) how the different components of the method impact performance; and (4) how it compares to sequence-level paraphrastic data augmentation.

5.1 MT Data Ablation

In order to better understand how our method performs across data sizes on the same corpus, we ablate Bengali-English bitext from GlobalVoices.

Figure 2 plots the performance of our method and the baseline against the log of the data amount. Our improvements of 2.7, 3.7, 1.6, and 0.8 BLEU at the 15k, 25k, 50k, and 100k subsets are statistically significant at the 95% confidence level; the 0.1 improvement for the full 132k data amount is not. Similar to Table 1, we see larger improvements in lower-resource ablations.

5.2 Back-translation

Back-translation (Sennrich et al., 2016) is the de facto method for incorporating non-parallel data in NMT, so we investigate how our method interacts with it. Table 2 shows the results for back-translation, our work, and the combination of both.[6] Adding our method to back-translation improves results by an additional 0.5 to 5.7 BLEU.[7]

For all language pairs, the best performance is achieved by our method combined with back-translation, or our method alone. For 9 of 12 corpora, back-translation and our proposed method are complementary, with improvements of 1.2 to 7.8 BLEU[7] over the baseline when combining the two. For cs-en and tl-en, adding back-translation to our method does not change BLEU. In the lowest-resource setting (hu-en) our method alone outperforms the baseline by 3.1 BLEU, but adding back-translation reduces the improvement by 0.5 BLEU.

5.3 Method Ablation

In Table 3 we analyze the contributions of each part of our proposed method. We compare four

---

[5] All BLEU scores are SacreBLEU (Post, 2018).

[6] We use a 1:1 ratio of bitext to back-translated bitext. We use newscrawl2016 (`data.statmt.org/news-crawl`) as monolingual text. When combining with our work, we run our method on both the original and back-translation data.

[7] All statistically significant at the 95% confidence level.

Table 3: We compare four conditions to the baseline: (1) paraphrasing the reference, without sampling or the distribution in the loss; (2) sampling from the paraphraser in the training objective, without the distribution; (3) using the distribution in the training objective, without sampling; and (4) the proposed method. We **bold** the best test set BLEU score, and others where the difference is not statistically significant at the 95% confidence level.

conditions to the baseline:[8] (1) paraphrasing the reference, without sampling or the distribution in the loss;[9] (2) sampling from the paraphraser, without the distribution in the loss; (3) using the distribution in the training objective, without sampling the paraphrase; and (4) the proposed method.

We find that sampling is particularly important to the success for the method; removing it significantly degrades performance in all but 3 language pairs. Since we sample a paraphrase each batch, this exposes the model to a wide variety of different paraphrases. Using the distribution in the loss function is also beneficial, particularly for the lower resource settings and in the MATERIAL corpora.

5.4 Sequence-Level Paraphrastic Data Augmentation

As a contrastive experiment, we use the paraphraser to generate additional target-side data for use in data augmentation. For each target sentence (y) in the training data, we generate a paraphrase (y'). We then concatenate the original source-target pairs (x, y) with the paraphrased pairs (x, y') and perform standard standard $\mathcal{L}_{\text{NLL}}$ training. We consider 3 methods for generating paraphrases: beam search (beam of 5), greedy search, sampling (top-100 sampling). Greedy search tends to work best: see Table 4. It improves over the baseline for the 10 Global Voices datasets, but not for the two MATERIAL ones. Overall, our proposed method is more effective than this contrastive method. We hypothesize this is due to the wider variety of paraphases SMRT introduces by sampling and training toward the full distribution from the paraphraser.

6 Related Work

Knowledge Distillation Our proposed objective is similarly structured to word-level knowledge distillation (KD; Hinton et al., 2015; Kim and Rush, 2016), where a student model is trained to match the output distribution of a teacher model. Paraphrasing as preprocessed data augmentation, as discussed in § 5.4, is similarly analogous to sequence-level knowledge distillation (Kim and Rush, 2016).

---

[8] All use settings from § 3.2: we use the original reference with $\mathcal{L}_{\text{NLL}}$ with $1 - p = 0.5$ probability, and when sampling we sample from the top $w = 100$ tokens.

[9] This is equivalent to $\mathcal{L}_{\text{NLL}}$ using a paraphrase generated with greedy-search as the reference, see § 5.4.

Table 4: We compare three ways of generating paraphrases for preprocessed data augmentation: beam search, greedy search, and sampling. We **bold** the best BLEU score on the test set, as well as any result where the difference from it is not statistically significant at the 95% confidence level.

In typical KD both the student and teacher models are translation models trained on the same data, have the same input and output languages, and use the original reference for the previous token. In contrast, our teacher model is a paraphraser, which takes as input the original reference sentence (in the target language), with the sampled paraphrase as the previous token. KD is usually used to train smaller models and does not typically incorporate additional data sources, though it has been used for domain adaptation (Dakwale and Monz, 2017; Khayrallah et al., 2018).

Paraphrasing in MT Hu et al. (2019a) present case studies on paraphrastic data augmentation for NLP tasks, including NMT. They use sequence-level augmentation with heuristic constraints on the model's output. SMRT differs in that we train toward the paraphraser *distribution*, and we *sample* from the distribution rather than using heuristics.

Wieting et al. (2019a) used a paraphrastic-similarity metric for minimum risk training (MRT; Shen et al., 2016) in NMT. They note MRT is slow, and, following prior work, use it for fine-tuning after NLL training. While our method is about 3 times slower than standard $\mathcal{L}_{\text{NLL}}$, this is not prohibitive in low-resource conditions.

Paraphrasing was also used for statistical MT, including: *source-side* phrase table augmentation (Callison-Burch et al., 2006; Marton et al., 2009), and generation of additional references for tuning (Madnani et al., 2007, 2008).

Data Augmentation in NMT Back-translation (BT) translates target-language monolingual text to create synthetic source sentences (Sennrich et al., 2016). BT needs a reverse translation model for each *language pair*. In contrast, we need a paraphraser for each *target language*. Zhou et al. (2019) found BT is harmful in some low-resource settings, but a strong paraphraser can be trained as long as the target language is sufficiently high resource.

Fadaee et al. (2017) insert rare words in novel contexts in the existing bitext, using automatic word alignment and a language model. RAML (Norouzi et al., 2016) and SwitchOut (Wang et al., 2018) randomly replace words others from the vocabulary. In contrast to random or targeted word replacement, we generate semantically similar sentential paraphrases.

Label Smoothing Label smoothing (which we use when training with $\mathcal{L}_{\text{NLL}}$) spreads probability mass over all non-reference tokens equally (Szegedy et al., 2016); $\mathcal{L}_{\text{SMRT}}$ places higher probability on semantically plausible tokens.

7 Conclusion

We present Simulated Multiple Reference Training (SMRT), which significantly improves performance in low-resource settings—by 1.2 to 7.0 BLEU—and is complementary to back-translation.

Neural paraphrasers are rapidly improving (Wieting et al., 2017, 2019b; Li et al., 2018; Wieting and Gimpel, 2018; Hu et al., 2019a,b,c), and the concurrently released PRISM multi-lingual paraphraser Thompson and Post (2020a,b) has coverage of 39 languages and outperforms prior work in English paraphrasing. As paraphrasing continues to improve and cover more languages, we are optimistic SMRT will provide larger improvements across the board—including for higher-resource MT and for additional target languages beyond English.

Automatic Machine Translation Evaluation in Many Languages via Zero-Shot Paraphrasing

Brian Thompson

Abstract

We frame the task of machine translation evaluation as one of scoring machine translation output with a sequence-to-sequence paraphraser, conditioned on a human reference. We propose training the paraphraser as a multilingual NMT system, treating paraphrasing as a zero-shot translation task (e.g., Czech to Czech). This results in the paraphraser's output mode being centered around a copy of the input sequence, which represents the best case scenario where the MT system output matches a human reference. Our method is simple and intuitive, and does not require human judgements for training. Our single model (trained in 39 languages) outperforms or statistically ties with all prior metrics on the WMT 2019 segment-level shared metrics task in all languages (excluding Gujarati where the model had no training data). We also explore using our model for the task of quality estimation as a metric—conditioning on the source instead of the reference—and find that it significantly outperforms every submission to the WMT 2019 shared task on quality estimation in every language pair.

1 Introduction

Machine Translation (MT) systems have improved dramatically in the past several years. This is largely due to advances in neural MT (NMT) methods, but the pace of improvement would not have been possible without automatic MT metrics, which provide immediate feedback on MT quality without the time and expense associated with obtaining human judgments of MT output.

However, the improvements that existing automatic metrics helped enable are now causing the correlation between human judgments and automatic metrics to break down (Ma et al., 2019; Mathur et al., 2020) especially for BLEU (Papineni et al., 2002), which has been the de facto standard metric since its introduction almost two decades ago. The problem currently appears limited to very strong systems, but as hardware, modeling, and available training data improve, it is likely BLEU will fail more frequently in the future. This could prove extremely detrimental if the MT community fails to adopt an improved metric, as good ideas could quietly be discarded or rejected from publication because they do not correlate with BLEU. In fact, this may already be happening.

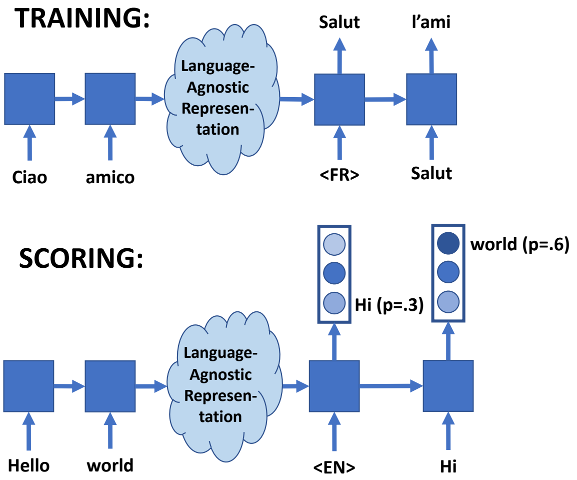

Figure 1: Our model is trained on multilingual parallel examples such as "Ciao amico" translated to French is "Salut l'ami." At evaluation time, the model is used in zero-shot mode to score MT system outputs conditioned on their corresponding human references. For example, the MT system output "Hi world" conditioned on the human reference "Hello world" is found to have token probabilities [0.3, 0.6].

We propose using a sentential, sequence-to-sequence paraphraser to force-decode and score MT outputs conditioned on their corresponding human references. Our model implicitly represents the entire (exponentially large) set of potential paraphrases of a sentence, both valid and invalid; by "querying" the model with a particular system out-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 90–121,
November 16–20, 2020.

put, we can use the model score to measure how well the system output paraphrases the human reference translation. Our model is not trained on any human quality judgements, which are not available in many domains and/or language pairs.

The best possible MT output is one which perfectly matches a human reference; therefore, for evaluation, an ideal paraphraser would be one with an output distribution centered around a copy of its input sentence. We denote such a model a "lexically/syntactically unbiased paraphraser" to distinguish it from a standard paraphraser trained to produce output which conveys the meaning of the input while also being *lexically and/or syntactically different from it.* For this reason, we propose using a multilingual NMT system as an unbiased paraphraser by treating paraphrasing as zero-shot "translation" (e.g., Czech to Czech). We show that a multilingual NMT model is much closer to an ideal lexically/syntactically unbiased paraphraser than a generative paraphraser trained on synthetic paraphrases. It also allows a single model to work in many languages, and can be applied to the task of "Quality estimation (QE) as a metric" (Fonseca et al., 2019) by conditioning on the source instead of the reference. Figure 1 illustrates our method, which we denote *Prism* (Probability is the metric).

We train a single model in 39 languages and show that it:

- Outperforms or ties with prior metrics and several contrastive neural methods on the segment-level WMT 2019 MT metrics task in every language pair;[1]
- Is able to discriminate between very strong neural systems at the system level, addressing a problem raised at WMT 2019; and
- Significantly outperforms all QE metrics submitted to the WMT 2019 QE shared task

Finally, we contrast the effectiveness of our model when scoring MT output using the source vs the human reference. We observe that human references substantially improve performance, and, crucially, allow our model to rank systems that are *substantially better than our model at the task of translation.* This is important because it establishes that our method does not require building a state-of-the-art multilingual NMT model in order to produce a state-of-the-art MT metric capable of evaluating state-of-the-art MT systems.

We release our model, metrics toolkit, and preprocessed training data.[2]

2 Related Work

MT Metrics Early MT metrics like BLEU (Papineni et al., 2002) and NIST (Doddington, 2002) use token-level n-gram overlap between the MT output and the human reference. Overlap can also be measured at the character level (Popović, 2015, 2017) or using edit distance (Snover et al., 2006). Many metrics use word- and/or sentence-level embeddings, including ReVal (Gupta et al., 2015), RUSE (Shimanaka et al., 2018), WMDO (Chow et al., 2019), and ESIM (Mathur et al., 2019). MEANT (Lo and Wu, 2011) and MEANT 2.0 (Lo, 2017) measure similarity between semantic frames and role fillers. State-of-the-art methods including YiSi (Lo, 2019) and BERTscore (Zhang et al., 2019, 2020) rely on contextualized embeddings (Devlin et al., 2019) trained on large (non-parallel) corpora. BLEURT (Sellam et al., 2020) applies fine tuning of BERT, including training on prior human judgements. In contrast, our work exploits parallel bitext and doesn't require training on human judgements.

Paraphrase Databases Prior work explored using parallel bitext to identify phrase level paraphrases (Bannard and Callison-Burch, 2005; Ganitkevitch et al., 2013) including bitext in multiple language pairs (Ganitkevitch and Callison-Burch, 2014). Paraphrase tables were, in turn, used in MT metrics to reward systems for paraphrasing words (Banerjee and Lavie, 2005) or phrases (Zhou et al., 2006; Denkowski and Lavie, 2010) from the human reference. Our work can be viewed as extending this idea to the sentence level, without having to enumerate the millions or billions of paraphrases (Dreyer and Marcu, 2012) for each sentence.

Multilingual NMT Multilingual NMT (Dong et al., 2015) has been shown to rival performance of single language pair models in high-resource languages (Aharoni et al., 2019; Arivazhagan et al., 2019) while also improving low-resource translation via transfer learning from higher-resource languages (Zoph et al., 2016; Nguyen and Chiang, 2017; Neubig and Hu, 2018). An extreme low-resource setting is where the system translates between languages seen during training, but in a language *pair* where it did not see *any* training

Table 1: Example token-level log probabilities from our model for various output sentences, conditioned on input sentence (i.e., human reference) *"Jason went to school at the University of Madrid."* H(out|in) denotes the average token-level log probability. We observe that our model generally penalizes any deviations (**bolded**) from the input sentence, but tends to penalize deviations which change the meaning of the sentence or introduce a disfluency more harshly than those which are fluent and adequate. Sentence-level BLEU with smoothing=1 ("sBLEU") and LASER embedding cosine similarity ("LASER") are shown for comparison. We note that LASER appears fairly insensitive to disfluencies, and sentenceBLEU struggles to reward valid paraphrases.

data, denoted 'zero-shot' translation. Despite evidence that intermediate representations are not truly language-agnostic (Kudugunta et al., 2019), zero-shot translation has been shown successful, especially between related languages (Johnson et al., 2017; Gu et al., 2018; Pham et al., 2019).

Generative Paraphrasing Sentential paraphrasing can be accomplished by training an MT system on paraphrase examples instead of translation pairs (Quirk et al., 2004). While natural paraphrase datasets do exist (Quirk et al., 2004; Coster and Kauchak, 2011; Fader et al., 2013; Lin et al., 2014; Federmann et al., 2019), they are somewhat limited. An alternative is to start with much more plentiful bitext and back-translate one side into the language of the other to create synthetic paraphrases on which to train (Prakash et al., 2016; Wieting and Gimpel, 2018; Hu et al., 2019a,b,c). Tiedemann and Scherrer (2019) propose using paraphrasing as a way to measure the semantic abstraction of multilingual NMT. They also propose using a multilingual NMT model as a generative paraphraser.[3]

Semantic Similarity Parallel corpora in many language pairs have been used to produce fixed-size, multilingual sentence representations (Schwenk and Douze, 2017; Wieting et al., 2017; Artetxe and Schwenk, 2018; Wieting et al., 2019; Raganato et al., 2019). LASER (Artetxe and Schwenk, 2018), for example, trains a variant of NMT with a fixed-size intermediate representation in 93 languages. Embeddings produced by the encoder can be compared to measure intra- or interlingual semantic similarity.

3 Method

We propose using a paraphraser to force-decode and estimate probabilities of MT system outputs, conditioned on their corresponding human references. Let $p(y_t|y_{i<t}, x)$ be the probability our paraphraser assigns to the t^{th} token in output sequence y, given the previous output tokens $y_{i<t}$ and the input sequence x. Table 1 shows an example of how token-level probabilities from our model (described in §4) penalize both fluency and adequacy errors given a human reference. We consider two ways of combining token-level probabilities from the model—sequence-level log probability (G) and average token-level log probability (H):

$$G(y|x) = \sum_{t=1}^{|y|} \log p(y_t|y_{i<t}, x)$$

$$H(y|x) = \frac{1}{|y|} G(y|x)$$

Let sys denote an MT system output, ref denote a human reference, and src denote the source. We expect scoring sys conditioned on ref to be most indicative of the quality of sys. However, we also explore scoring ref conditioned on sys as we find qualitatively that output sentences which drop some

---

[3] We find that generating from a well trained multilingual NMT system tends to produce copies of the input, as opposed to interesting paraphrases (see Appendix A).

meaning conveyed by the input sentence are penalized less harshly by the model than output sentences which contain extra information not present in the input. Scoring in both directions to penalize the presence of information in one sentence but not the other is similar, in spirit, to methods which use bi-directional textual entailment as an MT metric (Padó et al., 2009; Khobragade et al., 2019).[4]

We postulate that the output sentence that best represents the meaning of an input sentence is, in fact, simply a copy of the input sentence, as precise word order and choice often convey subtle connotations. As such, we seek a model whose output distribution is *centered around a copy of the input sentence*, which we denote a "lexically/syntactically unbiased paraphraser." While a standard generative paraphraser is trained to retain semantic meaning, it does not meet our criteria because it is *simultaneously* trained to produce output which is lexically/syntactically different than its input, a key element in generative paraphrasing (Bhagat and Hovy, 2013).

We propose using a multilingual NMT system as a lexically/syntactically unbiased paraphraser. A multilingual NMT system consists of an encoder which maps a sentence in to an (ideally) language-agnostic semantic representation, and decoder to map that representation back to a sentence. The model has only seen bitext in training, but we propose to treat paraphrasing as a zero-shot "translation" (e.g., Czech to Czech).

Because our model is multilingual, we can also score MT system output conditioned on the source sentence instead of the human reference. This task is known as "quality estimation (QE) as a metric," and was part of the WMT19 QE shared task (Fonseca et al., 2019). We use "Prism-ref" to denote our reference-based metric and "Prism-src" to denote our system applied as a QE metric.

Our final metric and QE metric are defined based on results on our development set (see §5.2) as follows:

$$\begin{aligned}\text{Prism-ref} &= \frac{1}{2}H(\text{sys}|\text{ref}) + \frac{1}{2}H(\text{ref}|\text{sys})\\ \text{Prism-src} &= H(\text{sys}|\text{src})\end{aligned}$$

To obtain system-level scores, we average segment-level scores over all segments in the test set.

4 Experiments

We train a multilingual NMT model and explore the extent to which it functions as a lexically/syntactically unbiased paraphraser. We then conduct several preliminary experiments on the WMT18 MT metrics data (Ma et al., 2018) to determine how to best utilize the token-level probabilities from the paraphraser, and report results on the WMT19 system- and segment-level metric tasks (Ma et al., 2019) and QE as a metric task (Fonseca et al., 2019).

4.1 Data Preparation

Our method requires a model, which in turn relies heavily on the data on which it is trained, so we describe here the rationale behind the design decisions made regarding the training data. Full details sufficient for replication are provided in Appendix B.

Language-Agnostic Representations To encourage our intermediate representation to be as language-agnostic as possible, we choose datasets with as much language pair diversity as possible (i.e., not just en–* and *–en), as Kudugunta et al. (2019) has shown that encoder representation is affected by both the source language and target language. While it is common to append the target language token to the source sentence, we instead prepend it to the target sentence so that the encoder cannot do anything target-language specific with this tag. At test time, we force-decode the desired language tag prior to scoring.

Noise NMT systems are known to be sensitive to noise, including sentence alignment errors (Khayrallah and Koehn, 2018), so we perform filtering with LASER (Schwenk, 2018; Chaudhary et al., 2019). We also perform language ID filtering using FastText (Joulin et al., 2016) to avoid training the decoder with incorrect language tags.

Number of Languages Aharoni et al. (2019) found that performance of zero-shot translation in a related language pair increased substantially when increasing the number of languages from 5 languages and 25, with a performance plateau somewhere between 25 and 50 languages. We view paraphrasing as zero-shot translation between sentences in the same language, so we expect to need a similar number of languages.

---

[4] Conditional probabilities of MT systems in each direction have been shown effective at filtering MT training data (Junczys-Dowmunt, 2018).

Copies We filter sentence pairs with excessive copies and partial copies, as multiple studies (Ott et al., 2018; Khayrallah and Koehn, 2018) have noted that MT performance degrades substantially when systems are exposed to copies in training.

4.2 Model Training

We train a Transformer (Vaswani et al., 2017) model with approximately 745M parameters to translate between 39 languages. The full list of languages and data amounts used is provided in Appendix B, and model training details sufficient for replication are given in Appendix C. Training a single large model consumed the majority of our compute budget, thus performing ablations is beyond the scope of this work.

Our data comes primarily from WikiMatrix (Schwenk et al., 2019), Global Voices,[5] EuroParl (Koehn, 2005), SETimes,[6] and United Nations (Eisele and Chen, 2010). The data processing described above and in Appendix B results in 99.8M sentence pairs in 39 languages.[7] The most common language is English, at 16.7% of our data, while the least common 20 languages account for 21.9%.

4.3 Baselines and Contrastive Methods

We compare to all systems from the WMT19 shared metrics task, as well as BERTscore (Zhang et al., 2020) and the recent BLEURT method (Sellam et al., 2020). We also explore several contrastive methods. Training details sufficient for replication for each model/baseline are given in Appendix C.

Generative Sentential Paraphraser We compare scoring with our Prism model vs a standard, English-only paraphraser trained on the ParaBank 2 dataset (Hu et al., 2019c). ParaBank 2 contains $\sim$ 50M synthetic paraphrastic pairs derived from back-translating a Czech–English corpus, and the authors report state-of-the-art paraphrasing results.

Auto-encoder Auto-encoders provide an alternative means of training seq2seq models, without the need for parallel bitext. We compare to scoring with the "multilingual denoising pre-trained model" (mBART) of Liu et al. (2020), as it works in all languages of interest.

LASER We explore using the cosine distance between LASER embeddings of the MT output and human reference, using the pretrained 93-language model provided by the authors.[8] We are particularly interested in LASER as it, like our model, is trained on parallel bitext in many languages.

Language Model We find qualitatively that LASER is fairly insensitive to disfluencies (see Table 1), so we also explore augmenting it with language model (LM) scores of the system outputs. We train a multilingual language model (see Appendix C) on the same data as our multilingual NMT system.

4.4 Paraphraser Bias

We expect that a lexically/syntactically unbiased measure of translation quality should (on average) increase with increased lexical similarity between a translation and reference. To explore the extent to which Prism and the model trained on ParaBank 2 are biased, we consider average $H(\text{sys}|\text{ref})$ as a function of binned lexical similarity (approximated by sentBLEU, with smoothing=1) for all (sys, ref) pairs for all systems submitted to WMT19 in all language pairs into English. We also contrast the conditional probabilities of three outputs for the same input: (1) the sequence generated by the model via beam search; (2) a copy of the input; and (3) a human paraphrase of the input. Finally, we generate from the model using beam search and examine the outputs to see how much they differ from the inputs.

4.5 MT Metrics Evaluation

We report results and statistical significance using scripts released with the WMT19 shared task. Segment-level performance is reported as the Kendall's τ variant used in the shared task, and system-level performance is reported as Pearson correlation with the mean of the human judgments. Bootstrap resampling (Koehn, 2004; Graham et al., 2014) is used to estimate confidence intervals for each metric, and metrics with non-overlapping 95% confidence intervals are identified as having a statistically significant difference in performance.

Table 2: WMT19 segment-level human correlation (τ), to non-English (top) and to English (bottom). **Bold** denotes top scoring method and any other methods with whose 95% confidence interval overlaps with that of a top method. ‡:WMT19 Metric Submission. For brevity, only competitive baselines are shown. For complete results see Appendix E. Our models were not trained on Gujarati (gu). "LASER + LM" denotes the optimal linear combination found on the development set.

5 Results

5.1 Paraphraser Bias Results

We find $H(\text{sys}|\text{ref})$ increases monotonically with sentBLEU for the Prism model, but the model trained on ParaBank 2 has nearly the same scores for output with sentBLEU in the range of 60 to 100; however that range accounts for only about 8.5% of all system outputs (see Figure 2). We find that a copy of the input is almost as probable as beam search output for the Prism model. In contrast, the model trained on ParaBank 2 prefers its own beam search output to a copy of the input. Additionally, beam search from our model produces output which is more lexically similar to the input (BLEU of 82.8 with respect to input, vs 31.9 for ParaBank 2). ParaBank 2 tends to change the output in ways which occasionally significantly alter the meaning of the sentence. See Appendix A for more details. All of these findings support our hypothesis that our model is closer to an ideal lexically/syntactically unbiased paraphraser than the contrastive model trained on synthetic paraphrases.

---

5.2 Preliminary (Development) Results

We find that length-normalized log probability (H) slightly outperforms un-normalized log probability (G). When using the reference, we find an equal weighting of $H(\text{sys}|\text{ref})$ and $H(\text{ref}|\text{sys})$ to be approximately optimal, but we find that when using the source, $H(\text{src}|\text{sys})$ does not appear to add useful information to $H(\text{sys}|\text{src})$. Full results can be found in Appendix D. These findings were used to select the Prism-ref and Prism-src definitions (§3).

We find that the probability of sys as estimated by an LM, as well as and the cosine distance between LASER embeddings of sys and ref, both have decent correlation with human judgments and are complementary. However, cosine distance between LASER embeddings of sys and src have only weak correlation.

5.3 Segment-Level Metric Results

Segment-level metric results are shown in Table 2. On language pairs into non-English, we outperform prior work by a statistically significant margin in 7 of 11 language pairs[9] and are statistically tied for best in the rest, with the exception of Gujarati (gu) where the model had no training data. Into English, our metric is statistically tied with the best prior work in every language pair. Our metric tends to significantly outperform our contrastive LASER + LM and mBART methods, although LASER + LM performs surprisingly well in en–ru.

5.4 System-Level Metric Results

Table 3 shows system-level metric performance on the top four systems submitted to WMT19 compared to selected metrics. While correlations are not high in all cases for Prism, they are at least all positive. In contrast, BLEU has negative correlation in 5 language pairs, and BERTscore and YiSi-1 variants are each negative in at least two. BLEURT has positive correlations in all language pairs into English, but is English-only. Note that Pearson's correlation coefficient may be unstable in this setting (Mathur et al., 2020). For full top four system-level results see Appendix F.

We do not find the system-level results computed against *all* submitted MT systems (see Appendix G) to be particularly interesting; as noted by Ma et al. (2019), a single weak system can result in high overall system-level correlation even for a very poor metric.

5.5 QE as a Metric Results

We find that our reference-less Prism-src outperforms all QE as a metrics systems from the WMT19 shared task by a statistically significant margin, in every language pair at segment-level human correlation (Table 4), and outperforms or statistically ties at system-level human correlation (Appendix G).

6 Analysis and Discussion

How helpful are human references? The fact that our model is multilingual allows us to explore the extent to which the human reference actually improves our model's ability to judge MT system output, compared to using the source instead. The underlying assumption with any MT metric is that the work done by the human translator makes it easier to automatically judge the quality of MT output. However, if our model or the MT systems being judged were strong enough, we would expect this assumption to break down.

Comparing the performance of our method with access to the human reference (Prism-ref) vs our method with access to only the source (Prism-src), we find that the reference-based method statistically outperforms the source-based method in all but one language pair. We find the case where they are not statistically different, de–cs, to be particularly interesting: de–cs was the only language pair in WMT19 where the systems were unsupervised (i.e., did not use parallel training data). As a result, it is the only language pair where our model outperformed the best WMT system at translation. In most cases, our model is *substantially worse at translation* than the best WMT systems. For example, in en–de and zh–en, two language pairs where strong NMT systems were especially problematic for MT metrics, the Prism model is 6.8 and 19.2 BLEU points behind the strongest WMT systems, respectively (see Table 5 for the Prism model compared to the best system submitted in each WMT19 language pair). Thus the performance difference between Prism-ref and Prism-src would suggest that the model needs no help in judging MT systems which are weaker than it is, but *the human references are assisting our model in evaluating MT systems which are stronger than it is.* This means that we have not simply reduced the task of MT evaluation to that of building a state-of-the-art MT

---

[9] In en–ru, Prism-ref is statistically tied with YiSi-1, ESIM, and BERTscore.

system. We see that a good (but not state-of-the-art) multilingual NMT system can be a state-of-the-art MT metric and judge state-of-the-art MT systems.

Finally, with the exception of de–cs discussed above, we see statistically significant improvements for Prism-ref over Prism-src both into English (where human judgments were reference-based) and into non-English (where human judgments were source-based). This suggests that the high correlation of Prism-ref with human judgements is not simply the result of reference bias (Fomicheva and Specia, 2016).

Does paraphraser bias matter? Our lexically/syntactically unbiased paraphraser tends to outperform the generative English-only ParaBank 2 paraphraser, but usually not by a statistically significant margin. Analysis indicate the lexical/syntactic bias is only harmful in somewhat infrequent cases where MT systems match or nearly match the reference, suggesting it would be more detrimental with stronger systems or multiple references. Our multilingual training method is much simpler than the alternative of creating synthetic paraphrases and training individual models in 39 languages, and our model may benefit from transfer learning to lower-resource languages.

Does fluency matter? Despite NMT being very fluent, our results suggest that fluency is fairly discriminative, especially in non-English: LM scoring outperforms sentenceBLEU at segment-level correlation in 7/10 language pairs to non-English languages (excluding Gujarati), for example. This is consistent with recent findings that LM scores can be used to augment BLEU (Edunov et al., 2020).

Table 5: BLEU scores for our multilingual NMT system on WMT19 testsets, compared to best system from WMT19. Our multilingual system achieves state-of-the-art performance as an MT metric despite substantially under performing all the best WMT19 MT systems at translation (excluding unsupervised). †: WMT systems were unsupervised (no parallel data). ‡: Multilingual system did not train on Gujarati (gu). Systems are not trained on the same data, so this should not be interpreted as a comparison between multilingual and single-language pair MT. ISO 639-1 language codes.

Can we measure adequacy and fluency separately? The proposed method significantly outperforms the contrastive LASER-based method in most language pairs, even when LASER is augmented with a language model. This suggests that jointly optimizing a model for adequacy and fluency is better than optimizing them independently and combining after the fact—this is unsurprising given that neural MT has shown significant improvements over statistical MT, where a phrase table and language model were trained separately.

Can we train on monolingual data instead of bitext? The proposed method significantly outperforms scoring with the mBART auto-encoder, which is trained on large amounts of monolingual data, despite using substantially less compute power (1.3 weeks on 8 V100s for Prism vs 2.5 weeks on 256 V100s for mBART).

7 Conclusion and Future Work

We show that a multilingual NMT system can be used as a lexically/syntactically unbiased, multilingual paraphraser, and that the resulting paraphraser can be used as an MT metric and QE metric. Our method achieves state-of-the-art performance on the most recent WMT shared metrics and QE tasks, without training on prior human judgements.

We release a single model which supports 39 languages. To the best of our knowledge, we are the first to release a large multilingual NMT system, and we hope others follow suit. We are optimistic our method will improve further as stronger multilingual NMT models become publicly available.

We compare our method to several contrastive methods and present analysis showing that we have not simply reduced the task of evaluation to that of building a state-of-the-art MT system; the work done by the human translator to create references helps the evaluation model to judge systems that are stronger (at translation) than it is.

Nothing in our method is specific to sentence-level MT. In future work, we would like to extend Prism to paragraph- or document-level evaluation by training a paragraph- or document-level multilingual NMT system, as there is growing evidence that MT evaluation would be better conducted at the document level, rather than the sentence level (Läubli et al., 2018).

A Generation Examples

Figure 3 shows sentences generated from both our model and the model trained on ParaBank 2.

We also contrast the conditional probabilities of three outputs for the same input: (1) the sequence generated by the model via beam search; (2) a copy of the input; and (3) a human paraphrase of the input. We use the English side of the zh–en newstest17 (Bojar et al., 2017) as input, so that we can use the second human reference released by Hassan et al. (2018) as a human paraphrase. Table 6 shows the results of scoring a copy of the input, a human paraphrase of the input, and a model's beam search output, for both our multilingual paraphraser and the ParaBank 2 model.

	ParaBank 2	This Work
$H(BS\|r0)$	-0.501	-0.225
$H(r0\|r0)$	-1.157	-0.303
$H(r1\|r0)$	-2.246	-2.187
$BLEU(BS, r0)$	31.9	82.8

Table 6: Average token log probability (H) for a sequence generated via beam search (BS), a copy of the input ($r0$), and a high-quality human paraphrase of the input ($r1$), for a generative paraphraser vs our model, conditioned on $r0$ in all cases. BLEU is also computed for the beam search output of each model, with respect to $r0$. Note that BLEU for $r1$ with respect to $r0$ is 17.1.

Figure 3: Sentences generated via beam search (beamwidth 5) for the multilingual model presented in this work vs ParaBank 2. We note that our model tends to produces copies or near copies of the input, which is the desired behavior for our application. Changes are emphasized with **bold** or ~~**strikethrough**~~. The model trained on ParaBank 2 tends to produce output with lexical/syntactic changes, which occasionally also significantly change the meaning of the sentence (denoted in red). References (paraphraser inputs) are the first ten sentences of WMT17 zh–en.

B Data Details for Replication

Much of our data comes from WikiMatrix (Schwenk et al., 2019), a large collection of parallel data extracted from Wikipedia, and for more domain variety, we added Global Voices,[10] EuroParl (Koehn, 2005) (random subset of to 100k sentence pairs per language pair), SETimes,[11] United Nations (Eisele and Chen, 2010) (random sample of 1M sentence pairs per language pair). We also included WMT Kazakh–English and Kazakh–Russian data from WMT, to be able to evaluate on Kazakh.

WMT Kazakh–English and Kazakh–Russian were limited to the best 1M and 200k sentence pairs, respectively, as judged by LASER. We used a margin threshold of 1.05 for WikiMatrix and a threshold of 1.04 for the remaining datasets, as we expect them to be cleaner. We find that FastText classifies many sentences as non-English when they contain mostly English but also contain a few non-English words, especially from lower resource languages. To remedy this, we performed language identification (LID) on 5-grams and filtered out sentences for which LID did not classify at least half of the 5-grams as the expected language.

We filtered out sentences where there was more than 60% overlap in 3-grams or 40% overlap in 4-grams. Via manual inspection, this seemed to provide a good trade-off between allowing numbers and named entities to be copied, and filtering out sentences that were clearly not translated. We perform tokenization with SentencePiece (Kudo and Richardson, 2018) prior to filtering, using a 200k vocabulary for all language pairs, to account for languages like Chinese which do not denote word boundaries. Note that this vocabulary was used only for filtering, not for training the final model.

We limited training to languages with at least 1M examples, which resulted in 39 languages. Figure 4 shows the languages and amount of data in each language.

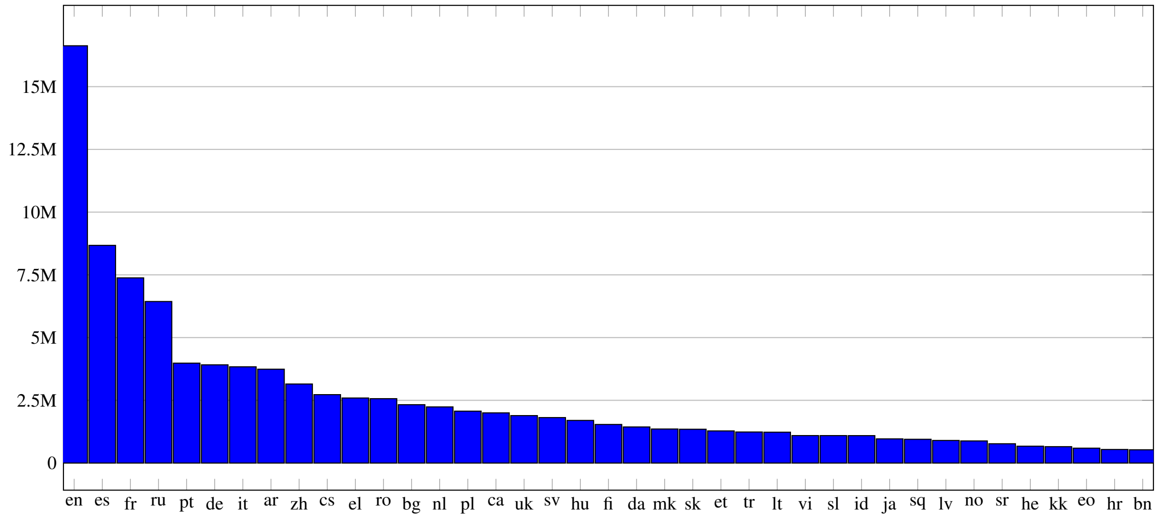

Figure 4: Distribution of the 39 languages (ISO 639-1 language code) of the 99.8M training sentences. English accounts for 16.7%. Spanish, French, Russian, Portuguese, German, and Italian account for a combined 34.3%. The bottom 20 languages account for only 21.9% combined.

C Model Training Details for Replication

C.1 Primary Model

We train a SentencePiece (Kudo and Richardson, 2018) model with a 64k vocabulary size on the concatenation of all data, and filter sentences with length greater than 200 subwords. Multilingual NMT performance has been found to increase significantly with model size – tor example, the best performance of Huang et al. (2019) is with their largest model which has 6 billion parameters. Training such a model is well beyond the scope of this work, but we train a model as large a feasible given our compute budget constraints. We train a Transformer (Vaswani et al., 2017) in fairseq (Ott et al., 2019) with eight encoder layers, eight decoder layers, an embedding size of 1280, feed forward layer size of 12288, 20 attention heads, learning rate of 0.0004, batch size of 1800 tokens with gradient accumulation over 200 batches, gradient clipping of 1.2, and dropout of 0.1. The model has approximately 745M parameters for 39 languages. We train for 6 epochs, which takes approximately 9 days on a `p3.16xlarge` instance rented from Amazon AWS, which has 8 Volta V100 GPUs with 16 GB of memory each. No hyperparameters were swept, as training a single model used the majority of our compute budget (the total cost for training this model was approximately $13,000 USD). However, we did restart training after discovering that LID was not performing well and adding the 5-gram LID filtering.

C.2 ParaBank 2 Model

We train a contrastive, English-only paraphraser on the ParaBank 2 dataset (Hu et al., 2019c). We train a Transformer with an 8-layer encoder, 8-layer decoder, 1024 dimensional embeddings, embedding sizes of 1024, feed-forward size of 4096, and 16 attention heads. We use a SentencePiece model with a 16k vocabulary size. Dropout is 0.3, label smoothing is 0.1, and learning rate is 0.0005. The model has approximately 253M parameters for 1 language. Batch size is 31200 tokens, and the model trains for approximately 6 weeks (33 epochs) on 4 Nvidia 2080 GPUs.

C.3 Language Model

We train a multilingual language model on the same data as our multilingual NMT system.

The model architecture is based on GPT-2 (Radford et al., 2019), and we use the fairseq `transformer_lm_gpt2_small` implementation. We train for 200k updates (18 epochs) of approximately 131k tokens. The model has 369M parameters for 39 languages. We train with shared embeddings and a learning rate of 0.0005, and we stop gradients at sentence boundaries, using `--sample-break-mode eos` as the model will be used to evaluate individual sentences. Other parameters match the fairseq defaults. The model trained for approximately 4 weeks on 4 Nvidia TITAN RTX GPUs.

C.4 Autoencoder

We use the pretrained "multilingual denoising pre-trained model" (mBART) model of Liu et al. (2020), as it works in all languages of interest. Their model is designed to be fine-tuned to translation tasks, and their fine-tuning introduces subtle changes to the decoder that are required for inference. In order to adapt it to our task, we therefore fine-tune for a single update with a learning rate of 0. We then produce scores with the model in the same manner as Prism-ref. The model has approximately 680M parameters for 25 languages. We did not train this model but note that doing so required substantial compute power – Liu et al. (2020) note that they trained for approximately 2.5 weeks on 256 Nvidia V100 GPUS, each with 32GB of memory.

C.5 Baselines

We compare to BLEURT (Sellam et al., 2020) using the authors' recommended "BLEURT-Base 128"[12] We compare to BERTscore F1 (Zhang et al., 2020) using the model and code provided by the authors.[13]

---

[12] `https://github.com/google-research/bleurt`

[13] `https://github.com/Tiiiger/bert_score`

The remaining baseline results are computed using the metric scores as submitted to (Ma et al., 2019)[14]

D WMT 2018 (Development set) Results: System-level, Segment-level, and Sweeps

Figure 5 shows results on the development set (WMT18) for sweeping various linear combinations.

Table 7, Table 8, Table 9 and Table 10, show full segment- and system- level results, into and out of English, for the WMT 2018 MT metrics shared task, along with all baselines and submitted systems.

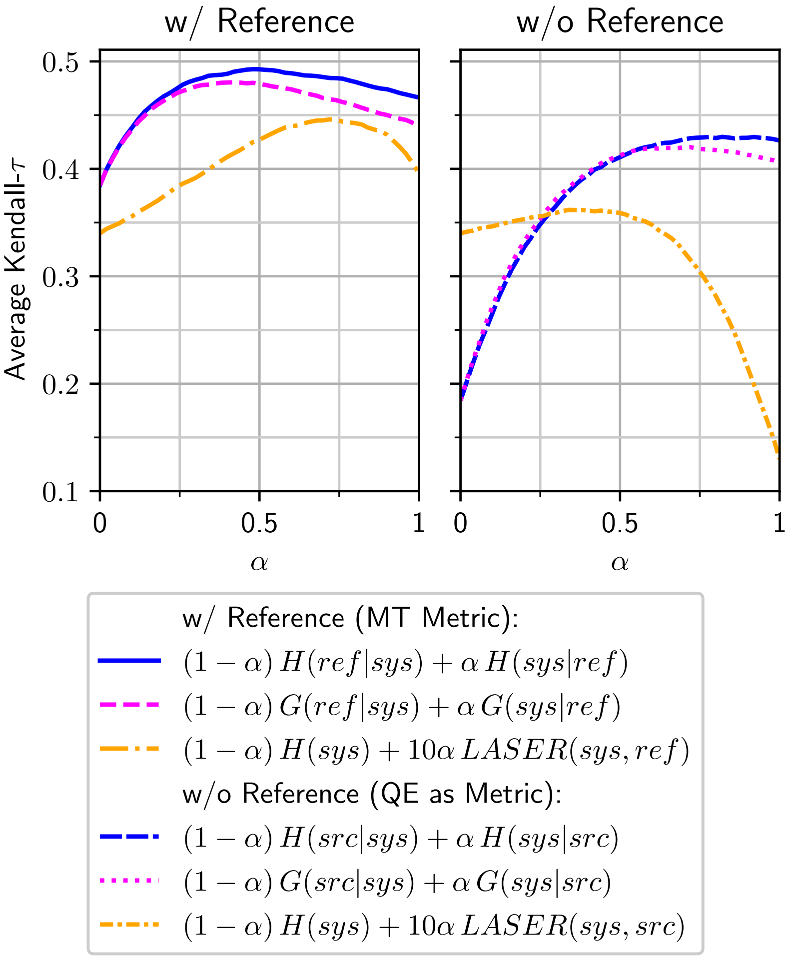

Figure 5: Linear combinations of scoring each direction using length-normalized (H) vs un-normalized (G) log probability for our method, and length-normalized language model probabilities (H) vs LASER for our contrastive method. In both cases, we explore scoring using the human reference ref vs the source src. Results are segment-level τ on our development set (WMT18), averaged across all language pairs.

F WMT 2019 System-Level results for Top 4 Systems

Table 17 Table 18, and Table 19 show system-level results for just the top 4 systems, for language pairs into, out of, and not including English, for WMT 2019. We show statistical significance following the shared task but note it appears extremely noisy.

G WMT 2019 Metric and QE as Metric System-Level Results

Table 20, Table 21, and Table 22, show system-level results, for metrics (excludes QE as metric) for language pairs into, out of, and not including English, for the WMT 2019 MT metrics shared task, along with all baselines and submitted systems.

Table 23, Table 24, and Table 25, show system-level results, for QE as metric, for language pairs into, out of, and not including English, for the WMT 2019 MT metrics shared task, along with all baselines and submitted systems.

PRover: Proof Generation for Interpretable Reasoning over Rules

UNC Chapel Hill
`{swarna, sayghosh, ssrivastava, mbansal}@cs.unc.edu`

Abstract

Recent work by Clark et al. (2020) shows that transformers can act as "soft theorem provers" by answering questions over explicitly provided knowledge in natural language. In our work, we take a step closer to emulating formal theorem provers, by proposing PRover, an interpretable transformer-based model that jointly answers binary questions over rule-bases and generates the corresponding proofs. Our model learns to predict nodes and edges corresponding to proof graphs in an efficient constrained training paradigm. During inference, a valid proof, satisfying a set of global constraints is generated. We conduct experiments on synthetic, hand-authored, and human-paraphrased rule-bases to show promising results for QA and proof generation, with strong generalization performance. First, PRover generates proofs with an accuracy of 87%, while retaining or improving performance on the QA task, compared to RuleTakers (up to 6% improvement on zero-shot evaluation). Second, when trained on questions requiring lower depths of reasoning, it generalizes significantly better to higher depths (up to 15% improvement). Third, PRover obtains near perfect QA accuracy of 98% using only 40% of the training data. However, generating proofs for questions requiring higher depths of reasoning becomes challenging, and the accuracy drops to 65% for "depth 5", indicating significant scope for future work.[1]

1 Introduction

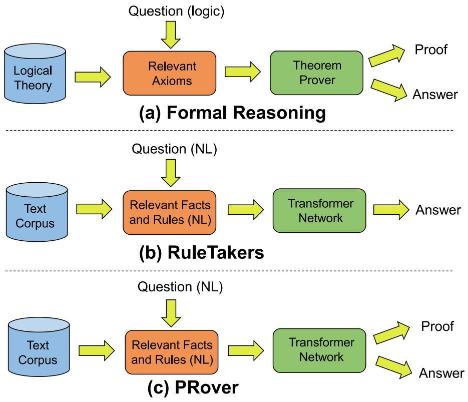

Figure 1: Block diagram showing that PRover is a closer linguistic analog of formal reasoning.

Developing systems that can understand and reason over explicitly provided knowledge has been a fundamental goal of AI (Newell and Simon, 1956). Owing to the challenges posed in reasoning over formal representations (Musen and Van Der Lei, 1988), and backed by the recent successes of transformers (Vaswani et al., 2017) in NLP, Clark et al. (2020) propose a new version of the problem by replacing the formal representations of rule-bases with natural language (English). Specifically, their task requires predicting the truth value of a statement by reasoning over a set of facts and rules, all expressed in natural language. Figure 2 shows some examples of the task. Clark et al. (2020) propose RuleTakers, a fine-tuned RoBERTa model (Liu et al., 2019b) to show that transformers can act as "soft theorem provers" by predicting the final answer in such reasoning-based problems with high accuracy.

We argue that to use transformers for natural language reasoning reliably, they should be able to generate proofs that provide rationales for the predicted answer. Proof generation is vital for emulating formal reasoning but also for moving towards human-interpretable models that alleviate concerns about the black-box nature of deep architectures (Rudin, 2019). Towards this, we present PRover, a transformer-based model that jointly answers questions over natural language rule-bases and generates corresponding proofs. Figure 1 illustrates our method as a closer linguistic analog

---

November 16–20, 2020.

of formal reasoning, as it generates proofs along with answers. However, unlike formal reasoners, PRover can operate on natural language text that provides the underlying theory, rather than rely on formal logical representations. Such methods that combine interpretability and flexibility in reasoning can have wide applications across domains.

PRover's architecture consists of three modules that together generate answers along with proofs. In this work, proofs are represented as directed graphs consisting of the relevant rules and facts needed to prove or disprove the question statement. Section 3.1 contains details of this representation. A QA module predicts a binary answer for the question, a node module chooses which rules and facts are part of the proof, and an edge module predicts the presence and the direction of the edges between the chosen nodes. Model training minimizes a joint cross-entropy loss over the three modules. To guide the model to predict edges between valid nodes only, we enforce global constraints on the structure of the proof during training, by masking out labels for impossible edges, resulting in a more efficient learning problem. PRover generates valid proofs during inference by solving an ILP over the edge potentials, subject to multiple semantic constraints, such as ensuring proof graph connectivity. Our contributions are:

- We present PRover, an interpretable joint model that learns to reason over natural language rule-bases and generate corresponding proofs.
- PRover performs similarly or improves upon state-of-the-art QA accuracy for the task, with up to 6% improvement on zero-shot evaluation, and generates exact proofs at 87% accuracy. Unlike RuleTakers, it does not require additional fine-tuning on the RACE (Lai et al., 2017) dataset.
- PRover demonstrates significantly better generalization. When trained on lower depth questions, it shows better QA accuracy (up to 15%) on higher depth ones.

2 Related Work

Our work is related to multiple bodies of previous work in NLP and formal reasoning.

QA and NLI: The rule reasoning task is related to reasoning tasks that have been proposed recently. These include tasks in the bAbI dataset (Weston et al., 2015), synthetically generated probe tasks (Richardson et al., 2020) or reading comprehension tasks in datasets such as QuaRTz (Tafjord et al., 2019) and ROPES (Lin et al., 2019). Unlike our task, most of these require reasoning over implicit rules, the focus being on language understanding and one step of rule application. Multi-hop QA datasets like HotpotQA (Yang et al., 2018) require multiple reasoning steps, but the inference rules needed are again implicitly inferred, rather than explicitly provided. Our task also bears similarity with Natural Language Inference (MacCartney and Manning, 2014), but NLI also allows unsupported inferences by filling gaps in explicitly stated knowledge (Dagan et al., 2013).

Formal Reasoning and Neural Theorem Proving: Semantic parsing (Zettlemoyer and Collins, 2005; Berant et al., 2013; Berant and Liang, 2014) of multi-sentence texts into logical forms has proved to be challenging, restricting the application of semantic parsers to formal reasoning systems (Kamath and Das, 2019). PRover bypasses this expensive and error-prone process and attempts to solve the problem in an end-to-end manner, without any intermediate logical representations.

Our approach is conceptually similar to a body of work on Neural Theorem Proving (Weber et al., 2019) that has focused on developing theorem provers by combining reasoning from symbolic techniques with the possibility of differentiable learning from neural networks. These include neuro-symbolic methods for table comprehension (Neelakantan et al., 2016), executing basic compositional programs (Reed and de Freitas, 2016), SAT solving (Selsam et al., 2019), formula embedding (Abdelaziz et al., 2020), approximate (DNF) model counting (Abboud et al., 2020), etc. However, PRover diverges from these in working with free-form natural language input to generate proofs similar to formal reasoners.

Model Interpretability: PRover follows a significant body of previous work on developing interpretable neural models for NLP tasks to foster explainability. Several approaches have focused on formalizing the notion of interpretability (Rudin, 2019; Doshi-Velez and Kim, 2017; Hase and Bansal, 2020), tweaking features for local model interpretability (Ribeiro et al., 2016, 2018) and exploring interpretability in latent spaces (Joshi et al., 2018; Samangouei et al., 2018). Our work can be seen as generating explanations in the form of proofs for an NLP task. While there has been prior work on generating natural language explana-

Figure 2: Diagram showing two rule-bases with rules, facts, questions, answers and proofs. PROVER answers all the questions correctly and also generates all the corresponding proofs accurately in the above scenarios.

tions for multiple NLP tasks, including NLI (Camburu et al., 2018), commonsense reasoning (Rajani et al., 2019; Zhang et al., 2020) and generic text classification tasks (Liu et al., 2019a), our novelty lies in generating compositional explanations consisting of proof graphs that detail the chain of reasoning, starting from language. We use a max-flow ILP formulation for checking proof graph connectivity (Even and Tarjan, 1975). Multiple approaches for NLP tasks such as sentiment analysis and content selection (Pang and Lee, 2004; Barzilay and Lapata, 2005; Bansal et al., 2008) have been framed as optimal flow problems on graphs.

Program Synthesis with Transformers: Existing works show that transformers already capture some knowledge from pre-training for algorithm emulation (Talmor et al., 2019) or can be fine-tuned for tasks like semantic parsing (He and Choi, 2020), translation (Wang et al., 2019), symbolic integration (Lample and Charton, 2020) and mathematics (Saxton et al., 2019). In our work, we also employ a transformer-based pre-trained language model (RoBERTa (Liu et al., 2019b)) but for the downstream task of rule-based reasoning.

3 Method

Each input to PROVER is a context C (consisting of facts F and rules R) and a question Q, about the context. PROVER predicts the answer $A \in \{True, False\}$ and generates a proof $\mathcal{P}$.

3.1 Proof Representation

A proof, $\mathcal{P} = (\mathcal{N}, \mathcal{E})$, is a directed graph with nodes $n \in \mathcal{N}$ and edges $e \in \mathcal{E}$. Each node is either a fact $f \in F$, a rule $r \in R$ or a special NAF node (Negation As Failure, as described below). Edges in the proof are directed either from a fact (or NAF) to a rule or from a rule to another rule. These indicate that a fact (or NAF) is consumed by a rule, or the output of a rule (a new fact) is consumed by another rule, respectively. We use these constraints both during PROVER's training and inference, as described later in the paper. Formally, we have:

$$\mathcal{P} = (\mathcal{N}, \mathcal{E})$$
$$\mathcal{N} \subseteq R \cup F \cup NAF$$
$$\mathcal{E} \subseteq \mathcal{N} \times \mathcal{N}$$

Figure 2 shows examples of two contexts (consisting of facts and rules), five questions about the contexts, along with their answers and proofs. Each proof has a depth (Q_1's proof has a depth of 1). The maximum proof depth in all the datasets considered in this work (Clark et al., 2020) is 5. Proofs in the datasets are of three types:

Successful proof with NAF: The proof of Q_1 in Figure 2 is one such such example. F_2 acts on R_4 to prove that "The wire is conducting." and hence the answer is false.

Successful proof with NAF: Given a statement s, NAF in logic programming is a non-monotonic inference rule used to derive "not s" (negation of the statement) from failure to derive s. Hence, a proof may contain NAF node(s), representing the truthfulness of the negation of statement(s) that cannot be proved using the set of rules. Consider the proofs for Q_4 and Q_5 where the NAF node in Q_4 represents "The bald eagle is not kind.".

Failed proof: This happens when a statement cannot be derived using the given rule-base and the shallowest branch of the proof tree that fails is shown. Q_3's proof in Figure 2 is an example as "The radio is playing." cannot be proved.

Note that a proof can have edges between two rules in both directions. E.g., consider the edges $R_4 \rightarrow R_5$ and $R_5 \rightarrow R_4$ in Q_5's proof in Figure 2. A node can have more than two incoming edges – the node R_6 in Q_2 has three incoming edges from R_1, R_3, and R_4.

3.2 Task Description

Each training example is a tuple $(C_i := \{F_i, R_i\}, Q_i, A_i, \mathcal{P}_i)$ consisting of a context (set of rules and facts), a question, the corresponding answer, and a proof. Generating a proof graph requires (1) identifying the nodes (set of relevant facts, NAF and rules) that are part of the proof, (2) identifying the edges connecting these nodes, and (3) verifying a set of global constraints such as proof connectivity that ensure a valid proof.

For the first, we predict a binary label over each rule, fact and NAF denoting their presence or absence in the proof. For the second, we also predict binary labels denoting the presence or absence of each edge. For the third, we enforce constraints during both training and inference (Section 3.4). During training, we mask out the edge labels[2] corresponding to (1) self-loops, (2) edges between absent nodes, and (3) edges between facts to facts and rules to facts. This enforces a semantic constraint that the set of candidate edges in the ensuing proof is consistent with the chosen set of nodes, and also simplifies the learning problem, since a smaller number of edges need to be labeled.

3.3 PROVER: Joint QA and Proof Generation Model

Figure 3 shows the architecture of PROVER, built on top of RoBERTa (Liu et al., 2019b). Our model consists of three modules: (1) QA module, (2) Node module, and (3) Edge module. The QA module is exactly the same as the RuleTakers model (Clark et al., 2020), thus allowing us to directly evaluate the effectiveness of our node and edge modules. The input to RoBERTa is the concatenation of the context and the question, separated by the $[SEP]$ tokens. The context is represented by concatenating the text consisting of facts and rules. Formally, if the rules and facts are denoted by $\{RF_i\}_{i=1}^{k}$ and the question by Q, the input is

$$[CLS]\ \{RF_i\}_{i=1}^{k}\ [SEP][SEP]\ Q\ [SEP]$$

QA Module: The output of RoBERTa contains an embedding for each token in the context and a global embedding corresponding to the $[CLS]$ token. The QA classification head H_{QA} is a sequence of two linear layers with dropout probability of p. Formally, if $t_{[CLS]}$ denotes the $[CLS]$ token embedding, we obtain the class-wise probability values P_{QA} using the softmax function σ.

$$P_{QA} = \sigma(H_{QA}(t_{[CLS]}))$$

Node Module: Let $\{w_j^{(i)}\}_{j=1}^{m}$ denotes the m tokens corresponding to RF_i. Assuming the corresponding RoBERTa embeddings are denoted by $\{t_{w_j^{(i)}}\}_{j=1}^{m}$, we learn a representation t_{RF_i} for each RF_i, by performing a mean pooling MP of the constituent token embeddings.

$$t_{RF_i} = MP(\{t_{w_j^{(i)}}\}_{j=1}^{m})$$

We also learn a representation of the NAF node t_{NAF} as a linear transformation on $t_{[CLS]}$. Note that due to the self-attention layers of RoBERTa, $t_{[CLS]}$ summarizes the set of all derivable facts given the context and the question. We want the NAF node to encode information about all facts containing negation (e.g.,"The bald eagle is not kind" in Q_4's proof of Figure 2) in the context. These are taken as true as their positive counterparts ("The bald eagle is kind") are non-derivable given the context. Thus, if a statement s cannot be derived from the facts and the rules in a context, the NAF node should infer that "not s" is true. We model this notion of the negation of all unprovable statements (given a context) by learning NAF as a function of everything provable in the context, encoded by the $t_{[CLS]}$ embedding.[3]

---

[2] The masked edges do not contribute to the training loss.

[3] We note that a proof can have multiple NAF nodes, each representing a different negated fact. Since the datasets label

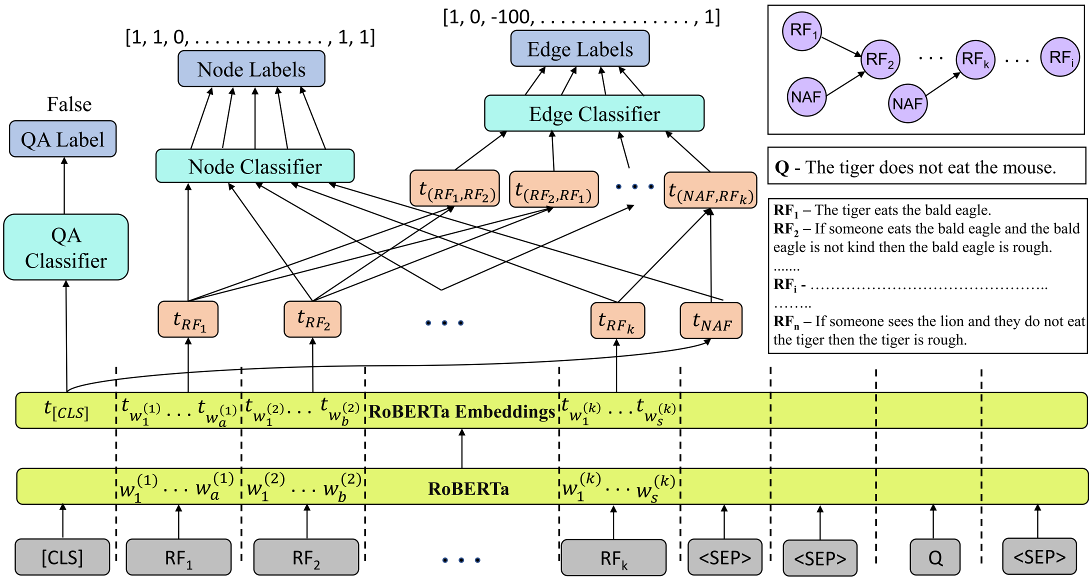

Figure 3: Architecture diagram of PROVER. The presence and absence of nodes/edges are labeled by 1 and 0 respectively while -100 represents masked out edges.

The node classifier H_{Node} has a similar architecture to the QA classifier and predicts a presence and absence probability score for each node.

$$P_{Node} = \sigma(H_{Node}(\{t_{RF_i}\}_{i=1}^{k}, t_{NAF}))$$

Edge Module: Now, given the representations of each fact, rule and NAF, we learn a representation for each edge between these. Formally, we define the edge embedding $t_{(RF_i,RF_j)}$ from node RF_i to node RF_j by concatenating their individual embeddings t_{RF_i} and t_{RF_j} with their element-wise difference (which gives the directionality vector).

$$t_{(RF_i,RF_j)} = [t_{RF_i}, t_{RF_j}, (t_{RF_j} - t_{RF_i})]$$

The above formulation also helps learn separate representations for edges $RF_i \rightarrow RF_j$ and $RF_j \rightarrow RF_i$. This is essential for our task as a proof can have edges between two rules in both directions. In Section 4.7, we see that this formulation leads to a near perfect empirical performance in predicting the directionality of edges. The edge classifier H_{Edge} outputs probability scores representing the presence and absence of each edge.

$$P_{Edge} = \sigma(H_{Edge}(\{t_{(RF_i,RF_j)}\}_{i,j=1}^{k+1}))$$
$$t_{RF_{k+1}} = t_{NAF}$$

We train our model by using binary cross-entropy loss for each of the three modules. Formally, if L_{QA}, L_{Node} and L_{Edge} denote the three losses, the overall loss L is given by:

$$L = L_{QA} + L_{Node} + L_{Edge}$$

3.4 ILP Inference for Global Constraints

As mentioned previously, during inference, we enforce additional constraints on the structure of the predicted proof graph. For this, we frame inference as Integer Linear Program (ILP) optimization, which we describe next. We follow the generative process of a graph wherein the nodes are defined first, followed by the edges on that set of nodes. Thus, we fix the nodes first based on the predictions by the node module of our model and maximize a global score over the set of edges only. This reduces the large search space and ensures that all constraints can be expressed as linear expressions.

Proof Connectivity Formulation: An important constraint is to ensure that the predicted proof graphs are connected.[4] To check if a proof graph $\mathcal{P}$ is connected, we define an augmented graph $\mathcal{P}_{aug} = (\mathcal{N}_{aug}, \mathcal{E}_{aug})$ with two added nodes "source" and "sink". We add an edge from the source to any one of the nodes x in $\mathcal{P}$. We also define edges from all nodes in $\mathcal{P}$ to the sink.

$$\mathcal{N}_{aug} = \mathcal{N} \cup \{source, sink\}$$
$$\mathcal{E}_{aug} = \mathcal{E} \cup \{(source, x)\} \cup \{(n, sink) \forall n \in \mathcal{N}\}$$

Having defined $\mathcal{P}_{aug}$, we can reduce the graph connectivity in $\mathcal{P}$ to a maximum flow problem

---

all these as NAF, we collapse all the NAF nodes into a single node and learn a unified representation for them.

[4] Proofs are directed graphs. We check connectivity in the equivalent undirected graphs.

(Leighton and Rao, 1999) in $\mathcal{P}_{aug}$ (Even and Tarjan, 1975). For this, we define the capacity variable $c_{(m,n)}$ for each edge, $m \rightarrow n$ in P_{aug}, as follows.

$$\begin{aligned} c_{(source,x)} &= |\mathcal{N}| \text{ and } c_{(x,source)} = 0 \\ \forall n \in \mathcal{N}, c_{(n,sink)} &= 1 \text{ and } c_{(sink,n)} = 0 \\ \forall m, n \in \mathcal{N}, c_{(m,n)} &= |\mathcal{N}| \\ c_{(m,n)} &= 0 \text{ if } m \notin \mathcal{N} \text{ or } n \notin \mathcal{N} \end{aligned}$$

Now, there can be a maximum total flow of $|\mathcal{N}|$ from the source to the sink, if and only if the graph is connected. We use this flow formulation to provide additional constraints for our ILP inference procedure that ensure connectivity of proof graphs.

Final Optimization Problem: Our maximization objective, subject to the connectivity constraint and all other constraints (that ensure a valid proof) is as follows. Let $\phi_{(m,n)}$ represent the probability that an edge $m \rightarrow n$ is present, as predicted by PROVER. We want to infer 0/1 assignments for our optimization variables $e_{(m,n)}$ (a value of 1 means the edge is part of the proof, while 0 means it is not) such that the following objective is maximized:

$$\underset{e_{(m,n)}, f_{(m,n)}}{argmax} \sum_{m,n,m \neq n} (\phi_{(m,n)} e_{(m,n)} + (1 - \phi_{(m,n)})(1 - e_{(m,n)}))$$

subject to constraints:

$$\forall m, n \in F \cup R \cup NAF, e_{(m,n)} \in \{0, 1\} \quad (1)$$

$$e_{(m,n)} = 0, \text{if } m \notin \mathcal{N} \text{or } n \notin \mathcal{N} \quad (2)$$

$$e_{(m,n)} = 0, \text{if } m \in F \text{ and } n \in F \quad (3)$$

$$e_{(m,n)} = 0, \text{if } m \in R \text{ and } n \in F \quad (4)$$

$$\forall m, n \in \mathcal{N}_{aug}, 0 \leq f_{(m,n)} \leq c_{(m,n)} \quad (5)$$

$$\forall n \in \mathcal{N}_{aug}, \sum_{m:(m,n) \in \mathcal{E}_{aug}} f_{(m,n)} = \sum_{o:(n,o) \in \mathcal{E}_{aug}} f_{(n,o)} \quad (6)$$

$$f_{(source,x)} = |\mathcal{N}| \quad (7)$$

$$\forall m, n \in \mathcal{N}_{aug}, e_{(m,n)} + e_{(n,m)} - (f_{(m,n)}/|\mathcal{N}|) \geq 0 \quad (8)$$

Note that $\mathcal{N}$, F, and R refer to the set of predicted nodes (from the model), the set of facts, and the set of rules, respectively. Equations 2, 3 and 4 ensure that edges are present only when the corresponding nodes are present and that there are no edges between two facts and from a rule to a fact. Next, to ensure proof connectivity, we first define the flow constraints in Equations 5 and 6 constrained by the flow variables $f_{(m,n)}$ for each edge $m \rightarrow n$. These maintain the capacity constraints (the flow at each edge should be less than its capacity) and the flow conservation constraints (the total flow through the incoming edges at a node is equal to the total flow through the outgoing edges). Equation 7 ensures connectivity in the proof graph, by enforcing the total flow to be $|\mathcal{N}|$. Finally, we ensure that the proof connectivity is checked on the valid edges only (which are part of the proof) through the last constraint, since a max-flow of $|\mathcal{N}|$ is achievable for any connected graph.

4 Experiments

Our experiments evaluate the effectiveness of PROVER (PR), our joint QA, and proof model against RuleTakers (RT). Details of our experimental setup are in the appendix.

4.1 Datasets and Evaluation Metrics

We conduct experiments on all the three sets of datasets introduced in Clark et al. (2020) and consisting of gold answers and proofs. Further details of the datasets can be found in the appendix.

DU0-DU5: The first set consists of five datasets, each containing 100k questions with theories in synthetic language and requiring reasoning paths up to depth D ($D = 0, 1, 2, 3, 5$). We refer to these datasets as DU0, DU1, DU2, DU3 and DU5, where DU stands for "Depth Upto".

Birds-Electricity: It consists of two test-only datasets of 5k samples used to evaluate the out-of-distribution performance of the models.

ParaRules: ParaRules consists of 40k questions against 2k theories expressed in paraphrased natural language, obtained through crowdsourcing.

We evaluate QA performance through accuracy. For proofs, we introduce three metrics: (1) **Node Accuracy (NA):** Fraction of examples where the predicted node set matches exactly with the gold node set, (2) **Edge Accuracy (EA):** Fraction of examples where the predicted edge set match exactly with the gold set, and (3) **Proof Accuracy (PA):** Fraction of examples where the generated proof matches exactly with the gold proof. For examples with multiple gold proofs, we give credit if the prediction matches exactly with any one of the proofs. We also evaluate **Full Accuracy (FA)**, denoting the fraction of samples where both the answer and the

proof are exactly correct.

4.2 QA and Proof Results for Varying Depths

We first train and evaluate PROVER on the train and test splits of the DU5 dataset, and compare its QA performance with RuleTakers for questions of varying depths (D). Table 1 shows these results and the proof-related metrics for PROVER. The corresponding validation set results can be found in the appendix. Overall, and at each depth, PROVER matches the QA performance of RuleTakers. PROVER is also able to generate exact proofs fairly accurately at 87%. Perhaps unsurprisingly, we find that edge prediction is a harder task than node prediction, and performance worsens with increasing depth due to an increasingly large number of edges to be labeled. The proof accuracy matches the edge accuracy at each depth, suggesting that proofs are almost always correct if the edges are correct. Similarly, the full accuracy matches the proof accuracy, showing that the predicted answer is almost always correct when the corresponding proof is correct. This points to an interesting observation – QA is easier than node prediction, which in turn is easier than edge prediction. All the datasets experimented with exhibit this behavior, as we also describe later. Proof generation becomes harder with increasing depth (and hence, more nodes and edges), as the exact proof generation accuracy drops to 65% for depth 5. On analyzing further, we find that on average, PROVER correctly predicts 6 out of 7 edges present in a depth 5 proof. Overall, PROVER is interpretable yet efficient, as it generates proofs fairly accurately without any loss in QA performance.

4.3 Zero-Shot Evaluation

Following previous work (Clark et al., 2020), we now test the out-of-distribution performance of PROVER on the Birds-Electricity dataset (Table 2). The DU5-trained model is tested on six datasets, two from the birds domain (B1, B2) and another four from the electricity domain (E1, E2, E3, E4). Overall, our model achieves a 6% QA improvement over RuleTakers. More importantly, PROVER outperforms RuleTakers by 8% on the hardest and largest E4 subset of the data. The proof accuracy is also fairly high, demonstrating good proof generation ability of our model for out-of-distribution data as well. Similar to the test results on DU5, the full accuracy matches the proof accuracy, demonstrating proof consistency with the predicted answers. We show examples of proofs generated by PROVER in Figure 2 and in the appendix.

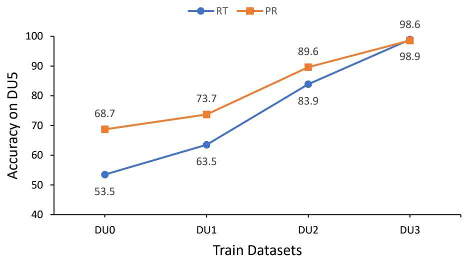

Figure 4: QA performance comparison between PROVER and RuleTakers with models trained on DU0, DU1, DU2 and DU3 and tested on DU5.

4.4 Generalization to Higher Depths

We evaluate the generalization ability of PROVER compared to RuleTakers by training models on the train splits of DU0, DU1, DU2 and DU3, and testing the QA performance on the overall test set for DU5, which includes questions with higher depth than seen during training. The corresponding validation set and proof-related results can be found in the appendix. As shown in Figure 4, PROVER, when trained on depth 0 examples only, performs significantly better than RuleTakers with an improvement of 15%. A similar trend is observed for DU1 and DU2, where PROVER improves by 10%

Table 3: Comparison of models trained on DU3 and ParaRules training sets and tested on ParaRules test set.

and 6%, respectively. On DU3, both models show high and comparable performance. PRover's superior generalization ability can be attributed to the extra training supervision incorporated in the form of proofs and an inductive bias for making proof-based predictions. While proof construction for supervised training is expensive, PRover's superior QA results on out-of-distribution data (Table 2) and higher depth questions is a potential first step to showing that limited proof supervision can still lead to effective generalization.

4.5 Varying Training Data Size

We explore varying the amount of training data from 10k to 30k to all the examples (70k) in DU5. As shown in Table 4, when trained with only 40% of the data, PRover obtains a near-perfect QA accuracy of 97.8%. Thus, for QA, PRover's joint training with proofs can compensate for the lack of training data. Proof generation, however, is much harder and with increased training data, the rate of increase in proof accuracy is much more gradual.

4.6 Evaluation on Complex Language

We also test PRover's ability to generate proofs for more human-like natural language theories. More details on the ParaRules dataset can be found in the appendix. Following Clark et al. (2020), we train a model by combining the DU3 and ParaRules training partitions and test on the ParaRules test partition. Table 3 again shows that PRover matches the QA performance of RuleTakers, and also generates proofs with a high accuracy of 95%. Following previous trends, the proof accuracy drops as the depth increases, and QA performance is higher than for node prediction, which in turn is higher than for edge prediction.

4.7 Ablation and Error Analysis

Table 5 analyzes the effectiveness of the individual components of PRover through an ablation study. These ablated variants also provide natural baselines for our proof-related results. Specifically, we train and test the following models on DU5: (1) **QA+Node:** We train a model consisting of only the QA and Node modules; (2) **No NAF:** We train a model using random NAF embeddings; (3) **Unconstrained Train (UT) + No ILP:** We remove constraints both during training and inference; (4) **Unconstrained Train (UT) + ILP:** We remove constraints only during training; (5) **No Connectivity:** Finally, we train a model where we only remove the connectivity constraint during inference. More details about these models in appendix.

Count	QA	NA	EA	PA	FA
10k	87.1	48.1	44.7	44.0	42.7
30k	97.8	77.9	73.2	72.5	72.4
70k	99.3	89.2	87.5	87.1	87.1

Table 4: Comparison of PRover models trained with varying amount of training data on DU5. Count = Number of training examples.

The QA accuracy is mostly unaffected in all our models and all but "No NAF" have similar node accuracy. The "No NAF" model does not learn a representation for NAF, leading to 5-6% drop in both node and edge accuracy. The 5-6% drop in edge and proof accuracy for the "Unconstrained Train + No ILP" model, compared to PRover, shows that removing constraints results in a harder learning problem and the model fails to automatically learn all the constraints. The proof accuracy improves slightly when we add constraints only during inference ("Unconstrained Train + ILP"). The connectivity constraint provides only marginal improvement as our model mostly predicts connected proofs without any explicit supervision. Specifically, only 57 examples have disconnected proofs without this constraint. The overall PRover model outperforms all variants in full accuracy.

To better understand the loss of accuracy for higher depth proofs, we perform error analysis of PRover for the depth 5 subset of DU5. We find that our NAF learning module is highly accurate – PRover correctly predicts NAF in a proof 95% of the time. Among all examples with incorrectly predicted node sets, 42% are such that the predicted set is a subset of the gold set while for 25% examples, it is a superset, demonstrating that our model tends to underestimate the number of essential rules and facts. PRover almost perfectly identifies the direction of edges. We find only 1 example where the proof is incorrect solely due to the incorrect

identification of directionality. Further, 21% of the incorrectly predicted edges are subsets of the gold sets, while 35% are supersets.

5 Discussion and Future Work

Graph-based Explanations: While we have presented PROVER as a model that can emulate formal reasoning, it has further potential use as an explanation generation system. PROVER generates compositional explanations in the form of graphs and QA systems, in general, can potentially benefit from generating such graphical explanations. For example, in multi-hop QA tasks, the node module can choose all the relevant sentences in the context and the edge module can identify the flow of information between these to arrive at the answer (in the presence of task-specific constraints). Graphical explanations, in contrast to natural language ones, are more structured and can allow explicit modeling of causality (and are easier to evaluate, as opposed to free-form natural language generation). We hope that PROVER will encourage further work towards developing interpretable NLP models with structured explanations.

QA and Proof Consistency: Currently, PROVER predicts the answer and generates the proof by jointly optimizing the QA, node and edge modules using a shared RoBERTa model. Another modeling choice could explicitly condition the QA module on the node and edge modules so that the answer is predicted from the proof. We empirically verify the consistency between the predicted answer and the generated proof by showing that the full accuracy matches the proof accuracy. However, in scenarios where questions have open-ended answers, generating answer from a 'proof' in a consistent manner needs more exploration. PROVER's constraints like ensuring connectivity are necessary constraints for generating valid proofs for any graph-based explanation generation system. However, other tasks may require imposing additional constraints to ensure valid explanations.PROVER's inference mechanism can be extended to incorporate these.

Broader Implications in Formal Logic: PROVER's framework is not conceptually constrained to a particular logic fragment. PROVER uses the idea that applying a rule to fact(s) can produce new fact(s). All logic fragments from formal logic fit this idea and may only differ in the nature of the graphs generated. For a fact "Robin is a bird" and a rule with universal quantification "All birds can fly", PROVER's graph will have an edge from the fact to the rule to generate "Robin can fly". We experiment with datasets which already contain negations in facts. While these datasets currently do not contain disjunctions, our graphical representations of proofs allow an easy extension in such scenarios. E.g., if there is a disjunction rule "If X or Y then Z" instead of a conjunction rule "If X and Y then Z", only the shape of the graph changes. In the former, Z is proved by either an edge from X or from Y to the rule, while in the latter, both edges have to be necessarily present. Inferences over modals like "might" and disjunction rules like "If X then Y or Z" will mean that both the answer and the proof will be probabilistic. In such scenarios, PROVER's unweighted proof graphs can be extended to weighted ones to represent this probabilistic nature.

6 Conclusion

We introduce PROVER, an interpretable joint model that answers binary questions over natural language rule-bases and generates corresponding proofs. The proofs are generated through the node and edge modules of the model in the presence of multiple global constraints during training and ILP inference. Our model improves state-of-the-art QA accuracy in the zero-shot scenario by 6% and generates proofs accurately. PROVER also generalizes much better to higher depth questions with up to 15% absolute improvement in QA performance over RuleTakers. PROVER's modeling is relatively generic, and similar proof generation methods can be explored in traditional multi-hop QA tasks. PROVER can also be a helpful aid to formal reasoners in scenarios where rules are fuzzy and creating rule-bases in a formal language is tedious or infeasible.

A Appendix

A.1 Experimental Setup

We build our model on top of the Hugging Face Transformers library (Wolf et al., 2019).[5] All hyperparamters are chosen based on the best validation set performance (Full Accuracy) of the corresponding dataset. We use RoBERTa-large (Liu et al., 2019b) as the pre-trained Language Model and all our models are trained using a batch size of 8 and a maximum sequence length of 300. We train the models for a maximum of 5 epochs using an initial learning rate of 10^{-5}, with linear decay and a weight decay of 0.1 . The dropout probability is chosen to be 0.1. The random seed used in all the experiments is 42. Each epoch of PROVER takes 2.5 hours to run on one V100 Volta GPU. The total number of parameters of PROVER is similar to that of RoBERTa-large ($355M$). Batch size and learning rate are manually tuned in the range $\{8{,}16\}$ and $\{10^{-5}, 2*10^{-5}\}$ respectively. The ILP is modeled using PuLP.[6] Proofs in the datasets are represented as bracketed strings, which are pre-processed into graph representations consisting of unique nodes and edges. The maximum number of facts and rules corresponding to a context is 25.[7]

A.2 Dataset Details

Below we briefly describe the three sets of datasets we conduct experiments on.[8] Each dataset has a train, validation and test split, except for the zero-shot test-only one. Further details about these can be found in Clark et al. (2020).

DU0-DU5: The first set consists of five datasets, each containing 100k questions with theories in synthetic language and requiring reasoning paths up to depth D ($D = 0, 1, 2, 3, 5$). For example, $D = 0$ means the true facts can be proved by simple lookup in the context. The samples are randomly split 70/10/20 into train/dev/test partitions such that there is no overlap of theories between the partitions.

Birds-Electricity: The second set consists of two test-only datasets used to evaluate robustness and out-of-distribution performance of the models. The contexts are about birds and an electric circuit, and consist of 5k samples in total. The vocabulary of entities, attributes and predicates, apart from `is()` are all new at test time.

ParaRules: The final dataset, ParaRules consists of 40k questions against 2k theories expressed in paraphrased natural language, obtained through crowdsourcing. While the previous datasets contain synthetic language, ParaRules tests the models' ability to reason over more human-like paraphrased language.

A.3 QA and Proof Results for Varying Depths

Table 7 shows the DU5 validation set performance of PROVER trained on the training split of DU5. PROVER obtains a near perfect QA accuracy and a proof accuracy of 88%. While the QA accuracy remains equally high at all depths, the proof accuracy drops with increasing depth. Full accuracy matches the proof accuracy, demonstrating consistency between the predicted answers and generated proofs.

A.4 Generalization to Higher Depths

In Table 6, we provide detailed results of PROVER's generalization ability to higher depth questions. Specifically, we evaluate four models, trained on the training splits of DU0, DU1, DU2 and DU3 and tested on the validation and test splits of DU5. We have shown previously that PROVER does significantly better than RuleTakers (Clark et al., 2020) on QA generalization. The proofs, however, do not generalize that well. Note that depth 0 proofs are rather simple (consisting of a

Table 8: PROVER results on the ParaRules validation set after training on DU3+ParaRules training splits.

single fact) and a model trained on only such proofs, unsuprisingly, fails to generate proofs for higher depth questions. However, the proof results start improving as the model gets trained on more complex proofs and reaches an accuracy of 79%, when trained on DU3 questions.

A.5 Evaluation on Complex Language

In Table 8, we report the ParaRules validation set results of PROVER trained on the combination of DU3 and ParaRules training splits (following previous work (Clark et al., 2020)). ParaRules is created by first separating the fact groups (a fact group is the set of all facts in the theory concerning a particular person) and the rules from a theory and then asking crowdworkers to paraphrase these in their own words. For example, a fact group "Alan is blue. Alan is rough. Alan is young.", may be reworded into "Alan is on the young side, but rough. He often feels rather blue.". Thus, unlike the previous datasets where the proof graphs are composed of facts and rules, ParaRules proofs are composed of fact groups and rules.[9] PROVER obtains high QA and proof accuracy on complex human-parapharsed rule-bases, showing good generalization on such language. However, the proof accuracy again drops as the depth of the questions increases.

A.6 Ablation Models and Simpler Baselines

We provide brief descriptions of our ablation models. These are (1) **QA+Node:** We model PROVER consisting of only the QA and Node modules. Since there is no edge module, this model does not require any constrained training or inference; (2) **No NAF:** We train a model using random NAF embeddings with no learning. This helps us understand the effectiveness of our NAF learning; (3) **Unconstrained Train + No ILP:** Through this model, we study the effectiveness of our global constraints. Specifically, no edges are masked for training and during inference, the edge labels are predicted based on the model's probability scores only; (4) **Unconstrained Train + ILP:** Here the constraints are employed only during inference. Note that the reverse configuration, constrained training without ILP inference, is not included as the edge logits for the masked out labels would be random (since they are not learned). (5) **No Connectivity:** Finally, we train a model where we only remove the connectivity constraint during ILP optimization, keeping everything else same.

We also experiment with simpler baselines for edge prediction like training a Random Forest with lexical features (BLEU scores, length difference,

---

[9] The original ParaRules dataset released by Clark et al. (2020) has proofs for the unparaphrased theories (consisting of facts and rules). Using the mapping from a fact to the corresponding fact group, we replace the fact nodes in the proof graph with the corresponding fact group nodes. Note that this is done to report proof accuracy for this dataset as well.

word overlap, etc.) and this obtains a much lower edge accuracy of 47%. This fails primarily because (1) proof graphs can contain NAF which account for 9% of the data and edges from it cannot be learned without learning a latent representation; (2) overlap features are mostly symmetric and hence are not enough for learning directionality; (3) there is lack of overall context information.

A.7 Critical Sentence Identification

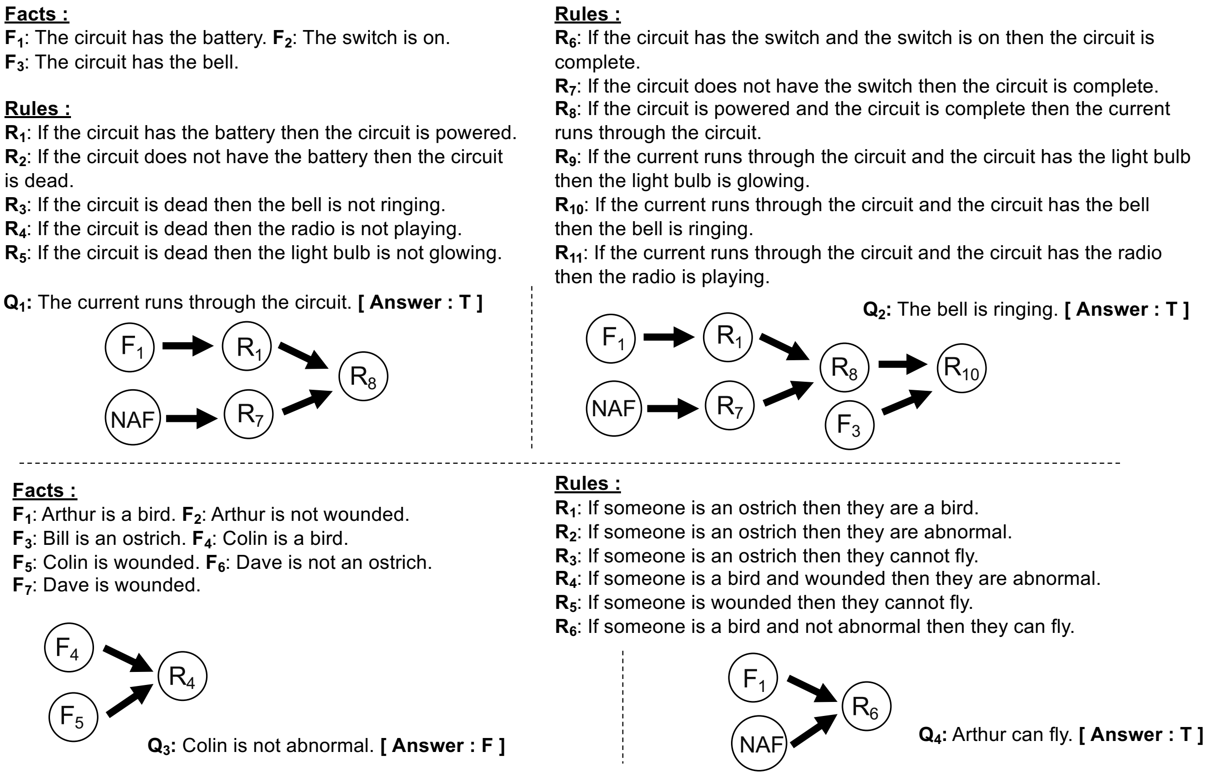
Clark et al. (2020) provide an initial solution towards generating explanations for the predicted answers by using a post-hoc method – they remove each fact or rule from the theory and check if the predicted answer changes with the new theory. They define all such rules and facts which flip the answer as critical sentences. If an example has multiple gold proofs, a critical sentence is one which is present in all the proofs. We argue that this leave-one-out analysis is not ideal for multiple reasons - (1) This does not work if the theory has negations, (2) This only predicts the presence or absence of rules and facts, and does not look at the entire chain of reasoning, which our model achieves through the edge module. In our final experiment, we still apply the leave-one-out-strategy on the no-negation subset of the DU5 test set for a direct comparison with RuleTakers. As shown in Table 9, our model identifies the exact critical sentences in an example in 78% of the cases, a 4% improvement over RuleTakers.

	Accuracy	Precision	Recall	F1
RuleTakers	74.5	**98.7**	86.9	92.4
PROVER	**78.1**	**98.7**	**87.2**	**92.6**

Table 9: Comparison of critical sentence identification on the No Negation subset of DU5 test set.

A.8 Proofs Generated by PROVER

In Figure 5, we show two rule-bases, one about electric circuits and another about birds from the Birds-Electricity dataset. PROVER not only answers the questions correctly but also generates the proofs accurately. These proofs are complex because of the presence of NAF and also the long chains of reasoning needed in the inference process. Figure 6 shows three more accurate proofs generated by PROVER for three questions from the DU5 datset.



Facts :

F_1: The circuit has the battery. **F_2**: The switch is on.
F_3: The circuit has the bell.

Rules :

R_1: If the circuit has the battery then the circuit is powered.
R_2: If the circuit does not have the battery then the circuit is dead.
R_3: If the circuit is dead then the bell is not ringing.
R_4: If the circuit is dead then the radio is not playing.
R_5: If the circuit is dead then the light bulb is not glowing.
R_6: If the circuit has the switch and the switch is on then the circuit is complete.
R_7: If the circuit does not have the switch then the circuit is complete.
R_8: If the circuit is powered and the circuit is complete then the current runs through the circuit.
R_9: If the current runs through the circuit and the circuit has the light bulb then the light bulb is glowing.
R_{10}: If the current runs through the circuit and the circuit has the bell then the bell is ringing.
R_{11}: If the current runs through the circuit and the circuit has the radio then the radio is playing.

Q_1: The current runs through the circuit. **[Answer : T]**

Q_2: The bell is ringing. **[Answer : T]**

Facts :

F_1: Arthur is a bird. **F_2**: Arthur is not wounded.
F_3: Bill is an ostrich. **F_4**: Colin is a bird.
F_5: Colin is wounded. **F_6**: Dave is not an ostrich.
F_7: Dave is wounded.

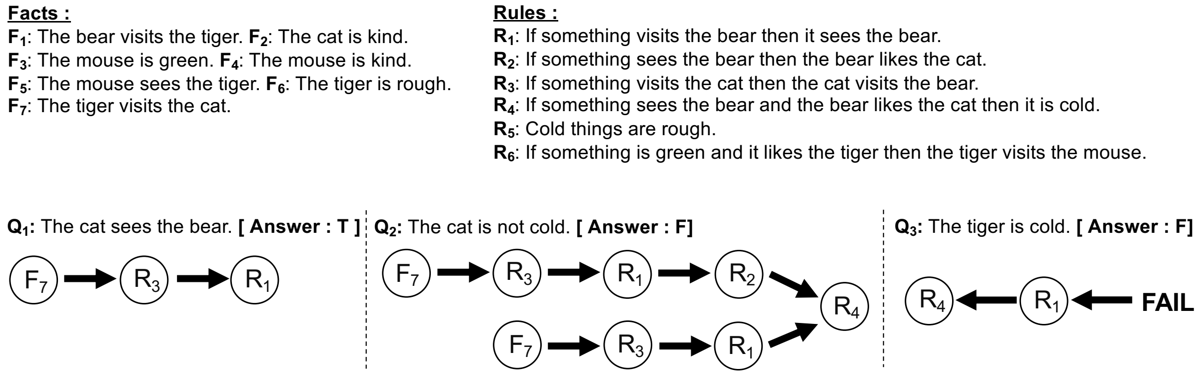
Rules :

R_1: If someone is an ostrich then they are a bird.
R_2: If someone is an ostrich then they are abnormal.
R_3: If someone is an ostrich then they cannot fly.
R_4: If someone is a bird and wounded then they are abnormal.
R_5: If someone is wounded then they cannot fly.
R_6: If someone is a bird and not abnormal then they can fly.

Q_3: Colin is not abnormal. **[Answer : F]**

Q_4: Arthur can fly. **[Answer : T]**

Figure 5: Examples of proofs generated by PRover for four questions on two rule-bases about electric circuits and birds from the Birds-Electricity dataset. PRover not only answers the questions correctly but also accurately predicts the long reasoning chains with multiple branches.



Facts :

F_1: The bear visits the tiger. **F_2**: The cat is kind.
F_3: The mouse is green. **F_4**: The mouse is kind.
F_5: The mouse sees the tiger. **F_6**: The tiger is rough.
F_7: The tiger visits the cat.

Rules :

R_1: If something visits the bear then it sees the bear.
R_2: If something sees the bear then the bear likes the cat.
R_3: If something visits the cat then the cat visits the bear.
R_4: If something sees the bear and the bear likes the cat then it is cold.
R_5: Cold things are rough.
R_6: If something is green and it likes the tiger then the tiger visits the mouse.

Q_1: The cat sees the bear. **[Answer : T]**

Q_2: The cat is not cold. **[Answer : F]**

Q_3: The tiger is cold. **[Answer : F]**

Figure 6: Examples of proofs generated by PRover for three questions on a rule-base from the DU5 dataset. The proof corresponding to the last question is a failed case.

Learning to Explain: Datasets and Models for Identifying Valid Reasoning Chains in Multihop Question-Answering

Harsh Jhamtani [1] **Peter Clark** [2]

`jharsh@cs.cmu.edu, peterc@allenai.org`

Abstract

Despite the rapid progress in multihop question-answering (QA), models still have trouble explaining *why* an answer is correct, with limited explanation training data available to learn from. To address this, we introduce three explanation datasets in which explanations formed from corpus facts are annotated. Our first dataset, `eQASC`, contains over 98K explanation annotations for the multihop question answering dataset QASC, and is the first that annotates *multiple* candidate explanations for each answer. The second dataset `eQASC-perturbed` is constructed by crowd-sourcing perturbations (while preserving their validity) of a subset of explanations in QASC, to test consistency and generalization of explanation prediction models. The third dataset `eOBQA` is constructed by adding explanation annotations to the OBQA dataset to test generalization of models trained on `eQASC`. We show that this data can be used to significantly improve explanation quality (+14% absolute F1 over a strong retrieval baseline) using a BERT-based classifier, but still behind the upper bound, offering a new challenge for future research. We also explore a delexicalized chain representation in which repeated noun phrases are replaced by variables, thus turning them into *generalized reasoning chains* (for example: ”X is a Y” AND ”Y has Z” IMPLIES ”X has Z”). We find that generalized chains maintain performance while also being more robust to certain perturbations.[1]

Q: What can cause a forest fire?
(1) rain (2) static electricity (3) microbes (4) ...
A: static electricity
Q+A (declarative): Static electricity can cause a forest fire.

Explanation (reasoning chain): [positive (valid)]
Static electricity can cause sparks // (from corpus)
AND *Sparks can start a forest fire* // (from corpus)
→ *Static electricity can cause a forest fire* // (Q+A)

Explanation (Generalized reasoning chain, GRC):
X *can cause* **Y** **AND Y** *can start* **Z** → **X** *can cause* **Z**

Figure 1: Our datasets contain annotated (valid and invalid) *reasoning chains* in support of an answer, allowing explanation classifier models to be trained and applied. We also find that using a variabilized version of the chains improves the models' robustness.

1 Introduction

While neural systems have become remarkably adept at question answering (QA), e.g., (Clark and Gardner, 2018), their ability to *explain* those answers remains limited. This creates a barrier for deploying QA systems in practical settings, and limits their utility for other tasks such as education and tutoring, where explanation plays a key role. This need has become particularly important with *multihop question-answering*, where multiple facts are needed to derive an answer. In this context, seeing a *chain of reasoning* leading to an answer, can help a user assess an answer's validity. Our research here contributes to this goal.

We are interested in questions where the decomposition into subquestions - hence the explanation structure - is *not evident from the question*, but has to be found. For example, "Does a suit of armor conduct electricity?" might be answered (hence explained) by first identifying what material armor is made of, even though the question itself does not mention materials. This contrasts with earlier multihop QA datasets, e.g., HotpotQA (Yang et al., 2018), where the explanation structure is evident in the question itself. For example, "What nationality was James Miller's wife?" implies a chain of reasoning to first finds Miller's wife, then her nationality. Such cases are easier but less representative of natural questions. Multihop datasets of the kind where explanation structure is not evident

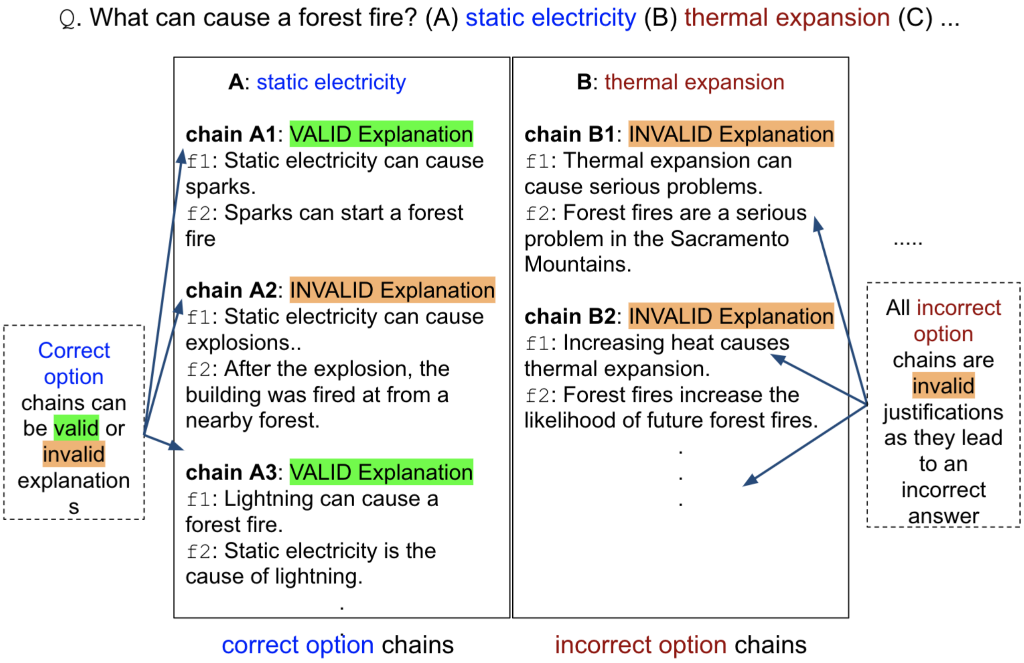

Figure 2: QASC contains multiple-choice questions, plus one gold (valid) reasoning chain for the correct answer. To find valid reasoning chains, we first generate candidates for each answer option using a 2-step retrieval process (Section 3.2). We then collect annotations for the correct answer option chains to train and evaluate models to detect valid reasoning chains. (Above, chains A1 and A3 are valid, while A2, B1, and B2 are invalid).

include OpenBookQA (Mihaylov et al., 2018) and more recently QASC (Khot et al., 2020). However, although providing QA pairs, these datasets provide limited explanation information. OpenBookQA does not come with any explanation data, and QASC only provides a single gold explanation for each answer, while in practice there may be multiple valid explanations.

To alleviate this lack of data, we contribute three new datasets: The first (and largest) is `eQASC`, containing annotations on over 98K candidate explanations for the QASC dataset, including on *multiple* (typically 10) possible explanations for each answer, including both valid and invalid explanations. The second, `eQASC-perturbed`, contains semantically invariant perturbations of a subset of QASC explanations, for better measuring the generality of explanation prediction models. Finally `eOBQA` adds adding explanation annotations to the OBQA test set, to further test generality of models trained on `eQASC`. In addition, we use these datasets to build models for detecting valid explanations, to establish baseline scores. Finally, we explore a delexicalized chain representation in which repeated noun phrases are replaced by variables, thus turning them into *generalized reasoning chains*, as illustrated in Figure 1. We find that generalized chains maintain performance while also being more robust to perturbations, suggesting a promising avenue for further research.

2 Related Work

In the context of QA, there are multiple notions of explanation/justification, including showing an authoritative, answer-bearing sentence (Perez et al., 2019), a collection of text snippets supporting an answer (DeYoung et al., 2020), an attention map over a passage (Seo et al., 2016), a synthesized phrase connecting question and answer (Rajani et al., 2019), or the syntactic pattern used to locate the answer (Ye et al., 2020; Hancock et al., 2018). These methods are primarily designed for answers to "lookup" questions, to explain where and how an answer was found in a corpus.

For questions requiring inference, the focus of this paper, an explanation is often taken as the chain of steps (typically sentences) leading to an answer. HotpotQA's support task goes partway towards this by asking for answer-supporting sentences (but not how they combine) (Yang et al., 2018). The R4C dataset takes this further, annotating how (and which) HotpotQA supporting sentences chain together (Inoue et al., 2019). However, in HotpotQA and R4C, the decomposition (hence structure of the explanation) is evident in the question (Mihaylov et al., 2018), simplifying the task. More recently, multihop datasets where the decomposition is not evident have appeared, e.g., WikiHop (Welbl et al., 2018), OBQA (Mihaylov et al., 2018), and QASC (Khot et al., 2020), posing more a realistic explanation challenge. However, explanation annotations are sparse (only QASC contains a single gold explanation per question), limiting their support for both training and evaluation of explanation systems, hence motivating this work.

Finally there are a few human-authored explanation datasets. e-SNLI (Camburu et al., 2018) adds crowdsourced explanations to SNLI entailment problems (Bowman et al., 2015), and CoS-E (Rajani et al., 2019) adds explanations for CommonsenseQA questions (Talmor et al., 2019). This work differs from ours in two ways. First, the authored explanations are single-hop, directly linking a question to an answer. Second, the datasets were primarily designed for (explanation) language generation, while our goal is to assemble explanations from an authoritative corpus so that they have credible provenance.

Our work is quite different from prior work focusing on textual entailment. Our goal is not to decide if a sentence is entailed, but to identify a valid explanation for why. For example, a SciTail (Khot et al., 2018) model may predict that "metals conduct heat" entails "a spoon transmits energy", but not offer an explanation as to why. Our work fills this gap by providing an explanation (e.g., "spoon is made of metal", "heat is energy" from a larger retrieved context). Similarly, another entailment-based dataset is FEVER (Thorne et al., 2018), testing where a larger context entails a claim. However, the FEVER task requires finding a context sentence that simply paraphrases the claim, rather than a reasoned-based explanation from more general statements - the aim of this work.

3 Explanation Datasets

We now present our new datasets, first describing how we construct candidate chains for each QA pair, and then how they were annotated.

3.1 Task Definition

We consider the task where the input is a question Q, (correct) answer A, and a corpus of sentences T. The (desired) output is a valid reasoning chain, constructed from sentences in T, that supports the answer. We define a reasoning chain as a sequence of sentences $C = [s_1, ..., s_n]$ plus a conclusion sentence H, and a *valid* reasoning chain as one where C *entails* H. Following the textual entailment literature (Dagan et al., 2013), we define entailment using human judgements rather than formally, i.e., C entails H if a person would reasonably conclude H given C. This definition directly aligns with our end-goal, namely to provide users with a credible reason that an answer is correct.

	Train	**Dev**	**Test**
Total number of questions	8134	926	920
Total no. of chains tagged	80449	9190	9141
No. of valid chains	21551	2186	2210
No. of invalid chains	58898	7004	6931

Table 1: Summary statistics for `eQASC`, the annotated chains for the correct answers in QASC. Each chain is tagged by three annotators, and we use majority judgement.

For generating candidate chains C, we construct each C from sentences in the corpus T, as described below. Following the design of the QASC dataset, we consider just 2-sentence chains, as this was the maximum chain length used in its creation, although our approach could be extended to N-sentence chains.

3.2 Candidate Chain Construction

Given Q + A, we use the procedure described in (Khot et al., 2020) to assemble candidate chains from T (below). This procedure aims to find plausible chains by encouraging word overlap:

(1) Using ElasticSearch (a standard retrieval engine), retrieve K (=20 for efficiency) facts F1 from T using Q+A as the search query.
(2) For each fact f1 $\in$ F1, retrieve L (=4 to promote diversity) facts F2, each of which contains at least one word from Q+A $\setminus$ f1 and from f1 $\setminus$ Q+A;
(3) Remove [f1,f2] pairs that do not contain any word from Q or A;
(4) Select the top M (here, =10) [f1,f2] pairs sorted by the sum of their individual IR (ElasticSearch) scores.

Step (3) ensures that the chain contains at least some mention of part of Q and part of A, a minimal requirement. Step (4) imposes a preference for chains with greater overlap with Q+A, and between f1 and f2. Note that this procedure does not guarantee *valid* chains, rather it only finds candidates that may be plausible because of their overlap. Some example chains are produced by this method are shown in Figure 2. In all our experiments, we use the QASC corpus[2] as the corpus T, namely the same corpus of 17M cleaned up facts as used in (Khot et al., 2020).

3.3 eQASC - Explanations for QASC

The original QASC dataset includes only a single gold (valid) reasoning chain for each correct answer, and no examples of invalid chains. To develop a richer explanation dataset, suitable for both training and evaluation, we generate eQASC as follows. First, we use the above algorithm to generate (up to) 10 candidate chains for each Q + correct answer option A pair. This resulted in a total of **98780 chains** for QASC's 9980 questions.

We then use (Amazon Turk) crowdworkers to annotate each chain. Workers were shown the question, correct answer, and reasoning chain, e.g.:

Question: **What is formed by rivers flowing over rocks?**
Answer: **soil**
Because:
fact 1: **Rivers erode the rocks they flow over**, *and*
fact 2: **soil is formed by rocks eroding**

They were then asked if fact 1 and fact 2 *together* were a reasonable chain of reasoning for the answer, and to promote thought were offered several categories of "no" answer: fact 1 alone, or fact 2 alone, or either alone, justified the answer; or the answer was not justified; or the question/answer did not make sense. (Two "unsure" categories were also offered but rarely selected). The full instructions to the workers are provided in the Appendix. Each chain was annotated by 3 workers. To ensure quality, only AMT Masters level workers were used, and several checks were performed: First, for cases where at least two workers agreed, if a worker's annotations disagreed with the majority unreasonably often (from inspection, judged as more than 25% of the time), then the worker was (paid but then) blocked, and his/her annotations redone. Second, if a worker's distribution of labels among the six categories substantially deviated from other workers (e.g., almost always selecting the same category), or if his/her task completion time was unrealistically low, then his/her work was sampled and checked. If it was of low quality then he/she again was (paid and) blocked, and his/her annotations redone. Pairwise agreement was 74% (2 class) or 45% (for all six subclasses), with a Fleiss κ (inter-annotator agreement) of 0.37 ("fair agreement" (Landis and Koch, 1977)). There was a majority agreement (using all six subclasses) of 84%, again suggesting fair annotation quality. For the final dataset, we adopt a conservative approach and treat the no majority agreement cases as invalid chains. Summary statistics are in Table 1.

3.4 eQASC-perturbed - Testing Robustness

For a test of robustness of model for reasoning chain explanation detection, we also created `eQASC-perturbed`, a dataset of valid eQASC reasoning chains, perturbed in a way so as to preserve their validity. To do this, we first randomly selected a subset of the valid reasoning chains from the test split of `eQASC-perturbed`. We then asked crowdworkers to modify the chains by replacing a word or phrase shared between at least two sentences with a different word or phrase, and to make sure that the resulting new chain remained valid. (e.g., *"amphibians"* became *"frogs"*, or *"eats other animals"* became *"consumes its prey"*). We collected **855 perturbed**, (still) valid reasoning chains in this way.

3.5 eOBQA - Testing Generalization

Finally, to further measure the generality of our model (without re-fine-tuning), we created a smaller set of annotations for a different dataset, namely OBQA (4-way multiple choice) (Mihaylov et al., 2018). The original dataset has no explanations and no associated corpus. Thus to generate explanations, we use sentences from the QASC corpus, and annotate the top two (for all test questions) formed by the retrieval step (Section 3.2). Note that for some questions, there may be no valid justification which can be formed from the corpus. We followed the same annotation protocol as for `eQASC` to have crowd workers annotate the chains (Section 3.3). The resulting dataset containing **998 annotated chains**, of which 9.5% were marked as valid reasoning explanations.

4 Learning to Score Chains

Our full approach to explaining an answer has two steps, namely candidate chain retrieval followed by chain scoring, to find the highest-ranked chain supporting an answer. For chain retrieval, we assume the same procedure described earlier to identify candidate chains. For chain scoring, we train a BERT-based model to distinguish valid chains from invalid ones, using the training data collected in the `eQASC` dataset, as we now describe.

---

Q: What eats krill and plankton? **A**: Sponges	
Transforming a valid reasoning chain	**Transforming an invalid reasoning chain**
Filter feeders eat **krill and plankton**. **AND Sponges** are **filter feeders** ⟶ **Sponges** eat **krill and plankton**.	Whales eat **krill and plankton**, which are tiny **animals**. **AND Sponges** contain microscopic **animals.** ⟶ **Sponges** eat **krill and plankton.**
GRC representation **X** eat **Y** **AND Z** are **X** ⟶ **Z** eat **Y**	GRC representation Whales eat **X** which are tiny **Y** **AND Z** contain microscopic **Y** ⟶ **Z** eat **X**

Figure 3: Generalized reasoning chains (GRCs) are formed by replacing repeated noun phrases with variables.

We evaluate using all three collected datasets. We also evaluate two different ways of presenting the chain to the model to score (both train and test): (a) in its original form (with Q+A flipped to a declarative sentence), (b) in a generalized form, where repeated noun phrases are variabilized. Our interest is how well a model can perform, both to assess practical use and as a baseline for further improvement; and how the two different chain representations impact performance.

4.1 Chain Representation

Declarative form For a chain to support the answer to a question, we construct H as a declarative form of the question + answer using standard QA2D tools, e.g., (Demszky et al., 2018). For example, for the question + answer "What can cause a forest fire? Static electricity", the hypothesis H to be entailed by C is "Static electricity can cause a forest fire.". An alternate representation for H is to simply append answer to the end of the question. We did not observe any significant change in the best dev split performances on switching to the alternate representation described above.

Generalized Reasoning Chains (GRC) : We observe that specific reasoning chains are often instantiations of more general patterns. For example, in Figure 1, the specific explanation can be seen as an instantiation of the more general pattern "X can cause Y" AND "Y can start Z" IMPLIES "X can cause Z". We refer to such patterns as *Generalized Reasoning Chains* (GRCs). To encourage our model to recognize valid and invalid chains at the pattern level, we explore the following strategy: First, we transform candidate chains into generalized chains (GRCs) by replacing repeated noun phrases with variables (special tokens), a process known as delexicalization (Suntwal et al., 2019). We then train and test the model using the GRC representation. We hypothesize that distinguishing a valid justification chain from an invalid one should not need typing information in most cases.

To identify the phrases to variabilize, (1) we first perform part-of-speech tagging on the sentences, and (2) extract candidate entities by identifying repeating nouns i.e. those which occur in at least two of the sentences in the chain (We stem the words before matching, and include any matching preceding determiners and adjectives into detected entities). e.g. 'the blue whale is a mammal' and 'the blue whale breathes..' leads to detection of 'the blue whale'). (3) Then, we assign a special token to each of the candidates, using a predefined set of unused tokens, which can be viewed as a set of variables. Some examples of GRCs are shown in Figure 3 and later in Figure 4, using `X`, `Y`, `Z` as the special token set (As our models are BERT-based, we use `unusedi` $i \in \{1, 2, ...\}$ to denote these tokens).

4.2 Model Training

To distinguish valid from invalid chains, we fine-tune a pre-trained BERT model (Devlin et al., 2019) for scoring the possible explanation chains. We encode a chain $f1$ AND $f2 \rightarrow H$ as:

$$\text{[CLS]}\ \ f1\ \ \text{[SEP]}\ \ f2\ \ \text{[SEP]}\ \ H$$

where [SEP] is a sentence boundary marker. Thereafter, we pass the chain through the BERT model (BERT-base-uncased). We employ a two layer feedforward neural network with ReLU non-linearity, as a binary classifier on the pooled [CLS] representation to predict valid vs invalid reasoning chains. Model parameters are trained to minimize the binary cross entropy loss.

5 Experiments

For training, we use the annotated chains in the train split of `eQASC` alongwith the 'gold' chains provided in the QASC dataset (QSC gold chains

Model	Delexicalized Representation	Classification F1 (dev) test	Classification AUC-ROC (dev) test	Ranking P@1 (dev) test	Ranking NDCG (dev) test
RETRIEVAL	n/a	(0.52) 0.50	(0.75) 0.74	(0.47) 0.47	(0.59) 0.60
BERT-QA	n/a	(0.44) 0.43	(0.52) 0.51	(0.47) 0.47	(0.48) 0.49
BERT-CHAIN	No	(0.68) **0.64**	(0.88) **0.87**	(0.57) **0.55**	(0.65) **0.65**
BERT-GRC	Yes	(0.63) **0.62**	(0.85) **0.85**	(0.55) **0.54**	(0.64) **0.64**
Performance upper-bound:		(1.00) 1.00	(1.00) 1.00	(0.76) 0.76	(0.76) 0.76

Table 2: The ability of models to identify valid explanations (classification) or rank the set of explanations for each answer (ranking), with best test results highlighted. BERT-GRC and BERT-CHAIN perform better than RETRIEVAL and BERT-QA methods, though fall short of the upper bound. Using the generalized chains (BERT-GRC) performs similarly to BERT-CHAIN, even though it is using less information (masking out overlapping noun phrases).

are always considered valid reasoning chains). We try two different ways of presenting chains to the model, namely the original and generalized chain representations (GRCs), thus produce two models that we refer to as **BERT-CHAIN** and **BERT-GRC** respectively. In earlier experiments, we did not find using chains for negative answer options (which are all invalid chains) to be useful (see Section 6.3), so we use chains for correct answer options only. We use AllenNLP (Gardner et al., 2018) toolkit to code our models.

We test on all the three proposed datasets. Since we are interested in finding explanations for the correct answer, we ignore the incorrect answer chains for the purpose of testing (they still accompany the dataset and can be used as additional training data since they are invalid reasoning chains by definition: Section 6.3). For `eQASC` and `eOBQA`, we evaluate in two ways: First, treating the task as classification, we measure F1 and AUC-ROC (below). Second, treating the task as ranking the *set* of explanations for each answer, we measure P@1 and Normalized Discounted Cumulative Gain (NDMC) (also below). We use the trained model's probability of a chain being valid to rank the retrieved candidate chains for a given question and answer.

5.1 Metrics

F1 and **AUC-ROC**: Viewing the task as classifying individual explanations, we report the area under the ROC (Receiver Operating Characteristics) curve, treating the valid explanation chains as the positive class. ROC curves are plots of true positive rate on the Y-axis against false positive rate on the X-axis. A larger area under the curve is better, with 1.0 being the best. Additionally, we report F1 for the positive class.

P@1 and **NDCG**: Viewing the task as ranking the *set* of explanations for each answer, P@1 measures the fraction of cases where the topmost ranked chain is a valid chain. This reflects the model's ability to find a valid explanation for an answer, given the retrieval module. Note that the upper bound for this measure is less than 1.0 for `eQASC`, as there are questions for which *none* of the candidate chains are valid (discussed shortly in Section 6.4). NDCG (Normalized Discounted Cumulative Gain) measures how well ranked the candidates are when ordered by score, and is a measure widely used in the learning-to-rank literature. Consider an ordered (as per decreasing score) list of N(=10) chains and corresponding labels $y_i \in \{0, 1\}; i \in 1, 2, .., N$, where $y_i = 1$ represents a valid chain. NDCG is defined per question (then averaged) as:

$$\text{NDCG} = \frac{1}{Z} \sum_{i=1}^{N} \frac{y_i}{\log_2(i+1)}$$

where Z is a normalization factor so that perfect ranking score (when all the valid chains are ranked above all the invalid chains) is 1. We define NDCG as 0 if there are no valid chains.

5.2 Baselines

We compare our model with two baselines, **RETRIEVAL** and **BERT-QA**. Recall that our method first collects the top M candidate chains, ordered by retrieval score (Section 3.2). Thus a simple baseline is to use that retrieval score itself as a measure of chain validity. This is the **RETRIEVAL** baseline.

We also consider a baseline, **BERT-QA**, by adapting the approach of Perez et al. (2019) to our task. In the original work, given a passage of text and a multiple choice question, the system identifies the sentence(s) S that are the most convincing evidence for a given answer option a_i. To do this, it iteratively finds the sentence that most increases the probability of a_i when added to an (initially empty) pool of evidence, using a QA system originally trained on the entire passage. In other words, the probability increase is used as a measure of how

Original chain	Edited chain	BERT -CHAIN	BERT -GRC
tadpole changes into a frog **AND** the frog is a totem of *metamorphosis* → tadpoles undergo *metamorphosis*	tadpole changes into a frog **AND** the frog is a totem of *transformation* → tadpoles undergo *transformation*	0.21	0.00
insects can spread disease and destroy crops **AND** food crops are produced for local consumption → insects can destroy food	insects can spread disease and decimate crops **AND** food crops are produced for local consumption → insects can decimate food	0.11	0.00

Table 3: Prediction Consistency: Examples from `eQASC-perturbed` with changes in probability score (of being a valid reasoning chain) for different methods. Here, BERT-GRC has (desirably) not changed its score due to an immaterial perturbation, while BERT-CHAIN has, indicating greater stability for the GRC representation. This trend holds generally (Table 4).

Model	% cases with 0.0 change
BERT-CHAIN	0.23%
BERT-GRC	**40.80%**

Table 4: Given an immaterial perturbation to a reasoning chain, a model's predicted probability of validity should not change if it is making consistent predictions. We evaluate the absolute difference in probability scores of original and edited reasoning chains in `eQASC-perturbed`. We observe that for 40.8% and 0.23% of the cases did not show any change in score for BERT-GRC and BERT-GRC respectively. The results suggest that GRCs improve prediction consistency.

Model	P@1	AUC-ROC
RETRIEVAL	0.70	0.58
BERT-CHAIN	0.85	0.89
BERT-GRC	**0.89**	0.86

Table 5: Application of our (`eQASC`-trained) model to a new dataset `eOBQA`. The high AUC-ROC figure suggests the model remains good at distinguishing valid from invalid chains. We report P@1 only for the questions which have at least one valid chain, i.e., where ranking is meaningful.

convincing the evidence sentence is. We adapt this by instead finding the *chain* that most increases the probability of a_i (compared with an empty pool of evidence), using a QA system originally trained with all the candidate chains for a_i. For the QA system, we use the straightforward BERT-based model described in (Khot et al., 2020). We then use that increase in probability of the correct answer option, measured for each chain, as a measure of chain validity. We call this baseline **BERT-QA**.

5.3 Results: Performance on eQASC

The test results on the `eQASC` are shown in Table 2. There are several important findings:

1. The best performing versions of BERT-CHAIN and BERT-GRC significantly outperforms the baselines. In particular, the AUC-ROC is 11% higher (absolute), NDCG rises from 0.60 to 0.64, and P@1 rises from 0.47 to 0.54 for BERT-GRC, indicating substantial improvement.

2. The generalized chain representation does not lead to a significant reduction (nor gain) in performance, despite abstracting away some of the lexical details through variabilization. This suggests the abstracted representation is as good as the original, and may have some additional benefits (Section 5.4).

3. The BERT-QA baseline scores surprisingly low. A possible explanation is that, in the original setting, Perez et al. (2019)'s model learned to spot a (usually) single relevant sentence among a passage of irrelevant sentences. In our setting, though, all the chains are partially relevant, making it harder for the model to distinguish just one as central.

5.4 Results:Consistency in eQASC-perturbed

We posit that the generalized (GRC) chain representation may improve robustness to small changes in the chains, as the GRC abstracts away some of the lexical details. To evaluate this, we use the crowdworker-perturbed, (still) valid chains in `eQASC-perturbed`. As the perturbed chain often follows the same/similar reasoning as the original one, this test can be considered one of consistency: the model's prediction should stay same. To measure this, we record the model's predicted probability of a chain being valid, then compare these probabilities for each pair of original and perturbed chains. Ideally, if the model is consistent and the perturbations are immaterial, then these probabilities should not change.

The results are shown in Table 4. In a large fraction of the instances, generalized chain representation exhibits no change. This is perhaps expected given the design of the GRC representations. Thus,

X can cause Y AND Y can start Z → X can cause Z
X is used for Y AND Z are X → Z are used for Y
X are formed by Y AND Y are made of Z
→ X are formed by Z
X are Y AND Y are Z → X are Z
X produce Y AND Y is a Z → X produce Z
X increases Y AND X occurs as Z → Z increases Y
X changes Y AND Y is Z → X changes Z
X is Y AND X carries Z → Y carries Z
X changes an Y AND Z are examples of X → Z change an Y
X are formed by Y AND X are formed through Z
→ Y can cause Z
X changes a Y AND Z start most X → Z can change Y

Figure 4: Examples of some of the highest scoring generalized reasoning chains (GRCs) found in eQASC.

using GRC not only achieves similar performance (Table 2), but produces more consistent predictions for certain types of perturbations. Table 3 shows some examples.

5.5 Results: Generalization to eOBQA

We are also interested in the generality of the model, i.e., how well it can transfer to a new dataset with no explanation training data (i.e., the situation with most datasets). To measure this, we ran our (`eQASC`-trained) models on `eOBQA`, namely the annotated top-2 candidate chains for OBQA test questions, to see if the models can still detect valid chains in this new data.

The results are shown in Table 5, and again illustrate that the BERT trained models continue to significantly outperform the retrieval baseline. High $P@1$ scores suggest that model is able to score a valid reasoning as the highest among the candidate whenever there is at least one such valid chain. The high AUC-ROC suggests that the model is able to effectively distinguish valid from invalid chains.

6 Analysis and Discussions

6.1 GRC as Explicit Reasoning Rationale

A potentially useful by-product of GRCs is that the underling reasoning *patterns* are made explicit. For example, Figure 4 show some of the top-scoring GRCs. This may be useful for helping a user understand the rationale behind a chain, and a repository of high-scoring patterns may be useful as a knowledge resource in its own right. This direction is loosely related to certain prior works on inducing general semantic reasoning rules (such as Tsuchida et al. (2011) who propose a method that induces rules for semantic relations based on a set of seed relation instances.)

6.2 Error Analysis

However, the BERT-GRC model was not always able to correctly distinguish valid from invalid GRC explanations. To better understand why, we analyzed 100 scoring failures on `eQASC` (dev), looking at the top 50 chains (i.e., ranked as most valid by our model) that were in fact annotated as invalid (false positives, FP), and the bottom 50 chains (ranked most invalid) that were in fact marked valid (false negatives, FN). We observed four main sources of error:

1. Over-generalization: (≈ 45% of the FP cases, ≈ 40% of FN cases). Some generalized reasoning chains are merely plausible rather than a deductive proof, meaning that their instantiations may be annotated as valid or invalid depending on the context. For example, for the GRC

X contains Y AND *Z are in X → Z are in Y*

its instantation may have been marked as valid in

Cells contain nuclei AND *Proteins are in cells*
→ Proteins are in nuclei

but not for

Smog contains ozone AND *Particulates are in*
smog → Particulates are in ozone

(Ozone itself does not contain particulates). Here the context is important to the perception of validity, but has been lost in the generalized form.

2. Incorrect Declarative Form: (FP ≈ 20%, FN ≈ 30%). Sometimes the conversion from question + answer to a declarative form H goes wrong, eg

What do octopuses use ink to hide from? sharks

was converted to the nonsensical sentence

Octopuses do use sharks ink to hide from.

In these cases, the annotations on chains supporting the original answer do not meaningfully transfer to the declarative formulation. (Here, FP/FN are due to label rather than prediction errors).

3. Shared Entity Detection: (FP ≈ 10%, FN ≈ 10%) To detect and variabilize shared entities during GRC construction, we search for repeated noun phrases in the sentences. This operational definition of "shared entities" can sometimes make mistakes, for example sometimes shared entities may be missed, e.g., *frog* and *bullfrog*, or incorrectly equated due to stemming or wrong part of speech tagging, e.g., *organic* and *organism*. The resulting GRC may be thus wrong or not fully generalized, causing some errors.

4. Model Failures: (FP ≈ 25%, FN ≈ 10%) The remaining failures appear to be simply due the model itself, representing incorrect generalization from the training data. Additional training data may help alleviate such problems.

Despite these, GRCs often abstract away irrelevant details, and may be worthy of further study in explanation research.

6.3 Chains for Negative Answer Options

We also investigated whether we could skip using the eQASC annotations completely, and instead simply use the single QASC gold chains as positives, and chains for wrong answers as negatives (a form of distant supervision). However, we observed that but the results were significantly worse. We also tried adding chains for wrong answers as additional negative examples to the full `eQASC` dataset. However, we observed that this did not significantly improve (or hurt) scores. One possible reason for this is that `eQASC` may already contain enough training signal. Another possible reason is that (invalid) chains for wrong answers may qualitatively differ in some way from invalid reasoning chains for right answers, thus this additional data does not provide reliable new signal.

6.4 Limitations of Retrieval

Our focus in this paper has been on recognizing valid chains of reasoning, assuming a retrieval step that retrieves a reasonable pool of candidates to start with (Section 3.2). However, the retrieval step itself is not perfect: For QASC, designed so that at least one valid chain always exists, the retrieved pool of 10 contains no valid chains for 24% of the questions (upper bound in Table 2), capping the overall system's performance. To gauge the performance of our model when coupled with an improved retrieval system, we ran an experiment where, at test time, we explicitly add the gold chain to the candidate pool if it does not get retrieved (and even if there is some other valid chain already in the pool). We find the P@1 score rises from 0.54 (Table 2) to 0.82 (upper bound is now 1.0). This indicates the model scoring algorithm is performing well, and that improving the retrieval system, e.g., by considering may more chains per question or modifying the search algorithm itself, is likely to have the biggest impact on improving the overall system. Note also that the corpus itself is an important component: finding valid chains requires the corpus to contain a broad diversity of general facts to build chains from, hence expanding/filtering the corpus itself is another avenue for improvement.

6.5 Future Directions

The main purpose of this dataset is to generate explanations as an end-goal in itself, rather than improve QA scores (we do not make any claims in terms of QA accuracy or ability to improve QA scores). Although much of NLP has focused on QA scores, more recent work has targeted explanation as an end-goal in itself, with ultimate benefits for tutoring, validation, and trust. Nonetheless, a useful future direction is exploring answer prediction and explanation prediction as joint goals, and perhaps they can benefit each other.

Additionally, in the current work we have explored only a sequence of two sentences as an explanation for the third. Extending the proposed approaches for longer chains is an important future direction. We have proposed a technique for reducing reasoning chains to abstract chains. This technique makes assumptions about being able to match overlapping words. A future extension could explore more robust techniques for identifying abstract chains which do not make such assumptions.

7 Summary

Explaining answers to multihop questions is important for understanding *why* an answer may be correct, but there is currently a dearth of suitable, annotated data. To address this, and promote progress in explanation, we contribute three new explanation datasets, including one with over 98k annotated reasoning chains - by far the largest repository of annotated, corpus-derived explanations to date. We also have shown this data can significantly improve explanation quality on both in-domain (QASC) and out-of-domain (OBQA) tasks. Finally, we have proposed and explored using a lightweight method to achieve a delexicalized representation of reasoning chains. While preserving explanation quality (despite removing details), this representation appears to be more robust to certain perturbations.

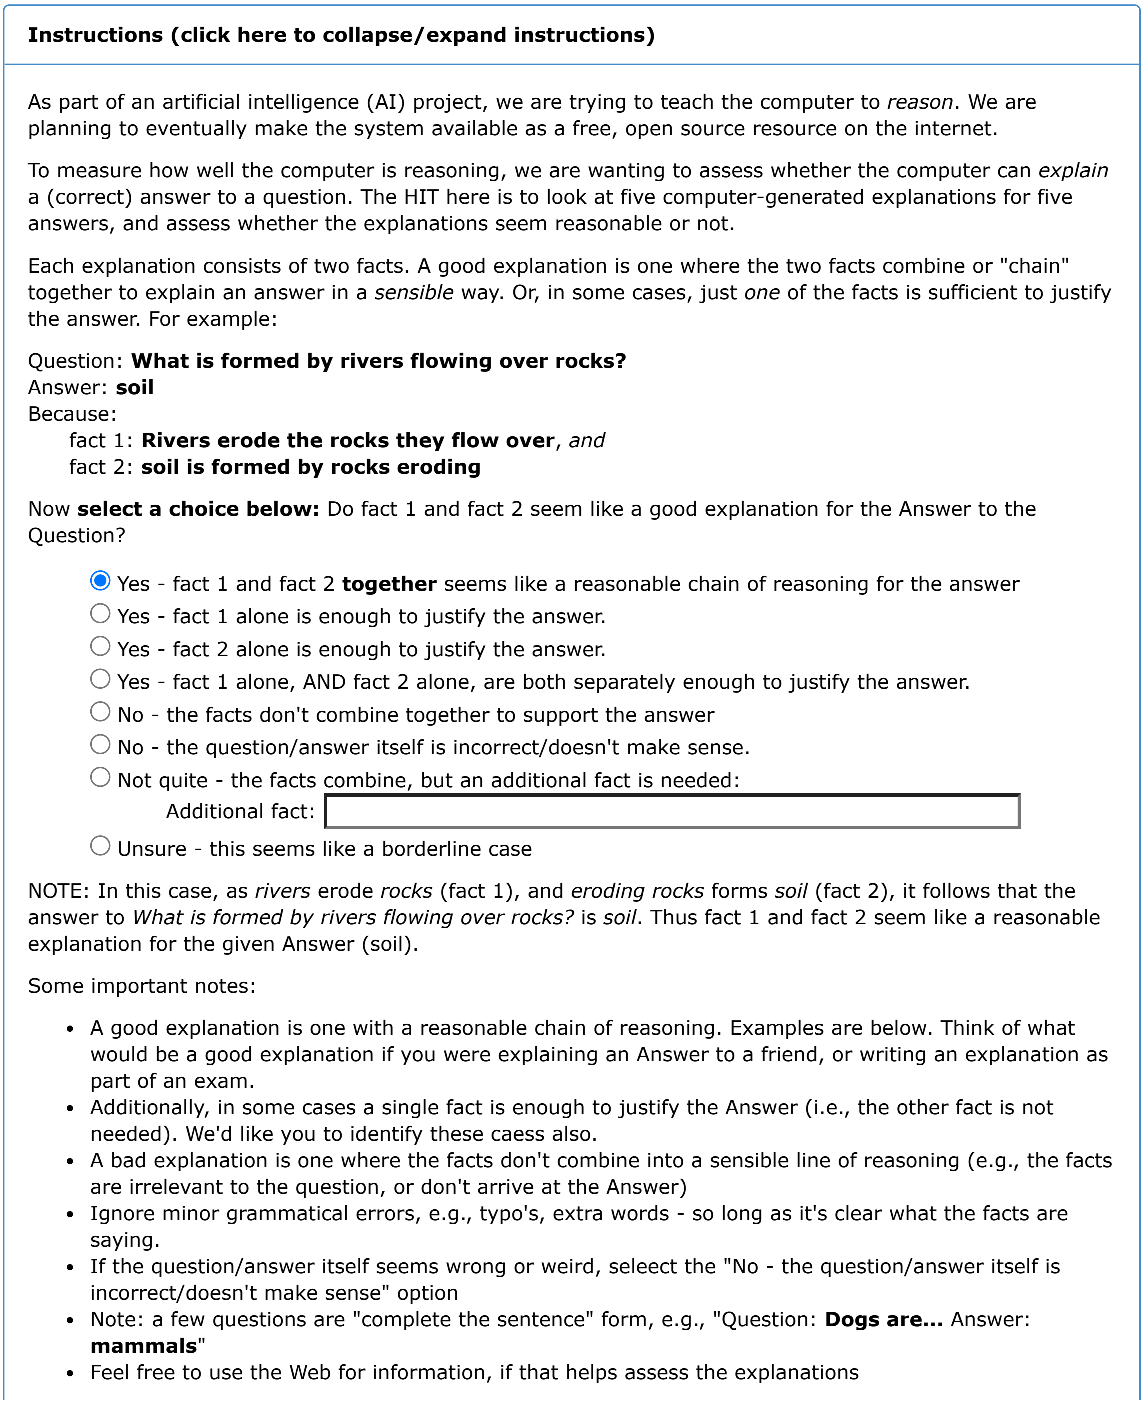
APPENDIX

A. Additional Implementation Details

- Optimizer: We use Adam optimizer with initial learning rate of 2e-5
- Number of params: $\sim$ 110M parameters (Bert-base uncased and classification layer)
- Hyper-parameters: We search over following options for hyperparameter (1) one layer vs two layer classifier (2) negative class weight ($(0.1, 0.2, ..., 0.9)$) (3) using negative option chains or not; for BERT-GRC as well as BERT-CHAIN. We perform model selection based on best dev split performance as per $P@1$.
- Best model configuration for BERT-Chain: negative class weight = 0.2; without using negative option chains; using a two layer classifier. Best model configuration for BERT-GRC: negative class weight = 0.3; without using negative option chains; using a two layer classifier.
- We have uploaded code at `https://github.com/harsh19/Reasoning-Chains-MultihopQA`

B. Instructions to Crowdworkers

Below are the instructions provided to the (Amazon Mechanical Turk) crowdworkers for chain annotation.



Instructions (click here to collapse/expand instructions)

As part of an artificial intelligence (AI) project, we are trying to teach the computer to *reason*. We are planning to eventually make the system available as a free, open source resource on the internet.

To measure how well the computer is reasoning, we are wanting to assess whether the computer can *explain* a (correct) answer to a question. The HIT here is to look at five computer-generated explanations for five answers, and assess whether the explanations seem reasonable or not.

Each explanation consists of two facts. A good explanation is one where the two facts combine or "chain" together to explain an answer in a *sensible* way. Or, in some cases, just *one* of the facts is sufficient to justify the answer. For example:

Question: **What is formed by rivers flowing over rocks?**
Answer: **soil**
Because:
fact 1: **Rivers erode the rocks they flow over**, *and*
fact 2: **soil is formed by rocks eroding**

Now **select a choice below:** Do fact 1 and fact 2 seem like a good explanation for the Answer to the Question?

● Yes - fact 1 and fact 2 **together** seems like a reasonable chain of reasoning for the answer
○ Yes - fact 1 alone is enough to justify the answer.
○ Yes - fact 2 alone is enough to justify the answer.
○ Yes - fact 1 alone, AND fact 2 alone, are both separately enough to justify the answer.
○ No - the facts don't combine together to support the answer
○ No - the question/answer itself is incorrect/doesn't make sense.
○ Not quite - the facts combine, but an additional fact is needed:
Additional fact:
○ Unsure - this seems like a borderline case

NOTE: In this case, as *rivers* erode *rocks* (fact 1), and *eroding rocks* forms *soil* (fact 2), it follows that the answer to *What is formed by rivers flowing over rocks?* is *soil*. Thus fact 1 and fact 2 seem like a reasonable explanation for the given Answer (soil).

Some important notes:

- A good explanation is one with a reasonable chain of reasoning. Examples are below. Think of what would be a good explanation if you were explaining an Answer to a friend, or writing an explanation as part of an exam.
- Additionally, in some cases a single fact is enough to justify the Answer (i.e., the other fact is not needed). We'd like you to identify these caess also.
- A bad explanation is one where the facts don't combine into a sensible line of reasoning (e.g., the facts are irrelevant to the question, or don't arrive at the Answer)
- Ignore minor grammatical errors, e.g., typo's, extra words - so long as it's clear what the facts are saying.
- If the question/answer itself seems wrong or weird, seleect the "No - the question/answer itself is incorrect/doesn't make sense" option
- Note: a few questions are "complete the sentence" form, e.g., "Question: **Dogs are...** Answer: **mammals**"
- Feel free to use the Web for information, if that helps assess the explanations

- Thank you for your help!!

Now please read the examples below carefully!

The following are examples of **good** explanations ("Yes - fact 1 and fact 2 together seems like a reasonable explanation for the answer")

Question: **What are some invertebrates?** Answer: **insects**
Because:
fact 1: **Some examples of invertebrates are arthropods.**, *and*
fact 2: **Most arthropods are insects.**

Question: **Black objects...** Answer: **absorb sunlight**
fact 1: **Black objects are the best heat absorbers.**, *and*
fact 2: **absorbing sunlight causes objects to heat**

Question: **what is very deadly?** Answer: **the ground shaking**
Because:
fact 1: **Earthquakes Earthquakes are very deadly.**, *and*
fact 2: **an earthquake causes the ground to shake**

Question: **What can our ears detect?** Answer: **matter vibrating**
Because:
fact 1: **When the waves pass our ears, a sound is detected.**, *and*
fact 2: **matter vibrating can cause sound**

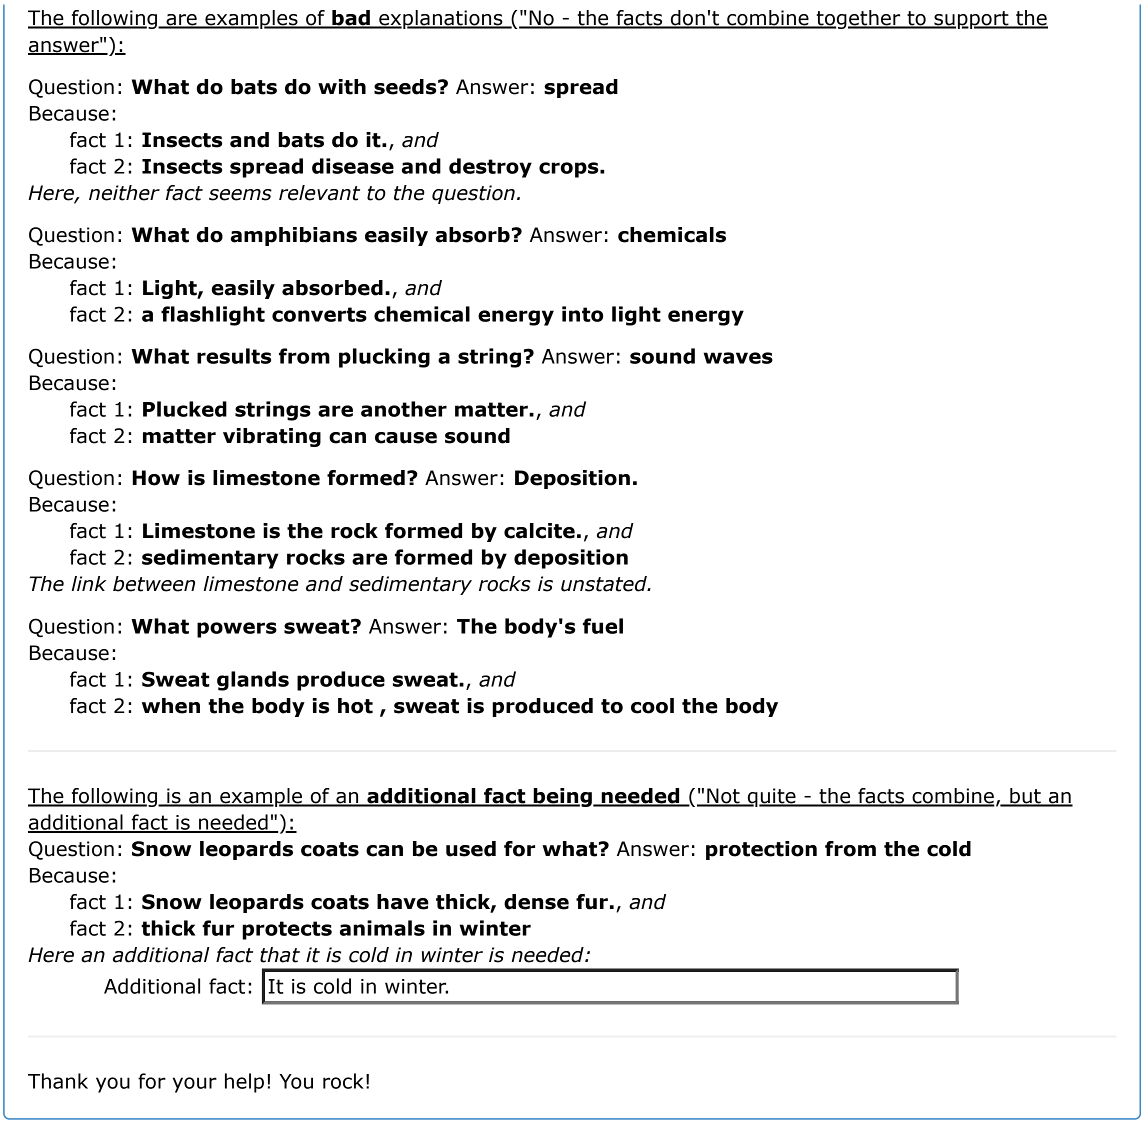
In all these cases, you can see a chain of reasoning from the question to the answer using the facts.

The following are examples of a **single fact** explanations ("Yes - fact 1/2 alone is enough to justify the answer"):

Question: **what do flowers attract?** Answer: **bees**
Because:
fact 1: **How flowers attract honey bees and why they do it.**, *and*
fact 2: **bees convert nectar into honey**
Here, fact 1 alone is enough to justify the answer that "flowers attract bees"

Question: **What has permeable skin?** Answer: **frogs**
Because:
fact 1: **skin is used for breathing air by frogs**, *and*
fact 2: **Frogs have permeable skin that both breathes and takes in water.**
Here, fact 2 alone is enough to justify the answer that "frogs have permeable skin"

The following is an example of a **bad question/answer** ("No - the question/answer itself is incorrect/doesn't make sense.")
Question: **What powers rockets?** Answer: **Mechanical energy**
Because:
fact 1: **Power is what they seek, and power is what they get.**, *and*
fact 2: **Most ecosystems get energy from sunlight.**
The answer seems wrong here - rockets are powered by chemical energy, not mechanical energy.



The following are examples of **bad** explanations ("No - the facts don't combine together to support the answer"):

Question: **What do bats do with seeds?** Answer: **spread**
Because:
fact 1: **Insects and bats do it.**, *and*
fact 2: **Insects spread disease and destroy crops.**
Here, neither fact seems relevant to the question.

Question: **What do amphibians easily absorb?** Answer: **chemicals**
Because:
fact 1: **Light, easily absorbed.**, *and*
fact 2: **a flashlight converts chemical energy into light energy**

Question: **What results from plucking a string?** Answer: **sound waves**
Because:
fact 1: **Plucked strings are another matter.**, *and*
fact 2: **matter vibrating can cause sound**

Question: **How is limestone formed?** Answer: **Deposition.**
Because:
fact 1: **Limestone is the rock formed by calcite.**, *and*
fact 2: **sedimentary rocks are formed by deposition**
The link between limestone and sedimentary rocks is unstated.

Question: **What powers sweat?** Answer: **The body's fuel**
Because:
fact 1: **Sweat glands produce sweat.**, *and*
fact 2: **when the body is hot , sweat is produced to cool the body**

The following is an example of an **additional fact being needed** ("Not quite - the facts combine, but an additional fact is needed"):
Question: **Snow leopards coats can be used for what?** Answer: **protection from the cold**
Because:
fact 1: **Snow leopards coats have thick, dense fur.**, *and*
fact 2: **thick fur protects animals in winter**
Here an additional fact that it is cold in winter is needed:
Additional fact: It is cold in winter.

Thank you for your help! You rock!

Self-Supervised Knowledge Triplet Learning for Zero-Shot Question Answering

Pratyay Banerjee and **Chitta Baral**
Department of Computer Science, Arizona State University
`pbanerj6,chitta`@asu.edu

Abstract

The aim of all Question Answering (QA) systems is to generalize to unseen questions. Current supervised methods are reliant on expensive data annotation. Moreover, such annotations can introduce unintended annotator bias, making systems focus more on the bias than the actual task. This work proposes Knowledge Triplet Learning (KTL), a self-supervised task over knowledge graphs. We propose heuristics to create synthetic graphs for commonsense and scientific knowledge. We propose using KTL to perform zero-shot question answering, and our experiments show considerable improvements over large pre-trained transformer language models.

1 Introduction

The ability to understand natural language and answer questions is one of the core focuses in the field of natural language processing. To measure and study the different aspects of question answering, several datasets are developed, such as SQuaD (Rajpurkar et al., 2018), HotpotQA (Yang et al., 2018), and Natural Questions (Kwiatkowski et al., 2019) which require systems to perform extractive question answering. On the other hand, datasets such as SocialIQA (Sap et al., 2019b), CommonsenseQA (Talmor et al., 2018), Swag (Zellers et al., 2018) and Winogrande (Sakaguchi et al., 2019) require systems to choose the correct answer from a given set. These multiple-choice question answering datasets are very challenging, but recent large pre-trained language models such as BERT (Devlin et al., 2018), XLNET (Yang et al., 2019b) and RoBERTa (Liu et al., 2019b) have shown very strong performance on them. Moreover, as shown in Winogrande (Sakaguchi et al., 2019), acquiring unbiased labels requires a "carefully designed crowdsourcing procedure", which adds to the cost of data annotation. This is also quantified in other natural language tasks such as Natural Language Inference (Gururangan et al., 2018) and Argument Reasoning Comprehension (Niven and Kao, 2019), where such annotation artifacts lead to "Clever Hans Effect" in the models (Kaushik and Lipton, 2018; Poliak et al., 2018). One way to resolve this is to design and create datasets in a clever way, such as in Winogrande (Sakaguchi et al., 2019), another way is to ignore the data annotations and to build systems to perform unsupervised question answering (Teney and Hengel, 2016; Lewis et al., 2019). In this paper, we focus on building unsupervised zero-shot multiple-choice QA systems.

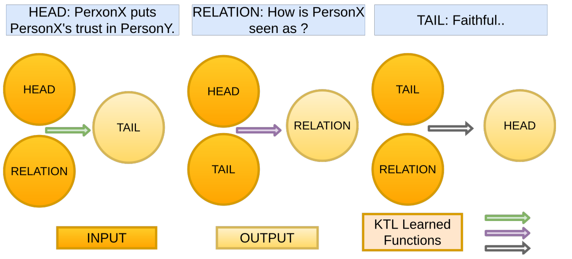


Figure 1: Knowledge Triplet Learning Framework, where given a triple (h, r, t) we learn to generate one of the inputs given the other two.

Recent work (Fabbri et al., 2020; Lewis et al., 2019) try to generate a synthetic dataset using a text corpus such as Wikipedia, to solve extractive QA. Other works (Bosselut and Choi, 2019; Shwartz et al., 2020) use large pre-trained generative language models such as GPT-2 (Radford et al., 2019) to generate knowledge, questions, and answers and compare against the given answer choices.

In this work, we utilize the information present in Knowledge Graphs such as ATOMIC (Sap et al., 2019a). We define a new task of Knowledge Triplet Learning (KTL) over these knowledge graphs. For tasks which do not have appropriate knowledge graphs, we propose heuristics to create synthetic knowledge graphs. Knowledge Triplet Learning

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 151–162,
November 16–20, 2020. ©2020 Association for Computational Linguistics

is like Knowledge Representation Learning and Knowledge Graph Completion but not limited to it. Knowledge Representation Learning (Lin et al., 2018) learns the low-dimensional projected and distributed representations of entities and relations defined in a knowledge graph. Knowledge Graph Completion (Ji et al., 2020) aims to identify new relations and entities to expand an incomplete input knowledge graph.

In KTL, as shown in Figure 1, we define a triplet (h, r, t), and given any two as input, we learn to generate the third. This tri-directional reasoning forces the system to learn all the possible relations between the three inputs. We map the question answering task to KTL, by mapping the *context*, *question* and *answer* to (h, r, t) respectively. We define two different ways to perform self-supervised KTL. This task can be designed as a representation generation task or a masked language modeling task. We compare both the strategies in this work. We show how to use models trained on this task to perform zero-shot question answering without any additional supervision. We also show how models pre-trained on this task perform considerably well compared to strong pre-trained language models on few-shot learning. We evaluate our approach on the three commonsense and three science multiple-choice QA datasets.

The contributions of this paper are summarized as follows:

- We define the Knowledge Triplet Learning over Knowledge Graph and show how to use it for zero-shot question answering.
- We compare two strategies for the above task.
- We propose heuristics to create synthetic knowledge graphs.
- We perform extensive experiments of our framework on three commonsense and three science question-answering datasets.
- We achieve state-of-the-art results for zero-shot and propose a strong baseline for the few-shot question answering task.

2 Knowledge Triplet Learning

We define the task of Knowledge Triplet Learning (KTL) in this section. We define $G = (V, E)$ as a Knowledge Graph, where V is the set of vertices, E is the set of edges. V consists of entities which can be phrases or named-entities depending on the given input Knowledge Graph. Let S be a set of fact triples, $S \subseteq V \times E \times V$ with the format (h, r, t), where h and t belong to set of vertices V and r belongs to set of edges. The h and t indicates the head and tail entities, whereas r indicates the relation between them.

For example, from the ATOMIC knowledge graph, (*PersonX puts PersonX's trust in PersonY*, **How is PersonX seen as?**, *faithful*) is one such triple. Here the head is *PersonX puts PersonX's trust in PersonY*, relation is **How is PersonX seen as?** and the tail is *faithful*. Do note V does not contain homogenous entities, i.e, both *faithful* and *PersonX puts PersonX's trust in PersonY* are in V.

We define the task of KTL as follows: Given input a triple (h, r, t), we learn the following three functions.

$$f_t(h, r) \Rightarrow t, \quad f_h(r, t) \Rightarrow h, \quad f_r(h, t) \Rightarrow r \tag{1}$$

That is, each function learns to generate one component of the triple given the other two. The intuition behind learning these three functions is as follows. Let us take the above example: (*PersonX puts PersonX's trust in PersonY*, **How is PersonX seen as?**, *faithful*). The first function $f_t(h, r)$ learns to generate the answer t given the context and the question. The second function $f_h(r, t)$ learns to generate one context where the question and the answer may be valid. The final function $f_r(h, t)$ is a Jeopardy-style generating the question which connects the context and the answer.

In Multiple-choice QA, given the context, two choices may be true for two different questions. Similarly, given the question, two answer choices may be true for two different contexts. For example, given the context: *PersonX puts PersonX's trust in PersonY*, the answers *PersonX is considered trustworthy by others* and *PersonX is polite* are true for two different questions **How does this affect others?** and **How is PersonX seen as?**. Learning these three functions enables us to score these relations between the context, question, and answers.

2.1 Using KTL to perform QA

After learning this function in a self-supervised way, we can use them to perform question answering. Given a triple (h, r, t), we define the following scoring function:

$$\begin{aligned} &D_t = D(t, f_t(h, r)), \quad D_h = D(h, f_h(r, t)), \\ &D_r = D(r, f_r(h, t)) \\ &score(h, r, t) = D_t * D_h * D_r \end{aligned} \tag{2}$$

where h is the context, r is the question and t is one of the answer options. D is a distance function which measures the distance between the generated output and the ground-truth. The distance function varies depending on the instantiation of the framework, which we will study in the following sections. The final answer is selected as:

$$ans = \arg\min_t (score(h, r, t)) \tag{3}$$

As the scores are the distance from the ground-truth we select the choice that has the minimum score.

We define the different ways we can implement this framework in the following sections.

2.2 Knowledge Representation Learning

In this implementation, we use Knowledge representation learning to learn equation (1). In contrast to triplet classification and graph completion, where systems try to learn a score function $f_r(h, t)$, i.e, is the fact triple (h, r, t) true or false; in this method we learn to generate the inputs vector representations, i.e, $f_r(h, t) \Rightarrow r$. We can view equation 1 as generator functions, which given the two input vector encodings learns to generate a vector representation of the third. The vector encodings can be pre-computed sentence vector representations or contextual vector representations. As our triples (h, r, t) can have a many to many relations between each pair, we first project the two inputs from input vector encoding space to a different space similar to the work of TransD (Ji et al., 2015). We use a Transformer encoder Enc to encode our triples to the vector encoding space. We learn two projection functions, M_{i1} and M_{i2} to project the two inputs, and a third projection function M_o to project the entity to be generated. We combine the two projected inputs using a function C. These functions can be implemented using feedforward networks.

$$I_{e1} = Enc(I_1), I_{e2} = Enc(I_2), O_e = Enc(O)$$
$$I_{e1} = M_{i1}(I_{e1}), I_{e2} = M_{i2}(I_{e2}), O_p = M_o(O_e)$$
$$\hat{O} = C(I_{e1}, I_{e2})$$
$$loss = LossF(\hat{O}, O_p)$$

where I_i is the input, $\hat{O}$ is the generated output vector and O_p is the projected vector. M and C functions are learned using fully connected networks. In our implementation, we use RoBERTa as the Enc transformer, with the output representation of the $[cls]$ token as the phrase representation.

We train this model using two types of loss functions, L2Loss where we try to minimize the L2 norm between the generated and the projected ground-truth, and Noise Contrastive Estimation (Gutmann and Hyvärinen, 2010) where along with the ground-truth we have k noise-samples. These noise samples are selected from other (h, r, t) triples such that the target output is not another true fact triple, i.e, (h, r, t_{noise}) is false. The NCELoss is defined as:

$$NCELoss(\hat{O}, O_p, [N_0 ... N_k]) =$$
$$-\log \frac{\exp sim(\hat{O}, O_p)}{\exp sim(\hat{O}, O_p) + \sum_{k \in N} \exp(sim(\hat{O}, N_k))}$$

where N_k are the projected noise samples, sim is the similarity function which can be the L2 norm or Cosine similarity, $\hat{O}$ is the generated output vector and O_p is the projected vector.

The D distance function (2) for such a model is defined by the distance function used in the loss function. For L2Loss, it is the L2 norm, and in the case of NCELoss, we use $1 - sim$ function.

2.3 Span Masked Language Modeling

In Span Masked Language Modeling (SMLM), we model the equation 1 as a masked language modeling task. We tokenize and concatenate the triple (h, r, t) with a separator token between them, i.e, $[cls][h][sep][r][sep][t][sep]$. For the function $f_r(h, t) \Rightarrow r$, we mask all the tokens present in r, i.e, $[cls][h][sep][mask][sep][t][sep]$. We feed these tokens to a Transformer encoder Enc and use a feed forward network to unmask the sequence of tokens. Similarly, we mask h to learn f_h and t to learn f_t

We train the same Transformer encoder to perform all the three functions. We use the cross-entropy loss to train the model:

$$CELoss(h, r, mask(t), t) =$$
$$-\frac{1}{n}\sum_{i=1}^{n} log_2 P_{MLM}(t_i | h, r, t_{1..t_i..tn})$$

where P_{MLM} is the masked language modeling probability of the token t_i, given the unmasked tokens h and r and other masked tokens in t. Do note we do not do progressive unmasking, i.e, all the masked tokens are jointly predicted.

The D distance function (2) for this model is same as the loss function defined above.

3 Synthetic Graph Construction

This section describes our method to create a synthetic knowledge graph from a text corpus containing sentences. Not all types of knowledge are present in a structured knowledge graph, such as ATOMIC, which might help answer questions. For example, the questions in QASC dataset (Khot et al., 2019) require knowledge about scientific concepts, such as, "Clouds regulate the global engine of atmosphere and ocean.". The QASC dataset contains a textual knowledge corpus containing science facts. Similarly, the Open Mind Commonsense (OMCS) knowledge corpus contains knowledge about different commonsense facts, such as, "You are likely to find a jellyfish in a book". Another kind of knowledge about social interactions and story progression is present in several story understanding datasets, such as RoCStories and the Story Cloze Test (Mostafazadeh et al., 2016). To perform question answering using this knowledge and KTL, we create the following two graphs: the Common Concept Graph and the Directed Story Graph.

Common Concept Graph To create the Common Concept Graph, we extract noun-chunks and verb-chunks from each of the sentences using the Spacy Part-of-Speech tagger (Honnibal and Montani, 2017). We assign all the extracted chunks as the graph's vertices and the sentences as the graph's edges. To generate training samples for KTL, we assign triples (h, R, t) as (e_1, e_2, v_i) where v_i is the common concept present in both the sentences e_1 and e_2. For example, in the sentence *Clouds regulate the global engine of atmosphere and ocean.*, the extracted concepts are *clouds*, *global engine*, *atmosphere*, *ocean* and *regulate*. The triplet assignment will be, [*Warm moist air from the Pacific Ocean brings fog and low stratus clouds to the maritime zone.*, *Clouds regulate the global engine of atmosphere and ocean.*, **clouds**]. We create two such synthetic graphs using the QASC science corpus and the OMCS concept corpus. Our hypothesis is this graph, and the KTL framework will allow the model to understand the concepts common in two facts, which allows question answering.

Directed Story Graph This graph is created using short stories from the RoCStories and Story Cloze Test datasets. This graph is different from the above graph as this graph has a directional property, and each story graph is disconnected. To create this graph, we take each short story with k sentences, $[s_1, s_2, s_3.., s_k]$ and create a directed graph such that all sentences are vertices and each sentence is connected with a directed edge only to sentences that occur after it. For example, s_1 is connected to s_2 with a directed edge but not vice versa. We generate triples (h, R, t) by sampling vertices (s_i, s_j, s_k) such that there is a directed path between the sentences s_i and s_k through s_j. This format captures a smaller story where the head is an event that occurs before the relation and the tail. This graph is designed for story understanding and abductive reasoning using the KTL framework.

Random Sampling There are around 17M sentences in the QASC text corpus; similarly, there are 640K sentences in the OMCS text corpus. Our synthetic triple generation leads to a significantly large set of triples in order of 10^{12} and more. To restrict the train dataset size for our KTL framework, we randomly sample triples and limit the train dataset size to be at max 1M samples; we refer to this as Random Sampling.

Curriculum Filtering Here, we extract the noun and verb chunks from the context, question, and answer options present in the question answering datasets. We filter triples from the generated dataset and keep only those triples where at least one of the entities is present in the extracted noun and verb chunks set. This filtering is analogous to a real-life human examination setting where a teacher provides the set of concepts upon which questions would be asked, and the students can learn the concepts. We perform the sampling and filtering only on the huge Common Concept Graphs generated from QASC and OMCS corpus.

4 Datasets

We evaluate our framework on the following six datasets: SocialIQA (Sap et al., 2019b), aNLI (Bhagavatula et al., 2019), CommonsenseQA (Talmor et al., 2018), QASC (Khot et al., 2019), OpenBookQA (Mihaylov et al., 2018) and ARC (Clark et al., 2018). SocialIQA, aNLI, and CommonsenseQA require commonsense reasoning and external knowledge to answer the questions. Similarly, QASC, OpenBookQA, and ARC require scientific knowledge. Table 1 shows the dataset statistics and the corresponding knowledge graph used to train our KTL model. Table 2 shows the statistics for the triples extracted from the graphs. From the two tables we can observe our KTL triples have different number of words when compared to the target question answering tasks. Especially where the context is significantly larger and human anno-

tated as in SocialIQA, increasing the challenge for unsupervised learning.

4.1 Question to Hypothesis Conversion and Context Creation

We can observe the triples in our synthetic graphs, QASC-CCG and OMCS-CCG contain factual statements, and our target question answering datasets have questions that contain *wh* words or fill-in-the-blanks. We translate each question to a hypothesis using the question and each answer option. To create hypothesis statements for questions containing *wh* words, we use a rule-based model (Demszky et al., 2018). For fill-in-the-blank and cloze style questions, we replace the blank or concat the question and the answer option.

For questions that do not have a context, such as in QASC or CommonsenseQA, we retrieve the top five sentences using the question and answer options as query and perform retrieval from respective source knowledge sentence corpus. For each retrieved-context, we evaluate the answer option score using equation 2 and take the mean score.

5 Experiments

5.1 Baselines

We compare our models to the following baselines.

1. **GPT-2 Large** with language modeling cross-entropy loss as the scoring function. We concatenate the context and question and find the cross-entropy loss for each answer choices and choose the answer with minimum loss.
2. **Pre-trained RoBerta-large** used as is, without any fine-tuning or further pre-training, with scoring the same as our defined SMLM model. We refer to it as Rob-MLM.
3. **RoBerta-large** model further fine-tuned using the original Masked Language Modeling task over our concatenated fact triples (h, r, t), with scoring same as SMLM. We refer to it as Rob-FMLM.
4. **IR Solver** described in ARC (Clark et al., 2016), which sends the context, question, and answer option as a query to Elasticsearch. The top retrieved sentence, which has a non-stop-word overlap with both the question and the answer, is used as a representative, and its corresponding IR ranking score is used as confidence for the answer. The option with the highest score is chosen as the answer.

5.2 KTL Training

We train the Knowledge Representation Learning (KRL) model using both L2Loss and NCELoss. For NCELoss, we also train it with both L2 norm and Cosine similarity. Both the KRL model (365M) and the SMLM model (358M) uses RoBERTa-large (355M) as the encoder. We train the model for three epochs with the following hyper-parameters: batch sizes [512,1024] for SMLM and [32,64] for KRL; learning rate in range: [1e-5,5e-5]; warm-up steps in range [0,0.1]; in 4 Nvidia V100s 16GB. We use the transformers package (Wolf et al., 2019). All triplets from the training graphs are positive samples. We learn using these triplets. For NCE, we choose k equal to ten, i.e., ten negative samples.

Table 3: Results for the Unsupervised QA task. Mean accuracy on Train, Dev and Test is reported. For Self-Talk and BIDAF Sup. we report the Dev and Test splits, for Roberta Sup. we report Test split. Test is reported if labels are present. **Best** scores, Second Best.

We perform three hyper-parameter trials using ten percent of the training data for each model, and train models with three different seeds. We report the mean accuracy of the three random seed runs for each of our experiments and report the standard deviation if space permits. Code is available here.

6 Results and Discussion

6.1 Unsupervised Question Answering

Table 3 compares our different KTL methods with our four baselines for the six question-answering datasets on the zero-shot question answering task. We use Hypothesis Conversion, Curriculum Filtering, and Context Creation for ARC, QASC, OBQA, and CommonsenseQA for both the baselines and our models. We compare the models on the Train, Dev and Test split if labels are available, to capture the statistical significance better.

We can observe that our KTL trained models perform statistically significantly better than the baselines. When comparing the different KRL models, the NCELoss with Cosine similarity performs the best. This observation might be due to the additional supervision provided by the negative samples as the L2Loss model only tries to minimize the distance between the generated and the target projections. When comparing different KTL instantiations, we can see that the SMLM model performs the best overall. SMLM and KRL differ in their core approaches. We hypothesize that multi-layered attention in a transformer encoder enables the SMLM model to distinguish between a true and false statement. In KRL, we are learning from both positive and negative samples, but the model still under-performs. On analysis, we observe the random negative samples may make the training task biased for KRL. Our future work would be to utilize alternative negative sampling techniques, such as selecting samples closer in contextual vector space.

Model	QASC ↑	OBQA ↑	aNLI ↑	ComQA ↑	SocIQA ↑
RoBerta	44.5 ± 1.2	47.8 ± 1.4	68.8 ± 1.3	46.4 ± 1.5	44.4 ± 1.2

Table 4: Accuracy comparison of the KTL pre-trained RoBerta encoder when used for Few-shot learning Question Answering task on the Validation split.

The improvements in ARC-Challenge task are considerably less. It is observed that the fact corpus for QASC, although it contains a vast number of science facts, does not contain sufficient knowledge to answer ARC questions. There is a substantial improvement in SocialIQA, aNLI, QASC, and CommonsenseQA as the respective KTL knowledge corpus contains sufficient knowledge to answer the questions. It is interesting to note that for QASC, we can reduce the problem from an eight-way to a four-way classification, as our top-4 accuracy on QASC is above 92%. Our unsupervised model outperforms previous approaches, such as Self-Talk (Shwartz et al., 2020). It approaches prior supervised approaches like BIDAF (Seo et al., 2017), and even surpasses it on two tasks.

6.2 Few-Shot Question Answering

Table 4 compares our KTL pre-trained transformer encoder in the few-shot question answering task. We fine-tune the encoder with a simple feedforward

Table 6: Effect of Question to Hypothesis Conversion (Hypo), Curriculum Filtering (CF) and providing the Gold Fact context on the Validation split.

network for a n-way classification task, the standard question-answering approach using RoBerta with n being the number of answer options during training with only 8% of the training data. We train on three randomly sampled splits of training data and report the mean. We can observe our KTL pre-trained encoders perform significantly better than the baselines and approach the fully supervised model, with only 7.5% percent behind the fully supervised model on SocialIQA. We also observe that our pre-trained models have a lower deviation.

6.3 Ablation studies and Analysis

Effect of Context, Question, Answer Distance In Table 5, we compare the effect of the three different distance scores. It is interesting to observe, in OpenBookQA, QASC, and CommonsenseQA, the three datasets which do not provide a context, the model is more perplexed to predict the question when given a wrong answer option, leading to higher accuracy for only Question distance score. On the other hand, in aNLI all three distance scores have nearly equal performance. In SocialIQA, the question has the least accuracy, whereas the model is more perplexed when predicting the context given a wrong answer option. This observation confirms our hypothesis that given a task predicting context and question can contain more information than discriminating between options alone.

Effect of Hypothesis Conversion, Curriculum Filtering and Context Retrieval In Table 6, we observe the effect of hypothesis conversion, curriculum filtering, and our context creation. Converting the question to a hypothesis provides a slight improvement, but a significant improvement is observed when we filter our KTL training samples and keep only those concepts that are present in the target question answering task, compared to when the KTL model is trained with a random sample of 1M. Curriculum filtering is impactful because there are many concepts present in our source knowledge corpus, and the randomly sampled training corpus only contains 50% of the target question answering task concepts on an average. Another critical thing to note in Table 6 is our KTL models can strongly perform like supervised models, when the gold knowledge context is provided, which are available in QASC and OpenBookQA. This observation indicates a better retrieval system for context creation can further improve our models.

Effect of Sythetic Triple corpus size Figure 2 compares our two modeling approaches when we train them with varying numbers of KTL training samples. NCE refers to our KRL model trained with NCELoss and Cosine similarity. We can observe that our KRL model learns faster due to additional supervision, but the SMLM model performs the best when trained with more samples. The performance tapers after 10^5 samples, indicating the models are overfitting to the synthetic data.

Error Analysis We sampled 50 error cases from each of our question-answering tasks. Our KTL framework allows learning from knowledge graphs, that includes synthetic knowledge graphs. Both our instantiation, SMLM, and KRL function as a knowledge base score generator, were given the inputs, and a target, the generator yields a score, how improbable is the target to be present in the knowledge base. Most of our errors are when all context, question, and answer-option have a large distance score, and the model accuracy degenerates to that of a random model. This more considerable distance indicates the model is highly perplexed to see the input text. For aNLI and SocialIQA, we possess relevant context, and our performance is significantly better in these datasets, but for other tasks, we have another source of error, i.e., context creation. In several cases, the context is irrelevant and acts as a noise. Other errors include when the questions require complex reasoning such as understanding negation, conjunctions, and disjunctions; temporal reasoning such as “6 am” being before “10 am”, and multi-hop reasoning. These complex reasoning tasks are required to answer a significant number of questions in the science and commonsense QA tasks. We also tried to utilize a text generation model, such as GPT-2, to generate and compare with ground truth text using our KTL framework, but preliminary results show the model is overfitting to the synthetic dataset and leads to significantly low performance.

Other Instantiations Our KTL framework can be implemented using other methods, such as using a Generator/Discriminator pre-training proposed in Electra (Clark et al., 2019), and sequence-to-sequence methods. The distance functions for sequence-to-sequence models can be similar to our SMLM model, the cross-entropy loss for the expected generated sequence. Discriminator based methods can adapt to the negative class probabilities as the distance function. Studying different instantiations and their implications are some of the fascinating future works.

7 Related Work

7.1 Unsupervised QA

Recent work on unsupervised question answering approach the problem in two ways, a domain adaption or transfer learning problem (Chung et al., 2018), or a data augmentation problem (Yang et al., 2017; Dhingra et al., 2018; Wang et al., 2018; Alberti et al., 2019). The work of (Lewis et al., 2019; Fabbri et al., 2020; Puri et al., 2020) use style transfer or template-based question, context and answer triple generation, and learn using these to perform unsupervised extractive question answering. There is another approach to learning generative models, generating the answer given a question or clarifying explanations and questions, such as GPT-2 (Radford et al., 2019) to perform unsupervised question answering (Shwartz et al., 2020; Bosselut and Choi, 2019; Bosselut et al., 2019). In the visual domain, zero-shot visual question answering is studied in (Teney and Hengel, 2016), and a self-supervised learning method for logical compositions of visual questions is proposed in (Gokhale et al., 2020).

In contrast, our work focuses on learning from knowledge graphs and generate vector representations or sequences of tokens not restricted to the answer but including the context and the question using the masked language modeling objective.

7.2 Use of External Knowledge for QA

There are several approaches to add external knowledge into models to improve question answering. Broadly they can be classified into two, learning from unstructured knowledge and structured knowledge. In learning from unstructured knowledge, recent large pre-trained language models (Peters et al., 2018; Radford et al., 2019; Devlin et al., 2018; Liu et al., 2019b; Clark et al., 2020; Lan et al., 2019; Joshi et al., 2020; Bosselut et al., 2019) learn general-purpose text encoders from a huge text corpus. On the other hand, learning from structured knowledge includes learning from structured knowledge bases (Yang and Mitchell, 2017; Bauer et al., 2018; Mihaylov and Frank, 2018; Wang and Jiang, 2019; Sun et al., 2019) by learning knowledge enriched word embeddings. Using structured knowledge to refine pre-trained contextualized representations learned from unstructured knowledge is another approach (Peters et al., 2019; Yang et al., 2019a; Zhang et al., 2019; Liu et al., 2019a).

Another approach of using external knowledge includes retrieval of knowledge sentences from a text corpora (Das et al., 2019; Chen et al., 2017; Lee et al., 2019; Banerjee et al., 2019; Banerjee and Baral, 2020; Mitra et al., 2019; Banerjee, 2019), or knowledge triples from knowledge bases (Min et al., 2019; Wang et al., 2020) that are useful to answer a specific question. Another recent approach uses language model as knowledge bases (Petroni et al., 2019), where they query a language model to un-mask a token given an entity and a relation in a predefined template. We use knowledge graphs to learn a self-supervised generative task to perform zero-shot multiple-choice QA in our work.

7.3 Knowledge Representation Learning

Over the years there are several methods discovered to perform the task of knowledge representation learning. Few of them are: TransE (Bordes et al., 2013) that views relations as a translation vector between head and tail entities, TransH (Wang et al., 2014) that overcomes TransE's inability to model complex relations, and TransD (Ji et al., 2015) that aims to reduce the parameters by proposing two different mapping matrices for head and tail. KRL has been used in various ways to generate natural answers (Yin et al., 2016; He et al., 2017) and generate factoid questions (Serban et al., 2016). The task of Knowledge Graph Completion (Yao et al., 2019) is to either predict unseen relations r between two existing entities: $(h, ?, t)$ or predict the tail entity t given the head entity and the query relation: $(h, r, ?)$. Whereas we are learning to predict including the head, $(?, r, t)$. In KTL, head and tail are not similar text phrases (context and answer) unlike Graph completion. We further modify TransD and adapt it to our KTL framework to perform zero-shot QA.

8 Conclusion

This work proposes a new framework of Knowledge Triplet Learning over knowledge graph entities and relations. We show learning all three possible functions, f_r, f_h, and f_t help the model perform zero-shot multiple-choice question answering, where we do not use question-answering annotations. We learn from both human-annotated and synthetic knowledge graphs and evaluate our framework on the six question-answering datasets. Our framework achieves state-of-the-art in the zero-shot question answering task achieving performance like prior supervised work and sets a strong baseline in the few-shot question answering task.

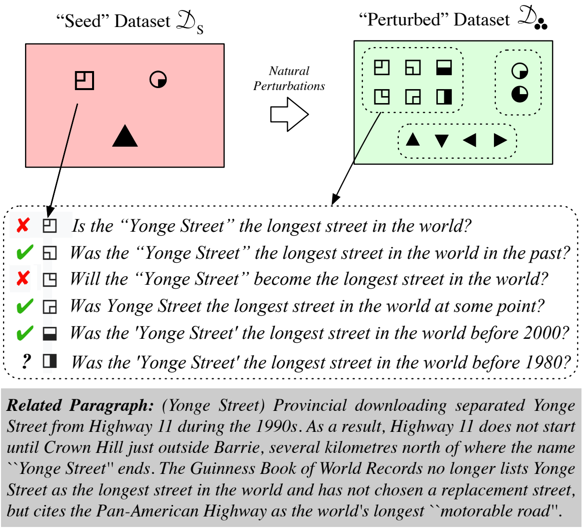
Abstract

Deep learning models for linguistic tasks require large training datasets, which are expensive to create. As an alternative to the traditional approach of creating new instances by repeating the process of creating one instance, we propose doing so by first collecting a set of seed examples and then applying human-driven *natural perturbations* (as opposed to rule-based machine perturbations), which often change the gold label as well. Such perturbations have the advantage of being relatively easier (and hence cheaper) to create than writing out completely new examples. Further, they help address the issue that even models achieving human-level scores on NLP datasets are known to be considerably sensitive to small changes in input. To evaluate the idea, we consider a recent question-answering dataset (BOOLQ) and study our approach as a function of the *perturbation cost ratio*, the relative cost of perturbing an existing question vs. creating a new one from scratch. We find that when natural perturbations are moderately cheaper to create (cost ratio under 60%), it is more effective to use them for training BOOLQ models: such models exhibit 9% higher robustness and 4.5% stronger generalization, while retaining performance on the original BOOLQ dataset.

1 Introduction

Creating large datasets to train NLP models has become increasingly expensive. While many datasets (Bowman et al., 2015; Rajpurkar et al., 2016) targeting different linguistic tasks have been proposed, nearly all are created by repeating a fixed process used for writing a single example. This approach results in many *independent* examples, each generated from scratch. We propose an alternative, often substantially cheaper training set construction method where, after collecting a few seed examples, the set is expanded by applying human-authored *minimal perturbations* to the seeds.



✗ *Is the "Yonge Street" the longest street in the world?*
✓ *Was the "Yonge Street" the longest street in the world in the past?*
✗ *Will the "Yonge Street" become the longest street in the world?*
✓ *Was Yonge Street the longest street in the world at some point?*
✓ *Was the 'Yonge Street' the longest street in the world before 2000?*
? *Was the 'Yonge Street' the longest street in the world before 1980?*

Related Paragraph: *(Yonge Street) Provincial downloading separated Yonge Street from Highway 11 during the 1990s. As a result, Highway 11 does not start until Crown Hill just outside Barrie, several kilometres north of where the name ``Yonge Street'' ends. The Guinness Book of World Records no longer lists Yonge Street as the longest street in the world and has not chosen a replacement street, but cites the Pan-American Highway as the world's longest ``motorable road''.*

Figure 1: Training set creation via minimal-perturbation clusters. Left: Seed dataset $\mathcal{D}_S$ with 3 instances (shown as different shapes). Right: Expanded dataset $\mathcal{D}_{\therefore}$ with 10 instances, comprising 2-4 minimal-perturbations (illustrated as rotation, fills, etc.) of each seed instance. Human-authored perturbations aren't required to always preserve the answer (yes/no in the example) and often add richness by altering the answer.

Fig. 1 illustrates our proposal of using *natural perturbations*. We use the traditional approach to first create a small scale *seed dataset* $\mathcal{D}_S$, shown as the red rectangle on the left with three instances (denoted by different shapes). However, rather than simply repeating this process to scale up $\mathcal{D}_S$ to a larger dataset $\mathcal{D}$, we set up a different task: ask crowdworkers to create multiple *minimal perturbations* of each seed instance (shown as rotation, fills, etc.) with an encouragement to change the answer. The end result is a larger dataset $\mathcal{D}_{\therefore}$ of a similar size as $\mathcal{D}$ but with an inherent structure: *clusters* of *minimally-perturbed* instances with mixed labels, denoted by the green rectangle at the right in Fig. 1.

An inspiration for our approach is the lack of robustness of current state-of-the-art models to mi-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 163–170,
November 16–20, 2020.

nor adversarial changes in the input (Jia and Liang, 2017). We observed a similar phenomenon even with model-agnostic, human-authored changes to yes/no questions (as shown in Fig.1), despite models achieving near-human performance on this task. Specifically, we found the accuracy of a RoBERTa model trained on BoolQ (Clark et al., 2019) to drop by 15% when evaluated on locally perturbed questions. These new questions were, however, no harder for humans. This raises the question: *Can a different way of constructing training sets help alleviate this issue?* Minimal perturbations, as we show, provide an affirmative answer.

Perturbing a given example is generally a simpler task, costing only a fraction of the cost of creating a new example from scratch. We call this fraction the *perturbation cost ratio* (henceforth referred to as *cost ratio*), and assess the value of our perturbed training datasets as a function of it. As this ratio decreases (i.e., perturbations become cheaper), one, of course, obtains a larger dataset than the traditional method, at the same cost. More importantly, even when the ratio is only moderately low (at 0.6), models trained on our perturbed datasets exhibit desirable advantages: They are 9% more robust to minor changes and generalize 4.5% better across datasets than models trained on BoolQ.

Specifically, our *generalization experiment* with the MultiRC (Khashabi et al., 2018) dataset demonstrates that models trained on perturbed data outperform those trained on traditional data when evaluated on unseen, unperturbed questions from a different domain. Second, we *assess robustness* by evaluating on BoolQ-*e*♣ (Gardner et al., 2020), a test set of expert-generated perturbations that deviate from the patterns common in large-scale crowdsourced perturbations. Our zero-shot results here indicate that models trained on perturbed questions go beyond simply learning to memorize particular patterns in the training data. Third, we find that training on the perturbed data, for the most part, continues to *retain performance* on the original task.

Even with the worst case cost ratio of 1.0 (when perturbing existing questions is no cheaper than writing new ones), models trained on perturbed examples remain competitive on all our evaluation sets. This is an important use case for situations that simply do not allow for sufficiently many distinct training examples (e.g., low resource settings, limited amounts of real user data, etc.). Our results at ratio 1.0 suggest that simply applying minimal perturbations to the limited number of real examples available in these situations can be just as effective as (hypothetically) having access to large amounts of real data.

In summary, we propose a novel method to construct datasets that combines traditional independent example collection approach with minimal natural perturbations. We show that for many reasonable cases, using perturbation clusters for training can result in cost-efficiently trained high-quality, robust models that generalize across datasets.

2 Related Work

Data augmentation. There is a handful of work that studies semi-automatic contextual augmentation (Kobayashi, 2018; Cheng et al., 2018), often with the goal of creating better systems. We, however, study natural human-authored perturbations as an alternative dataset construction method. A related recent work is by Kaushik et al. (2020), who, unlike the goal here, study the value of natural-perturbations in reducing artifacts.

Adversarial perturbations. A closely relevant line of work is *adversarial perturbations* to expose the weaknesses of systems upon local changes and criticize their lack robustness (Ebrahimi et al., 2018; Glockner et al., 2018; Dinan et al., 2019). For instance, Khashabi et al. (2016) showed significant drops upon perturbing answer-options for multiple-choice question-answering. Such rule-based perturbations have simple definitions leading to them being easily reverse-engineered by models (Jia and Liang, 2017) and generally use label-preserving, shallow perturbations (Hu et al., 2019). In contrast, our natural human-authored perturbations are harder for models.[1] More broadly, adversarial perturbations research seeks examples that stumble existing models, while our focus is on expanding datasets in a cost-efficient way.

Minimal-pairs in NLP. Datasets with minimal-pair instances are relatively well-established in certain tasks, such as *Winograd schema* datasets (Levesque et al., 2011; Peng et al., 2015; Sakaguchi et al., 2020), or the recent *contrast sets* (Gardner et al., 2020). However, the importance of datasets with *pairs* (i.e., *clusters* of size two) is not well-understood. Our findings about

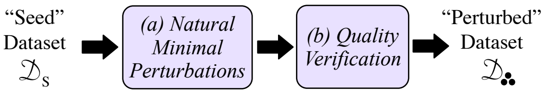
---

[1] We tried the system by Hu et al. (2019) on our questions, but it resulted in very limited variations. See Appendix E.

perturbation clusters could potentially be useful for the future construction of datasets for such tasks.

3 Expansion via Perturbation Clusters

Our approach mainly differs from traditional approaches in how we expand the dataset given seed examples. Rather than repeating the process to generate more examples, we apply minimal alterations to the seed examples, in two high-level steps:



The first step generates the initial set of examples with natural perturbations. It should respect certain principles: (a) The construction should apply minimal changes (similar to the ones in Fig. 1), otherwise the resulting clusters might be too heterogeneous and less meaningful. (b) A substantial proportion of natural perturbations should *change* the answer to the questions. (c) It should incentivize creativity and diversity in local perturbations by, for instance, showing thought-provoking suggestions, using a diverse pool of annotators (Geva et al., 2019), etc. The second independent verification step ensures dataset quality by (a) getting the true gold label and (b) ensuring all generated questions are answerable given the relevant paragraph, in isolation from the original question.

BoolQ∴: BoolQ Expansion. We obtain $\mathcal{D}_S$ by sampling questions from BoolQ (Clark et al., 2019), which is a QA dataset where each boolean ("yes"/"no" answer) question could be inferred from an associated passage. We then follow the above two-step process, resulting in BoolQ∴, a naturally perturbed dataset with $17k$ questions derived from $4k$ seed questions:

a) minimal perturbations: Crowdworkers are given a question and its corresponding gold answer based on supporting paragraph. Then the workers are asked to change the question in order to *flip the answer to the question*. While making changes, the workers are guided to keep their changes minimal (adding or removing up to 4 terms) while resulting in proper English questions. Additionally, for each seed question, crowd-workers are asked to generate perturbations till the modified question is challenging for a machine solver (i.e., RoBERTa trained on BoolQ, should have low confidence on the correct answer). Note that we do not require the model to answer the question incorrectly and not all questions are challenging for the model. Our main goal here is to encourage interesting questions by using the trained model as the guide.

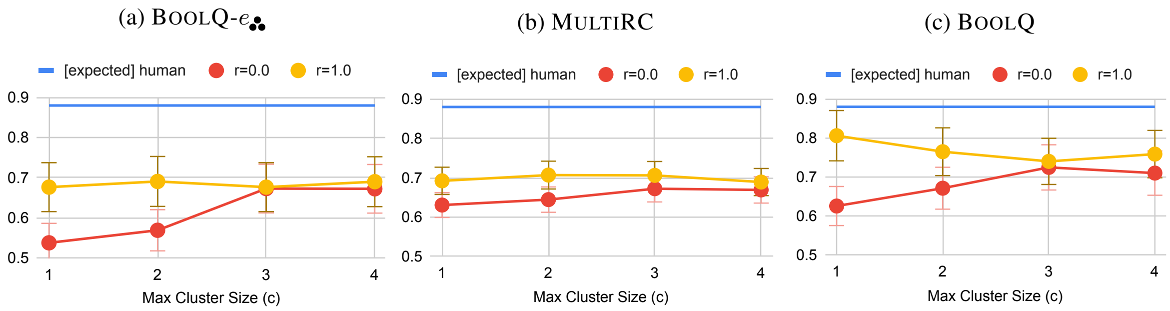
b) question verification. Given the perturbed questions, we asked multiple annotators to answer these questions. These annotations served to eliminate ambiguous questions as well as those that cannot be answered from the provided paragraph. The annotation was done in two steps: (i) in the first step, we ask 3 workers to answer each question with one of the three options ("yes", "no" and "cannot be inferred from the paragraph"). We filtered out the subset of the questions that were not agreed upon (i.e., not a consistent majority label) or were marked as "cannot be inferred from the paragraph" by majority of the annotators. To speed up the annotations, the annotation were done on a cluster-level, i.e., annotators could see all the different modified questions corresponding to a paragraph. (ii) subsequently, each modified questions is also annotated *individually* to ensure that questions can be answered in isolation (as opposed to answering them while seeing all the questions in a cluster.) The annotations in this step only have two labels ("yes"/"no") and again questions that were not agreed upon were filtered.

Sample questions generated by our process are shown in Fig. 1. We evaluate the impact of perturbations via this dataset.

Dataset subsampling. We sample questions from this expanded dataset to evaluate the value of perturbations as a function of different parameters. To simplify exposition, we will use the following notation. We assume a fixed budget b for constructing the dataset where each new question costs 1 unit, i.e., traditional methods would construct a dataset of size b in the given budget. The perturbation cost ratio $r \leq 1$ is the cost of creating a perturbed question. When $r \approx 1$, perturbations are equally costly as writing out new instances. If $r \ll 1$, perturbations are cheap. For instance, if $r = 0.5$, each hand-written question costs the same as two perturbed questions.

We denote the total number of instances and clusters with N, C, respectively. We use BoolQ∴^{b,c,r} to denote the largest subset of BoolQ∴ that can be generated with a total budget of b, with a *maximum* cluster size of c, and relative cost ratio of r. In the special case where all clusters are of the exact same size c, these parameters are related as follows:

$$b = \big(1 + (c-1)r\big) \times C,$$



(a) BoolQ-$e_{\therefore}$ (b) MultiRC (c) BoolQ

Figure 2: Model accuracy (y-axis) with a fixed budget b and varying cluster size c (x-axis), for two extreme cases: (i) $r = 1.0$ denoting a fixed total number of *questions*, (ii) $r = 0.0$ denoting a fixed total number of *clusters*. The plots indicate that including additional perturbations in each cluster (going left to right), particularly when they are cheap (closer to the $r = 0$ case), adds value to the dataset by increasing model accuracy.

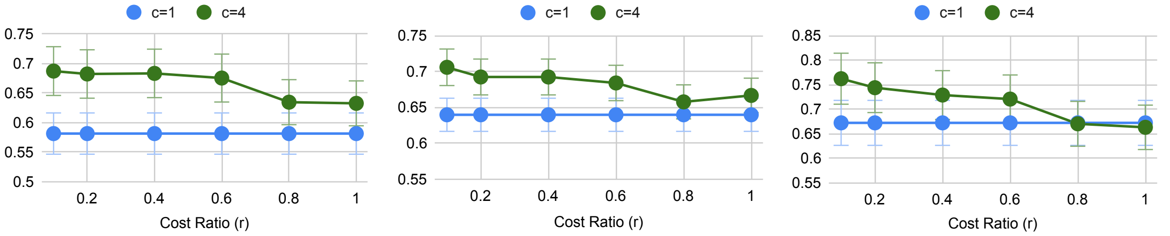


Figure 3: Model accuracy (y-axis) with a fixed total budget b and varying cost ratio r (x-axis), in two cases: (i) $c = 1$ denoting singleton clusters (standard approach), (ii) $c = 4$ denoting cluster size 4 (our approach). The smaller the cost, the higher the returns. For a moderately low cost ratio such as 0.6, the model trained on our perturbed datasets gains of 3-5% over a model trained on the traditionally constructed dataset.

where $1 + (c - 1)r$ is the cost of a single cluster calculated as the cost of one seed examples and its $c - 1$ perturbations.

To create BoolQ$_{\therefore}^{b,c,r}$ we subsample a maximum of c questions from each perturbation cluster, such that total number of clusters is no more than $\frac{b}{1+(c-1)r}$ and the ratio of "yes" to "no" questions is 0.55. Our subsampling starts with clusters of size at least c and also considers smaller clusters if necessary. BoolQ$_{\therefore}^{b,1,r}$ (singleton clusters) corresponds to a dataset constructed in a similar fashion to BoolQ, whereas BoolQ$_{\therefore}^{b,4,r}$ (big clusters) roughly corresponds to the BoolQ$_{\therefore}$ dataset.

4 Experiments

To assess the impact of our perturbation approach, we evaluate standard RoBERTa-large model that has been shown to achieve state-of-the-art results on many tasks. Each experiment considers the effect of training on subsamples of BoolQ$_{\therefore}$ obtained under different conditions.

Each of the points in the figures are averaged over 5 random subsampling of the dataset (with error bars to indicate the standard deviation). The Appendix includes further details about the setup as well as additional experiments.

We evaluate the QA model trained on various question sets on three test sets. (i) For assessing **robustness**, we use an expert-generated set BoolQ-$e_{\therefore}$ published in Gardner et al. (2020) with 339 high-quality perturbed questions based on BoolQ. (ii) For assessing **generalization**, we use the subset of 260 training questions from MultiRC (Khashabi et al., 2018) that have binary (yes/no) answers, from training section of the their data.[2] (c) The original BoolQ test set, to ensure models trained on perturbed questions also **retain performance** on the original task.

4.1 Effect of Cluster Size (c)

We study the value of clusters sizes in the perturbations in two extreme cases: (i) when perturbations cost the same as new questions ($r = 1.0$) and the only limit is the our overall budget ($b = 3.7k$), and (ii) when the perturbations cost negligible ($r = 0.0$) but we are limited by the max cluster size c and $b = 1k$.[3] For each case, we vary the max cluster size in the following rage: $[1, 2, 3, 4]$. As a result, in (i), C vary from $3.7k$ to 951 ($N = 3.7k$), and in (ii), N vary from $1k$ to $4k$ ($C = 1k$).

---

[2] The yes/no subset of dev was too small.

[3] In practice, we expect r to lie somewhere in-between these two extremes, such as $r = 0.3$ as discussed in §4.2.

Fig. 2 shows the accuracy of models trained on these subsets across our three evaluation sets. In scenario (i) with a fixed number of instances ($r = 1$), it is evident that the size of the clusters (the number of perturbations) does not affect the model quality (on 2 out of 3 datasets). This shows that perturbation clusters are equally informative as (traditional) independent instances. However, in scenario (ii) with a fixed number of clusters ($r = 0$), the system performance consistently gets higher with larger clusters, even though the number of clusters is kept constant. This indicates that each additional perturbation adds value to the existing ones, especially in terms of model robustness and retaining performance on the original task.

4.2 Effect of Perturbations Cost Ratio (r)

We now study the value of perturbations as a function of their cost (r). We vary this parameter within the range $(0, 1]$ for $b = 1.5k$ and two max clusters sizes, $c = \{1, 4\}$. When $c = 1$ (no perturbations), N stays constant at $1.5k$. When $c = 4$, N varies from $4.6k$ to $1.5k$. Fig. 3 presents the accuracy of our model as a function of r.

While we don't know the exact crowdsourcing cost for BoolQ, a typical question writing task might cost USD 0.60 per question. With our perturbed dataset costing USD 0.20 per question, we have r = 0.33. Given the same total budget $b = 1500$, we can thus infer from Fig. 3 that training on a dataset of perturbed questions would be about 10% and 5% more effective on BoolQ-e∴ and MultiRC, respectively.

The result on all datasets indicates that there is value in using perturbations clusters when $r \leq 0.6$, i.e., larger clusters can be more cost-effective for build better training sets. Even when they are not much cheaper, they retain the same performance as independent examples, making them a good alternative for dataset expansion given few sources of examples (e.g., low resource languages).

5 Discussion

A key question with respect to the premise of this work is whether the idea would generalize to other tasks. Here, we chose yes/no questions since this is the least-explored sub-area of QA (compared to extractive QA, for example) and hence could benefit from more efficient dataset construction. We (the authors) are cautiously optimistic that it would, although that is subject to factors such as the relative cost of creating diverse and challenging perturbations. Concurrent works have also explored a similar construction for other tasks but with different purposes (Gardner et al., 2020; Kaushik et al., 2020).

We note that we assume a typical QA dataset construction process where workers write questions based on given fixed contexts (Rajpurkar et al., 2016). This assumption may not always hold for alternative dataset generation pipelines, such as using an already available set of questions (Kwiatkowski et al., 2019). Even in such cases, one can still use the lessons learned here to apply *natural perturbations* to a different stage in the annotation pipeline to make it more cost efficient.

6 Conclusion

We proposed an alternative approach for constructing training sets, by expanding seed examples via natural perturbations. Our results demonstrate that models trained on perturbations of BoolQ questions are more robust to minor variations and generalize better, while preserving performance on the original BoolQ test set as long as the natural perturbations are moderately cheap to create. Creating perturbed examples is often cheaper than creating new ones and we empirically observed notable gains even at a moderate cost ratio of 0.6.

While this is *not* a dataset paper (since our focus is on more on the value of natural perturbations for robust model design), we provide the natural perturbations resource for BoolQ constructed during the course of this study.[4]

This work suggests a number of interesting lines of future investigation. For instance, how do the results change as a function of the total dataset budget b or large values of c? Over-generation of perturbations can result in overly-similar (less-informative) variations of a seed example, making larger clusters valuable only up to a certain extent. While we leave a detailed study to future work, we expect general trends regarding the value of perturbations to hold broadly.

Acknowledgments

The authors would like to thank Chandra Bhagavatula, Sihao Chen, and Niket Tandon for discussions and suggestions on early versions of this work, and anonymous Amazon Mechanical Turk workers for their help with annotation.

A Question Perturbations: Further Details

We provide further details about the annotation.

The task starts with a qualification step: we ask annotators to read a collection of meticulously designed instructions that describe the task. The annotators are allowed to participate, only after successfully passing the test included in the instructions.

In addition, we restrict the task to "Master" workers from English-speaking countries (USA, UK, Canada, and Australia), at least 500 finished HITs and at least a 95% acceptance rate.

Here is an screen cast of the relevant annotation interface interface: `https://youtu.be/MWbCRwanbOA`

During our earlier pilot experiments, we observed that the strategies used for perturbing "yes" questions tend to be different from those used for "no" questions. To make the task less demanding and help workers focus on a limited cognitive task, the annotation is done in two phases; one for "yes" questions, and another for "no" questions.

Table 1 provides a summary of BoolQ∴ stats.

Measure	Full	Train	Dev	Test
# of questions	17,323	9727	4434	3162
# of "yes" questions	9,724	5733	2263	1728
# of "no" questions	7,599	3994	2171	1434
# of clusters	4064	2408	919	737
average cluster size	4.3	4.1	4.8	4.3
median cluster size	3.0	3.0	3.0	3.0

Table 1: Statistics of BoolQ∴.

B Details of RoBERTa Training

We train the model on two-way questions using the input format: "`[CLS]` passage `[SEP]` question `[SEP]` answer". The model scores each answer ("yes" or "no") by applying a linear classifier over the `[CLS]` representation for each answer's corresponding input. We train the linear classifier (and fine-tune RoBERTa weights) on the training sets and evaluate them on their corresponding dev/test sets. We fixed the learning rate to 1e-5 as it generally performed the best on our datasets. We only varied the number of training epochs: $\{7, 9, 11\}$ and effective batch sizes: 16, 32. We chose this small hyper-parameter sweep to ensure that each model was fine-tuned using the same hyper-parameter sweep while not being prohibitively expensive. Each model was selected based on the best validation set accuracy. We report the numbers corresponding to the selected models on the test set.

C Performances Across Datasets

We compare a collection of solvers across our target datasets: the complete BoolQ∴ dataset (dataset constructed from $\mathcal{D}_S$ via perturbation), the original BoolQ dataset, expert perturbations on BoolQ, and binary subset of MultiRC.

The results are summarized in Table 2. Most of the rows are RoBERTa trained on a specified dataset. We have also included a row corresponding a system trained on the union of BoolQ and BoolQ∴, referred to as BoolQ++ for brevity. Most of the datasets are slightly skewed between the two classes, which is why the majority label baseline (*Always-Yes* or *Always-No*) achieves scores above 50%. Rows indicated with * are reported directly from prior work. The human prediction on BoolQ∴ is the majority label of 5 independent AMT annotators. The human performance on BoolQ and MultiRC are directly reported from SuperGLUE (Wang et al., 2019) leaderboard.[5]

Here are the key observations in this table:

- While RoBERTa has almost human-level performance when trained and tested within BoolQ, it suffers significant performance degradation when evaluated on other datasets (e.g., 68.7% on BoolQ∴).
- The systems fine-tuned on BoolQ++ consistently generalize better across datasets.

D Cluster-Level Evaluation

An additional benefit of our approach is that it produces datasets with an inherent cluster structure. This enables the use of metrics such as ConsensusScore (Shah et al., 2019) to evaluate the extent to which a model acts *consistently* within each cluster, which provides another measure of robustness.

While evaluation measures are often computed on *per-instance* level, the cluster structure of BoolQ∴ enables us to provide *per-cluster* metrics of quality. In particular, we are interested in the following question: *to what extent do our models act consistently across questions in each cluster?*

To measure this, we use the *consensus score* $CS(k)$ introduced by Shah et al. (2019). For an

Table 2: Various systems trained and evaluated on different datasets. Best non-human scores are in **bold**. Numbers in percentage.

integer parameter $k \geq 1$, the score $CS(k)$ for a single cluster C is defined as the fraction of size-k sub-clusters of C where the model answers *all* instances correctly. The $CS(k)$ score for a clustered dataset is the average of these scores across all clusters. Intuitively, $k = 1$ represents the traditional un-clustered accuracy (assuming all clusters with the same size). As k grows to reach the cluster size, models must answer the *entire* cluster correctly in order to score positively on that cluster.

We plot this score for $k \in \{1, 2, 3, 4\}$ for various QA models in Fig 4. While all the models (including human) have deceasing consensus score for larger values of k, machine solvers have a steeper slope compared to human. As a result, we have an even larger gap of 17% between human-RoBERTa (at $k = 4$), when evaluated on their consistency.

E Rule-Based Perturbations

An alternate way to get cheap perturbations would be to use rule-based paraphrase systems — which are arguably cheaper than human-annotated perturbations.

Our intuition is that rule-based perturbations generally have simplistic definitions and hence, rarely benefit general reasoning problems in language. Interesting and diverse rule-based perturbations can be difficult to develop, and existing approaches are often reverse-engineered by QA models. Further, unlike our proposal, automatic perturbation approaches, such as question rephrasing, generally preserve the answer and do not use the provided context the question is referring to, limiting their richness.

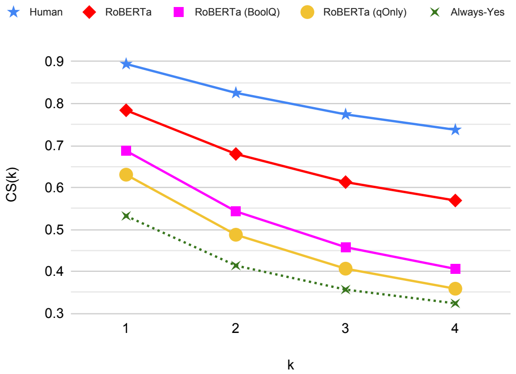

Figure 4: Consensus metric $CS(k)$ on the y-axis for various values of k on the x-axis.

That being said, we put some effort into developing rule-based/machine-generated baselines for comparison. However, since these efforts did not result in any reasonably sophisticated baselines, we decided to not include them in the main text.

Here we're showing examples of perturbations generated via a recent machine paraphraser system.[6]

Original Question: Will there be a season 4 of da vincis demons? FALSE

The corresponding machine-perturbed questions are:

Will there be a season four of da vinci demons? FALSE
Will there be season four of da vinci demons? FALSE
Is there a season four of da vinci demons? FALSE
Is there gonna be a season four of da vinci demons? FALSE

These automated perturbations stand in contrast with our human-perturbed questions, which also take the provided context into account:

Was there a season 3 of da vinci's demons? TRUE
There be a season 4 of da vinci's demons? FALSE
Will there be no season 4 of da vinci's demons? TRUE

As evident by the example, the machine-generated perturbations are generally minor and, not surprisingly, did not provide a useful enough signal to the model to improve its accuracy. We are open to suggestions if the reviewers have any suggestion on creating more reasonable rule-based perturbation baselines.

A Matter of Framing:
The Impact of Linguistic Formalism on Probing Results

Ilia Kuznetsov and **Iryna Gurevych**
Ubiquitous Knowledge Processing Lab (UKP-TUDA)
Department of Computer Science, Technische Universität Darmstadt
`http://www.ukp.tu-darmstadt.de/`

Abstract

Deep pre-trained contextualized encoders like BERT (Devlin et al., 2019) demonstrate remarkable performance on a range of downstream tasks. A recent line of research in probing investigates the linguistic knowledge implicitly learned by these models during pre-training. While most work in probing operates on the task level, linguistic tasks are rarely uniform and can be represented in a variety of formalisms. Any linguistics-based probing study thereby inevitably commits to the formalism used to annotate the underlying data. Can the choice of formalism affect probing results? To investigate, we conduct an in-depth cross-formalism layer probing study in role semantics. We find linguistically meaningful differences in the encoding of semantic role- and proto-role information by BERT depending on the formalism and demonstrate that layer probing can detect subtle differences between the implementations of the same linguistic formalism. Our results suggest that linguistic formalism is an important dimension in probing studies and should be investigated along with the commonly used cross-task and cross-lingual experimental settings.

1 Introduction

The emergence of deep pre-trained contextualized encoders has had a major impact on the field of natural language processing. Boosted by the availability of general-purpose frameworks like AllenNLP (Gardner et al., 2018) and Transformers (Wolf et al., 2019), pre-trained models like ELMO (Peters et al., 2018) and BERT (Devlin et al., 2019) have caused a shift towards simple architectures where a strong pre-trained encoder is paired with a shallow downstream model, often outperforming the intricate task-specific architectures of the past.

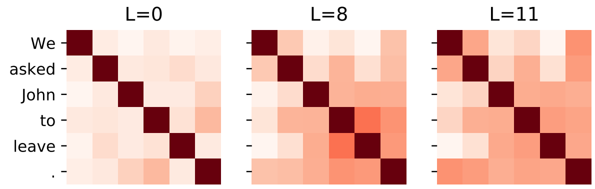

Figure 1: Intra-sentence similarity by layer L of the multilingual BERT-base. Functional tokens are similar in $L = 0$, syntactic groups emerge at higher levels.

The versatility of pre-trained representations implies that they encode some aspects of general linguistic knowledge (Reif et al., 2019). Indeed, even an informal inspection of layer-wise intra-sentence similarities (Fig. 1) suggests that these models capture elements of linguistic structure, and those differ depending on the layer of the model. A grounded investigation of these regularities allows to interpret the model's behaviour, design better pre-trained encoders and inform the downstream model development. Such investigation is the main subject of probing, and recent studies confirm that BERT implicitly captures many aspects of language use, lexical semantics and grammar (Rogers et al., 2020).

Most probing studies use linguistics as a theoretical scaffolding and operate on a task level. However, there often exist multiple ways to represent the same linguistic phenomenon: for example, English dependency syntax can be encoded using a variety of *formalisms*, incl. Universal (Schuster and Manning, 2016), Stanford (de Marneffe and Manning, 2008) and CoNLL-2009 dependencies (Hajič et al., 2009), all using different label sets and syntactic head attachment rules. Any probing study inevitably commits to the specific theoretical framework used to produce the underlying data. The differences between linguistic formalisms, however, can be substantial.

Can these differences affect the probing results? This question is intriguing for several reasons. Lin-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 171–182,
November 16–20, 2020.

guistic formalisms are well-documented, and if the choice of formalism indeed has an effect on probing, cross-formalism comparison will yield new insights into the linguistic knowledge obtained by contextualized encoders during pre-training. If, alternatively, the probing results remain stable despite substantial differences between formalisms, this prompts a further scrutiny of what the pre-trained encoders in fact encode. Finally, on the reverse side, cross-formalism probing might be used as a tool to empirically compare the formalisms and their language-specific implementations. To the best of our knowledge we are the first to explicitly address the influence of formalism on probing.

Ideally, the task chosen for a cross-formalism study should be encoded in multiple formalisms using the same textual data to rule out the influence of the domain and text type. While many linguistic corpora contain several layers of linguistic information, having the same textual data annotated with multiple formalisms for the *same* task is rare. We focus on role semantics – a family of shallow semantic formalisms at the interface between syntax and propositional semantics that assign roles to the participants of natural language utterances, determining *who* did *what* to *whom*, *where*, *when* etc. Decades of research in theoretical linguistics have produced a range of role-semantic frameworks that have been operationalized in NLP: syntax-driven PropBank (Palmer et al., 2005), coarse-grained VerbNet (Kipper-Schuler, 2005), fine-grained FrameNet (Baker et al., 1998), and, recently, decompositional Semantic Proto-Roles (SPR) (Reisinger et al., 2015; White et al., 2016). The SemLink project (Bonial et al., 2013) offers parallel annotation for PropBank, VerbNet and FrameNet for English. This allows us to isolate the object of our study: apart from the role-semantic labels, the underlying data and conditions for the three formalisms are identical. SR3DE (Mújdricza-Maydt et al., 2016) provides compatible annotation in three formalisms for German, enabling cross-lingual validation of our results. Combined, these factors make role semantics an ideal target for our cross-formalism probing study.

A solid body of evidence suggests that encoders like BERT capture syntactic and lexical-semantic properties, but only few studies have considered probing for predicate-level semantics (Tenney et al., 2019b; Kovaleva et al., 2019). To the best of our knowledge we are the first to conduct a cross-formalism probing study on role semantics, thereby contributing to the line of research on how and whether pre-trained BERT encodes higher-level semantic phenomena.

Contributions. This work studies the effect of the linguistic formalism on probing results. We conduct cross-formalism experiments on PropBank, VerbNet and FrameNet role prediction in English and German, and show that the **formalism can affect probing results** in a linguistically meaningful way; in addition, we demonstrate that layer probing can detect subtle differences between implementations of the same formalism in different languages. On the technical side, we advance the recently introduced edge and layer probing framework (Tenney et al., 2019b); in particular, we introduce **anchor tasks** - an analytical tool inspired by feature-based systems that allows deeper qualitative insights into the pre-trained models' behaviour. Finally, advancing the current knowledge about the encoding of predicate semantics in BERT, we perform a fine-grained semantic proto-role probing study and demonstrate that **semantic proto-role properties can be extracted from pre-trained BERT**, contrary to the existing reports. Our results suggest that along with task and language, linguistic formalism is an important dimension to be accounted for in probing research.

2 Related Work

2.1 BERT as Encoder

BERT is a Transformer (Vaswani et al., 2017) encoder pre-trained by jointly optimizing two unsupervised objectives: masked language model and next sentence prediction. It uses WordPiece (WP, Wu et al. (2016)) subword tokens along with positional embeddings as input, and gradually constructs sentence representations by applying token-level self-attention pooling over a stack of layers L. The result of BERT encoding is a layer-wise representation of the input wordpiece tokens with higher layers representing higher-level abstractions over the input sequence. Thanks to the joint pre-training objective, BERT can encode words and sentences in a unified fashion: the encoding of a sentence or a sentence pair is stored in a special token *[CLS]*.

To facilitate multilingual experiments, we use the multilingual BERT-base (mBERT) published by Devlin et al. (2019). Although several recent encoders have outperformed BERT on benchmarks

(Liu et al., 2019; Lan et al., 2019; Raffel et al., 2019), we use the original BERT architecture, since it allows us to inherit the probing methodology and to build upon the related findings.

2.2 Probing

Due to space limitations we omit high-level discussions on benchmarking (Wang et al., 2018) and sentence-level probing (Conneau et al., 2018a), and focus on the recent findings related to the representation of linguistic structure in BERT. Surface-level information generally tends to be represented in the lower layers of deep encoders, while higher layers store hierarchical and semantic information (Belinkov et al., 2017; Lin et al., 2019). Tenney et al. (2019a) show that the abstraction strategy applied by the English pre-trained BERT encoder follows the order of the classical NLP pipeline. Strengthening the claim about linguistic capabilities of BERT, Hewitt and Manning (2019) demonstrate that BERT implicitly learns syntax, and Reif et al. (2019) show that it encodes fine-grained lexical-semantic distinctions. Rogers et al. (2020) provide a comprehensive overview of BERT's properties discovered to date.

While recent results indicate that BERT successfully represents lexical-semantic and grammatical information, the evidence of its high-level semantic capabilities is inconclusive. Tenney et al. (2019a) show that the English PropBank semantics can be extracted from the encoder and follows syntax in the layer structure. However, out of all formalisms PropBank is most closely tied to syntax, and the results on proto-role and relation probing do not follow the same pattern. Kovaleva et al. (2019) identify two attention heads in BERT responsible for FrameNet relations. However, they find that disabling them in a fine-tuning evaluation on the GLUE (Wang et al., 2018) benchmark does not result in decreased performance.

Although we are not aware of any systematic studies dedicated to the effect of formalism on probing results, the evidence of such effects is scattered across the related work: for example, the aforementioned results in Tenney et al. (2019a) show a difference in layer utilization between constituents- and dependency-based syntactic probes and semantic role and proto-role probes. It is not clear whether this effect is due to the differences in the underlying datasets and task architecture or the formalism per se.

Our probing methodology builds upon the edge and layer probing framework. The encoding produced by a frozen BERT model can be seen as a layer-wise snapshot that reflects how the model has constructed the high-level abstractions. Tenney et al. (2019b) introduce the edge probing task design: a simple classifier is tasked with predicting a linguistic property given a pair of spans encoded using a frozen pre-trained model. Tenney et al. (2019a) use edge probing to analyse the layer utilization of a pre-trained BERT model via scalar mixing weights (Peters et al., 2018) learned during training. We revisit this framework in Section 3.

2.3 Role Semantics

We now turn to the object of our investigation: role semantics. For further discussion, consider the following synthetic example:

a. *[John]$_{Ag}$ gave [Mary]$_{Rc}$ a [book]$_{Th}$.*

b. *[Mary]$_{Rc}$ was given a [book]$_{Th}$ by [John]$_{Ag}$.*

Despite surface-level differences, the sentences express the same meaning, suggesting an underlying semantic representation in which these sentences are equivalent. One such representation is offered by role semantics - a shallow predicate-semantic formalism closely related to syntax. In terms of role semantics, *Mary*, *book* and *John* are **semantic arguments** of the **predicate** *give*, and are assigned **roles** from a pre-defined inventory, for example, `Agent`, `Recipient` and `Theme`.

Semantic roles and their properties have received extensive attention in linguistics (Fillmore, 1968; Levin and Rappaport Hovav, 2005; Dowty, 1991) and are considered a universal feature of human language. The size and organization of the role and predicate inventory are subject to debate, giving rise to a variety of role-semantic formalisms.

PropBank assumes a predicate-independent labeling scheme where predicates are distinguished by their sense (`get.01`), and semantic arguments are labeled with generic numbered core (`Arg0-5`) and modifier (e.g. `AM-TMP`) roles. Core roles are not tied to specific definitions, but the effort has been made to keep the role assignments consistent for similar verbs; `Arg0` and `Arg1` correspond to the Proto-Agent and Proto-Patient roles as per Dowty (1991). The semantic interpretation of core roles depends on the predicate sense.

VerbNet follows a different categorization scheme. Motivated by the regularities in verb behavior, Levin (1993) has introduced the grouping of verbs into intersective classes (ILC). This methodology has been adopted by VerbNet: for example, the VerbNet class `get-13.5.1` would include verbs *earn*, *fetch*, *gain* etc. A verb in VerbNet can belong to several classes corresponding to different senses; each class is associated with a set of roles and licensed syntactic transformations. Unlike PropBank, VerbNet uses a set of approx. 30 thematic roles that have universal definitions and are shared among predicates, e.g. `Agent`, `Beneficiary`, `Instrument`.

FrameNet takes a meaning-driven stance on the role encoding by modeling it in terms of frame semantics: predicates are grouped into frames (e.g. `Commerce_buy`), which specify role-like slots to be filled. FrameNet offers fine-grained frame distinctions, and roles in FrameNet are frame-specific, e.g. `Buyer`, `Seller` and `Money`. The resource accompanies each frame with a description of the situation and its core and peripheral participants.

SPR follows the work of Dowty (1991) and discards the notion of categorical semantic roles in favor of feature bundles. Instead of a fixed role label, each argument is assessed via a 11-dimensional cardinal feature set including Proto-Agent and Proto-Patient properties like `volitional`, `sentient`, `destroyed`, etc. The feature-based approach eliminates some of the theoretical issues associated with categorical role inventories and allows for more flexible modeling of role semantics.

Each of the role labeling formalisms offers certain advantages and disadvantages (Giuglea and Moschitti, 2006; Mújdricza-Maydt et al., 2016). While being close to syntax and thereby easier to predict, PropBank doesn't contribute much semantics to the representation. On the opposite side of the spectrum, FrameNet offers rich predicate-semantic representations for verbs and nouns, but suffers from high granularity and coverage gaps (Hartmann et al., 2017). VerbNet takes a middle ground by following grammatical criteria while still encoding coarse-grained semantics, but only focuses on verbs and core (not modifier) roles. SPR avoids the granularity-generalization trade-off of the categorical inventories, but is yet to find its way into practical NLP applications.

3 Probing Methodology

We take the edge probing setup by Tenney et al. (2019b) as our starting point. Edge probing aims to predict a label given a pair of contextualized span or word encodings. More formally, we encode a WP-tokenized sentence $[wp_1, wp_2, ...wp_k]$ with a frozen pre-trained model, producing contextual embeddings $[e_1, e_2, ...e_k]$, each of which is a layered representation over $L = \{l_0, l_1, ...l_m\}$ layers, with encoding at layer l_n for the wordpiece wp_i further denoted as e_i^n. A trainable scalar mix is applied to the layered representation to produce the final encoding given the per-layer mixing weights $\{a^0, a^1..a^m\}$ and a scaling parameter γ:

$$\overline{e}_i = \gamma \sum_{l=0}^{m} softmax(a^l) e_i^l$$

Given the source src and target tgt wordpieces encoded as $\overline{e}_{src}$ and $\overline{e}_{tgt}$, our goal is to predict the label y.

Due to its task-agnostic architecture, edge probing can be applied to a wide variety of unary (by omitting tgt) and binary labeling tasks in a unified manner, facilitating the cross-task comparison. The original setup has several limitations that we address in our implementation.

Regression tasks. The original edge probing setup only considers classification tasks. Many language phenomena - including positional information and semantic proto-roles, are naturally modeled as regression. We extend the architecture by Tenney et al. (2019b) and support both classification and regression: the former achieved via softmax, the latter via direct linear regression to the target value.

Flat model. To decrease the models' own expressive power (Hewitt and Liang, 2019), we keep the number of parameters in our probing model as low as possible. While Tenney et al. (2019b) utilize pooled self-attentional span representations and a projection layer to enable cross-model comparison, we directly feed the wordpiece encoding into the classifier, using the first wordpiece of a word. To further increase the selectivity of the model, we directly project the source and target wordpiece representations into the label space, opposed to the two-layer MLP classifier used in the original setup.

Separate scalar mixes. To enable fine-grained analysis of probing results, we train and analyze separate scalar mixes for source and target wordpieces, motivated by the fact that the classifier might utilize different aspects of their representation for prediction[1]. Indeed, we find that the

---

[1] Tenney et al. (2019b, Appendix C) also use separate pro-

mixing weights learned for source and target wordpieces might show substantial – and linguistically meaningful – variation. Combined with regression-based objective, separating the scalar mixes allows us to scrutinize layer utilization patterns for semantic proto-roles.

Sentence-level probes. Utilizing the BERT-specific sentence representation *[CLS]* allows us to incorporate the sentence-level natural language inference (NLI) probe into our kit.

Anchor tasks. We employ two analytical tools from the original layer probing setup. Mixing weight plotting compares layer utilization among tasks by visually aligning the respective learned weight distributions transformed via a softmax function. Layer center-of-gravity is used as a summary statistic for a task's layer utilization. While the distribution of mixing weights along the layers allows us to estimate the order in which information is processed during encoding, it doesn't allow to directly assess the *similarity* between the layer utilization of the probing tasks.

Tenney et al. (2019a) have demonstrated that the order in which linguistic information is stored in BERT mirrors the traditional NLP pipeline. A prominent property of the NLP pipelines is their use of low-level features to predict downstream phenomena. In the context of layer probing, probing tasks can be seen as end-to-end feature extractors. Following this intuition, we define two groups of probing tasks: *target tasks* – the main tasks under investigation, and *anchor tasks* – a set of related tasks that serve as a basis for qualitative comparison between the targets. The softmax transformation of the scalar mixing weights allows to treat them as probability distributions: the higher the mixing weight of a layer, the more likely the probe is to utilize information from this layer during prediction. We use Kullback-Leibler divergence to compare target tasks (e.g. role labeling in different formalisms) in terms of their similarity to lower-level anchor tasks (e.g. dependency relation and lemma). Note that the notion of anchor task is contextual: the same task can serve as a target and as an anchor, depending on the focus of the study.

Table 1: Statistics for CoNLL+SemLink (English) and SR3de (German), only core roles.

4 Setup

4.1 Source data

For German we use the SR3de corpus (Mújdricza-Maydt et al., 2016) that contains parallel PropBank, FrameNet and VerbNet annotations for verbal predicates. For English, SemLink (Bonial et al., 2013) provides mappings from the original PropBank corpus annotations to the corresponding FrameNet and VerbNet senses and semantic roles. We use these mappings to enrich the CoNLL-2009 (Hajič et al., 2009) dependency role labeling data – also based on the original PropBank – with roles in all three formalisms via a semi-automatic token alignment procedure. The resulting corpus is substantially smaller than the original, but still an order of magnitude larger than SR3de (Table 1). Both corpora are richly annotated with linguistic phenomena on word level, including part-of-speech, lemma and syntactic dependencies. The XNLI probe is sourced from the corresponding development split of the XNLI (Conneau et al., 2018b) dataset. The SPR probing tasks are constructed from the original data by Reisinger et al. (2015).

aim to provide a representational upper bound to predicate semantics. We follow the training, test and development splits from the original SR3de, CoNLL-2009 and SPR data. The XNLI task is sourced from the development set and only used for scalar mix analysis. To reduce the number of labels in some of the probing tasks, we collect frequency statistics over the corresponding training sets and only consider up to 250 most frequent labels. Below we define the tasks in order of their complexity, Table 2 provides the probing task statistics, Table 3 compares the categorical role labeling formalisms in terms of granularity, and Table 4 provides examples. We evaluate the classification performance using Accuracy, while regression tasks are scored via R^2.

Token type (`ttype`) predicts the type of a word. This requires contextual processing since a word might consist of several wordpieces;

Token position (`token.ix`) predicts the linear position of a word, cast as a regression task over the first 20 words in the sentence. Again, the task is non-trivial since it requires the words to be assembled from the wordpieces.

Part-of-speech (`pos`) predicts the language-specific part-of-speech tag for the given token.

Lexical unit (`lex.unit`) predicts the lemma and POS of the given word – a common input representation for the entries in lexical resources. We extract coarse POS tags by using the first character of the language-specific POS tag.

Dependency relation (`deprel`) predicts the dependency relation between the parent `src` and dependent `tgt` tokens;

Semantic role (`role.[frm]`) predicts the semantic role given a predicate `src` and an argument `tgt` token in one of the three role labeling formalisms: PropBank `pb`, VerbNet `vn` and FrameNet `fn`. Note that we only probe for the role label, and the model has no access to the verb sense information from the data.

Semantic proto-role (`spr.[prop]`) is a set of eleven regression tasks predicting the values of the proto-role properties as defined in (Reisinger et al., 2015), given a predicate `src` and an argument `tgt`.

XNLI is a sentence-level NLI task directly sourced from the corresponding dataset. Given two sentences, the goal is to determine whether an entailment or a contradiction relationship holds between them. We use NLI to investigate the layer utilization of mBERT for high-level semantic tasks. We extract the sentence pair representation via the *[CLS]* token and treat it as a unary probing task.

5 Results

Our probing framework is implemented using AllenNLP.[2] We train the probes for 20 epochs using the Adam optimizer with default parameters and a batch size of 32. Due to the frozen encoder and flat model architecture, the total runtime of the main experiments is under 8 hours on a single Tesla V100 GPU. In addition to pre-trained mBERT we report baseline performance using a frozen untrained mBERT model obtained by randomizing the encoder weights post-initialization as in Jawahar et al. (2019).

5.1 General Trends

While absolute performance is secondary to our analysis, we report the probing task scores on respective development sets in Table 5. We observe that grammatical tasks score high, while core role labeling lags behind - in line with the findings of Tenney et al. (2019a)[3] We observe lower scores for German role labeling which we attribute to the lack of training data. Surprisingly, as we show below, this doesn't prevent the edge probe from

learning to locate relevant role-semantic information in mBERT's layers.

The untrained mBERT baseline expectedly underperforms; however, we note good baseline results on surface-level tasks for English, which we attribute to memorizing token identity and position: although the weights are set randomly, the frozen encoder still associates each wordpiece input with a fixed random vector. We have confirmed this assumption by scalar mix analysis of the untrained mBERT baseline: in our experiments the baseline probes for both English and German attended almost exclusively to the first few layers of the encoder, independent of the task. For brevity, here and further we do not examine baseline mixing weights and only report the scores.

Our main probing results mirror the findings of Tenney et al. (2019a) about the sequential processing order in BERT. We observe that the layer utilization among tasks (Fig. 2) generally aligns for English and German[4], although we note that in terms of center-of-gravity mBERT tends to utilize deeper layers for German probes. Basic word-level tasks are indeed processed early by the model, and XNLI probes focus on deeper levels, suggesting that the representation of higher-level semantic phenomena follows the encoding of syntax and predicate semantics.

5.2 The Effect of Formalism

Using separate scalar mixes for source and target tokens allows us to explore the cross-formalism encoding of role semantics by mBERT in detail. For both English and German role labeling, the probe's layer utilization drastically differs for predicate and argument tokens. While the argument representation `role*tgt` mostly focuses on the same layers as the dependency parsing probe, the layer utilization of the predicates `role*src` is affected by the chosen formalism. In English, PropBank predicate token mixing weights emphasize the same layers as dependency parsing – in line with the previously published results. However, the probes for VerbNet and FrameNet predicates (`role.vn src` and `role.fn src`) utilize the layers associated with `ttype` and `lex.unit` that contain lexical information. Coupled with the fact that both VerbNet and FrameNet assign semantic roles based on lexical-semantic predicate groupings (frames in FrameNet and verb classes in VerbNet), this suggests that the lower layers of mBERT implicitly encode predicate sense information; moreover, sense encoding for VerbNet utilizes deeper layers of the model associated with syntax, in line with VerbNet's predicate classification strategy. This finding confirms that the formalism can indeed have linguistically meaningful effects on probing results.

5.3 Anchor Tasks in the Pipeline

We now use the scalar mixes of the role labeling probes as target tasks, and lower-level probes

---

[4] Echoing the recent findings on mBERT's multilingual capacity (Pires et al., 2019; Kondratyuk and Straka, 2019).

as anchor tasks to qualitatively explore the differences between how our role probes learn to represent predicates and semantic arguments[5] (Fig. 3). The results reveal a distinctive pattern that confirms our previous observations: while VerbNet and FrameNet predicate layer utilization `src` is similar to the scalar mixes learned for `ttype` and `lex.unit`, the learned argument representations `tgt` and the PropBank predicate attend to the layers associated with dependency relation and POS probes. Aside from the PropBank predicate encoding which we address below, the pattern reproduces for English and German. This aligns with the traditional separation of the semantic role labeling task into predicate disambiguation followed by semantic argument identification and labeling, along with the feature sets employed for these tasks (Björkelund et al., 2009). Note that the observation about the pipeline-like task processing within the BERT encoders thereby holds, albeit on a sub-task level.

5.4 Formalism Implementations

Both layer and anchor task analysis reveal a prominent discrepancy between English and German role probing results: while the PropBank predicate layer utilization for English mostly relies on syntactic information, German PropBank predicates behave similarly to VerbNet and FrameNet. The lack of systematic cross-lingual differences between layer utilization for other probing tasks[6] allows us to rule out the effect of purely typological features such as word order and case marking as a likely cause.

The difference in the number of role labels for English and German PropBank, however, points at possible qualitative differences in the labeling schemes (Table 3). The data for English stems from the token-level alignment in SemLink that maps the original PropBank roles to VerbNet and FrameNet. Role annotations for German have a different lineage: they originate from the FrameNet-annotated SALSA corpus (Burchardt et al., 2006) semi-automatically converted to PropBank style for the CoNLL-2009 shared task (Hajič et al., 2009), and enriched with VerbNet labels in SR3de (Mújdricza-Maydt et al., 2016). As a result, while English PropBank labels are assigned in a *predicate-independent* manner, German PropBank, following the same numbered labeling scheme, keeps this scheme *consistent within the frame*. We assume that this incentivizes the probe to learn semantic verb groupings and reflects in our probing results. The ability of the probe to detect subtle differences between formalism implementations constitutes a new use case for probing, and a promising direction for future studies.

(P) *stationary	0.39 (0.05)

Table 6: Best dev R^2 for proto-role probing tasks over 20 epochs; A - Proto-Agent, P - Proto-Patient; Baseline in parentheses.

5.5 Encoding of Proto-Roles

We now turn to the probing results for decompositional semantic proto-role labeling tasks. Unlike (Tenney et al., 2019b) who used a multi-label classification probe, we treat SPR properties as separate regression tasks. The results in Table 6 show that the performance varies by property, with some of the properties attaining reasonably high R^2 scores despite the simplicity of the probe architecture and the small dataset size. We observe that properties associated with Proto-Agent tend to perform better. The untrained mBERT baseline performs poorly which we attribute to the lack of data and the fine-grained semantic nature of the task.

Our fine-grained, property-level task design allows for more detailed insights into the layer utilization by the SPR probes (Fig. 4). The results indicate that while the layer utilization on the predicate side (`src`) shows no clear preference for particular layers (similar to the results obtained by Tenney et al. (2019a)), some of the proto-role features follow the pattern seen in the categorical role labeling and dependency parsing tasks for the argument tokens `tgt`. With few exceptions, we observe that the properties displaying that behavior

---

[5] Darker color corresponds to higher similarity.

[6] Apart from the general tendency to use deeper layers in German reported in 5.1

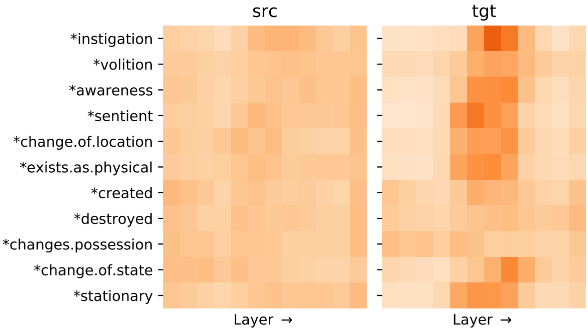

Figure 4: Layer utilization for SPR properties.

are Proto-Agent properties; moreover, a close examination of the results on syntactic preference by Reisinger et al. (2015, p. 483) reveals that these properties are also the ones with strong preference for the subject position, including the outlier case of `stationary` which in their data behaves like a Proto-Agent property. The correspondence is not strict, and we leave an in-depth investigation of the reasons behind these discrepancies for follow-up work.

6 Conclusion

We have demonstrated that the choice of linguistic formalism can have substantial, linguistically meaningful effects on role-semantic probing results. We have shown how probing classifiers can be used to detect discrepancies between formalism implementations, and presented evidence of semantic proto-role encoding in the pre-trained mBERT model. Our refined implementation of the edge probing framework coupled with the anchor task methodology enabled new insights into the processing of predicate-semantic information within mBERT. Our findings suggest that linguistic formalism is an important factor to be accounted for in probing studies.

This prompts several recommendations for the follow-up probing studies. First, the formalism and implementation used to prepare the linguistic material underlying a probing study should be always explicitly specified. Second, if possible, results on multiple formalisations of the same task should be reported and validated for several languages. Finally, assembling corpora with parallel cross-formalism annotations would facilitate further research on the effect of formalism in probing.

While our work illustrates the impact of formalism using a single task and a single probing framework, the influence of linguistic formalism per se is likely to be present for any probing setup that builds upon linguistic material. An investigation of how, whether, and why formalisms and their implementations affect probing results for tasks beyond role labeling and for frameworks beyond edge probing constitutes an exciting avenue for future research.

Information-Theoretic Probing with Minimum Description Length

Elena Voita[1,2] **Ivan Titov**[1,2]

Abstract

To measure how well pretrained representations encode some linguistic property, it is common to use accuracy of a probe, i.e. a classifier trained to predict the property from the representations. Despite widespread adoption of probes, differences in their accuracy fail to adequately reflect differences in representations. For example, they do not substantially favour pretrained representations over randomly initialized ones. Analogously, their accuracy can be similar when probing for genuine linguistic labels and probing for random synthetic tasks. To see reasonable differences in accuracy with respect to these random baselines, previous work had to constrain either the amount of probe training data or its model size. Instead, we propose an alternative to the standard probes, information-theoretic probing with *minimum description length* (MDL). With MDL probing, training a probe to predict labels is recast as teaching it to effectively transmit the data. Therefore, the measure of interest changes from probe accuracy to the description length of labels given representations. In addition to probe quality, the description length evaluates 'the amount of effort' needed to achieve the quality. This amount of effort characterizes either (i) size of a probing model, or (ii) the amount of data needed to achieve the high quality. We consider two methods for estimating MDL which can be easily implemented on top of the standard probing pipelines: variational coding and online coding. We show that these methods agree in results and are more informative and stable than the standard probes.[1]

1 Introduction

To estimate to what extent representations (e.g., ELMo (Peters et al., 2018) or BERT (Devlin et al., 2019)) capture a linguistic property, most previous work uses 'probing tasks' (aka 'probes' and 'diagnostic classifiers'); see Belinkov and Glass (2019) for a comprehensive review. These classifiers are trained to predict a linguistic property from 'frozen' representations, and accuracy of the classifier is used to measure how well these representations encode the property.

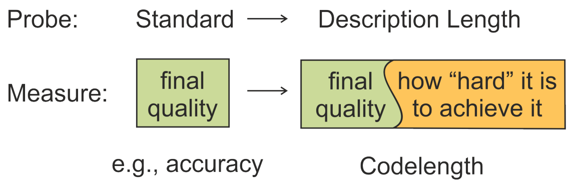

Figure 1: Illustration of the idea behind MDL probes.

Despite widespread adoption of such probes, they fail to adequately reflect differences in representations. This is clearly seen when using them to compare pretrained representations with randomly initialized ones (Zhang and Bowman, 2018). Analogously, their accuracy can be similar when probing for genuine linguistic labels and probing for tags randomly associated to word types ('control tasks', Hewitt and Liang (2019)). To see differences in the accuracy with respect to these *random baselines*, previous work had to reduce the amount of a probe training data (Zhang and Bowman, 2018) or use smaller models for probes (Hewitt and Liang, 2019).

As an alternative to the standard probing, we take an information-theoretic view at the task of measuring relations between representations and labels. Any regularity in representations with respect to labels can be exploited both to make predictions and to compress these labels, i.e., reduce length of the code needed to transmit them. Formally, we recast learning a model of data (i.e., training a probing classifier) as training it to transmit the data (i.e., labels) in as few bits as possible. This naturally leads to a change of measure: instead of evaluating

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 183–196,
November 16–20, 2020.

probe accuracy, we evaluate *minimum description length (MDL)* of labels given representations, i.e. the minimum number of bits needed to transmit the labels knowing the representations. Note that since labels are transmitted using a model, the model has to be transmitted as well (directly or indirectly). Thus, the overall codelength is a combination of the quality of fit of the model (compressed data length) with the cost of transmitting the model itself.

Intuitively, codelength characterizes not only the final quality of a probe, but also the 'amount of effort' needed achieve this quality (Figure 1). If representations have some clear structure with respect to labels, the relation between the representations and the labels can be understood with less effort; for example, (i) the 'rule' predicting the label (i.e., the probing model) can be simple, and/or (ii) the amount of data needed to reveal this structure can be small. This is exactly how our vague (so far) notion of 'the amount of effort' is translated into codelength. We explain this more formally when describing the two methods for evaluating MDL we use: *variational coding* and *online coding*; they differ in a way they incorporate model cost: directly or indirectly.

Variational code explicitly incorporates cost of transmitting the model (probe weights) in addition to the cost of transmitting the labels; this joint cost is exactly the loss function of a variational learning algorithm (Honkela and Valpola, 2004). As we will see in the experiments, close probe accuracies often come at a very different model cost: the 'rule' (the probing model) explaining regularity in the data can be either simple (i.e., easy to communicate) or complicated (i.e., hard to communicate) depending on the strength of this regularity.

Online code provides a way to transmit data without directly transmitting the model. Intuitively, it measures the ability to learn from different amounts of data. In this setting, the data is transmitted in a sequence of portions; at each step, the data transmitted so far is used to understand the regularity in this data and compress the following portion. If the regularity in the data is strong, it can be revealed using a small subset of the data, i.e., early in the transmission process, and can be exploited to efficiently transmit the rest of the dataset. The online code is related to the area under the learning curve, which plots quality as a function of the number of training examples.

If we now recall that, to get reasonable differences with random baselines, previous work manually tuned (i) model size and/or (ii) the amount of data, we will see that these were indirect ways of accounting for the 'amount of effort' component of (i) variational and (ii) online codes, respectively. Interestingly, since variational and online codes are different methods to estimate the same quantity (and, as we will show, they agree in the results), we can conclude that the ability of a probe to achieve good quality using a *small amount of data* and its ability to achieve good quality using a *small probe architecture* reflect the same property: *strength of the regularity in the data*. In contrast to previous work, MDL incorporates this naturally in a theoretically justified way. Moreover, our experiments show that, differently from accuracy, conclusions made by MDL probes are not affected by an underlying probe setting, thus no manual search for settings is required.

We illustrate the effectiveness of MDL for different kinds of random baselines. For example, when considering control tasks (Hewitt and Liang, 2019), while probes have similar accuracies, these accuracies are achieved with a small probe model for the linguistic task and a large model for the random baseline (control task); these architectures are obtained as a byproduct of MDL optimization and not by manual search.

Our contributions are as follows:

- we propose information-theoretic probing which measures MDL of labels given representations;
- we show that MDL naturally characterizes not only probe quality, but also 'the amount of effort' needed to achieve it;
- we explain how to easily measure MDL on top of standard probe-training pipelines;
- we show that, compared to standard probes, MDL results are more informative and stable.

2 Information-Theoretic Viewpoint

Let $\mathcal{D} = \{(x_1, y_1), \dots, (x_n, y_n)\}$ be a dataset, where $x_{1:n} = (x_1, x_2, \dots, x_n)$ are representations from a model and $y_{1:n} = (y_1, y_2, \dots, y_n)$ are labels for some linguistic task (we assume that $y_i \in \{1, 2, \dots, K\}$, i.e. we consider classification tasks). As in standard probing task, we want to measure to what extent $x_{1:n}$ encode $y_{1:n}$. Differently from standard probes, we propose to look at this question from the information-theoretic perspective and define the goal of a probe as learning to effectively transmit the data.

Setting. Following the standard information theory notation, let us imagine that Alice has all (x_i, y_i) pairs in $\mathcal{D}$, Bob has just the x_i's from $\mathcal{D}$, and that Alice wants to communicate the y_i's to Bob. The task is to encode the labels $y_{1:n}$ knowing the inputs $x_{1:n}$ in an optimal way, i.e. with minimal codelength (in bits) needed to transmit $y_{1:n}$.

Transmission: Data and Model. Alice can transmit the labels using some probabilistic model of data $p(y|x)$ (e.g., it can be a trained probing classifier). Since Bob does not know the precise trained model that Alice is using, some explicit or implicit transmission of the model itself is also required. In Section 2.1, we explain how to transmit data using a model p. In Section 2.2, we show direct and indirect ways of transmitting the model.

Interpretation: quality and 'amount of effort'. In Section 2.3, we show that total codelength characterizes both probe quality and the 'amount of effort' needed to achieve it. We draw connections between different interpretations of this 'amount of effort' part of the code and manual search for probe settings done in previous work.[2]

2.1 Transmission of Data Using a Model

Suppose that Alice and Bob have agreed in advance on a model p, and both know the inputs $x_{1:n}$. Then there exists a code to transmit the labels $y_{1:n}$ losslessly with codelength[3]

$$L_p(y_{1:n}|x_{1:n}) = -\sum_{i=1}^{n} \log_2 p(y_i|x_i). \qquad (1)$$

This is the *Shannon-Huffman code*, which gives an optimal bound on the codelength if the data are independent and come from a conditional probability distribution $p(y|x)$.

Learning is compression. The bound (1) is exactly the categorical cross-entropy loss evaluated on the model p. This shows that the task of compressing labels $y_{1:n}$ is equivalent to learning a model $p(y|x)$: quality of a learned model $p(y|x)$ is the codelength needed to transmit the data.

Compression is usually compared against *uniform encoding* which does not require any learning from data. It assumes $p(y|x) = p_{unif}(y|x) = \frac{1}{K}$, and yields codelength $L_{unif}(y_{1:n}|x_{1:n}) = n \log_2 K$ bits. Another trivial encoding ignores input x and relies on class priors $p(y)$, resulting in codelength $H(y)$ for a datapoint.

Relation to Mutual Information. If the inputs and the outputs come from a true joint distribution $q(x, y)$, then, for any transmission method with codelength L, it holds $\mathbb{E}_q[L(y|x)] \geq H(y|x)$ (Grunwald, 2004). Therefore, the gain in codelength over the trivial codelength $H(y)$ is $H(y) - \mathbb{E}_q[L(y|x)] \leq H(y) - H(y|x) = I(y; x)$. In other words, the compression is limited by the mutual information (MI) between inputs (i.e. pretrained representations) and outputs (i.e. labels).

Note that total codelength includes model codelength in addition to the data code. This means that while high MI is necessary for effective compression, a good representation is the one which also yields simple models predicting y from x, as we formalize in the next section.

2.2 Transmission of the Model (Explicit or Implicit)

We consider two compression methods that can be used with deep learning models (probing classifiers):

- *variational code* – an instance of *two-part* codes, where a model is transmitted explicitly and then used to encode the data;
- *online code* – a way to encode both model and data without *directly* transmitting the model.

2.2.1 Variational Code

We assume that Alice and Bob have agreed on a model class $\mathcal{H} = \{p_\theta | \theta \in \Theta\}$. With *two-part* codes, for any model p_{θ^*}, Alice first transmits its parameters θ^* and then encodes the data while relying on the model. The description length decomposes accordingly:

$$L^{\textit{2-part}}_{\theta^*}(y_{1:n}|x_{1:n}) = \\ = L_{param}(\theta^*) + L_{p_{\theta^*}}(y_{1:n}|x_{1:n})$$

To compute the description length of the parameters $L_{param}(\theta^*)$, we can further assume that Alice and Bob have agreed on a prior distribution over the parameters $\alpha(\theta^*)$. Now, we can rewrite the total description length (using also eq. (1)) as

---

[2] Note that in this work, we do not consider practical implementations of transmission algorithms; everywhere in the text, 'codelength' refers to the theoretical codelength of the associated encodings.

[3] Up to at most one bit on the whole sequence; for datasets of reasonable size this can be ignored.

$$-\log_2(\alpha(\theta^*)\epsilon^m) - \sum_{i=1}^{n} \log_2 p_{\theta^*}(y_i|x_i),$$

where m is the number of parameters and ϵ is a prearranged precision for each parameter. With deep learning models, such straightforward codes for parameters are highly inefficient. Instead, in the variational approach, weights are treated as random variables, and the description length is given by the expectation

$$\begin{aligned} L_{\beta}^{var}(y_{1:n}|x_{1:n}) &= \\ = \text{-}\mathbb{E}_{\theta\sim\beta}&\left[\log_2\alpha(\theta) \text{-} \log_2\beta(\theta) + \sum_{i=1}^{n} \log_2 p_{\theta}(y_i|x_i)\right] \\ = KL(\beta \parallel \alpha) \text{ - } &\mathbb{E}_{\theta\sim\beta}\sum_{i=1}^{n} \log_2 p_{\theta}(y_i|x_i), \qquad (2) \end{aligned}$$

where $\beta(\theta) = \prod_{i=1}^{m} \beta_i(\theta_i)$ is a distribution encoding uncertainty about the parameter values. The distribution $\beta(\theta)$ is chosen by minimizing the codelength given in Expression (2). The formal justification for the description length relies on the *bits-back* argument (Hinton and von Cramp, 1993; Honkela and Valpola, 2004; MacKay, 2003). However, the underlying intuition is straightforward: parameters we are uncertain about can be transmitted at a lower cost as the uncertainty can be used to determine the required precision. The entropy term in Equation (2), $H(\beta) = \text{-}\mathbb{E}_{\theta\sim\beta}\log_2\beta(\theta)$, quantifies this discount.

The negated codelength $-L_{\beta}^{var}(y_{1:n}|x_{1:n})$ is known as the evidence-lower-bound (ELBO) and used as the objective in variational inference. The distribution $\beta(\theta)$ approximates the intractable posterior distribution $p(\theta|x_{1:n}, y_{1:n})$. Consequently, any variational method can in principle be used to estimate the codelength.

In our experiments, we use the network compression method of Louizos et al. (2017). Similarly to variational dropout (Molchanov et al., 2017), it uses sparsity-inducing priors on the parameters, pruning neurons from the probing classifier as a byproduct of optimizing the ELBO. As a result we can assess the probe complexity both using its description length $KL(\beta \parallel \alpha)$ and by inspecting the discovered architecture.

2.2.2 Online (or Prequential) Code

The online (or prequential) code (Rissanen, 1984) is a way to encode both the model and the labels without directly encoding the model weights. In the online setting, Alice and Bob agree on the form of the model $p_\theta(y|x)$ with learnable parameters θ, its initial random seeds, and its learning algorithm. They also choose timesteps $1 = t_0 < t_1 < \dots < t_S = n$ and encode data by blocks.[4] Alice starts by communicating $y_{1:t_1}$ with a uniform code, then both Alice and Bob learn a model $p_{\theta_1}(y|x)$ that predicts y from x using data $\{(x_i, y_i)\}_{i=1}^{t_1}$, and Alice uses that model to communicate the next data block $y_{t_1+1:t_2}$. Then both Alice and Bob learn a model $p_{\theta_2}(y|x)$ from a larger block $\{(x_i, y_i)\}_{i=1}^{t_2}$ and use it to encode $y_{t_2+1:t_3}$. This process continues until the entire dataset has been transmitted. The resulting online codelength is

$$L^{online}(y_{1:n}|x_{1:n}) = t_1 \log_2 K - \sum_{i=1}^{S-1} \log_2 p_{\theta_i}(y_{t_i+1:t_{i+1}}|x_{t_i+1:t_{i+1}}). \qquad (3)$$

In this sequential evaluation, a model that performs well with a limited number of training examples will be rewarded by having a shorter codelength (Alice will require fewer bits to transmit the subsequent $y_{t_i:t_{i+1}}$ to Bob). The online code is related to the area under the learning curve, which plots quality (in case of probes, accuracy) as a function of the number of training examples. We will illustrate this in Section 3.2.

2.3 Interpretations of Codelength

Connection to previous work. To get larger differences in scores compared to random baselines, previous work tried to (i) reduce size of a probing model and (ii) reduce the amount of a probe training data. Now we can see that these were indirect ways to account for the 'amount of effort' component of (i) variational and (ii) online codes, respectively.

Online code and model size. While the online code does not incorporate model cost explicitly, we can still evaluate model cost by interpreting the difference between the cross-entropy of the model trained on all data and online codelength as the cost of the model. The former is codelength of the data if one knows model parameters, the latter (online codelength) — if one does not know them. In Section 3.2 we will show that trends for model cost evaluated for the online code are similar to those for the variational code. It means that in terms of a

---

[4] In all experiments in this paper, the timesteps correspond to 0.1, 0.2, 0.4, 0.8, 1.6, 3.2, 6.25, 12.5, 25, 50, 100 percent of the dataset.

code, the ability of a probe to achieve good quality using *small amount of data* or using *a small probe architecture* reflect the same property: the *strength of the regularity in the data*.

Which code to choose? In terms of implementation, the online code uses a standard probe along with its training setting: it trains the probe on increasing subsets of the dataset. Using the variational code requires changing (i) a probing model to a Bayesian model and (ii) the loss function to the corresponding variational loss (2) (i.e. adding the model KL term to the standard data cross-entropy). As we will show later, these methods agree in results. Therefore, the choice of the method can be done depending on the preferences: the variational code can be used to inspect the induced probe architecture, but the online code is easier to implement.

3 Description Length and Control Tasks

Hewitt and Liang (2019) note that probe accuracy does not necessarily reveal if the representations encode the linguistic annotation or if the probe 'itself' learned to predict this annotation. They introduce control tasks which associate word types with random outputs, and each word token is assigned its type's output, regardless of context. By construction, such tasks can only be learned by the probe itself. The authors argue that selectivity, i.e. difference between linguistic task accuracy and control task accuracy, reveals how much the linguistic probe relies on the regularities encoded in the representations. They propose to tune probe hyperparameters to maximize selectivity. In contrast, we will show that MDL probes do not require such tuning.

3.1 Experimental Setting

In all experiments, we use the data and follow the setting of Hewitt and Liang (2019); we build on top of their code and release our extended version to reproduce the experiments.

In the main text, we use a probe with default hyperparameters which was a starting point in Hewitt and Liang (2019) and was shown to have low selectivity. In the appendix, we provide results for 10 different settings and show that, in contrast to accuracy, codelength is stable across settings.

Task: part of speech. Control tasks were designed for two tasks: part-of-speech (PoS) tagging and dependency edge prediction. In this work, we focus only on the PoS tagging task, the task of assigning tags, such as noun, verb, and adjective, to individual word tokens. For the control task, for each word type, a PoS tag is independently sampled from the empirical distribution of the tags in the linguistic data.

Data. The pretrained model is the 5.5 billion-word pre-trained ELMo (Peters et al., 2018). The data comes from Penn Treebank (Marcus et al., 1993) with the traditional parsing training/development/testing splits[5] without extra preprocessing. Table 7 shows dataset statistics.

Probes. The probe is MLP-2 of Hewitt and Liang (2019) with the default hyperparameters. Namely, it is a multi-layer perceptron with two hidden layers defined as: $y_i \sim \text{softmax}(W_3 ReLU(W_2 ReLU(W_1 h_i)))$; hidden layer size h is 1000 and no dropout is used. Additionally, in the appendix, we provide results for both MLP-2 and MLP-1 for several h values: 1000, 500, 250, 100, 50.

For the variational code, we replace dense layers with the Bayesian compression layers from Louizos et al. (2017); the loss function changes to Eq. (2).

Optimizer. All of our probing models are trained with Adam (Kingma and Ba, 2015) with learning rate 0.001. With standard probes, we follow the original paper (Hewitt and Liang, 2019) and anneal the learning rate by a factor of 0.5 once the epoch does not lead to a new minimum loss on the development set; we stop training when 4 such epochs occur in a row. With variational probes, we do not anneal learning rate and train probes for 200 epochs; long training is recommended to enable pruning (Louizos et al., 2017).

3.2 Experimental Results

Results are shown in Table 1.[6]

Different compression methods, similar results. First, we see that both compression methods show similar trends in codelength. For the linguistic task, the best layer is the first one. For the control task, codes become larger as we move up from the embedding layer; this is expected since the control

---

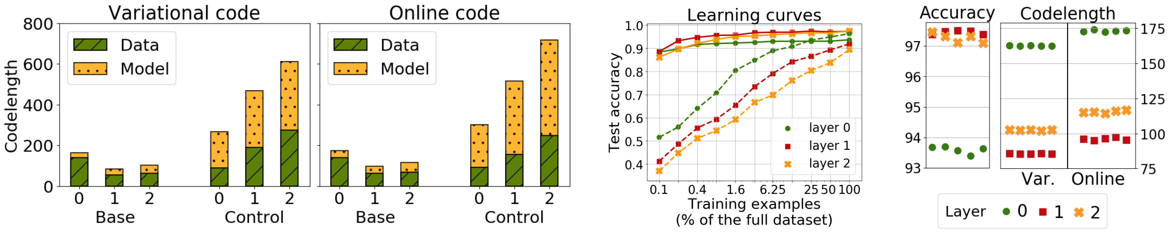
LAYER 1	97.5 / 91.9	85 / 470	59.76 / 10.85	96 / 515	53.06 / 9.89
LAYER 2	97.3 / 89.4	103 / 612	49.67 / 8.33	115 / 717	44.3 / 7.11

Table 1: Experimental results (MLP-2, $h = 1000$); shown in pairs: linguistic task / control task. Codelength is measured in kbits (variational codelength is given in equation (2), online – in equation (3)). Accuracy is shown for the standard probe as in Hewitt and Liang (2019); for the variational probe, scores are similar (see Table 2).



(a)

(b)

(c)

(d) random seeds

Figure 2: (a), (b): codelength split into data and model codes; (c): learning curves corresponding to online code (solid lines for linguistic task, dashed – for control); (d): results for 5 random seeds, linguistic task (for control task, see appendix).

task measures the ability to memorize word type. Note that codelengths for control tasks are substantially larger than for the linguistic task (at least twice larger). This again illustrates that description length is preferable to probe accuracy: in contrast to accuracy, codelength is able to distinguish these tasks without any search for settings.

LAYER 0: MDL is correct, accuracy is not. What is even more surprising, *codelength identifies the control task even when accuracy indicates the opposite*: for LAYER 0, accuracy for the control task is higher, but the code is twice longer than for the linguistic task. This is because codelength characterizes how hard it is to achieve this accuracy: for the control task, accuracy is higher, but the cost of achieving this score is very big. We will illustrate this later in this section.

Embedding vs contextual: drastic difference. For the linguistic task, note that codelength for the embedding layer is approximately twice larger than that for the first layer. Later in Section 4 we will see the same trends for several other tasks, and will show that even contextualized representations obtained with a randomly initialized model are a lot better than with the embedding layer alone.

Model: small for linguistic, large for control. Figure 2(a) shows data and model components of the variational code. For control tasks, model size is several times larger than for the linguistic task. This is something that probe accuracy alone is not able to reflect: representations have structure with respect to the linguistic labels and this structure can be 'explained' with a small model. The same representations do not have structure with respect to random labels, therefore these labels can be predicted only using a larger model.

Using interpretation from Section 2.3 to split the online code into data and model codelength, we get Figure 2(b). The trends are similar to the ones with the variational code; but with the online code, the model component shows how easy it is to learn from small amount of data: if the representations have structure with respect to some labels, this structure can be revealed with a few training examples. Figure 2(c) shows learning curves showing the difference between behavior of the linguistic and control tasks. In addition to probe accuracy, such learning curves have also been used by Yogatama et al. (2019) and Talmor et al. (2019).

Architecture: sparse for linguistic, dense for control. The method for the variational code we use, Bayesian compression of Louizos et al. (2017), lets us assess the induced probe complexity not only by using its description length (as we did above), but also by looking at the induced architecture (Table 2). Probes learned for linguistic tasks are much smaller than those for control tasks, with only 33-75 neurons at the second and third layers. This relates to the work by Hewitt and Liang (2019).

Layer	Task	Accuracy	Final probe
0	base	93.5	406-33-49
	control	96.3	427-214-137
1	base	97.7	664-55-35
	control	92.2	824-272-260
2	base	97.3	750-75-41
	control	88.7	815-308-481

Table 2: Pruned architecture of a trained variational probe (starting probe: 1024-1000-1000).

The authors considered several predefined probe architectures and picked one of them based on a manually defined criterion. In contrast, the variational code gives probe architecture as a byproduct of training and does not need human guidance.

3.3 Stability and Reliability of MDL Probes

Here we discuss stability of MDL results across compression methods, underlying probing classifier setting and random seeds.

The two compression methods agree in results. Note that the observed agreement in codelengths from different methods (Table 1) is rather surprising: this contrasts to Blier and Ollivier (2018), who experimented with images (MNIST, CIFAR-10) and argued that the variational code yields very poor compression bounds compared to online code. We can speculate that their results may be due to the particular variational approach they use. The agreement between different codes is desirable and suggests sensibility and reliability of the results.

Hyperparameters: change results for accuracy, do not for MDL. While here we will discuss in detail results for the default settings, in the appendix we provide results for 10 different settings; for LAYER 0, results are given in Figure 3. We see that accuracy can change greatly with the settings. For example, difference in accuracy for linguistic and control tasks varies a lot; for LAYER 0 there are settings with contradictory results: accuracy can be higher either for the linguistic or for the control task depending on the settings (Figure 3). In striking contrast to accuracy, *MDL results are stable across settings*, thus *MDL does not require search for probe settings*.

Random seed: affects accuracy but not MDL. We evaluated results from Table 1 for random seeds from 0 to 4; for the linguistic task, results are shown in Figure 2(d). We see that using accuracy can lead to different rankings of layers depending on a random seed, making it hard to draw conclusions about their relative qualities. For example, accuracy for LAYER 1 and LAYER 2 are 97.48 and 97.31 for seed 1, but 97.38 and 97.48 for seed 0. On the contrary, the MDL results are stable and the scores given to different layers are well separated.

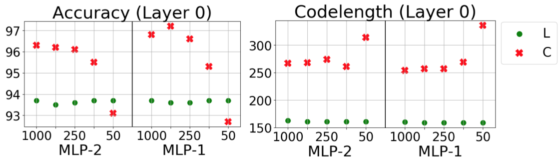


Figure 3: Results for 10 probe settings: accuracy is wrong for 8 out of 10 settings, MDL is always correct (for accuracy higher is better, for codelength – lower).

Note that for this 'real' task, where the true ranking of layers 1 and 2 is not known in advance, tuning a probe setting by maximizing difference with the synthetic control task (as done by Hewitt and Liang (2019)) does not help: in the tuned setting, scores for these layers remain very close (e.g., 97.3 and 97.0 (Hewitt and Liang, 2019)).

4 MDL and Random Models

Now, from random labels for word types, we come to another type of random baselines: randomly initialized models. Probes using these representations show surprisingly strong performance for both token (Zhang and Bowman, 2018) and sentence (Wieting and Kiela, 2019) representations. This again confirms that accuracy alone does not reflect what a representation encodes. With MDL probes, we will see that codelength shows large difference between trained and randomly initialized representations.

In this part, we also experiment with ELMo and compare it with a version of the ELMo model in which all weights above the lexical layer (LAYER 0) are replaced with random orthonormal matrices (but LAYER 0, is retained from trained ELMo). We conduct a line of experiments using a suite of edge probing tasks (Tenney et al., 2019). In these tasks, a probe can access only representations within given spans, such as a predicate-argument pair, and must predict properties, such as semantic roles.

We build our experiments on top of the original code by Tenney et al. (2019) and release our extended version. Examples for each task are shown in Table 3; more details on dataset statistics, probe architecture and optimization are in the appendix.

Table 4: Results are shown in pairs: trained / randomly initialized model. Codelength is measured in kbits (variational codelength is given in equation (2), online – in (3)), compression – with respect to the corresponding uniform code.

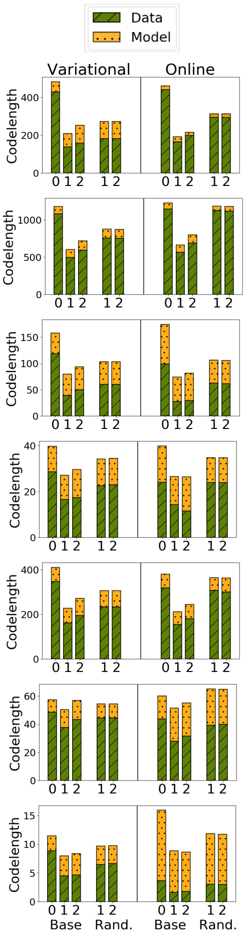

Table 5: Data and model code components for the tasks from Table 4.

4.1 Experimental Results

Results are shown in Table 4.

LAYER 0 vs contextual. As we have already seen in the previous section, codelength shows drastic difference between the embedding layer (LAYER 0) and contextualized representations: codelengths differ about twice for most of the tasks. Both compression methods show that even for the randomly initialized model, contextualized representations are better than lexical representations. This is because context-agnostic embeddings do not contain enough information about the task, i.e., MI between labels and context-agnostic representations is smaller than between labels and contextualized representations. Since compression of the labels given model (i.e., data component of the code) is limited by the MI between the representations and the labels (Section 2.1), the data component of the codelength is much bigger for the embedding layer than for contextualized representations.

Trained vs random. As expected, codelengths for the randomly initialized model are larger than for the trained one. This is more prominent when not just looking at the bare scores, but comparing compression against context-agnostic representations. For all tasks, compression bounds for the randomly initialized model are closer to those of context-agnostic LAYER 0 than representations from the trained model. This shows that gain from using context for the randomly initialized model is at least twice smaller than for the trained model.

Note also that *randomly initialized layers do not evolve*: for all tasks, MDL for layers of the randomly initialized model is the same. Moreover, Table 5 shows that not only total codelength but data and model components of the code for random model layers are also identical. For the trained model, this is not the case: LAYER 2 is worse than LAYER 1 for all tasks. This is one more illustration of the general process explained in Voita et al. (2019a): the way representations evolve between layers is defined by the training objective. For the randomly initialized model, since no training objective has been optimized, no evolution happens.

5 Related work

Probing classifiers are the most common approach for associating representations with linguistic properties (see Belinkov and Glass (2019) for a survey). Among the works highlighting limitations of standard probes (not mentioned above) is the work by Saphra and Lopez (2019), who show that probes are not suitable for analyzing learning dynamics.

In addition to task performance, learning curves have also been used before by Yogatama et al. (2019) to evaluate how quickly a model learns a new task, and by Talmor et al. (2019) to understand whether the performance of a LM on a task should be attributed to the pre-trained representations or to the process of fine-tuning on the task data.

Other methods for analyzing NLP models include (i) inspecting the mechanisms a model uses to encode information, e.g. attention weights (Voita et al., 2018; Raganato and Tiedemann, 2018; Voita et al., 2019b; Clark et al., 2019; Kovaleva et al., 2019) or individual neurons (Karpathy et al., 2015; Pham et al., 2016; Bau et al., 2019), (ii) looking at model predictions using manually defined templates, either evaluating sensitivity to specific grammatical errors (Linzen et al., 2016; Gulordava et al., 2018; Tran et al., 2018; Marvin and Linzen, 2018) or understanding what language models know when applying them as knowledge bases or in QA settings (Radford et al., 2019; Petroni et al., 2019; Poerner et al., 2019; Jiang et al., 2019). An information-theoretic view on analysis of NLP models has been previously attempted in Voita et al. (2019a) when explaining how representations in the Transformer evolve between layers under different training objectives.

In context of probing, Pimentel et al. (2020) attempted to formalize probing for linguistic structure from the information-theoretic perspective. The authors measure mutual information between representations and labels, and argue the importance of defining and taking into account "ease of extraction", though they do not formalize this notion. That work can serve as an additional motivation for using MDL. Namely, minimum description length is the sum of (i) the data codelength, which is related to mutual information, and (ii) the model codelength, which measures "the amount of effort" needed to extract labels from representations; in Pimentel et al. (2020), this is referred to as "ease of extraction".

6 Conclusions

We propose information-theoretic probing which measures *minimum description length (MDL)* of labels given representations. We show that MDL naturally characterizes not only probe quality, but also 'the amount of effort' needed to achieve it (or, intuitively, *strength of the regularity* in representations with respect to the labels); this is done in a theoretically justified way without manual search for settings. We explain how to easily measure MDL on top of standard probe-training pipelines. We show that results of MDL probing are more sensible compared to standard probes.

B MDL and Random Models

B.1 Experimental Setting

Tasks and datasets. We focus on several core NLP tasks: PoS tagging, syntactic constituent and dependency labeling, named entity recognition, semantic role labeling, coreference resolution, and relation classification. Examples for each task are shown in Table 3, dataset statistics are in Table 8. See extra details in Tenney et al. (2019).

We follow Tenney et al. (2019) and use ELMo (Peters et al., 2018) trained on the Billion Word Benchmark dataset (Chelba et al., 2014).

Probes and optimization. Probing architecture is illustrated in Figure 5. It takes a list of contextual vectors $[e_0, e_1, \dots, e_n]$ and integer spans $s_1 = [i_1, j_1)$ and (optionally) $s_2 = [i_2, j_2)$ as inputs, and uses a projection layer followed by the self-attention pooling operator of Lee et al. (2017) to compute fixed-length span representations. The span representations are concatenated and fed into a two-layer MLP followed by a softmax output layer. As in the original paper, we use the standard cross-entropy loss, hidden layer size of 256 and dropout of 0.3. For further details on training, we refer the reader to the original paper by Tenney et al. (2019).[7]

For the variational code, the layers are replaced with that of Bayesian compression by Louizos et al. (2017); loss function changes to (2) and no dropout is used. Similar to the experiments in the previous section, we do not anneal learning rate and train at least 200 validations to enable pruning.

We build our experiments on top of the original code by Tenney et al. (2019) and release our extended version.

---

[7] The differences with the original implementation by Tenney et al. (2019) are: softmax with the cross-entropy loss instead of sigmoid with binary cross-entropy, using the loss instead of F1 in the early stopping criterion.

Intrinsic Probing through Dimension Selection

Abstract

Most modern NLP systems make use of pretrained contextual representations that attain astonishingly high performance on a variety of tasks. Such high performance should not be possible unless some form of linguistic structure inheres in these representations, and a wealth of research has sprung up on probing for it. In this paper, we draw a distinction between intrinsic probing, which examines *how linguistic information is structured* within a representation, and the extrinsic probing popular in prior work, which only argues for the *presence* of such information by showing that it can be successfully extracted. To enable intrinsic probing, we propose a novel framework based on a decomposable multivariate Gaussian probe that allows us to determine whether the linguistic information in word embeddings is dispersed or focal. We then probe fastText and BERT for various morphosyntactic attributes across 36 languages. We find that most attributes are reliably encoded by only a few neurons, with fastText concentrating its linguistic structure more than BERT.[1]

1 Introduction

Natural language processing (NLP) is enamored of contextual word representations—and for good reason! Contextual word-embedders, e.g. BERT (Devlin et al., 2019) and ELMo (Peters et al., 2018), have bolstered NLP model performance on myriad tasks, such as syntactic parsing (Kitaev et al., 2019), coreference resolution (Joshi et al., 2019), morphological tagging (Kondratyuk, 2019) and text generation (Zellers et al., 2019). Given the large empirical gains observed when they are employed, it is all but certain that word representations derived from neural networks encode some continuous analogue of linguistic structures.

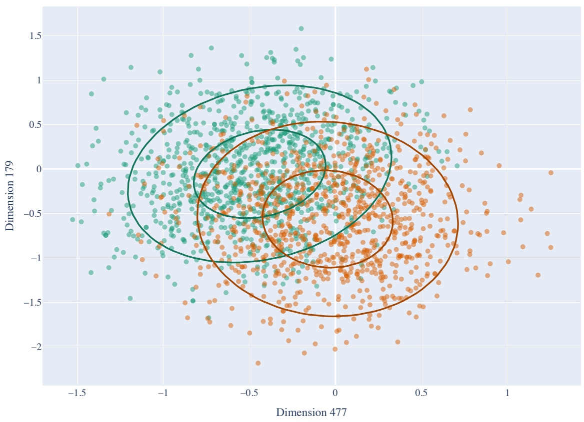

Figure 1: Scatter plot of the two most informative BERT dimensions for English present and past tense. The contours belong to our probe.

Exactly *what* these representations encode about linguistic structure, however, remains little understood. Researchers have studied this question by attributing function to specific network cells with visualization methods (Karpathy et al., 2015; Li et al., 2016) and by **probing** (Alain and Bengio, 2017; Belinkov and Glass, 2019), which seeks to extract structure from the representations. Recent work has probed various representations for correlates of morphological (Belinkov et al., 2017; Giulianelli et al., 2018), syntactic (Hupkes et al., 2018; Zhang and Bowman, 2018; Hewitt and Manning, 2019; Lin et al., 2019), and semantic (Kim et al., 2019) structure.

Most current probing efforts focus on what we term **extrinsic probing**, where the goal is to determine whether the posited linguistic structure is predictable from the learned representation. Generally, extrinsic probing works argue for the presence of linguistic structure by showing that it is extractable from the representations using a machine learning model. In contrast, we focus on **intrinsic probing**—whose goals are a proper superset of the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 197–216,
November 16–20, 2020.

goals of extrinsic probing. In intrinsic probing, one seeks to determine not only whether a signature of linguistic structure can be found, but also how it is encoded in the representations. In short, we aim to discover which particular "neurons" (a.k.a. dimensions) in the representations *correlate* with a given linguistic structure.Intrinsic probing also has ancillary benefits that extrinsic probing lacks; it can facilitate manual analyses of representations and potentially yield a nuanced view about the information encoded by them.

The technical portion of our paper focuses on developing a novel framework for intrinsic probing: we scan sets of dimensions, or neurons, in a word vector representation which activate when they correlate with target linguistic properties. We show that when intrinsically probing high-dimensional representations, the present probing paradigm is insufficient (§2). Current probes are too slow to be used under our framework, which invariably leads to low-resolution scans that can only look at one or a few neurons at a time.Instead, we introduce **decomposable probes**, which can be trained once on the whole representation and henceforth be used to scan *any* selection of neurons. To that end, we describe one such probe that leverages the multivariate Gaussian distribution's inherent decomposability, and evaluate its performance on a large-scale, multi-lingual, morphosyntactic probing task (§3).

We experiment on 36 languages[2] from the Universal Dependencies treebanks (Nivre et al., 2017). We find that all the morphosyntactic features we considered are encoded by a relatively small selection of neurons. In some cases, very few neurons are needed; for instance, for multilingual BERT English representations, we see that, with two neurons, we can largely separate past and present tense in Fig. 1. In this, our work is closest to Lakretz et al. (2019), except that we extend the investigation beyond *individual* neurons—a move which is only made tractable by decomposable probing. We also provide analyses on morphological features beyond number and tense. Across all languages, 35 out of 768 neurons on average suffice to reach a reasonable amount of encoded information, and adding more yields diminishing returns (see Fig. 2). Interestingly, in our head-to-head comparison of BERT and fastText, we find that fastText almost always encodes information about morphosyntactic properties using fewer dimensions.

2 Probing through Dimension Selection

The goal of intrinsic probing is to reveal how "knowledge" of a target linguistic property is structured within a neural network-derived representation. If said property can be predicted from the representations, we expect that this is because the neural network encodes this property (Giulianelli et al., 2018).We can then determine whether a probe requires a large subset or a small subset of dimensions to predict the target property reliably.[3] Particularly small subsets could be used to manually analyze a network and its decision process, and potentially reveal something about how specific neural architectures learn to encode linguistic information.

To formally describe our framework, we first define the necessary notation. We consider the probing of a word representation $\boldsymbol{h} \in \mathbb{R}^d$ for morphosyntax. In this work, our goal is find a subset of dimensions $C \subseteq D = \{1, \ldots, d\}$ such that the corresponding subvector of $\boldsymbol{h}_C$ contains only the dimensions that are necessary to predict the target morphosyntactic property we are probing for. For all possible subsets of dimensions $C \subseteq D$, and some random variable Π that ranges over P property values $\{\pi_1, \ldots, \pi_P\}$, we consider a general probabilistic probe: $p_{\boldsymbol{\theta}_C}(\Pi = \pi \mid \boldsymbol{h}_C)$; note that the model is conditioned on $\boldsymbol{h}_C$, not on $\boldsymbol{h}$. Our goal is to select a subset of dimensions using the log-likelihood of held-out data. We term this type of probing **dimension selection**. One can express dimension selection as the following combinatorial optimization problem:

$$C^\star = \underset{\substack{C \subseteq D, \\ |C| \leq k}}{\operatorname{argmax}} \sum_{n=1}^{N} \log p_{\boldsymbol{\theta}_C}(\pi^{(n)} \mid \boldsymbol{h}_C^{(n)}) \tag{1}$$

where $\{(\boldsymbol{h}_C^{(n)}, \pi^{(n)})\}_{n=1}^N$ is a held-out dataset. Importantly, for complicated models we will require a *different* parameter set $\boldsymbol{\theta}_C$ for each subset $C \subseteq D$. In the general case, solving a subset selection problem such as eq. (1) is NP-Hard (Binshtok et al., 2007). Indeed, without knowing more about the

---

[2] See App. F for a list.

[3] By analogy to the "distributed" and "focal" neural processes in cognitive neuroscience (see e.g. Bouton et al. 2018), an intrinsic framework also imparts us with the ability to formulate much higher granularity hypotheses about whether particular morphosyntactic attributes will be widely or focally encoded in representations.

structure of $p_{\boldsymbol{\theta}_C}$ we would have to rely on enumeration to solve this problem exactly. As there are $\binom{d}{k}$ possible subsets, it takes a prohibitively long time to enumerate them all for even small d and k.

Greed is not Enough. A natural first approach to approximate a solution to eq. (1) is a greedy algorithm (Kleinberg and Tardos, 2005, Chapter 4). Such an algorithm chooses the dimension that results in the largest increase to the objective at every iteration. However, some probes, such as neural network probes, need to be trained with a gradient-based method for many epochs. In such a case, even a greedy approximation is prohibitively expensive. For example, to select the first dimension, we train d probes and take the best. To select the second dimension, we train $d-1$ probes and take the best. This requires training $\mathcal{O}(dk)$ networks! In the case of BERT, we have $d = 768$ and we would generally like to consider k at least up to 50. Training on the order of 38400 neural models to probe for just *one* morphosyntactic property is generally not practical. What we require is a **decomposable** probe, which can be trained once on all dimensions and then be used to evaluate the log-likelihood of any subset of dimensions in constant or near-constant time. To the best of our knowledge, no probes in the literature exhibit this property; the primary technical contribution of the paper is the development of such a probe in §3.

Other Selection Criteria. Our exposition above uses the log-likelihood of held-out data as a selection criterion for a subset of dimensions; however, any function that scores a subset of dimensions is suitable. For example, much of the current probing literature relies on accuracy to evaluate probes (Conneau et al., 2018; Liu et al., 2019, *inter alia*), and two recent papers motivate a probabilistic evaluation with information theory (Pimentel et al., 2020b; Voita and Titov, 2020). One could select based on accuracy, mutual information, or anything else within our framework. In fact, recent work in intrinsic probing by Dalvi et al. (2019) could be recast into our framework if we chose a dimension selection criterion based on the magnitude of the weights of a linear probe. However, we suspect that a performance-based dimension selection criterion (e.g., log-likelihood) should be more robust given that a weight-based approach is sensitive to feature collinearity, variance and regularization. As we mentioned before, performance-based selection requires a probe to be decomposable, and to the best of our knowledge, this is not the case for the the linear probe of Dalvi et al. (2019).

3 A Decomposable Probe for Morphosyntactic Properties

Using the framework introduced above, our goal is to probe for morphosyntactic properties in word representations. We first describe the multivariate Gaussian distribution as it is responsible for our probe's decomposability (§3.1), and provide some more notation (§3.2). We then describe our model (§3.3) and a Bayesian formulation (§3.4).

3.1 Properties of the Gaussian

The multivariate Gaussian distribution is defined as

$$\mathcal{N}(\mathbf{x} \mid \boldsymbol{\mu}, \Sigma) = |2\pi\Sigma|^{-\frac{1}{2}} \exp\left(-\frac{1}{2}(\mathbf{x}-\boldsymbol{\mu})^\top \Sigma^{-1}(\mathbf{x}-\boldsymbol{\mu})\right) \tag{2}$$

where $\boldsymbol{\mu}$ is the mean of the distribution and Σ is the covariance matrix. We review the multivariate Gaussian with emphasis on the properties that make it ideal for intrinsic morphosyntactic probing.

Firstly, it is decomposable. Given a multivariate Gaussian distribution over $\mathbf{x} = [\mathbf{x}_1\ \mathbf{x}_2]^\top$

$$p(\mathbf{x}) = \mathcal{N}(\mathbf{x} \mid \boldsymbol{\mu}, \Sigma) = \mathcal{N}\left(\begin{bmatrix}\mathbf{x}_1 \\ \mathbf{x}_2\end{bmatrix} \,\middle|\, \begin{bmatrix}\boldsymbol{\mu}_1 \\ \boldsymbol{\mu}_2\end{bmatrix}, \begin{bmatrix}\Sigma_{11} & \Sigma_{12} \\ \Sigma_{12}^\top & \Sigma_{22}\end{bmatrix}\right) \tag{3}$$

the marginals for $\mathbf{x}_1$ and $\mathbf{x}_2$ may be computed as

$$p(\mathbf{x}_1) = \mathcal{N}(\mathbf{x}_1 \mid \boldsymbol{\mu}_1, \Sigma_{11}) \tag{4}$$

$$p(\mathbf{x}_2) = \mathcal{N}(\mathbf{x}_2 \mid \boldsymbol{\mu}_2, \Sigma_{22}) \tag{5}$$

This means that if we know $\boldsymbol{\mu}$ and Σ, we can obtain the parameters for *any subset* of dimensions of $\mathbf{x}$ by selecting the appropriate subvector (and submatrix) of $\boldsymbol{\mu}$ (Σ).[4] As we will see in §3.3, this property is the very centerpiece of our probe. Secondly, the Gaussian distribution is the maximum entropy distribution over the reals given a finite mean and covariance and no further information. Thus, barring additional information, the Gaussian is a good default choice. Jaynes (2003, Chapter 7) famously argued in favor of the Gaussian because it is the real-valued distribution with support $(-\infty, \infty)$ that makes the fewest assumptions about the data (beyond its first two moments).

---

[4] The other variable, Σ_{12}, is a matrix that contains the covariances of each dimension of $\mathbf{x}_1$ with each dimension of $\mathbf{x}_2$. We do not need it for our purposes.

3.2 Notation for Morphosyntactic Probing

We now provide some notation for our morphosyntactic probe. Let $\{\boldsymbol{h}^{(1)}, \ldots, \boldsymbol{h}^{(N)}\}$ be word representation vectors in $\mathbb{R}^d$ for N words $\{w^{(1)}, \ldots, w^{(N)}\}$ from a corpus. For example, these could be embeddings output by fastText (Bojanowski et al., 2017), or contextual representations according to ELMo (Peters et al., 2018) or BERT (Devlin et al., 2019). Furthermore, let $\{\mathbf{m}^{(1)}, \ldots, \mathbf{m}^{(N)}\}$ be the morphosyntactic tags associated with each of those words in the sentential context in which they were found.[5]

Let $\mathcal{A} = \{a_1, \ldots, a_{|\mathcal{A}|}\}$ be a universal[6] set of morphosyntactic attributes in a language, e.g. PERSON, TENSE, NUMBER, etc. For each attribute $a \in \mathcal{A}$, let $\mathcal{V}_a$ be that attribute's universal set of possible values. For instance, we have $\mathcal{V}_{\text{PERSON}} = \{1, 2, 3\}$ for most languages. For this task, we will further decompose each morphosyntactic tag as a set of attribute–value pairs $\mathbf{m}^{(i)} = \langle a_1 = v_1, \ldots, a_{|\mathbf{m}^{(i)}|} = v_{|\mathbf{m}^{(i)}|} \rangle$ where each attribute a_j is taken from the universal set of attributes $\mathcal{A}$, and each value v_j is taken from a set $\mathcal{V}_{a_j}$ of universal values specific to that attribute. For example, the morphosyntactic tag $\mathbf{m}$ for the English verb "has" would be $\{\text{PERSON} = 3, \text{NUMBER} = \text{SG}, \text{TENSE} = \text{PRS}\}$.

3.3 Our Decomposable Generative Probe

We now present our decomposable probabilistic probe. We model the joint distribution between embeddings and a specific attribute's values

$$p(\boldsymbol{h}, v) = p(\boldsymbol{h} \mid v)\, p(v) \tag{6}$$

where we define

$$p(\boldsymbol{h} \mid v) = \mathcal{N}(\boldsymbol{h} \mid \boldsymbol{\mu}_v, \Sigma_v) \tag{7}$$

where $\boldsymbol{\mu}_v$ and Σ_v are the value-specific mean and covariance. We further define

$$p(v) = \text{Categorical}\,(\mathcal{V}_a) \tag{8}$$

This allows each value to have a different probability of occurring. This is important since our probe should be able to model that, e.g. the 3rd person is more prevalent than the 1st person in corpora derived from Wikipedia. We can then probe with

$$p(v \mid \boldsymbol{h}) = \frac{p(\boldsymbol{h}, v)}{\sum_{v' \in \mathcal{V}_a} p(\boldsymbol{h}, v')} \tag{9}$$

which can be computed quickly as $|\mathcal{V}_a|$ is small.[7] This model is also known as quadratic discriminant analysis (Murphy, 2012, Chapter 4).Another interpretation of our model is that it amounts to a generative classifier where, given some specific morphosyntactic attribute, we first sample one of its possible values v, and then sample an embedding from a value-specific Gaussian. Compared to a linear probe (e.g. Hewitt and Liang 2019), whose decision boundary is linear for two values, the decision boundary of this model generalizes to conic sections, including parabolas, hyperbolas and ellipses (Murphy, 2012, Chapter 4).

This formulation allows us to model the word representations of each attribute's value as a separate Gaussian. Since the Gaussian distribution is decomposable (§3.1), we can train a single model and from it obtain a probe for *any* subset of dimensions in $\mathcal{O}(1)$ time. To the best of our knowledge, no other probes in the literature possess this desirable property, which is what enables us to intrinsically probe representations for morphosyntax.

3.4 Bayesically Done Now

All that is left now is to obtain the value-specific Gaussian parameters $\boldsymbol{\theta}_v = \{\boldsymbol{\mu}_v, \Sigma_v\}$. Let $\mathcal{D}^{(v)} = \{\boldsymbol{h}^{(1)}, \boldsymbol{h}^{(2)}, \ldots, \boldsymbol{h}^{(N_v)}\}$ be a sample of d-dimensional word representations for a value v for some language. One simple approach is to use maximum-likelihood estimation (MLE) to estimate $\boldsymbol{\theta}_v$; this amounts to computing the empirical mean and covariance matrix of $\mathcal{D}^{(v)}$. However, in preliminary experiments we found that a Bayesian approach is advantageous since it precludes degenerate Gaussians when there are more dimensions under consideration than training datapoints (Srivastava et al., 2007).

Under the Bayesian framework, we seek to compute the posterior distribution over the probe's parameters given our training data,

$$p(\boldsymbol{\theta}_v \mid \mathcal{D}^{(v)}) \propto p(\boldsymbol{\theta}_v) \times p(\mathcal{D}^{(v)} \mid \boldsymbol{\theta}_v) \tag{10}$$

where $p(\boldsymbol{\theta}_v)$ is our Bayesian prior. The prior encodes our *a priori* belief about the parameters in

---

[5] Crucially, some words may have different morphosyntactic tags depending on their context. For example, the number attribute of "make" could be either singular ("I make") or plural ("They make").

[6] "Universal" here refers to the set of all UniMorph dimensions and their possible features (Sylak-Glassman, 2016; Kirov et al., 2018).

[7] UniMorph's most varied attribute is CASE, with 32 values, though most languages do not exhibit all of them.

the absence of any data, and $p(\mathcal{D}^{(v)} \mid \boldsymbol{\theta}_v)$ is the likelihood of the data under our model given a parameterization $\boldsymbol{\theta}_v$. In the case of a Gaussian–inverse-Wishart prior,[8]

$$\begin{aligned} p(\boldsymbol{\theta}_v) &= \mathrm{GIW}(\boldsymbol{\mu}_v, \Sigma_v \mid \boldsymbol{\mu}_0, k_0, \Lambda_0, \nu_0) \qquad (11) \\ &= \mathcal{N}(\boldsymbol{\mu}_v \mid \boldsymbol{\mu}_0, \frac{1}{k_0}\Sigma_v) \times \mathrm{IW}(\Sigma_v \mid \Lambda_0, \nu_0) \end{aligned}$$

there is an exact expression for the posterior. The GIW prior has hyperparameters $\boldsymbol{\mu}_0, k_0, \Lambda_0, \nu_0$, where the inverse-Wishart distribution (IW, see App. B) defines a distribution over covariance matrices (Murphy, 2012, Chapter 4), and the Gaussian defines a distribution over the mean. As this prior is conjugate to the multivariate Gaussian distribution, our posterior over the parameters after observing $\mathcal{D}^{(v)}$ will also have a Gaussian–inverse-Wishart distribution, $\mathrm{GIW}(\boldsymbol{\mu}_v, \Sigma_v \mid \boldsymbol{\mu}_n, k_n, \Lambda_n, \nu_n)$, with known parameters (see App. A).

We did not perform full Bayesian inference as we found a maximum a posteriori (MAP) estimate to be sufficient for our purposes.[9] MAP estimation uses the parameters at the posterior mode

$$\begin{aligned} \boldsymbol{\theta}_v^\star &= \operatorname*{argmax}_{\boldsymbol{\theta}_v} p(\boldsymbol{\theta}_v \mid \mathcal{D}^{(v)}) \qquad (12) \\ &= \operatorname*{argmax}_{\boldsymbol{\mu}_v, \Sigma_v} \mathrm{GIW}(\boldsymbol{\mu}_v, \Sigma_v \mid \boldsymbol{\mu}_n, k_n, \Lambda_n, \nu_n) \end{aligned}$$

which are (Murphy, 2012, Chapter 4)

$$\boldsymbol{\mu}_v^\star = \boldsymbol{\mu}_n \qquad (13)$$

$$\Sigma_v^\star = \frac{1}{\nu_n + d + 2}\Lambda_n \qquad (14)$$

where d is the dimensionality of the Gaussian.

4 Probing Metrics

In this section, we describe the metrics that we compute. We track both accuracy (§4.1) and mutual information (§4.2).

4.1 Accuracy

As with most probes in the literature, we compute the accuracy of our model on held-out data. We report the lower-bound accuracy (LBA) of a set of dimensions C, which is defined as the highest accuracy achieved by any subset of dimensions $C' \subseteq C$. This metric counteracts a decrease in performance due to the model overfitting in certain dimensions. In principle, if a model was able to achieve a higher score using fewer dimensions, then there exists a model that can be at least as effective using a superset of those dimensions.

Despite its popularity, accuracy also has its downsides. In particular, we found it to be misleading when not taking a majority-class baseline into account, which complicates comparisons. For example, in fastText and BERT Latin (lat), our probe achieved slightly over 65% accuracy when averaging over attributes. This appears to be high, but 65% is the average majority-class baseline accuracy. Conversely, LBNMI (see §4.2) is roughly zero, which more intuitively reflects performance. Hence, we prioritize mutual information in our analysis.

4.2 Mutual Information

Recent work has advocated for information-theoretic metrics in probing (Voita and Titov, 2020; Pimentel et al., 2020b). One such metric, mutual information (MI), measures how predictable the occurrence of one random variable is given another.

We estimate the MI between representations and particular attributes using a method similar to the one proposed by Pimentel et al. (2019) (refer to App. D for an extended derivation). Let V_a be a $\mathcal{V}_a$-valued random variable denoting the value of a morphosyntactic attribute, and H be a $\mathbb{R}^d$-valued random variable for the word representation.

The mutual information between V_a and H is

$$\mathrm{MI}(V_a; H) = \mathrm{H}(V_a) - \mathrm{H}(V_a \mid H) \qquad (15)$$

The attribute's entropy, $\mathrm{H}(V_a)$, depends on the true distribution over values $\overline{p}(v)$. For this, we use the plug-in approximation $p(v)$, which is estimated from held-out data.The conditional entropy, $\mathrm{H}(V_a \mid H)$ is trickier to compute, as it also depends on the true distribution of embeddings given a value, $\overline{p}(\boldsymbol{h} \mid v)$, which is high-dimensional and poorly sampled in our data.[10] However, we can obtain an upper-bound if we use our probe $p(v \mid \boldsymbol{h})$ and

---

[8] Also known as a Normal–inverse-Wishart prior.

[9] The posterior predictive of this model is a Student's t-distribution (Murphy, 2007). Future work will explore a fully Bayesian implementation.

[10] When considering few dimensions in $\boldsymbol{h}$ this can be estimated, e.g. by binning. However, we cannot rely on such estimates for intrinsic probing in general.

compute (Brown et al., 1992)

$$\mathrm{H}(V_a \mid H) \leq \mathrm{H}_p(V_a \mid H) \tag{16}$$
$$= -\sum_{v \in \mathcal{V}_a} \overline{p}(v) \int \overline{p}(\boldsymbol{h} \mid v) \log_2 p(v \mid \boldsymbol{h}) \, \mathrm{d}\boldsymbol{h}$$
$$\approx -\frac{1}{N} \sum_{n=1}^{N} \log_2 p(\tilde{v}^{(n)} \mid \tilde{\boldsymbol{h}}^{(n)}) \tag{17}$$

using held-out data, $\tilde{\mathcal{D}} = \{(\tilde{\boldsymbol{h}}^{(n)}, \tilde{v}^{(n)})\}_{n=1}^{N}$. Incidentally, this is equivalent to computing the average negative log-likelihood of the probe on held-out data. Using these estimates in eq. (15), we obtain an empirical lower-bound on the MI.

For ease of comparison across languages and morphosyntactic attributes, we define two metrics associated to MI. The lower-bound MI (LBMI) of any set of neurons C is defined as the *highest* MI estimate obtained by any subset of those neurons $C' \subseteq C$. While true MI can never decrease upon adding a variable, our estimate may decrease due to overfitting in our model, or by it being unable to capture the complexity of $\overline{p}(\boldsymbol{h} \mid v)$. LBMI offers a way to counteract this limitation by using the very best estimate at our disposal for any set of dimensions. In practice, we report lower-bound normalized MI (LBNMI), which normalizes LBMI by the entropy of V_a, because normalizing MI estimates drawn from different samples enables them to be compared (Gates et al., 2019).

5 Experimental Setup

In this section we outline our experimental setup.

Selection Criterion. We use log-likelihood as our greedy selection criterion. We select 50 dimensions, and keep selecting even if the estimate has decreased.[11]

Data. We map the UD v2.1 treebanks (Nivre et al., 2017) to the UniMorph schema (Kirov et al., 2018; Sylak-Glassman, 2016) using the mapping by McCarthy et al. (2018). We keep only the "main" treebank for a language (e.g. UD_Portuguese as opposed to UD_Portuguese_PUD). We remove any sentences that would have a sub-token length greater than 512, the maximum allowed for our BERT model.[12] We assign any tags from the constituents of a contraction to the contracted word form (e.g., for Portuguese, we copy annotations from *de* and *a* to the contracted word form *da*). We use the UD train split to train a probe for each attribute, the validation split to choose which dimensions to select using our greedy scheme, and the test split to evaluate the performance of the probe after dimension selection.

We do not include in our estimates any morphological attribute–value pairs with fewer than 100 word types in *any* of our splits, as we might not be able to model or evaluate them accurately. This removes certain constructions that mostly pertain to function words (e.g. as definiteness is marked only in articles in Portuguese, the attribute is dropped), but we found it also removed rare inflected forms in our data, which may be due to inherent biases in the domain of text found in the treebanks (e.g. the future tense in Spanish). We use all the words that have been tagged in one of the filtered attribute–value pairs (this includes both function and content words). Finally, we apply some minor post-processing to the annotations (App. C).

Word Representations. We probe the multilingual fastText vectors,[13] and the final layer of the multilingual release of BERT.[14] We compute word-level embeddings for BERT by averaging over sub-token representations as in Pimentel et al. (2020b). We use the tokenization in the UD treebanks.

Hyperparameters. Our model has four hyperparameters, which control the Gaussian–inverse-Wishart prior. We choose hyperparameter settings that have been shown to work well in the literature (Fraley and Raftery, 2007; Murphy, 2012). We set $\boldsymbol{\mu}_0$ to the empirical mean, Λ_0 to a diagonalized version of the empirical covariance, $\nu_0 = d + 2$, and $k_0 = 0.01$. We note that the resulting prior is degenerate if the data contains only one datapoint, since the covariance is not well-defined. However, since we do not consider attribute–values with less that 100 word types, this does not affect our experiments.

6 Results and Discussion

Overall, our results strongly suggest that morphosyntactic information tends to be highly focal

---

[11] Log-likelihood, unlike accuracy, is sensitive to confident but incorrect estimates. We found that this change allowed us to keep selecting dimensions that increase accuracy but decrease log-likelihood, as they may be informative but contain some noise or outliers.

[12] Out of a total of 419943 sentences in the treebanks, 4 were removed.

[13] We use the implementation by Grave et al. (2018).

[14] We use the implementation by Wolf et al. (2020).

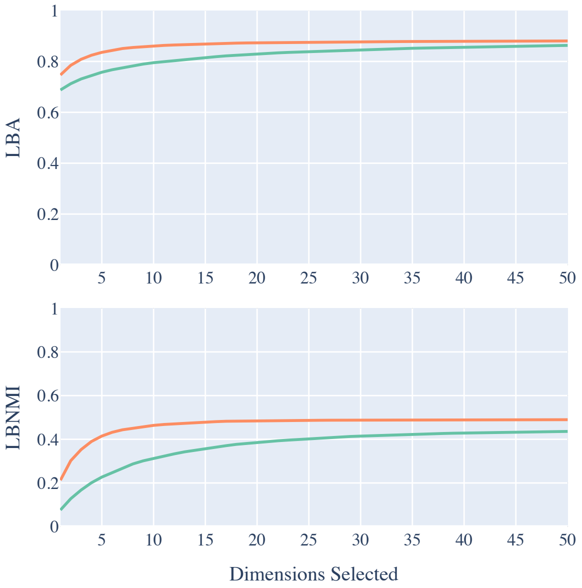

Figure 2: The average lower-bound accuracy (LBA) and lower-bound normalized mutual information (LBNMI) across all evaluated attributes and languages for fastText and BERT.

(concentrated in a small set of dimensions) in fastText, whereas in BERT it is more dispersed. Averaging across all languages and attributes (Fig. 2), fastText has on average 0.306 LBNMI at two dimensions, which is around twice as much as BERT at the same dimensionality. However, the difference between the two becomes progressively smaller, reducing to 0.053 at 50 dimensions. A similar trend holds for LBA (§4.1), with an even smaller difference at higher dimensions. On the whole, roughly 10 dimensions are required to encode any morphosyntactic attribute we probed fastText for, compared to around 35 dimensions for BERT.

The pattern above holds across attributes (Fig. 3), and languages (Fig. 4). There is little improvement in fastText performance when adding more than 10 dimensions and, in some cases, two fastText dimensions can explain half of the information achieved when selecting 50. In contrast, while BERT also displays highly informative dimensions, a substantial increase in LBNMI can be obtained by going from 2 selected dimensions to 10 and 50. Among languages, the only exceptions to this are the Indic languages, where BERT concentrates more morphological information than fastText already at 2 dimensions. Interestingly, when looking at attributes, our results suggest that fastText encodes most attributes better than BERT (when considering the

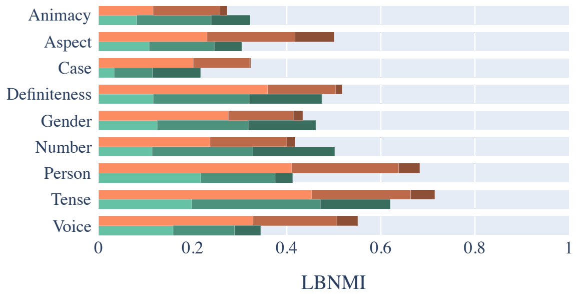

Figure 3: Comparison of per-attribute average lower-bound normalized mutual information (LBNMI) for fastText and BERT. Each bar is broken up into three components, which denote the LBNMI after selecting 2, 10 and 50 dimensions.

50 most informative dimensions), except animacy, gender and number. These findings also hold for LBA, where we additionally find little to no gain when comparing LBA after 50 dimensions to accuracy on the full vector.

Visualizing the most informative dimensions for BERT and fastText may give some intuition for how this trend manifests. Fig. 5 shows a scatter plot of the two most informative dimensions selected by our probe for English tense in fastText and BERT. We observed similar patterns for other morphosyntactic attributes. Both embeddings have dimensions that induce some separability in English tense, but this is more pronounced in fastText than BERT. We cannot clearly plot more than two dimensions at a time, but based on the trend depicted in Fig. 2, we can intuit that BERT makes up for at least part of the gap by inducing more separability as dimensions are added.

6.1 Limitations

The generative nature of our probe means that adequately modeling the embedding distribution $p(\boldsymbol{h} \mid v)$ is of paramount importance. We choose a Gaussian model in order to assume as little as possible about the distribution of BERT and fastText embeddings; however, as one reviewer pointed out, the embedding distribution is unlikely to be Gaussian (see Fig. 6 for an example). This results in a looser bound on the mutual information for dimensions in which the Gaussian assumption does not hold, which leads to decreasing mutual information estimates after a certain number of dimensions are selected (see Fig. 7). As we compute and report an empirical lower-bound on the mutual information for any subset of dimensions (LBMI), we have evidence that there is *at least* that amount

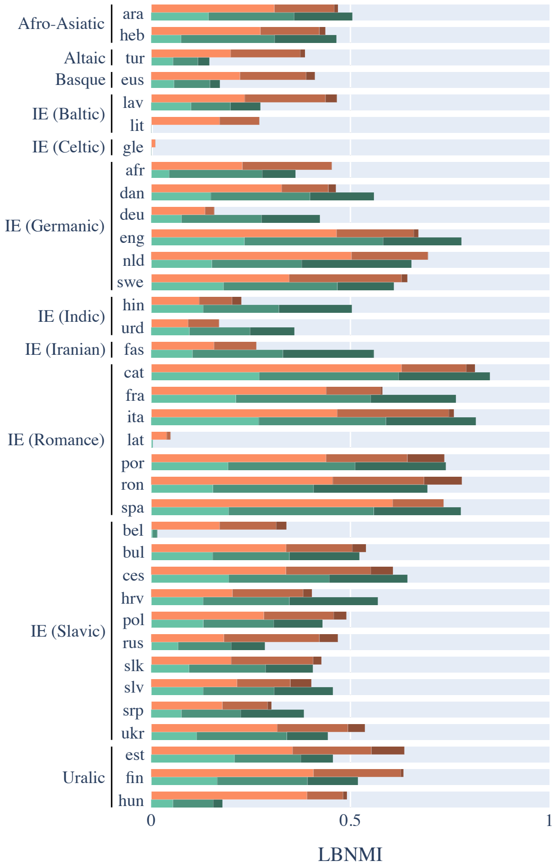

Figure 4: Comparison of per-language average lower-bound normalized mutual information (LBNMI) for fastText and BERT. Each bar is broken up into three components, which denote the LBNMI after selecting 2, 10 and 50 dimensions.

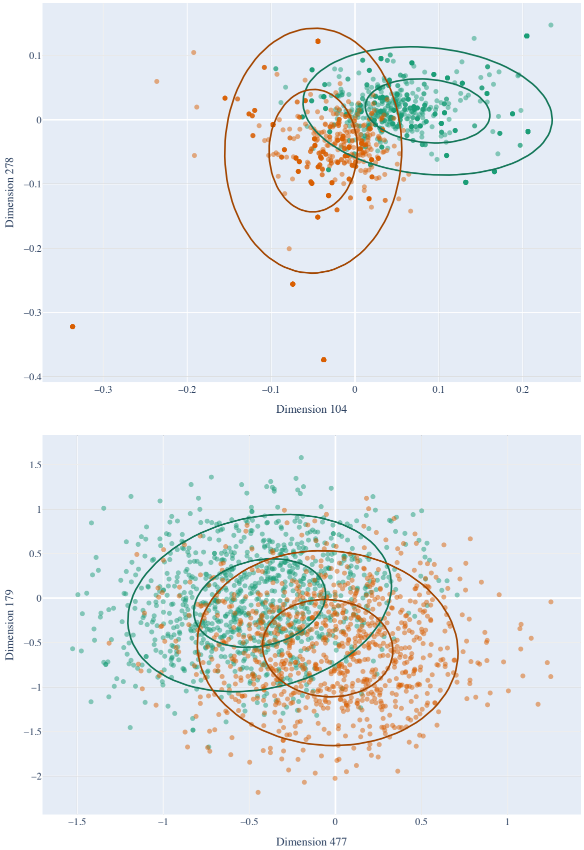

Figure 5: Scatter graph of two most informative fastText (above) and BERT (below) dimensions for English present and past tense. Contours belong to our probe.

of information for any given subset of dimensions. However, we expect that better modeling of the embedding distribution should improve our bound on the mutual information and thus yield a better probe (Pimentel et al., 2020b).

7 Related Work

There has been a growing interest in understanding what information is in NLP models' internal representations. Studies vary widely, from detailed analyses of particular scenarios and linguistic phenomena (Linzen et al., 2016; Gulordava et al., 2018; Ravfogel et al., 2018; Krasnowska-Kieraś and Wróblewska, 2019; Wallace et al., 2019; Warstadt et al., 2019; Sorodoc et al., 2020) to extensive investigations across a wealth of tasks (Tenney et al., 2018; Conneau et al., 2018; Liu et al., 2019). A plethora of methods have been designed and applied (e.g. Li et al., 2016; Saphra and Lopez, 2019; Jumelet et al., 2019) to answer this question. Probing (Adi et al., 2017; Hupkes et al., 2018; Conneau et al., 2018) is one prominent method, which consists of using a lightly parameterized model to predict linguistic phenomena from intermediate representations, albeit recent work has raised concerns on how model parameterization and evaluation metrics may affect the effectiveness of this approach (Hewitt and Liang, 2019; Pimentel et al., 2020b; Maudslay et al., 2020; Pimentel et al., 2020a).

Most work in intrinsic probing has focused in the identification of individual neurons that are important for a task (Li et al., 2016; Kádár et al., 2017; Li et al., 2017; Lakretz et al., 2019). Similarly, Clark et al. (2019) and Voita et al. (2019) use probing to analyze BERT's attention heads, finding some interpretable heads that attend to positional and syntactic features. However, there has also been some work investigating collections of neurons. For example, Shi et al. (2016) observe that different training objectives can affect how focal an intermediate representation is. Recently, Dalvi et al. (2019) use the magnitude of the weights learned by a linear probe as a proxy for dimension informativeness,

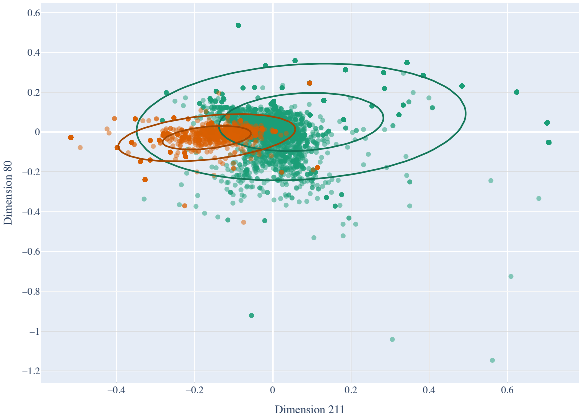

Figure 6: Two fastText dimensions that are informative for Portuguese number, but which do not appear jointly Gaussian. This dimensions pair was *not* favored by our Gaussian probing model; we found it by modeling $p(\boldsymbol{h} \mid v)$ with a Gaussian–Cauchy mixture model.

and find dispersion varies depending on linguistic category. Bau et al. (2019) use unsupervised methods to find neurons that are correlated across various models, quantify said correlation, and upon manual analysis find interpretable neurons. In concurrent work in computer vision, Bau et al. (2020) identify units whose local, peak activations correlate with features in an image (e.g., material, door presence), show that ablation of these units has a disproportionately big impact on the classification of their respective features, and can be manually controlled, with interpretable effects.

Most similar to our analysis is LINSPECTOR (Şahin et al., 2020), a suite of probing tasks that includes probing for morphosyntax. Our work differs in two respects. Firstly, whereas LINSPECTOR focuses on extrinsic probing, we probe intrinsically. Secondly, the scope of our morphosyntactic study is more typologically diverse (36 vs. 5 languages), albeit they consider more varieties of word representations, such as GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018)—but not BERT.

8 Conclusion

In this paper, we introduce an alternative framework for intrinsic probing, which we term dimension selection. The idea is to use probe performance on different subsets of dimensions as a gauge for how much information about a linguistic property different subsets of dimensions jointly encode. We show that current probes are unsuitable for intrinsic probing through dimension selection as they are not inherently decomposable, which is required to make the procedure computationally tractable. Therefore, we present a decomposable probe which is based on the Gaussian distribution, and evaluate its effectiveness by probing BERT and fastText for morphosyntax across 36 languages. Overall, we find that fastText is more focal than BERT, requiring fewer dimensions to capture most of the information pertaining to a morphosyntactic property.

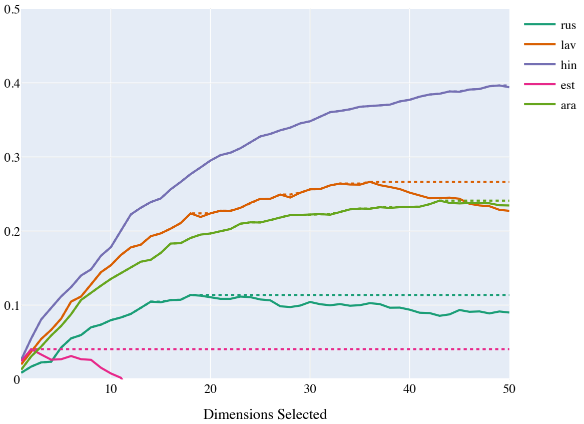

Figure 7: Plot of LBNMI (dotted) and normalized MI (solid) curves for case in 5 randomly selected languages. Note that the y-axis ranges from 0–0.5 unlike other graphs. Observe how the normalized MI estimates start to decrease after a certain number of dimension have been selected.

Future Work. Future work will be separated into two strands. The first will focus on how to better model the distribution of embeddings given a morphosyntactic attribute; as mentioned above, this should yield a better probe overall. The second strand of work pertains to a deeper analysis of our results, and expansion to other probing tasks.

A Gaussian–inverse-Wishart Posterior Parameters

Using the notation introduced in §3.4, the parameters of the Gaussian–inverse-Wishart distribution $\mathrm{GIW}(\boldsymbol{\mu}_v, \Sigma_v \mid \boldsymbol{\mu}_n, k_n, \Lambda_n, \nu_n)$, are (Murphy, 2012)

$$
\begin{aligned}
\boldsymbol{\mu}_n &= \frac{k_0 \boldsymbol{\mu}_0 + N_v \bar{\boldsymbol{h}}}{k_n} && (18)\\
k_n &= k_0 + N_v && (19)\\
\nu_n &= \nu_0 + N_v && (20)\\
\Lambda_n &= \Lambda_0 + S && (21)\\
&\quad + \frac{N_v k_0}{N_v + k_0}(\bar{\boldsymbol{h}} - \boldsymbol{\mu}_0)(\bar{\boldsymbol{h}} - \boldsymbol{\mu}_0)^\top
\end{aligned}
$$

where $\bar{\boldsymbol{h}}$ is the empirical mean of $\mathcal{D}^{(v)}$ and S is the scatter matrix

$$
S = \sum_{i=1}^{N_v} (\boldsymbol{h}^{(i)} - \bar{\boldsymbol{h}})(\boldsymbol{h}^{(i)} - \bar{\boldsymbol{h}})^\top \qquad (22)
$$

B Inverse-Wishart Distribution

The inverse-Wishart distribution is defined as (Murphy, 2007)

$$
\begin{aligned}
\mathrm{IW}(\Sigma \mid \Lambda^{-1}, \nu) &= \frac{1}{Z} |\Sigma|^{-\frac{\nu+d+1}{2}}\\
&\times \exp\left(-\frac{1}{2}\mathrm{Tr}(\Lambda \Sigma^{-1})\right) \qquad (23)
\end{aligned}
$$

where

$$
Z = \frac{|\Lambda|^{\frac{\nu}{2}}}{2^{\frac{\nu d}{2}} \Gamma_d(\frac{\nu}{2})} \qquad (24)
$$

where Σ is a positive-definite $d \times d$ matrix, and Γ_d is the multivariate Gamma function.

C Changes to UD Annotations

We apply some post-processing to canonicalize the automatically-converted UniMorph annotations. The changes we make are:

1. We remove any annotations with disjunctions. These constitute a minority of annotations, and handling them adequately requires language-specific knowledge.
2. We fix some annotations that we believe are typos, e.g. replace "{CMPR}" with "CMPR".
3. We let "PST+PRF" be a Tense annotation. This is a recurrent annotation in Latin, Romanian and Turkish.

4. We canonicalize conjunctive features by sorting them alphabetically, ensuring they all belong to the same morphological attribute, and joining them into a new feature. So the annotation “MASC+FEM” becomes “FEM+MASC”.
5. We discard language-specific annotations as this is not a canonical UniMorph dimension.

D Mutual Information Approximation

Let V_a be a $\mathcal{V}_a$-valued random variable denoting the value of a morphosyntactic attribute, and H be a $\mathbb{R}^d$-valued random variable for the word representation. The mutual information between V_a and H is

$$\mathrm{MI}(V_a; H) = \mathrm{H}(V_a) - \mathrm{H}(V_a \mid H) \tag{25}$$

To compute the entropy $\mathrm{H}(V_a)$, we would ideally need the true attribute distribution $\overline{p}(v)$ for a language. We can empirically approximate it using $p(v)$, which has been computed from held-out data

$$\mathrm{H}(V_a) = \sum_{v \in \mathcal{V}_a} \overline{p}(v) \log_2 \frac{1}{\overline{p}(v)} \tag{26}$$

$$\approx \sum_{v \in \mathcal{V}_a} p(v) \log_2 \frac{1}{p(v)} \tag{27}$$

Computing $\mathrm{H}(V_a \mid H)$ is trickier as it relies on the true distribution of the representations for a value, $\overline{p}(\boldsymbol{h} \mid v)$, which is hard to estimate as it is high-dimensional and poorly sampled in our data.

$$\begin{aligned} &\mathrm{H}(V_a \mid H) && (28)\\ &= \int \sum_{v \in \mathcal{V}_a} \overline{p}(v, \boldsymbol{h}) \log_2 \frac{1}{\overline{p}(v \mid \boldsymbol{h})} \, \mathrm{d}\boldsymbol{h} \\ &= \sum_{v \in \mathcal{V}_a} \overline{p}(v) \int \overline{p}(\boldsymbol{h} \mid v) \log_2 \frac{1}{\overline{p}(v \mid \boldsymbol{h})} \, \mathrm{d}\boldsymbol{h} \end{aligned}$$

Note that by using an approximation $\overline{p}(v \mid \boldsymbol{h}) \approx p(v \mid \boldsymbol{h})$ instead (a.k.a. our probe), we obtain an upper bound on the true conditional entropy (Brown et al., 1992)

$$\begin{aligned} &\mathrm{H}(V_a \mid H) \leq \mathrm{H}_p(V_a \mid H) && (29)\\ &= \sum_{v \in \mathcal{V}_a} \overline{p}(v) \underbrace{\int \overline{p}(\boldsymbol{h} \mid v) \log_2 \frac{1}{p(v \mid \boldsymbol{h})} \, \mathrm{d}\boldsymbol{h}}_{I_v} \end{aligned}$$

While $\overline{p}(v) \approx p(v)$ should be reasonable for our purposes, the integral I_v is intractable as it still depends on $\overline{p}(\boldsymbol{h} \mid v)$. However, we can use held-out data to approximate I_v (Pimentel et al., 2019)

$$I_v = -\int \overline{p}(\boldsymbol{h} \mid v) \log_2 p(v \mid \boldsymbol{h}) \, \mathrm{d}\boldsymbol{h} \tag{30}$$

$$\approx -\frac{1}{N_v} \sum_{i=1}^{N_v} \log_2 p(v \mid \tilde{\boldsymbol{h}}^{(i)}) \tag{31}$$

where $\{\tilde{\boldsymbol{h}}^{(i)}\}_{i=1}^{N_v}$ are held-out word representations for a value v, and thus obtain an empirical upper-bound on $\mathrm{H}(V_a \mid H)$.

E Reproducibility Details

All experiments were run on an AWS `p2.xlarge` instance, with 1 Tesla K80 GPU, 4 CPU cores, and 61 GB of RAM. The total runtime of the experiments was 2 days, 18 hours, 42 minutes and 14 seconds.

In total, when considering a d-dimensional word representation, this model has

$$\underbrace{|\mathcal{V}_a| \left(\frac{d(d+1)}{2} + d \right)}_{\text{Gaussians}} + \underbrace{(|\mathcal{V}_a| - 1)}_{\text{Categorical}} \tag{32}$$

parameters. In practice, this means that for every value, a fastText Gaussian we fit has 45450 parameters, whereas a BERT Gaussian has 296064 parameters.

F Probed Attributes by Language

Tab. 1 shows a list of all languages that were probed, which attributes were probed, and which values were considered. The number of example words for a value in the train/validation/test split is shown in parenthesis.

Table 1: Table of attributes that were probed for each language, and the values that were considered for that attribute. The number of example words for a value in the train/validation/test split is shown in parenthesis.

Learning Which Features Matter: RoBERTa Acquires a Preference for Linguistic Generalizations (Eventually)

Abstract

One reason pretraining on self-supervised linguistic tasks is effective is that it teaches models features that are helpful for language understanding. However, we want pretrained models to learn not only to represent linguistic features, but also to *use* those features preferentially during fine-turning. With this goal in mind, we introduce a new English-language diagnostic set called MSGS (the Mixed Signals Generalization Set), which consists of 20 ambiguous binary classification tasks that we use to test whether a pretrained model prefers linguistic or surface generalizations during fine-tuning. We pretrain RoBERTa models from scratch on quantities of data ranging from 1M to 1B words and compare their performance on MSGS to the publicly available RoBERTa$_{\text{BASE}}$. We find that models can learn to represent linguistic features with little pretraining data, but require far more data to learn to *prefer* linguistic generalizations over surface ones. Eventually, with about 30B words of pretraining data, RoBERTa$_{\text{BASE}}$ does demonstrate a linguistic bias with some regularity. We conclude that while self-supervised pretraining is an effective way to learn helpful inductive biases, there is likely room to improve the rate at which models learn which features matter.

1 Introduction

Self-supervised pretraining through language modeling on massive datasets has revolutionized NLP. One reason this method works is that pretraining shapes a model's hypothesis space, giving it inductive biases that help it learn linguistic tasks (Howard and Ruder, 2018). Numerous probing studies have provided support for this idea by showing that language models learn representations that encode linguistic features (Gulordava et al., 2019; Tenney et al., 2019; Hewitt and Manning, 2019).

However, feature learning is just the first step to acquiring helpful inductive biases. Models must also be able to learn which features matter. The NLU datasets these models are often fine-tuned on are ambiguous and contain artifacts, and often support multiple possible generalizations. Neural networks are not mind readers: Models that have been shown to represent linguistic features sometimes fail to use them during fine-tuning on NLU tasks, instead adopting shallow surface generalizations (Jia and Liang, 2017; McCoy et al., 2019). To this end, recent work in probing pretrained models advocates for shifting the focus of study away from whether they represent linguistic features and in favor of whether they learn *useful* representations of those features (Voita and Titov, 2020; Pimentel et al., 2020; Elazar et al., 2020).

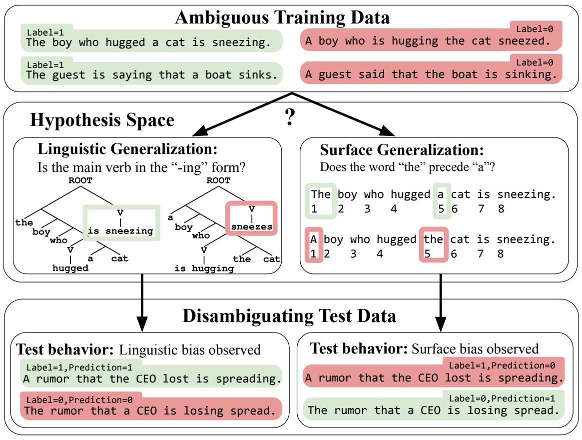

Figure 1: Example of an ambiguous experiment (without inoculation). A model is trained on ambiguous data whose labels are consistent with either a linguistic or a surface generalization, and tested on disambiguating data whose labels support only the linguistic generalization. Light green and dark red shading represents data or features associated with the positive and negative labels/predictions, respectively.

We investigate how RoBERTa (Liu et al., 2019b) acquires language-specific inductive biases during self-supervised pretraining. We track separately

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 217–235,
November 16–20, 2020.

	Feature type	Feature description	Positive example	Negative example
Surface	Absolute position	Is the first token of S "the"?	The cat chased a mouse.	A cat chased a mouse.
	Length	Is S longer than n (e.g., 3) words?	The cat chased a mouse.	The cat meowed.
	Lexical content	Does S contain "the"?	That cat chased the mouse.	That cat chased a mouse.
	Relative position	Does "the" precede "a"?	The cat chased a mouse.	A cat chased the mouse.
	Orthography	Does S appear in title case?	The Cat Chased a Mouse.	The cat chased a mouse.
Linguistic	Morphology	Does S have an irregular past verb?	The cats slept.	The cats meow.
	Syn. category	Does S have an adjective?	Lincoln was tall.	Lincoln was president.
	Syn. construction	Is S the control construction?	Sue is eager to sleep.	Sue is likely to sleep.
	Syn. position	Is the main verb in "ing" form?	Cats who eat mice are purring.	Cats who are eating mice purr.

Table 1: Schematic examples of the linguistic and surface features in our experiments.

how RoBERTa's representation of linguistic features and its preferences for linguistic generalizations over surface generalizations change as the amount of pretraining data increases. We pretrain RoBERTa from scratch on datasets ranging from 1M to 1B words and evaluate these models alongside RoBERTa$_{\text{BASE}}$ in a series of experiments to probe the inductive biases of a pretrained model at the time of fine-tuning on a downstream task.

We probe these models in three kinds of experiments: First, we conduct *control* experiments where we fine-tune models on unambiguous binary classification tasks to test whether they learn to represent simple linguistic and surface features. Second, we conduct *ambiguous* experiments following the *poverty of the stimulus* design (Wilson, 2006), as illustrated in Figure 1. In these experiments, we fine-tune a pretrained model on an ambiguous binary classification task in which the training set is consistent with both a linguistic generalization and a surface one. We then test the classifier on disambiguating data to reveal which generalization the model adopted, and by extension its preference among the two features. Third, we conduct *inoculation* experiments (following Liu et al., 2019a) to test how hard it is to sway a model with a surface bias to adopt a linguistic generalization. We do this by introducing small amounts of disambiguating data into an otherwise ambiguous training set. We automatically generate data for all these tasks, and call the resulting dataset MSGS (Mixed Signals Generalization Set), pronounced "messages".

The results show that RoBERTa acquires a stronger linguistic bias as pretraining increases. RoBERTa$_{\text{BASE}}$ has the strongest linguistic bias, and requires little to no inoculating data to reliably make the linguistic generalization. In general, models with more pretraining data can generally be induced to adopt linguistic generalizations with less inoculating data. We also find a large gap between the amount of pretraining data that RoBERTa needs to learn the linguistic features necessary to generalize out-of-domain and the amount it needs to learns that it should *prefer* those features when generalizing. The control experiments on unambiguous data reveal that models with little pretraining do actually represent the linguistic features, but nonetheless show a strong surface bias. In other words, the main contribution of pretraining to linguistic bias learning is devoted not to extracting features, but to learning which features matter.

We conclude that helpful inductive biases can be learned through pretraining, but current models require abundant data to do so. The implications of this conclusion point in two directions: First, we can probably continue to pretrain on increasingly massive training sets to improve on the generalization and few-shot learning abilities of models like T5 (Raffel et al., 2019) and GPT-3 (Brown et al., 2020). Second, since models learn useful features early, there is hope that future advances could accelerate by reducing the amount of data needed to learn which features matter. To aid in this effort, we release the MSGS dataset, our pretrained RoBERTas, and all our code: `https://github.com/nyu-mll/msgs`.

2 Inductive Bias

Background: Learning Inductive Bias Any finite set of training examples shown to a learning algorithm like a neural network is consistent with infinitely many generalizable decision functions. Inductive biases are a learner's preferences among these functions. An inductive bias can eliminate certain possible functions altogether, or result in a preference for some over others (Haussler, 1988). For instance, an RNN classifier is capable of representing *any* function, but prefers ones that focus mostly on local relationships within the input sequence (Dhingra et al., 2018; Ravfogel et al., 2019).

Some recent work seeks to design neural architectures that build in desirable inductive biases (Dyer et al., 2016; Battaglia et al., 2018), or compares the immutable biases of different architectures (McCoy et al., 2020; Hu et al., 2020). However, inductive biases can also be *learned* by biological (Harlow, 1949) and artificial systems alike (Lake et al., 2017). In the language model finetuning paradigm proposed by Howard and Ruder (2018) and popularized by models such as BERT (Devlin et al., 2019), a pretrained neural network plays the role of the learner. Pretraining adjusts a model's weights so that it will navigate the hypothesis space during training on a downstream task more effectively than a randomly initialized model.

There is a difference between learning to extract a linguistic feature and acquiring a bias towards using it when generalizing. There is ample evidence that BERT encodes features such as syntactic category and constituency (Tenney et al., 2019; Clark et al., 2019; Hewitt and Manning, 2019). The acquisition of linguistic features is a *prerequisite* for a linguistic bias. However, these findings do not tell us if the model will make use of these features to form generalizations during target task training, or if it will fall back on surface features that account for most of the data.

Methods: Measuring Inductive Bias We conduct three kinds of experiments to probe a model's preference for linguistic or surface generalizations: unambiguous control experiments, fully ambiguous experiments, and partially ambiguous inoculation experiments. Figure 1 gives an overview of the ambiguous experiment design.

First, it only makes sense to compare a model's preference between two features if it actually represents both features. This is the goal behind *control experiments*, in which we fine-tune RoBERTa to classify sentences based on a single linguistic or surface feature in a totally unambiguous setting.

Second, we conduct *ambiguous experiments* on models that pass the controls. We fine-tune a pretrained model on a binary sentence classification task using *ambiguous* data, which equally supports both a simple linguistic generalization and a simple surface one. For example, Figure 1 shows a linguistic task where sentences in the positive class are defined by having a main verb in the "ing" form. We make the training data ambiguous by introducing a surface feature that distinguishes the two classes: In all (and only) training examples with label 1, the word "the" precedes the word "a". Based on this training data, a model could reasonably adopt either a linguistic generalization or a surface one.

We then test the classifier on disambiguating data to observe which generalization it made. In this kind of data, the labels align with the linguistic generalization, and contradict the surface one: For example, in Figure 1, "a" now always precedes "the" in the positive test examples with label 1. We quantify a model's inductive bias using a metric we call the *linguistic bias score* (LBS). We define LBS as the Matthews correlation between the model predictions and the labels on the disambiguating test set (Matthews, 1975). If LBS is 1, the learner shows a systematic linguistic bias. If LBS is -1, it shows a systematic surface bias. If LBS is 0, it shows neither bias.

Finally, while the fully ambiguous experiments probe models' biases in an idealized setting, training data in more naturalistic contexts often does contain some evidence supporting a linguistic generalization over a simple surface one. To simulate this, we also conduct a series of *inoculation experiments* (following Liu et al., 2019a), in which we introduce small amounts of disambiguating data into an otherwise ambiguous training set. For each experiment, we replace 0.1%, 0.3%, or 1% of the training data with examples that support the linguistic generalization and contradict the surface one. These experiments allow us to compare the strength of linguistic bias in models that show an overall surface bias: If two models adopt the surface generalization in the fully ambiguous case, we can still say that one has a stronger linguistic bias than the other if it requires less inoculation data to be swayed towards the linguistic generalization.

3 Evaluation Data

We introduce MSGS (Mixed Signals Generalization Set), pronounced "messages", a dataset we design to be used in poverty of the stimulus and inoculation experiments. With the goal of contrasting inductive biases that are helpful and harmful in most NLP applications, the tasks in MSGS test a model's preferences for generalizations based on linguistic or surface features.

Features under Study Table 3 illustrates the 4 linguistic features and 5 surface features we con-

Dom.	Split	L_L	L_S	Sentence
In	Train (Ambiguous)	1	1	These men weren't hating that this person who sang tunes destroyed the vase.
		0	0	These men hated that this person who sang tunes was destroying some vase.
	Inoc. (Disamb.)	1	0	These men weren't hating that this person who sang tunes destroyed some vase.
		0	1	These men hated that this person who sang tunes was destroying the vase.
Out	Test (Disamb.)	1	0	These reports that all students built that school were impressing some children.
		0	1	These reports that all students were building the school had impressed some children.
	Aux. (Ambiguous)	1	1	These reports that all students built the school were impressing some children.
		0	0	These reports that all students were building that school had impressed some children.

Table 2: A full paradigm from the SYNTACTIC POSITION × LEXICAL CONTENT task. $\mathbf{L_L}$ and $\mathbf{L_S}$ mark the presence of the linguistic feature (*Is the main verb in the "ing" form?*) and surface feature (*Does S contain "the"?*), respectively. *Dom.* is short for *domain*.

sider.[1] Each feature is meant to be representative of a broad category of features (e.g. morphological features), though the precise implementation of each feature is necessarily much narrower (e.g. *Does the sentence have an irregular past verb?*). Forming generalizations based on surface features entails knowledge of the identity of certain words (in our case, only "the" and "a"), the positional indices of words in the string, the total number of words in a string, or whether certain characters are lowercase or uppercase.[2] Forming generalizations based on linguistic features requires more abstract knowledge of tense and inflectional morphemes, parts of speech, the control construction,[3] and hierarchical syntactic structures, none of which are encoded in the surface string.

Dataset Structure MSGS contains 20 ambiguous binary classification tasks each gotten by pairing one of 4 linguistic features with one of 5 surface features. We write $\text{FEAT}_1 \times \text{FEAT}_2$ to denote a task that combines features FEAT_1 and FEAT_2. Each ambiguous dataset contains 50k sentences split into training, evaluation, and inoculation sets. MSGS also includes 9 unambiguous *control tasks*—one for each feature. Each control dataset contains 30k sentences split into training and evaluation sets.

For ambiguous tasks, we generate data in paradigms of 8 sentences following a 2 × 2 × 2 design, as shown in Table 2. We vary the following three features: a binary linguistic feature, a binary surface feature, and the domain from which the sentence is sampled. We generate in-domain and out-of-domain sentences from different templates (see §3:Data Generation for more detail).

As shown in Table 2, we split the data into four contrasting pairs with different purposes: (1) *Training data* is ambiguous in-domain data makes up 99% to 100% of the training set. (2) *Inoculating data* is disambiguating in-domain data which makes up 0.1% to 1% of the training set in experiments with inoculation. We show the classifier only the linguistic label ($\mathbf{L_L}$) to nudge it towards adopting a linguistic generalization. (3) *Test data* is disambiguating out-of-domain data used to test whether the model adopted the linguistic or surface generalization. (4) *Auxiliary data* is ambiguous out-of-domain data used to test how well the model adapts to the out-of-domain templates, regardless of which generalization it makes.

For control tasks, we generate data in paradigms of 4 sentences following a 2 × 2 design by varying the feature and domain. We use control tasks to test whether each pretrained model represents each feature well enough to fine-tune an effective classifier in an unambiguous setting.

Data Generation The data is generated from templates using a generation toolkit from Warstadt et al. (2020). This toolkit includes a vocabulary of over 3000 entries labeled with grammatical fea-

---

[1] We explored a slightly larger set of linguistic features and excluded several based on initial experiments showing our models did not encode them. For example, we constructed a task with the objective of identifying sentences that contain antonyms (e.g. *The little girl likes the big dog.*), but found that only $\text{RoBERTa}_{\text{BASE}}$ could solve the unambiguous control task.

[2] Although these are surface properties of the string, they are not all trivial for RoBERTa due to its subword tokenization.

[3] The *control construction* is a syntactic construction in which a semantic argument of a predicate fills or *controls* an argument slot of an embedded verb. The *raising construction* is superficially similar, but the filler of the embedded argument slot is not a *semantic* argument of the main predicate (Sag et al., 2003). For instance, *Sue is eager to sleep* is an example of control because the NP *Sue* is the semantic subject of both *eager* and *sleep*. By contrast, *Sue is likely to sleep* is an example of raising because *Sue* is the semantic subject of *sleep*, but not of *likely*. These two phenomena have different syntactic derivations in some theories (Chomsky, 1981).

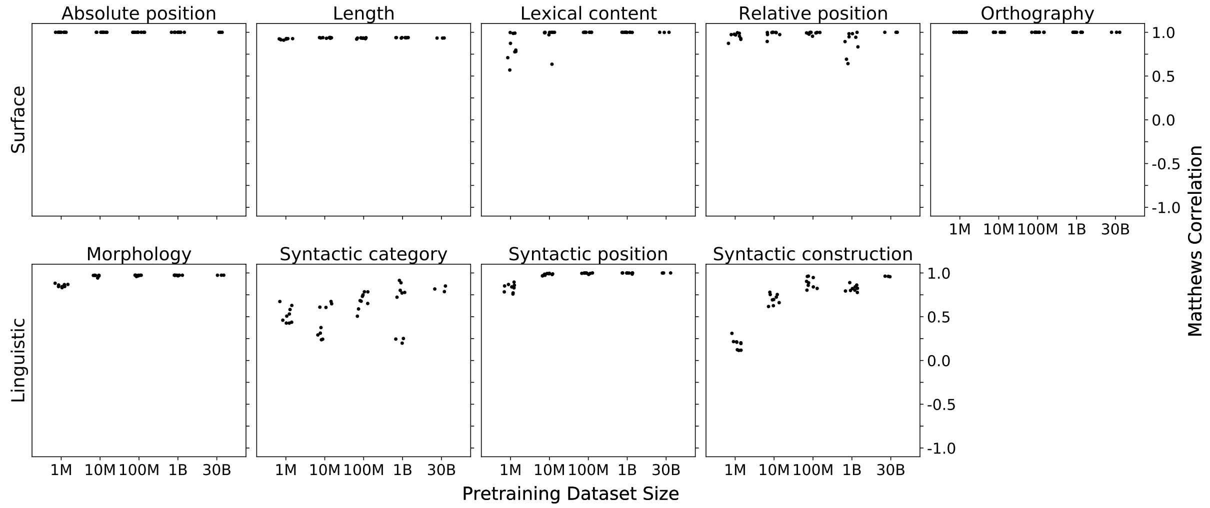

Figure 2: Results on the main experiments measured in Matthews correlation for the surface control tasks (top) and linguistic control tasks (bottom). Note: For surface tasks a positive score represents a surface generalization.

tures that allow for lexical variation in the data while maintaining grammatical well-formedness. Although generated sentences often describe unlikely or implausible scenarios (e.g., *The lawyer was sinking all canoes*), semantic plausibility is independent of all the features we examine, so this should not affect a model that genuinely encodes these features. To prevent out-of-vocabulary tokens affecting our results, we ensure that every word stem in the vocabulary appears in the pretraining datasets for our RoBERTa models (see §4.1).

Our experimental logic only makes sense if we are reasonably confident that models can only achieve high test performance by genuinely adopting a linguistic generalization. However, training models on generated data can easily lead to overfitting, and classifiers trained and tested on data from the same domain can achieve perfect performance even on arbitrary tasks with random labels (Hewitt and Liang, 2019). For this reason, our primary evaluations test models' ability to *generalize* out-of-domain. We manipulate domain in two ways:

First, we generate training data and test data for each dataset from separate in-domain and out-of-domain templates. Thus a model cannot succeed at test time simply by recognizing a template or a key part of a template. For example, in the SYNTACTIC POSITION × LEXICAL CONTENT paradigm shown in Table 2, the in-domain data contrasts the main verb with a verb in a relative clause embedded in the complement clause of a verb; while the out-of-domain data contrasts the main verb with a verb in the complement clause of a noun. In most tasks, each domain itself is generated from multiple templates as well to widen the domain and encourage better generalization during training.

Second, on tasks that test lexical knowledge (for instance, the knowledge that *slept* is an irregular past verb and *meow* is not), we divide the crucial lexical items into in-domain and out-of-domain sets. Thus, a model cannot succeed by memorizing the keywords associated with each class. See the Appendix for a more detailed description of the implementation details for each feature.

4 Models, Pretraining, & Fine-Tuning

We test 13 RoBERTa models in our main experiments: We pretrain 12 from scratch, and also test RoBERTa$_{\text{BASE}}$ pretrained by Liu et al. (2019b).

4.1 Pretraining

Pretraining Data We pretrain RoBERTa using scaled-down recreations of the dataset used by Devlin et al. (2019) to train BERT, i.e English Wikipedia (2.5 billion tokens) and BookCorpus (800 million tokens). Both are included in the RoBERTa pretraining data.[4] We download the latest Wikipedia dump as of Feb 1, 2020. The original BookCorpus (Zhu et al., 2015) is no longer available, so we collect similar data from Smashwords, the original source of BookCorpus.[5]

---

[4] RoBERTa uses English Wikipedia, BookCorpus, CC-News, OpenWebText, and STORIES in pretraining.

[5] We collect our data using the Wikipedia XML dump https://dumps.wikimedia.org/mirrors.html and data-processing code https://github.com/attardi/wikiextractor, and a Smashwords crawler https://github.com/soskek/bookcorpus.

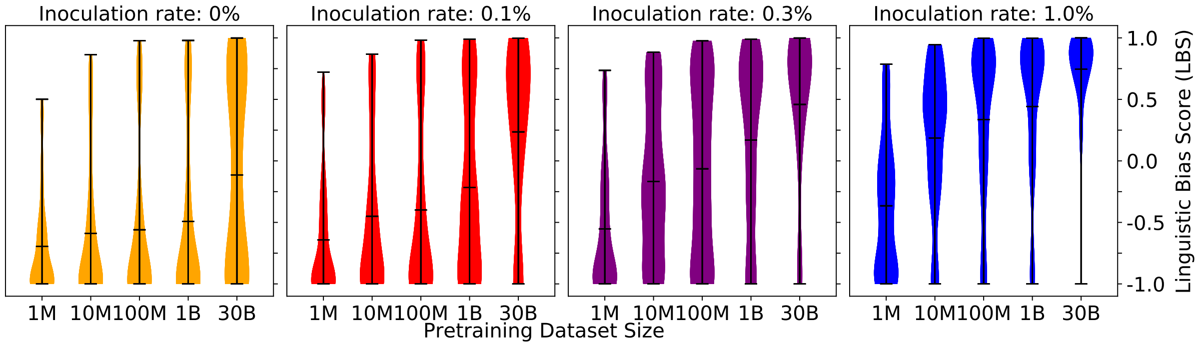

Figure 3: Results measured in LBS for each pretraining and inoculating data amount, aggregated over the 20 tasks in MSGS. We exclude models that fail the corresponding controls, as described in Section 5. High density near LBS of 1 means many models in that group have a linguistic bias; high density near -1 means many models have a surface bias. Models with stronger linguistic bias achieve higher LBS with less inoculation data.

We pretrain RoBERTa on four training sets containing different numbers of words: 1M, 10M, 100M, and 1B.[6] To make these datasets, we sample entire Wikipedia articles and Smashwords books independently, keeping the proportions of Wikipedia and Smashwords text approximately constant.

Model Sizes Model size is the only hyperparameter we systematically search over during pretraining. We consider smaller model sizes to prevent overfitting on small training sets. The detailed configurations of the model sizes are summarized in the Appendix. We use RoBERTa$_{\text{BASE}}$ from Liu et al. (2019b) as our largest model size. The other configurations represent a scale roughly based on settings used in Sanh et al. (2019), Vaswani et al. (2017), Jiao et al. (2019), and Tsai et al. (2019).

Search Range For dropout, attention dropout, learning rate decay, weight decay and the Adam parameters, we adopt the same parameter values used in Liu et al. (2019b). We fix warm up steps to be 6% of max steps, peak learning rate to be 5e-4, early stopping patience to be 100M tokens, and heuristically define the search range of model size, max steps and batch size for each training set.

Search Results We randomly sample hyperparameters from the search range and train 25 models for each of the 1M, 10M, 100M datasets. We train 10 models on the largest (1B) dataset due to resource limitations. For each training set size, we choose three of the resulting models to evaluate. In order to avoid confounds caused by different model sizes, for each training set we choose three models of the same size that have the lowest perplexity. The hyperparameters and validation perplexities of the selected models are listed in the Appendix.

4.2 Fine-Tuning

We loosely follow the hyperparameter settings that Liu et al. (2019b) used for fine-tuning on GLUE tasks (Wang et al., 2018), and use the following learning rates: {1E-5, 2E-5, 3E-5}. We depart from Liu et al. in using a batch size of 16 and training for 5 epochs without early-stopping in all runs. These changes are based on pilots that showed that larger batch sizes and longer fine-tuning were no more effective for our tasks.

We conduct 3,471 fine-tuning runs: We fine-tune 13 RoBERTa models: (3 random initializations) × (4 pretraining data amounts) + (1 RoBERTa$_{\text{base}}$). We fine-tune each model 267 times: (3 learning rates) × ((9 control tasks) + (20 ambiguous tasks) × (4 inoculation amounts)). We evaluate model performance using LBS (see §2:Methods: Measuring Inductive Bias).

5 Results & Discussion

We have several main findings: (1) models learn to *represent* both surface features and linguistic features with relatively little data; (2) RoBERTa begins to acquire a linguistic bias with over 1B words of pretraining data; (3) increasing pretraining data strengthens linguistic bias; (4) there is considerable variation in models' preferences between specific pairs of linguistic and surface features.

Control results Figure 2 shows the results for the controls. Performance is near ceiling for most models and features. Because we evaluate all the

---

[6] The publicly available RoBERTa$_{\text{BASE}}$ is trained on 160GB of data, which we estimate to be about 30B words.

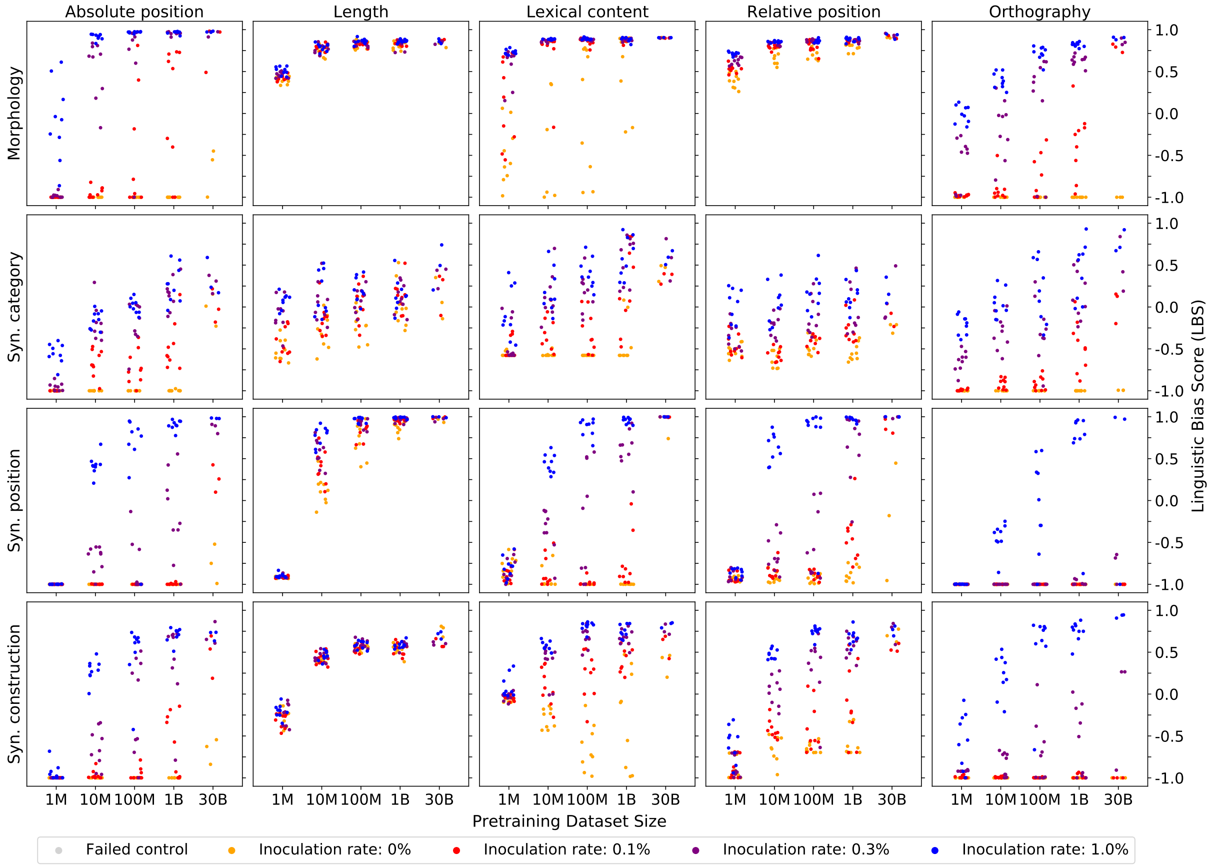

Figure 4: Results of the ambiguous binary classification tasks measured in LBS for every (linguistic feature, surface feature) pair. Each plot in the matrix shows the results on the disambiguating test items after training on an ambiguous task. All experiments on the same row investigate the same linguistic feature; all experiments on the same column investigate the same surface feature. Each data point represents one run. The x-axis of the point is the pretraining size of the model, and the y-axis is its LBS. Models with stronger linguistic bias achieve higher LBS with less inoculation data. Gray points show runs where the corresponding controls did not pass. A black-and-white version of this figure separating color channels into separate plots, can be found in the Appendix.

models out-of-domain, this result cannot be explained by the models simply memorizing the features from the task training data. Thus, we conclude that most pretrained models we test encode both linguistic and surface features.

The only exceptions are the syntactic category and syntactic construction features, for which models with less than 100M perform poorly. In subsequent plots, we filter out results where the controls are not passed. Specifically, if a particular combination of model checkpoint and learning rate achieves a Matthews correlation of less than 0.7 on the control task for feature F, we eliminate all results with this combination for any task involving F in Figure 3, or represent them as gray points in Figure 4.

Main Experiment Results Figure 3 summarizes the main experiment results. For a given amount of pretraining and inoculation data, we consider all classifiers trained on all 20 tasks in MSGS and plot the density of their linguistic bias scores (LBSs).

The results in the leftmost box (with 0% inoculation) show that only RoBERTa$_{\text{BASE}}$ demonstrates a consistent linguistic bias in the fully unambiguous setting. That said, it still adopts the surface bias much of the time. The other models show a clear surface bias overall. The results of experiments with inoculation data show that models with more pretraining data require less inoculation data to be swayed towards the linguistic generalization. We consistently observe, for each pretraining quantity, a phase transition where the linguistic generalization begins to overtake the surface generalization upon exposure to a certain amount of inoculating data. For example, the 1B model goes through this transition between 0.1% and 0.3% inoculating data. The 100M and 10M models go through this transition between 0.3% and 1% inoculating data. The phase transition comes earlier for models with more pretraining, indicating they have a stronger linguistic bias. We also notice distinctive behavior for the models at the extreme ends of pretraining data quantity: The 1M model never completes the transition, suggesting it has a strong surface bias, and RoBERTa$_{\text{BASE}}$ appears to be in the middle of this transition with 0% inoculating data, suggesting that even more pretraining data could produce a model with a more consistent linguistic bias.

These findings are echoed in individual task results in Figure 4.[7] In each plot, models with the same amount of inoculation data (i.e. points with a given color) have higher LBS as the amount of pretraining data increases. Notably, on ambiguous tasks involving LEXICAL CONTENT, RoBERTa$_{\text{BASE}}$ usually favors generalizations based on linguistic features without any inoculating data, which no other pretrained model does. We find this result quite striking: Even if the labels are perfectly correlated with the presence or absence of the word "the", RoBERTa$_{\text{BASE}}$ overlooks that fact in favor of a deeper generalization based on an abstract feature like the inflectional form of a verb in a particular syntactic position. Furthermore, this preference is clearly *acquired* through additional pretraining. The results for MORPHOLOGY × ORTHOGRAPHY is a typical illustration of the differences between models. The 1M model never adopts the linguistic generalization based on the morphological feature, though it eventually rejects the surface generalization. The 100M and 1B models make robust linguistic generalizations only with 1.0% inoculating data. By contrast, RoBERTa$_{\text{BASE}}$ requires only 0.1% inoculating data (i.e. 10 out of 10k examples) to adopt the linguistic generalization.

Surface Biases of RoBERTa Our results also suggest some specific conclusions about which kinds of surface features RoBERTa pays attention to.[8] For instance, these models have little preference for sentence length. As shown in the second column of Figure 4, most of the models form linguistic generalizations rather than generalizations based on sentence length, even with no inoculating data. By contrast, the models strongly prefer generalizations based on orthography—and to a lesser extent lexical content and word order—over linguistic generalizations.

The Success of Pretrained Models Our findings provide insight into why pretraining on massive datasets is so successful. While linguistic feature learning is a major effect of pretraining, it is far from the end of the story: Pretraining also helps models learn which features are central to language. However, this second kind of learning seems to require far more exposure to data with current models and pretraining techniques. Therefore, massive datasets are needed to teach models which features are useful for generalizing.

The data scale at which we observe RoBERTa beginning to show a linguistic bias (between 1B and 30B words) is similar to the amount of pretraining data used by the first pretrained LMs to achieve major successes at NLU tasks, such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). This suggests a crucial data threshold below which language model pretraining is unlikely to be significantly helpful for most applications with current model architectures, and may explain the many-year gap between the development of neural LMs and the first major applications of LM pretraining: The early LMs must have not have been trained sufficiently to cross that threshold, yielding consistently poor results.

6 Related work

There is increasing interest in studying the inductive biases of neural networks. Much of this work has grown out of numerous findings that these models often fail to generalize in ways that task designers intend. For example, Jia and Liang (2017) and McCoy et al. (2019) demonstrate that ambiguity in widely used NLU datasets like SQuAD (Rajpurkar et al., 2016) and MultiNLI (Williams et al., 2018) leads models like BERT to adopt some surface generalizations, despite the fact that they represent linguistic features. This continues to be a problem for models like RoBERTa$_{\text{BASE}}$ which show an overall linguistic bias in our experiments. However, for tasks like NLI, the underlying linguistic feature depends on a combination of significant syntactic knowledge, semantic knowledge, and world knowledge. It stands to reason that representations and preferences for such high level features require more data to learn than the features we probe.

Other work has used the poverty of stimulus design to study inductive biases associated with particular neural architectures during syntactic gen-

---

[7] Analogous results for the held out training-condition data, inoculation data, and auxiliary data are in the Appendix.

[8] MSGS does not come close to representing the full range of possible relevant lexical or syntactic features, preventing us from making strong conclusions about which specific linguistic features RoBERTa has biases in favor of.

eralization. Ravfogel et al. (2019) train RNNs on a morphological prediction task using artificial languages derived from naturally occurring English text, finding that RNNs show a recency bias in acquiring agreement rules. McCoy et al. (2018, 2020) train a seq2seq models on generated data ambiguous between a surface and a structural generalization to learn the subject-auxiliary inversion rule in English question formation. They find that, while tree-structured models show a structural bias, sequence models do not. Warstadt and Bowman (2020) conduct related experiments on subject-auxiliary inversion and other English structural rules, and find that BERT likely acquires a structural bias from pretraining.

More abstract inductive biases have also been studied. Using zero-shot learning in an artificial language, Lake and Baroni (2018) show that RNNs lack a bias in favor of learning compositional meanings for new symbols. Gandhi and Lake (2019) and Gulordava et al. (2020) explore conditions under which neural networks exhibit a bias towards learning mutually exclusive meanings for new symbols.

Data augmentation and inoculation have also been explored previously as a way to influence how models generalize. McCoy et al. (2019) and Min et al. (2020) show that small amounts of inoculating data during training on textual entailment help BERT overlook certain surface generalizations. Jha et al. (2020) study inoculation using a constructed language of numerical sequences. Like us, they generate ambiguous datasets, though they only compare features that resemble our surface features. They find that it is relatively easy to nudge models away from shallow generalizations, but harder to nudge them towards deeper ones.

Finally, several earlier studies explored how increasing training data impacts linguistic knowledge in LMs. Unlike the present study, these studies evaluate LMs using an unsupervised acceptability judgment task on minimal pairs (i.e. not during fine-tuning), and do not attempt to separate feature learning from feature preferences. van Schijndel et al. (2019) find the greatest increase in sensitivity to acceptability contrasts occurs between training on 2M and 10M words. Warstadt et al. (2020) find that while LMs learn agreement phenomena at a similarly early stage, other phenomena require more data to learn. Finally, Hu et al. (2020) find that adopting architectures that build in linguistic bias, such as RNNGs (Dyer et al., 2016), has a bigger effect on the acceptability task than increasing training data from 1M to 40M words.

7 Future Work & Conclusion

Our experiments shed light on the relationship between pretraining data and an inductive bias towards linguistic generalization. Our results indicate that, although some abstract linguistic features are learnable from relatively small amounts of pretraining data, models require significant pretraining after discovering these features to develop a bias towards *using* them when generalizing. This gives some insight into why extensive pretraining helps general-purpose neural networks adapt to downstream tasks with relative ease.

We also introduce MSGS, a new diagnostic dataset for probing the inductive biases of learning algorithms using the poverty of the stimulus design and inoculation, and also introduce a set of 12 RoBERTa models we pretrain on smaller data quantities. These models could prove to be a helpful resource for future studies looking to study learning curves of various kinds with respect to the quantity of pretraining data.

Finally, while our results naturally lead to the conclusion that we should continue to pursue models with ever more pretraining, such as GPT-3 (Brown et al., 2020), we do not wish to suggest that this will be the only or best way to build models with stronger inductive biases. Future work might use MSGS as a diagnostic tool to measure how effectively new model architectures and self-supervised pretraining tasks can more efficiently equip neural networks with better inductive biases.

A Data Description

MSGS contains 5 surface features and 4 linguistic features, summarized in Table 3 (repeated from the main body of the paper, for convenience). Implementation details for the features are described below. The implementation of one feature sometimes depends on other feature it is paired with in an ambiguous dataset.

Absolute position This feature is 1 *iff* the sentence begins with the word "the". We generally ensure that sentences bearing a value for this feature contains two clauses and four determiners total. Some sentences in SYNTACTIC CATEGORY × ABSOLUTE POSITION contain fewer than four NPs. The in-domain and out-of-domain sentences differ in the order or position of the clauses.

Length This feature is 1 *iff* the sentence exceeds some number of tokens. The exact threshold varies depending on the linguistic feature in an ambiguous task, since different linguistic features lead to sentences of different length, on average. In mixed tasks, we vary the length of sentences by adjoining subordinate clauses (e.g. *If Sue wakes*) of varying length to the clause in which the linguistic feature is varied.

Lexical content This feature is 1 *iff* the sentence contains *the*. The sentences generally contain at least two clauses and four determiners. The position of *the* varies between in-domain and out-of-domain sentences.

Relative position This feature is 1 when *the* precedes *a*, and 0 when *a* precedes *the*. The sentences generally contain at least two clauses and four determiners. Thus, there are six different configurations in which *the* precedes *a*, and these are separated into in-domain and out-of-domain templates.

Orthography This feature is 1 *iff* the sentence appears in title case. In the control paradigm, the sentences generally contain two clauses, whose positions are varied between in-domain and out-of-domain sentences.

Lexical semantics This feature is 1 *iff* the sentence contains a pair of antonyms. In sentences with label 0, there is a pair of words in a hypernym/hyponym or synonym relation. There are 21 pairs of adjective antonyms and 21 pairs of verb antonyms (not accounting for different inflectional forms). To prevent the task being solvable using lexical content, these pairs are divided into in-domain and out-of-domain sets. There are different templates corresponding to whether the antonyms are adjectives, intransitive verbs, or transitive verbs. Each template appears in both in-domain and out-of-domain sentences.

Morphology This feature is 1 when the sentence contains an irregular past tense verb, and 0 when it contains a 3rd person present plural verb (identical to the bare form). Sentences either contain an irregular past tense verb or a regular 3rd person present plural verb (identical to the bare form). We do this because other verb forms can be identified by inflectional morphemes such as *-s* or auxiliaries such as *have*, and so discrimination between them could in some cases reduce to a lexical content task. The verbs are divided into in-domain and out-of-domain sets.

Syntactic category This feature is 1 *iff* the sentence contains an adjective. To diversify the templates, we consider all grammatical combinations of a noun, an adjective, a locative PP, and a proper name (e.g., *Sue is the tall actress in the park*, or *The actress is Sue*). In out-of-domain sentences we also include single-word nominal predicates like *president* (see the example in Table 3 to control for the fact that predicative adjectives are always a single, lowercase word. This gives a total of 19 templates divided into in-domain and out-of-domain sets, some with adjectives and some without. The set of adjectives is also split between domains.

Syntactic construction This feature has value 1 *iff* the sentence contains the control construction. In the control construction a semantic argument of a predicate fills or *controls* an argument slot of an embedded verb (Sag et al., 2003). For instance, in *Sue is eager to sleep*, the NP *Sue* surfaces as the syntactic subject of *eager*, but *Sue* is also understood as the semantic subject of *sleep*. This contrasts with the *raising* construction in *Sue is likely to sleep*, where *Sue* is again surfaces as the syntactic subject of *likely* in the main clause, and is the semantic subject of *sleep* in the embedded position, but is not a semantic argument of *likely*. Different predicates are compatible with control and raising: *eager* is a control predicate and *likely* is a raising predicate. We include control and raising predicates of three kinds: subject control/raising verbs, object control/raising verbs, and control/raising adjectives. Specific predicates are divided into in-domain and

	Feature type	Feature description	Positive example	Negative example
Surface	Absolute position	Is the first token of S "the"?	The cat chased a mouse.	A cat chased a mouse.
	Length	Is S longer than n (e.g., 3) words?	The cat chased a mouse.	The cat meowed.
	Lexical content	Does S contain "the"?	That cat chased the mouse.	That cat chased a mouse.
	Relative position	Does "the" precede "a"?	The cat chased a mouse.	A cat chased the mouse.
	Orthography	Does S appear in title case?	The Cat Chased a Mouse.	The cat chased a mouse.
Linguistic	Morphology	Does S have an irregular verb?	The cat slept.	The cat meows.
	Syn. category	Does S have an adjective?	Lincoln was tall.	Lincoln was president.
	Syn. construction	Is S the control construction?	Sue is eager to sleep.	Sue is likely to sleep.
	Syn. position	Is the main verb in "ing" form?	Cats who eat mice are purring.	Cats who are eating mice purr.

Table 3: Schematic examples of the linguistic and surface features.

out-of-domain sets, but all three kinds of predicates appear in both domains.

Syntactic position All sentences contain at one or two embedded clauses. We include six sentence types, divided into in-domain and out-of-domain. For example, some sentences contain a relative clause within a relative clause, or a verb phrase with a complement clause. Each sentence type is generated from multiple templates varying the position of the clauses. The set of *-ing* verbs is not split between domains.

Abstract

The neural attention mechanism plays an important role in many natural language processing applications. In particular, multi-head attention extends single-head attention by allowing a model to jointly attend information from different perspectives. However, without explicit constraining, multi-head attention may suffer from *attention collapse*, an issue that makes different heads extract similar attentive features, thus limiting the model's representation power. In this paper, for the first time, we provide a novel understanding of multi-head attention from a Bayesian perspective. Based on the recently developed particle-optimization sampling techniques, we propose a non-parametric approach that explicitly improves the repulsiveness in multi-head attention and consequently strengthens model's expressiveness. Remarkably, our Bayesian interpretation provides theoretical inspirations on the not-well-understood questions: why and how one uses multi-head attention. Extensive experiments on various attention models and applications demonstrate that the proposed repulsive attention can improve the learned feature diversity, leading to more informative representations with consistent performance improvement on multiple tasks.

1 Introduction

Multi-head attention (Vaswani et al., 2017) is an effective module in deep neural networks, with impressive performance gains in many natural-language-processing (NLP) tasks. By extending a single head to multiple paralleled attention heads, the architecture is widely adopted to capture different attentive information and strengthen the expressive power of a model. Lin et al. (2017) applied the idea of multi-heads on self-attention and extract a 2-D matrix instead of a vector to represent different contexts of a sentence. The Transformer (Vaswani et al., 2017) and its variants such as BERT (Devlin et al., 2019) are influential architectures solely based on multi-head attention, achieving state-of-the-art performance on plenty of NLP tasks. The key of multi-head attention is its ability to jointly attend to information from different representation subspaces at different positions, which results in multiple latent features depicting the input data from different perspectives. However, there are no explicit mechanisms guaranteeing this desired property, leading to potential attention redundancy or attention collapse, which has been observed in previous research (Voita et al., 2019; Kovaleva et al., 2019). Although there exist works by directly adding regularization on loss functions to encourage diversity in multi-head attention (Lin et al., 2017; Li et al., 2018), the underlying working principle has not been well-validated, and performance improvement is limited. Furthermore, an important problem on why and how multi-head attention improves over its single-head counterpart is poorly understood.

In this paper, we provide a novel understanding of multi-head attention from a Bayesian perspective by adapting the deterministic attention to a stochastic setting. The standard multi-head attention can be understood as a special case of our framework, where attention-parameter updates between heads are independent, instead of sharing a common prior distribution. Based on our framework, attention repulsiveness could then be imposed by performing Bayesian inference on attention parameters with the recently developed particle-optimization sampling methods (Liu and Wang, 2016), which has been shown to be effective in avoiding mode collapse. These methods treat each head as a particle/sample, which is then optimized to approximate a posterior distribution of an attention model. With it, multiple heads are enforced to move to modes in the parameter space to be far from each other, thus improving the repulsiveness in multi-head at-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 236–255,
November 16–20, 2020.

tention and enhancing model's expressiveness. Our Bayesian interpretation also provides a theoretical understanding of the reason and benefits of applying multi-head attention. Experiments on various attention models demonstrate the effectiveness of our framework.

Our contributions are summarized as follow:

- We provide a new understanding of multi-head attention from a Bayesian perspective, yielding a more principled and flexible interpretation of multi-head attention.
- Based on the recently developed particle-optimization sampling techniques, we propose an algorithm to explicitly encourage repulsiveness in multi-head attention without introducing extra trainable parameters or explicit regularizers. The proposed method can be implemented with an efficient end-to-end training scheme.
- Our Bayesian interpretation provides a theoretical foundation to understand the benefits of multi-head attention, which reveals the existence of an optimal number of attention heads in a specific model.
- We apply our approach on four attention models with a wide range of tasks. Experimental results show that repulsive attention improves the expressiveness of models, and yields consistent performance gains on all the tasks considered.

2 Preliminaries

2.1 Multi-head Attention

The attention mechanism aims at modeling dependencies among elements of a learned representation at different positions. The two commonly used attention functions are additive attention (Lin et al., 2017; Bahdanau et al., 2015) and dot-product attention (Vaswani et al., 2017). We review the popularly used dot-product attention below and defer the additive attention to Appendix A.

Dot-product Attention The multi-head scaled dot-product attention is used in the Transformer model (Vaswani et al., 2017). The attention function for a single head is formulated as mapping a query and a set of key-value pairs to output as

$$\mathbf{A}_i = \text{Softmax}(\mathbf{Q}_i\mathbf{K}_i^T/\sqrt{d_k}), \mathbf{Z}_i = \mathbf{A}_i\mathbf{V}_i \quad (1)$$

where $\mathbf{Q}_i = \mathbf{Q}\mathbf{W}_i^Q, \mathbf{K}_i = \mathbf{K}\mathbf{W}_i^K, \mathbf{V}_i = \mathbf{V}\mathbf{W}_i^V$ $\mathbf{Q}, \mathbf{K}, \mathbf{V}$ are matrices depicting the hidden representation of every word in one sentence (*i.e.* self-attention) or two sentences (*i.e.* inter-attention); d_k is the dimension of key and query; $\mathbf{Z}_i$ is the attention feature of the input sentence from the i-th head; $\{\mathbf{W}_i^Q, \mathbf{W}_i^K, \mathbf{W}_i^V\}$ are the corresponding learnable attention parameters. The M-head attention projects the queries, keys and values into M subspaces with different learnable linear projections. These attention functions are performed in parallel and are concatenated at last, resulting in a final latent representation:

$$\text{Multi-head}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathbf{Z}\mathbf{W}^O, \text{ with} \quad (2)$$
$$\mathbf{Z} = \text{Concat}(\mathbf{Z}_1, \cdots, \mathbf{Z}_M)$$

2.2 Particle-optimization Sampling

Particle-optimization sampling is a recently developed Bayesian sampling technique that interactively transports a set of particles/samples to a target distribution p by minimizing the KL divergence between the particle density and the target p. In our case, p would be a posterior distribution, $p(\boldsymbol{\theta}|\mathcal{D}) \propto \exp(-U(\boldsymbol{\theta}))$, of the parameter $\boldsymbol{\theta} \in \mathbb{R}^d$, defined over an observed dataset $\mathcal{D} = \{D_k\}_{k=1}^N$. Here $U(\boldsymbol{\theta}) \triangleq -\log p(\mathcal{D}|\boldsymbol{\theta}) - \log p_0(\boldsymbol{\theta}) = -\sum_{k=1}^N \log p(D_k|\boldsymbol{\theta}) - \log p_0(\boldsymbol{\theta})$ is called the potential energy with p_0 a prior over $\boldsymbol{\theta}$. In our case, the model parameter $\boldsymbol{\theta}$ could be one or several of the attention parameters such as $\mathbf{W}_i^Q$. For simplicity, we will stick to $\boldsymbol{\theta}$ in the presentation. In particle-optimization sampling, a total of M particles $\{\boldsymbol{\theta}^{(i)}\}_{i=1}^M$ are updated iteratively to approximate $p(\boldsymbol{\theta}|\mathcal{D})$. In this paper, we use two representative algorithms, the Stein Variational Gradient Descent (SVGD) and the Stochastic Particle-Optimization Sampling (SPOS), for sampling.

SVGD In SVGD (Liu and Wang, 2016), the i-th particle in the $(\ell+1)$-th iteration is updated with stepsize $\epsilon_{\ell+1}$ as

$$\boldsymbol{\theta}_{\ell+1}^{(i)} = \boldsymbol{\theta}_\ell^{(i)} + \epsilon_{\ell+1}\phi(\boldsymbol{\theta}_\ell^{(i)}) \quad (3)$$

$$\phi(\boldsymbol{\theta}_\ell^{(i)}) = \frac{1}{M}\sum_{j=1}^M [-\kappa(\boldsymbol{\theta}_\ell^{(j)}, \boldsymbol{\theta}_\ell^{(i)})\nabla_{\boldsymbol{\theta}_\ell^{(j)}} U(\boldsymbol{\theta}_\ell^{(j)}) + \nabla_{\boldsymbol{\theta}_\ell^{(j)}}\kappa(\boldsymbol{\theta}_\ell^{(j)}, \boldsymbol{\theta}_\ell^{(i)})] \quad (4)$$

where $\kappa(\cdot,\cdot)$ is a positive definite kernel (*e.g.*, RBF kernel). The two terms in ϕ play different roles: the first term drives the particles towards high density regions of $p(\boldsymbol{\theta}|\mathcal{D})$; whereas the second term acts as a repulsive force that prevents all the particles from collapsing together into local modes of $p(\boldsymbol{\theta}|\mathcal{D})$.

SPOS Though obtaining significant empirical success, under certain conditions, SVGD experiences a theoretical pitfall, where particles tend to collapse. To overcome this, Zhang et al. (2020) generalize SVGD to a stochastic setting by injecting random noise into particle updates. The update rule for particles $\boldsymbol{\theta}_\ell^{(i)}$ is

$$\phi(\boldsymbol{\theta}_\ell^{(i)}) = \frac{1}{M}\sum_{j=1}^{M}[-\kappa(\boldsymbol{\theta}_\ell^{(j)}, \boldsymbol{\theta}_\ell^{(i)})\nabla_{\boldsymbol{\theta}_\ell^{(j)}} U(\boldsymbol{\theta}_\ell^{(j)}) + \nabla_{\boldsymbol{\theta}_\ell^{(j)}} \kappa(\boldsymbol{\theta}_\ell^{(j)}, \boldsymbol{\theta}_\ell^{(i)})] - \beta^{-1}\nabla_{\boldsymbol{\theta}_\ell^{(i)}} U(\boldsymbol{\theta}_\ell^{(i)}) + \sqrt{2\beta^{-1}\epsilon_\ell^{-1}}\boldsymbol{\xi}_\ell^{(i)} \quad (5)$$

where $\beta > 0$ is a hyperparameter, $\boldsymbol{\xi}_\ell^{(i)} \sim \mathcal{N}(\mathbf{0}, \boldsymbol{I})$ is the injected random Gaussian noise to enhance the ability of escaping local modes, leading to better ergodic properties compared to standard SVGD.

3 A Bayesian Inference Perspective of Multi-head Attention

In this section, we interpret multi-head attention as Bayesian inference of latent representation via particle-optimization sampling. We denote $\boldsymbol{x}$ and $\boldsymbol{z}$ as the input and output (latent representation) of the attention model, respectively. The single-head attention can be written as a deterministic mapping $\boldsymbol{z} = f_{att}(\boldsymbol{x}; \boldsymbol{\theta})$, with $\boldsymbol{\theta}$ the parameter of the mapping. Standard multi-head attention defines multiple parallel attention mappings, each endowed with independent parameters. The attention features are finally aggregated via a function $g(\cdot)$ as

$$\boldsymbol{z} = g(\boldsymbol{z}_1, ..., \boldsymbol{z}_M), \quad \boldsymbol{z}_i = f_{att}(\boldsymbol{x}; \boldsymbol{\theta}_i) \ . \quad (6)$$

Next, we generalize (6) as a Bayesian inference problem for the latent representation $\boldsymbol{z}$.

Attention as Bayesian Inference We first generalize the deterministic transformation, $\boldsymbol{z} = f_{att}(\boldsymbol{x}; \boldsymbol{\theta})$, to a stochastic generative process as:

$$\boldsymbol{\theta} \sim p(\boldsymbol{\theta}|\mathcal{D}), \ \ \boldsymbol{z} = f_{att}(\boldsymbol{x}; \boldsymbol{\theta}) \ ,$$

where a sample of the posterior of the global attention parameter $\boldsymbol{\theta}$, $p(\boldsymbol{\theta}|\mathcal{D}) \propto p(\mathcal{D}|\boldsymbol{\theta})p(\boldsymbol{\theta})$, is used as the parameter when generating the latent attention feature $\boldsymbol{z}$. Bayesian inference for attention then computes the predictive distribution $p(\boldsymbol{z}|\boldsymbol{x}, \mathcal{D})$ of the attentive latent representation $\boldsymbol{z}$ for a new input $\boldsymbol{x}$ given the training data $\mathcal{D}$ by $p(\boldsymbol{z}|\boldsymbol{x}, \mathcal{D}) = \int \delta_{f_{att}(\boldsymbol{x};\boldsymbol{\theta})}(\boldsymbol{z}) p(\boldsymbol{\theta}|\mathcal{D}) d\boldsymbol{\theta}$, where $\delta_{\boldsymbol{z}}(\cdot)$ is the delta function with point mass at $\boldsymbol{z}$. To enable efficient evaluation of the integral, we adopt Bayesian sampling for approximation, *i.e.*, $p(\boldsymbol{z}|\boldsymbol{x}, \mathcal{D})$ is approximated by a set of M samples/particles initialized from $p(\boldsymbol{\theta}|\mathcal{D})$, leading to the following generative process:

$$\begin{aligned} \boldsymbol{z} &= g(\boldsymbol{z}_1, ..., \boldsymbol{z}_M) \\ \boldsymbol{z}_i &= f_{att}(\boldsymbol{x}; \boldsymbol{\theta}_i), \quad \text{with} \quad \boldsymbol{\theta}_i \sim p(\boldsymbol{\theta}|\mathcal{D}) \end{aligned} \quad (7)$$

The above formulation defines a principled version of multi-head attention from a Bayesian view. One can see that (7) reduces to the standard multi-head attention if all $\boldsymbol{\theta}_i$ are treated independently without sharing the common parameter distribution $p(\boldsymbol{\theta}|\mathcal{D})$. In other words, our reformulation of multi-head attention is a stochastic generative process, thus is more general. Furthermore, efficient end-to-end learning can be performed by conducting repulsive Bayesian sampling for all parameters $\{\boldsymbol{\theta}_i\}_{i=1}^M$, which consequently could diversify the attention features $\{\boldsymbol{z}_i\}_{i=1}^M$.

4 Repulsive Attention Optimization

The Bayesian multi-head attention in (7) further inspires us to develop the repulsive attention. The idea is to learn to generate repulsive samples from the posterior $p(\boldsymbol{\theta}|\mathcal{D})$. We propose to adopt the particle-optimization sampling methods, which could explicitly encourage repulsiveness between samples. In our algorithm, the parameter of $p(\boldsymbol{z}|\boldsymbol{x}; \boldsymbol{\theta})$ for each head is considered as one particle. Following the particle-optimization rules, M heads $\{\boldsymbol{\theta}_i\}_{i=1}^M$ are updated iteratively to approximate the posterior distribution of attention parameter $p(\boldsymbol{\theta}|\mathcal{D})$.

4.1 Learning Repulsive Multi-head Attention

We propose to learning repulsive attention by replacing the standard updates of attention parameters via stochastic gradient descent (SGD) with particle-optimization sampling methods while keeping the multi-head attention model unchanged. This procedure forms an efficient end-to-end training scheme similar to standard attention learning. To be specific, in standard multi-head attention, the parameter of every head is updated independently according to the respective gradient of a loss function. To achieve repulsive multi-head attention, we follow the particle-optimization sampling update rule (*e.g.* (3) and (4)) to update the parameter of every head while keeping the update for the remaining parameters via SGD unchanged. Equations (4) and (5) can be viewed as modified gradients with explicit repulsive force and can be integrated into any optimizer, *e.g.*, Adam (Kingma and Ba, 2015). Note that $\nabla_{\boldsymbol{\theta}_\ell^{(i)}} U(\boldsymbol{\theta}_\ell^{(i)})$ equals to the gradient of $\boldsymbol{\theta}_\ell^{(i)}$ in standard multi-head attention when the negative log-likelihood is used as the loss function and the prior of $\boldsymbol{\theta}^{(i)}$ is assumed to be uniform. The learning algorithm is illustrated in Algorithm 1. In practice, the update of M heads can be performed in parallel with efficient matrix operations.

Algorithm 1 Repulsive Multi-head Attention

Input: Initialized M-head attention model $\mathcal{A}$ with attention parameters $\boldsymbol{\Theta}_0 = \{\boldsymbol{\theta}_i\}_{i=1}^M$ and all the other parameters $\boldsymbol{\Omega}_0$; Training data $\mathcal{D} = \{D_k\}_{k=1}^N = \{(\boldsymbol{x}_k, y_k)\}_{k=1}^N$;

Output: Optimized attention model with learned parameters $\hat{\boldsymbol{\Theta}}$ and $\hat{\boldsymbol{\Omega}}$;

Train:

```
for iteration $\ell$ do
    forward: $\hat{y}_k = \mathcal{A}(\boldsymbol{x}_k; \boldsymbol{\Theta}_\ell, \boldsymbol{\Omega}_\ell), \forall k$;
    calculate loss: $\mathcal{L}(\{\hat{y}_k\}, \{y_k\})$;
    backward and calculate gradients:
    gradient of $\boldsymbol{\Omega}_\ell$: $\varphi(\boldsymbol{\Omega}_\ell) \leftarrow \nabla_{\boldsymbol{\Omega}_\ell}\mathcal{L}$
    for attention head $i$ do
        calculate $\phi(\boldsymbol{\theta}_\ell^{(i)})$ with Eq (4) or (5);
        gradient of $\boldsymbol{\theta}_\ell^{(i)}$:$\varphi(\boldsymbol{\theta}_\ell^{(i)}) \leftarrow \epsilon_\ell \phi(\boldsymbol{\theta}_\ell^{(i)})$;
    end for
    update parameters:
    $\boldsymbol{\Omega}_{\ell+1} \leftarrow$ Optimizer$(\boldsymbol{\Omega}_\ell, \varphi(\boldsymbol{\Omega}_\ell))$
    $\boldsymbol{\Theta}_{\ell+1} \leftarrow$ Optimizer$(\boldsymbol{\Theta}_\ell, \varphi(\boldsymbol{\Theta}_\ell))$
end for
```

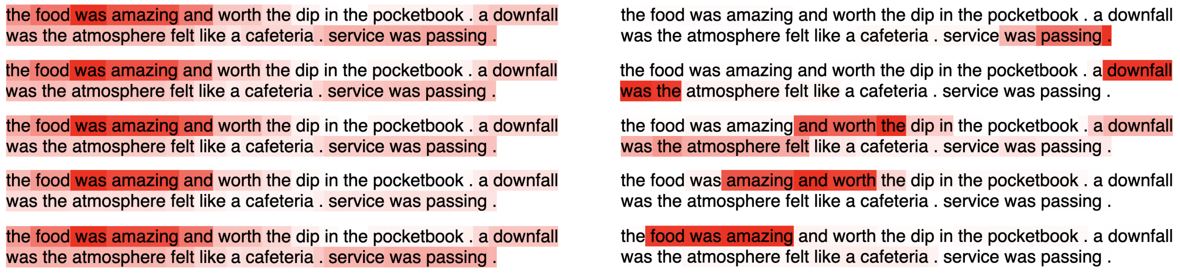
4.2 In-depth Analysis

Why Multi-head Attention? Our Bayesian interpretation of the attention mechanism naturally provides an answer to the question of why one needs multi-head attention. By treating each head as one sample, adopting multiple heads means using more samples to approximate an underlying posterior distribution. The question comes to should one use more heads (samples). Intuitively this seems to be true because more samples typically make more accurate approximations. However, this could not be the case in practice. The reason might be two-fold: *i*) *Overfitting*: Learning with a limited amount of data could easily causes overfitting, thus requiring a smaller model (less attention heads); *ii*) *Numerical error*: Our proposed method to update samples (attention-head parameters) is essentially a discrete numerical method of the corresponding continuous-time partial differential equation, *i.e.*, the samples are not exact samples from the target distribution. Thanks to the recently developed theory for particle-optimization sampling (Zhang et al., 2020), one can conclude that more heads could accumulate more numerical errors, leading to performance deterioration. More formally, when using particles to approximate a target posterior distribution, there exists a gap (approximation error) between the particle distribution and the true distribution (Zhang et al., 2020). This approximation error, when applied to our setting, approximately scales in the order of $O(\frac{1}{\sqrt{M}} + M\epsilon_0^{1/2} + e^{-\sum_\ell \epsilon_\ell})$. Please refer to Theorem 10 in (Zhang et al., 2020) for a formal description.

How Many Heads are Enough? The above error bound suggests that there is a trade-off between approximation accuracy and the number of heads M. Specifically, we have *i*) when M is small, the term $\frac{1}{\sqrt{M}}$ in the bound would dominate, leading to decreasing errors (increasing performance) with increasing M; *ii*) when M is large enough, the term $M\epsilon_0^{1/2}$ dominates, suggesting that larger M could actually increase the approximation error (decreased performance). These phenomena are consistent with our experimental results. We note that an exact form of the optimal M is not available due to a number of unknown constants (omitted in the big-O notation). Therefore, one should seek other ways such as cross-validation to choose a good M in practice. Our argument also aligns with recent research, which found that more heads do not necessarily lead to better performance (Michel et al., 2019).

5 Experiments

We demonstrate the effectiveness of our method with representative multi-head attention models on a broad range of tasks including sentence classification, machine translation, language modeling and text generation. This section summarizes key results on different models. More detailed experiment settings and analysis are deferred to the appendix. To apply our approach, only the learning method of multi-head attention is adapted.



(a) detailed attentions (b) detailed attentions

Table 1: Performance (accuracy) comparison on Age, Yelp and SNLI dataset. Dist: the average 2-norm distance between each pair of the latent representation encoded from different heads on test set. MA: standard multi-head attention. RMA: proposed repulsive multi-head attention. R: regularization approach.

5.1 Self-attentive Sentence Classification

Model & Baselines We first apply our method to the self-attentive sentence classification model (Lin et al., 2017) which combines BiLSTM with additive attention to learn the sentence embedding and then does classification on it. We compare our method with the one using the standard multi-head attention (BiLSTM + MA) and the one applying the Frobenius regularization (BiLSTM + MA + R) on it to introduce diversity as in Lin et al. (2017).

Tasks & Datasets Following Lin et al. (2017), three sentence classification tasks including author profiling, sentiment analysis, and textual entailment are evaluated on the Age, Yelp, and SNLI datasets respectively.

Results As shown in Table 1, with the proposed repulsive multi-head attention, the model achieves higher accuracy on all three tasks. Especially on the sentiment analysis task which often contains multiple aspects in one sentence. Our methods also outperform the regularization method proposed in Lin et al. (2017). With different particle-optimization rules, SPOS is able to achieve better performance due to its extra advance discussed by Zhang et al. (2020). We further evaluate the diversity of multiple heads by calculating the average distance between each pair of latent representations. Results show that our methods indeed enforce heads to be more diverse, compared with the standard multi-head attention. The less diverse of the regularization-based method also indicates the validness of our argument in Appendix C.6.

Repulsive-attention visualization We further visualize attention maps in the learned sentence embedding space in Figure 1. It is interesting to see attention collapse indeed happens in the standard multi-head attention, where almost all heads focus on one single factor *"amazing"*. On the contrary, the proposed method is able to capture multiple key factors in the review that are strong indicators of the sentiment behind the sentence. For example, *"downfall"* and *"service was passing"* are key factors for this 4-star review captured by our repulsive

multi-head attention, which are missed by the standard attention. The full attention heatmaps of all 30 heads and more examples are in Appendix D.

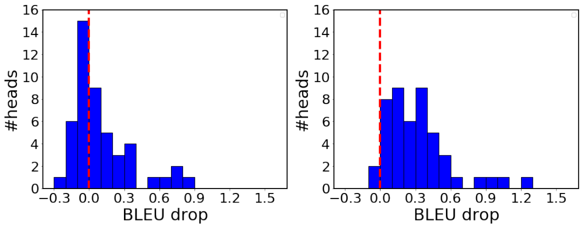
5.2 Transformer-based Neural Translation

Model & Baselines The Transformer (Vaswani et al., 2017) is a representative multi-head attention based model. We apply the proposed repulsive multi-head attention (RMA) on it and compare our method with the original one (MA) and the disagreement regularization method (R) (Li et al., 2018) which encourages the diversity in attention by a cosine similarity penalty on attention outputs.

Tasks & Datasets Following Vaswani et al. (2017) , we apply Transformer for machine translation, with two standard translation datasets: the IWSLT14 German-to-English (De-En) dataset , and the WMT14 English-to-German (En-De) dataset.

Results Results are presented in Table 2. With the repulsive multi-head attention, Transformer models achieve noticeable improvement on the BLEU score on both datasets, compared with both baselines. It is also encouraging to see that the Transformer-`base`-RMA with a much smaller model achieves comparable performance as Transformer-`big`. As for training time, our approach takes slightly more time than the baseline, but is much more efficient than the regularization approach.

Which attention module to be diversified? We conduct extra experiments on Transformer-`small` to investigate which attention module benefits most from the repulsiveness. Results (see Appendix C.3) suggest that diversifying different attention module benefits differently. Remarkably, only diversifying the attention in the first layer is able to achieve comparable performance to the case of diversifying attention in all layers, with little computational time increased. This finding suggests that the repulsiveness in the first layer's attention plays an important role for modelling language.



(a) Transformer-`base`-MA (b) Transformer-`base`-RMA

Figure 2: Distribution of heads by performance drop after masking at test time. The redundancy of heads in RMA is much less.

Redundancy in heads The redundancy problem in attention has been observed in recent works (Michel et al., 2019), that a large percentage of attention heads can be removed at test time without significantly impacting performance. Following Michel et al. (2019), we analysis the redundancy in Transformer by ablating each head at testing and evaluating the performance drop. The more drops, the more important of the head. Figure 2 shows that the majority of heads in standard multi-head attention are redundant for the performance is comparable before and after masking. However, the repulsive attention largely alleviates the redundancy. More interestingly, there are a lot of counter-intuitive cases in standard attention: removing a head results in an increase in performance. However, this does not seem to happen in repulsive attention model, indicating better leveraging of the superior expressiveness of multi-head mechanism.

5.3 Language Representation Learning

Model ELECTRA (Clark et al., 2020) is an efficient approach to self-supervised language representation learning. It consists of two networks, *Generator* and *Discriminator*, both of which are parameterized by Transformers. The pre-trained Discriminator is used in various downstream tasks via fine-tuning. We apply the proposed repulsive multi-head attention to ELECTRA (small setting) in the pre-training stage. We only make the first layer attention of Discriminator to be repulsive, according to the finding in Section 5.2 that the diversity in the first attention layer of Transformer

Pre-training Data	Model	Prams	CoLA	SST	MRPC	STS	QQP	MNLI	QNLI	RTE	Avg.

Table 3: Results on the GLUE test set. For RMA, repulsive attention is only applied to pre-training. For RTE, the left value is fine-tuned from pre-trained models, the right value is from intermediate task training.

benefits the most.

Tasks & Dataset We train ELECTRA models on OpenWebText Corpus due to the data used in Clark et al. (2020) is not publicly available. The pretrained models are then fine-tuned and evaluated on the General Language Understanding Evaluation (GLUE) (Wang et al., 2019) benchmark on eight datasets (Warstadt et al., 2019; Socher et al., 2013; Dolan and Brockett, 2005; Cer et al., 2017; Williams et al., 2018; Rajpurkar et al., 2016; Dagan et al., 2005; Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009).

Results Results are shown in Table 3. For each task, we perform single-task fine-tuning 50 times, and report the averaged results. The training time with and without repulsive attention is almost the same. It shows that repulsive attention improves the baseline results (Clark et al., 2020) in seven out of eight tasks on GLUE, and the gains are larger especially on MNLI (the largest dataset on GLUE) and CoLA . This suggests that repulsive attention can yield better language representations. Since MNLI and RTE are both entailment tasks, following Clark et al. (2020) and Phang et al. (2018), we use intermediate task training for RTE. We first fine-tune the pre-trained model on MNLI, then continuously fine-tune it on RTE. The repulsive attention outperforms the baseline method by a large margin in this setting. This is probably because the repulsive attention particularly favor large data variability (e.g., MNLI dataset), where different aspects of data can be uniquely represented in different heads.

5.4 Graph-to-Text Generation

Model & Baselines GraphWriter (Koncel-Kedziorski et al., 2019) is a knowledge-graph-to-text model, which aims at generating coherent multi-sentence abstract given a knowledge graph and a title. There is a Transformer-style encoder defined with graph attention modules (Velickovic et al., 2018) that could also be easily adapted to our method. We compare our method with the original one that has the standard multi-head attention, and the one with the cosine similarity regularization on attention parameters in encoder layers.

Metrics	GW	+ R	+ RMA
BLEU-1	42.56	42.25	**45.60**
BLEU-2	27.64	27.98	**29.96**
BLEU-3	19.27	19.77	**21.07**
BLEU-4	13.75	14.21	**15.12**
METEOR	18.11	18.61	**19.52**
ROUGE-1	35.80	37.24	**38.23**
ROUGE-2	16.83	17.78	**18.39**
ROUGE-L	27.21	26.90	**28.55**

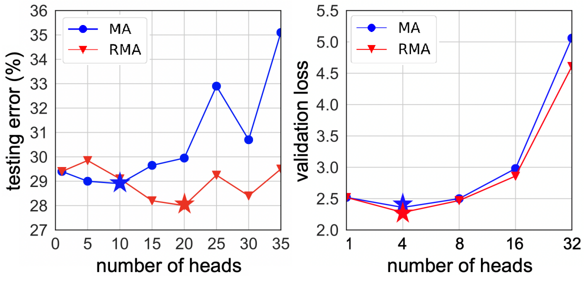
Table 4: Automatic evaluations of generation systems on test set of AGENDA.

	Win	Lose	Tie
Structure	51%	12%	37%
Informativeness	66%	13%	21%
Grammar	37%	17%	46%
Overall	65%	14%	21%

Table 5: Human judgments of GraphWriter with and without repulsive attention.

Tasks & Datasets & Metrics Experiments are conducted on the Abstract GENeration DAtaset (AGENDA) (Koncel-Kedziorski et al., 2019), a dataset of knowledge graphs paired with scientific abstracts. We evaluate the quality of abstracts with 3 major metrics: BLEU (uni-gram to 4-gram BLEU) (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE (Lin and Hovy, 2003). In ROUGE, the unigram and bigram overlap (ROUGE-1 and ROUGE-2) are a proxy for assessing informativeness and the longest common subsequence (ROUGE-L) represents fluency.

Results The results are shown in Table 4. The GraphWriter model with repulsive multi-head attention significantly outperforms the original model and regularization approach in all metrics. Espe-



(a) (b)

Figure 3: Demonstration on performance difference with different number of heads. (a) Testing error of the self-attentive sentence classification model on Yelp dataset. (b) Negative log likelihood loss of Transformer-`small` on IWSLT14 De-En dataset.

cially, the higher recall score in ROUGE shows that there are more N-grams across the reference abstracts that can be found in the generated abstracts. Similar observations are noticed when analyzing the generated examples in detail (an example is illustrated in Appendix E). Koncel-Kedziorski et al. (2019) pointed out one limitation of their model is 40% of entities in the knowledge graphs do not appear in the generated text. With the repulsive attention, remarkably, the GraphWriter model is observed to perform much better with a 10% improvement on the knowledge graph coverage and fewer repeat clauses.

Human Evaluation To further illustrate the improvement of using diverse attention, we conduct human evaluation. Following Koncel-Kedziorski et al. (2019), we give 50 test datapoints to experts (5 computer science students) and ask them to provide per-criterion judgments for the generated abstracts. Comparisons of the two methods from 4 aspects are shown in Table 5. The human judgment indicates that the repulsive attention improves both the structure and informativeness of generated abstracts significantly, which is consistent with the automatic evaluation and our observations.

5.5 On the Number of Attention Heads

Our analysis in Section 4.2 suggests the existence of the optimal number of attention heads. To verify this, we further conduct experiments on sentence classification and translation tasks by varying the number of attention heads in models. The results are shown in Figure 3. The model error/loss first decreases then increases w.r.t. M, the number of attention heads. The optimal M are around 20 and 4 for the sentiment analysis and the Transformer, respectively. Interestingly, the Transformer degrades quickly as the number of heads increases. This might because the constant corresponding to the $O(M\epsilon_0)$ term in the bound is too large, making this term quickly dominate with increasing M. Furthermore, it is also observed that the standard multi-head attention follows the same trend, but performs much worse and is more sensitive to the M. This indicates the benefit of Bayesian modeling, which could usually stabilize a model better.

6 Related Work

We provide a first explanation of multi-head attention from a Bayesian perspective, and propose particle-optimization sampling for repulsive attention. Most previous works aim at improving attention diversity with regularization-based methods, *e.g.*, the Frobenius regularization on attention weights in Lin et al. (2017) and the cosine similarity regularization on attention outputs in Li et al. (2018). These works focus on a particular model and the underlying working principle has not been well-validated. Our approach is a principled one that is more interpretable and widely applicable.

The attention collapse belongs to a feature-overlapping problem, which also happens in other areas. Some works tackle this problem by changing architectures, for example ResNet (He et al., 2016) and DenseNet (Huang et al., 2017) implicitly reduce feature correlations by summing or concatenating activation from previous layers. There are also works done by altering the training method as we do. Han et al. (2017) adopt the dropout mechanism and propose a dense-sparse-dense training flow, for regularizing deep neural networks. Prakash et al. (2019) attempt addressing the unnecessary overlap in features captured by image filters with pruning-restoring scheme in training. To our knowledge, we are the first to tackle the attention-feature overlap problem from a Bayesian view with a principled interpretation.

7 Conclusion

We propose a principled way of understanding multi-head attention from a Bayesian perspective. We apply particle-optimization sampling to train repulsive multi-head attention with no additional trainable parameters nor explicit regularizers. Our Bayesian framework explains the long-standing question of why and how multi-head attention affects model performance. Extensive experimental results on representative attention models demonstrate that our approach can significantly improve the diversity in multi-head attention, resulting in more expressiveness attention models with performance improvement on a wide range of tasks.

A Additive Attention

First proposed by (Bahdanau et al., 2015), additive attention uses a one-hidden layer feed-forward network to calculate the attention alignment. We use the attention function in Lin et al. (2017), which is also a self-attention, as an example. It aims at extracting the latent representation of a sentence. The single-head attention function is:

$$\boldsymbol{a} = \mathsf{Softmax}(\boldsymbol{v}^\top \mathsf{tanh}(\mathbf{W}\mathbf{H}^\top)), \boldsymbol{z} = \boldsymbol{a}\mathbf{H}$$

where $\mathbf{H} \in \mathbb{R}^{n\times d}$ is the hidden state matrix of a sentence with n words, every word is embedded in a d dimensional vector. $\boldsymbol{v} \in \mathbb{R}^{1\times n}$ is the normalized alignment score vector for each word. $\mathbf{W} \in \mathbb{R}^{d_a\times d}$ and $\boldsymbol{v} \in \mathbb{R}^{d_a\times 1}$ are attention parameters. The final sentence representation vector $\boldsymbol{z}$ is a weighted sum of words' hidden states weighted by attention vector. In order to capture overall semantics of the sentence instead of a specific component, multi-head attention could be applied as

$$\mathbf{A} = \mathsf{Softmax}(\mathbf{V}^\top \mathsf{tanh}(\mathbf{W}\mathbf{H}^\top)), \mathbf{Z} = \mathbf{A}\mathbf{H}$$

where $\mathbf{V} \in \mathbb{R}^{d_a\times M}$ is the matrix performs M heads, $\mathbf{A} \in \mathbb{R}^{M\times n}$ is the M-head attention matrix and $\mathbf{Z} \in \mathbb{R}^{M\times d}$ is the resulting sentence representation matrix contains semantics from multiple aspects.

B Additional Experimental Details

For our approach, RBF kernel $\kappa(x, y) = \exp(-\frac{1}{h}\|x - y\|_2^2)$ with the bandwidth $h = med^2/\log M$ is used as the kernel function, where med denotes the median of the pairwise distance between current particles. The prior distribution of attention parameters is assumed to be uniform. We find that adding an repulsive weight before the repulsive term (i.e. the second term in Eq. 4) in particle-optimization update rules could help adjusting the degree of diversity in attention and achieving better performance. In our experiments, we adopt this trick and use the hyper-parameter α to denote the repulsive weight. Since our method only modifies the learning process of attention, all models and settings in our experiments kept the same with the corresponding previous work unless stated otherwise.

B.1 Self-attentive Sentence Classification

Dataset Three tasks are conducted on three public sentence classification datasets. *Author profiling* (Age dataset [1]) is to predict the age range of the user by giving their tweets. *Sentiment analysis* (Yelp dataset [2]) is to predict the number of stars the user assigned to by analysis their reviews. *Textual entailment* (SNLI dataset [3]) is to tell whether the semantics in the two sentences are entailment or contradiction or neutral. Following Lin et al. (2017), the train / validate / test split of Age is 68485 / 4000 / 4000, Yelp is 500K / 2000 / 2000, SNLI is 550K / 10K / 10K.

Experimental settings We implement the standard multi-head attention model in Lin et al. (2017) following the settings in it except that we use Spacy toolkit [4] as the tokenizer and GloVe [5] (GloVe 840B 300D) as the pre-trained word embedding. For repulsive multi-head attention learning, we keep all settings the same with the standard one (Lin et al., 2017). Hyper-parameters ϵ and α in SVGD are selected with grid search. For SPOS, we fix these two hyper-parameters and only tune β. The selection is based on the performance on the validation data. We train and evaluate all the models with 10 random seeds and compare their average performance. Models are trained on one TITAN Xp GPU.

B.2 Transformer-based Neural Translation

Dataset IWSLT14 German-to-English (De-En) dataset contains 153K / 7K / 7K sentence pairs. WMT14 English-to-German (En-De) dataset contains about 4.5 million training sentence pairs and uses newstest2013 dataset as the validation set, newstest2014 dataset as the test set. Data and the processing scripts could be found here [6].

Experimental settings Our implementation is based on the open-sourced `fairseq` [7] (Ott et al., 2019). We follow the settings in Vaswani et al. (2017) and have reproduced their reported results. For the WMT14 dataset, the `base` Transformer is used, which consists of a 6-layer encoder and a 6-layer decoder. The size of the hidden units and embeddings is 512 and the number of heads is 8. The `big` Transformers has 1024 hidden units and 16 heads, which is listed as a reference. For IWSLT14 dataset, the `small` setting is used and

the number of heads in every layer is set to 4. All the configurations are kept the same when applying our method or the regularization method. In our method, only the training process is changed and SVGD update rule is utilized in our algorithm. The stepsize ϵ in our method is set to 0.1 and the repulsive term α is set to 0.01. The Transformer-*small* model is trained on one TITAN Xp GPU. The Transformer-*base* model is trained on four GTX 1080Ti GPUs.

Additional Results To support a fair comparison, we also evaluate the Transformer-base model on WMT14 En-De task. The SACREBLEU score (Post, 2018) with and without our approach is 27.1 and 26.2[8], respectively.

B.3 ELECTRA

Dataset Following the official code of Clark et al. (2020), ELECTRA models are pretrained on the OpenWebTextCorpus [9] dataset, an open source effort to reproduce OpenAI's WebText dataset. OpenWebTextCorpus containes 38GB of text data from 8,013,769 documents. The pretrained model is then finetuned and evaluated on GLUE benchmark [10]. GLUE contains a variety of tasks covering textual entailment (RTE and MNLI) question-answer entailment (QNLI), paraphrase (MRPC), question paraphrase (QQP), textual similarity (STS), sentiment (SST), and linguistic acceptability (CoLA). Our evaluation metrics are Spearman correlation for STS, Matthews correlation for CoLA, and accuracy for the other GLUE tasks.

Experiment settings The ELECTRA-*small* model we implemented follow all official settings [11] except that it is fully-trained on one GTX 1080Ti GPU for 6 days. The ELECTRA-*small* model has 12 layers with 4 heads in every layer's attention. For our method, the stepsize ϵ is set to 0.01 and the repulsive term α is set to 0.1. The repulsive learning of attention is only applied to the pre-training stage. The fine-tuning remains the same with the original one.

B.4 GraphWriter

Dataset Experiments are conducted on the Abstract GENeration DAtaset (AGENDA) (Koncel-Kedziorski et al., 2019), a dataset of knowledge graphs paired with scientific abstracts. It consists of 40k paper titles and abstracts from the Semantic Scholar Corpus taken from the proceedings of 12 top AI conferences. We use the standard split of AGENDA dataset in our experiments: 38,720 for training, 1000 for validation, and 1000 for testing.

Experimental settings We follow the official settings [12] in Koncel-Kedziorski et al. (2019) with the encoder containing 6 layers and 4-head graph attention in every layer. We reproduce their results and keep all settings the same when applying the proposed repulsive attention. The SVGD update rule is used in our algorithm and applied to all layers. The stepsize ϵ is set to 0.1 and the repulsive weight is set to 0.01 in this experiment. The model is trained on one TITAN Xp GPU.

C Additional Analysis of Our Approach

C.1 Comparison with SGLD

We also conducted a comparison of our method with Stochastic gradient Langevin dynamics (SGLD) (Welling and Teh, 2011), which is also a Bayesian sampling method. Results are in Table 6. Though random noise brought by SGLD might help achieving diversity, it's sub-optimal. Using particle-optimization to add the repulsive term makes it more effective.

Sampling Method	Age	Yelp	SNLI	IWSLT14 De-En
None	81.47	69.3	83.79	34.4
SGLD	81.57	70.1	83.80	34.7
SVGD	**81.82**	**71.2**	**84.58**	**35.2**

Table 6: Performance of attention models with different sampling methods on four tasks. For Age, Yelp and SNLI sentence classification tasks, the evaluation metric is accuracy (%). For IWSLT14 De-En translation task, the evaluation metric is BLEU score. "None" here means the standard multi-head attention models.

C.2 What Prior to Use?

In our approach, the repulsiveness is imposed by the inference algorithm (*i.e.* SVGD), not prior. To study the impact of different priors, we also tested

---

[8] SacreBLEU hash: `BLEU+case.mixed+lang.en-de+numrefs.1+smooth.exp+test.wmt14/full+tok.13a+version.1.4.12`

[10] https://gluebenchmark.com/

[11] https://github.com/google-research/electra

[12] https://github.com/rikdz/GraphWriter

the Gaussian prior. We found that (see Table 7) different priors have little impact on the final results, *i.e.*, there is not a consistent winner for different priors. This suggests that, the prior has little impact on repulsiveness in our framework. But one can still impose prior knowledge of the attention to help our algorithm learn a better attention model. We would like to explore that in future works.

Prior	Age	Yelp	SNLI
Uniform	81.82	71.7	84.58
Gaussian	81.88	71.6	84.28

Table 7: Performance of our approach with different priors on three sentence classification tasks.The evaluation metric is accuracy (%)

C.3 Which attention modules to be diversified?

Models	BLEU	Time
MA	34.4	1
RMA (Q)	34.7	1.06
RMA (K)	34.7	
RMA (V)	34.9	
RMA (En)	34.6	1.06
RMA (De)	34.7	
RMA (En-De)	34.9	
RMA (first layer)	**35.1**	1.03
RMA (last layer)	34.7	
RMA (All)	**35.2**	1.13

Table 8: Ablation study of Transformer-`small`-RMA model on IWSLT14 De-En dataset with repulsive multi-head attention applied on different part of the model. En: self-attention in encoder. De: self-attention in decoder. En-De: inter-attention between encoder and decoder. Time: relative training time of every step versus MA.

There are three types of attention in Transformer: self-attention in the encoder, self-attention in the decoder, and inter-attention between the encoder and decoder. We conduct extra experiments on Transformer-`small` to investigate which attention module benefits most from the repulsiveness. Results are shown in Table 8. We first apply the repulsive attention on each of {Q,K,V} parameters in every attention module for all layers. The results indicate that diversifying the V-parameter seems to yield better performance. We then compare repulsive attention inside the encoder, inside the decoder and between them, respectively. The results show improvement in all cases, and diversifying inter-attention seems to achieve the most benefit. Finally, we diversify the attention in different layers of the Transformer. The results suggest that only diversifying the attention in the first layer is able to achieve comparable performance to the case of diversifying all layers, with little computational time increased.

C.4 Improved Calibration

A reliable model must not only be accurate, but also indicate when it is likely to get the wrong answer. It means the confidence of a well calibrated model should be indicative of the actual likelihood of correctness. Following the calibration metrics in Guo et al. (2017) and Thulasidasan et al. (2019), we evaluate the calibration of the model in Figure 4. For classifiers, the predicted softmax scores of winning class are represented as the confidence of models. Expected Calibration Error (ECE) and Overconfidence Error (OE) are two calibration metrics evaluating the reliability of a model. Following Guo et al. (2017) and Thulasidasan et al. (2019), softmax predictions are grouped into M interval bins of equal size. Let B_m be the set of samples whose prediction scores (the winning softmax score) fall into bin B_m. The accuracy and confidence of B_m are defined as

$$\begin{aligned}\text{acc}(B_m) &= \frac{1}{|B_m|}\sum_{i\in B_m}\mathbf{1}(\hat{y}_i = y_i)\\ \text{conf}(B_m) &= \frac{1}{|B_m|}\sum_{i\in B_m}\hat{p}_i\end{aligned}$$

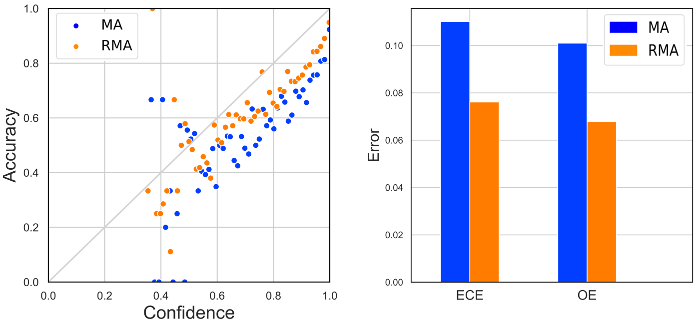
where $\hat{p}_i$ is the confidence (winning score) of sample i. The Expected Calibration Error (ECE) is then defined as:

$$\text{ECE} = \sum_{m=1}^{M}\frac{|B_m|}{n}|\text{acc}(B_m) - \text{conf}(B_m)|$$

In high-risk applications, confident but wrong predictions can be especially harmful. Overconfidence Error (OE) is defined as follow for this case.

$$\begin{aligned}\text{OE} = \sum_{m=1}^{M}\frac{|B_m|}{n}[&\text{conf}(B_m)\times\\ &\max(\text{conf}(B_m) - \text{acc}(B_m), 0)]\end{aligned}$$

As shown in Figure 4, the standard attention model is prone to be over-confident, meaning that the accuracy is likely to be lower than what is indicated



(a) (b)

Figure 4: (a) Scatterplots for accuracy and confidence for SNLI test set. The repulsive case (RMA) is much better calibrated with the points lying closer to the $y = x$ line, while in the standard case (MA), points tend to lie in the overconfident region. (b) Expected Calibration Error (ECE) and Overconfidence Error (OE) for two cases.

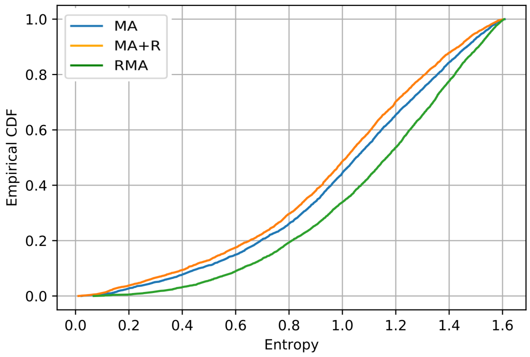


Figure 5: Empirical CDF for the entropy of the predictive distributions on Age dataset from the model trained on Yelp dataset. Curves that are closer to the bottom right part of the plot are preferable, as it denotes that the probability of observing a high confidence prediction is low.

by the predictive score. With the proposed repulsive training of attention, the model becomes better calibrated with much lower calibration error and overconfidence error, indicating that our method is beneficial for training more reliable multi-head attention models.

C.5 Improved Uncertainty Prediction

We follow Louizos and Welling (2017) to evaluate the predictive uncertainty. We estimate the entropy of the predictive distributions on Age dataset (out-of-distribution entropy) from the models trained on Yelp dataset. Since we a-priori know that none of the Age classes correspond to a trained class (they are two different tasks), the ideal predictive distribution is uniform over the Age dataset, i.e. a maximum entropy distribution. We plot the empirical CDF for the entropy in Figure 5. It shows that the uncertainty estimates from the repulsive multi-head attention model is better than the standard attention and the regularization approach.

Methods	**Acc(%)**	
	Age	Yelp
cosine similarity regularization	81.35	68.50
$i->j$	81.65	71.45
$i->j$, +smooth	81.85	71.50

Table 9: Adapt cosine similarity regularization on attention parameters gradually to our framework. Accuracy of the model is evaluated on the test set of Age and Yelp dataset.

C.6 Discussion with Existing Regularization-based Methods

Learning diverse attentions has been proposed in Lin et al. (2017) and Li et al. (2018), with different regularization techniques to enforce repulsiveness. In fact, we can show that existing methods are simplified versions of our framework, but with a potential mismatch between their algorithm and the underlying repulsiveness guarantee. To explain this, we follow Li et al. (2018) and apply cosine similarity regularizer to the attention parameter $\boldsymbol{\theta}$. When negative log-likelihood is used as the loss function and the prior of $\boldsymbol{\theta}^{(i)}$ is assumed to be uniform, the update function ϕ becomes:

$$\phi(\boldsymbol{\theta}_\ell^{(i)}) = -\nabla_{\boldsymbol{\theta}_\ell^{(i)}} U(\boldsymbol{\theta}_\ell^{(i)}) + \nabla_{\boldsymbol{\theta}_\ell^{(i)}} \frac{1}{M} \sum_{j=1}^{M} \frac{\boldsymbol{\theta}_\ell^{(i)} \boldsymbol{\theta}_\ell^{(j)}}{\|\boldsymbol{\theta}_\ell^{(i)}\| \|\boldsymbol{\theta}_\ell^{(j)}\|}$$

One can consider the cosine similarity as a kernel function. Applying this new kernel function to our framework results in the following update:

$$\phi(\boldsymbol{\theta}_\ell^{(i)}) = \frac{1}{M}\sum_{j=1}^{M} -\frac{\boldsymbol{\theta}_\ell^{(i)}\boldsymbol{\theta}_\ell^{(j)}}{\|\boldsymbol{\theta}_\ell^{(i)}\|\|\boldsymbol{\theta}_\ell^{(j)}\|}\nabla_{\boldsymbol{\theta}_\ell^{(j)}} U(\boldsymbol{\theta}_\ell^{(j)}) + \frac{1}{M}\sum_{j=1}^{M}\nabla_{\boldsymbol{\theta}_\ell^{(j)}}\frac{\boldsymbol{\theta}_\ell^{(i)}\boldsymbol{\theta}_\ell^{(j)}}{\|\boldsymbol{\theta}_\ell^{(i)}\|\|\boldsymbol{\theta}_\ell^{(j)}\|}$$

It is clear that our method (**??**) reduces to the regularizing method when 1) removing the smoothing term $\frac{\boldsymbol{\theta}_\ell^{(i)}\boldsymbol{\theta}_\ell^{(j)}}{\|\boldsymbol{\theta}_\ell^{(i)}\|\|\boldsymbol{\theta}_\ell^{(j)}\|}$ for $j \neq i$; and 2) replacing the derivative $\nabla_{\boldsymbol{\theta}_\ell^{(j)}}$ with $\nabla_{\boldsymbol{\theta}_\ell^{(i)}}$ in the repulsive term. For this reason, we argue that the regularization method lacks of a formal guarantee on the repulsiveness.

To show this, we adapt the cosine similarity regularization on attention parameters gradually to our framework by 1) replacing the derivative $\nabla_{\boldsymbol{\theta}_\ell^{(i)}}$ with $\nabla_{\boldsymbol{\theta}_\ell^{(j)}}$ in the repulsive term; 2) adding the smoothing term $\kappa(\boldsymbol{\theta}_\ell^{(j)}, \boldsymbol{\theta}_\ell^{(i)})$. Table 9 shows that both the smoothing and the corrected gradient lead to performance improvement over the standard regularization methods.

E A Generation Sample of Graph-to-Text Task

Title	Bilinear signal synthesis in array processing
Knowledge	(source positions, CONJUNCTION, angular separations); (time-frequency synthesis techniques, USED-FOR, multiple source signals); (non-integer values, USED-FOR, weighing function); (weighing function, USED-FOR, time-frequency domain); (quadratic t-f distributions, USED-FOR, source separation techniques); (spatial time-frequency distributions, USED-FOR, blind source separation methods); (time-frequency synthesis techniques, USED-FOR, antenna array)
GraphWriter	In this paper, we propose a novel method for blind source separation methods based on a weighing function. In the proposed method, the spatial signatures of sources is modeled as a weighing function, and the spatial time-frequency distributions is modeled as a weighing function. The spatial time-frequency distributions is modeled as a weighing function in the time-frequency domain. The proposed method is based on the use of a weighing function to estimate the parameters of the blind source separation methods. The proposed method is based on the use of a weighing function to estimate the parameters of the blind source separation methods. The proposed method is applied to the problem of multiple source signals in the time-frequency domain. The proposed method is applied to the problem of multiple source signals in the time-frequency domain. The proposed method is shown to be robust to noise levels, whitening, and angular separations.
+ RMA	In this paper, we present a novel approach to multiple source signals based on the spatial signatures of sources and angular separations. In particular, we consider the problem of estimating the spatial signatures of sources from a single image of an antenna array. We propose a novel method for estimating the spatial signatures of sources using a weighing function, where the source positions and angular separations are estimated in a time-frequency domain. We show that the proposed method can be used to derive a weighing function for the communication channel. The proposed method is based on the use of quadratic t-f distributions in the time-frequency domain and the non-integer values. The proposed method is applied to the problem of whitening and angular separations. The experimental results show that the proposed method is more robust to noise levels and noise levels.
Gold	Multiple source signals impinging on an antenna array can be separated by time-frequency synthesis techniques. Averaging of the time-frequency distributions of the data across the array permits the spatial signatures of sources to play a fundamental role in improving the synthesis performance. Array averaging introduces a weighing function in the time-frequency domain that decreases the noise levels, reduces the interactions of the source signals, and mitigates the crossterms. This is achieved independent of the temporal characteristics of the source signals and without causing any smearing of the signal terms. The weighing function may take non-integer values, which are determined by the communication channel, the source positions and their angular separations. Unlike the recently devised blind source separation methods using spatial time-frequency distributions, the proposed method does not require whitening or retrieval of the source directional matrix. The paper evaluates the proposed method in terms of performance and computations relative to the existing source separation techniques based on quadratic t-f distributions.

Abstract

Syntactic parsers have dominated natural language understanding for decades. Yet, their syntactic interpretations are losing centrality in downstream tasks due to the success of large-scale textual representation learners. In this paper, we propose KERMIT (Kernel-inspired Encoder with Recursive Mechanism for Interpretable Trees) to embed symbolic syntactic parse trees into artificial neural networks and to visualize how syntax is used in inference. We experimented with KERMIT paired with two state-of-the-art transformer-based *universal sentence encoders* (BERT and XLNet) and we showed that KERMIT can indeed boost their performance by effectively embedding human-coded universal syntactic representations in neural networks.

1 Introduction

Universal sentence embeddings (Conneau et al., 2018), which are task-independent, distributed sentence representations, are redesigning the way linguistic models in natural language processing are defined. These embeddings are usually created from scratch over large corpora without human supervision (Cho et al., 2014; Kiros et al., 2015; Conneau et al., 2017; Subramanian et al., 2018; Cer et al., 2018) or are crafted with compositional distributional semantics methods (Clark and Pulman, 2007; Mitchell and Lapata, 2008; Baroni and Zamparelli, 2010; Zanzotto et al., 2010).

Traditional task-independent, symbolic, human-defined syntactic interpretations for sentences, which may be referred to as *universal syntactic interpretations*, are losing their centrality in language understanding systems due to the success of transformer-based neural networks (Vaswani et al., 2017) that have boosted performances on a wide variety of linguistic tasks (Devlin et al., 2018; Liu et al., 2019; Yang et al., 2019).

There is evidence that universal sentence embeddings store bits of universal syntactic interpretations. Even if not explicitly designed for encoding syntax, these embeddings implicitly capture syntactic relations among words with different strategies. Transformers (Devlin et al., 2018; Liu et al., 2019; Yang et al., 2019; Dai et al., 2019) seem to capture syntactic relations among words by "focusing the attention". Yet, to be sure that syntax is encoded, many syntactic *probes* (Conneau et al., 2018) for neural networks have been designed to test for specific phenomena (Kovaleva et al., 2019; Jawahar et al., 2019; Hewitt and Manning, 2019; Ettinger, 2019; Goldberg, 2019) or for full syntactic trees (Hewitt and Manning, 2019; Mareček and Rosa, 2019). Indeed, some syntax is correctly encoded in these universal sentence embeddings.

However, universal sentence embeddings encode syntax in a way that is opaque and not so universal. Firstly, and perhaps surprisingly, task-adapted universal sentence embeddings encode syntax better than general universal sentence embeddings (Jawahar et al., 2019). Secondly, even if these embeddings contains syntactic information and may be "just another way in which traditional syntactic models are encoded" (Fodor and Pylyshyn, 1988), there is no clear view on how this information is encoded and, hence, on how syntactic information is *holistically* (Chalmers, 1992) used in inference. Then, it is difficult to envisage ways to symbolically control the behavior of neural networks.

In this paper, we investigate whether explicit *universal syntactic interpretations* can be used to improve state-of-the-art universal sentence embeddings and to create neural network architectures where syntax decisions are less obscure and, thus, syntactically explainable. For this purpose we propose KERMIT, a Kernel-inspired Encoder with a Recursive Mechanism for Interpretable Trees, and KERMIT*viz* . KERMIT is a lightweight en-

coder for embedding syntax parse trees in universal-syntax-encoding vectors by explicitly embedding subtrees in the representation space. KERMIT*viz* is a visualizer to inspect how syntax is used in taking final decisions in specific tasks. We showed that KERMIT can effectively embed different syntactic information and KERMIT*viz* can explain KERMIT's decisions. Furthermore, paired with universal sentence embeddings, KERMIT outperforms state-of-the-art models - BERT (Devlin et al., 2018) and XLNet (Yang et al., 2019) - in three different downstream tasks, albeit findings in Kuncoro et al. (2020), showing that traditional syntactic information is not represented in universal sentence embeddings.

2 Background and Related Work

Embedding symbolic syntactic or structured information within neural networks is a very active research field given the impression that using pre-existing syntactic knowledge in neural networks can be beneficial for many tasks. Initial attempts have tried to recursively encode structures in distributed representations to use them inside neural networks (Pollack, 1990; Goller and Kuechler, 1996). More recently, Socher et al. (2011) have defined the notion of Recursive Neural Networks (RecNN) that are Recurrent Neural Networks applied to binary trees. Initially, these RecNNs have been used to parse sentences and not to include pre-existing syntax in a final task (Socher et al., 2011). Then, these RecNNs have been used to encode pre-existing syntax in the specific task of Sentiment Analysis (Socher et al., 2012, 2013). With the rise of Long Short-Term Memories (LSTMs), Tai et al. (2015); Zhu et al. (2015) and Zhang et al. (2016) independently proposed TreeLSTM as an adapted version of LTSM that may use syntactic information. In TreeLSTM, the LSTM is applied following the structure of a binary tree instead of following an input sequence. In semantic relatedness and in sentiment classification, TreeLSTM has outperformed RecNN (Tai et al., 2015) by using pre-existing syntactic information. TreeLSTM has also been used to induce task-specific trees while learning a novel task (Choi et al., 2018). Moreover, Munkhdalai and Yu (2017) have specialized LSTM for binary and n-ry trees with their Neural Tree Indexers and Strubell et al. (2018) have encoded syntactic information by using multi-head attention within a transformer architecture.

However, there is a major problem with the methods for embedding syntactic structures in neural networks, it is unclear which parts of the parse trees are represented, and how. Hence, the behavior of neural networks that use these embeddings is obscure. It is then difficult to understand what kind of syntactic knowledge is encoded in the different layers and how this syntactic knowledge is used.

Some initial attempts to clarify which syntactic parts are encoded in embedding vectors exist. Zhang et al. (2018) have encoded parse trees by means of paths connecting the root of parse trees with words. Yet, these attempts are still far from completely representing parse trees.

For a long time, structural kernel functions have been the way to exploit syntactic information in learning but these functions cannot be used within neural networks. Kernel machines (Cristianini and Shawe-Taylor, 2000) exploit these, generally recursive, structural kernel functions that define a similarity measure between two trees counting common substructures. Hence, these structural *kernel functions* are built over a clear, although hidden, space of substructures. Structural kernels have been defined for both constituency-based (Collins and Duffy, 2002; Moschitti, 2006) and dependency-based parse trees (Culotta and Sorensen, 2004). As underlying spaces are well defined, it is even possible to extract back substructures that are relevant in each decision (Pighin and Moschitti, 2010). However, these structural kernel functions are *generally recursive algorithms* that hide the real underlying space of features. Thus, structures are never represented as vectors in the target representation spaces as these spaces are generally huge. It is generally impossible then to use these clear spaces in learning with neural networks.

In the field of structural kernels, distributed tree kernels (Zanzotto and Dell'Arciprete, 2012) have opened an interesting possibility. To reduce the computational cost of tree kernels, these distributed tree kernels embed the huge space of substructures in a smaller space. This embedding is obtained by using recursive functions, which are linear with respect to the tree size. Hence, structures are represented in a smaller vector in an embedded space that represents the original space of structures. Hence, DTKs open an interesting path to include clear syntactic information in neural network architectures (Zanzotto and Ferrone, 2017; Santilli and Zanzotto, 2018).

3 The model

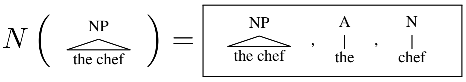
This section introduces our Kernel-inspired Encoder with a Recursive Mechanism for Interpretable Trees (KERMIT) (Sec.3.2) along its visualizer KERMIT*viz* (Sec.3.3). KERMIT is a lightweight encoder for universal syntactic interpretations which can be used in combination with transformer-based networks such as BERT (Devlin et al., 2018) and XLNet (Yang et al., 2019) (Fig. 1). Some preliminary notations are given in Section 3.1.

3.1 Preliminary notation

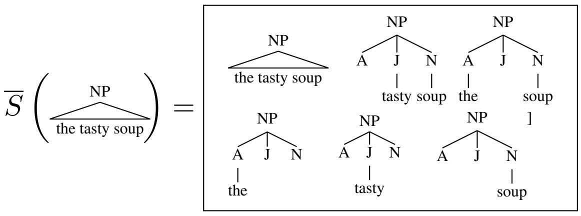
This section fixes the notation for parse trees, random vectors and operations on random vectors as these are core representations in our model to deal with universal syntactic interpretations.

Parse trees $\mathcal{T}$ and parse subtrees τ are recursively represented as trees $t = (r, [t_1, ..., t_k])$ where r is the label representing the root of the tree and $[t_1, ..., t_k]$ is the list of child trees t_i. Leaves t are represented as trees $t = (r, [])$ with an empty list of children or directly as $t = r$.

On parse trees $\mathcal{T}$, our model KERMIT requires the definition of three sets of subtrees: the set $N(\mathcal{T})$, the set $\overline{S}(\mathcal{T})$ and the set of $S(\mathcal{T})$. The last two sets are defined according to subtrees we want to model in the embeddings of the universal syntactic interpretations. We use subtrees defined in Collins and Duffy (2002). The set $N(\mathcal{T})$ contains all the complete subtrees of $\mathcal{T}$. Given a tree $\mathcal{T}$ and r one of its nodes, a complete subtree of $\mathcal{T}$ from r is the subtree rooted in r that reaches the leaves, for example (see the parse tree in Fig. 1):



The set $\overline{S}(\mathcal{T})$ contains all the valid subtrees of $\mathcal{T} = (r, [t_1, ..., t_k])$ as follows $(r, [])$ is in $\overline{S}(\mathcal{T})$ and each $(r, [\tau_1, ..., \tau_k])$ where $\tau_i \in \overline{S}(t_i)$ are in $\overline{S}(\mathcal{T})$, for example:



Finally, the set $S(\mathcal{T})$ is the union of the sets $\overline{S}(t)$ for all the trees $t \in N(\mathcal{T})$, that is:

$$S(\mathcal{T}) = \bigcup_{t \in N(\mathcal{T})} \overline{S}(t)$$

and it contains the subtrees used during training and inference.

Finally, to build the untrained KERMIT encoder, we use the properties of random vectors drawn from a multivariate Gaussian distribution $\boldsymbol{v} \sim \mathcal{N}(0, \frac{1}{\sqrt{d}}\mathbb{I})$. These vectors guarantee that $\boldsymbol{u}^T\boldsymbol{v} \approx 0$ if $u \neq v$ and $\boldsymbol{u}^T\boldsymbol{u} \approx 1$. This property is extremely important for interpretability. To compose vectors, we use the shuffled circular convolution $\boldsymbol{u} \otimes \boldsymbol{v}$. If these vectors are drawn from a multivariate Gaussian distribution, the function guarantees that $(\boldsymbol{u} \otimes \boldsymbol{v})^T\boldsymbol{u} \approx 0$, $(\boldsymbol{u} \otimes \boldsymbol{v})^T\boldsymbol{v} \approx 0$ and $(\boldsymbol{u} \otimes \boldsymbol{v}) \neq (\boldsymbol{v} \otimes \boldsymbol{u})$. This operation is a circular convolution $\star$ (as for Holographic Reduced Representations (Plate, 1995)) with a permutation matrix Φ: $\boldsymbol{u} \otimes \boldsymbol{v} = \boldsymbol{u} * \Phi\boldsymbol{v}$. This operation is extremely important for soundly composing node vectors.

3.2 The encoder for parse trees and its sub-network

KERMIT is a lightweight neural layer that allows the encoding and use of universal syntactic interpretations in neural networks architectures. This layer has two main components. The first component is the KERMIT encoder that actually encodes parse trees $\mathcal{T}$ in embedding vectors:

$$\boldsymbol{y} = \mathcal{D}(\mathcal{T}) \tag{1}$$

which corresponds to the gray arrow and the gray box in the KERMIT side of Fig. 1. The second component is a multi-layer perceptron that exploits these embedding vectors:

$$\boldsymbol{z} = mlp(\boldsymbol{y}) \tag{2}$$

which corresponds to green area in the KERMIT side of Fig. 1.

The KERMIT encoder $\mathcal{D}$ in Eq. 1 stems from tree kernels (Collins and Duffy, 2002) and distributed tree kernels (Zanzotto and Dell'Arciprete, 2012). It makes it possible to represent parse trees in vector spaces $\mathbb{R}^d$ that embed huge spaces of subtrees $\mathbb{R}^n$ where n is the huge number of different subtrees. Each tree $\mathcal{T}$ is represented by using the set of its valid subtrees $S(\mathcal{T})$. The encoder is based on an embedding layer for tree node labels $\boldsymbol{x_r} = \boldsymbol{W_o r} \in \mathbb{R}^d$ and on a recursive encoding function based on the shuffled circular convolution $\otimes$ introduced by Zanzotto and Dell'Arciprete (2012). The embedding layer $\boldsymbol{x_r} = \boldsymbol{W_o r} \in \mathbb{R}^d$ is an untrained encoding function that maps one-hot vectors $\boldsymbol{r}$ of tree node labels r to random vectors drawn from the previously introduced multivariate Gaussian distribution $\mathcal{N}(0, \frac{1}{\sqrt{d}}\mathbb{I})$. Hence, $\boldsymbol{W_o} \in R^{m \times d}$ is a matrix of m columns where m is the cardinality of the set of node labels and each column $\boldsymbol{w^{(i)}}$ of the matrix $\boldsymbol{W_o}$ is $\boldsymbol{w^{(i)}} \sim \mathcal{N}(0, \frac{1}{\sqrt{d}}\mathbb{I})$. The function $\mathcal{D}(\mathcal{T})$ is defined as a the sum of recursive function $\Upsilon(t)$ on parse trees:

$$\boldsymbol{y} = \mathcal{D}(\mathcal{T}) = \sum_{t \in N(\mathcal{T})} \Upsilon(t)$$

where $N(\mathcal{T})$ is the previously defined set of complete subtrees of $\mathcal{T}$. Then, $\Upsilon(t)$ is defined as:

$$\Upsilon(t) = \begin{cases} \sqrt{\lambda}\boldsymbol{W_o r} & \text{if } t = (r, []) \\ \sqrt{\lambda}(\boldsymbol{W_o r} + \boldsymbol{W_o r} \otimes \Upsilon(t_1) \otimes ... \otimes \Upsilon(t_k)) \\ \qquad \text{if } t = (r, [t_1, ..., t_k]) \end{cases}$$

where $0 < \lambda \leq 1$ is a decaying factor penalizing large subtrees (Collins and Duffy, 2002; Zanzotto and Dell'Arciprete, 2012). By implementing $\mathcal{D}(\mathcal{T})$ with a dynamic algorithm, its computational cost is linear with respect to the nodes of the tree $\mathcal{T}$ and the cost of the basic function $\otimes$ is $d \log d$ where d is the size of the representation space $\mathbb{R}^d$. In fact, the circular convolution can be computed with Fast Fourier Transformation.

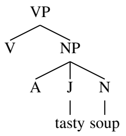
Given its nature, the tree neural encoder has a nice interpretation as a very simple embedding layer, that is, $\boldsymbol{W_\Upsilon} \in \mathbb{R}^{d \times n}$ that embeds the space of subtrees in a smaller space $\mathbb{R}^d$. This is in line with the Johnson-Lindenstrauss Transformation (Johnson and Lindenstrauss, 1984). Hence, $\mathcal{D}(\mathcal{T})$ can be seen as the following:

$$\boldsymbol{y} = \mathcal{D}(\mathcal{T}) = \boldsymbol{W_\Upsilon x} \tag{3}$$

where $\boldsymbol{x}$ is the vector representing the set of subtrees $S(\mathcal{T})$, that is, the sum of $\sqrt{\lambda^k}\boldsymbol{x}_t$ where $\boldsymbol{x}_t$ is one-hot vector representing $t \in S(\mathcal{T})$, λ is the decaying factor for penalizing large trees and k is the number of nodes of the tree t. It is possible and easy to show that columns $\boldsymbol{w_i}$ of $\boldsymbol{W_\Upsilon}$ encode subtrees t as follows:

$$w^{(i)} = \Gamma(t^{(i)}) = \begin{cases} \boldsymbol{W_o r} & \text{if } t^{(i)} = (r, []) \\ \boldsymbol{W_o r} \otimes \Gamma(t_1^{(i)}) \otimes ... \otimes \Gamma(t_k^{(i)}) \\ \qquad \text{if } t = (r, [t_1^{(i)}, ..., t_k^{(i)}]) \end{cases}$$

for example:



$$\Gamma(\quad) = \boldsymbol{W_o e_{VP}} \otimes (\boldsymbol{W_o e_N} \otimes \boldsymbol{W_o e_{NP}} \otimes(\boldsymbol{W_o e_A} \otimes (\boldsymbol{W_o e_J} \otimes \boldsymbol{W_o e_{tasty}}) \otimes(\boldsymbol{W_o e_N} \otimes \boldsymbol{W_o e_{soup}})))$$

where $\sqrt{\lambda^8}$ is the decay factor applied to the sample subtree with 8 nodes.

Given the properties of the vectors $E(r) \sim \mathcal{N}(0, \frac{1}{\sqrt{d}}\mathbb{I})$ and the properties of the shuffled circular convolution $\otimes$, it is possible to empirically demonstrate that $\Gamma(t_i)^T\Gamma(t_i) \approx 1$ and $\Gamma(t_i)^T\Gamma(t_j) \approx 0$ (Plate, 1995; Zanzotto and Dell'Arciprete, 2012). Hence, this property can be used to interpret the behavior of the decision in the neural network.

3.3 Visualizing Neural Network Activation on Syntactic Trees

The definitions of the KERMIT encoder make it possibile to devise KERMIT*viz* , which offers *prediction interpretability* (Jacovi et al., 2018) in the context of textual classification. We propose a clear *causal relation for explaining* (Lipton, 2016) classification decisions where syntax is important by defining *heat parse trees* and calculating the relevance of single subtrees with layer-wise relevance propagation (LRP) (Bach et al., 2015). LRP has already been used in the context of explaining decisions in natural language processing tasks (Croce et al., 2019b,a).

Heat parse trees (HPTs), similarly to "heat trees" in biology (Foster et al., 2017), are heatmaps over parse trees (see the colored tree in Fig. 1). The underlying representation is an *active tree* $\bar{t}$, that is a tree where each node $\bar{t} = (r, v_r, [\bar{t}_1, ..., \bar{t}_k])$ has an activation value $v_r \in \mathbb{R}$ associated. HPTs are graphical visualizations of active trees $\bar{t}$ where colors and sizes of nodes r depend on their activation values v_r. In this way, HPTs highlight parts of parse trees relevant in final decisions.

To draw HPTs, we compute activation value v_r of nodes r in *active tree* $\bar{t}$ by using Layer-wise Relevance Propagation (LRP) (Bach et al., 2015) and the property in Eq. 3 of the KERMIT encoder $\mathcal{D}$. LRP is a framework which explains decisions of a generic neural network using local redistribution rules that propagate back decisions to activation values of initial features. In our case, this is used as a sort of inverted function of the multi-layer perceptron in Eq. 2, that is:

$$\boldsymbol{y}_{LRP} = mlp^{-1}_{LRP}(\boldsymbol{z})$$

The property in Eq. 3 enables the activation of each subtree $t \in \mathcal{T}$ to be computed back by transposing the matrix $\boldsymbol{W}_{\boldsymbol{\Upsilon}}$, that is:

$$\boldsymbol{x}_{LRP} = \boldsymbol{W}_{\boldsymbol{\Upsilon}}{}^{T}\boldsymbol{y}_{LRP}$$

To make the computation feasible, $\boldsymbol{W}_{\boldsymbol{\Upsilon}}{}^{T}$ is produced on-the-fly for each tree $\mathcal{T}$. Finally, activation values v_r of nodes $r \in \mathcal{T}$ are computed by summing up values $\boldsymbol{x}^{(i)}_{LRP}$ if $r \in t^{(i)}$.

4 Experiments

We aim to investigate whether KERMIT can be used to create neural network architectures where *universal syntactic interpretations* are useful: (1) to improve state-of-the-art universal sentence embeddings, especially in computationally light environments, and (2) to syntactically explain decisions.

The rest of the section describes the experimental set-up, the quantitative experimental results of KERMIT and discusses how KERMIT*viz* can be used to explain inferences made by neural networks over examples.

4.1 Experimental Set-up

This section describes the general experimental set-up of our experiments, the specific configurations adopted in the *completely universal* and *task-specific* settings, the used computational architecture and the datasets.

The general experimental settings are described hereafter. Firstly, the core of our method KERMIT encoder has been tested on a distributed representation space $\mathbb{R}^d$ with $d = 4000$ with the penalizing factor λ set to $\lambda = 0.4$ as this has been considered a common value in previous works (Moschitti, 2006). Secondly, constituency parse trees for KERMIT have been obtained by using Stanford's CoreNLP probabilistic context-free grammar parser (Manning et al., 2014). Thirdly, the following transformer sub-networks have been used: (1) BERT$_{\text{BASE}}$, used in the uncased setting with the pre-trained English model; (2) BERT$_{\text{LARGE}}$, used with the same settings of BERT$_{\text{BASE}}$; and, (3) XLNet base cased. All the models were implemented using Huggingface's transformers library (Wolf et al., 2019). The input text for BERT and XLNet has been preprocessed and tokenized as specified in respectively in Devlin et al. (2018) Yang et al. (2019). Fourthly, as the experiments are text classification tasks, the decoder layer of our KERMIT+Tranformer architecture is a fully connected layer with the softmax activation function applied to the concatenation of the KERMIT output and the final *[CLS]* token representation of the selected transformer model. Finally, the optimizer used to train the whole architecture is AdamW (Loshchilov and Hutter, 2019) with the learning rate set to $3e^{-5}$.

In the *completely universal* setting, KERMIT is composed only by the first lightweight encoder layer (grey layer in Figure 1) (KERMIT$_{\text{ENC}}$). In this setting, we used BERT$_{\text{BASE}}$ and XLNet. To study universality, transformers' weights are fixed in order to avoid the representation drifting toward the data distribution of the task. Moreover, we also experimented with BERT$_{\text{BASE}}$-Reverse and BERT$_{\text{BASE}}$-Random to understand whether syntactic or structural information is important for the specific task. In fact, BERT$_{\text{BASE}}$-Reverse is BERT$_{\text{BASE}}$ with a reversed text as input and BERT$_{\text{BASE}}$-Random is BERT$_{\text{BASE}}$ with a randomly shuffled text as input. Comparing BERT$_{\text{BASE}}$ with BERT$_{\text{BASE}}$-Reverse and BERT$_{\text{BASE}}$-Random is in itself an extremely important test as it offers also a way to determine if syntactic information is useful for a specific task. The KERMIT+Tranformer is trained with a batch size of 125 for 50 epochs. In addition, each experiment has been repeated 5 times with 5 different fixed seeds to assess the statistical significance of experimental results. This setting is designed to asses whether *universal syntactic interpretations*

add different information with respect to *universal sentence embeddings* and whether *universal syntactic interpretations* are a viable solution to increase the performance of neural networks in *light computational systems*.

In the *task-adapted* setting, we used two different architecture of BERT, BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$, and we trained different layers of these architectures. In this way, $BERT$ may adapt the *universal sentence embeddings* to include task-specific information which is the specific lexicon that may drive syntactic analysis. For the KERMIT side of the architecture, we used two different multi-layer perceptrons: (1) a *funnel* MLP with two linear layers that brings the 4,000 units of the KERMIT encoder down to 200 units with an intermediate level of 300 units (KERMIT$_{\triangleright}$); (2) a *diamond* MLP with four linear layers forming a diamond shape: 4,000 units, 5,000 units, 8,000 units, 5,000 units and, finally 4,000 units (KERMIT$_{\diamond}$). Both KERMIT$_{\triangleright}$ and KERMIT$_{\diamond}$ have ReLU (Agarap, 2018) activation functions and dropout (Srivastava et al., 2014) set to 0.25 for each layer. Due to the computational demand of these architectures and these experiments, we used the *heavy system* and we trained the overall model in two settings: a *one-epoch training session* and a *normal training session*. In the one-epoch training session, we trained the architecture with 1 epoch (Komatsuzaki, 2019) to avoid overfitting and to guarantee the possibility of having a relatively light computational burden. In the normal training session, we trained the architecture for 5 epochs. The batch size for these two settings was 32.

We experimented with two hardware systems: a *light system* and a *heavy system*. The *light system* is an affordable old desktop consisting of a 4 Cores Intel Xeon E3-1230 CPU with 62 Gb of RAM and 1 Nvidia 1070 GPU with 8Gb of onboard memory. The *heavy system* is a more expensive, dedicated server consisting of an IBM PowerPC 32 Cores CPU with 256 Gb of RAM and 2 Nvidia V100 GPUs with 32Gb of on board memory each.

To verify our model, we experimented with four classification tasks[1] (Zhang et al., 2015) which should be sensitive to syntactic information. The tasks include: (1) AGNews, a news classification task with 4 target classes; (2) DBPedia, a classification task over wikipedia with 14 classes; (3) Yelp Polarity, a binary sentiment classification task of Yelp reviews; and (4) Yelp Review, a sentiment classification task with 5 classes. Given the computational constraints of the *light system* setting, we created a smaller version of the original training datasets by randomly sampling 11% of the examples and keeping the datasets balanced as the original versions.

For reproducibility, the source code of our experiments is publically available[2].

4.2 Results and Discussion

Results from the *completely universal* experimental setting suggest that *universal syntactic interpretations complement syntax in universal sentence embeddings*. This conclusion is derived from the following observations of Table 1, which reports results in terms of the accuracy of the different models based on the different datasets. All these experiments were carried out on the *light system*.

Firstly, syntactic or structural information seems to be relevant in three out of four tasks. Syntactic information in AGNews seems to be irrelevant as there is a small difference in results between BERT$_{\text{BASE}}$, on the one side, with 82.88(±0.09) and BERT$_{\text{BASE}}$-Reverse with 79.72(±0.11) and

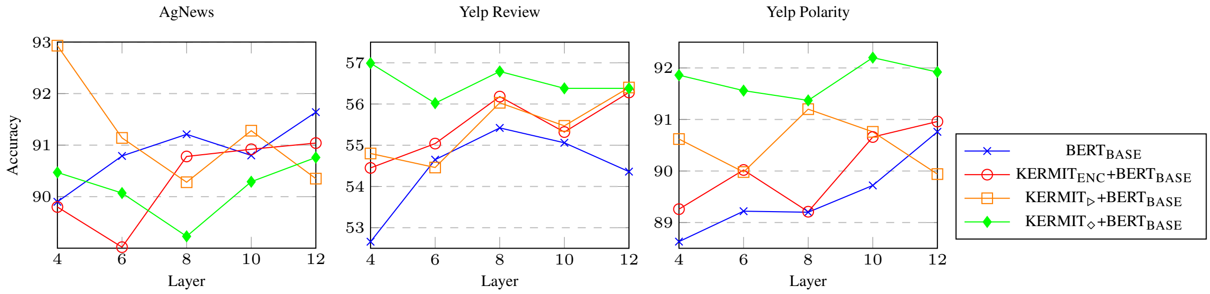
[2] The code is available at `https://github.com/ART-Group-it/KERMIT`

Setting: 1 Epoch learning



Setting: 5 Epoch learning (compared with the best of 1-epoch learning setting)

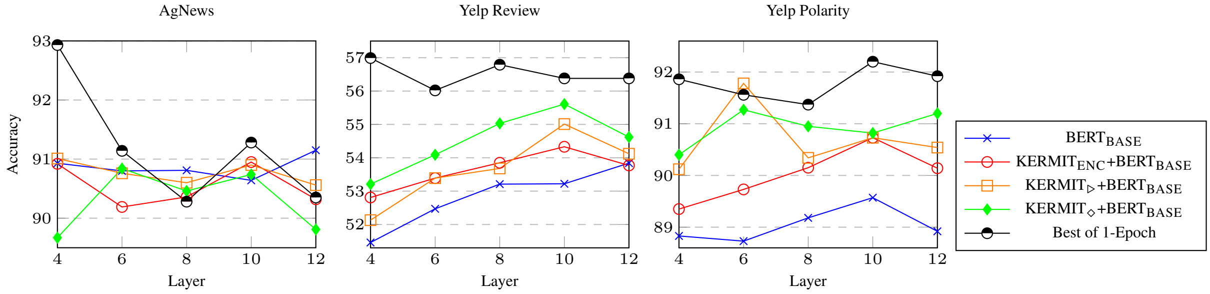


Figure 2: Comparison between KERMIT+BERT and BERT when training layers in BERT: Accuracy vs. Learned Layers in two different learning configurations - 1-Epoch and 5-Epoch training

$\text{BERT}_{\text{BASE}}$-Random with 80.39(±0.20), on the other. This small difference suggests that the order of words in the text is not particularly relevant and the classification is made on the lexical level. This justifies the very poor result from $\text{KERMIT}_{\text{ENC}}$ in this dataset, that is 25.23(±0.14).

Secondly, $\text{KERMIT}_{\text{ENC}}$ alone outperforms $\text{BERT}_{\text{BASE}}$ and XLNet in two cases where syntactic information is relevant, that is, 49.58(±0.1) vs. 42.90(±0.05) and 46.26(±0.13) in Yelp Review and 85.91(±0.03) vs. 79.21(±0.5) and 81.99(±0.15) in Yelp polarity. Hence, $\text{KERMIT}_{\text{ENC}}$ provides a good model for including *universal syntactic interpretations* in a neural network architecture. However, $\text{KERMIT}_{\text{ENC}}$ performed worse with respect to XLNet and $\text{BERT}_{\text{BASE}}$ in DBPedia even if syntactic information seems to be useful. This may be justified as both XLNet and $\text{BERT}_{\text{BASE}}$ are trained on Wikipedia, thus *universal sentence embeddings* are already adapted to the specific dataset.

Thirdly, in the three cases where syntactic information is relevant (Yelp Review, Yelp Polarity and DBPedia), the complete KERMIT+Transformer outperforms the model that is based only on the related Transformer, and the difference is statistically significant: 53.72(±0.14) vs. 46.26(±0.13) in Yelp Review, 94.51(±0.05) vs. 92.46(±0.09) in DBPedia and 88.99(±0.17) vs. 81.99(±0.15) in Yelp Polarity for XLNet and 52.02(±0.06) vs. 42.90(±0.05) in Yelp Review, 97.73(±0.16) vs. 97.11(±0.27) in DBPedia and 87.58(±0.17) vs. 79.21(±0.50) in Yelp Polarity for $\text{BERT}_{\text{BASE}}$. Even in DBPedia where transformers' embeddings are pretrained, KERMIT+Transformer outperforms the model based only on the related transformer.

This last observation is a very important indication and, together with the other observations, confirms that *universal sentence embeddings* encode different syntactic information with respect to that defined in *universal syntactic interpretations*. Moreover, our KERMIT encoder allows neural networks to positively use *universal syntactic interpretations*. Hence, using *universal syntactic interpretations* is a viable solution also when only light computational systems are available.

Experiments in the *task adapted* setting: (1) show that *universal syntactic interpretation* is still useful even when *universal sentence embeddings* are adapted to the specific task; (2) confirm the conclusions of Jawahar et al. (2019) that *universal sentence embeddings* better capture syntactic phenomena when the middle layers of BERT are learned over the task. The results of these experiments are plotted in Figure 2 where system accuracy is plotted against the number of BERT's learned layers starting from the output layer. In fact, it seems that different BERT's layers encode different in-

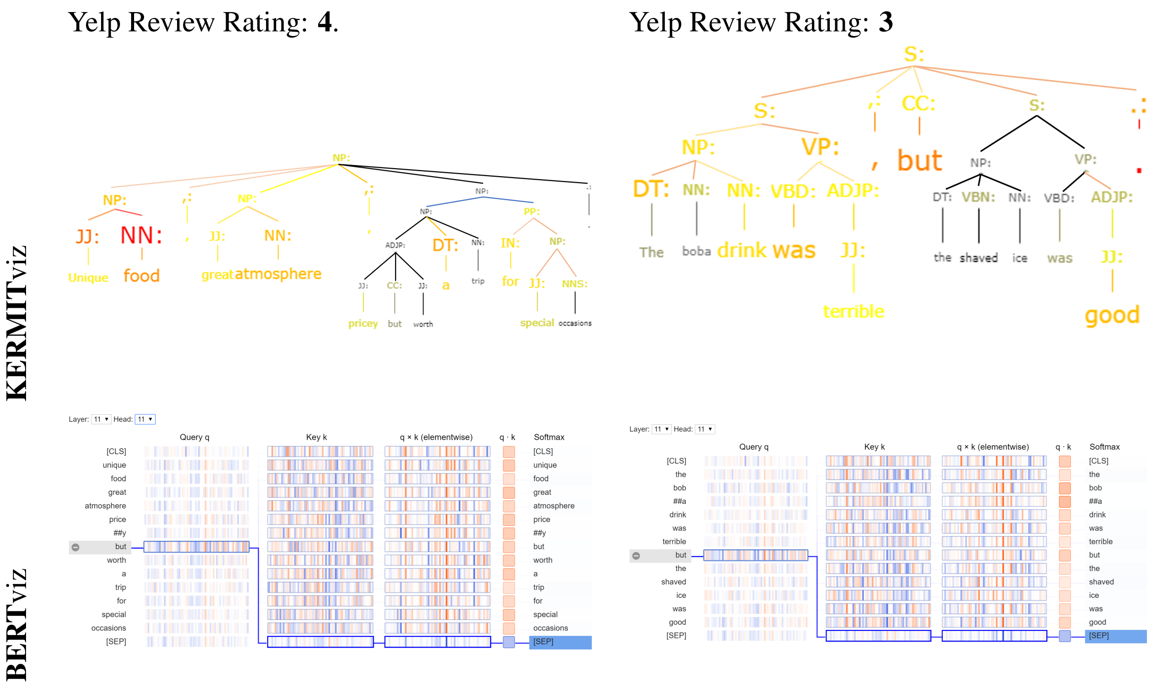

Figure 3: KERMIT*viz* vs. BERTviz: Comparing interpretations over KERMIT and over BERT on two sample sentences of Yelp Review where the word *but* is correlated or not with the final polarity.

formation Jawahar et al. (2019). Hence, learning different layers in a specific setting means adapting that kind of information. We experimented with two sub-settings: (1) a computationally lighter setting where training is done only for 1 epoch; (2) a more expensive setting where training is done for 5 epochs.

Our results in the task adapted setting confirms that BERT adapts *universal sentence embeddings* to include a better syntactic model when its weights in different layers are trained over the specific corpus. Moreover, as shown in Jawahar et al. (2019), layers in the middle cover better syntactic phenomena. In fact, when BERT learns up to the 8th layer, BERT's accuracy seems to come closer to the best model including *universal syntactic interpretations* (see Figure 2) . This suggests that more syntax is encoded in BERT.

All these experiments were performed also using $\text{BERT}_{\text{LARGE}}$ in place of $\text{BERT}_{\text{BASE}}$, but in all the experiments results were worse compared to the base version, therefore not reported in the paper.

When syntax matters, that is, in Yelp Review and in Yelp Polarity, KERMIT is able to exploit *universal syntactic interpretation* to compensate for missing syntactic information in the *task-adapted sentence embeddings* of a trained BERT. In fact, KERMIT+BERT outperforms a trained $\text{BERT}_{\text{BASE}}$in both the 1-epoch and 5-epoch settings for any number of trained layers (see Figure 2). In the 1-epoch setting, $\text{KERMIT}_{\diamond}$+$\text{BERT}_{\text{BASE}}$ outperforms $\text{BERT}_{\text{BASE}}$ and all the other configurations. In the 5-epoch setting, $\text{KERMIT}_{\text{ENC}}$+$\text{BERT}_{\text{BASE}}$ is the best model.

Moreover, KERMIT-based models behave better with less training. In fact, KERMIT-based models learned in the 1-epoch setting, outperform models learned in the 5-epoch setting. Plots in Figure 2 report the best 1-epoch setting model in the plots of the 5-setting model. This can be linked to the fact that KERMIT with more parameters overfits on training. In fact, $\text{KERMIT}_{\text{ENC}}$+$\text{BERT}_{\text{BASE}}$ outperforms the *funnel* and *diamond* KERMIT-based systems. $\text{KERMIT}_{\text{ENC}}$ has fewer parameters than $\text{KERMIT}_{\triangleright}$ and $\text{KERMIT}_{\diamond}$.

Finally, we explored the interpretative power of KERMIT*viz* comparing it with the transformer visualizer BERTviz (Vig, 2019). We focused on two examples of Yelp Reviews where the coordinating conjunction *but* plays an important role (see Fig. 3): (1) *"Unique food, great atmosphere, pricey* ***but*** *worth a trip for special occasions."*; (2) *"The boba drink was terrible,* ***but*** *the shaved ice was good."*. The two sentences have 4 and 3 as ratings, respectively. In fact, the *but* in the first sentence introduces a coordinated sentence that does not change the rating. On the contrary, the *but* in the second sentence introduces a coordinated sentence *but the shaved ice was good* that radically changes the polarity. In the case of BERTviz, this causal relationship is extremely difficult to grasp from the visual representation. In fact, BERTviz is a good visualization mechanism for seeing how models assign weights to different input elements (Bahdanau et al., 2015; Belinkov and Glass, 2019), but it is extremely obscure in explaining causal relations in classification predictions (Wiegreffe and Pinter, 2019). Instead, KERMIT*viz* with its tree heat maps show exactly that the *but* and the related syntactic structure is irrelevant in the first sentence and extremely relevant in the second. Hence, our heat parse trees can be useful to draw the causal relation between the decision and the information used.

5 Conclusions

Universal syntactic interpretations are valuable language interpretations, which have been developed in years of study. In this paper, we introduced KERMIT to show that these interpretations can be effectively used in combination with *universal sentence embeddings* produced from scratch. Moreover, KERMIT*viz* allows us to explain how syntactic information is used in classification decisions within networks combining KERMIT, on the one side, and BERT or XLNet on the other. We also showed that KERMIT can be easily used in situations where training large transformers is extremely difficult.

As KERMIT has a clear description of the used syntactic subtrees and gives the possibility of visualizing how syntactic information is exploited during inference, it opens the possibility of devising models to include explicit syntactic inference rules in the training process.

Finally, KERMIT is in the line of research of Human-in-the-Loop Artificial Intelligence (Zanzotto, 2019), since it gives the opportunity to track how human knowledge is used by learning algorithms.

Abstract

Transformer models have advanced the state of the art in many Natural Language Processing (NLP) tasks. In this paper, we present a new Transformer architecture, *Extended Transformer Construction* (ETC), that addresses two key challenges of standard Transformer architectures, namely scaling input length and encoding structured inputs. To scale attention to longer inputs, we introduce a novel global-local attention mechanism between global tokens and regular input tokens. We also show that combining global-local attention with relative position encodings and a *Contrastive Predictive Coding* (CPC) pre-training objective allows ETC to encode structured inputs. We achieve state-of-the-art results on four natural language datasets requiring long and/or structured inputs.

1 Introduction

Models based on Transformers (Vaswani et al., 2017), such as BERT (Devlin et al., 2018), or other variants (Yang et al., 2019; Lan et al., 2019; Raffel et al., 2019) have yielded state-of-the-art results in many NLP tasks such as language modeling (Child et al., 2019; Sukhbaatar et al., 2019; Rae et al., 2019; Kitaev et al., 2020), question answering (Lan et al., 2019; Beltagy et al., 2020), and summarization (Zhang et al., 2019). We present the *Extended Transformer Construction* (ETC) architecture[1], targeting two limitations of the original models: (1) scaling input length, (2) encoding structured inputs.

The computational and memory complexity of attention in the original Transformer scales quadratically with the input length, typically limiting input length to around 512 tokens. While 512 might be enough for some tasks (e.g., co-reference resolution seems to benefit from even smaller input lengths (Joshi et al., 2019)), this is problematic in others. Consider question answering (QA) tasks that require reasoning across multiple documents (e.g., the *HotpotQA* dataset (Yang et al., 2018)) all of which must simultaneously fit in the model input. Other examples are summarization, or QA on long documents. Many approaches have been proposed to address this, like hierarchical processing (Zhang et al., 2019), sparse attention (Child et al., 2019), and segment-level recurrence (Dai et al., 2019).

A second limitation is that few models focus on *structured inputs*, by which we refer to any underlying graph or hierarchical structure among the input tokens. Although ETC can encode more general graph structure, in this work we focus on representing hierarchical structure in NLP tasks, not usually modeled by Transformer models. For example, text is organized into sentences and paragraphs, and while these have a sequential order, different input documents might not hold any order between them (e.g., the HotpotQA dataset). Additionally, web text contains markup and is laid out using a DOM tree, giving additional structure. We show ETC can represent these and other types of structure, like linking different entity mentions.

To address these challenges, we present a novel attention mechanism called *global-local attention*, which divides the input into two sequences (which we call the *global* input and the *long* input). This mechanism introduces local sparsity to reduce the quadratic scaling of the attention mechanism. When this is coupled with relative position encodings (Shaw et al., 2018), it allows for handling structured inputs in a natural way. Additionally, unlike previous Transformer extensions, ETC can be initialized from existing pre-trained standard BERT models (which together with a GPU/TPU-friendly implementation, allows for efficient model training)[2]. Our results show that initializing from

[2] An exception to this is *Longformer* (Beltagy et al., 2020),

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 268–284,
November 16–20, 2020.

RoBERTa (Liu et al., 2019) significantly improves performance. Finally, we show that by adding a pre-training *Contrastive Predictive Coding* (CPC) task (Oord et al., 2018), performance improves even further for tasks where structure is important, as CPC plays the role of a masked language model (MLM) task, but at a sentence level of granularity.

We report experiments on four datasets: *Natural Questions* (NQ) (Kwiatkowski et al., 2019), HotpotQA (Yang et al., 2018), WikiHop (Welbl et al., 2018), and OpenKP (part of MS MARCO) (Xiong et al., 2019), which have long and/or structured inputs. We set a new state of the art in all of them.

Moreover, although in this paper we strictly focus on ETC, in a related model called BigBird (Zaheer et al., 2020), we experimented with an alternative set of ideas to handle long inputs and its extensions to a decoder for text generation. The focus of BigBird is on the idea of adding random sparse attention patterns to global-local attention, and on showing under which conditions models like BigBird/ETC are universal approximators of sequence functions and are Turing complete. While the key ideas and techniques required to achieve the state-of-the-art results mentioned above for QA tasks are the focus of this paper, the reader is referred to the BigBird work for a joint evaluation of ETC (referred to as BigBird-ETC in that work) and the idea of random sparse attention patterns.

2 Background

Many variants of the original Transformer model (Vaswani et al., 2017) have been proposed for scaling up training (RoBERTa, Liu et al., 2019), the internal representation (ALBERT, Lan et al., 2019), or both (T5, Raffel et al., 2019), outperforming BERT (Devlin et al., 2018) in tasks such as GLUE (Wang et al., 2018), SQuAD (Rajpurkar et al., 2016) or RACE (Lai et al., 2017). However, these models typically limit inputs to $n = 512$ tokens due to the $O(n^2)$ cost of attention. We classify prior approaches to scale up attention into four categories: sparse attention, recurrence, hierarchical mechanisms, and compressed attention.

Sparse Attention involves limiting each token to attend to a subset of the other tokens. For example, the *Sparse Transformer* (Child et al., 2019) used predefined attention patterns for both text and image generation. They showed that attending only to previous pixels in the same row or column was enough to generate high quality images, while keeping attention cost at $O(n\sqrt{n})$. In the *Adaptive Attention Span Transformer* (Sukhbaatar et al., 2019) each attention head is associated with a decaying learnable masking function, which limits the number of tokens it can attend to. They show that lower layers learn to use short attention spans, and only in higher layers are attention spans longer. Sparse attention has also been used to increase the interpretability of attention heads by allowing attention to assign exactly zero weight to certain input tokens (Correia et al., 2019). The *Reformer* (Kitaev et al., 2020) model finds the nearest neighbors of the attention query (those input tokens that would result in the highest attention weights) using locality sensing hashing (Andoni et al., 2015) and only uses those for attention. This reduces attention cost to $O(n\,log(n))$. The *Routing Transformer* (Roy et al., 2020) learns dynamic sparse attention patterns using online k-means, reducing complexity to $O(n^{1.5})$. Finally, the most related approach to the work presented in this paper is *Longformer* (Beltagy et al., 2020), developed concurrently to ETC, and which features a very similar global-local attention mechanism as ETC's but does not directly encode graph or hierarchical structure (more detailed comparison in Section 3).

Recurrence incorporates elements of recurrent neural networks into Transformer models to lengthen their attention span. *Transformer-XL* (Dai et al., 2019) takes this approach, dividing the input sequence into segments and then processing these segments one at a time. At each layer, the model attends to the layer immediately below for both the current and previous input segments. The effect is that layer k is influenced by the current segment and the $k - 1$ previous segments, as shown in the top-right of Figure 1.

In **Hierarchical Mechanisms** the input sequence is split into *blocks* that are ingested independently to produce summary embeddings that represent the whole block. Then, separate layers ingest the concatenation of these embeddings. For example, HIBERT (Zhang et al., 2019) uses this idea at the sentence level for extractive summarization (illustrated in the bottom-left of Figure 1). Hierarchical attention in Transformers has also been applied to other NLP tasks such as neural machine translation (Maruf et al., 2019). Moreover, notice that this idea of processing the input hierarchically

---

a new model developed concurrently to ETC, which also allows initialization from BERT/RoBERTa.

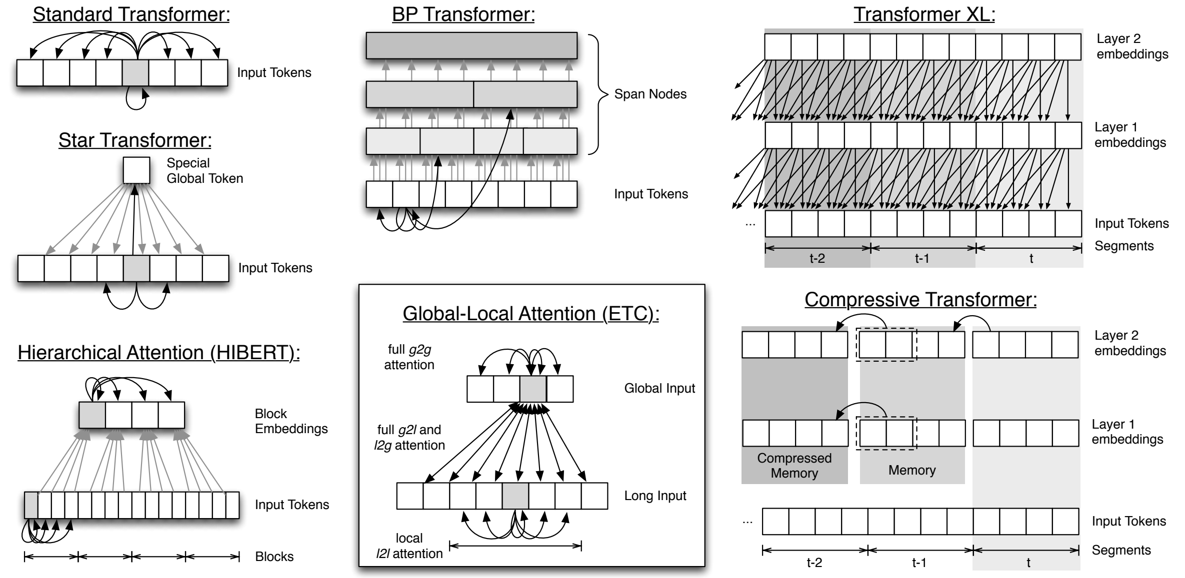

Figure 1: An illustration of mechanisms to scale attention to long inputs, including our proposed model, ETC.

is not specific to Transformer models, and it has been applied to recurrent neural network models both at the level of sentences (Yang et al., 2016; Miculicich et al., 2018) and blocks (Shen et al., 2018).

Compressed Attention takes the idea of hierarchical attention one step further by selectively compressing certain parts of the input. The *BP-Transformer* (Ye et al., 2019) model builds a binary partitioning tree over the input, and only lets the model attend to the leaves (the raw tokens) for nearby tokens, and higher nodes in the tree (summaries of groups of tokens) as tokens grow more distant (see Figure 1, middle top). Other ideas include *memory compressed attention* (Liu et al., 2018) where groups of k tokens are compressed via a convolution filter before they are attended to, and the *Star Transformer* (Guo et al., 2019), where each token can attend only to its immediate left/right neighbors and to a separate special auxiliary token that represents a summary of the whole input (see Figure 1, left). The *Compressive Transformer* (Rae et al., 2019) integrates this idea into Transformer-XL by compressing tokens in the input that are far away. The model benefits from detailed attention to nearby tokens, while using summarized information for more distant tokens (see Figure 1, lower right).

3 Extended Transformer Construction

Our model follows the original Transformer architecture (Vaswani et al., 2017), with key modifications to tackle long and structured inputs: relative position encoding, global-local attention, and a CPC pre-training task, explained below. In this paper, we consider only the encoder side of the Transformer, and leave the decoder for future work.

3.1 Relative Position Encoding

Inspired by the work of Shaw et al. (2018), ETC replaces absolute position encodings with relative position encodings, which provide information about the relative position of tokens in the input sequence with respect to one another. Given the input sequence $x = (x_1, ..., x_n)$, we can see it as a labeled fully connected and directed graph, where l_{ij} is the label of the edge that connects x_i to x_j. Given a maximum clipping distance k, Shaw et al. define $2k+1$ *relative position labels*: $l_{-k}, ..., l_k$. The label of the edge between two input tokens depends only on their relative position $j-i$. For input pairs with $j-i \geq k$, label l_k is given, and with $j-i \leq -k$, l_{-k} is given. Each label then becomes a learnable vector a_l^K, which modifies the attention mechanism (equations in the next section)[3].

Relative position encodings are independent of input length, so it is easy to adapt a model to greater input lengths than seen during pre-training. As other recent work (Shaw et al., 2019), ETC's attention mechanism uses relative position labels not just for relative positions in a sequence but also to express arbitrary pairwise token relations useful for

---

[3] In the work of Shaw et al., a second a_l^V vector was used, but their ablations showed it may not affect performance.

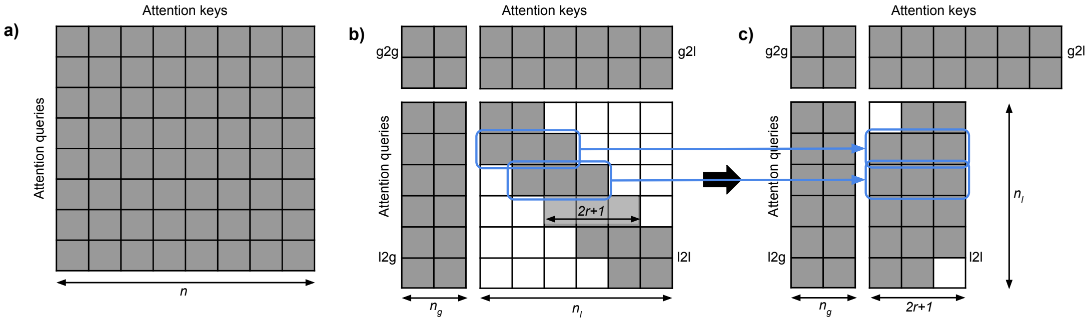

Figure 2: Sparsity diagram showing which attention queries (rows) can attend to which attention keys (columns) a) for standard Transformer attention with input size n; b) for global-local attention with input sizes n_g, n_l, and radius r; c) how the l2l attention piece is reshaped into a much smaller attention matrix, limited by local radius.

structured inputs, as explained below.

3.2 Global-Local Attention

Global-local attention is a generalization of several of the models presented above. ETC receives two separate input sequences: the *global input* $x^g = (x^g_1, ..., x^g_{n_g})$ and the *long input* $x^l = (x^l_1, ..., x^l_{n_l})$. Typically, the long input contains the input a standard Transformer would receive, while the global input contains a much smaller number of auxiliary tokens ($n_g \ll n_l$). Attention is then split into four separate pieces: *global-to-global* (g2g), *global-to-long* (g2l), *long-to-global* (l2g), and *long-to-long* (l2l). Attention in the l2l piece (the most computationally expensive piece) is restricted to a fixed radius $r \ll n_l$. To compensate for this limited attention span, the tokens in the global input have unrestricted attention, and thus long input tokens can transfer information to each other through global input tokens. Accordingly, g2g, g2l, and l2g pieces of attention are unrestricted.

This concept is illustrated in Figure 2, where each cell (row i, column j) is shaded grey if token x_i can attend to token x_j. As we can see, in a regular Transformer, attention is unrestricted (full $n \times n$ attention). ETC, illustrated in Figure 2b, however, restricts the l2l piece to a local radius, significantly reducing computational and memory complexity for very long inputs. Conceptually, the l2l attention piece is reshaped into a $n_l \times (2r+1)$ matrix as illustrated in Figure 2c.[4]

If $r = 1$ and $n_g = 1$, we recover exactly the Star Transformer (Section 2). Similarly, placing all the tokens in the global input and setting $n_l = 0$ yields standard Transformer attention. Attention in ETC is $O(n_g(n_g+n_l)+n_l(n_g+2r+1))$. If we assume $n_g = O(2r+1)$, we see attention is linear in the size of the long input: $O(n_g^2 + n_g n_l)$.

To provide flexible attention and help with structured inputs, per-instance Boolean attention matrices M^{g2g}, M^{g2l}, M^{l2g}, and M^{l2l} exist, with zeroes for those pairs of tokens that should not attend to one another. Each g2g attention head works as follows. Given the global input $x^g = (x^g_1, ..., x^g_{n_g})$, which is a sequence of token representations $x^g_i \in \mathbb{R}^{d_x}$, the output of attention is $z^g = (z^g_1, ..., z^g_{n_g})$, where each $z^g_i \in \mathbb{R}^{d_z}$ is calculated as follows:

$$z^g_i = \sum_{j=1}^{n_g} \alpha^{g2g}_{ij} x^g_j W^V$$

$$\alpha^{g2g}_{ij} = \frac{\exp(e^{g2g}_{ij})}{\sum_{\ell=1}^{n} \exp(e^{g2g}_{i\ell})}$$

$$e^{g2g}_{ij} = \frac{x^g_i W^Q (x^g_j W^K + a^K_{ij})^T}{\sqrt{d_z}} - (1 - M^{g2g}_{ij})C$$

where: M^{g2g} is a binary attention mask, W^Q, W^K, and W^V are learnable weight matrices, and a^K_{ij} are learnable vectors representing the relative position labels, and C is a large constant ($C = 10000$ in our experiments to follow the same convention as BERT). Attention for the other 3 pieces is analogous. We experiment with having separate W^K and W^V across all four attention pieces, or sharing them. And for W^Q, we experiment with having one for g2g and g2l, and a separate one for l2g and l2l; or sharing them also. To recover BERT as a special case when r is large enough to remove sparsity, attention is actually only split into 2 pieces internally instead of 4, as g2g+g2l can be computed jointly (top half of Figure 2c), and l2g+l2l can also be computed jointly (bottom half of Figure 2c). A single softmax is used to jointly calculate α^{g2g}_{ij} and α^{g2l}_{ij}, and another for α^{l2g}_{ij} and α^{l2l}_{ij}.

---

[4] In practice, for GPU/TPU efficiency, a different reshaping occurs that yields identical outputs (see the appendices).

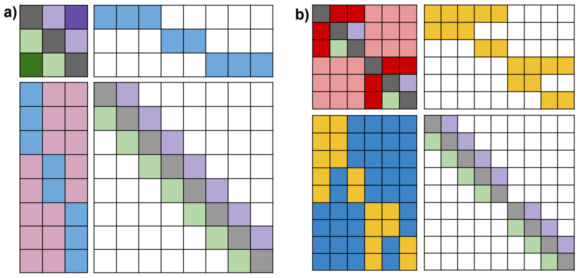

Figure 3: Example attention patterns for handling (a) long inputs and (b) structured inputs. White background means attention is masked via M, and the other colors indicate different relative position labels.

Thus, the output of global-local attention is a sequence of length n_g and one of length n_l. These sequences go through a layer normalization and feed forward layer in the same way as in the standard transformer.

3.3 Long Inputs and Global-Local Attention

Let us illustrate how ETC can be used to encode long inputs. A general way to handle long inputs in ETC is to place the entire sequence of input tokens (e.g., word pieces) in the long input, and then assuming some sort of division into segments (e.g., sentences), place one auxiliary token in the global input per segment in the long input. We then use one relative position label to link the global segment tokens with the word piece tokens that belong to them, and a different label for those that do not. Moreover, as we will show in the experiments below, we have seen that using the M^{g2l} attention masks to perform hard masking in one direction (g2l) can bring performance gains in some datasets. This last asymmetric hard-masking is illustrated in Figure 3a, where we used different colors to indicate different relative position labels. In this way, although tokens in the long input can only attend to the local neighborhood defined by the radius k, they can indirectly attend to all other tokens in the input sequence via the global tokens.

3.4 Structured Inputs

A standard Transformer resembles a graph neural network (Scarselli et al., 2008) over a fully connected graph g; see Ye et al. (2019). Thanks to the combination of global-local attention and relative position labels, ETC exploits this relation to encode *structured inputs*. Given the input $x = (x_1, ..., x_n)$, we use the term *structure* to refer to the relations that exist between the tokens in x. When x is a plain ordered sequence, the only relation is the *sequential order* of tokens, which is the only structure captured by BERT (encoded by absolute position encodings, used to modify attention). We define *structured inputs* as those that have additional relations between the tokens beyond sequential order. In principle, we could think of inputs with arbitrary graph structure (such as chemical molecule graphs), but here we focus on structure in NLP tasks.

ETC is particularly well suited to capture hierarchical structure thanks to three mechanisms. First, as originally conceived, the vocabulary of relative position labels is used to represent token relative positions. However, seeing a Transformer as a graph neural network over a graph g (with one vertex per token in x, and edges representing their relations), we can expand this vocabulary to label some edges with labels for relations such as *is-a*, *part-of*, or others. Second, the division between long and global input induces a natural structure where the global input contains summary tokens of sets of tokens in x (a 2-level hierarchy). However, we can also have tokens summarizing sets of summary tokens (constructing a 3-level hierarchy, or beyond). Third, if some pairs of tokens should not have an edge between them, this can be captured with the M^{g2g}, M^{g2l}, M^{l2g}, M^{l2l} masks. An illustration of all these concepts is shown in Figure 3b, which uses masking and relative position labels to represent a context-sentence-token hierarchy that includes within-context order of sentences but no order between contexts. Another example would be social community graphs structure, where we could partition the graph into components, use M^{l2l} to constrain attention to within components, and add per-component global tokens, linked to allow information to propagate from one component to another in a hierarchical way.

3.5 Pre-training Tasks

We use two pre-training tasks: (1) a masked language model (MLM) task with *whole word masking* (if one word piece token is masked, then all other tokens of the same word are masked); and (2) instead of using BERT's next sentence prediction (NSP), we adapt Contrastive Predictive Coding (CPC) (Oord et al., 2018) for ETC.

The goal of CPC is to predict subsequent inputs in latent space, i.e., to predict internal hidden representations of blocks of tokens. We adapted this idea in ETC by using global input sentence summary tokens. Given an input sequence containing n sentences, we mask all the tokens corresponding to a subset of sentences (but leave the sentence summary tokens in the global input). We then train the model to minimize the difference between the hidden representation of the global sentence summary tokens for the masked sentences with respect to that of a global summary token that can see the unmasked sentence and nothing else. We use a Noise Contrastive Estimation (NCE) loss as in the work of Oord et al. (2018) (details in the appendices).

Having described ETC, we can now compare it with Longformer (Beltagy et al., 2020), which uses a similar attention mechanism, except Longformer has a single input sequence with some tokens marked as *global* (the only ones that use full attention). The key differences are that (1) ETC's combination of global-local attention with relative position encodings and flexible masking enables it to encode structured inputs in a similar way as graph neural networks do; (2) global tokens in Longformer are never pre-trained with anything like our CPC loss, and thus their use must be learned during fine-tuning.

3.6 Lifting Weights from Existing Models

ETC and BERT share enough similarities that BERT parameters are useful to perform a warm start. The parameters are compatible because the global-local attention mechanism includes BERT as a special case if the input is small enough or the local radius is large enough to eliminate sparsity. Moreover, when lifting weights from BERT into an ETC model with separate W^Q, W^K, and W^V projection matrices, BERT's parameters are just copied over to the different matrices of ETC.

Although pre-training is still required to adapt the weights to use global tokens and relative position encodings, we show that initializing from RoBERTa results in significant performance improvements compared to pre-training from scratch. Specifically, we initialized from the RoBERTa checkpoints reported in the work of Rothe et al. (Rothe et al., 2020).

4 Empirical Evaluation

This section focuses on evaluating our two main contributions: (1) long inputs, and (2) structure in text inputs, as well as initialization from existing BERT models. We chose four datasets (Table 1) with long inputs or interesting input structure.

	Instances		*Instance length*		
Dataset	*Training*	*Dev*	*Median*	*95%*	*Max*
NQ	307373	7830	4004	17137	156551
HotpotQA	90447	7405	1227	1810	3560
WikiHop	43738	5129	1541	3994	20337
OpenKP	133724	6610	761	4546	89183

Table 1: Dataset stats (length in word piece tokens).

NQ (Kwiatkowski et al., 2019): in Google's *Natural Questions* (NQ) dataset the input consists of a question and a full Wikipedia article. The task is to identify both a *short answer* (a few words from the article) and a *long answer* (e.g., a whole paragraph), if they exist within the article (and otherwise, return null answers). Performance is measured based on the F1 score of the model predictions with respect to the human generated answers.

HotpotQA (Yang et al., 2018) is a question answering dataset where the goal is to combine evidence from multiple contexts. We use the *distractor* setting, where 10 paragraphs are provided: two of them contain useful information to answer the question, and the rest are distractors. The task is both to answer the question, and also to identify the supporting facts that are relevant to answer the questions (at a sentence granularity).

WikiHop (Welbl et al., 2018) is similar in structure to HotpotQA. The contexts correspond to portions of Wikipedia articles, and the goal is to answer about properties of an entity that cannot be found in the entity's article. Each instance contains a query, a collection of candidate answers, and a collection of contexts from which to obtain information to select among the candidate answers.

OpenKP (Xiong et al., 2019) is a keyphrase extraction dataset. Each document contains up to 3 short keyphrases to be identified. We selected this dataset as the input is not flat text sequences, but websites, including the hierarchical and spatial relations between the different DOM elements on the website, as well as other visual properties.

4.1 Training Configuration

We use two basic configurations: *base* and *large*. Base uses 12 layers, 768 hidden size, 12 attention heads, local attention radius $r = 84$, and relative position maximum distance $k = 12$. Large uses 24 layers, 1024 hidden size, 16 heads, $r = 169$, and $k = 24$. We used 128, 230 and 460 global tokens for models with 512, 4096 and 8192 long

Model	*Input length*	*Configuration*	*#Params*	*Long answer F1*	*Short answer F1*
BERT-base	512		110M	0.634	0.475
BERT-large	512		340M	0.647	0.527
RikiNet	512	lifting from RoBERTa$_{large}$	-	0.753	**0.593**
ETC	512	shared, no CPC, no hard g2l	109M	0.645	0.478
ETC	4096	shared, no CPC, no hard g2l	109M	0.692	0.497
ETC	4096	fixed blocks, shared, no CPC, no hard g2l	109M	0.697	0.508
ETC	4096	shared, no hard g2l	109M	0.717	0.524
ETC	4096	shared	109M	0.721	0.514
ETC	4096	-	166M	0.725	0.522
ETC	8192		166M	0.740	0.542
ETC	4096	2x local radius	166M	0.737	0.530
ETC	4096	2x relative vocab	166M*	0.733	0.532
ETC	4096	2x pre-training	166M	**0.746**	**0.558**
ETC-large	4096		539M	0.761	0.565
ETC-large	4096	lifting from RoBERTa	558M	**0.782**	0.585

Table 2: Empirical results on the dev sev set for the *Natural Questions* (NQ) dataset. Best results for *base* and *large* models highlighted. BERT-large results obtained from Alberti et al. (2019). * although not visible due to rounding to the closest million, doubling the relative position encoding vocabulary adds about 600k parameters.

input size respectively in NQ[5], 256 global tokens in HotpotQA, 430 in WikiHop, and 512 in OpenKP.

Pre-training: We place all word piece tokens in the long input and add one auxiliary token per sentence to the global input. We defaulted to BERT's 30k English uncased word piece vocabulary. Models were pre-trained using the original BERT datasets, except that documents with fewer than 7 sentences were filtered out. Unless stated otherwise, base models were pre-trained with the same total number of tokens as the original BERT, and for large models, twice as many. We used the *LAMB* optimizer (You et al., 2019) with learning rate set to $\sqrt{8} \times 10^{-3}$.

Fine-tuning: we put all input tokens in the long input (CLS, question, and context tokens for QA datasets), and use relative position labels to encode structure (see Section 3.4). Global input has a CLS token, tokens mirroring the question tokens in long, and one summary token per paragraph/sentence (or VDOM block in OpenKP). OpenKP had no CLS nor question tokens. For WikiHop, we also add one global token per candidate answer, and used a different relative position label to link these tokens to their string-matched mentions in the text (more details in the appendices).

4.2 Results on the Dev Set

NQ: We used NQ to study the different parts of ETC via ablations. Results are shown in Table 2. The first three rows show baseline models: BERT-base, BERT-large, and RikiNet (Liu et al., 2020) (one of the best models in the NQ leaderboard). BERT's performance is comparable to ETC using input length of 512. The smaller local radius of ETC (84) puts ETC at a disadvantage with respect to BERT, but other ETC improvements, such as dynamic whole word masking seem to compensate.

The rest of Table 2 shows performance under different ablations. Our default configuration (marked with a "-" in the configuration column) is ETC-base with long input length of 4096 tokens, using CPC, hard g2l masking, and separate W^Q, W^K, and W^V matrices for long/global inputs. We tested the following ablations: *shared* (sharing all model parameters for attention across both the global and long inputs), *no CPC* (removing the CPC pre-training task), *no hard g2l* (not having a hard g2l mask), and *fixed blocks* (which configures the global input to just have one global token per 97 long input tokens, to keep the same proportion as without fixed-blocks, ignoring sentence boundaries, and not having any other tokens in the global input for pre-training or fine-tuning). Sharing W^Q, W^K, and W^V and removing CPC significantly hurt the performance of ETC in NQ[7]. Using fixed blocks, surprisingly, seems to slightly help without CPC.

Increasing long input from 512 to 4096 significantly helped performance, and going to 8192 increased performance further to 0.740 / 0.542, highlighting the importance of longer inputs. Increasing the local radius, relative position vocabulary, or the amount of pre-training all helped performance (especially the latter, reaching 0.746 / 0.558). Moving to a large model also helped, especially when lifting from RoBERTa (both large models used the

---

[5] With gradient checkpointing, ETC can scale beyond this, but we limit our experiments to 8192 tokens for this paper.

[7] Separate projection matrices were also found to be helpful in other models, like Longformer (Beltagy et al., 2020).

Model	*Input length*	*Configuration*	*#Params*	*HotpotQA* Ans. F1 / Sup. F1	*WikiHop* Acc.
Longformer	4096		149M*	0.743 / 0.844	75.0

Leaderboard	Result	Position
NQ long answer	0.7778	1st
NQ short answer	0.5786	18th
HotpotQA Sup. F1	0.8909	1st
HotpotQA Overall	0.7362	3rd
WikiHop	0.8225	1st
OpenKP	0.4205	1st

Table 5: Official leaderboard results for ETC at the time of submission.

RoBERTa vocabulary). Lifting from RoBERTa achieved our best scores: 0.782 / 0.585, beating the best dev scores in the literature for long answer (compare with 0.754 / 0.593 for RikiNet). For short answer, we still lag behind RikiNet.

HotpotQA, WikiHop: Table 3 shows our results in HotpotQA and WikiHop. We show two Longformer models as baselines (which is currently the state-of-the-art model in WikiHop), as well as ablations to study the effect of structure in the results. In particular, we consider a *flat structure* ablation where: (1) we do not break long input attention by context boundaries, (2) we limit relative position labels between global and long tokens to representing only sentence-level relationships (this removes any special attention in WikiHop between candidate answers and their mentions).

Our results show that both our base and large models outperform their corresponding Longformer models in both HotpotQA and WikiHop. Besides parameter counts, the main factors that can explain this difference in performance are the different pre-training strategies and the different handling of structure in ETC and Longformer. Removing the CPC pre-training task, and not using a hard g2l mask significantly hurt the performance of the model in HotpotQA, going from a performance of 0.751 / 0.869 for the baseline model to 0.722 / 0.857 using none of those features. Using a flat structure (but keeping CPC and hard g2l) did not seem to hurt in HotpotQA. WikiHop shows a slightly different picture, as it seems that hard g2l masking and especially flat structure hurt performance in this dataset. Our best model is the base configuration without hard g2l masking, which achieves an accuracy of 75.9. Interestingly, sharing W^Q, W^K, and W^V seems to help performance in WikiHop. This is our smallest dataset, and maybe the added capacity of the model without sharing parameters leads it to overfit.

OpenKP: Table 4 shows our results on the OpenKP dataset, using RoBERTa-JointKPE (Sun et al., 2020) as the baseline, which is currently #1 in the leaderboard. This is an interesting structured dataset, and thus, we performed additional ablations to investigate the effect of removing such structural information. Our results show that even the most constrained ETC model already achieves very good performance (0.399), and scaling to 4096 length seems to give a slight boost. Using hard g2l also helps, and adding the visual features brings the largest benefit. Finally, we see that using a large model, and especially lifting weights from RoBERTa improve results significantly. As with WikiHop, sharing W^Q, W^K, and W^V does not hurt performance. Our default model uses the first occurrence of a keyphrase, but we saw that using the maximum logit of all occurrences (*max loss*) improved results.

4.3 Official Leaderboard Results

Finally, Table 5 shows official results on the leaderboards of each dataset. The model submitted to the leaderboards was the model with best dev set results (shown at the bottom of the respective results tables, lifting weights from RoBERTa). We set a new state of the art in WikiHop and OpenKP, NQ long answer, and HotpotQA Support F1. Remarkably, our submissions were all single model, outperforming the leaderboard ensemble models.

5 Conclusions

This paper introduced the Extended Transformer Construction (ETC), an architecture designed to (1) scale up the input length (linearly with input), and (2) encode structured inputs. ETC allows lifting weights from existing BERT models, improving results significantly. The key ideas are a new global-local attention mechanism, coupled with relative position encodings and a CPC pre-training task.

We showed that significant gains can be obtained thanks to increased input sequence length. The ability to represent dataset structure in ETC further improves the model quality. We hypothesize that CPC helps the model train the usage of the higher-level global input summary tokens, as CPC plays a role akin to MLM, but at the global input level. Notice that although our datasets contain a limited amount of structure (compared to graph datasets), our experiments show that ETC was able to exploit this existing structure.

As future work, we would like to investigate complementary attention mechanisms like those of Reformer (Kitaev et al., 2020) or Routing Transformer (Roy et al., 2020), push scalability with ideas like those from RevNet (Gomez et al., 2017), and study the performance of ETC in datasets with even richer structure.

Acknowledgements

We would like to thank Anna Goldie, Bhargav Kanagal, Ilya Eckstein, Manan Shah, Nich Kwon, Vikram Rao Sudarshan, Joshua Maynez, Manzil Zaheer, Kelvin Guu, Tom Kwiatkowski, Kristina Toutanova, and D. Sivakumar for helpful discussions, support, comments, and feedback on earlier versions of this work. We would also like to thank the Longformer authors (Iz Beltagy, Matthew E. Peters, Arman Cohan) for their useful feedback on earlier versions of this paper and for sharing parameter counts.

Appendix A: Implementation Details

Global-Local Attention Implementation

This appendix provides further details on the TPU/GPU-friendly implementation of global-local attention. Our implementation of sliding window local attention is similar to the approach in the `local_attention_1d` layer in Tensor2Tensor [8], but with the addition of flexible masking, relative position encoding, and global tokens as side keys/values. We use a simple example to describe the internal blocking logic. Let's say the input corresponds to embeddings for the following word pieces, each represented by a letter: `ABCDEFG`.

As usual, we project these embeddings into queries, keys, and values, yielding the following (for each attention head):

Queries: $\mathtt{A}_q\mathtt{B}_q\mathtt{C}_q\mathtt{D}_q\mathtt{E}_q\mathtt{F}_q\mathtt{G}_q$
Keys: $\mathtt{A}_k\mathtt{B}_k\mathtt{C}_k\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k\mathtt{G}_k$
Values: $\mathtt{A}_v\mathtt{B}_v\mathtt{C}_v\mathtt{D}_v\mathtt{E}_v\mathtt{F}_v\mathtt{G}_v$

Let's say we want to perform sliding window local attention with local radius $r = 2$. Internally, we split the input into blocks of length $r + 1$ (3 in our example) and add padding blocks to the left and right, resulting in the following five blocks for the queries (and similarly for keys and values), with `0` representing padding:

$\mathtt{000}$ $\mathtt{A}_q\mathtt{B}_q\mathtt{C}_q$ $\mathtt{D}_q\mathtt{E}_q\mathtt{F}_q$ $\mathtt{G}_q\mathtt{00}$ $\mathtt{000}$

Conceptually we'd like to compare each query with the $2r + 1$ (5 in our example) surrounding keys, as follows:

Queries	*Keys*
$\mathtt{A}_q$	$\mathtt{00A}_k\mathtt{B}_k\mathtt{C}_k$
$\mathtt{B}_q$	$\mathtt{0A}_k\mathtt{B}_k\mathtt{C}_k\mathtt{D}_k$
$\mathtt{C}_q$	$\mathtt{A}_k\mathtt{B}_k\mathtt{C}_k\mathtt{D}_k\mathtt{E}_k$
$\mathtt{D}_q$	$\mathtt{B}_k\mathtt{C}_k\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k$
$\mathtt{E}_q$	$\mathtt{C}_k\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k\mathtt{G}_k$
$\mathtt{F}_q$	$\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k\mathtt{G}_k\mathtt{0}$
$\mathtt{G}_q$	$\mathtt{E}_k\mathtt{F}_k\mathtt{G}_k\mathtt{00}$

But materializing each window of keys would be memory-intensive. Instead, we allow each block of queries to attend to 3 blocks of keys (the same block, and the blocks immediately to the left and right), resulting in the following:

Queries	*Keys*
$\mathtt{A}_q\mathtt{B}_q\mathtt{C}_q$	$\mathtt{000}$ $\mathtt{A}_k\mathtt{B}_k\mathtt{C}_k$ $\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k$
$\mathtt{D}_q\mathtt{E}_q\mathtt{F}_q$	$\mathtt{A}_k\mathtt{B}_k\mathtt{C}_k$ $\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k$ $\mathtt{G}_k\mathtt{00}$
$\mathtt{G}_q\mathtt{00}$	$\mathtt{D}_k\mathtt{E}_k\mathtt{F}_k$ $\mathtt{G}_k\mathtt{00}$ $\mathtt{000}$

Now each query can potentially see a few more tokens than it's strictly allowed to by the local radius r. For example, $\mathtt{A}_q$ takes a dot product with $\mathtt{D}_k$, $\mathtt{E}_k$ and $\mathtt{F}_k$, but this is easy to simply mask out, yielding the same sliding window local attention result. In this way, the blocking mechanism saves memory at the expense of some extra compute.

The values are also divided into the same blocks as the keys (concatenating 3 at a time), and standard scaled dot product attention is applied independently for each row in the table below, where Keys have been truncated for brevity:

Queries	*Keys*	*Values*
$\mathtt{A}_q\mathtt{B}_q\mathtt{C}_q$	...	$\mathtt{000}$ $\mathtt{A}_v\mathtt{B}_v\mathtt{C}_v$ $\mathtt{D}_v\mathtt{E}_v\mathtt{F}_v$
$\mathtt{D}_q\mathtt{E}_q\mathtt{F}_q$	...	$\mathtt{A}_v\mathtt{B}_v\mathtt{C}_v$ $\mathtt{D}_v\mathtt{E}_v\mathtt{F}_v$ $\mathtt{G}_v\mathtt{00}$
$\mathtt{G}_q\mathtt{00}$	...	$\mathtt{D}_v\mathtt{E}_v\mathtt{F}_v$ $\mathtt{G}_v\mathtt{00}$ $\mathtt{000}$

Efficient Relative Attention Implementation

To efficiently implement relative position encoding (a.k.a. relative attention), we take an approach similar to the optimization in Music Transformer (Huang et al., 2018) but generalized to allow arbitrary pairwise labels rather than adhering to a relative position pattern. We briefly describe our implementation in the case of full attention (with a single sequence length n), but the approach naturally extends to the case of the four attention pieces used in ETC. The original relative attention work (Shaw et al., 2018) reported $O(n^2 d_z)$ memory overhead (Section 3.3) by materializing a_{ij}^K for every query-key pair while sharing a_{ij}^K across all heads (or $O(hn^2 d_z)$ if not sharing across heads), where d_z is the dimension per head and h is the number of heads. We instead take a dot product between each query vector and all unique a_{ij}^K vectors in the relative attention vocabulary. Then we gather these scalar results for each query-key pair. This avoids the $O(n^2 d_z)$ memory overhead and allows us to use different a_{ij}^K per attention head with no additional activation memory cost. Note that our relative attention vocabulary sizes are noticeably smaller than n, so our implementation reduces the number of dot products required for relative attention also.

Appendix B: CPC Loss in ETC

We adapted the original formulation of CPC for ETC by modeling it as a dual encoder problem. We have two instances of the same ETC model g_1 and g_2 (using the same weights). g_1 is the main encoder we are training, and we divide its long input into segments (e.g., sentences) and have one global token in global input for each segment. We

---

[8] https://arxiv.org/abs/1803.07416

mask some segments in the long input, and encode those segments independently using g_2 (by having as input just the tokens of that segment in the long input, and a single global token in the global input). Then, we train g_1 and g_2 so that the encodings of the global tokens corresponding to the masked segments should be as similar as possible as the encoding of the global segment token obtained via g_2. We use within-batch random negatives for this process as well, and use a Noise Contrastive Estimation (NCE) loss, in the same way as in the original CPC work (Oord et al., 2018).

Appendix C: Training Details

Our default pre-training procedure used the same Wikipedia and Books training corpora as BERT, but we filtered to remove those documents with fewer than 7 sentences. Models were pre-trained for 33 epochs to match the amount of pre-training of the original BERT model, which used batches of 256 sequences of 512 tokens each, and pre-trained for 1,000,000 iterations. Instead, we used batches of 512 sequences of 4096 tokens each and pre-trained for 63,000 iterations. The ETC-large models were pre-trained for 66 epochs by using a batch size of 1024 instead. When lifting weights from RoBERTa, we found that decreasing the learning rate to 2×10^{-3} improved model quality.

When pre-training models, we split any input documents that are longer than the long input length. For efficiency, we also concatenate as many shorter documents as will fit into the 512/4096/8192 window and mask attention to prevent them from influencing each other. This results in a roughly 3x speedup in pre-training time for 4096-token models, highlighting once more the advantage of flexible masking.

When pre-training with CPC, we randomly select 10% of sentences to be masked for the CPC task. Subsequently, 15% of the remaining tokens are masked for MLM.

In the models where we use both MLM and CPC, we used a 0.8 weight for MLM and a 0.2 weight for CPC to combine them into a single loss.

NQ

Data Download Link: `https://ai.google.com/research/NaturalQuestions/download`

Data Pre-processing: Following Alberti's BERT implementation (Alberti et al., 2019), long input in NQ contains a CLS token followed by the question word pieces, then a separator followed by the long document, a final separator, and padding. Global input contains a CLS token, one special "question" token per token in the question, and then one special "segment" token per paragraph (long answer candidate) in the long input. Moreover, since the ground truth indexes in this dataset are word indexes, in order to be able to align tokens with words, sentences are first tokenized by words, and then each word is given to the BERT/RoBERTa tokenizer.

Fine-Tuning: After pre-training, all models were fine-tuned with a hyperparameter sweep consisting of learning rates in $\{3 \times 10^{-5}, 5 \times 10^{-5}\}$ and number of epochs in $\{3, 5\}$ ($\{2, 3\}$ for large models) with a batch size of 64 on the NQ training set using the Adam optimizer. The model is trained to predict four logits coming out of the long input tokens: long answer start, long answer end, short answer start, and short answer end. A final prediction (predicted from the long input CLS token embedding) is the answer type (null, yes, no, short, long). For NQ instances that are longer than long input size, a sliding window approach is used (with stride 128 for input lengths of 512, 2048 for input lengths of 4096, and 4096 for input lengths of 8192).

Model Selection: we performed a single hyperparameter sweep for each model (i.e., we tested a single random seed per parameter configuration). The best model was selected as the highest average F1 score on dev at the end of fine-tuning. Our best model (large, lifting from RoBERTa) was trained for 2 epochs with learning rate 3×10^{-5}.

Inference: Final predictions are then aggregated similarly as in the work of Alberti et al. (2019), but with two improvements: First, instead of predicting start and end of short/long answer separately, we first select the best start position, and then select the best end location that occurs after the start position. For short answer, we also filter out all end positions further than 38 words from the start position. Second, when the logit for a yes/no answer is higher than the logits for short, long or null answer, we replace the short answer with a corresponding yes/no.

HotpotQA

Data Download Link: `https://hotpotqa.github.io/`

Data Pre-processing: Only 90,431 out of the

90,447 instances were used for training, as we model the task as extractive QA and thus filtered out the 16 instances where the answer could not be found in the contexts. Long input in HotpotQA is organized as follows: CLS token followed by question tokens followed by all the context tokens. Each context is represented as the concatenation of its title, and then all the sentences. Global input has a CLS token, and then one token per question token (as in NQ), followed by global tokens representing the contexts. For every context, in global, we have one token representing the whole context, and then one per sentence. We did not use any windowing approach for longer instances, and just fit as many tokens as possible within the 4096 long input. Global input length was set to 256.

Fine-Tuning: After pre-training, all base models were fine-tuned with a hyperparameter sweep consisting of learning rates in $\{3 \times 10^{-5}, 5 \times 10^{-5}\}$, number of epochs in $\{3, 5, 7, 9\}$, batch size in $\{32, 64\}$, and supporting fact threshold in $linspace(0, 1, 11)$ on the training set using the Adam optimizer. Large models were tested with learning rate in $\{1 \times 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}, 5 \times 10^{-5}, 7 \times 10^{-5}\}$, number of epochs in {2, 5, 9, 13}, and batch size in {32, 64, 128}.

Model Selection: we performed a single hyperparameter sweep to determine the best parameter configuration for each model, and then we tried 3 different random seeds for the best configuration. The best model was selected as the one with the best joint F1 score on dev. Our best model (large, lifting from RoBERTa) was trained for 5 epochs, with a learning rate of 3×10^{-5}, batch size of 32 and supporting fact threshold of 0.4.

Inference: In order to make predictions, supporting facts are predicted using a single dense layer taking the global input embeddings as input with a threshold over the output logits. Output type is predicted with a single dense layer from the global CLS token. Answer spans where predicted also with dense layers, but using the long input embeddings as inputs, using the following criteria: begin/end positions must be in sentences or titles, begin/end must be in the same sentence/title, spans must belong to a supporting fact, begin must be before end, and spans cannot exceed a maximum answer length of 30 tokens. Within spans satisfying those criteria, a single span with top $\mathrm{begin\_prob} * \mathrm{end\_prob}$ is selected.

WikiHop

Data Download Link: `https://qangaroo.cs.ucl.ac.uk/`

Data Pre-processing: Global and Long input was set similarly as in HotpotQA, except that global input was set to 430, and that instead of a CLS token in global, we have one token per candidate answer (WikiHop provides a list of candidate answers, and the model needs to select among them). We used a relative position label (the same used to link sentence summary tokens with its corresponding tokens) to link candidate answers to their mentions in the text, where mentions are determined only by string matching. Also, as in HotpotQA, no sliding window was used, and instances were just cropped to a length of 4096. A MaxHeap was used to ensure that in case a context is truncated, truncation happens from the contexts with the larger number of sentences.

Fine-Tuning: After pre-training, all base models were fine-tuned with a hyperparameter sweep consisting of learning rates in $\{1 \times 10^{-5}, 2 \times 10^{-5}, 3 \times 10^{-5}, 4 \times 10^{-5}, 5 \times 10^{-5}\}$, and number of epochs in $\{5, 10, 15\}$ with a batch size of 64 on the training set using the Adam optimizer. For large models, we narrowed down the hyperparameter sweep to learning rates in $\{2 \times 10^{-5}, 3 \times 10^{-5}, 4 \times 10^{-5}, 5 \times 10^{-5}\}$, and number of epochs in $\{5, 10\}$. For this dataset we also experimented with the LAMB optimizer (in addition to Adam), which was used for our leaderboard submission.

Model Selection: we performed a single hyperparameter sweep to determine the best parameter configuration for each model (i.e., single random seed per parameter configuration). The best model was selected as the one with the highest accuracy on dev. Our best model (large, lifting from RoBERTa) was trained for 10 epochs, with a learning rate of 5×10^{-5}. Finally, for the final leaderboard submission, we selected the checkpoint of the model that had the highest dev set accuracy.

Inference: For final prediction, we used a dense layer from the global input embeddings, after that, the candidate with the highest logit is selected as the final prediction.

OpenKP

Data Download Link: `https://microsoft.github.io/msmarco/`

Data Pre-processing: Long input in OpenKP contains all the word pieces of the input. One global token per VDOM node was added to the global input (notice this is like the pre-training setup, except instead of sentences we have VDOM nodes as the higher-level units). No sliding windowing was used, and we simply truncate instances to whichever of max tokens in long input or max VDOM tokens in global ends up being more constraining. Long input length was set to 4096 and global input length to 512 by default in this dataset. After url deduplication and skipping examples without keyphrases in the truncated document, there were 133,374 valid training examples. Regarding visual features, we embed font sizes based on 24 bucket ranges, and we also construct an embedding for the cross of "block", "heading", and "bolded" Boolean features in the input data. All other visual features were treated as dense features, with the floating point features clipped to reasonable ranges and re-scaled to the $[-1, 1]$ interval. These dense features are then transformed to the same embedding space as the other embeddings, and all visual feature embeddings are added to both the relevant long and global input tokens.

Fine-Tuning: After pre-training, all models were fine-tuned with a hyperparameter sweep consisting of learning rates in $\{3 \times 10^{-5}, 5 \times 10^{-5}\}$ and number of epochs in $\{2, 3\}$ with a batch size of 64 on the OpenKP training set using the Adam optimizer. To generate predictions, we first sum the embeddings (from the long input) of all the word pieces for each word to form word embeddings. Then we run convolutions with kernel size 1, 2, 3, 4, and 5 to form the respective n-gram embeddings. Finally, a dense linear layer is used to form logits for all the n-grams and concatenate them together for one combined softmax. The loss is cross entropy where the ground truth probabilities are divided equally among the keyphrase labels (up to 3). By default we used the first occurrence of each keyphrase as the label. Our improved "max loss" takes the max of logits across all occurrences of the same keyphrase in the text, rather than just the first occurrence.

Model Selection: we performed a single hyperparameter sweep to determine the best parameter configuration for each model (i.e., single random seed per parameter configuration). The best model was selected as the one with the highest F1@3 on dev. Our best model (large, max loss, lifting from RoBERTa) was trained for 2 epochs, with a learning rate of 3×10^{-5}.

Model	*Time*	*Hardware*
ETC (share)	11h 13m	256 core TPU v3
ETC	11h 46m	256 core TPU v3
ETC-large	63h 41m	512 core TPU v3

Table 6: Time taken for pre-training the different model types used in our experiments, together with the hardware configuration used (2 cores = 1 chip). This corresponds to 63k pre-training iterations, with batch size 512 for base models (33 epochs), and 1024 for large models (66 epochs).

Dataset	*Epochs*	*Time*	*Hardware*
NQ	5	10h 47m	32 core TPU v3
HotpotQA	9	2h 59m	32 core TPU v3
WikiHop	15	5h 55m	32 core TPU v3
OpenKP	3	2h 5m	32 core TPU v3

Table 7: Time taken for fine-tuning the baseline ETC (base) model on different datasets, together with the hardware configuration used (2 cores = 1 chip). As we did a hyper-parameter sweep with different number of epochs, we report the time of the largest number of epochs we tried.

Inference: During inference, we select the top 5 keyphrases ordered by logits, removing any duplicates. All keyphrases were treated as uncased for the purpose of deduplication.

Appendix D: Lifting Weights from BERT/RoBERTa

When lifting weights from BERT or RoBERTa, the weights that can be lifted are (for every Transformer layer): feed forward layer, W^Q, W^K, W^V (since BERT/RoBERTa only have one copy of such matrices, in models where we use different matrices for global and long inputs, we initialize both sets of matrices to the same BERT/RoBERTa weights), attention output projection, and layer normalization. Additionally, we can also lift the token embedding matrix. Absolute position embeddings and next sentence prediction weights from BERT are discarded. After that, weights for the layers necessary for the CPC loss, and those involved in relative position encodings are randomly initialized.

For lifting to be possible, the number of layers, hidden size, number of attention heads, and size of the feed forward intermediate layers of the BERT/RoBERTa model need to match with the ETC model.

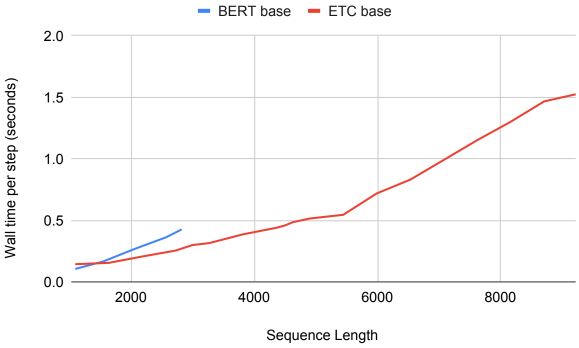

Figure 4: Wall time per step for different input lengths for both BERT and ETC with their base configurations. For ETC, global input length was set to 1/16th of the long input length until reaching a ceiling of 512 global length at 8192 long length, and Sequence Length is the sum of long and global lengths.

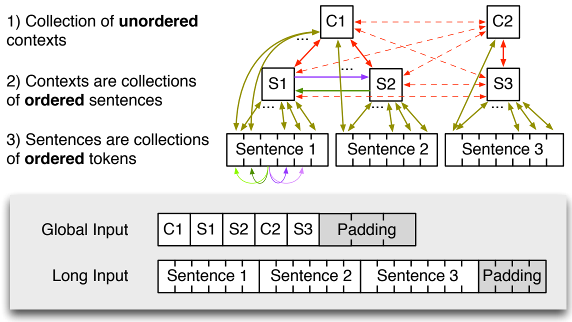

Figure 5: Illustration of structure encoding with ETC (using the same example shown in Figure 3b). Top: each box represents an input token, and arrows represent attention. The different colors and dash patterns in arrows represent the different relative position labels. Bottom: illustration of where each token would appear in the input of ETC.

Appendix E: Model Computational Requirements

Memory: To gauge headroom for scaling input lengths beyond what we used in this paper, we ran some additional experiments on TPU v3 hardware with gradient checkpointing and removing the extra gradient moments required by optimizers like Adam and LAMB. Fixing global input length to 512 tokens, we were able to push *base* models to long input size of 22656, and *large* models to long input size of 8448 before running out of memory on a single TPU v3 core. We leave for future work experimentation with more memory-efficient optimizers like Adafactor (Shazeer and Stern, 2018) and model-parallelism techniques in ETC.

Model	*Parameters*
ETC base (shared)	109M
ETC base	166M
ETC large (RoBERTa vocab)	558M
BERT base	110M
BERT large (RoBERTa vocab)	355M

Table 8: Number of trainable parameters for the different models evaluated in this paper.

Compute: As stated above, the computational complexity of attention in ETC is $O(n_g(n_g+n_l)+n_l(n_g+2r+1))$ and if we assume $n_g = O(2r+1)$, this results in a complexity of $O(n_g^2+n_g n_l)$, which is linear in the size of the long input. Table 6 shows pre-training times in our experiments, together with the hardware used in each experiment. Table 7 shows the fine-tuning times taken by the baseline ETC model on the different datasets. Notice that pre-training is the most computational intensive part, and thus, we used significantly more hardware. In order to gain further insights into the common use case of running the models using GPUs, Figure 4 shows a comparison of the wall-time used per step when using a single NVIDIA Tesla V100 GPU as the input length increases, for both BERT and ETC in their base configurations. As the plot shows ETC is initially slower, but it becomes faster than BERT for input lengths larger than about 1500. Moreover, the BERT plot ends earlier due to memory constraints. Finally, notice that the ETC wall time is not linear in this figure, as we also increased the size of the global input together with the long input.

Parameters: Finally, Table 8 shows the total number of parameters of the ETC model for the different configurations used in our experiments. The most important consideration is that the number of trainable parameters does not depend on the input length. As a matter of fact, it only depends on: the embedding dimensionality (d), the number of layers (l), and the number of relative position labels (which depends on k). The parameter count also depends on the fully connected feed forward intermediate size, but this is $4d$ by convention and for all ETC models in this paper. Our baseline model uses separate W^Q, W^K, W^V, and output projection matrices for global and long inputs, resulting in about 50% more parameters than BERT. But the configuration with shared W^Q, W^K, W^V, and output projection has a similar number of parameters as BERT. Parameter count for BERT base is reported from the original paper (Devlin et al.,

2018) and BERT large (RoBERTa vocab) from the original RoBERTa paper (Liu et al., 2019).

Appendix F: Structured Input Example

Figure 3b shows an illustration of a possible attention pattern for a dataset like WikiHop, where the input consists of contexts, made out of sentences. There is no order among the contexts, but there is among the sentences within a context. Figure 5 illustrates how this can be encoded in ETC, putting all the word piece tokens in the long input, and using the global input for special "context" and "sentence" tokens. Different relative position labels are used to indicate the different relations (token part of a sentence, sentence part of a context, order between sentences, order between tokens, etc.).

Pre-Training Transformers as Energy-Based Cloze Models

Kevin Clark[1] **Minh-Thang Luong**[2] **Quoc V. Le**[2] **Christopher D. Manning**[1]

`qvl@google.com, manning@cs.stanford.edu`

Abstract

We introduce Electric, an energy-based cloze model for representation learning over text. Like BERT, it is a conditional generative model of tokens given their contexts. However, Electric does not use masking or output a full distribution over tokens that could occur in a context. Instead, it assigns a scalar energy score to each input token indicating how likely it is given its context. We train Electric using an algorithm based on noise-contrastive estimation and elucidate how this learning objective is closely related to the recently proposed ELECTRA pre-training method. Electric performs well when transferred to downstream tasks and is particularly effective at producing likelihood scores for text: it re-ranks speech recognition n-best lists better than language models and much faster than masked language models. Furthermore, it offers a clearer and more principled view of what ELECTRA learns during pre-training.

1 Introduction

The cloze task (Taylor, 1953) of predicting the identity of a token given its surrounding context has proven highly effective for representation learning over text. BERT (Devlin et al., 2019) implements the cloze task by replacing input tokens with [MASK], but this approach incurs drawbacks in efficiency (only 15% of tokens are masked out at a time) and introduces a pre-train/fine-tune mismatch where BERT sees [MASK] tokens in training but not in fine-tuning. ELECTRA (Clark et al., 2020) uses a different pre-training task that alleviates these disadvantages. Instead of masking tokens, ELECTRA replaces some input tokens with fakes sampled from a small generator network. The pre-training task is then to distinguish the original vs. replaced tokens. While on the surface it appears quite different from BERT, in this paper we elucidate a close connection between ELECTRA and cloze modeling. In particular, we develop a new way of implementing the cloze task using an energy-based model (EBM). Then we show the resulting model, which we call Electric, is closely related to ELECTRA, as well as being useful in its own right for some applications.[1]

EBMs learn an energy function that assigns low energy values to inputs in the data distribution and high energy values to other inputs. They are flexible because they do not have to compute normalized probabilities. For example, Electric does not use masking or an output softmax, instead producing a scalar energy score for each token where a low energy indicates the token is likely given its context. Unlike with BERT, these likelihood scores can be computed simultaneously for all input tokens rather than only for a small masked-out subset. We propose a training algorithm for Electric that efficiently approximates a loss based on noise-contrastive estimation (Gutmann and Hyvärinen, 2010). Then we show that this training algorithm is closely related to ELECTRA; in fact, ELECTRA can be viewed as a variant of Electric using negative sampling instead of noise-contrastive estimation.

We evaluate Electric on GLUE (Wang et al., 2019) and SQuAD (Rajpurkar et al., 2016), where Electric substantially outperforms BERT but slightly under-performs ELECTRA. However, Electric is particularly useful in its ability to efficiently produce pseudo-likelihood scores (Salazar et al., 2020) for text: Electric is better at re-ranking the outputs of a speech recognition system than GPT-2 (Radford et al., 2019) and is much faster at re-ranking than BERT because it scores all input tokens simultaneously rather than having to be run multiple times with different tokens masked out. In total, investigating Electric leads to a more principled understanding of ELECTRA and our results

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 285–294,
November 16–20, 2020.

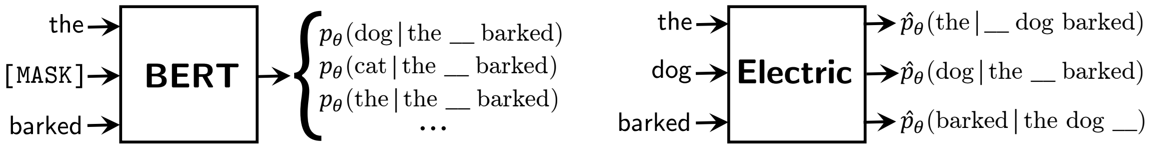

Figure 1: Comparison of BERT and Electric. Both model the probability of a token given its surrounding context, but BERT produces a full output distribution over tokens only for masked positions while Electric produces un-normalized probabilities (but no full distribution) for all input tokens.

suggest that EBMs are a promising alternative to the standard generative models currently used for language representation learning.

2 Method

BERT and related pre-training methods (Baevski et al., 2019; Liu et al., 2019; Lan et al., 2020) train a large neural network to perform the cloze task. These models learn the probability $p_{\text{data}}(x_t|\boldsymbol{x}_{\backslash t})$ of a token x_t occurring in the surrounding context $\boldsymbol{x}_{\backslash t} = [x_1, ..., x_{t-1}, x_{t+1}, ..., x_n]$. Typically the context is represented as the input sequence with x_t replaced by a special `[MASK]` placeholder token. This masked sequence is encoded into vector representations by a transformer network (Vaswani et al., 2017). Then the representation at position t is passed into a softmax layer to produce a distribution over tokens $p_\theta(x_t|\boldsymbol{x}_{\backslash t})$ for the position.

2.1 The Electric Model

Electric also models $p_{\text{data}}(x_t|\boldsymbol{x}_{\backslash t})$, but does not use masking or a softmax layer. Electric first maps the unmasked input $\boldsymbol{x} = [x_1, ..., x_n]$ into contextualized vector representations $\boldsymbol{h}(\boldsymbol{x}) = [\boldsymbol{h}_1, ..., \boldsymbol{h}_n]$ using a transformer network. The model assigns a given position t an energy score

$$E(\boldsymbol{x})_t = \boldsymbol{w}^T \boldsymbol{h}(\boldsymbol{x})_t$$

using a learned weight vector $\boldsymbol{w}$. The energy function defines a distribution over the possible tokens at position t as

$$\begin{aligned} p_\theta(x_t|\boldsymbol{x}_{\backslash t}) &= \exp\left(-E(\boldsymbol{x})_t\right)/Z(\boldsymbol{x}_{\backslash t}) \\ &= \frac{\exp\left(-E(\boldsymbol{x})_t\right)}{\sum_{x' \in \mathcal{V}} \exp\left(-E(\text{REPLACE}(\boldsymbol{x}, t, x'))_t\right)} \end{aligned}$$

where $\text{REPLACE}(\boldsymbol{x}, t, x')$ denotes replacing the token at position t with x' and $\mathcal{V}$ is the vocabulary, in practice usually word pieces (Sennrich et al., 2016). Unlike with BERT, which produces the probabilities for all possible tokens x' using a softmax layer, a candidate x' is passed in as *input* to the transformer. As a result, computing p_θ is prohibitively expensive because the partition function $Z_\theta(\boldsymbol{x}_{\backslash t})$ requires running the transformer $|\mathcal{V}|$ times; unlike most EBMs, the intractability of $Z_\theta(\boldsymbol{x}_{\backslash t})$ is due to the expensive scoring function rather than having a large sample space.

2.2 NCE Loss

As computing the exact likelihood is intractable, training energy-based models such as Electric with standard maximum-likelihood estimation is not possible. Instead, we use (conditional) Noise-Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2010; Ma and Collins, 2018), which provides a way of efficiently training an un-normalized model that does not compute $Z_\theta(\boldsymbol{x}_{\backslash t})$. NCE learns the parameters of a model by defining a binary classification task where samples from the data distribution have to be distinguished from samples generated by a noise distribution $q(x_t|\boldsymbol{x}_{\backslash t})$. First, we define the un-normalized output

$$\hat{p}_\theta(x_t|\boldsymbol{x}_{\backslash t}) = \exp\left(-E(\boldsymbol{x})_t\right)$$

Operationally, NCE can be viewed as follows:

- A positive data point is a text sequence $\boldsymbol{x}$ from the data and position in the sequence t.
- A negative data point is the same except x_t, the token at position t, is replaced with a noise token $\hat{x}_t$ sampled from q.
- Define a binary classifier D that estimates the probability of a data point being positive as
$$\frac{n \cdot \hat{p}_\theta(x_t|\boldsymbol{x}_{\backslash t})}{n \cdot \hat{p}_\theta(x_t|\boldsymbol{x}_{\backslash t}) + k \cdot q(x_t|\boldsymbol{x}_{\backslash t})}$$
- The binary classifier is trained to distinguish positive vs negative data points, with k negatives sampled for every n positive data points.

Formally, the NCE loss $\mathcal{L}(\theta)$ is

$$n \cdot \mathop{\mathbb{E}}_{\boldsymbol{x},t} \left[-\log \frac{n \cdot \hat{p}_\theta(x_t|\boldsymbol{x}_{\backslash t})}{n \cdot \hat{p}_\theta(x_t|\boldsymbol{x}_{\backslash t}) + k \cdot q(x_t|\boldsymbol{x}_{\backslash t})} \right] +$$
$$k \cdot \mathop{\mathbb{E}}_{\substack{\boldsymbol{x},t \\ \hat{x}_t \sim q}} \left[-\log \frac{k \cdot q(\hat{x}_t|\boldsymbol{x}_{\backslash t})}{n \cdot \hat{p}_\theta(\hat{x}_t|\boldsymbol{x}_{\backslash t}) + k \cdot q(\hat{x}_t|\boldsymbol{x}_{\backslash t})} \right]$$

This loss is minimized when $\hat{p}_\theta$ matches the data distribution p_{data} (Gutmann and Hyvärinen, 2010). A consequence of this property is that the model learns to be self-normalized such that $Z_\theta(\boldsymbol{x}_{\setminus t}) = 1$.

2.3 Training Algorithm

To minimize the loss, the expectations could be approximated by sampling as shown in Algorithm 1. Taking the gradient of this estimated loss produces an unbiased estimate of $\nabla_\theta \mathcal{L}(\theta)$. However, this algorithm is computationally expensive to run, since it requires $k+1$ forward passes through the transformer to compute the $\hat{p}_\theta$s (once for the positive samples and once for each negative sample). We propose a much more efficient approach that replaces k input tokens with noise samples *simultaneously* shown in Algorithm 2. It requires just one pass through the transformer for k noise samples and $n-k$ data samples. However, this procedure only truly minimizes $\mathcal{L}$ if $\hat{p}_\theta(x_t|\boldsymbol{x}_{\setminus t}) = \hat{p}_\theta(x_t|\boldsymbol{x}^{\text{noised}}_{\setminus t})$. To apply this efficiency trick we are making the assumption they are approximately equal, which we argue is reasonable because (1) we choose a small k of $\lceil 0.15n \rceil$ and (2) q is trained to be close to the data distribution (see below). This efficiency trick is analogous to BERT masking out multiple tokens per input sequence.

Algorithm 1 Naive NCE loss estimation

```
Given: Input sequence $\boldsymbol{x}$, number of negative samples $k$, noise distribution $q$, model $\hat{p}_\theta$.
1. Initialize the loss as $\sum_{t=1}^{n}\left(-\log\frac{n\cdot\hat{p}_\theta(x_t|\boldsymbol{x}_{\setminus t})}{n\cdot\hat{p}_\theta(x_t|\boldsymbol{x}_{\setminus t})+k\cdot q(x_t|\boldsymbol{x}_{\setminus t})}\right)$.
2. Sample $k$ negative samples according to $t \sim \text{unif}\{1,n\}$, $\hat{x}_t \sim q(x_t|\boldsymbol{x}_{\setminus t})$.
3. For each negative sample, add to the loss $-\log\frac{k\cdot q(\hat{x}_t|\boldsymbol{x}_{\setminus t})}{n\cdot\hat{p}_\theta(\hat{x}_t|\boldsymbol{x}_{\setminus t})+k\cdot q(\hat{x}_t|\boldsymbol{x}_{\setminus t})}$.
```

Algorithm 2 Efficient NCE loss estimation

```
Given: Input sequence $\boldsymbol{x}$, number of negative samples $k$, noise distribution $q$, model $\hat{p}_\theta$.
1. Pick $k$ unique random positions $R = \{r_1, ..., r_k\}$ where each $r_i$ is $1 \le r_i \le n$.
2. Replace the $k$ random positions with negative samples: $\hat{x}_i \sim q(x_i|\boldsymbol{x}_{\setminus i})$ for $i \in R$,
   $\boldsymbol{x}^{\text{noised}} = \text{REPLACE}(\hat{\boldsymbol{x}}, R, \hat{X})$.
3. For each position $t = 1$ to $n$: add to the loss
   $-\log\frac{k\cdot q(\hat{x}_t|\boldsymbol{x}_{\setminus t})}{(n-k)\cdot\hat{p}_\theta(\hat{x}_t|\boldsymbol{x}^{\text{noised}}_{\setminus t})+k\cdot q(\hat{x}_t|\boldsymbol{x}_{\setminus t})}$   if $t \in R$
   $-\log\frac{(n-k)\cdot\hat{p}_\theta(x_t|\boldsymbol{x}^{\text{noised}}_{\setminus t})}{(n-k)\cdot\hat{p}_\theta(x_t|\boldsymbol{x}^{\text{noised}}_{\setminus t})+k\cdot q(x_t|\boldsymbol{x}_{\setminus t})}$   otherwise
```

2.4 Noise Distribution

The noise distribution q comes from a neural network trained to match p_{data}. NCE commonly employs this idea to ensure the classification task is sufficiently challenging for the model (Gutmann and Hyvärinen, 2010; Wang and Ou, 2018). In particular, we use a two-tower cloze model as proposed by Baevski et al. (2019), which is more accurate than a language model because it uses context to both sides of each token. The model runs two transformers T_{LTR} and T_{RTL} over the input sequence. These transformers apply causal masking so one processes the sequence left-to-right and the other operates right-to-left. The model's predictions come from a softmax layer applied to the concatenated states of the two transformers:

$$\overrightarrow{\boldsymbol{h}} = T_{\text{LTR}}(\boldsymbol{x}), \quad \overleftarrow{\boldsymbol{h}} = T_{\text{RTL}}(\boldsymbol{x})$$

$$q(x_t|\boldsymbol{x}_{\setminus t}) = \text{softmax}(\boldsymbol{W}[\overrightarrow{\boldsymbol{h}}_{t-1}, \overleftarrow{\boldsymbol{h}}_{t+1}])_{x_t}$$

The noise distribution is trained simultaneously with Electric using standard maximum likelihood estimation over the data. The model producing the noise distribution is much smaller than Electric to reduce the computational overhead.

2.5 Connection to ELECTRA

Electric is closely related to the ELECTRA pre-training method. ELECTRA also trains a binary classifier (the "discriminator") to distinguish data tokens from noise tokens produced by a "generator" network. However, ELECTRA's classifier is simply a sigmoid layer on top of the transformer: it models the probability of a token being negative (i.e., as replaced by a noise sample) as $\sigma(E(\boldsymbol{x})_t)$ where σ denotes the sigmoid function. Electric on the other hand models this probability as

$$\frac{k\cdot q(x|\boldsymbol{x}_{\setminus t})}{n\cdot\exp\left(-E(\boldsymbol{x})_t\right)+k\cdot q(x|\boldsymbol{x}_{\setminus t})} = \sigma\left(E(\boldsymbol{x})_t+\log\left(\frac{k\cdot q(x|\boldsymbol{x}_{\setminus t})}{n}\right)\right)$$

While ELECTRA learns whether a token is more likely to come from the data distribution p_{data} or noise distribution q, Electric only learns p_{data} because q is passed into the model directly. This difference is analogous to using negative sampling (Mikolov et al., 2013) vs. noise-contrastive estimation (Mnih and Kavukcuoglu, 2013) for learning word embeddings.

Model	**MultiNLI**	**SQuAD 2.0**	**GLUE Avg.**
BERT	84.3	73.7	82.2
XLNet	85.8	78.5	–
ELECTRA	86.2	80.5	85.1
Electric	85.7	80.1	84.1

Table 1: Dev-set scores of pre-trained models on downstream tasks. To provide direct comparisons, we only show base-sized models pre-trained on WikiBooks.

A disadvantage of Electric compared to ELECTRA is that it is less flexible in the choice of noise distribution. Since ELECTRA's binary classifier does not need to access q, its q only needs to be defined for negative sample positions in the input sequence. Therefore ELECTRA can use a masked language model rather than a two-tower cloze model for q. An advantage of Electric is that it directly provides (un-normalized) probabilities $\hat{p}_\theta$ for tokens, making it useful for applications such as re-ranking the outputs of text generation systems. The differences between ELECTRA and Electric are summarized below:

Model	Noise Dist.	Binary Classifier
Electric	Two-Tower Cloze Model	$\sigma\left(E(\boldsymbol{x})_t + \log\left(\frac{k \cdot q(x \mid \boldsymbol{x}_{\setminus t})}{n}\right)\right)$
ELECTRA	Masked LM	$\sigma(E(\boldsymbol{x})_t)$

3 Experiments

We train two Electric models the same size as BERT-Base (110M parameters): one on Wikipedia and BooksCorpus (Zhu et al., 2015) for comparison with BERT and one on OpenWebTextCorpus (Gokaslan and Cohen, 2019) for comparison[2] with GPT-2. The noise distribution transformers T_{LTR} and T_{RTL} are 1/4 the hidden size of Electric. We do no hyperparameter tuning, using the same hyperparameter values as ELECTRA. Further details on training are in the appendix.

3.1 Transfer to Downstream Tasks

We evaluate fine-tuning the Electric model on the GLUE natural language understanding benchmark (Wang et al., 2019) and the SQuAD 2.0 question answering dataset (Rajpurkar et al., 2018). We report exact-match for SQuAD, average score[3] over the GLUE tasks[4], and accuracy on the multi-genre natural language inference GLUE task. Reported scores are medians over 10 fine-tuning runs with different random seeds. We use the same fine-tuning setup and hyperparameters as ELECTRA.

Results are shown in Table 1. Electric scores better than BERT, showing the energy-based formulation improves cloze model pre-training. However, Electric scores slightly lower than ELECTRA. One possible explanation is that Electric's noise distribution is worse because a two-tower cloze model is less expressive than a masked LM. We tested this hypothesis by training ELECTRA with the same two-tower noise model as Electric. Performance did indeed go down, but it only explained about half the gap. The surprising drop in performance suggests that learning the difference between the data and generations from a low-capacity model leads to better representations than only learning the data distribution, but we believe further research is needed to fully understand the discrepancy.

3.2 Fast Pseudo-Log-Likelihood Scoring

An advantage of Electric over BERT is that it can efficiently produce pseudo-log-likelihood (PLL) scores for text (Wang and Cho, 2019). PLLs for Electric are

$$\text{PLL}(\boldsymbol{x}) = \sum_{t=1}^{n} \log(\hat{p}_\theta(x_t \mid \boldsymbol{x}_{\setminus t})) = \sum_{t=1}^{n} -E(\boldsymbol{x})_t$$

PLLs can be used to re-rank the outputs of an NMT or ASR system. While historically log-likelihoods from language models have been used for such re-ranking, recent work has demonstrated that PLLs from masked language models perform better (Shin et al., 2019). However, computing PLLs from a masked language model requires n passes of the transformer: once with each token masked out. Salazar et al. (2020) suggest distilling BERT into a model that uses no masking to avoid this cost, but this model considerably under-performed regular LMs in their experiments.

Electric can produce PLLs for all input tokens in a single pass like a LM while being bidirectional like a masked LM. We use the PLLs from Electric for re-ranking the 100-best hypotheses of a 5-layer BLSTMP model from ESPnet (Watanabe et al., 2018) on the 960-hour LibriSpeech corpus (Panayotov et al., 2015) following the same experimental setup and using the same n-best lists as Salazar

---

[2] The original GPT-2 dataset is not public, so we use a public re-implementation.

[3] Matthews correlation coefficient for CoLA, Spearman correlation for STS, accuracy for the other tasks.

[4] We exclude WNLI, for which models do not outperform the majority baseline.

et al. (2020). Given speech features $\boldsymbol{s}$ and speech recognition model f the re-ranked output is

$$\underset{\boldsymbol{x} \in \text{n-best}(f, \boldsymbol{s})}{\arg\max} \quad f(\boldsymbol{x}|\boldsymbol{s}) + \lambda \text{PLL}(\boldsymbol{x})$$

where n-best$(f, \boldsymbol{s})$ consists of the top n (we use $n = 100$) predictions from the speech recognition model found with beam search, $f(\boldsymbol{x}|\boldsymbol{s})$ is the score the speech model assigns the candidate output sequence $\boldsymbol{x}$. We select the best λ on the dev set out of $[0.05, 0.1, ..., 0.95, 1.0]$, with different λs selected for the "clean" and "other" portions of the data.

We compare Electric against GPT-2 (Radford et al., 2019), BERT (Devlin et al., 2019), and two baseline systems that are bidirectional while only requiring a single transformer pass like Electric. TwoTower is a two-tower cloze model similar to Electric's noise distribution, but of the same size as Electric. ELECTRA-TT is identical to ELECTRA except it uses a two-tower noise distribution rather than a masked language model.[5] The noise distribution probabilities and binary classifiers scores of ELECTRA can be combined to assign probabilities for tokens as shown in Appendix G of the ELECTRA paper.

Results are shown in Table 2. Electric scores better than GPT-2 when trained on comparable data. While scoring worse than BERT, Electric is much faster to run. It also slightly outperforms ELECTRA-TT, which is consistent with the finding from Labeau and Allauzen (2018) that NCE outperforms negative sampling for training language models. Furthermore, Electric is simpler and faster than ELETRA-TT in that it does not require running the generator to produce PLL scores. TwoTower scores lower than Electric, presumably because it is not a "deeply" bidirectional model and instead just concatenates forward and backward hidden states.

Model	Pre-train Data	Clean WER	Other WER	Runtime
None	–	7.26	20.37	0
BERT	WikiBooks	5.41	17.41	n
Electric	WikiBooks	5.65	17.42	1
GPT-2	OWT	5.64	17.60	1
TwoTower	OWT*	5.32	17.25	1
ELECTRA-TT	OWT*	5.22	17.01	1
Electric	OWT*	5.18	16.93	1

Table 2: Test-set word error rates on LibriSpeech after rescoring with base-sized models. None, GPT-2, and BERT results are from Salazar et al. (2020). Runtime is measured in passes through the transformer. "Clean" and "other" are easier and harder splits of the data. *We use a public re-implementation of OpenWebText.

4 Related Work

Language modeling (Dai and Le, 2015; Radford et al., 2018; Peters et al., 2018) and cloze modeling (Devlin et al., 2019; Baevski et al., 2019; Liu et al., 2019) have proven to be effective pre-training tasks for NLP. Unlike Electric, these methods follow the standard recipe of estimating token probabilities with an output softmax and using maximum-likelihood training.

Energy-based models have been widely explored in machine learning (Dayan et al., 1995; LeCun et al., 2007). While many training methods involve sampling from the EBM using gradient-based MCMC (Du and Mordatch, 2019) or Gibbs sampling (Hinton, 2002), we considered these approaches too slow for pre-training because they require multiple passes through the model per sample. We instead use noise-contrastive estimation (Gutmann and Hyvärinen, 2010), which has widely been used in NLP for learning word vectors (Mnih and Kavukcuoglu, 2013) and text generation models (Jean et al., 2014; Józefowicz et al., 2016). While EBMs have previously been applied to left-to-right (Wang et al., 2015) or globally normalized (Rosenfeld et al., 2001; Deng et al., 2020) text generation, they have not previously been applied to cloze models or for pre-training NLP models. Several papers have pointed out the connection between EBMs and GANs (Zhao et al., 2016; Finn et al., 2016), which is similar to the Electric/ELECTRA connection.

5 Conclusion

We have developed an energy-based cloze model we call Electric and designed an efficient training algorithm for Electric based on noise-contrastive estimation. Although Electric can be derived solely from the cloze task, the resulting pre-training method is closely related to ELECTRA's GAN-like pre-training algorithm. While slightly underperforming ELECTRA on downstream tasks, Electric is useful for its ability to quickly produce pseudo-log-likelihood scores for text. Furthermore, it offers a clearer and more principled view of the ELECTRA objective as a "negative sampling" version of cloze pre-training.

---

[5] With ELECTRA's original masked LM generator, it would be impossible to score all tokens in a single pass.

A Pre-Training Details

The neural architectures of our models are identical to BERT-Base (Devlin et al., 2019), although we believe incorporating additions such as relative position encodings (Shaw et al., 2018) would improve results. Our pre-training setup is the same as ELECTRA's (Clark et al., 2020), which adds some additional ideas from Liu et al. (2019) on top of the BERT codebase, such as dynamic masking and removing the next-sentence prediction task. We use the weight sharing trick from ELECTRA, where the transformers producing the proposal distribution and the main transformer share token embeddings. We do not use whole-word or n-gram masking, although we believe it would improve results too.

We did no hyperparameter tuning, directly using the hyperparameters from ELECTRA-Base for Electric and our baselines. These hyperparameters are slightly modified from the ones used in BERT; for completeness, we show these values in Table 3. The hidden sizes, feed-forward hidden sizes, and number of attention heads of the two transformers T_{LTR} and T_{RTL} used to produce the proposal distribution are 1/4 the size of Electric. We chose this value because it keeps the compute comparable to ELECTRA; running two 1/4-sized transformers takes roughly the same compute as running one 1/3-sized transformer, which is the size of ELECTRA's generator. To make the compute exactly equal, we train Electric for slightly fewer steps than ELECTRA. This same generator architecture was used for ELECTRA-TT. The TwoTower baseline consists of two transformers 2/3 the size of BERT's, which takes approximately the same compute to run. The Electric models, ELECTRA-Base, and BERT-Base all use the same amount of pre-train compute (e.g., Electric is trained for fewer steps than BERT due to the extra compute from the proposal distribution), which equates to approximately three days of training on 16 TPUv2s.

B Fine-Tuning Details

We use ELECTRA's top-level classifiers and hyperparameter values for fine-tuning as well. For GLUE tasks, a simple linear classifier is added on top of the pre-trained transformer. For SQuAD, a question answering module similar XLNet's (Yang et al., 2019) is added on top of the transformer, which is slightly more sophisticated than BERT's in that it jointly rather than independently predicts the start and end positions and has an "answerability" classifier added for SQuAD 2.0. ELECTRA's hyperparameters are similar to BERT's, with the main difference being the addition of a layer-wise learning rate decay where layers of the network closer to the output have a higher learning rate. Following BERT, we submit the best of 10 models fine-tuned with different random seeds to the GLUE leaderboard for test set results.

C Dataset Details

We provide details on the fine-tuning datasets below. All datasets are in English. GLUE data can be downloaded at `https://gluebenchmark.com/` and SQuAD data can be downloaded at `https://rajpurkar.github.io/SQuAD-explorer/`.

- **CoLA:** Corpus of Linguistic Acceptability (Warstadt et al., 2018). The task is to determine whether a given sentence is grammatical or not. The dataset contains 8.5k train examples from books and journal articles on linguistic theory.

- **SST:** Stanford Sentiment Treebank (Socher et al., 2013). The tasks is to determine if the sentence is positive or negative in sentiment. The dataset contains 67k train examples from movie reviews.

- **MRPC:** Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005). The task is to predict whether two sentences are semantically equivalent or not. The dataset contains 3.7k train examples from online news sources.

- **STS:** Semantic Textual Similarity (Cer et al., 2017). The tasks is to predict how semantically similar two sentences are on a 1-5 scale. The dataset contains 5.8k train examples drawn from new headlines, video and image captions, and natural language inference data.

- **QQP:** Quora Question Pairs (Iyer et al., 2017). The task is to determine whether a pair of questions are semantically equivalent. The dataset contains 364k train examples from the community question-answering website Quora.

- **MNLI:** Multi-genre Natural Language Inference (Williams et al., 2018). Given a premise sentence and a hypothesis sentence, the task is to predict whether the premise entails the hypothesis, contradicts the hypothesis, or neither. The dataset contains 393k train examples drawn from ten different sources.

Hyperparameter	**Pre-Training**	**Fine-Tuning**
Number of layers	12	
Hidden Size	768	
FFN inner hidden size	3072

Attention Dropout	0.1	
Dropout	0.1	
Weight Decay	0.01	0
Batch Size	256	32
Train Steps	700K	10 epochs for RTE and STS 2 for SQuAD, 3 for other tasks

Table 3: Hyperparameters for Electric; the values are identical to ELECTRA's other than the train steps and different-sized proposal network (see text), but we include them here for completeness. If not shown, the fine-tuning hyperparameter is the same as the pre-training one.

- **QNLI:** Question Natural Language Inference; constructed from SQuAD (Rajpurkar et al., 2016). The task is to predict whether a context sentence contains the answer to a question sentence. The dataset contains 108k train examples from Wikipedia.
- **RTE:** Recognizing Textual Entailment (Giampiccolo et al., 2007). Given a premise sentence and a hypothesis sentence, the task is to predict whether the premise entails the hypothesis or not. The dataset contains 2.5k train examples from a series of annual textual entailment challenges.
- **SQuAD 1.1:** Stanford Question Answering Dataset (Rajpurkar et al., 2016). Given a context paragraph and a question, the task is to select the span of text in the paragraph answering the question. The dataset contains 88k train examples from Wikipedia.
- **SQuAD 2.0:** Stanford Question Answering Dataset version 2.0 (Rajpurkar et al., 2018). This task adds addition questions to SQuAD whose answer does not exist in the context; models have to recognize when these questions occur and not return an answer for them. The dataset contains 130k train examples,

We report Spearman correlation for STS, Matthews correlation coefficient (MCC) for CoLA, exact match for SQuAD, and accuracy for the other tasks. We use the provided evaluation script for SQuAD[6], scipy to compute Spearman scores[7], and sklearn to compute MCC[8]. We use the standard train/dev/test splits.

D Detailed Results

We show detailed results on GLUE and SQuAD in Table 4 and detailed results on LibriSpeech reranking in Table 5. Following BERT, we do not show results on the WNLI GLUE task, as it is difficult to beat even the majority classifier using a standard fine-tuning-as-classifier approach. We show dev rather than test results on GLUE in the main paper because they are more reliable; the performance of fine-tuned models varies substantially based on the random seed (Phang et al., 2018; Clark et al., 2019; Dodge et al., 2020), but GLUE only supports submitting a single model rather than getting a median score of multiple models. While

using dev-set model selection to choose the test set submission may alleviate the high variance of fine-tuning to some extent, such model selection is still not sufficient for reliable comparisons between methods (Reimers and Gurevych, 2018).

Calibration of Pre-trained Transformers

Shrey Desai and **Greg Durrett**
Department of Computer Science
The University of Texas at Austin
`shreydesai@utexas.edu` `gdurrett@cs.utexas.edu`

Abstract

Pre-trained Transformers are now ubiquitous in natural language processing, but despite their high end-task performance, little is known empirically about whether they are calibrated. Specifically, do these models' posterior probabilities provide an accurate empirical measure of how likely the model is to be correct on a given example? We focus on BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) in this work, and analyze their calibration across three tasks: natural language inference, paraphrase detection, and commonsense reasoning. For each task, we consider in-domain as well as challenging out-of-domain settings, where models face more examples they *should* be uncertain about. We show that: (1) when used out-of-the-box, pre-trained models are calibrated in-domain, and compared to baselines, their calibration error out-of-domain can be as much as 3.5× lower; (2) temperature scaling is effective at further reducing calibration error in-domain, and using label smoothing to deliberately increase empirical uncertainty helps calibrate posteriors out-of-domain.[1]

1 Introduction

Neural networks have seen wide adoption but are frequently criticized for being black boxes, offering little insight as to why predictions are made (Benítez et al., 1997; Dayhoff and DeLeo, 2001; Castelvecchi, 2016) and making it difficult to diagnose errors at test-time. These properties are particularly exhibited by pre-trained Transformer models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019), which dominate benchmark tasks like SuperGLUE (Wang et al., 2019), but use a large number of self-attention heads across many layers in a way that is difficult to unpack (Clark et al., 2019; Kovaleva et al., 2019). One step towards understanding whether these models can be trusted is by analyzing whether they are *calibrated* (Raftery et al., 2005; Jiang et al., 2012; Kendall and Gal, 2017): how aligned their posterior probabilities are with empirical likelihoods (Brier, 1950; Guo et al., 2017). If a model assigns 70% probability to an event, the event should occur 70% of the time if the model is calibrated. Although the model's mechanism itself may be uninterpretable, a calibrated model at least gives us a signal that it "knows what it doesn't know," which can make these models easier to deploy in practice (Jiang et al., 2012).

In this work, we evaluate the calibration of two pre-trained models, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), on three tasks: natural language inference (Bowman et al., 2015), paraphrase detection (Iyer et al., 2017), and commonsense reasoning (Zellers et al., 2018). These tasks represent standard evaluation settings for pre-trained models, and critically, challenging out-of-domain test datasets are available for each. Such test data allows us to measure calibration in more realistic settings where samples stem from a dissimilar input distribution, which is exactly the scenario where we hope a well-calibrated model would avoid making confident yet incorrect predictions.

Our experiments yield several key results. First, even when used out-of-the-box, pre-trained models are calibrated in-domain. In out-of-domain settings, where non-pre-trained models like ESIM (Chen et al., 2017) are overconfident, we find that pre-trained models are significantly better calibrated. Second, we show that temperature scaling (Guo et al., 2017), multiplying non-normalized logits by a single scalar hyperparameter, is widely effective at improving in-domain calibration. Finally, we show that regularizing the model to be less certain during training can beneficially smooth probabilities, improving out-of-domain calibration.

2 Related Work

Calibration has been well-studied in statistical machine learning, including applications in forecasting (Brier, 1950; Raftery et al., 2005; Gneiting et al., 2007; Palmer et al., 2008), medicine (Yang and Thompson, 2010; Jiang et al., 2012), and computer vision (Kendall and Gal, 2017; Guo et al., 2017; Lee et al., 2018). Past work in natural language processing has studied calibration in the non-neural (Nguyen and O'Connor, 2015) and neural (Kumar and Sarawagi, 2019) settings across several tasks. However, past work has not analyzed large-scale pre-trained models, and we additionally analyze out-of-domain settings, whereas past work largely focuses on in-domain calibration (Nguyen and O'Connor, 2015; Guo et al., 2017).

Another way of hardening models against out-of-domain data is to be able to explicitly detect these examples, which has been studied previously (Hendrycks and Gimpel, 2016; Liang et al., 2018; Lee et al., 2018). However, this assumes a discrete notion of domain; calibration is a more general paradigm and gracefully handles settings where domains are less quantized.

3 Posterior Calibration

A model is calibrated if the confidence estimates of its predictions are aligned with empirical likelihoods. For example, if we take 100 samples where a model's prediction receives posterior probability 0.7, the model should get 70 of the samples correct. Formally, calibration is expressed as a joint distribution $P(Q, Y)$ over confidences $Q \in \mathbb{R}$ and labels $Y \in \mathcal{Y}$, where perfect calibration is achieved when $P(Y = y|Q = q) = q$. This probability can be empirically approximated by binning predictions into k disjoint, equally-sized bins, each consisting of b_k predictions. Following previous work in measuring calibration (Guo et al., 2017), we use *expected calibration error* (ECE), which is a weighted average of the difference between each bin's accuracy and confidence: $\sum_k \frac{b_k}{n}|\text{acc}(k) - \text{conf}(k)|$. For the experiments in this paper, we use $k = 10$.

4 Experiments

4.1 Tasks and Datasets

We perform evaluations on three language understanding tasks: natural language inference, paraphrase detection, and commonsense reasoning. Significant past work has studied cross-domain robustness using sentiment analysis (Chen et al., 2018; Peng et al., 2018; Miller, 2019; Desai et al., 2019). However, we explicitly elect to use tasks where out-of-domain performance is substantially lower and challenging domain shifts are exhibited. Below, we describe our in-domain and out-of-domain datasets.[2] For all datasets, we split the development set in half to obtain a held-out, non-blind test set.

Model	Parameters	Architecture	Pre-trained
DA	382K	LSTM	✗
ESIM	4M	Bi-LSTM	✗
BERT	110M	Transformer	✓
RoBERTa	110M	Transformer	✓

Table 1: Models in this work. Decomposable Attention (DA) (Parikh et al., 2016) and Enhanced Sequential Inference Model (ESIM) (Chen et al., 2017) use LSTMs and attention on top of GloVe embeddings (Pennington et al., 2014) to model pairwise semantic similarities. In contrast, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) are large-scale, pre-trained language models with stacked, general purpose Transformer (Vaswani et al., 2017) layers.

Natural Language Inference. The Stanford Natural Language Inference (SNLI) corpus is a large-scale entailment dataset where the task is to determine whether a hypothesis is entailed, contradicted by, or neutral with respect to a premise (Bowman et al., 2015). Multi-Genre Natural Language Inference (MNLI) (Williams et al., 2018) contains similar entailment data across several domains, which we can use as unseen test domains.

Paraphrase Detection. Quora Question Pairs (QQP) contains sentence pairs from Quora that are semantically equivalent (Iyer et al., 2017). Our out-of-domain setting is TwitterPPDB (TPPDB), which contains sentence pairs from Twitter where tweets are considered paraphrases if they have shared URLs (Lan et al., 2017).

Commonsense Reasoning. Situations With Adversarial Generations (SWAG) is a grounded commonsense reasoning task where models must select the most plausible continuation of a sentence among four candidates (Zellers et al., 2018). HellaSWAG (HSWAG), an adversarial out-of-domain dataset, serves as a more challenging benchmark for pre-trained models (Zellers et al., 2019); it is

---

[2] Dataset splits are detailed in Appendix A. Furthermore, out-of-domain datasets are strictly used for evaluating the generalization of in-domain models, so the training split is unused.

Model	Accuracy		ECE	
	ID	OD	ID	OD
Task: SNLI/MNLI				
DA	84.63	57.12	**1.02**	8.79
ESIM	88.32	60.91	1.33	12.78
BERT	90.04	73.52	2.54	7.03
RoBERTa	**91.23**	**78.79**	1.93	**3.62**
Task: QQP/TwitterPPDB				
DA	85.85	83.36	3.37	9.79
ESIM	87.75	84.00	3.65	**8.38**
BERT	90.27	**87.63**	2.71	8.51
RoBERTa	**91.11**	86.72	**2.33**	9.55
Task: SWAG/HellaSWAG				
DA	46.80	32.48	5.98	40.37
ESIM	52.09	32.08	7.01	19.57
BERT	79.40	34.48	2.49	12.62
RoBERTa	**82.45**	**41.68**	**1.76**	**11.93**

Table 2: Out-of-the-box calibration results for in-domain (SNLI, QQP, SWAG) and out-of-domain (MNLI, TwitterPPDB, HellaSWAG) datasets using the models described in Table 1. We report accuracy and expected calibration error (ECE), both averaged across 5 fine-tuning runs with random restarts.

distributionally different in that its examples exploit statistical biases in pre-trained models.

4.2 Systems for Comparison

Table 1 shows a breakdown of the models used in our experiments. We use the same set of hyperparameters across all tasks. For pre-trained models, we omit hyperparameters that induce brittleness during fine-tuning, e.g., employing a decaying learning rate schedule with linear warmup (Sun et al., 2019; Lan et al., 2020). Detailed information on optimization is available in Appendix B.

4.3 Out-of-the-box Calibration

First, we analyze "out-of-the-box" calibration; that is, the calibration error derived from evaluating a model on a dataset without using post-processing steps like temperature scaling (Guo et al., 2017). For each task, we train the model on the in-domain training set, and then evaluate its performance on the in-domain and out-of-domain test sets. Quantitative results are shown in Table 2. In addition, we plot reliability diagrams (Nguyen and O'Connor, 2015; Guo et al., 2017) in Figure 1, which visualize the alignment between posterior probabilities (confidence) and empirical outcomes (accuracy), where a perfectly calibrated model has $\text{conf}(k) = \text{acc}(k)$ for each bucket of real-valued predictions k. We

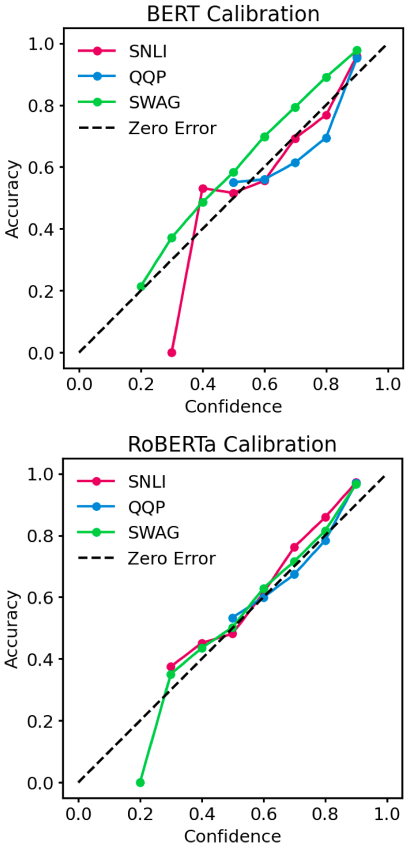

Figure 1: In-domain calibration of BERT and RoBERTa when used out-of-the-box. Models are both trained and evaluated on SNLI, QQP, and SWAG, respectively. ZERO ERROR depicts perfect calibration (e.g., expected calibration error = 0). Note that low-confidence buckets have zero accuracy due to a small sample count; however, as a result, these buckets do not influence the expected error as much.

remark on a few observed phenomena below:

Non-pre-trained models exhibit an inverse relationship between complexity and calibration. Simpler models, such as DA, achieve competitive in-domain ECE on SNLI (1.02) and QQP (3.37), and are notably better than pre-trained models on SNLI in this regard. However, the more complex ESIM, both in number of parameters and architecture, sees increased in-domain ECE despite having higher accuracy on all tasks.

However, pre-trained models are generally more accurate and calibrated. Rather surprisingly, pre-trained models do not show characteristics of the aforementioned inverse relationship, despite having significantly more parameters. On SNLI, RoBERTa achieves an ECE in the ballpark of DA and ESIM, but on QQP and SWAG, both

BERT and RoBERTa consistently achieve higher accuracies and lower ECEs. Pre-trained models are especially strong out-of-domain, where on HellaSWAG in particular, RoBERTa reduces ECE by a factor of 3.4 compared to DA.

Using RoBERTa always improves in-domain calibration over BERT. In addition to obtaining better task performance than BERT, RoBERTa consistently achieves lower in-domain ECE. Even out-of-domain, RoBERTa outperforms BERT in all but one setting (TwitterPPDB). Nonetheless, our results show that representations induced by robust pre-training (e.g., using a larger corpus, more training steps, dynamic masking) (Liu et al., 2019) lead to more calibrated posteriors. Whether other changes to pre-training (Yang et al., 2019; Lan et al., 2020; Clark et al., 2020) lead to further improvements is an open question.

4.4 Post-hoc Calibration

There are a number of techniques that can be applied to correct a model's calibration post-hoc. Using our in-domain development set, we can, for example, post-process model probabilities via temperature scaling (Guo et al., 2017), where a scalar temperature hyperparameter T divides non-normalized logits before the softmax operation. As $T \to 0$, the distribution's mode receives all the probability mass, while as $T \to \infty$, the probabilities become uniform.

Furthermore, we experiment with models trained in-domain with label smoothing (LS) (Miller et al., 1996; Pereyra et al., 2017) as opposed to conventional maximum likelihood estimation (MLE). By nature, MLE encourages models to sharpen the posterior distribution around the gold label, leading to confidence which is typically unwarranted in out-of-domain settings. Label smoothing presents one solution to overconfidence by maintaining uncertainty over the label space during training: we minimize the KL divergence with the distribution placing a $1 - \alpha$ fraction of probability mass on the gold label and $\frac{\alpha}{|\mathcal{Y}|-1}$ fraction of mass on each other label, where $\alpha \in (0, 1)$ is a hyperparameter.[3] This re-formulated learning objective does not require changing the model architecture.

For each task, we train the model with either MLE or LS ($\alpha = 0.1$) using the in-domain training set, use the in-domain development set to learn an optimal temperature T, and then evaluate the model (scaled with T) on the in-domain and out-of-domain test sets. From Table 3 and Figure 2, we draw the following conclusions:

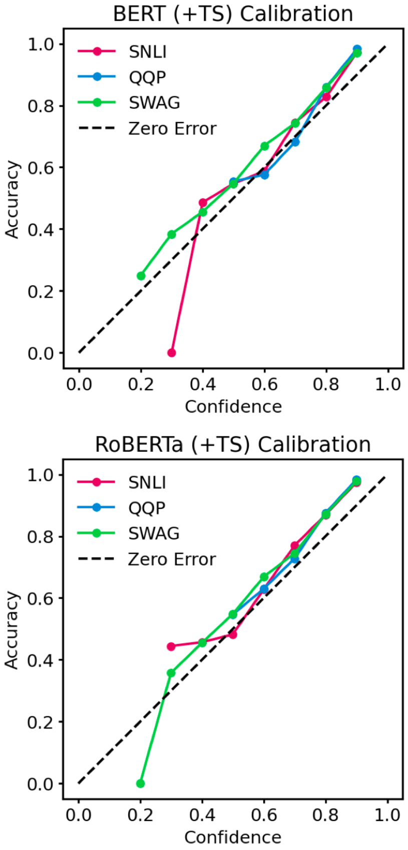

Figure 2: In-domain calibration of BERT and RoBERTa with temperature scaling (TS). Both temperature-scaled models are much better calibrated than when used out-of-the-box, with BERT especially showing a large degree of improvement.

MLE models with temperature scaling achieve low in-domain calibration error. MLE models are always better than LS models in-domain, which suggests incorporating uncertainty when in-domain samples are available is not an effective regularization scheme. Even when using a small smoothing value (0.1), LS models do not achieve nearly as good out-of-the-box results as MLE models, and temperature scaling hurts LS in many cases. By contrast, RoBERTa with temperature-scaled MLE achieves ECE values from 0.7-0.8, implying that MLE training yields scores that are fundamentally good but just need some minor rescaling.

However, out-of-domain, label smoothing is generally more effective. In most cases, MLE models do not perform well on out-of-domain

---

[3] For example, the one-hot target [1, 0, 0] is transformed into [0.9, 0.05, 0.05] when $\alpha = 0.1$.

Method	In-Domain						Out-of-Domain					
	SNLI		QQP		SWAG		MNLI		TPPDB		HSWAG	
	MLE	LS	MLE	LS	MLE	LS	MLE	LS	MLE	LS	MLE	LS
Model: BERT												
Out-of-the-box	2.54	7.12	2.71	6.33	2.49	10.01	7.03	3.74	8.51	6.30	12.62	5.73
Temperature scaled	1.14	8.37	0.97	8.16	0.85	10.89	3.61	4.05	7.15	5.78	12.83	5.34
Model: RoBERTa												
Out-of-the-box	1.93	6.38	2.33	6.11	1.76	8.81	3.62	4.50	9.55	8.91	11.93	2.14
Temperature scaled	0.84	8.70	0.88	8.69	0.76	11.4	1.46	5.93	7.86	5.31	11.22	2.23

Table 3: Post-hoc calibration results for BERT and RoBERTa on in-domain (SNLI, QQP, SWAG) and out-of-domain (MNLI, TwitterPPDB, HellaSWAG) datasets. Models are trained with maximum likelihood estimation (MLE) or label smoothing (LS), then their logits are post-processed using temperature scaling (§4.4). We report expected calibration error (ECE) averaged across 5 runs with random restarts. Darker colors imply lower ECE.

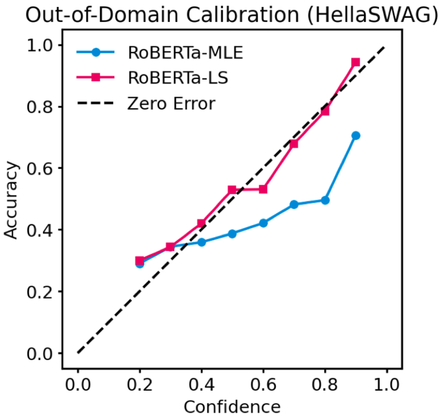

Figure 3: Out-of-domain calibration of RoBERTa fine-tuned on SWAG with different learning objectives and used out-of-the-box on HellaSWAG. Without seeing HellaSWAG samples during fine-tuning, RoBERTa-LS achieves significantly lower calibration error than RoBERTa-MLE.

datasets, with ECEs ranging from 8-12. However, LS models are forced to distribute probability mass across classes, and as a result, achieve significantly lower ECEs on average. We note that LS is particularly effective when the distribution shift is strong. On the adversarial HellaSWAG, for example, RoBERTa-LS obtains a factor of 5.8 less ECE than RoBERTa-MLE. This phenomenon is visually depicted in Figure 3 where we see RoBERTa-LS is significantly closer to the identity function despite being used out-of-the-box.

Optimal temperature scaling values are bounded within a small interval. Table 4 reports the learned temperature values for BERT-MLE and RoBERTa-MLE. For in-domain tasks, the optimal temperature values are generally in the range 1-1.4. Interestingly, out-of-domain, TwitterPPDB and HellaSWAG require larger temperature values than MNLI, which suggests the degree of distribution shift and magnitude of T may be closely related.

Model	In-Domain			Out-of-Domain		
	SNLI	QQP	SWAG	MNLI	TPPDB	HSWAG
BERT	1.20	1.34	0.99	1.41	2.91	3.61
RoBERTa	1.16	1.39	1.10	1.25	2.79	2.77

Table 4: Learned temperature scaling values for BERT and RoBERTa on in-domain (SNLI, QQP, SWAG) and out-of-domain (MNLI, TwitterPPDB, HellaSWAG) datasets. Values are obtained by line search with a granularity of 0.01. Evaluations are very fast as they only require rescaling cached logits.

5 Conclusion

Posterior calibration is one lens to understand the trustworthiness of model confidence scores. In this work, we examine the calibration of pre-trained Transformers in both in-domain and out-of-domain settings. Results show BERT and RoBERTa coupled with temperature scaling achieve low ECEs in-domain, and when trained with label smoothing, are also competitive out-of-domain.

A Dataset Splits

Dataset splits are shown in Table 5.

Dataset	Train	Dev	Test
SNLI	549,368	4,922	4,923
MNLI	392,702	4,908	4,907
QQP	363,871	20,216	20,217
TwitterPPDB	46,667	5,060	5,060
SWAG	73,547	10,004	10,004
HellaSWAG	39,905	5,021	5,021

Table 5: Training, development, and test dataset sizes for SNLI (Bowman et al., 2015), MNLI (Williams et al., 2018), QQP (Iyer et al., 2017), TwitterPPDB (Lan et al., 2017), SWAG (Zellers et al., 2018), and HellaSWAG (Zellers et al., 2019).

B Training and Optimization

For non-pre-trained model baselines, we use the open-source implementations of DA (Parikh et al., 2016) and ESIM (Chen et al., 2017) in AllenNLP (Gardner et al., 2018), except in the case of SWAG/HellaSWAG, where we run the baselines available in the authors' code.[4] For BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), we use `bert-base-uncased` and `roberta-base`, respectively, from HuggingFace Transformers (Wolf et al., 2019). BERT is fine-tuned with a maximum of 3 epochs, batch size of 16, learning rate of 2e-5, gradient clip of 1.0, and no weight decay. Similarly, RoBERTa is fine-tuned with a maximum of 3 epochs, batch size of 32, learning rate of 1e-5, gradient clip of 1.0, and weight decay of 0.1. Both models are optimized with AdamW (Loshchilov and Hutter, 2019). Other than early stopping on the development set, we do not perform additional hyperparameter searches. Finally, all experiments are conducted on NVIDIA V100 32GB GPUs, with the total time for fine-tuning all models being under 24 hours.

Furthermore, temperature scaling line searches are performed in the range [0.01, 5.0] with a granularity of 0.01. These searches are quite fast and can be performed on a CPU; we simply evaluate calibration error by rescaling cached logits. On a Intel Xeon E3-1270 v3 CPU, all searches can be completed in under 15 minutes.

C Reproducibility

Model	Accuracy		ECE	
	ID	OD	ID	OD
Task: SNLI/MNLI				
BERT	90.18	74.04	3.43	8.18
RoBERTa	**91.20**	**79.17**	**1.18**	**1.41**
Task: QQP/TwitterPPDB				
BERT	**90.22**	86.02	4.68	11.30
RoBERTa	89.97	**86.17**	**3.09**	**9.57**
Task: SWAG/HellaSWAG				
BERT	78.82	38.01	**2.51**	**2.24**
RoBERTa	**81.85**	**59.03**	3.02	5.71

Table 6: Out-of-the-box calibration *development set* results for in-domain (SNLI, QQP, SWAG) and out-of-domain (MNLI, TwitterPPDB, HellaSWAG) datasets using pre-trained models.

Table 6 shows the accuracy and expected calibration error (ECE) of BERT and RoBERTa on the development sets of the datasets we consider. We do not report post-hoc calibration results using the development set since these require tuning on the development set itself.

Near-imperceptible Neural Linguistic Steganography via Self-Adjusting Arithmetic Coding

Jiaming Shen, Heng Ji, Jiawei Han
Department of Computer Science, University of Illinois Urbana-Champaign, IL, USA
{js2, hengji, hanj}@illinois.edu

Abstract

Linguistic steganography studies how to hide secret messages in natural language cover texts. Traditional methods aim to transform a secret message into an innocent text via lexical substitution or syntactical modification. Recently, advances in neural language models (LMs) enable us to directly generate cover text conditioned on the secret message. In this study, we present a new linguistic steganography method which encodes secret messages using self-adjusting arithmetic coding based on a neural language model. We formally analyze the statistical imperceptibility of this method and empirically show it outperforms the previous state-of-the-art methods on four datasets by 15.3% and 38.9% in terms of bits/word and KL metrics, respectively. Finally, human evaluations show that 51% of generated cover texts can indeed fool eavesdroppers.[1]

1 Introduction

Privacy is central to modern communication systems such as email services and online social networks. To protect privacy, two research fields are established: (1) *cryptography* which encrypts secret messages into codes such that an eavesdropper is unable to decrypt, and (2) *steganography* which encodes messages into cover signals such that an eavesdropper is not even aware a secret message exists (Westfeld and Pfitzmann, 1999; bin Mohamed Amin et al., 2003; Chang and Clark, 2014). One useful cover signal for steganography is natural language text because of its prevalence and innocuity in daily life.

Traditional linguistic steganography methods are mostly edit-based, i.e., they try to directly edit the secret message and transform it into an innocent text that will not raise the eavesdropper's suspicious eyes. Typical strategies include synonym substitution (Topkara et al., 2006), paraphrase substitution (Chang and Clark, 2010), and syntactic transformation (Safaka et al., 2016), applied to various text media such as Email (Tutuncu and Hassan, 2015) and Twitter (Wilson et al., 2014). Although being able to maintain the grammatical correctness of output text, those edit-based methods cannot encode information efficiently. For example, the popular CoverTweet system (Wilson and Ker, 2016) can only encode two bits of information in each tweet on average.

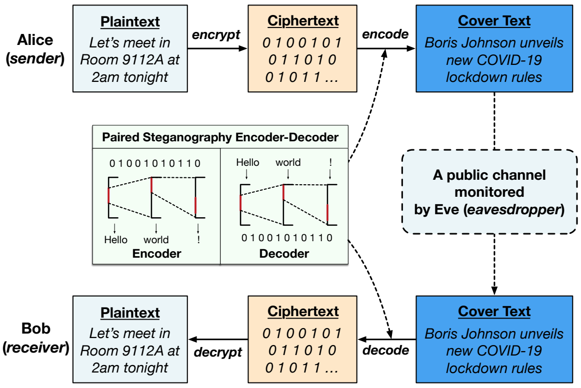

Figure 1: Linguistic steganography pipeline.

Recent advances in neural language models (LMs) (Józefowicz et al., 2016; Radford et al., 2019; Yang et al., 2019a) have enabled a diagram shift from edit-based methods to generation-based methods which directly output a cover text by encoding the message reversibly in the choices of tokens. Various encoding algorithms (Fang et al., 2017; Yang et al., 2019b; Ziegler et al., 2019) have been proposed to leverage neural LMs to generate high-quality cover texts in terms of both fluency and information hiding capacity. However, most of the existing methods do not provide explicit guarantees on the imperceptibility of generated cover text (i.e., to what extent the cover text is indistinguishable from natural texts without hidden messages). One recent exception is the work (Dai

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 303–313,
November 16–20, 2020. ©2020 Association for Computational Linguistics

and Cai, 2019) which shows the imperceptibility of the method in Fang et al. (2017). Nevertheless, for other more advanced steganography methods (Yang et al., 2019b; Ziegler et al., 2019), their imperceptibilities still remain unknown.

In this work, we propose a new linguistic steganography method with guaranteed imperceptibility. Our new method is built based on the previous study (Ziegler et al., 2019) which views each secret message as a binary fractional number and encodes it using arithmetic coding (Rissanen and Langdon, 1979) with a pretrained neural LM. This method generates cover text tokens one at a time (c.f. Fig. 2). At each time step t, it computes a distribution of the t-th token using the given LM; truncates this distribution to include only top K most likely tokens, and finally outputs the t-th token based on the secret message and the truncated distribution. In their study, this hyperparameter K is the same across all generation steps. We analyze this method's imperceptibility and show it is closely related to the selected K. Specifically, increasing K will improve the method's imperceptibility at the cost of a larger probability of generating rarely-used tokens and slower encoding speed. When the cover text token distribution is flat and close to the uniform distribution, we need a large K to achieve the required imperceptibility guarantee. When the cover text token distribution is concentrated, we can use a small K to avoid generating rarely-used tokens and to increase encoding speed. As different generation steps will witness different underlying cover text token distributions, using a static K is clearly sub-optimal.

To address this issue, we propose a new algorithm SAAC[2] which automatically adjusts K by comparing the truncated cover text token distribution with the original LM's output at each generation step and selects the minimal K that achieves the required imperceptibility. We theoretically prove the SAAC algorithm is near-imperceptible for linguistic steganography and empirically demonstrate its effectiveness on four datasets from various domains. Furthermore, we conduct human evaluations via crowdsourcing and show 51% of cover texts generated by SAAC can indeed fool eavesdropper.

Contributions. This study makes the following contributions: (1) We formally analyze the imperceptibility of arithmetic coding based steganography algorithms; (2) We propose SAAC, a new near-imperceptible linguistic steganography method that encodes secret messages using self-adjusting arithmetic coding with a neural LM; and (3) Extensive experiments on four datasets demonstrate our approach can on average outperform the previous state-of-the-art method by 15.3% and 38.9% in terms of bits/word and KL metrics, respectively.

2 Background

2.1 Linguistic Steganography

We consider the following scenario where Alice (sender) wants to send Bob (receiver) a secret message (plaintext) through a public text channel (e.g., Twitter and Reddit) monitored by Eve (eavesdropper). This is also known as the "prisoner problem" (Simmons, 1984). Eve expects to see fluent texts in this public channel and will suspect every non-fluent text of concealing some hidden messages. Therefore, Alice's goal is to transform the plaintext into a fluent cover text that can pass through Eve's suspicious eyes while ensuring that only Bob can read the secret message.

To achieve this goal, Alice could take the "encrypt-encode" approach (c.f. Fig. 1). Namely, she first encrypts the plaintext into a ciphertext (i.e., a bit sequence indistinguishable from a series of fair coin flips) and then encodes the ciphertext into the cover text using an encoder f. When Bob receives the cover text, he first decodes it into the ciphertext using the decoder f^{-1} and then decrypts the ciphertext into the plaintext. Linguistic steganography research focuses on the encoding/decoding steps, i.e., how to design the encoder that transforms the bit sequence into a fluent cover text and its paired decoder that maps the cover text back to the original bit sequence. Note here we introduce the middle ciphertext for two purposes. First, it increases communication security as more advanced encryption/decryption methods (e.g., AES, RSA, *etc.*) can be used on top of the steganography encoder/decoder. Second, it enlarges the output cover text space by removing the unnecessary restriction that the cover text must be transformed from the original plaintext.

2.2 Statistical Imperceptibility

Notations. A vocabulary $\mathcal{V}$ is a finite set of tokens[3]. A language model (LM) inputs a token

---

[2] SAAC is short for Self-Adjusting Arithmetic Coding.

[3] Each token can be a single word, a subword unit, or even a character, depending on the tokenizer choice.

sequence $\mathbf{x} = [x_1, x_2, \dots, x_n]$ and returns the joint probability $\mathbf{P}_{LM}(\mathbf{x})$. From this joint probability, we can derive the conditional probability $\mathbf{P}_{LM}(x_{t+1}|x_1, \dots, x_t)$ which enables us to sample a text $\mathbf{x}$ by drawing each token $x_t, t = 1, 2, \dots,$ one at a time.

A steganography encoder f inputs a language model $\mathbf{P}_{LM}$ as well as a length-L ciphertext $\mathbf{m} \sim$ Unif($\{0,1\}^L$), and outputs its corresponding cover text $\mathbf{y} = f(\mathbf{m}; \mathbf{P}_{LM})$. To ensure the receiver can uniquely decode the cover text, this encoder function f must be both deterministic and invertible. Moreover, this encoder f, together with the ciphertext distribution and the input LM, implicitly define a distribution of cover text $\mathbf{y}$ which we denote as $\mathbf{Q}(\mathbf{y})$. When cover texts are transmitted in the public channel, this distribution $\mathbf{Q}(\mathbf{y})$ is what an eavesdropper would observe.

Imperceptibility. To avoid raising eavesdropper's suspicion, we want the cover text distribution $\mathbf{Q}$ to be similar to the true natural language distribution (i.e., what this eavesdropper would expect to see in this public channel). Following (Dai and Cai, 2019), we formulate "imperceptibility" using the total variation distance (TVD) as follows:

$$\text{TVD}(\mathbf{P}^*_{LM}, \mathbf{Q}) = \frac{1}{2}\|\mathbf{Q} - \mathbf{P}^*_{LM}\|_1, \quad (1)$$

where $\mathbf{P}^*_{LM}$ denotes the true language distribution. As we approximate $\mathbf{P}^*_{LM}$ using a LM $\mathbf{P}_{LM}$ (e.g., OpenAI GPT-2 (Radford et al., 2019)), we further decompose TVD($\mathbf{P}^*_{LM}, \mathbf{Q}$) as follows:

$$\text{TVD}(\mathbf{P}^*_{LM}, \mathbf{Q}) \leq \frac{1}{2}\|\mathbf{P}^*_{LM} - \mathbf{P}_{LM}\|_1 + \frac{1}{2}\|\mathbf{P}_{LM} - \mathbf{Q}\|_1, \quad (2)$$

where the first term measures how good this LM is and the second term, that is the main focus of this study, indicates the gap induced by the steganography encoder. Even without knowing the first term, we can still obtain a relative imperceptibility guarantee based on the second term, which enables us to compare different steganography algorithms.

Using Pinsker's inequality (Fedotov et al., 2003), we set the upper-bound for the total variation distance using the KL divergence[4]:

$$\frac{1}{2}\|\mathbf{P}_{LM} - \mathbf{Q}\|_1 \leq \sqrt{\frac{\ln 2}{2} D_{KL}(\mathbf{Q}\|\mathbf{P}_{LM})}. \quad (3)$$

Then, we further decompose the right hand side of the above inequality based on the additivity of KL divergence and obtain the following result:

$$\frac{1}{2}\|\mathbf{P}_{LM} - \mathbf{Q}\|_1 \leq \sqrt{\frac{\ln 2}{2} \sum_{t=1}^{\infty} D_{KL}(\mathbf{Q}(\cdot|\mathbf{y}_{<t})\|\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t}))}, \quad (4)$$

where $\mathbf{y}_{<t} = [y_1, \dots, y_{t-1}]$ is a cover text prefix. $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$ and $\mathbf{Q}(\cdot|\mathbf{y}_{<t})$ are distributions over the next token y_t conditioned on the prefix $\mathbf{y}_{<t}$ before and after the steganography encoding algorithm, respectively. This inequality provides a formal framework to analyze the imperceptibility of a steganography encoder. Moreover, it implies that in order to achieve the near-imperceptibility, we must guarantee the encoder's output $\mathbf{Q}(\cdot|\mathbf{y}_{<t})$ being close to its input $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$ at all steps.

3 Self-Adjusting Arithmetic Coding

In this section, we first introduce the general arithmetic coding and discuss its practical limitations. We then present SAAC, a self-adjusting arithmetic coding algorithm and analyze its imperceptibility.

3.1 Arithmetic Coding

Arithmetic coding is a method initially proposed to compress a string of elements sampled from a known probability distribution (Rissanen and Langdon, 1979). For data compression, arithmetic coding is asymptotically optimal in the sense that it can compress information within a long string to its entropy. In practice, it also outperforms the better-known Huffman coding method (Huffman, 1952) because it does not partition the input string into blocks. Traditionally, arithmetic coding encodes a string of elements into a bit sequence. To use such a coding for linguistic steganography, we follow (Ziegler et al., 2019) and reverse the encoding order. Namely, we *encode* a bit sequence (ciphertext) into a string of tokens (cover text) and *decode* a cover text to its original ciphertext.

Encoding. During the encoding stage, we view the bit sequence $\mathbf{m} = [m_1, m_2, \dots, m_L]$ as the binary representation of a single number $B(\mathbf{m}) = \sum_{i=1}^{L} m_i \times 2^{-i}$. For example, if $\mathbf{m} = [1, 0, 1]$, we have $B(\mathbf{m}) = 1 \times 2^{-1} + 1 \times 2^{-3} = 0.625$.

The encoder generates the cover text token one at a time. At each time step t, the encoder has access to an underlying language model $\mathbf{P}_{LM}$ and considers three things: (1) the number $B(\mathbf{m})$, (2) the cover text prefix $\mathbf{y}_{<t}$, and (3) the current interval $[l_t, u_t)$ (at the beginning of the encoding process, this interval $[l_1, u_1)$ is set to [0, 1), but it will

---

[4] We will consistently compute KL divergence in base 2.

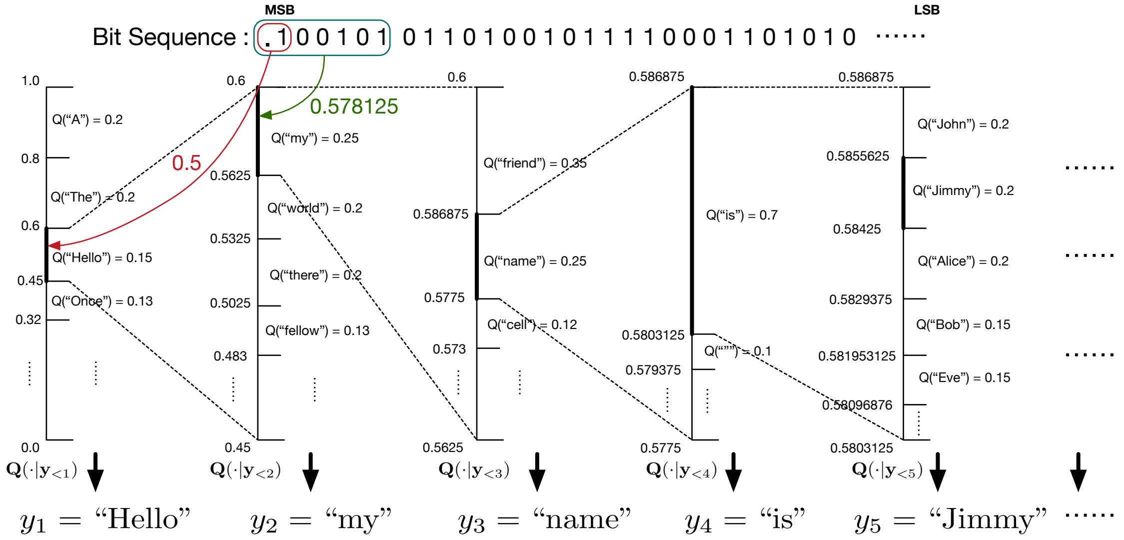

Figure 2: A running example of arithmetic coding. We input a bit sequence (i.e., the ciphertext) with the most significant bit (MSB) at the left and output the encoded cover text.

change). Based on the LM and cover text prefix, the encoder first computes the conditional distribution of the next token $\mathbf{Q}(y_t|\mathbf{y}_{<t})$. Then, it divides the current interval $[l_t, u_t)$ into sub-intervals, each representing a fraction of the current interval proportional to the conditional probability of a possible next token. Whichever interval contains the number $B(\mathbf{m})$ becomes the interval used in the next step (i.e., $[l_{t+1}, u_{t+1})$) and its corresponding token becomes the cover text token y_t. The encoding process stops when all $\mathbf{m}$-prefixed fractions fall into the final interval, that is, the generated cover text unambiguously defines the bit sequence $\mathbf{m}$. Before we discuss and analyze the concrete design of $\mathbf{Q}(\cdot|\mathbf{y}_{<t})$ in the next section, we first present a running example in Figure 2.

Suppose we want to encode a bit sequence $\mathbf{m} = [1, 0, 0, 1, 0, 1, \dots]$. This bit sequence represents a fraction $B(\mathbf{m}) \in [0.58425, 0.58556)$. At the time step $t = 1$, we divide the initial interval $[0, 1)$ and find $B(\mathbf{m})$ falling into the sub-interval $[0.45, 0.6)$ which induces the first cover text token y_1 = "Hello". At the time step $t = 2$, we further divide the interval $[0.45, 0.6)$ and observe that $B(\mathbf{m})$ belongs to the range $[0.5625, 0.6)$ corresponding to the second cover text token y_2 = "my". We repeat this process until the final interval covers all binary fractions starting with $\mathbf{m}$ and output the generated cover text by then.

Decoding. During the decoding stage, we are given a cover text $\mathbf{y} = [y_1, \dots, y_n]$ as well as the same language model $\mathbf{P}_{LM}$ used in the encoding stage, and aim to recover the original ciphertext $\mathbf{m}$. We achieve this goal by reversing the encoding process and gradually narrowing the range of possible bit sequences. At each time step t, the decoder first generates the conditional distribution $\mathbf{Q}(y_t|\mathbf{y}_{<t})$. Then, it divides the current interval $[l_t, u_t)$ (initialized to $[0, 1)$) into sub-intervals based on $\mathbf{Q}(y_t|\mathbf{y}_{<t})$ and the one corresponding to y_t becomes the interval used in the next step, that is, $[l_{t+1}, u_{t+1})$. The decoding process stops after we process the last cover text token y_n and outputs the decoded ciphertext to be the shared common prefix of the binary representations of l_{n+1} and u_{n+1}.

3.2 Imperceptibility Analysis

One important issue remained in the general arithmetic coding procedure is how to design the conditional distribution $\mathbf{Q}(\cdot|\mathbf{y}_{<t})$. As we discussed in Section 2.2, this distribution should be close to the underlying model LM. Ideally, we may just set $\mathbf{Q}(\cdot|\mathbf{y}_{<t})$ to be the same as $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$. However, this naïve design has several problems. First, it may generate a rarely-used cover text token because we are actually reading off the tokens based on the ciphertext, instead of really sampling the LM. This could harm the cover text fluency and raises the eavesdropper's suspicion. Second, $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$ is a distribution over the entire vocabulary $\mathcal{V}$ (with a full rank $|\mathcal{V}|$) and using it to divide the $[0, 1)$ interval will quickly encounter the precision problem, even if we implement the coding scheme using a fixed precision binary fractions (Witten et al., 1987). Finally, this design further slows down the coding speed and the slow speed is the major weak-

ness of arithmetic coding compared to its rival Huffman method (Duda, 2013).

Due to the above reasons, people in practice will truncate the LM distribution to include only top K most likely tokens (Ziegler et al., 2019), which leads to the following distribution:

$$\mathbf{Q}(y_t|\mathbf{y}_{<t}) \propto \begin{cases} \mathbf{P}_{LM}(y_t|\mathbf{y}_{<t}) & \text{if } y_t \in \mathcal{T}_K(\mathbf{y}_{<t}) \\ 0 & \text{otherwise} \end{cases} \quad (5)$$

where $\mathcal{T}_K(\mathbf{y}_{<t}) = \mathtt{argtopK}_{y'}\ \mathbf{P}_{LM}(y'|\mathbf{y}_{<t})$. Accordingly, we have the imperceptibility of one generation step to be:

$$D_{KL}(\mathbf{Q}(y_t|\mathbf{y}_{<t})\|\mathbf{P}_{LM}(y_t|\mathbf{y}_{<t})) = -\log Z_K,$$
$$Z_K = \sum_{y' \in \mathcal{T}_K(\mathbf{y}_{<t})} \mathbf{P}_{LM}(y'|\mathbf{y}_{<t}), \quad (6)$$

where Z_K is essentially the cumulative probability of top K most likely tokens. From this equation, we can see that the imperceptibility of arithmetic coding depends crucially on how the underlying LM distribution concentrates on its top K predictions. Previous study uses the same K across *all* generation steps and ignores the different distribution characteristics in different steps. This strategy is sub-optimal because in some steps, the predefined K is too small to achieve good imperceptibility, while in the other steps, the same K is too large and slows down the encoding speed.

In this study, we propose a new *self-adjusting* arithmetic coding algorithm SAAC to remedy the above problem. The idea is to dynamically select the most appropriate K that satisfies a pre-defined per-step imperceptibility guarantee. Specifically, the sender can set a small per-step imperceptibility gap $\delta \ll 1$ and at time step t, we set the K_t as:

$$K_t = \min(\{K | \sum_{y' \in \mathcal{T}_K(\mathbf{y}_{<t})} \mathbf{P}_{LM}(y'|\mathbf{y}_{<t}) \geq 2^{-\delta}\}). \quad (7)$$

This selected K_t is essentially the smallest K that can achieve the imperceptibility guarantee. As we later show in the experiment, this selected K varies a lot in different steps, which further confirms the sub-optimality of using a static K.

The above method guarantees that each step incurs no more additional imperceptibility than the threshold δ. This makes the imperceptibility of *an entire sequence* dependent on the length of bit sequence. To achieve a length-agnostic imperceptibility bound, we may choose a convergent series for per-step threshold. For example, if we set $\delta_t = \frac{\delta_0}{t^2}$

Dataset	Drug	News	COVID-19	Random
Num. of Sentences	3972	6437	2000	3000
Avg. Num. of Words	19.01	14.30	24.21	—
Avg. Num. of Bits	289.75	211.08	308.65	256

Table 1: Datasets statistics.

and based on the inequality 4 we will have:

$$\frac{1}{2}\|\mathbf{P}_{LM} - \mathbf{Q}\|_1 \leq \sqrt{\frac{\ln 2}{2}\sum_{t=1}^{\infty}\frac{\delta_0}{t^2}} = \sqrt{\frac{\pi^2 \ln 2}{12}\delta_0}. \quad (8)$$

This result shows our proposed SAAC algorithm is near-imperceptible for linguistic steganography.

4 Experiments

4.1 Experiment Setups

Datasets. We conduct our experiments on four datasets from different domains: (1) **Drug** (Ji and Knight, 2018), which contains a set of Reddit comments related to drugs, (2) **News**, which includes a subset of news articles in the CNN/DailyMail dataset (Hermann et al., 2015), (3) **COVID-19**, which is a subset of research papers related to COVID-19 in the CORD-19 dataset (Wang et al., 2020), and (4) **Random**, which is a collection of uniformly sampled bit sequences. The first three datasets contain natural language texts and we convert them into bit sequences[5] following the same process in Ziegler et al. (2019). Table 1 summarizes the dataset statistics.

Compared Methods. We compare the following linguistic steganography methods.

1. Bin-LM (Fang et al., 2017): This method first splits the vocabulary $\mathcal{V}$ into 2^B bins and represents each bin using a B-bit sequence. Then, it chunks the ciphertext into $\lceil L/B \rceil$ blocks and encodes the t-th block by taking the most likely token (determined by the underlying LM) that falls in the t-th bin.
2. RNN-Stega (Yang et al., 2019b): This method first constructs a Huffman tree for top 2^H most likely tokens at each time step t according to $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$. Then, it follows the bits in ciphertext to sample a cover text token y_t from the constructed Huffman tree. It improves the above Bin-LM method by encoding one or more bits per generated cover text token.
3. Patient-Huffman (Dai and Cai, 2019): This method improves RNN-Stega by explicitly checking if the KL divergence between the

Table 2: Quantitative performance of linguistic steganography methods across all datasets. Each method has one parameter controlling various tradeoffs (c.f. detailed discussions in Compared Method subsection) and we indicate them in the parentheses. Larger *bits/word* values ↑ and smaller D_{KL} values ↓ indicate better performance.

LM distribution and the Huffman distribution is smaller than a specified threshold ϵ. If the KL divergence is larger than ϵ, it samples from the base LM distribution and *patiently* waits for another opportunity.

4. Arithmetic (Ziegler et al., 2019): This method also uses the arithmetic coding to generate cover text tokens. At each time step t, it truncates the $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$ distribution to include only top K most likely tokens and samples one cover text tokens from the truncated distribution.
5. SAAC: This method is our proposed Self-Adjusting Arithmetic Coding algorithm which automatically adjusts $\mathbf{P}_{LM}(\cdot|\mathbf{y}_{<t})$ to achieve the required imperceptibility guarantee δ.

Evaluation Metrics. We follow previous studies and evaluate the results using two metrics:

1. *Bits/word*: This metric is the average number of bits that one cover text token can encode. A larger bits/word value indicates the algorithm can encode information more efficiently.
2. D_{KL}: This metric is the KL divergence between the LM distribution and the cover text distribution. A smaller D_{KL} value indicates the model has better imperceptibility (c.f. Section 2.2).

Implementation Details. We implement all compared methods based on the codebase in (Ziegler et al., 2019). All the code and data are publicly available[6]. Specifically, we use PyTorch 1.4.0 and the pretrained OpenAI GPT-2 medium model in the Huggingface library as the underlying LM for all methods. This LM includes 345M parameters and there is no additional parameter introduced by steganography encoding algorithms. For baseline method Bin-LM, we choose its block size B in $[1, 2, 3, 4, 5]$. For RNN-Stega method, we vary the Huffman tree depth H in $[3, 5, 7, 9, 11]$. For Patient-Huffman method, we change the patience threshold ϵ in $[0.8, 1.0, 1.5]$. For Arithmetic method, we select its hyperparameter K ranging from 100 to 1800 with an increment 300 and fix its temperature parameter $\tau = 1$. Finally, we choose the imperceptibility gap δ in our SAAC method in $[0.01, 0.05, 0.1]$. For both Arithmetic and SAAC methods, we implement the arithmetic coding using a fixed 26-bits precision binary fractions. We do not perform any hyperparameter search and directly report all the results in the main text.

Discussions on LM Sharing. We note that all compared methods require the employed LM to be shared between the sender and the receiver beforehand. Therefore, in practice, people typically use a popular public language model (e.g., GPT2) available to everyone. This allows two parties to directly download the same LM from a centroid place (e.g., an OpenAI hosted server) and removes the necessity of sending the LM though some communication channel.

4.2 Experiment Results

Overall Performance. Table 2 shows the overall performance. First, we can see all variable

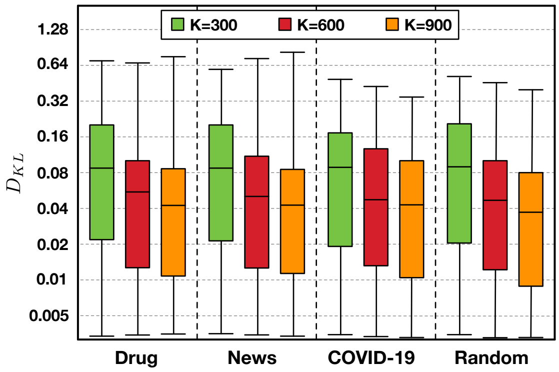

Figure 3: D_{KL} for static arithmetic coding with different Ks. Note that the Y axis is in the log scale.

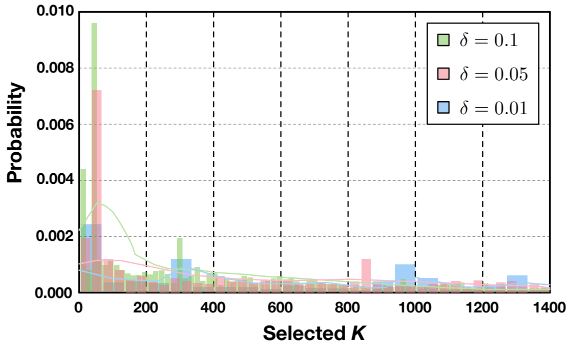

Figure 4: Histogram of selected Ks in our SAAC method's next token distribution $\mathbf{Q}(y_t|\mathbf{y}_{<t})$.

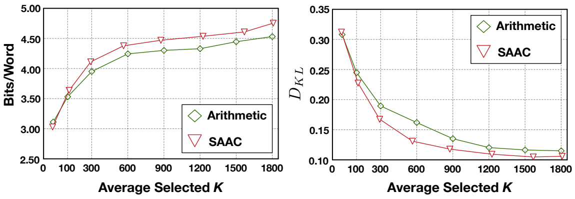

Figure 5: Comparison of baseline Arithmetic method with SAAC across (roughly) the same average Ks. Larger *bits/word* values ↑ and smaller D_{KL} values ↓ indicate better performance.

length coding algorithms (i.e., RNN-Stega, Patient-Huffman, Arithmetic, SAAC) outperform the fixed length coding algorithm Bin-LM. The Bin-LM method achieves worse imperceptibility (i.e., larger D_{KL}) when it encodes message bits at higher compression rate (i.e., larger *Bits/Word*), which aligns with the previous theoretical result in (Dai and Cai, 2019). Second, we observe that Patient-Huffman method improves RNN-Stega as it achieves smaller D_{KL} when *Bits/Word* is kept roughly the same. Third, we find the arithmetic coding based methods (i.e., Arithmetic and SAAC) outperform the Huffman tree based methods (i.e., RNN-Stega and Patient-Huffman). Finally, we can see our proposed SAAC method can beat Arithmetic by automatically choosing the most appropriate K values and thus achieves the best overall performance.

Comparison with Arithmetic Baseline. We further analyze where SAAC's gains over the Arithmetic baseline method come from. Fig. 3 shows the KL divergence between LM's distribution $\mathbf{P}_{LM}$ and steganography encoder's distribution $\mathbf{Q}$ across all time steps. We can see that although most of KL values are less than 0.08, the 95th percentiles are all above 0.32, which means even for large predefined $K = 900$, five percent of generation steps induce KL values larger than 0.32. Fig. 4 shows three histograms of SAAC selected Ks, one for each required imperceptibility bound δ. We observe that these histograms have several modes with one (largest) mode around 50 and one mode larger than 300. This indicates that for a majority of generation steps, choosing a $K < 50$ is enough to guarantee the required imperceptibility bound and thus fixing a static $K = 300$ is a big waste for those steps. Meanwhile, the LM distributions at some generation steps are too "flat" and we indeed need to use a larger K to achieve the required imperceptibility bound δ. Finally, we vary the imperceptibility bound δ and calculate the average K selected by SAAC. Fig. 5 compares the baseline Arithmetic method (of different predefined Ks) with SAAC method that has the (roughly) same average selected K. We can see that using about the same Ks, our SAAC method can clearly outperform the Arithmetic baseline method in terms of both *Bits/word* and D_{KL} metrics.

Efficiency Analysis. We run all our experiments on a machine with one single RTX 8000 GPU and 80 Intel Xeon Gold 6230 CPUs. On average, encoding one sentence takes Bin-LM 2.361 second, RNN-Stega 1.617 second, Arithmetic 2.085 second, Patient-Huffman 4.443 second, and our proposed SAAC method 1.722 second. This result shows dynamic selection of step-wise K will not introduce many computational overhead and can sometimes even improve the efficiency of the static arithmetic coding method.

Case Studies. We show some concrete examples of generated cover texts in Fig. 6. Following (Ziegler et al., 2019), we use an introductory context c for generating the first cover text token (i.e., replace $\mathbf{Q}(\cdot|\mathbf{y}_{<1})$ with $\mathbf{Q}(\cdot|[c; \mathbf{y}_{<1}])$). This strategy helps to improve the cover text quality and will later also be used in the human evaluation. We can see that those generated cover texts are fluent and grammatically correct. Besides, they are

Figure 7: One step-by-step example of cover text generation. When less variety exists in the next token distribution $\mathbf{Q}(\cdot|\mathbf{y}_{<t})$, we will choose a smaller K (lines in blue color). Otherwise, we select a larger K (lines in pink color).

topically similar to the provided introductory context and effectively hide messages in the original plaintexts. In Fig. 7, we further show a step-by-step generation example. We can see that in step 4, the next token distribution $\mathbf{Q}(\cdot|\mathbf{y}_{<4})$ following word “retreat” exhibits less variety, and thus we select a small $K = 10$. On the other hand, in step 6, the next token distribution $\mathbf{Q}(\cdot|\mathbf{y}_{<6})$ following word “the” has more variety and we use a larger $K = 1059$ to satisfy the required imperceptibility.

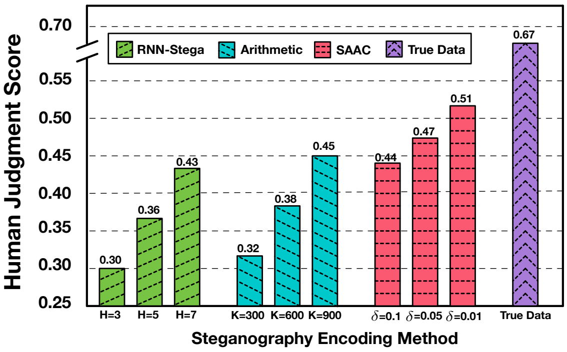

Figure 8: Human evaluation results. Y axis shows the percentage of cover texts (generated by one method) that are considered by humans to be a proper continuation of the context.

4.3 Human Evaluation

We conduct human evaluation to test whether generated cover texts can indeed fool human eavesdroppers via crowdsourcing. First, we select 100 news articles from the CNN/DM dataset and treat each article’s first 3 sentences as the context. Next, we sample 100 ciphertexts uniformly at random and pair each of them with the above 3 sentence context. Then, for each $\langle$context, ciphertext$\rangle$ pair, we generate a cover text using different steganography methods, including RNN-Stega with Huffman tree depths 3, 5, 7, arithmetic coding with top Ks 300, 600, 900, and SAAC with imperceptibility gaps 0.1, 0.05, 0.01. Finally, we gather all the generated cover texts; mix them with the original human-written sentences (i.e., the 4th sentence in each news article), and send them to crowd accessors on Amazon Mechanical Turk.

In each HIT, the assessor is given one context paired with one sentence and is asked “Given the start of a news article: <context>, is the following a likely next sentence: <sentence>? Yes or No?”. We explicitly ask assessors to consider whether this sentence is grammatically correct, contains no factual error, and makes sense in the given context. To ensure the quality of collected data, we require crowd assessors to have a 95% HIT acceptance rate, a minimum of 1000 HITs, and be located in the United States or Canada. Moreover, we include a simple attention check question in 20% of HITs and filter out the results from assessors who do not pass the attention check.

Fig. 8 shows the human evaluation results. First, we can see this test itself is challenging as only 67% of time people can correctly identify the true follow-up sentence. Second, more encouragingly, we find the cover texts generated by our SAAC algorithm can indeed fool humans 51% of times. For those cover texts that do not pass the human test, we analyze crowd assessor's feedbacks and find they are rejected mostly because they contain some factual errors. Thus, we believe improving the generation factual accuracy is an important direction for future linguistic steganography research.

5 Related Work

Early steganography methods (Marvel et al., 1999; Gopalan, 2003) use image and audio as the cover signal because they have a high information theoretic entropy. However, sending an image or audio recording abruptly though a public channel will likely cause the eavesdropper's suspicion. Thus, linguistic steganography methods are proposed to leverage text as the cover signal because natural language is prevalent and innocuous in daily life.

Linguistic steganography methods can be categorized into two types, edit-based or generation-based (Bennett, 2004). Edit-based methods try to directly edit the secret message and transform it into an innocent text. Typical transformations are synonym substitution (Topkara et al., 2006; Chang and Clark, 2014), paraphrase substitution (Chang and Clark, 2010; Ji and Knight, 2018), and syntactic transformation (Thamaraiselvan and Saradha, 2015; Safaka et al., 2016). Instead of editing all words in the secret message, (Zhang et al., 2014, 2015) take an entity-oriented view and focus on encoding/decoding morphs of important entities in the message. Finally, some work (Grosvald and Orgun, 2011; Wilson et al., 2014) allows human agents to assist the cover text generation process.

One major limitation of edit-based methods is that they cannot encode information efficiently. (Wilson and Ker, 2016) show the popular CoverTweet system (Wilson et al., 2014) can encode only two bits information in each transformed tweet on average. To address this limitation, generation-based methods try directly output the cover text based on the secret message. Early study (Chapman and Davida, 1997) utilizes a generative grammar to output the cover text. More recently, people leverage a neural language model for linguistic steganography. One pioneering work by (Fang et al., 2017) divides the message bits into equal-size blocks and encodes each block using one cover text token. (Yang et al., 2019b) improves the above method by constructing a Huffman tree and encoding the message in variable length chunks via a Huffman tree. (Dai and Cai, 2019) presents the first theoretical analysis of the above two methods and proposes a modified Huffman algorithm. The method most related to this study is (Ziegler et al., 2019) where the arithmetic coding algorithm is introduced for steganography. In this study, we present a more formal analysis of arithmetic coding based steganography method and propose a better self-adjusting algorithm to achieve the statistical imperceptibility.

6 Discussions and Future Work

This work presents a new linguistic steganography method that encodes secret messages using self-adjusting arithmetic coding. We formally prove this method is near-imperceptible and empirically show it achieves the state-of-the-art results on various text corpora. There are several directions we will further explore in the future. First, we may combine the edit-based steganography with generative steganography method by first transforming the original plaintext in a semantics-preserving way and then encoding the transformed plaintext. Second, we will study whether this current method is still effective when a small-scale neural LM (e.g., distilGPT-2) is applied. Finally, this study assumes a passive eavesdropper who does not modify the transmitted cover text. Adapting the current methods to be robust to an active eavesdropper who may alter the cover text is another interesting direction.

Abstract

Machine learning models are trained to find patterns in data. NLP models can inadvertently learn socially undesirable patterns when training on gender biased text. In this work, we propose a novel, general framework that decomposes gender bias in text along several pragmatic and semantic dimensions: bias from the gender of the person being spoken about, bias from the gender of the person being spoken to, and bias from the gender of the speaker. Using this fine-grained framework, we automatically annotate eight large scale datasets with gender information. In addition, we collect a new, crowdsourced evaluation benchmark. Distinguishing between gender bias along multiple dimensions enables us to train better and more fine-grained gender bias classifiers. We show our classifiers are valuable for a variety of applications, like controlling for gender bias in generative models, detecting gender bias in arbitrary text, and classifying text as offensive based on its genderedness.

1 Introduction

Language is a primary means by which people communicate, express their identities, and categorize themselves and others both explicitly and implicitly. Such social information is present in the words we write and, consequently, in the text we use to train our NLP models. In particular, models often can unwittingly learn negative associations about protected groups present in their training data and propagate them. In particular, NLP models often learn to replicate unwanted gender biases present in society (Bolukbasi et al., 2016; Hovy and Spruit, 2016; Caliskan et al., 2017; Rudinger et al., 2017; Garg et al., 2018; Gonen and Goldberg, 2019; Dinan et al., 2020). Since unwanted gender biases can affect downstream applications—sometimes even leading to poor user experiences—understanding and mitigating gender bias is an important step towards making NLP tools and models safer and more equitable. In this paper, we provide a fine-grained framework for that purpose, analyze the presence of gender bias in models and data, and empower others by releasing tools that can be further applied to numerous text-based use-cases.

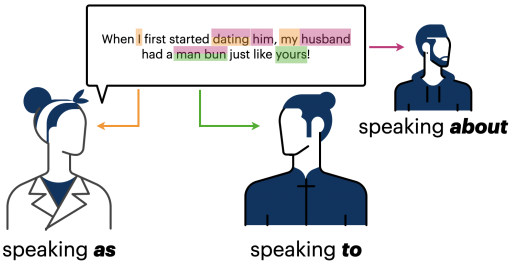

Figure 1: **Framework for Gender Bias in Dialogue**. We propose a framework separating gendered language based on who you are speaking ABOUT, speaking TO, and speaking AS.

While many works have explored methods for removing gender bias from text (Emami et al., 2019; Hall Maudslay et al., 2019; Ravfogel et al., 2020), no extant work on classifying gender or removing gender bias has foregrounded the fact that we use language, at least in part, to collaboratively and socially construct our gender identities. We propose a pragmatic and semantic framework for measuring bias along three dimensions that is sensitive to conversational and performative aspects of gender, as illustrated in Figure 1. Recognizing these dimensions is important, because gender along each dimension can affect text differently, for example, by modifying word choice or imposing different preferences on sentence structure.

Decomposing gender into separate dimensions also allows for better identification of gender bias, which subsequently enables us to train a suite of classifiers for detecting different kinds of gender

Table 1: **Bias in Wikipedia**. We compare the most over-represented adjectives in Wikipedia biographies of men and women to those in gender-neutral pages. We use a part-of-speech tagger (Honnibal and Montani, 2017), and computed $P(\text{word} \mid \text{gender})/P(\text{word})$ for words that appear more than 500 times.

bias in text. We train several classifiers on publicly available data that we annotate with gender information along our dimensions. We also collect a new crowdsourced dataset (MDGENDER) for better fine-grained evaluation of gender classifier performance. The classifiers we train have a wide variety of potential applications. We evaluate them on three: controlling the genderedness of generated text, detecting gender biased text, and examining the relationship between gender bias and offensive language. In addition, we expect these classifiers to be useful for future text applications such as detecting gender imbalance in newly created training corpora or model-generated text.

This paper makes four novel contributions: (i) we propose a multi-dimensional framework (ABOUT, AS, TO) for measuring and mitigating gender bias in language and NLP models, (ii) we introduce an evaluation dataset for performing gender identification that contains utterances re-written from the perspective of a specific gender along all three dimensions, (iii) we build a suite of classifiers capable of labeling gender in both a single and multitask set up, and finally (iv) we illustrate our classifiers' utility for several downstream applications. All datasets, annotations, and classifiers will be released publicly to facilitate further research into the important problem of gender bias in text.

2 Related Work

Gender affects myriad aspects of NLP, including corpora, tasks, algorithms, and systems (Chang et al., 2019; Costa-jussà, 2019; Sun et al., 2019). For example, statistical gender biases are rampant in word embeddings (Jurgens et al., 2012; Bolukbasi et al., 2016; Caliskan et al., 2017; Garg et al., 2018; Zhao et al., 2018b; Basta et al., 2019; Chaloner and Maldonado, 2019; Du et al., 2019; Ethayarajh et al., 2019; Gonen and Goldberg, 2019; Kaneko and Bollegala, 2019; Kurita et al., 2019; Zhao et al., 2019; Wang et al., 2020)—including multilingual ones (Escudé Font and Costa-jussà, 2019; Gonen et al., 2019; Zhou et al., 2019)—and affect a wide range of downstream tasks including coreference resolution (Zhao et al., 2018a; Cao and Daumé III, 2020; Emami et al., 2019), part-of-speech and dependency parsing (Garimella et al., 2019), language modeling (Qian et al., 2019; Nangia et al., 2020), appropriate turn-taking classification (Lepp, 2019), relation extraction (Gaut et al., 2020), identification of offensive content (Sharifirad and Matwin, 2019; Sharifirad et al., 2019), and machine translation (Stanovsky et al., 2019; Hovy et al., 2020).

For dialogue, gender biases in training corpora have been found to be amplified in machine learning models (Lee et al., 2019; Dinan et al., 2020; Liu et al., 2019). While many of the works cited above proposed methods of mitigating the unwanted effects of gender on text, Hall Maudslay et al. (2019), Liu et al. (2019), Zmigrod et al. (2019), and Dinan et al. (2020) in particular relied on counterfactual data to alter the training distribution to offset gender-based statistical imbalances (see §4.2 for more discussion of training set imbalances). Also relevant is Kang et al. (2019, PASTEL), which introduced a parallel style corpus and showed gains on style-transfer across binary genders.

Most relevant to this work, Sap et al. (2020) proposed a framework for modeling pragmatic aspects of many social biases in text. Our work and theirs focus on complementary aspects of a larger goal—namely, making NLP safe and inclusive for everyone—but the two approaches differ in several ways. We treat statistical gender bias in human or model generated text specifically, and in detail. Sap et al. (2020) proposed a different but compatible perspective, and aimed to situate gender bias within the broader landscape of negative stereotypes in social media text, an approach that can make parallels apparent across different kinds of harmful text. Moreover, they considered different pragmatic dimensions than we do: they targeted negatively stereotyped commonsense implications in arguably innocuous statements, whereas we investigate pragmatic dimensions that straightforwardly map to conversational roles (i.e., topics, addressees, and creators of text).

Finally, when investigating gender biases, one cannot ignore the **intersectionality** of gender identities, i.e., when gender non-additively interacts with other identity characteristics. Negative gender stereotyping is known to be alternatively weakened or reinforced by the presence of social attributes like dialect (Tatman, 2017), class (Degaetano-Ortlieb, 2018) and race (Davis, 1981; Crenshaw, 1989). These differences have been found to affect gender classification in images (Buolamwini and Gebru, 2018), and also in sentences encoders (May et al., 2019). We acknowledge that these are crucial considerations, and intend to incorporate them in future work. For a thorough survey and a critical discussion of best practices for researching social "biases" in NLP, including and beyond gender, see Blodgett et al. (2020).

3 Dimensions of Gender Bias

Gender permeates language differently depending on the conversational role played by the people using that language (see Figure 1). We decompose gender bias along multiple dimensions: bias when speaking ABOUT someone, bias when speaking TO someone, and bias from speaking AS someone. This framework enables both finer-grained understanding of bias and better classification of gender's effects on text from multiple domains.

Definition of Gender We annotate gender with four potential values: *masculine, feminine, neutral* and *unknown*. We take *neutral* to contain characters with either non-binary gender identity, or an identity which is unspecified for gender *by definition* (e.g. a talking tree). We include an *unknown* category for when the gender is genuinely not known.

***Speaking About*: Gender of the Topic.** It's well known that we change how we speak about others depending on who they are (Hymes, 1974; Rickford and McNair-Knox, 1994), and what their gender identity is (Lakoff, 1973; Eckert and McConnell-Ginet, 1992). For example, adjectives which describe women have been shown to differ from those used to describe men in numerous situations (Trix and Psenka, 2003; Gaucher et al., 2011; Moon, 2014; Hoyle et al., 2019), as do verbs that take nouns referring to men as opposed to women (Guerin, 1994; Hoyle et al., 2019).

***Speaking To*: Gender of the Addressee.** People often adjust their speech based on who they are speaking with—their addressee(s)—to show solidarity with their audience or to express social distance (Wish et al., 1976; Bell, 1984; Hovy, 1987; Rickford and McNair-Knox, 1994; Bell and Johnson, 1997; Eckert and Rickford, 2001). We expect the addressee's gender to affect, for example, how a man might communicate with another man about hair styles or beard hygiene. This exchange would probably differ if the man was communicating instead with a woman about the same topic.

***Speaking As*: Gender of the Speaker.** People react to content differently depending on who created it. Like race, gender is often described as a "fundamental" category for self-identification and self-description (Banaji and Prentice, 1994, 315), with men, women, and non-binary people differing in how they actively create their own gender identities (West and Zimmerman, 1987). Who someone is *speaking as* strongly affects what they may say and how they say it, down to the level of their choices of adjectives and verbs in self-descriptions (Charyton and Snelbecker, 2007; Wetzel et al., 2012).

4 Creating Gender Classifiers

In an ideal world, we would expect little difference between texts describing men, women, and people with other gender identities. A machine learning model, then, would be unable to pick up on statistical differences in gendered language (i.e., statistical gender bias), because such differences would not exist. However, gender-based distributional differences *do* exist in current-day text (Table 1), and current-day gender bias classifiers *can* achieve much better than random performance (§5). Thus, we believe the aim of research like ours should be to work towards training the best and most sensitive gender classifier imaginable. If we had such an idealized classifier, it should eventually achieve random performance on future datasets, thereby signalling that we managed to create a dataset that is not gender biased. We take the classifiers we introduce here to be first steps towards this goal.

Previous work on gender bias classification has been predominantly single-task—often supervised on the task of analogy—and relied mainly on word lists, that are binarily gendered (Bolukbasi et al., 2016; Zhao et al., 2018b, 2019; Gonen and Goldberg, 2019)—sometimes also explicitly (Caliskan et al., 2017; Hoyle et al., 2019).[1] While wordlist-

---

[1] We draw the distinction between **explicitly gendered** words, like *mother* and *father* which only refer to people of a specific gender, and **statistically gendered** words, like *doctor* and *nurse*, which can refer to people of any gender but

based approaches provided a solid start, they ultimately prove insufficient. First, they conflate different conversational dimensions of gender bias, and are therefore unable to detect the subtle, but very well-described, pragmatic differences of interest here. Second, most existing gendered word lists are limited to explicitly binarily gendered words (e.g., *mom* vs. *dad*). Not only is binary gender completely inadequate for the task, but excluding statistically gendered words is problematic—because they are also strong anchors of gender stereotypes (Bolukbasi et al. 2016; Ethayarajh et al. 2019, i.a.).

Instead, we develop classifiers that decompose gender bias over sentences into semantic and/or pragmatic dimensions (*about/to/as*), including gender information that (i) falls outside the male-female binary, (ii) can be contextually determined, and (iii) is statistically as opposed to explicitly gendered. In the subsequent sections, we provide details regarding the annotation of data, and details for training these classifiers.

4.1 Data

In this section, we describe how we annotated our training data, including both the 8 existing datasets and our novel evaluation dataset, MDGender.

Annotation of Existing Datasets. We select a variety of existing datasets for training. Since one of our main contributions is a suite of open-source general-purpose gender bias classifiers, we selected datasets for training based on three criteria: inclusion of inferrable information about one or more of our dimensions, diversity in textual domain, and high quality, open-source data.

The datasets are: Wikipedia, Funpedia (a less formal version of Wikipedia) (Miller et al., 2017), Wizard of Wikipedia (knowledge-based conversation) (Dinan et al., 2019c), Yelp Reviews[2], ConvAI2 (chit-chat dialogue) (Dinan et al., 2019b), ImageChat (chit-chat dialogue about an image) (Shuster et al., 2018), OpenSubtitles (dialogue from movies) (Lison and Tiedemann, 2016), and LIGHT (chit-chat fantasy dialogue) (Urbanek et al., 2019). Table 2 presents dataset statistics.

Some of the datasets contain gender annotations provided by existing work. For example, classifiers trained for style transfer algorithms have previously annotated the gender of Yelp reviewers (Subramanian et al., 2018). In other datasets, we infer the gender labels. For example, in datasets where users are first assigned a *persona* to represent before chatting, often the gender of the persona is predetermined. In some cases gender annotations are not provided. In these cases, we sometimes impute the label if we are able to do so with high confidence. More details regarding how this was done can be found in §A.1.

Evaluation Dataset: MDGender. To make our classifiers reliable on all dimensions across multiple domains, we train on a variety of datasets. However, none of the existing data covers all three dimensions at the same time, and furthermore, many of the gender labels are noisy. To enable reliable evaluation, we collect a specialized corpus, MDGender, which acts as a gold-labeled dataset for the *masculine* and *feminine* classes.

First, we collect conversations between two speakers. Each speaker is provided with a persona description containing gender information, then tasked with adopting that persona and having a conversation. They are also provided with small sections of a biography from Wikipedia as the conversation topic. Using personas biographies to frame the conversation encourages crowdworkers to discuss ABOUT/TO/AS gender information.

To ensure there is ABOUT/TO/AS gender information contained in each utterance, we perform a second pass over the dataset. In this next phase, we ask a second set of annotators to rewrite each utterance to make it very clear that they are speaking ABOUT a man or a woman, speaking AS a man or a

Table 4: **Performance of the multitask model.** We evaluate the multitask model on the test sets from our training data. We report accuracy on each gold label—masculine, feminine, and neutral—and the average of the three. We do not report accuracy on imputed labels.

woman, and speaking TO a man or a woman. For example, given the utterance *Hey, how are you today? I just got off work*, a valid rewrite to make the utterance ABOUT a woman could be: *Hey, what's up? I went for a coffee with my friend and her dog after work* as the *her* indicates a woman. Annotators are additionally asked to label how confident they are that someone else could predict the given gender label, allowing for flexibility between explicit genderedness (like the use of *he* or *she*) and statistical genderedness. An example instance of the task is shown in Table 10 and the interface is shown in §A.2 Figure 2. Additionally, we provide demographic information about the annotators for this task in §A.2.

4.2 Models

We outline how these classifiers are trained to predict gender bias along the three dimensions, providing details of the classifier architectures as well as how the data labels are used. In the single-task setting, we predict *masculine*, *feminine*, or *neutral* for each dimension – allowing the classifier to predict any of the three labels for the *unknown* category). To obtain a classifier capable of multitasking across the *about/to/as* dimensions, we train a model to score and rank a set of possible classes given textual input. For example, if given *Hey, John, I'm Jane!*, the model is trained to rank elements of both the sets {TO:masculine, TO:feminine, TO:neutral} and {AS:masculine, AS:feminine, AS:neutral} and produce appropriate labels TO:masculine and AS:feminine. Models are trained and evaluated on the annotated datasets as well as MDGender.

Model Architectures. For single task and multitask models, we use a pretrained Transformer-based (Vaswani et al., 2017) architecture. The model takes a text sequence (such as "John Doe was a man") and a set of labels corresponding to the gender along a given dimension (such as {ABOUT:masculine, ABOUT:feminine, ABOUT:neutral}) as input; the model then ranks this set according to the textual input (as described), and outputs the top element from the set (such as 'ABOUT:masculine'). More specifically, the Transformer provides representations for the textual input and set of classes. Classes are then scored (and ranked) by taking a dot product between the representations of the textual input and a given class, following the bi-encoder architecture (Humeau et al., 2019) trained with cross entropy. We use the same architecture and pre-training as in BERT-base (Devlin et al., 2019): specifically, the architecture is a 12 layer transformer encoder base with 12 attention heads and an embedding size of 768. We use `ParlAI` for model training (Miller et al., 2017). We will release all data and models.

Model	Performance			
	M	F	N	Avg.
MultiTask	87.4	86.65	55.2	77.22
Wikipedia Only	88.65	88.22	68.58	81.82
-gend words	86.94	74.62	74.33	78.63
-gend words and names	82.10	82.52	55.21	73.28

Table 5: **Ablation of gender classifiers on the Wikipedia test set.** We report the model accuracy on the masculine, feminine, and neutral classes, as well as the average accuracy across them. We train classifiers (1) on the entire text (2) after removing explicitly gendered words using a word list and (3) after removing gendered words and names. While removing gendered words and names makes classification more challenging, the model still obtains high accuracy.

5 Results

5.1 About/To/As Gender Classification

Quality of Classification Models. We compare models that classify along a single dimension compared to one that multitasks across all three, using MDGENDERto evaluate. We measure the percentage accuracy for masculine and feminine classes. (Recall, the MDGENDERdoes not contain *unknown* or *neutral* classes.) More details on this new dataset can be found in Section 4.1. Classifier results on MDGENDER are shown in Table 3.

We find that the multitask classifier has the best average performance across all dimensions, with a small hit to single-task performance in the ABOUT and AS dimensions. As expected, the single task models are unable to transfer to other dimensions: this clearly shows that gender information manifests differently along each dimension. Further, it demonstrates that solely using existing datasets is inadequate, as they do not contain labeled data along all three dimensions. Training for a single task allows models to specialize to detect and understand the nuances of text that indicate bias along one of the dimensions. However, in a multitask setting, models can learn to generalize to understand what language characterizes bias across multiple dimensions: we particularly see this manifest in the TO dimension.

Performance by Dataset. The gender classifiers along the TO, AS and ABOUT dimensions are trained on a variety of different existing datasets across multiple domains. We analyze which datasets are the most difficult to classify correctly in Table 4. We find that ABOUT is the easiest dimension, particularly data from Wikipedia or based on Wikipedia, such as Funpedia and Wizard of Wikipedia, achieving almost 80% accuracy. This could be driven by the number of discussions about named entities, so classifying text ABOUT someone may be easier if a name is present.

The TO and AS directions are both more difficult, likely as they involve more context clues rather than relying on textual attributes and surface forms such as *she* and *he* to predict correctly. We find that generally the datasets have similar performance, except Yelp restaurant reviews, which has a higher accuracy (70%) on predicting AS.

Analysis of Classifier Performance. We break down choices made during training by comparing different models on Wikipedia (ABOUT dimension). We train with the variations of masking out gendered words and names. As gendered words and names are strongly correlated with gender, masking can force models into a more challenging but nuanced setting where they must learn to detect bias from the remaining text. We present the results in Table 5: masking out gendered words and names makes classification more challenging, but the model is still able to obtain high accuracy, indicating that gender bias is deeply embedded in the language used.

6 Applications

We demonstrate the broad utility of our multitask classifier by applying it to three different downstream applications. First, we show that we can use the classifier to control the genderedness of generated text. Next, we demonstrate its utility in biased text detection by applying it to Wikipedia to find the most gendered biographies. Finally, we evaluate our classifier on offensive text to explore the interplay between offensive text and gender.

6.1 Controllable Generation

By learning to associate control variables with textual properties, generative models can be controlled at inference time to adjust the generated text based on the desired properties of the user. This has been applied to a variety of different cases, including generating text of different lengths (Fan et al., 2018a), generating questions in chit-chat (See et al., 2019), and reducing bias (Dinan et al., 2020).

Previous work in gender bias used word lists to control bias, but found that word lists were lim-

Generation Statistics		
Control Token	*# Gend. words*	*Pct. masc.*
TO:feminine	246	48.0
AS:feminine	227	51.0
ABOUT:feminine	1151	19.72
Word list, feminine	1158	18.22
TO:masculine	372	75.0
AS:masculine	402	71.6
ABOUT:masculine	800	91.62
Word list, masculine	1459	94.8

Table 6: **Word statistics** measured on text generated from 1000 different seed utterances from ConvAI2 for each control token. We measure the number of gendered words (from a word list) that appear in the generated text, and the percentage of masculine-gendered words among all gendered words.

ited in coverage and applicability to a variety of domains (Dinan et al., 2020). However, by decomposing bias along the TO, AS, and ABOUT dimensions, fine-grained control models can be trained to control these different dimensions separately. This is important in various applications — for example, one may want to train a chatbot with a specific personality, leaving the AS dimension untouched, but want the bot to speak to and about everyone in a similar way. In this application, we train three different generative models, each of which controls generation for gender along one of the TO, AS, and ABOUT dimensions.

Methods We generate training data by taking the multitask classifier and using it to classify 250,000 textual utterances from Reddit, using a previously existing dataset extracted and obtained by a third party and made available on pushshift.io. This dataset was chosen as it is conversational in nature, but not one of the datasets that the classifier was trained on. We then use the labels from the classifier to prepend the utterances with tokens that indicate its gender label along the dimension. For example for the ABOUT dimension, we prepend utterances with tokens *ABOUT:<gender_label>*. At inference time, we choose control tokens to manipulate the text generated by the model.

We also compare to a baseline for which the control tokens are determined by a word list: if an utterance contains more masculine-gendered words than feminine-gendered words from the word list it is labeled as *masculine* (and vice versa for *feminine*); if it contains no gendered words or an equal number of masculine and feminine gendered words, it is labeled as *neutral*. Following Dinan et al. (2020), we combine several existing word lists (Zhao et al., 2018b, 2019; Hoyle et al., 2019).

For training, we fine-tune a large, Transformer sequence-to-sequence model pretrained on a Reddit dump made freely available by pushshift.io. At inference time, we generate text via top-k sampling (Fan et al., 2018b), with $k = 10$ with a beam size of 10, and 3-gram blocking. We force the model to generate a minimum of 20 BPE tokens.

Qualitative Results. Example generations from various methods are shown in Appendix Table 11. In these examples we see that controlling for gender along different dimensions yields highly varied responses, even for identical input. This illustrates why limiting control to word lists is not enough to capture different aspects of gender. For example, adjusting AS to 'feminine' causes the model to write *No, I've been working. I don't think I can make friendships online*, whereas setting ABOUT to 'feminine' for the same exact input causes the model to write *I think the problem is she's a girl, so there's not a lot of opportunity to make friends.*

We can also see from these examples how the genderedness of text differs along each axis when we switch between conditioning on *masculine* and *feminine*. For example, adjusting AS to 'feminine' causes the model to write *Awwww, that sounds wonderful*, whereas setting AS to masculine generates *You can do it bro!*

Quantitative Results. Quantitatively, we evaluate by generating 1000 utterances seeded from ConvAI2 using both *masculine* and *feminine* control tokens and counting the number of gendered words from a gendered word list that also appear in the generated text. Results are shown in Table 6.

Utterances generated using ABOUT control tokens contain many gendered words. One might expect this, as when one speaks ABOUT another person, one may refer to them using gendered pronouns. We observe that for the control tokens *TO:feminine* and *AS:feminine*, the utterances contain a roughly equal number of masculine-gendered and feminine-gendered words. This is a reflection of the distribution in the training data: the ConvAI2 and Opensubtitles data show similar trends: on the ConvAI2 data, fewer than half of the gendered words in *SELF:feminine* utterances are feminine-gendered, and on the Opensubtitles data, the ratio

Masculine genderedness scores		
Biographies	Average	Median
All	0.74	0.98
Men	0.90	0.99
Women	0.042	0.00085

Table 7: **Masculine genderedness scores of Wikipedia bios.** We calculate a *masculine genderedness score* for a Wikipedia page by taking the median $p_x = P(x \in \text{ABOUT:masculine})$ among all paragraphs x in the page, where P is the probability distribution given by the classifier. We report the average and median scores for all biographies, as well as for biographies of men and women respectively.

Percentage of masculine-gendered text				
Dim	*Safe*	*Offensive*	*t-statistic*	*p-value*
ABOUT	81.03	70.66	5.49	5.19e-08
TO	44.68	60.15	-22.02	1.94e-46
AS	42.29	65.12	-14.56	1.05e-99

Table 8: **Genderedness of offensive content.** We measure the percentage of utterances in both the ”safe” and ”offensive” classes that are classified as *masculine-gendered*, among utterances that are classified as either *masculine-* or *feminine-gendered*. We test the hypothesis that safe and offensive classes distributions of *masculine-gendered* utterances differ using a t-test and report the p-value for each dimension.

drops to one-third.[3]

6.2 Bias Detection

Creating classifiers along different dimensions can be used to detect gender bias in any form of text, beyond dialogue itself. Such methods are useful in applications such as detecting, removing, and rewriting biased writing. We investigate using the trained classifiers to detect the most gendered biographies in Wikipedia.

Methods. We apply the multitask model to detect the most gendered masculine and feminine biographies in Wikipedia. We calculate the probability of being *masculine* in the ABOUT dimension for each paragraph among $65,000$ biographies. We calculate a *masculine genderedness score* for the page by taking the median amongst all its paragraphs.

Quantitative Results. We report the average and median *masculine genderedness scores* for all biographies in the set of $65,000$ that fit this criteria Table 7. We observe that while on average, the biographies skew largely toward *masculine* (the average score is 0.74), the classifier is more confident in the *femininity* of pages about women than it is in the *masculinity* of pages about men: the average *feminine genderedness score* for pages about women is $1 - 0.042 = 0.958$, while the average *masculine genderedness score* for pages about men is 0.90. This might suggest that biographies about women contain more gendered text on average.

Qualitative Results. We show the pages with the minimum score (most feminine-gendered biographies) and the maximum score (most masculine-gendered biographies) in Table 12 in the Appendix. The most masculine-gendered biographies are mostly composers and conductors, likely due to the historical imbalance in these occupations. Amongst the most feminine gendered biographies, there are many actresses from the mid-20th century. By examining the *most feminine* gendered paragraphs, anecdotally we find these are often describing the subject's life after retirement. For example, Linda Darnell's biography contains the line *Because of her then-husband, Philip Liebmann, Darnell put her career on a hiatus,* which clearly reflects negative societal stereotypes about the importance of women's careers (Hiller and Philliber, 1982; Duxbury and Higgins, 1991; Pavalko and Elder Jr., 1993; Byrne and Barling, 2017; Reid, 2018).

6.3 Offensive Content

Finally, the interplay and correlation between gendered text and offensive text is an important area for study, as many examples of explicitly or contextually gendered text are disparaging or have negative connotations (e.g., “cat fight” and “doll”). Particularly for dialogue, neither form is desirable in the output of any chatbot system. There is a growing body of research on detecting offensive language in text. In particular, there has been recent work aimed at improving the detection of offensive language in the context of dialogue (Dinan et al., 2019a). We investigate this relationship by examining the distribution of labels output by our gender classifier on data that is labeled for offensiveness.

Methods. We use the *Standard* training and evaluation dataset from Dinan et al. (2019a). We examine the relationship between genderedness and

---

[3] The Opensubtitles data recalls the Bechdel test, which asks “whether a work [of fiction] features at least two women who talk to each other about something other than a man.” (Wikipedia contributors, 2020)

offensive utterances by labeling the gender of utterances (along the three dimensions) in the "safe" and "offensive" classes using our multitask classifier. We then measure the ratio of utterances labeled as *masculine-gendered* among utterances labeled as either *masculine-* or *feminine-gendered*.

Quantitative Results. Results are shown in Table 8. We observe that, on the ABOUT dimension, both the safe data and offensive data are more likely to be *masculine* than *feminine*; however, the offensive data is relatively less likely to be *masculine*. On the other hand, on the AS and TO dimensions, the safe data is more likely to be labeled as *feminine* and the offensive data is more likely to be labeled as *masculine*. We test the hypothesis that these distributions are unequal using a T-test, and find that these results are significant.

Qualitative Results. To explore how offensive content differs when it is ABOUT women and ABOUT men, we identified utterances for which the model had high confidence (probability > 0.70) that the utterance was *feminine* or *masculine* along the ABOUT dimension. After excluding stop words and words shorter than three characters, we hand-annotated the top 20 most frequent words as being *explicitly gendered*, a *swear word*, and/or bearing *sexual connotation*. For words classified as masculine, 25% of words fell into these categories, whereas for words classified as feminine, 75% of the words fell into these categories.

7 Conclusion

We propose a general framework for analyzing gender bias along three dimensions: (1) gender of the person being spoken about (ABOUT), (2) gender of the addressee (TO), and (3) gender of the speaker (AS). We annotate eight large existing datasets and create an evaluation dataset for the task of detect bias along each of these dimensions. We train classifiers (single and multitask) that demonstrate their broad utility by displaying strong performance in controlling bias in dialogue, detecting genderedness in text such as Wikipedia, and highlighting gender differences in offensive text.

A Appendices

A.1 Existing Data Annotation

Many of our annotated datasets contain cases where the ABOUT, AS, TO labels are not provided (i.e. *unknown*). For example, often we do not know the gender of the content creator for Wikipedia (i.e., the AS dimension is *unknown*). To retain such examples for training, we either impute the gender label or provide a label at random. We apply the imputation strategy for data for which the ABOUT label is *unknown* using a classifier trained only on other Wikipedia data for which this label *is* provided. Data without a TO or AS label was assigned one at random, choosing between *masculine* and *feminine* with equal probability. From epoch to epoch, we switch these arbitrarily assigned labels so that the model learns to label *unknown* examples as *masculine* or *feminine* with roughly equal probability. This label flipping allows us to retain greater quantities of data by preserving unknown samples. During training, we balance the data across the *masculine*, *feminine*, and *neutral* classes by up-sampling classes with fewer examples. We describe in more detail how each of the eight training datasets is annotated:

1. **Wikipedia** - to annotate ABOUT, we use a Wikipedia dump and extract biography pages. We identify biographies using named entity recognition applied to the title of the page (Honnibal and Montani, 2017). We label pages with a gender based on the number of gendered pronouns (*he* vs. *she* vs. *they*) and label each paragraph in the page with this label for the ABOUT dimension.[4] Wikipedia is well known to have gender bias in equity of biographical coverage and lexical bias in noun references to women (Reagle and Rhue, 2011; Graells-Garrido et al., 2015; Wagner et al., 2015; Klein and Konieczny, 2015; Klein et al., 2016; Wagner et al., 2016), making it an interesting test bed for our investigation.
2. **Funpedia** - Funpedia (Miller et al., 2017) contains rephrased Wikipedia sentences in a more conversational way. We retain only biography related sentences and annotate similar to Wikipedia, to give ABOUT labels.
3. **Wizard of Wikipedia** - Wizard of Wikipedia (Dinan et al., 2019c) contains two people discussing a topic in Wikipedia. We retain only the conversations on Wikipedia biographies and annotate to create ABOUT labels.
4. **ImageChat** - ImageChat (Shuster et al., 2018) contains conversations discussing the contents of an image. We use the Xu et al. image captioning system[5] to identify the contents of an image and select gendered examples.
5. **Yelp** - we use the Yelp reviewer gender predictor developed by (Subramanian et al., 2018) and retain reviews for which the classifier is very confident – this creates labels for the content creator of the review (AS). We impute ABOUT labels on this dataset using a classifier trained on the datasets 1-4.
6. **ConvAI2** - ConvAI2 (Dinan et al., 2019b) contains persona-based conversations. Many personas contain sentences such as *I am a old woman* or *My name is Bob* which allows annotators to annotate the gender of the speaker (AS) and addressee (TO) with some confidence. Many of the personas have unknown gender. We impute ABOUT labels on this dataset using a classifier trained on the datasets 1-4.
7. **OpenSubtitiles** - OpenSubtitles[6] (Lison and Tiedemann, 2016) contains subtitles for movies in different languages. We retain English subtitles that contain a character name or identity. We annotate the character's gender using gender kinship terms such as *daughter* and gender probability distribution calculated by counting the masculine and feminine names of baby names in the United States[7]. Using the character's gender, we get labels for the AS dimension. We get labels for the TO dimension by taking the gender of the next character to speak if there is another utterance in the conversation; otherwise, we take the gender of the *last* character to speak. We impute ABOUT labels on this dataset using a classifier trained on the datasets 1-4.
8. **LIGHT** - LIGHT contains persona-based conversation. Similarly to ConvAI2, annotators

---

[4] This method of imputing gender is similar to the one used in Reagle and Rhue (2011, 1142) and Bamman and Smith (2014), except we also incorporate non-oppositional gender categories, and rely on basic counts without scaling.

[7] https://catalog.data.gov/dataset/baby-names-from-social-security-card-applications-national-level-data

	Percent of total
Man	67.38
Woman	18.34
Non-binary	0.21
Prefer not to say	14.07

Table 9: Self-reported gender identities of annotators used to collect the new evaluation dataset MDGENDER. Annotators were given the option to not answer this question or to select "prefer not to say."

labeled the gender of each persona (Dinan et al., 2020), giving us labels for the speaker (AS) and speaking partner (TO). We impute ABOUT labels on this dataset using a classifier trained on the datasets 1-4.

A.2 New Evaluation Dataset

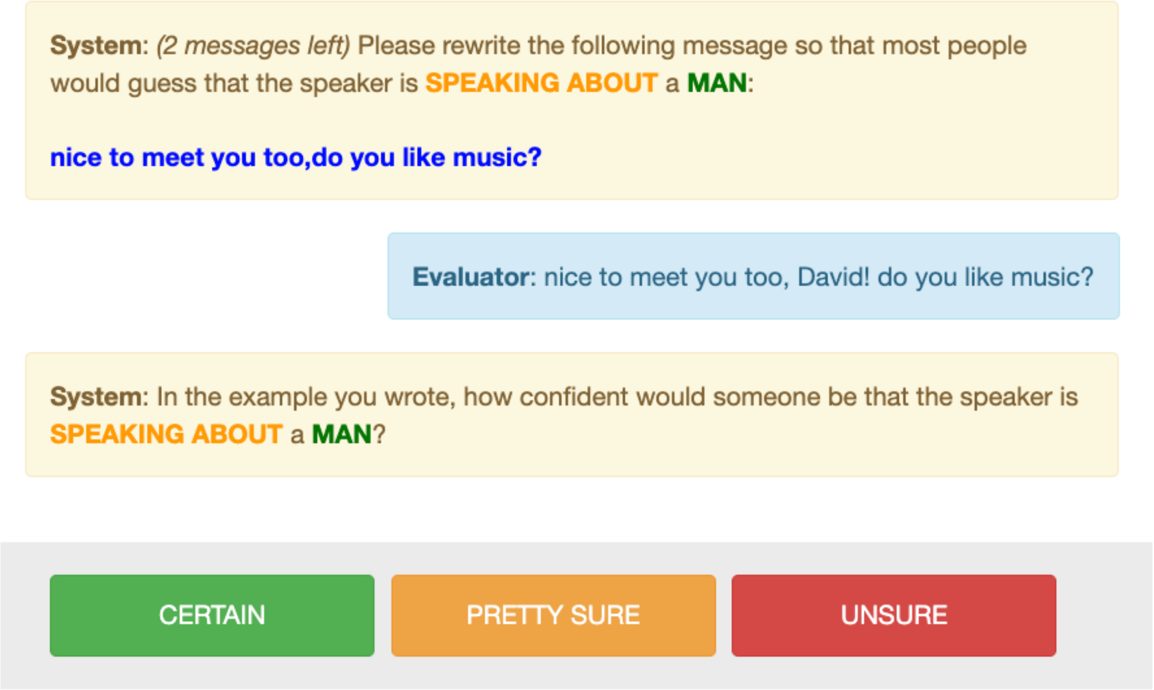
The interface for our new evaluation dataset MDGENDER can be seen in Figure 2. Examples from the new dataset can be found in Table 10.

This dataset was collected using crowdworkers from Amazon's Mechanical Turk. All workers are English-speaking and located in the United States. During the "re-write phase" (described in §4.1) crowdworkers were asked to provide their own gender identity if they were willing. Workers were given the option to not answer this question or to select "prefer not to say." Results from this survey are shown in Table 9. For privacy reasons we do not associate the self-reported gender of the annotator with the labeled examples in the dataset and only report these statistics in aggregate. Over two thirds of annotators identified as men, which may introduce its own biases into the dataset.

A.3 Applications

Example generations for various control tokens, as well as for our word list baseline, are shown in Table 11. See §6.1 on Controllable Generation in the main paper for more details.

The top 10 most gendered Wikipedia biographies are shown in Table 12. See §6.2 on Detecting Bias in the main paper for more details.



System: *(2 messages left)* Please rewrite the following message so that most people would guess that the speaker is **SPEAKING ABOUT** a **MAN**:

nice to meet you too,do you like music?

Evaluator: nice to meet you too, David! do you like music?

System: In the example you wrote, how confident would someone be that the speaker is **SPEAKING ABOUT** a **MAN**?

Figure 2: **Annotation interface**. Annotation interface for collecting MDGENDER. Annotators were shown an utterance from a conversation, and asked to re-write it such that it is clear they would be speaker about/to/as a man or a woman. They were then asked for their confidence level.

Utterance	Dim.	Gender	Confidence
Original: That's interesting. I am a Chef. What are your hobbies ***Rewrite***: that's interesting. i am a chef and nfl player what are your hobbies	AS	masc.	certain
Original: My name is Zachery but most call me Z. What's your name miss? ***Rewrite***: My name is Tina but most call me T. What's your name miss?	AS	fem.	pretty sure
Original: I said I like to wrestle with my kids for fun. What do you do for work? ***Rewrite***: i said i like to wrestle with my son for fun. what do you do for work?	ABOUT	masc.	certain
Original: just checking up on you by saying hi ***Rewrite***: Hanna said she was just checking up on you by saying hi	ABOUT	fem.	pretty sure
Original: How are you doing today Jahsim? ***Rewrite***: How are you doing today Mr. Jahsim?	TO	masc.	certain
Original: My name is Alexsandro and I am a bee farmer! ***Rewrite***: My name is alexsandro and I am a bee farmer! How about you ma'am?	AS	fem.	certain

Table 10: **Examples from the MDGENDER**. Crowdworkers were asked to re-write dialogue utterances such that most people would guess that the utterance was either said to, said by, or about a man or a woman. Afterwards, they were asked to give a confidence level in their re-write, meant to capture the differences between statistical biases (more men play football than women) and fact (you do not have to be a man to play football).

Input: Awww! Cute! Our are a handful, but they are my babies! 4 wiener dogs.
TO:feminine I can't wait for your children to get married.. I want one so badly! :)
AS:feminine Awwww, that sounds wonderful. Can't wait to see them in person! :)
ABOUT:feminine You're my hero. That's a cute dog. How long has she been with you?
Word list, feminine That's pretty awesome! She was a little bit overweight but she's a sweet girl now

Input: Does vegan mean you do not want to be a super hero?
TO:feminine I'd love to be vegan, but it just isn't something I have any interest in doing.
AS:feminine I don't want to become super heroes! I just think it would be cool to be vegan.
ABOUT:feminine She's a girl. She can't be a superhero!!! 11! 1! 1 1!
Word list, feminine It does. She is a vegan and I am a super - hero. I am not vegan, and I don't want to become any sort of superhero.

Input: That is an good. Maybe you can make friends in a club or on a job?
TO:feminine I was going to do that, but then I realized I didn't want to be alone.
AS:feminine No, I've been working. I don't think I can make friendships online.
ABOUT:feminine I think the problem is she's a girl, so there's not a lot of opportunity to make friends.
Word list, feminine I have a girlfriend and I live in a small town. I don't know what clubs she can make any friends in.

Input: Its been 2 years I am a grease monkey and been trying to stay busy
TO:masculine I'm not sure this is true. I've seen a lot of grease monkeys on reddit. I don't think there's any evidence it's true.
AS:masculine You can do it bro! Just keep at it! You got this!!! : d)
ABOUT:male I'd love to be a grease guy but I just can't make it to the gym. : (
Word list, masculine You're not alone bro. I'm trying to be that guy, but it's a little hard sometimes.

Input: Have you ever almost died? I nearly did from urinary cancer when I was 18.
TO:masculine No one in my family has died. I have only seen a handful of people die. I am sure you will be fine.
AS:masculine No I haven't. But it's a lot better now, thanks to all the help I've received.
ABOUT:masculine He said * nearly *. It's more likely to happen when you're older than the average person.
Word list, masculine I've only been alive for 3 days. I have no idea what I'm going to do next, but I'll be okay.

Input: I totally believe you. I love working out.
TO:masculine I'm going to start doing this, thanks! If it works, I'll post it on r / fitness!
AS:masculine Thanks! I've always been really into exercise, too, and it's definitely helped me.
ABOUT:masculine Thank you! I'm really glad he does :). I've been working out since october.
Word list, masculine Me too! I love being able to go to the gym without feeling like I'm just a little kid. It's so rewarding when you get back in the swing of things.

Table 11: **Example generations** from a generative model trained using controllable generation, with control tokens determined by the classifier. Sequences are generated with top-k sampling, $k = 10$, with a beam size of 10 and 3-gram blocking. Input is randomly sampled from the ConvAI2 dataset.

Most Feminine	*Most Masculine*
1. **Edie Sedgwick:** was an American actress and fashion model...	1. **Derek Jacobi:** is an English actor and stage director...
2. **Linda Darnell:** was an American film actress...	2. **Bohuslav Martinů:** was a Czech composer of modern classical music...
3. **Maureen O'Hara:** was an Irish actress and singer...	3. **Carlo Maria Giulini:** was an Italian conductor...
4. **Jessica Savitch:** was an American television news presenter and correspondent,...	4. **Zubin Mehta:** is an Indian conductor of Western classical music...
5. **Patsy Mink:** Mink served in the U.S. House of Representatives...	5. **John Barbirolli:** was a British conductor and cellist ...
6. **Shirley Chisholm:** was an American politician, educator, and author...	6. **Claudio Abbado:** was an Italian conductor...
7. **Mamie Van Doren:** is an American actress, model, singer, and sex symbol who is...	7. **Ed Harris:** is an American actor, producer, director, and screenwriter...
8. **Jacqueline Cochran:** was a pioneer in the field of American aviation and one of t...	8. **Richard Briers:** was an English actor...
9. **Chloë Sevigny:** is an American actress, fashion designer, director, and form...	9. **Artur Schnabel:** was an Austrian classical pianist, who also composed and tau...
10. **Hilda Solis:** is an American politician and a member of the Los Angeles Co...	10. **Charles Mackerras:** was an Australian conductor...

Table 12: **Most gendered Wikipedia biographies** We ran our multitask classifier over 68 thousand biographies of Wikipedia. After selecting for biographies with a minimum number of paragraphs (resulting in 15.5 thousand biographies) we scored them to determine the most *masculine* and *feminine* gendered.

.

FIND: Human-in-the-Loop Debugging Deep Text Classifiers

Piyawat Lertvittayakumjorn, Lucia Specia, Francesca Toni
Department of Computing, Imperial College London, UK
`{pl1515, l.specia, ft}@imperial.ac.uk`

Abstract

Since obtaining a perfect training dataset (i.e., a dataset which is considerably large, unbiased, and well-representative of unseen cases) is hardly possible, many real-world text classifiers are trained on the available, yet imperfect, datasets. These classifiers are thus likely to have undesirable properties. For instance, they may have biases against some sub-populations or may not work effectively in the wild due to overfitting. In this paper, we propose **FIND** – a framework which enables humans to debug deep learning text classifiers by disabling irrelevant hidden features. Experiments show that by using FIND, humans can improve CNN text classifiers which were trained under different types of imperfect datasets (including datasets with biases and datasets with dissimilar train-test distributions).

1 Introduction

Deep learning has become the dominant approach to address most Natural Language Processing (NLP) tasks, including text classification. With sufficient and high-quality training data, deep learning models can perform incredibly well (Zhang et al., 2015; Wang et al., 2019). However, in real-world cases, such ideal datasets are scarce. Often times, the available datasets are small, full of regular but irrelevant words, and contain unintended biases (Wiegand et al., 2019; Gururangan et al., 2018). These can lead to suboptimal models with undesirable properties. For example, the models may have biases against some sub-populations or may not work effectively in the wild as they overfit the imperfect training data.

To improve the models, previous work has looked into different techniques beyond standard model fitting. If the weaknesses of the training datasets or the models are anticipated, strategies can be tailored to mitigate such weaknesses. For example, augmenting the training data with gender-swapped input texts helps reduce gender bias in the models (Park et al., 2018; Zhao et al., 2018). Adversarial training can prevent the models from exploiting irrelevant and/or protected features (Jaiswal et al., 2019; Zhang et al., 2018). With a limited number of training examples, using human rationales or prior knowledge together with training labels can help the models perform better (Zaidan et al., 2007; Bao et al., 2018; Liu and Avci, 2019).

Nonetheless, there are side-effects of sub-optimal datasets that cannot be predicted and are only found after training thanks to post-hoc error analysis. To rectify such problems, there have been attempts to enable humans to fix the trained models (i.e., to perform *model debugging*) (Stumpf et al., 2009; Teso and Kersting, 2019). Since the models are usually too complex to understand, manually modifying the model parameters is not possible. Existing techniques, therefore, allow humans to provide feedback on individual predictions instead. Then, additional training examples are created based on the feedback to retrain the models. However, such local improvements for individual predictions could add up to inferior overall performance (Wu et al., 2019). Furthermore, these existing techniques allow us to rectify only errors related to examples at hand but provide no way to fix problems kept hidden in the model parameters.

In this paper, we propose a framework which allows humans to debug and improve deep text classifiers by disabling hidden features which are irrelevant to the classification task. We name this framework **FIND** (**F**eature **I**nvestigation a**N**d **D**isabling). FIND exploits an explanation method, namely layer-wise relevance propagation (LRP) (Arras et al., 2016), to understand the behavior of a classifier when it predicts each training instance. Then it aggregates all the information using word clouds to create a global visual picture of the model.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 332–348,
November 16–20, 2020.

This enables humans to comprehend the features automatically learned by the deep classifier and then decide to disable some features that could undermine the prediction accuracy during testing. The main differences between our work and existing work are: (i) first, FIND leverages human feedback on the model components, not the individual predictions, to perform debugging; (ii) second, FIND targets deep text classifiers which are more convoluted than traditional classifiers used in existing work (such as Naive Bayes classifiers and Support Vector Machines).

We conducted three human experiments (one feasibility study and two debugging experiments) to demonstrate the usefulness of FIND. For all the experiments, we used as classifiers convolutional neural networks (CNNs) (Kim, 2014), which are a popular, well-performing architecture for many text classification tasks including the tasks we experimented with (Gambäck and Sikdar, 2017; Johnson and Zhang, 2015; Zhang et al., 2019). The overall results show that FIND with human-in-the-loop can improve the text classifiers and mitigate the said problems in the datasets. After the experiments, we discuss the generalization of the proposed framework to other tasks and models. Overall, the **main contributions** of this paper are:

- We propose using word clouds as visual explanations of the features learned.
- We propose a technique to disable the learned features which are irrelevant or harmful to the classification task so as to improve the classifier. This technique and the word clouds form the human-debugging framework – FIND.
- We conduct three human experiments that demonstrate the effectiveness of FIND in different scenarios. The results not only highlight the usefulness of our approach but also reveal interesting behaviors of CNNs for text classification.

The rest of this paper is organized as follows. Section 2 explains related work about analyzing, explaining, and human-debugging text classifiers. Section 3 proposes FIND, our debugging framework. Section 4 explains the experimental setup followed by the three human experiments in Section 5 to 7. Finally, Section 8 discusses generalization of the framework and concludes the paper. Code and datasets of this paper are available at `https://github.com/plkumjorn/FIND`.

2 Related Work

Analyzing deep NLP models – There has been substantial work in gaining better understanding of complex, deep neural NLP models. By visualizing dense hidden vectors, Li et al. (2016) found that some dimensions of the final representation learned by recurrent neural networks capture the effect of intensification and negation in the input text. Karpathy et al. (2015) revealed the existence of interpretable cells in a character-level LSTM model for language modelling. For example, they found a cell acting as a line length counter and cells checking if the current letter is inside a parenthesis or a quote. Jacovi et al. (2018) presented interesting findings about CNNs for text classification including the fact that one convolutional filter may detect more than one n-gram pattern and may also suppress negative n-grams. Many recent papers studied several types of knowledge in BERT (Devlin et al., 2019), a deep transformer-based model for language understanding, and found that syntactic information is mostly captured in the middle BERT layers while the final BERT layers are the most task-specific (Rogers et al., 2020). Inspired by many findings, we make the assumption that each dimension of the final representation (i.e., the vector before the output layer) captures patterns or qualities in the input which are useful for classification. Therefore, understanding the roles of these dimensions (we refer to them as *features*) is a prerequisite for effective human-in-the-loop model debugging, and we exploit an explanation method to gain such an understanding.

Explaining predictions from text classifiers – Several methods have been devised to generate explanations supporting classifications in many forms, such as natural language texts (Liu et al., 2019), rules (Ribeiro et al., 2018), extracted rationales (Lei et al., 2016), and attribution scores (Lertvittayakumjorn and Toni, 2019). Some explanation methods, such as LIME (Ribeiro et al., 2016) and SHAP (Lundberg and Lee, 2017), are model-agnostic and do not require access to model parameters. Other methods access the model architectures and parameters to generate the explanations, such as DeepLIFT (Shrikumar et al., 2017) and LRP (layer-wise relevance propagation) (Bach et al., 2015; Arras et al., 2016). In this work, we use LRP to explain not the predictions but the learned features so as to expose the model behavior to humans and enable informed model debugging.

Debugging text classifiers using human feedback – Early work in this area comes from the human-computer interaction community. Stumpf et al. (2009) studied the types of feedback humans usually give in response to machine-generated predictions and explanations. Also, some of the feedback collected (i.e., important words of each category) was used to improve the classifier via a user co-training approach. Kulesza et al. (2015) presented an explanatory debugging approach in which the system explains to users how it made each prediction, and the users then rectify the model by adding/removing words from the explanation and adjusting important weights. Even without explanations shown, an active learning framework proposed by Settles (2011) asks humans to iteratively label some chosen features (i.e., words) and adjusts the model parameters that correspond to the features. However, these early works target simpler machine learning classifiers (e.g., Naive Bayes classifiers with bag-of-words) and it is not clear how to apply the proposed approaches to deep text classifiers.

Recently, there have been new attempts to use explanations and human feedback to debug classifiers in general. Some of them were tested on traditional text classifiers. For instance, Ribeiro et al. (2016) showed a set of LIME explanations for individual SVM predictions to humans and asked them to remove irrelevant words from the training data in subsequent training. The process was run for three rounds to iteratively improve the classifiers. Teso and Kersting (2019) proposed CAIPI, which is an explanatory interactive learning framework. At each iteration, it selects an unlabelled example to predict and explain to users using LIME, and the users respond by removing irrelevant features from the explanation. CAIPI then uses this feedback to generate augmented data and retrain the model.

While these recent works use feedback on low-level features (input words) and individual predictions, our framework (FIND) uses feedback on the learned features with respect to the big picture of the model. This helps us avoid local decision pitfalls which usually occur in interactive machine learning (Wu et al., 2019). Overall, what makes our contribution different from existing work is that *(i)* we collect the feedback on the model, not the individual predictions, and *(ii)* we target deep text classifiers which are more complex than the models used in previous work.

3 FIND: Debugging Text Classifiers

3.1 Motivation

Generally, deep text classifiers can be divided into two parts. The first part performs *feature extraction*, transforming an input text into a dense vector (i.e., a *feature vector*) which represents the input. There are several alternatives to implement this part such as using convolutional layers, recurrent layers, and transformer layers. The second part performs *classification* passing the feature vector through a dense layer with softmax activation to get predicted probability of the classes. These deep classifiers are not transparent, as humans cannot interpret the meaning of either the intermediate vectors or the model parameters used for feature extraction. This prevents humans from applying their knowledge to modify or debug the classifiers.

In contrast, if we understand which patterns or qualities of the input are captured in each feature, we can comprehend the overall reasoning mechanism of the model as the dense layer in the classification part then becomes interpretable. In this paper, we make this possible using LRP. By understanding the model, humans can check whether the input patterns detected by each feature are relevant for classification. Also, the features should be used by the subsequent dense layer to support the right classes. If these are not the case, debugging can be done by disabling the features which may be harmful if they exist in the model. Figure 1 shows the overview of our debugging framework, FIND.

3.2 Notation

Let us consider a text classification task with $|\mathcal{C}|$ classes where $\mathcal{C}$ is the set of all classes and let $\mathcal{V}$ be a set of unique words in the corpus (the vocabulary). A training dataset $\mathcal{D} = \{(x_1, y_1), \dots, (x_N, y_N)\}$ is given, where x_i is the i-th document containing a sequence of L words, $[x_{i1}, x_{i2}, ..., x_{iL}]$, and $y_i \in \mathcal{C}$ is the class label of x_i. A deep text classifier M trained on dataset $\mathcal{D}$ classifies a new input document x into one of the classes (i.e., $M(x) \in \mathcal{C}$). In addition, M can be divided into two parts – a feature extraction part M_f and a classification part M_c. Formally, $M(x) = (M_c \circ M_f)(x)$; $M_f(x) = \mathbf{f}$; $M(x) = M_c(\mathbf{f}) = \text{softmax}(\mathbf{W}\mathbf{f} + \mathbf{b}) = \mathbf{p}$ where $\mathbf{f} = [f_1, f_2, \dots, f_d] \in \mathbb{R}^d$ is the feature vector of x, while $\mathbf{W} \in \mathbb{R}^{|\mathcal{C}| \times d}$ and $\mathbf{b} \in \mathbb{R}^{|\mathcal{C}|}$ are parameters of the dense layer of M_c. The final output is the predicted probability vector $\mathbf{p} \in [0, 1]^{|\mathcal{C}|}$.

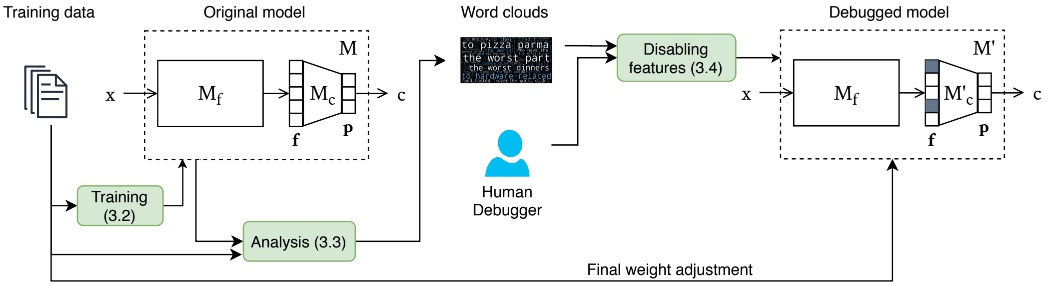


Figure 1: Overview of the proposed debugging framework, FIND. The numbers in the green boxes refer to the corresponding Sections in this paper.

3.3 Understanding the Model

To understand how the model M works, we analyze the patterns or characteristics of the input that activate each feature f_i. Specifically, using LRP[1], for each f_i of an example x_j in the training dataset, we calculate a relevance vector $\mathbf{r}_{ij} \in \mathbb{R}^L$ showing the relevance scores (the contributions) of each word in x_j for the value of f_i. After doing this for all d features of all training examples, we can produce word clouds to help the users better understand the model M.

Word clouds – For each feature f_i, we create (one or more) word clouds to visualize the patterns in the input texts which highly activate f_i. This can be done by analyzing $\mathbf{r}_{ij}$ for all x_j in the training data and displaying, in the word clouds, words or n-grams which get high relevance scores. Note that different model architectures may have different ways to generate the word clouds so as to effectively reveal the behavior of the features.

For CNNs, the classifiers we experiment with in this paper, each feature has one word cloud containing the n-grams, from the training examples, which were selected by the max-pooling of the CNNs. For instance, Figure 2, corresponding to a feature of filter size 2, shows bi-grams (e.g., “love love”, “love my”, “loves his”, etc.) whose font size corresponds to the feature values of the bi-grams. This is similar to how previous works analyze CNN features (Jacovi et al., 2018; Lertvittayakumjorn and Toni, 2019), and it is equivalent to back-propagating the feature values to the input using LRP and cropping the consecutive input words with non-zero LRP scores to show in the word clouds.[2]

Figure 2: A word cloud (or, literally, an n-gram cloud) of a feature from a CNN.

3.4 Disabling Features

As explained earlier, we want to know whether the learned features are valid and relevant to the classification task and whether or not they get appropriate weights from the next layer. This is possible by letting humans consider the word cloud(s) of each feature and tell us which class the feature is relevant to. A word cloud receiving human answers that are different from the class it should support (as indicated by $\mathbf{W}$) exhibits a flaw in the model. For example, if the word cloud in Figure 2 represents the feature f_i in a sentiment analysis task but the i^{th} column of $\mathbf{W}$ implies that f_i supports the negative sentiment class, we know the model is not correct here. If this word cloud appears in a product categorization task, this is also problematic because the phrases in the word cloud are not discriminative of any product category. Hence, we provide options for the users to disable the features which correspond to any problematic word clouds so that the features do not play a role in the classification. To enable this to happen, we modify M_c to be M'_c where $\mathbf{p} = M'_c(\mathbf{f}) = \text{softmax}((\mathbf{W} \odot \mathbf{Q})\mathbf{f} + \mathbf{b})$ and $\mathbf{Q} \in \mathbb{R}^{|\mathcal{C}| \times d}$ is a masking matrix with $\odot$ being an element-wise multiplication operator. Initially, all elements in $\mathbf{Q}$ are ones which enable all the connections between the features and the output. To disable feature f_i, we set the i^{th} column of $\mathbf{Q}$

---

[1] See Appendix A for more details on how LRP works.

[2] We also propose how to create word clouds and perform debugging for bidirectional LSTM networks (Hochreiter and Schmidhuber, 1997) in Appendix C.

Exp	Dataset	$\lvert\mathcal{C}\rvert$	Train / Dev / Test
1	Yelp	2	500 / 100 / 38000

to be a zero vector. After disabling features, we then freeze the parameters of M_f and fine-tune the parameters of M'_c (except the masking matrix $\mathbf{Q}$) with the original training dataset $\mathcal{D}$ in the final step.

4 Experimental Setup

All datasets and their splits used in the experiments are listed in Table 1. We will explain each of them in the following sections. For each classification task, we ran and improved three models, using different random seeds, independently of one another, and the reported results are the average of the three runs. Regarding the models, we used 1D CNNs with the same structures for all the tasks and datasets. The convolution layer had three filter sizes [2, 3, 4] with 10 filters for each size (i.e., $d = 10 \times 3 = 30$). All the activation functions were ReLU except the softmax at the output layer. The input documents were padded or trimmed to have 150 words ($L = 150$). We used pre-trained 300-dim GloVe vectors (Pennington et al., 2014) as non-trainable weights in the embedding layers. All the models were implemented using Keras and trained with Adam optimizer. We used iNNvestigate (Alber et al., 2018) to run LRP on CNN features. In particular, we used the LRP-ϵ propagation rule to stabilize the relevance scores ($\epsilon = 10^{-7}$). Finally, we used Amazon Mechanical Turk (MTurk) to collect crowdsourced responses for selecting features to disable. Each question was answered by ten workers and the answers were aggregated using majority votes or average scores depending on the question type (as explained next).

5 Exp 1: Feasibility Study

In this feasibility study, we assessed the effectiveness of word clouds as visual explanations to reveal the behavior of CNN features. We trained CNN models using small training datasets and evaluated the quality of CNN features based on responses from MTurk workers to the feature word clouds. Then we disabled features based on their average quality scores. The assumption was: if the scores of the disabled features correlated with the drop in the model predictive performance, it meant that humans could understand and accurately assess CNN features using word clouds. We used small training datasets so that the trained CNNs had features with different levels of quality. Some features detected useful patterns, while others overfitted the training data.

5.1 Datasets

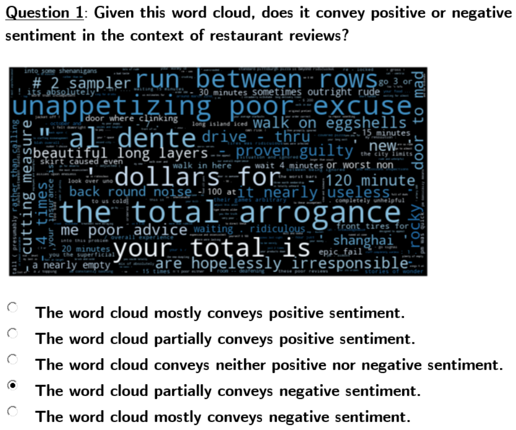
We used subsets of two datasets: *(1)* **Yelp** – predicting sentiments of restaurant reviews (positive or negative) (Zhang et al., 2015) and *(2)* **Amazon Products** – classifying product reviews into one of four categories (Clothing Shoes and Jewelry, Digital Music, Office Products, or Toys and Games) (He and McAuley, 2016). We sampled 500 and 100 examples to be the training data for Yelp and Amazon Products, respectively.

5.2 Human Feedback Collection and Usage

We used human responses on MTurk to assign ranks to features. As each classifier had 30 original features ($d = 30$), we divided them into three ranks (A, B, and C) each of which with 10 features. We expected that features in rank A are most relevant and useful for the prediction task, and features in rank C least relevant, potentially undermining the performance of the model. To make the annotation more accessible to lay users, we designed the questions to ask whether a given word cloud is (mostly or partially) relevant to one of the classes or not, as shown in Figure 3. If the answer matches how the model really uses this feature (as indicated by $\mathbf{W}$), the feature gets a positive score from this human response. For example, if the CNN feature of the word cloud in Figure 3 is used by the model for the negative sentiment class, the scores of the five options in the figure are -2, -1, 0, 1, 2, respectively. We collected ten responses for each question and used the average score to sort the features descendingly. After sorting, the 1st-10th features, 11th-20th features, and 21st-30th features are considered as rank A, B, and C, respectively.[3] To show the effects of feature disabling, we compared the original model M with the modified

---

[3] The questions and scoring criteria for the Amazon Products dataset, which is a multiclass classification task, are slightly different. See Appendix B for details.



Question 1: Given this word cloud, does it convey positive or negative sentiment in the context of restaurant reviews?

○ The word cloud mostly conveys positive sentiment.
○ The word cloud partially conveys positive sentiment.
○ The word cloud conveys neither positive nor negative sentiment.
● The word cloud partially conveys negative sentiment.
○ The word cloud mostly conveys negative sentiment.

Figure 3: A user interface in Experiment 1 (Yelp).

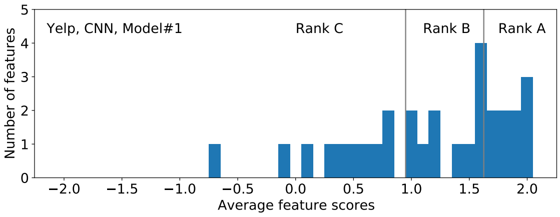


Figure 4: The distribution of average feature scores in a CNN model trained on the Yelp dataset.

model M' with features in rank X disabled where $X \in \{A, B, C, A \text{ and } B, A \text{ and } C, B \text{ and } C\}$.

5.3 Results and Discussions

Figure 4 shows the distribution of average feature scores from one of the three CNN instances for the Yelp dataset. Examples of the word clouds from each rank are displayed in Figure 5. We can clearly see dissimilar qualities of the three features. Some participants answered that the rank B feature in Figure 5 was relevant to the positive class (probably due to the word 'delicious'), and the weights of this feature in $\mathbf{W}$ agreed (Positive:Negative = 0.137:-0.135). Interestingly, the rank C feature in Figure 5 got a negative score because some participants believed that this word cloud was relevant to the positive class, but actually the model used this feature as evidence for the negative class (Positive:Negative = 0.209:0.385).

Considering all the three runs, Figure 6 (top) shows the average macro F1 score of the original model (the blue line) and of each modified model. The order of the performance drops is AB $>$ A $>$ AC $>$ BC $>$ B $>$ Original $>$ C. This makes sense because disabling important features (rank A and/or B) caused larger performance drops, and the overall results are consistent with the average feature scores given by the participants (as in Figure 4). It confirms that using word clouds is an effective way to assess CNN features. Also, it is worth noting that the macro F1 of the model slightly increased when we disabled the low-quality features (rank C). This shows that humans can improve the model by disabling irrelevant features.

Rank A - Average score = 2.0

Rank B - Average score = 1.2

Rank C - Average score = -0.7

Figure 5: Examples of word clouds of CNN features in ranks A, B, and C (Experiment 1, Yelp – sentiment).

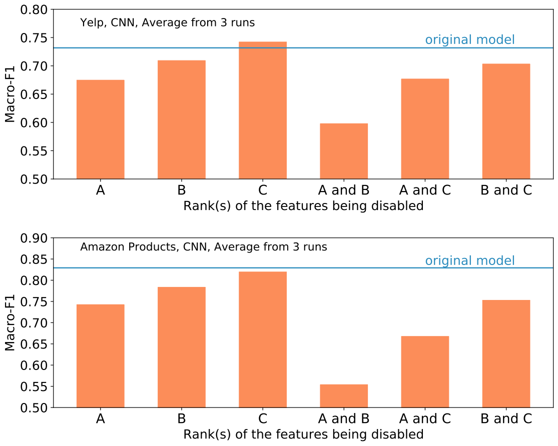

Figure 6: The average macro F1, from the three runs, of all the CNN models for the Yelp dataset (top) and the Amazon Products dataset (bottom).

The CNNs for the Amazon Products dataset also behaved in a similar way (Figure 6 – bottom), except that disabling rank C features slightly undermined, not increased, performance. This implies that even the rank C features contain a certain amount of useful knowledge for this classifier.[4]

6 Exp 2: Training Data with Biases

Given a biased training dataset, a text classifier may absorb the biases and produce biased predictions against some sub-populations. We hypothesize that if the biases are captured by some of the learned features, we can apply FIND to disable such features and reduce the model biases.

6.1 Datasets and Metrics

We focus on reducing gender bias of CNN models trained on two datasets – **Biosbias** (De-Arteaga et al., 2019) and **Waseem** (Waseem and Hovy, 2016). For Biosbias, the task is predicting the occupation of a given bio paragraph, i.e., whether the person is 'a surgeon' (class 0) or 'a nurse' (class 1). Due to the gender imbalance in each occupation, a classifier usually exploits gender information when making predictions. As a result, bios of female surgeons and male nurses are often misclassified. For Waseem, the task is abusive language detection – assessing if a given text is abusive (class 1) or not abusive (class 0). Previous work found that this dataset contains a strong negative bias against females (Park et al., 2018). In other words, texts related to females are usually classified as abusive although the texts themselves are not abusive at all. Also, we tested the models, trained on the Waseem dataset, using another abusive language detection dataset, **Wikitoxic** (Thain et al., 2017), to assess generalizability of the models. To quantify gender biases, we adopted two metrics – false positive equality difference (FPED) and false negative equality difference (FNED) (Dixon et al., 2018). The lower these metrics are, the less biases the model has.

6.2 Human Feedback Collection and Usage

Unlike the interface in Figure 3, for each word cloud, we asked the participants to select the relevant class from three options (Biosbias: surgeon, nurse, it could be either / Waseem: abusive, non-abusive, it could be either). The feature will be disabled if the majority vote does not select the class suggested by the weight matrix $\mathbf{W}$. To ensure that the participants do not use their biases while answering our questions, we firmly mentioned in the instructions that gender-related terms should not be used as an indicator for one or the other class.

6.3 Results and Discussions

The results of this experiment are displayed in Figure 7. For Biosbias, on average, the participants' responses suggested us to disable 11.33 out of 30 CNN features. By doing so, the FPED of the models decreased from 0.250 to 0.163, and the FNED decreased from 0.338 to 0.149. After investigating the word clouds of the CNN features, we found that some of them detected patterns containing both gender-related terms and occupation-related terms such as "his surgical expertise" and "she supervises nursing students". Most of the MTurk participants answered that these word clouds were relevant to the occupations, and thus the corresponding features were not disabled. However, we believe that these features might contain gender biases. So, we asked one annotator to consider all the word clouds again and disable every feature for which the prominent n-gram patterns contained any gender-related terms, no matter whether the patterns detect occupation-related terms. With this new disabling policy, 12 out of 30 features were disabled on average, and the model biases further decreased, as shown in Figure 7 (Debugged (One)). The side-effect of disabling 33% of all the features here was only a slight drop in the macro F1 from 0.950 to 0.933. Hence, our framework was successful in reducing gender biases without severe negative effects in classification performance.

Concerning the abusive language detection task, on average, the MTurk participants' responses suggested us to disable 12 out of 30 CNN features. Unlike Biosbias, disabling features based on MTurk responses unexpectedly increased the gender bias for both Waseem and Wikitoxic datasets. However, we found one similar finding to Biosbias, that many of the CNN features captured n-grams which were both abusive and related to a gender such as 'these

---

[4] We also conducted the same experiments here with bidirectional LSTM networks (BiLSTMs) which required a different way to generate the word clouds (see Appendix C). The results on BiLSTMs, however, are not as promising as on CNNs. This might be because the way we created word clouds for each BiLSTM feature was not an accurate way to reveal its behavior. Unlike for CNNs, understanding recurrent neural network features for text classification is still an open problem.

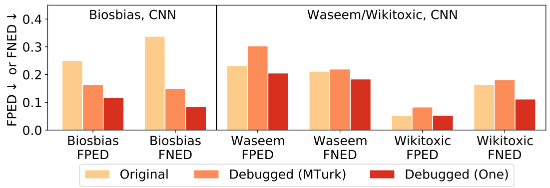

Figure 7: The average FPED and FNED of the CNN models in Experiment 2 (the lower, the better).

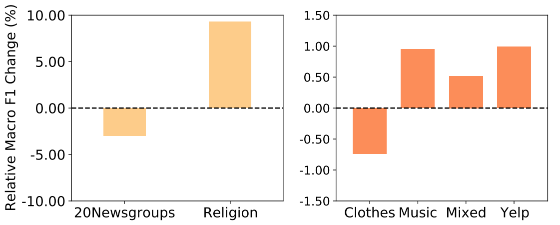

Figure 8: The relative Macro F1 changes (in %) of the CNN models for both tasks in Experiment 3.

girls are terrible' and 'of raping slave girls', and these features were not yet disabled. So, we asked one annotator to disable the features using the new "brutal" policy – disabling all which involved gender words even though some of them also detected abusive words. By disabling 18 out of 30 features on average, the gender biases were reduced for both datasets (except FPED on Wikitoxic which stayed close to the original value). Another consequence was that we sacrificed 4% and 1% macro F1 on the Waseem and Wikitoxic datasets, respectively. This finding is consistent with (Park et al., 2018) that reducing the bias and maintaining the classification performance at the same time is very challenging.

7 Exp 3: Dataset Shift

Dataset shift is a problem where the joint distribution of inputs and outputs differs between training and test stage (Quionero-Candela et al., 2009). Many classifiers perform poorly under dataset shift because some of the learned features are inapplicable (or sometimes even harmful) to classify test documents. We hypothesize that FIND is useful for investigating the learned features and disabling the overfitting ones to increase the generalizability of the model.

7.1 Datasets

We considered two tasks in this experiment. The first task aims to classify "Christianity" vs "Atheism" documents from the **20 Newsgroups** dataset[5]. This dataset is special because it contains a lot of artifacts – tokens (e.g., person names, punctuation marks) which are not relevant, but strongly co-occur with one of the classes. For evaluation, we used the **Religion** dataset by Ribeiro et al. (2016), containing "Christianity" and "Atheism" web pages, as a target dataset. The second task is sentiment analysis. We used, as a training dataset, **Amazon Clothes**, with reviews of clothing, shoes, and jewelry products (He and McAuley, 2016), and as test sets three out-of-distribution datasets – **Amazon Music** (He and McAuley, 2016), **Amazon Mixed** (Zhang et al., 2015), and the **Yelp** dataset (which was used in Experiment 1). Amazon Music contains only reviews from the "Digital Music" product category which was found to have an extreme distribution shift from the clothes category (Hendrycks et al., 2020). Amazon Mixed compiles the reviews from various kinds of products, while Yelp focuses on restaurant reviews.

7.2 Human Feedback Collection and Usage

We collected responses from MTurk workers using the same user interfaces as in Experiment 2. Simply put, we asked the workers to select a class which was relevant to a given word cloud and checked if the majority vote agreed with the weights in $\mathbf{W}$.

7.3 Results and Discussions

For the first task, on average, 14.33 out of 30 features were disabled and the macro F1 scores of the 20Newsgroups before and after debugging are 0.853 and 0.828, respectively. The same metrics of the Religion dataset are 0.731 and 0.799. This shows that disabling irrelevant features mildly undermined the predictive performance on the in-distribution dataset, but clearly enhanced the performance on the out-of-distribution dataset (see Figure 8, left). This is especially evident for the Atheism class for which the F1 score increased around 15% absolute. We noticed from the word clouds that many prominent words for the Atheism class learned by the models are person names (e.g., Keith, Gregg, Schneider) and these are not applicable to the Religion dataset. Forcing the models to use only relevant features (detecting terms like 'atheists' and 'science'), therefore, increased the macro F1 on the Religion dataset.

Unlike 20Newsgroups, Amazon Clothes does not seem to have obvious artifacts. Still, the re-

---

[5] `http://qwone.com/~jason/20Newsgroups/`

sponses from crowd workers suggested that we disable 6 features. The disabled features were correlated to, but not the reason for, the associated class. For instance, one of the disabled features was highly activated by the pattern “my .... year old” which often appeared in positive reviews such as “my 3 year old son loves this.”. However, these correlated features are not very useful for the three out-of-distribution datasets (Music, Mixed, and Yelp). Disabling them made the model focus more on the right evidence and increased the average macro F1 for the three datasets, as shown in Figure 8 (right). Nonetheless, the performance improvement here was not as apparent as in the previous task because, even without feature disabling, the majority of the features are relevant to the task and can lead the model to the correct predictions in most cases.[6]

8 Discussion and Conclusions

We proposed FIND, a framework which enables humans to debug deep text classifiers by disabling irrelevant or harmful features. Using the proposed framework on CNN text classifiers, we found that *(i)* word clouds generated by running LRP on the training data accurately revealed the behaviors of CNN features, *(ii)* some of the learned features might be more useful to the task than the others and *(iii)* disabling the irrelevant or harmful features could improve the model predictive performance and reduce unintended biases in the model.

8.1 Generalization to Other Models

In order to generalize the framework beyond CNNs, there are two questions to consider. First, what is an effective way to understand each feature? We exemplified this with two word clouds representing each BiLSTM feature in Appendix C, and we plan to experiment with advanced visualizations such as LSTMVis (Strobelt et al., 2018) in the future. Second, can we make the model features more interpretable? For example, using ReLU as activation functions in LSTM cells (instead of tanh) renders the features non-negative. So, they can be summarized using one word cloud which is more practical for debugging.

In general, the principle of FIND is understanding the features and then disabling the irrelevant ones. The process makes *visualizations* and *interpretability* more actionable. Over the past few years, we have seen rapid growth of scientific research in both topics (visualizations and interpretability) aiming to understand many emerging advanced models including the popular transformer-based models (Jo and Myaeng, 2020; Voita et al., 2019; Hoover et al., 2020). We believe that our work will inspire other researchers to foster advances in both topics towards the more tangible goal of model debugging.

8.2 Generalization to Other Tasks

FIND is suitable for any text classification tasks where a model might learn irrelevant or harmful features during training. It is also convenient to use since only the trained model and the training data are required as input. Moreover, it can address many problems simultaneously such as removing religious and racial bias together with gender bias even if we might not be aware of such problems before using FIND. In general cases, FIND is at least useful for model verification.

For future work, it would be interesting to extend FIND to other NLP tasks, e.g., question answering and natural language inference. This will require some modifications to understand how the features capture relationships between two input texts.

8.3 Limitations

Nevertheless, FIND has some limitations. First, the word clouds may reveal sensitive contents in the training data to human debuggers. Second, the more hidden features the model has, the more human effort FIND needs for debugging. For instance, BERT-base (Devlin et al., 2019) has 768 features (before the final dense layer) which require lots of human effort to perform investigation. In this case, it would be more efficient to use FIND to disable attention heads rather than individual features (Voita et al., 2019). Third, it is possible that one feature detects several patterns (Jacovi et al., 2018) and it will be difficult to disable the feature if some of the detected patterns are useful while the others are harmful. Hence, FIND would be more effective when used together with disentangled text representations (Cheng et al., 2020).

Acknowledgments

We would like to thank Nontawat Charoenphakdee and anonymous reviewers for helpful comments. Also, the first author wishes to thank the support from Anandamahidol Foundation, Thailand.

A Layer-wise Relevance Propagation

Layer-wise Relevance Propagation (LRP) is a technique for explaining predictions of neural networks in terms of importance scores of input features (Bach et al., 2015). Originally, it was devised to explain predictions of image classifiers by creating a heatmap on the input image highlighting pixels that are important for the classification. Then Arras et al. (2016) and Arras et al. (2017) extended LRP to work on CNNs and RNNs for text classification, respectively.

Consider a neuron k whose value is computed using n neurons in the previous layer,

$$x_k = g(\sum_{j=1}^{n} x_j w_{jk} + b_k)$$

where x_k is the value of the neuron k, g is a nonlinear activation function, w_{jk} and b_k are weights and bias in the network, respectively. We can see that the contribution of a single node j to the value of the node k is

$$z_{jk} = x_j w_{jk} + \frac{b_k}{n}$$

assuming that the bias term b_k is distributed equally to the n neurons. LRP works by propagating the activation of a neuron of interest back through the previous layers in the network proportionally. We call the value each neuron receives a relevance score (R) of the neuron. To back propagate, if the relevance score of the neuron k is R_k, the relevance score that the neuron j receives from the neuron k is

$$R_{j\leftarrow k} = \frac{z_{jk}}{\sum_{j'=1}^{n} z_{j'k}} R_k$$

To make the relevance propagation more stable, we add a small positive number ϵ (as a stabilizer) to the denominator of the propagation rule:

$$R_{j\leftarrow k} = \frac{z_{jk}}{\epsilon + \sum_{j'=1}^{n} z_{j'k}} R_k$$

We used this propagation rule, so called LRP-ϵ, in the experiments of this paper. For more details about LRP propagation rules, please see Montavon et al. (2019).

To explain a prediction of a CNN text classifier, we propagate an activation value of the output node back to the word embedding matrix. After that, the relevance score of an input word equals the sum of relevance scores each dimension of its word vector receives. However, in this paper, we want to analyze the hidden features rather than the output, so we start back propagating from the hidden features instead to capture patterns of input words which highly activate the features.

B Multiclass Classification

As shown in Figure 9, we used a slightly different user interface in Experiment 1 for the Amazon Products dataset which is a multiclass classification task. In this setting, we did not provide the options for mostly and partly relevant; otherwise, there would have been nine options per question which are too many for the participants to answer accurately. With the user interface in Figure 9, we gave a score to the feature f_i based on the participant answer. To explain, we re-scaled values in the i^{th} column of $\mathbf{W}$ to be in the range [0,1] using min-max normalization and gave the normalized value of the chosen class as a score to the feature f_i. If the participant selects None, this feature gets a zero score. The distribution of the average feature scores for this task (one CNN) is displayed in Figure 10.

Question 3: Given this wordcloud, please select a product category which is related to most of the text fragments in the word cloud.

○ Clothing Shoes and Jewelry
○ Digital Music
○ Office Products
● Toys and Games
○ None

Figure 9: A user interface in Experiment 1 (Amazon Products).

C Bidirectional LSTM networks

To understand BiLSTM features, we created two word clouds for each feature. The first word cloud contains top three words which gain the highest positive relevance scores from each training example, while the second word cloud does the same but for the top three words which gain the lowest negative relevance scores (see Figure 11).

Furthermore, we also conducted Experiment 1 for BiLSTMs. Each direction of the recurrent layer had 15 hidden units and the feature vector was obtained by taking element-wise max of all the hidden states (i.e., $d = 15 \times 2 = 30$). We adapted the code of (Arras et al., 2017) to run LRP on BiLSTMs. Regarding human feedback collection, we collected feedback from Amazon Mechanical Turk workers by splitting the pair of word clouds into two and asking the question about the relevant class independently of each other. The answer of the positive relevance word cloud should be consistent with the weight matrix $\mathbf{W}$, while the answer of the negative relevance word cloud should be the opposite of the weight matrix $\mathbf{W}$. The score of a BiLSTM feature is the sum of its scores from the positive word cloud and the negative word cloud.

The results of the extra BiLSTM experiments are shown in Table 4 and 5. Table 4 shows unexpected results after disabling features. For instance, disabling rank B features caused a larger performance drop than removing rank A features. This suggests that how we created word clouds for each BiLSTM feature (i.e., displaying top three words with the highest positive and lowest negative rel-

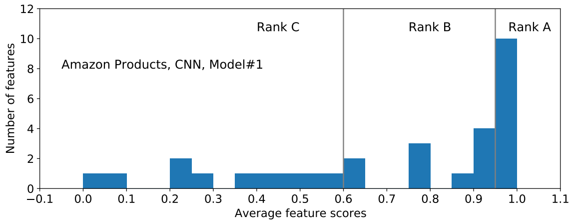

Figure 10: The distribution of average feature scores in a CNN model trained on the Amazon Products dataset.

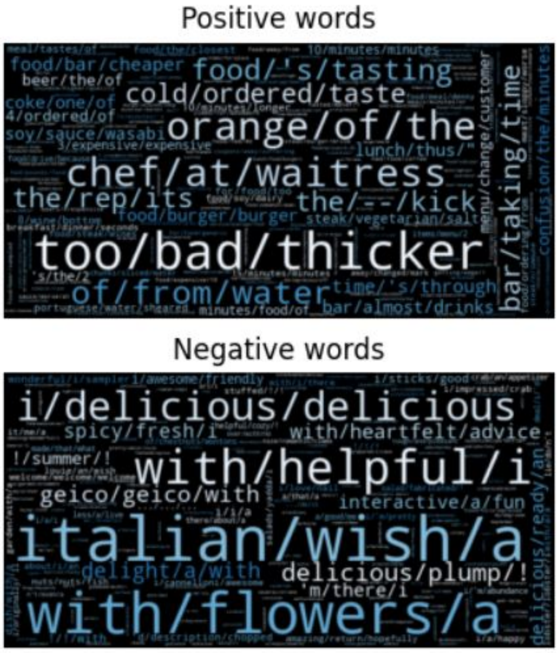

Figure 11: A pair of word clouds which represent one BiLSTM feature.

evance) might not be an accurate way to explain the feature. Nevertheless, another observation from Table 4 is that even when we disabled two-third of the BiLSTM features, the maximum macro F1 drop was less than 5%. This suggests that there is a lot of redundant information in the features of the BiLSTMs.

D Metrics for Biases

In this paper, we used two metrics to quantify biases in the models – False positive equality difference (FPED) and False negative equality difference (FNED) – with the following definitions (Dixon et al., 2018).

$$FPED = \sum_{t \in T} |FPR - FPR_t|$$

$$FNED = \sum_{t \in T} |FNR - FNR_t|$$

where T is a set of all sub-populations we consider (i.e., $T = \{\text{male}, \text{female}\}$). FPR and FNR stand for false positive rate and false negative rate, respectively. The subscript t means that we calculate the metrics using data examples mentioning the sub-population t only. We used the following keywords to identify examples which are related to or mentioning the sub-populations.

Male gender terms:

"male", "males", "boy", "boys", "man", "men", "gentleman", "gentlemen", "he", "him", "his", "himself", "brother", "son", "husband", "boyfriend", "father", "uncle", "dad"

Female gender terms:

"female", "females", "girl", "girls", "woman", "women", "lady", "ladies", "she", "her", "herself", "sister", "daughter", "wife", "girlfriend", "mother", "aunt", "mom"

E Additional Details for Reproducibility

E.1 Data Sources and Pre-processing

- **Yelp** and **Amazon Mixed**: We sampled examples from the datasets provided by Zhang et al. (2015) here[7].

- **Amazon Products**, **Amazon Clothes**, **Amazon Music**: We sampled examples from the datasets provided by He and McAuley (2016) here[8].

- **Biosbias**: We created the dataset using the code provided by De-Arteaga et al. (2019) here[9]. All the bios are from Common Crawl August 2018 Index.

- **Waseem**: The authors of (Waseem and Hovy, 2016) kindly provided the dataset to us by email. We considered "racism" and "sexism" examples as "Abusive" and "neither" examples as "Non-abusive".

- **Wikitoxic**: The dataset can be downloaded here[10]. We used only examples which were given the same label by all the annotators.

- **20Newsgroups**: We downloaded the standard splits of the dataset using scikit-learn[11]. The

E.2 Number of Model Parameters

Convolutional Neural Networks

- Fixed word embeddings: 120,000,600
- Convolutional layers: 27,030
- Final (masked) dense layer:
  - Binary classification: 62 (+60)
  - 4-class classification: 124 (+120)

Bidirectional LSTM networks

- Fixed word embeddings: 120,000,600
- Bidirectional LSTM layers: 37,920
- Final (masked) dense layer:
  - Binary classification: 62 (+60)
  - 4-class classification: 124 (+120)

E.3 Computing Infrastructure Used

- CPU: Intel Core i9-9900X (3.5GHz)
- GPU: 11GB NVIDIA GeForce RTX 2080 Ti
- RAM: 32GB Corsair Vengeance DDR4

F Full Experimental Results

Tables 2-9 in this section report the full results of all the experiments and datasets. All the results shown are averaged from three runs. Boldface numbers are the best scores in the columns. They are further underlined if they are significantly better than the scores of all the other models. We conducted the statistical significance analysis using approximate randomization test with 1,000 iterations and a significance level α of 0.05 (Noreen, 1989; Graham et al., 2014).

Abstract

A frequent pattern in customer care conversations is the agents responding with appropriate webpage URLs that address users' needs. We study the task of predicting the documents that customer care agents can use to facilitate users' needs. We also introduce a new public dataset[1] which supports the aforementioned problem. Using this dataset and two others, we investigate state-of-the-art deep learning (DL) and information retrieval (IR) models for the task. We also analyze the practicality of such systems in terms of inference time complexity. Our results show that an hybrid IR+DL approach provides the best of both worlds.

1 Introduction

Customer care (CC) agents play a crucial role as an organization's main representatives to the public. Our work is motivated by the observation that, in many conversations between CC agents and users, the former tend to provide links to documents that may help resolve user issues. This is a prevalent pattern that is found in around 5-9% of all customer care conversations in multiple domains that we have reviewed. To identify such documents, the agents manually extract the keywords from the conversation and search over their customer service knowledge base (Habibi and Popescu-Belis, 2015; Ferreira et al., 2019). Table 1 shows a conversation where the agent provides a URL[2] to the user.

Although responding with URLs is a common pattern, automating this process to aid the agents remains underexplored in the literature. This task of **Conversational Document Prediction** (*CDP*) can be viewed as a conversational search problem, where the entire conversation context or a subset of it could be used as the query for retrieving matching documents. Compared to ad-hoc retrieval settings, using a conversational interface, the agent/system can ask clarification questions and interactively modify the search results as the conversation progresses (Zhang et al., 2018; Aliannejadi et al., 2019).

Dialogue	
U:	My virtual keyboard seems to float in the screen. Not sure how to undo what I just did. Can you help me please?
A:	We're happy to help. To start, let us know which device you're working with, and the OS version installed on it.
U:	It is an iPad
A:	Ok, to check version, tap Settings; General ; About.
U:	It's iPad 4, 11 inch - model A1934
A:	Thank you. This article can help with how to merge a split keyboard and move the keyboard for an iPad: `https://support.apple.com/en-us/HT207521`. Let me know if this helps

Table 1: Sample dialog from Twitter where the Agent (**A**) utterance includes a URL to the User (**U**) query.

The CDP task has been primarily addressed so far using "traditional" information retrieval (IR) techniques. Habibi and Popescu-Belis (2015) proposed a document recommender system by extracting keywords from a conversation using topic modeling techniques. Ferreira et al. (2019) have used a similar keyword extraction framework and reported their results on a proprietary dataset.

Many aspects of IR systems have undergone a revolution with the advent of powerful Deep Learning (DL) techniques in recent years (Mitra et al., 2018; Yang et al., 2019). Yet this superior performance comes with high demand in computational resources as well as longer inference times, which hinders their application in real-world IR systems. Thus, the attention has been focused on techniques that reduce the computation complexity at the runtime without hindering the performance (Reimers and Gurevych, 2019; Lu et al., 2020).

Table 2: The overall statistics of the three datasets.

In this work, we formulate the CDP task to support CC agents. We further release a new public dataset which enables research on the aforementioned task and investigate the performance of state-of-the art DL and IR models side-by-side on a number of datasets. We also analyze the runtime complexity of such systems, and propose a hybrid solution which is applicable in real-life systems.

2 Data

We explore the CDP task using three datasets which contain human-to-human conversations between users and CC agents. Two of these datasets are internal: one from an internal customer support service on Mac devices (*Mac-Support*) and another from an external client in the telecommunication domain (*Telco-Support*). We also release a new *Twitter* dataset, containing conversations between users and CC agents in 25 organizations on the Twitter platform[3]. We summarize the statistics of the three datasets in Table 2.

For our internal datasets, we filter out dialogs where: a) the agent doesn't provide a URL to the user, b) the URL is not in-domain (e.g. Google searches, Microsoft forums, etc.), and focus on URLs from internal customer service knowledge base, and c) the URL is either no longer valid or has no content (e.g., login page). For Twitter dataset, we used the user_timeline API to collect the tweets from agents containing in-domain URLs. The dialogs were constructed starting from these tweets and identifying the previous user and agent tweets to these tweets. If a dialog contains multiple URLs, we only use the dialog till the first agent utterance containing a URL. The details for document content extraction are in Appendix.

From Table 2, we observe that, around 5-9% dialogs include a URL document provided by the agent. We also note that the website content for organizations gets updated frequently as many URLs return 404 errors. The average number of turns in a dialog and dialog length (in tokens) is much smaller for *Twitter* in comparison to the *Mac-Support* and *Telco-Support* datasets. Our experiments results in Section 4, particularly BM25 and IRC in Table 4, demonstrate the importance of dialog context for the CDP task, even when that context is not very rich, as is the case for the short dialogs of Twitter.

3 Approaches

We now formally introduce the CDP task and notations below. We then describe two alternative approaches (IR and DL) and their hybrid that we evaluate for this task.

3.1 Task Definition

We regard the CDP task as a dialogue-based document classification task, similar to next utterance classification (Lowe et al., 2015). This is achieved by processing the data as described in Section 3.3, without requiring any human labels.

Formally, let $d = \{s_1\colon t_1, s_2\colon t_2, \ldots, s_n\colon t_n\}$ denote an n-turn dialog, where s_i represents the speaker (*user* - *U* or *agent* - *A*), and t_i represents the i^{th} utterance. The dialog history is concatenated together to form dialog context of length m, represented as $d = (d_1, d_2, ..., d_i, ..., d_m)$, where d_i is the i^{th} word in context. Let Y denote the set of all documents which can be recommended to the user. Similar to dialogs, each document $y \in Y$ is represented as $y = (y_1, y_2, ..., y_j, ..., y_n)$, where y_j is the j^{th} word in the document. Given dialog query d, the goal of the CDP task is to recommend k documents in Y to the agent. For evaluation, we use Recall@k and Mean Reciprocal Rank, where the model is asked to select the k most likely documents, and it is correct if the correct URL document is among these k documents.

---

[3] The Twitter dataset is available at: `https://github.com/IBM/twitter-customer-care-document-prediction`

3.2 Information Retrieval approaches

Following previous works, the first approach we evaluate for this task is based on IR models. We use an Apache Lucene index, employed with English language analyzer and default BM25 similarity (Robertson and Zaragoza, 2009). Documents in the index are represented using two fields. The first field contains the actual document content. The second field augments the document's representation with the text of all dialogs that link to it in the train-set (Amitay et al., 2005).

For a given (dialog) query d, matching documents are retrieved using four different ranking steps, which are combined using a cascade approach (Wang et al., 2011). Following (Van Gysel et al., 2016), we obtain an initial pool of candidate documents using a lexical query aggregation approach. To this end, each utterance $t_i \in d$ is represented as a separate weighted query-clause, having its weight assigned relatively to its sequence position in the dialog (Van Gysel et al., 2016). Various sub-queries are then combined using a single disjunctive query. The second ranker evaluates each document y obtained by the first ranker against an expanded query (applying relevance model (Lavrenko and Croft, 2001)). The third ranker applies a manifold-ranking approach (Xu et al., 2011), aiming to score content-similar documents (measured by Bhattacharyya language-model based similarity) with similar scores.

The last ranker in the cascade treats the dialog query d as a verbose query and applies the *Fixed-Point* (FP) method (Paik and Oard, 2014) for weighting its words. Yet, compared to "traditional" verbose queries, dialogs are further segmented into distinct utterances. Using this observation, we implement an *utterance-biased* extension for enhanced word-weighting. To this end, we first score the various utterances based on the initial FP weights of words they contain and their relative position. We then propagate utterance scores back to their associated words. The IR model is denoted as *IRC*, short for *IR-Cascade* in Table 4.

3.3 Neural approaches

The second type of approaches we evaluate are neural models. We process the datasets to construct triples of <dialog context (d), URL document content (y), label ($1/0$)>from each dialog. For each d, we create a set of $k+1$ triples: one triple containing the correct URL provided by the agent (label - 1), and k triples containing incorrect URLs randomly sampled from Y (label - 0). We explore different values for k and share additional results in Appendix. During evaluation, we evaluate a given dialog context against the set of all documents (Y).

We evaluate the CDP task using three state-of-the-art neural models: *Enhanced Sequential Inference Model* (ESIM) proposed by Chen et al. (2017) which performs well on Natural Language Inference (NLI) and next utterance prediction tasks (Dong and Huang, 2018), *BertForSequenceClassification* model (Wolf et al., 2019) and *SBERT*. We next briefly describe the details for these models.

3.3.1 ESIM

The ESIM model takes two input sequences: dialog context (d) and document content (y), and feeds them through BiLSTM to generate local context-aware word representations denoted by $\bar{d}$ and $\bar{y}$. A co-attention matrix E, where $E_{ij} = \bar{d}_i^T \bar{y}_j$, computes the similarity between d and y. The attended dialog context and document content vectors denoted by $\tilde{d}$ and $\tilde{y}$ are computed using E, which represent the most relevant word in y's content for each word in d's context and vice-versa.

This local inference information is enhanced by computing the difference and the element-wise product for the tuple $<\bar{d}, \tilde{d}>$ as well as for $<\bar{y}, \tilde{y}>$. The difference and element-wise product are then concatenated with the original vectors, $\bar{d}$ and $\tilde{d}$ or $\bar{y}$ and $\tilde{y}$ respectively. The concatenated vectors are then fed to another set of BiLSTMs to compose the overall inference between the two sequences. Finally, the result vectors are converted to a fixed-length vector by max pooling and fed to a final classifier.

3.3.2 BERT

We use pre-trained BERT (Devlin et al., 2019) in two settings: a) fine-tuned on the training set, and b) an additional pre-training step on unlabeled data (dialogs in the training set and all documents) followed by fine-tuning on the training set (denoted as BERT* in Table 4). In both settings, evaluation is done on the test set.

We utilize the binary classifier (*BertForSequenceClassification*) of BERT, commonly used for GLUE tasks (Wang et al., 2018) as follows. A dialog context d and a document y are fed together to BERT as a sequence ([CLS] d [SEP] y [SEP]). To adapt to BERT's limitation of maximum sequence length, we use 512 tokens and feed BERT

Model	# param.	Inf. time (sec.)
BM25	2	0.02
IRC	12	0.03
ESIM	3.7M	2.37
BERT(*)	110M	0.95
SBERT(*)	110M	0.04

Table 3: Inference time for a single query from Twitter test set on a V100-PCIE-32GB GPU

with the 256 tokens each from d and y, decided by a heuristic explained in Appendix. We use the hidden state of the [CLS] token as the representation of the pair. Training is done using positive and negative examples (Sec. 3.3) with cross-entropy loss. Re-ranking of candidate documents $\{y \in Y\}$ for a given context d is done through the confidence score of each pair (d,y) which belongs to the positive class.

3.3.3 Sentence-BERT (SBERT)

We also explore SBERT (Reimers and Gurevych, 2019), which uses a Siamese network structure to fine-tune the pre-trained BERT network and derive semantically meaningful sentence embeddings. The sentence embeddings for d and y are derived by adding a pooling operation (default: mean) on the BERT outputs and then can be compared using cosine-similarity to achieve low inference time. We fine-tune SBERT in the same two settings as BERT mentioned above. The input handling and evaluation is same as BERT above. The fine-tuning and hyperparameter details are available in Appendix.

3.4 An hybrid approach

To investigate the real-world use of our approaches, we compare (in Table 3) the number of parameters of each model and inference time for a single query from the Twitter test set. The IRC model is much faster in comparison to the neural models. For incorporating the additional performance gain from neural models (in Table 4), we introduce an hybrid approach by a two-stage pipeline where we utilize the IRC model to generate a ranking of the document pool Y. The top-k documents (k : 20) are then re-ranked through ESIM and recommended to the CC agent. This hybrid approach (IRC+ESIM) combines the best of both worlds.

4 Results and Analysis

Results are presented in Table 4. We provide training setting and hyperparameter details for all neural models in Appendix. We observe that the ESIM model performs best across all datasets and the IRC model performs comparably to the ESIM model except for Telco-Support dataset. We observe a significant performance reduction with BERT models in comparison to both IRC and ESIM models. The BERT* model (additional pre-training) improves performance for Telco-Support dataset, but is still inferior to ESIM model. The SBERT models provide the benefit of low inference time, but reduce performance further. We conclude that for CDP task, explicit cross-attention between dialog context d and document y present in ESIM is crucial. The BERT models try to incorporate cross-attention through self-attention on the concatenated $<d, y>$ pair sequence, but still lag behind.

Model	**R@1**	**R@2**	**R@5**	**R@10**

SBERT	0.182	0.246	0.354	0.442
SBERT*	0.224	0.308	0.484	0.644
IRC+ESIM	**0.559**	**0.684**	**0.819**	**0.902**

Table 4: Performance of models on the test set of three datasets. R@k refers to Recall at position k. MRR and corresponding validation results are in Appendix.

Finally, the hybrid approach (IRC+ESIM) provides a significant boost in performance (e.g., between +7%-20% in R@1), and reduces the inference time of ESIM. This demonstrates the benefit and importance of combining IR models that are based on exact matching, with neural models that further allow semantic inference in the domain for real-world applications.

5 Conclusion and Future Work

We introduced the Conversational Document Prediction (CDP) task and investigated the performance of state-of-the-art DL and IR models. We also release a new public Twitter dataset on the CDP task. In this work, we considered only URL documents with content. Other potential document types that could be considered are PDFs, doc etc. and URLs without content (e.g. login, tracking). We plan to address these challenges in future work.

A Appendix: Additional results

The results for corresponding validation performance for Information Retrieval and Neural approaches, as well as Mean Reciprocal Rank (MRR) metric for both validation and test sets on all datasets are available in Table 7.

A.1 Negative samples for neural approaches

For creating training data for our neural approaches, we create k triples containing incorrect URLs sampled randomly from set of all documents. We experimented with different values for the hyperparameter *num_negative_samples* used for generating the training data. The results for ESIM model for the Mac-Support dataset are presented in Table 5. We observe that increasing the number of negative samples doesn't improve the ESIM model performance significantly and *num_negative_samples - 4* provides us the best of both worlds, i.e. good performance and lower training time, in comparison to using a higher negative sample ratio. We use the same value for all neural models for all datasets.

A.2 Input handling for BERT models

To handle the BERT model input limitation of 512 tokens max sequence length, we feed BERT with 256 tokens each from dialog context d and document content y. We observe that the initial sentences in a URL document always capture the core gist of the document, so we always use the first 256 tokens from the document content. For dialog context, we observe that as the conversation progresses over multiple turns and the user query gets more complex, the conversation shifts from the original query to another problem in many dialogs. We explore two input approaches for deciding which tokens to consider if dialog context sequence length $|d| > 256$:

1. Input-A: Truncate the dialog context d to consider only the first 256 tokens from the dialog context.
2. Input-B: Ignore tokens in the middle of dialog context sequence to reduce the $|d|$ to 256.

The results for both approaches for BERT model on the Telco-Support dataset are in Table 6. We use the same heuristic for all neural models for all datasets.

negative samples	R@1	R@2	R@5	R@10	MRR
4	0.417	0.535	0.676	0.745	0.534

B Appendix: Model Training and Hyperparameter Details

B.1 ESIM model

We used 300-dimensional Glove pre-trained vectors (Pennington et al., 2014), 100-dimensional word2vec vectors (Mikolov et al., 2013) and 80-dimensional character embedding vectors for generating the word representation. For training word2vec vectors, we use the `gensim` API with the following hyper-parameters: size=100, window=10, min_count=1 and epochs=20. We also incorporate character embeddings to our ESIM implementation (Dong and Huang, 2018). The final prediction layer is a 2-layer fully-connected feed-forward neural network with ReLu activation. We use sigmoid function and minimize binary cross-entropy loss for training and updating the model. We used Adam (Kingma and Ba, 2014) with a learning rate of 0.001 and exponential decay with a decay rate of 0.96 decayed every 5000 steps. The number of hidden units for BiLSTMs was 256. For the prediction layers, we used 256 hidden units with ReLU activation.

B.2 Additional pretraining for BERT model

We use the BERT-Base, Uncased model from BERT-Base-Uncased - 12-layer, 768-hidden, 12-heads, 110M parameters - as the base model for our experiments. For convenience, we refer to BERT-Base-Uncased as $BERT below. We use the code from Google-Research Bert Github for creating pretraining data as well as to run additional pretraining on our domain data. We only use the training dialogs and contents from all documents for creating pretraining data. The hyperparameters used for creating pretraining data are:

```
vocab_file=$BERT/vocab.txt
do_lower_case=True
max_seq_length=512
max_predictions_per_seq=20
masked_lm_prob=0.15
```

```
random_seed=12345
dupe_factor=10
```

The hyperparameters used to run LM-pretraining are:

```
train_batch_size=16
max_seq_length=512
max_predictions_per_seq=20
num_train_steps=100000
num_warmup_steps=10000
save_checkpoints_steps=20000
learning_rate=5e-5
```

B.3 Fine-tuning BERT model

The hyperparameters used for further fine-tuning BERT model are:

```
do_lower_case=True
max_seq_length=512
per_gpu_eval_batch_size=24
per_gpu_train_batch_size=24
learning_rate=2e-5
num_train_epochs=5
```

The model is periodically evaluated on the validation set after n steps, which is decided based on the training dataset size.

B.4 Fine-tuning SBERT model

The hyperparameters used for fine-tuning SBERT model are:

```
do_lower_case=True
max_seq_length=256
batch_size=16
learning_rate=2e-5
num_train_epochs=5
optimizer=Adam
```

We use a linear learning rate warm-up over 10% of the training data. We fine-tune SBERT with a 3-way softmax-classifier objective function and the default pooling strategy is MEAN. The max_seq_length is 256 each for dialog context d and document content y. For SBERT*, we use the same additional pre-trained BERT* model from before. The model is periodically evaluated on the validation set after n steps, which is decided based on the training dataset size.

C Appendix: Extracting content from URL documents

For the internal Mac-Support dataset, the document content for each URL was obtained by API calls to the customer service knowledge base. For the Telco-Support and Twitter datasets, we capture the HTML content using a Selenium Chrome webdriver, which renders the URL document by loading all CSS styling and Javascript. The extracted HTML was cleaned through a Markdown generation pipeline, where we manually identify and filter the DOM tags (using CSS id and/or class) which correspond to header(s), footer, navigation bars etc. This process is repeated for each URL domain in both datasets. The tools for data preprocessing are available here: `https://github.com/IBM/MDfromHTML`.

Incremental Processing in the Age of Non-Incremental Encoders: An Empirical Assessment of Bidirectional Models for Incremental NLU

Brielen Madureira **David Schlangen**

`{madureiralasota, david.schlangen}@uni-potsdam.de`

Abstract

While humans process language incrementally, the best language encoders currently used in NLP do not. Both bidirectional LSTMs and Transformers assume that the sequence that is to be encoded is available in full, to be processed either forwards and backwards (BiLSTMs) or as a whole (Transformers). We investigate how they behave under incremental interfaces, when partial output must be provided based on partial input seen up to a certain time step, which may happen in interactive systems. We test five models on various NLU datasets and compare their performance using three incremental evaluation metrics. The results support the possibility of using bidirectional encoders in incremental mode while retaining most of their non-incremental quality. The "omni-directional" BERT model, which achieves better non-incremental performance, is impacted more by the incremental access. This can be alleviated by adapting the training regime (truncated training), or the testing procedure, by delaying the output until some right context is available or by incorporating hypothetical right contexts generated by a language model like GPT-2.

1 Introduction

In "The Story of Your Life", a science fiction short story by Ted Chiang (2002), Earth is visited by alien creatures whose writing system does not unfold in time but rather presents full thoughts instantaneously. In our world, however, language *does* unfold over time, both in speaking and in writing. There is ample evidence (Marslen-Wilson, 1975; Tanenhaus and Brown-Schmidt, 2008, *inter alia*) that it is also *processed* over time by humans, in an incremental fashion where the interpretation of a full utterance is continuously built up while the utterance is being perceived.

In Computational Linguistics and Natural Language Processing, this property is typically abstracted away by assuming that the unit to be processed (*e.g.*, a sentence) is available as a whole.[1] The return and subsequent mainstreaming of Recurrent Neural Networks (RNNs), originally introduced by Elman (1990) and repopularized *i.a.* by Mikolov et al. (2010), may have made it seem that time had found a place as a first-class citizen in NLP. However, it was quickly discovered that certain technical issues of this type of model could be overcome, for example in the application of machine translation, by encoding input sequences in reverse temporal order (Sutskever et al., 2014).

This turns out to be a special case of the more general strategy of bidirectional processing, proposed earlier in the form of BiRNNs (Schuster and Paliwal, 1997; Baldi et al., 1999) and BiLSTMs (Hochreiter and Schmidhuber, 1997), which combine a forward and a backward pass over a sequence. More recently, Transformers (Vaswani et al., 2017) also function with representations that inherently have no notion of linear order. Atemporal processing has thus become the standard again.

In this paper, we explore whether we can adapt such bidirectional models to work in incremental processing mode and what the performance cost is of doing so. We first go back and reproduce the work of Huang et al. (2015), who compare the performance of LSTMs and BiLSTMs in sequence tagging, extending it with a BERT-based encoder and with a collection of different datasets for tagging and classification tasks. Then we address the following questions:

---

[1] An exception is the field of research on interactive systems, where it has been shown that incremental processing can lead to preferable timing behavior (Aist et al., 2007; Skantze and Schlangen, 2009) and work on incremental processing is ongoing (Žilka and Jurčíček, 2015; Trinh et al., 2018; Coman et al., 2019, *inter alia*).

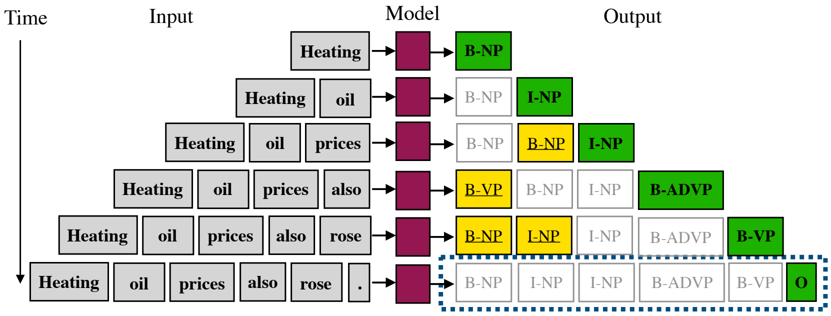

Figure 1: Incremental interface on a bidirectional tagging model (here for chunking). Each line represents the input and output at a time step. Necessary additions are green/bold, substitutions are yellow/underlined, and the dashed frame shows the output of the final time step, which is the same as the non-incremental model's.

Q1. If we employ inherently non-incremental models in an incremental system, do we get functional representations that are adequate to build correct and stable output along the way? We examine how bidirectional encoders behave under an incremental interface, revisiting the approach proposed by Beuck et al. (2011) for POS taggers. After standard training, we modify the testing procedure by allowing the system to see only successively extended prefixes of the input available so far with which they must produce successively extended prefixes of the output, as shown in Figure 1. The evaluation metrics are described in Section 3, and the discussion is anchored on the concepts of timeliness, monotonicity, and decisiveness and their trade-off with respect to the non-incremental quality (Beuck et al., 2011; Köhn, 2018). We show that it is possible to use them as components of an incremental system (*e.g.* for NLU) with some trade-offs.

Q2. How can we adapt the training regime or the real-time procedure to mitigate the negative effect that the non-availability of right context (i.e., future parts of the signal) has on non-incremental models? To tackle this question, we implement three strategies that help improve the models' incremental quality: *truncated training*, *delayed output* and *prophecies* (see Section 4).

Our results are relevant for incremental Natural Language Understanding, needed for the design of dialogue systems and more generally interactive systems, *e.g.* those following the incremental processing model proposed by Schlangen and Skantze (2011). These systems rely on the availability of partial results, on which fast decisions can be based. Similarly, simultaneous translation is an area where decisions need to be based on partial input with incomplete syntactical and semantic information.

2 Related Work

2.1 Bidirectionality

Language is one of the cognitive abilities that have a temporal nature. The inaugural adoption of RNNs (Elman, 1990) in NLP showed a pursuit to provide connectionist models with a dynamic memory in order to incorporate time implicitly, not as a dimension but through its effects on processing. Since then, the field has witnessed the emergence of a miscellany of neural architectures that take the temporal structure of language into account. In particular, LSTMs (Hochreiter and Schmidhuber, 1997) have been vastly used for sequence-to-sequence or sequence classification tasks, which are ubiquitous in NLP.

Bidirectional LSTMs (Schuster and Paliwal, 1997; Baldi et al., 1999) are an extension to LSTMs that exploit bidirectionality and whose basic processing units are full sentences. They achieved remarkable results in many tasks, *e.g.* part-of-speech tagging (Ling et al., 2015; Plank et al., 2016), chunking (Zhai et al., 2017), named entity recognition (Chiu and Nichols, 2016), semantic role labeling (He et al., 2017), slot filling and intent detection (E et al., 2019) and opinion mining (İrsoy and Cardie, 2014). Subsequent works have confirmed that bidirectionality can afford an increase in performance (Graves and Schmidhuber, 2005; Huang et al., 2015; Zhai et al., 2017).

More recently, Vaswani et al. (2017) has consolidated the application of attention mechanisms on NLP tasks with Transformers, which are not constrained by only two directions, as BiLSTMs. Instead, complete sentences are accessed at once. The need for NLP neural networks to be grounded on robust language models and reliable word representations has become clear. The full right and left context of words started to play a major role as in Peters et al. (2018), which resorts to bidirectionality to train a language model. In a combination of bidirectional word representations with the Transformer architecture, we observe the establishment of BERT (Devlin et al., 2019) as a current state-of-the-art model, on top of which an output layer can be added to solve classification and tagging tasks.

2.2 Incremental processing

The motivation to build incremental processors, as defined by Kempen and Hoenkamp (1982) and Levelt (1989), is twofold: they are more cognitively plausible and, from the viewpoint of engineering, real-time applications such as parsing (Nivre, 2004), SRL (Konstas et al., 2014), NLU (Peldszus et al., 2012), dialog state tracking (Trinh et al., 2018), NLG and speech synthesis (Buschmeier et al., 2012) and ASR (Selfridge et al., 2011) require that the input be continually evaluated based on incoming prefixes while the output is being produced and updated.

Another advantage is a better use of computational resources, as a module does not have to wait for the completion of another one to start processing (Skantze and Schlangen, 2009). In robots, linguistic processing must also be intertwined with its perceptions and actions, happening simultaneously (Brick and Scheutz, 2007).

Research on processing and generating language incrementally has been done long before the current wave of neural network models, using several different methods. For example, in ASR, a common strategy has been to process the input incrementally to produce some initial output, which was then re-scored or re-processed with a more complex model (Vergyri et al., 2003; Hwang et al., 2009). While the recent accomplishments of neural encoders are cherished, bidirectional encoders drift apart from a desirable temporal incremental approach because they are trained to learn from complete sequences.

There is some cognitive resemblance underlying RNNs in the sense that they can process sequences word-by-word and build intermediary representations at every time step. This feature provides a legitimate way to employ them in incremental systems. Trinh et al. (2018) and Žilka and Jurčíček (2015) explore this, for instance, using the LSTM's representations to predict dialogue states after each word. Recent works on simultaneous translation also use RNNs as incremental decoders (Dalvi et al., 2018).

Some works arouse interest in the incremental abilities of RNNs. Hupkes et al. (2018) use a diagnostic classifier to analyze the representations that are incrementally built by sequence-to-sequence models in disfluency detection and conclude that the semantic information is only kept encoded for a few steps after it appears in the dialogue, being soon forgotten afterwards. Ulmer et al. (2019) propose three metrics to assess the incremental encoding abilities of LSTMs and compare it with the addition of attention mechanisms.

According to Beuck et al. (2011) and Schlangen and Skantze (2011), incrementality is not a binary feature. Besides using inherently incremental algorithms, it is also possible to provide incremental *interfaces* to non-incremental algorithms. Such interfaces simply feed ever-increasing prefixes to what remains a non-incremental algorithm, providing some "housekeeping" to manage the potentially non-monotonic results.

To alleviate the effect of the partiality of the input, we test the use of anticipated continuations, inspired by the mechanism of predictive processing discussed in cognitive science (Christiansen and Chater, 2016) and the idea of interactive utterance completion introduced by DeVault et al. (2011). Related strategies to predict upcoming content and to wait for more right context are also applied in recent work on simultaneous translation (Grissom II et al., 2014; Oda et al., 2015; Ma et al., 2019). The use of truncated inputs during training, discussed below, aims at making intermediate structures available during learning, an issue discussed in Köhn (2018). This is a variation of chunked training used in Dalvi et al. (2018).

3 Evaluation of incremental processors

The hierarchical nature of language makes it likely that incremental processing leads to non-monotonic output due to re-analysis, as in the well-known "garden path" sentences. Incremental systems may edit the output by adding, revoking, and substituting its parts (Baumann et al., 2011). We expect an incremental system to produce accurate output as soon as possible (Trinh et al., 2018), with a minimum amount of revocations and substitutions, ideally only having correct additions, to avoid jittering that may be detrimental to subsequent processors working on partial outputs.

To assess the incremental behavior of sequence tagging and classification models, we use the evaluation metrics for incremental processors established by Schlangen et al. (2009) and Baumann et al. (2011). The latter defines three diachronic metrics: *edit overhead* (EO $\in [0, 1]$), the proportion of unnecessary edits (the closer to 0, the fewer edits were made); *correction time* (CT $\in [0, 1]$), the fraction of the utterance seen before the system commits on a final decision for a piece of the output (the closer to 0, the sooner final decisions were made); and *relative correctness* (RC $\in [0, 1]$), the proportion of outputs that are correct with respect to the non-incremental output (being close to 1 means the system outputs were most of the time correct prefixes of the non-incremental output).

The sequence tagging tasks we evaluate are massively incremental (Hildebrandt et al., 1999), meaning that a new label is always added to the output after a new word is processed. The models can also substitute any previous labels in the output sequence in the light of new input. Sequence classifiers must add one label (the sequence's class) after seeing the first word and can only substitute that single label after each new word. In both cases, additions are obligatory and substitutions should ideally be kept as low as possible, but there can be no revocations. Moreover, our data is sequential, discrete, and order-preserving (Köhn, 2018).

Given a sequence of length n, the number of necessary edits is always the number of tokens in the sequence (all additions) for sequence taggers and we set it to 1 for sequence classifiers. All other edits (substitutions) count as unnecessary and their number is bounded by $\sum_{i=1}^{n-1} i$ for tagging, and by $(n-1)$, for classification.

We need to slightly adapt the CT measure for sequences. It is originally defined as FD-F0, the time step of a final decision minus the time step when the output first appeared. F0 is fixed for every word in a sequence (the systems always output a new label corresponding to each new word it sees), but each label will have a different FD. In order not to penalize initial labels, which have more opportunities of being substituted than final ones, we instead sum the FD of each token and divide by the sum of the number of times each one could be modified, to get a score for the sequence as a whole. Let the sequence length be n, then here CTscore $= (\sum_{i=1}^{n} FD_i)/(\sum_{i=1}^{n} n - i)$. We define it to be 0 for sequences of one token. Again, 0 means every label is immediately committed, 1 means all final decisions are delayed until the last time step. Figure 2 presents a concrete example of how to estimate the metrics.

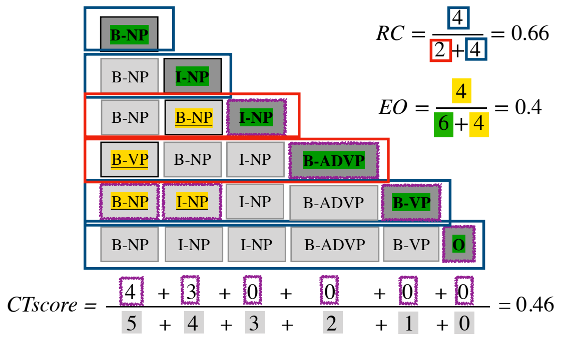

Figure 2: How we estimate the evaluation metrics for the complete sequence of outputs from Figure 1.

Based on the trade-off between responsiveness and output quality (Skantze and Schlangen, 2009), we also estimate whether there is any improvement in the quality of the outputs if the encoder waits for some right context to appear before committing on output previously generated. For that, we use delayed EO and delayed RC (also named *discounted* in Baumann et al., 2011), which allows one or two words of the right context to be observed before outputting previous labels, named EO/RCΔ1 and EO/RCΔ2, respectively.

In order to concentrate on the incremental quality despite the eventual non-incremental deficiencies, we follow the approach by Baumann et al. (2011) and evaluate intermediate outputs in comparison to the processor's final output, which may differ from the gold output but is the same as the non-incremental output. The general non-incremental correctness should be guaranteed by having high accuracy or F1 score in the non-incremental performance.

4 Models

We test the behavior of five neural networks, illustrated in Figure 3, under an incremental processing interface operating on word level and having full sentences as processing units: a) a vanilla LSTM; b) a vanilla BiLSTM; c) an LSTM with a CRF (Conditional Random Field) layer; d) a BiLSTM with a CRF layer; and e) BERT. The vanilla LSTM is the only model that works solely in temporal direction.

We choose to use the basic forms of each model to isolate the effect of bidirectionality. They per-

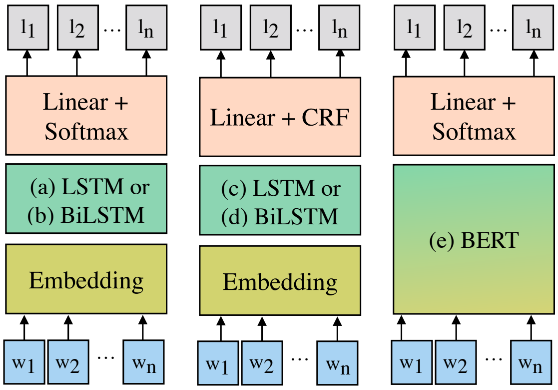

Figure 3: Models for sequence tagging, w=word and l=label. (a) is the only inherently incremental. (a), (b) and (e) can also be used for sequence classification if we consider only their final representation.

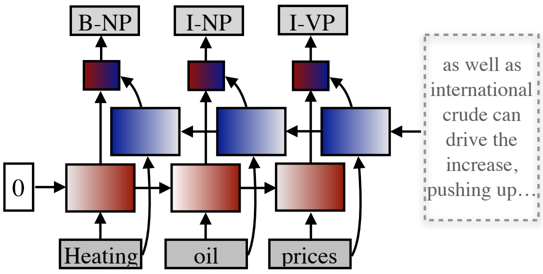

Figure 4: Incremental interface of a non-incremental bidirectional model, showing the input and output at time step 3. The context vector fed into the backward LSTM can be zero or initialized with a hypothetical right context generated by a language model.

form well enough on the tasks to enable a realistic evaluation (see Table 1). Note that state-of-the-art results are typically achieved by combining them with more sophisticated mechanisms.

We use the models for both sequence tagging and classification. They use the representation at each time step to predict a corresponding label for sentence tagging, whereas for sequence classification they use the representation of the last time step (LSTM) or a combination of the last forward and backward representations (BiLSTM) or, in case of BERT, the representation at the CLS (initial) token, as suggested in Devlin et al. (2019). The two models with CRF cannot be used for classification, as there are no transition probabilities to estimate.

Sequence tagging implies a one-to-one mapping from words to labels, so that for every new word the system receives, it outputs a sequence with one extra label. In sequence classification, we map every input to a single label. In that case, the LSTM can also edit the output since it can change the chosen label as it processes more information. Because the datasets we use are tokenized and each token has a corresponding label, we follow the instructions given by Devlin et al. (2019) for dealing with BERT's subtokenization: the scores of the first subtoken are used to predict its label, and further subtoken scores are ignored.

Except for the LSTM on sequence tagging, all models' outputs are non-monotonic, i.e., they may reassign labels from previous words. The concept of timeliness is trivial here because we know exactly that the label for the *t*-th word will appear for the first time at the *t*-th version of the output, for all *t*. Even so, we can delay the output to allow some lookahead. In terms of decisiveness, all models commit to a single output at every time step. Figure 4 shows an example of the computation graph. BiLSTMs can recompute only the backward pass, while BERT needs a complete recomputation.

4.1 Strategies

We check the effect of three strategies: *truncated training*, *delayed output* and *prophecies*. In the first case, we modify the training regime by stripping off the endings of each sentence in the training set. We randomly sample a maximum length $l \leq n$, where n is the original sentence length, and cut the subsequent words and labels. We expect this to encourage the model to know how to deal with truncated sequences that it will have to process during testing.

The second strategy involves allowing some upcoming words to be observed before outputting a label corresponding to previous words. This is a case of lookahead described in Baumann et al. (2011), where the processor is allowed to wait for some right context before making a first decision with respect to previous time steps. We experiment with right contexts of one or two words, $\Delta 1$ and $\Delta 2$, respectively. $\Delta 1$ means the model outputs the first label for word t once it consumes word $t+1$. Analogously, $\Delta 2$ means the model can observe words $t+1$ and $t+2$ before outputting the first label for word t. Figure 5 illustrates how to calculate EO with $\Delta 1$ delay for the same example as in Figure 2.

In the third strategy, we first feed each prefix as left context in the GPT-2 language model and let it generate a continuation up to the end of a sentence

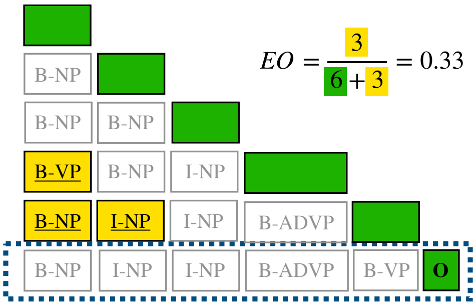

Figure 5: Example of the calculation of Edit Overhead with Δ1 delay for the example in Figure 2. The first choice for each label happens once the subsequent word has been observed, except for the last token in the sentence.

to create a hypothetical full context that meets the needs of the non-incremental nature of the models (see Figure 6 for an example). Not surprisingly, the mean BLEU scores of the prophecies with respect to the real continuation of the sentences are less than 0.004 for all datasets.[2]

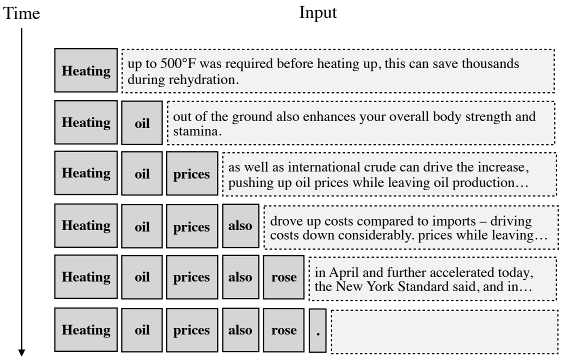

Figure 6: Input throughout time steps using hypothetical right contexts generated by GPT-2, providing a full sequence for the backward direction.

5 Experiments

5.1 Data

We examine the incremental evaluation metrics on ten datasets in English, six for sequence tagging: chunking (Sang et al., 2000), slot filling (Hemphill et al., 1990; Coucke et al., 2018, ATIS and SNIPS, respectively), named entity recognition, part-of-speech tagging and semantic role labeling (Weischedel et al., 2013); and four for sentence classification: intent (Hemphill et al., 1990; Coucke et al., 2018, ATIS and SNIPS, respectively) and sentiment (Kotzias et al., 2015; Ganapathibhotla and Liu, 2008, positive/negative and pros/cons, respectively).

Chunking, NER, SRL, and slot filling use the BIO labeling scheme and are evaluated using the F1 score adapted for sequence evaluation, whereas the performance on POS tagging and classification tasks is measured by accuracy.

The models map from raw words to labels without using any intermediate annotated layer, even though they are available in some datasets. The only exception is the SRL task, for which we concatenate predicate embeddings to word embeddings following the procedure described in He et al. (2017), because a sequence can have as many label sequences as its number of predicates.

5.2 Implementation

During training, we minimize cross entropy using the Adam method for optimization (Kingma and Ba, 2014). We perform hyperparameter search for the LSTM model using Comet's Bayes search algorithm,[3] to maximize the task's performance measure on the validation set and use its best hyperparameters for all other models, except BERT, for which we use HuggingFace's pre-trained bert-base-cased model.

We use GloVe embeddings (Pennington et al., 2014) to initialize word embeddings for all models except BERT, which uses its own embedding mechanism. Random embeddings are used for out-of-GloVe words. We randomly replace tokens by a general <unk> token with probability 0.02 and use this token for all unknown words in the validation and test sets (Žilka and Jurčíček, 2015).

No parameters are kept frozen during training. Overfitting is avoided with early stopping and dropout. Our implementation uses PyTorch v.1.3.1, and prophecies are generated with HuggingFace's port of the GPT-2 language model. The evaluation of incrementality metrics is done on the test sets. [4]

6 Results

The results in Table 1 (above) support the observation that, in general, bidirectional models do have a better non-incremental performance than LSTMs (except for IntentATIS and ProsCons) and that there

---

[2] Fine-tuning GPT-2 did not improve BLEU and caused marginal difference in the evaluation metrics. We thus present the results using the pre-trained model only, and leave more exploration of fine-tuning for future work.

Table 1: Non-incremental performance of all models on test sets (truncated training in parentheses). The results are not necessarily state-of-the-art because we use basic forms of each model in order to isolate the effect of bidirectionality and have comparable results among different tasks.

is an overall considerable improvement in the use of BERT model for all tasks. Truncated training reduces overall performance but even so BERT with truncated training outperforms all models, even with usual training, in most tasks (except for slot filling and IntentATIS).

Figure 7 presents an overview of the incremental evaluation metrics for all models and tasks. Sequence tagging has, in general, low EO and low CT score; i.e., labels are not edited much and a final decision is reached early. That does not hold for BERT, whose CT score and EO is, in general, higher. CT score and EO in sequence classification are also higher because the label in this case should capture a more global representation, which cannot reasonably be expected to be very good when only a small part of the sequence has yet been seen.

When it comes to RC (correctness relative to the final output), again BERT has worse results than other models, especially for tagging. For sequence classification, BERT's performance is more in line with the other models. Achieving high RC is desirable because it means that, most of the time, the partial outputs are correct prefixes of the non-incremental output and can be trusted, at least to the same degree that the final result can be trusted.

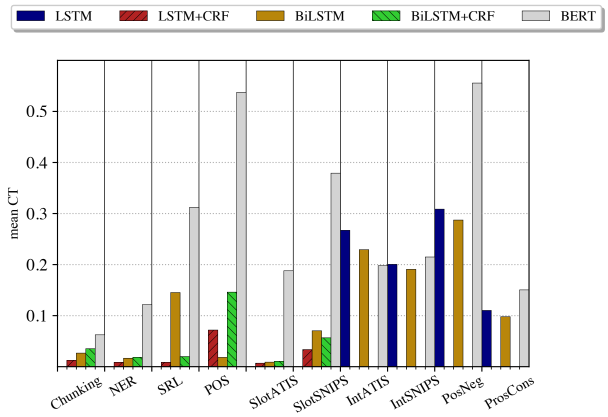
This overview shows that although BERT's non-incremental performance is normally the highest, the quality of its incremental outputs is more unstable. The next step is examining the effect of the three strategies that seek to improve the quality and stability of incremental outputs. Figure 8 shows that truncated training is always beneficial, as is delayed evaluation, with both strategies reducing EO and increasing RC. The fact that delay helps in all cases indicates that most substitutions happen in the last or last but one label (the right frontier, given the current prefix), or, in other words, that even having a limited right context improves quality substantially. [5]

Prophecies are detrimental in classification tasks, but they help in some tagging tasks, especially for BERT. Most importantly, any of the strategies cause a great improvement to BERT's incremental performance in sequence tagging, making its metrics be on the same level as other models while retaining its superior non-incremental quality.

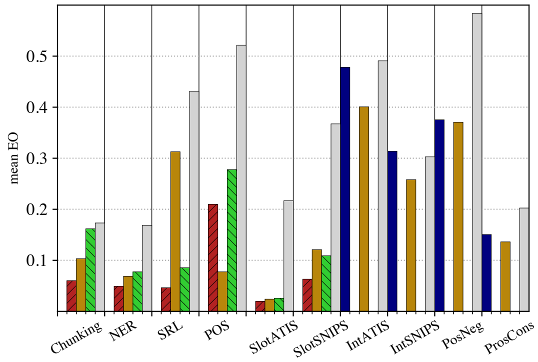
Note that while CT and RC can only be measured once the final output is available, an estimate of EO may be evaluated on the fly if we consider the edits and additions up to the last output. Figure 9 shows how the mean EO evolves, breaking out the results for cases where the non-incremental final output will be correct and those where it will not with respect to the gold labels. We can observe an intriguing pattern: the mean EO grows faster for cases where the final response will be wrong; this is most pronounced for the sequence classification task. It might be possible to use this observation as an indication of how much to trust the final result: If the incremental computation was more unstable than the average, we should not expect the final result to be good. However, initial experiments on building a classifier based on the instability of partial outputs have so far not been successful in cashing in on that observation.

---

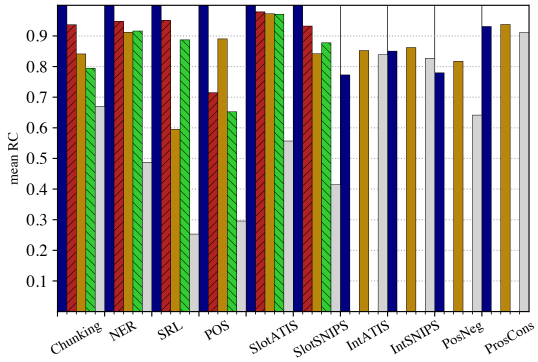
[5] Results for SRL are not included in Figure 8, because they go in the opposite direction of all other tasks. Since this task depends on the predicate embedding, both truncating the training sequence or adding a right context with no predicate information reduces performance in most cases, except for BERT. See Appendix for results separated by model and task.



(a) Mean Correction Time Score



(b) Mean Edit Overhead



(c) Mean Relative-Correctness

Figure 7: Comparison of evaluation metrics for all models and tasks. The incremental behavior is more stable for sequence tagging than for sequence classification. BERT takes longer to reach final decisions, and its outputs are edited more often than other models, especially in sequence tagging tasks.

7 Discussion and conclusion

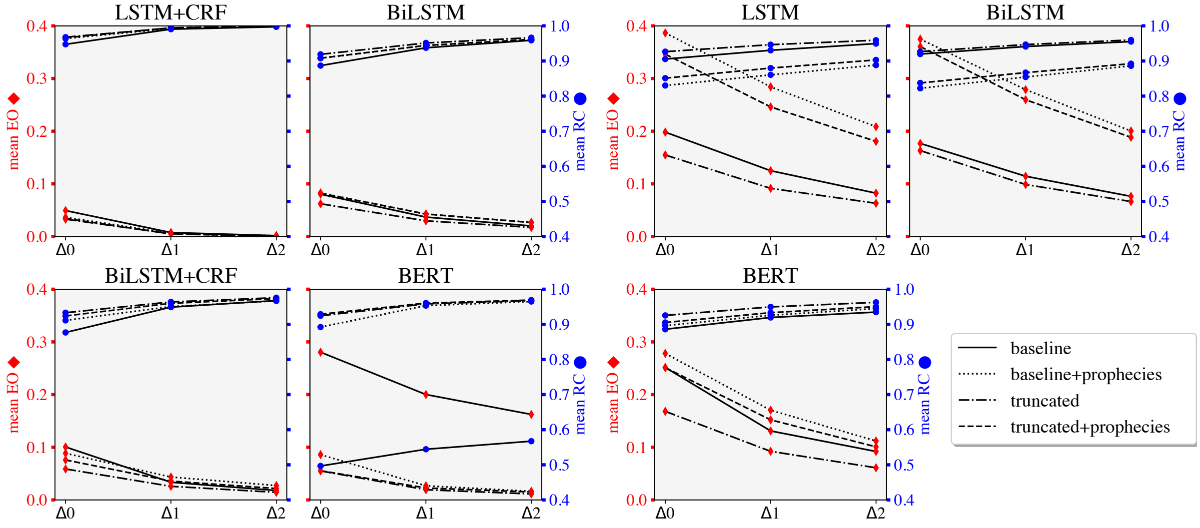
We show that bidirectional encoders can be adapted to work under an incremental interface without a too drastic impact on their performance. Even though the training (being done on complete sequences) differs from the testing situation (which exposes the model to partial input), the incremental metrics of most models are, in general, good: in sequence tagging, edit overhead is low, final decisions are taken early, and often partial outputs are a correct prefix of the complete non-incremental output. Sequence classification is more unstable because, at initial steps, there is a higher level of uncertainty on what is coming next. Our experiments show that the deficiencies of BERT in the incremental metrics can be mitigated with some adaptations (truncated training or prophecies together with delay), which make its incremental quality become as good as those of other models.

Since the semantic information is only kept encoded for a few steps in RNNs (Hupkes et al., 2018), this may be a reason why delay causes incremental metrics to be much better. If long-range dependencies are not captured, only neighboring words exert more influence in the choice of a label, so after seeing two words in the right context, the system rarely revises labels further back. BERT, having access to the whole sentence at any time step, is less stable because new input can cause it to reassess past labels more easily.

Besides, we also found evidence of different behavior of the instability of partial outputs between correct and incorrect output sequences, which could potentially be a signal of later lower quality. This could be used, for example, in dialog systems: if edit overhead gets too high, a clarification request should be made. A follow-up idea is training a classifier that predicts more precisely how likely it is that the final labels will be accurate based on the development of EO. However, our initial experiments on building such classifier were not successful. We suppose this is due to the fact that, in our datasets, incorrect final output sequences still usually have more than 90% correct labels, so the learnable signal may be too weak.

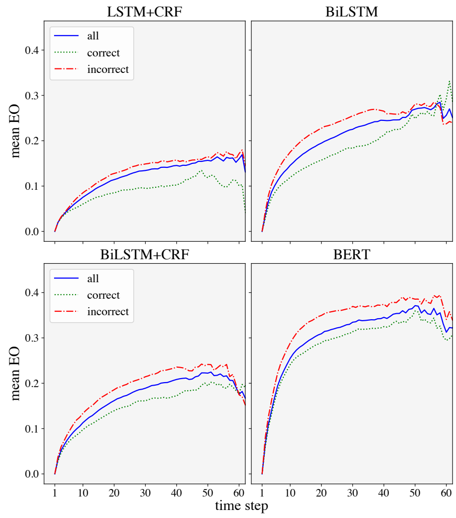
The use of GPT-2 prophecies led to promising improvements for BERT in sequence tagging. We see room for improvement, *e.g.* resorting to domain adaptation to make prophecies be more related to each genre. A natural extension is training a language model that generates the prophecies together with the encoder.

Finally, we believe that using attention mechanisms to study the grounding of the edits, similarly to the ideas in Köhn (2018), can be an important step towards understanding how the preliminary representations are built and decoded; we want to test this as well in future work.

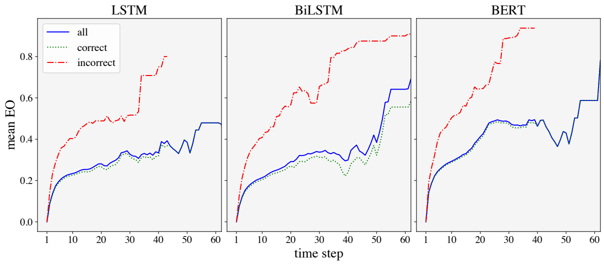


(a) Sequence tagging (b) Sequence classification

Figure 8: Comparison of mean Edit Overhead and mean Relative-Correctness on the baseline incremental interface and the three strategies using observations from all tasks except SRL.



(a) Sequence tagging



(b) Sequence classification

Figure 9: Development of mean Edit Overhead over time using observations from all tasks. *correct* means that all final output labels of a sentence are right and *incorrect* means that at least one label of the final output sequence is wrong. All models are more unstable when their non-incremental final output is incorrect with respect to the gold output.

Acknowledgments

We are thankful to the three anonymous reviewers and to our colleagues in the Foundations of Computational Linguistics Lab at the University of Potsdam for their valuable comments and insights. D.S. acknowledges the support by the Deutsche Forschungsgemeinschaft (DFG), grant SCHL 845/9-1.

A Reproducibility

Here we describe more details about hyperparameters and the models. Table 2 to Table 11 present more information about the hyperparameter search and the datasets as well as explicit results for each model and task, to be used for reproducibility purposes.

Data

- We use only the WSJ section of OntoNotes, with the train-valid-test splits provided by Pradhan et al. (2013), as well as their conversion to CoNLL format.
- The PosNeg and ProsCons datasets, which are not published with a train-valid-test split, were divided into 70%-10%-20% sets randomly.
- We removed the two longest sentences (>200 words) in Pros/Cons the dataset because they were infeasible to compute with BERT.
- Sentences longer than 60 words were removed in the hyperparameter search phase only.

Implementation

- Hyperparameter search is done for each dataset in both the LSTM model and BERT.
- We use Comet's Bayes algorithm[6], which balances exploration and exploitation and, in our experiments, tries to maximize the accuracy (for sequence classification) of F1 score (for sequence tagging) in the validation set.
- We set the maximum number of iterations to 50, but early stopping happens if no improvement is seen during 10 iterations.
- The best configuration of the LSTM model is also used for the LSTM+CRF, BiLSTM, and BiLSTM+CRF models.
- We use a five-dimensional embedding for the binary predicates in the SRL task.
- Hidden states are initialized as 0.
- All the weights and biases are initialized with PyTorch's default (uniformly sampled from $(-\sqrt{hidden\_size}), \sqrt{hidden\_size})$.
- Dropout is implemented after the embedding layer and after the encoder layer with the same value.
- PyTorch's and Numpy's manual seeds are set to 2204 for all experiments.
- All experiments were run on a GPU GeForce GTX 1080 Ti.

Hyperparameter	**LSTM**
Batch size	32, 64, 128, 512
Clipping	0.25, 0.5, 1
Dropout	0.1, 0.2, 0.3, 0.5

Abstract

We propose a generative framework for joint sequence labeling and sentence-level classification. Our model performs multiple sequence labeling tasks at once using a single, shared natural language output space. Unlike prior discriminative methods, our model naturally incorporates label semantics and shares knowledge across tasks. Our framework is general purpose, performing well on few-shot, low-resource, and high-resource tasks. We demonstrate these advantages on popular named entity recognition, slot labeling, and intent classification benchmarks. We set a new state-of-the-art for few-shot slot labeling, improving substantially upon the previous 5-shot (75.0% → 90.9%) and 1-shot (70.4% → 81.0%) state-of-the-art results. Furthermore, our model generates large improvements (46.27% → 63.83%) in low-resource slot labeling over a BERT baseline by incorporating label semantics. We also maintain competitive results on high-resource tasks, performing within two points of the state-of-the-art on all tasks and setting a new state-of-the-art on the SNIPS dataset.

1 Introduction

Transfer learning has been the pinnacle of recent successes in natural language processing. Large pre-trained language models are powerful backbones that can be fine-tuned for different tasks to achieve state-of-the-art performance in wide-raging applications (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019; Lewis et al., 2019; Yang et al., 2019; Liu et al., 2019).

While these models can be adapted to perform many tasks, each task is often associated to its own output space, which limits the ability to perform multiple tasks at the same time. For instance, a sentiment analysis model is normally a binary classifier that decides between class labels *"positive"* and *"negative"*, while a multi-class entailment system classifies each input as *"entail"*, *"contradict"*, or *"neither"*. This approach presents difficulty in knowledge sharing among tasks. That is, to train the model for a new task, the top-layer classifier is replaced with a new one that corresponds to novel classes. The class types are specified implicitly through different indices in the new classifier, which contain no prior information about the label meanings. This discriminative approach does not incorporate label name semantics and often requires a non-trivial amount of examples to train (Lee et al., 2020). While this transfer learning approach has been immensely successful, a more efficient approach should incorporate prior knowledge when possible.

Conditional generative modeling is a natural way to incorporate prior information and encode the output of multiple tasks in a shared predictive space. Recent work by Raffel et al. (2019) built a model called `T5` to perform multiple tasks at once using natural language as its output. The model differentiates tasks by using prefixes in its input such as *"classify sentiment:"*, *"summarize:"*, or *"translate from English to German:"* and classify each input by generating natural words such as *"positive"* for sentiment classification or *"This article describes ..."* for summarization.

However, the appropriate output format for important *sequence labeling* applications in NLP, such as named entity recognition (NER) and slot labeling (SL) is not immediately clear. In this work, we propose an *augmented natural language* format for sequence labeling tasks. Our format locally tags words within the sentence (Figure 1) and is easily extensible to sentence-level classification tasks, such as intent classification (IC).

Our highlighted contributions and main findings are as follows:

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 375–385,
November 16–20, 2020.

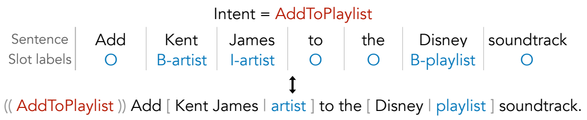

Figure 1: The conversion between the canonical BIO tagging format and our augmented natural language format.

1) We propose an effective new output format to perform joint sequence labeling and sentence classification through a generation framework.
2) We demonstrate the ability to perform multiple tasks such as named entity recognition, slot labeling and intent classification within a single model.
3) Our approach is highly effective in low-resource settings. Even without incorporating label type semantics as priors, the generative framework learns more efficiently than a token-level classification baseline. The model improves further given natural word labels, indicating the benefits of rich semantic information.
4) We show that supervised training on related sequence labeling tasks acts as an effective meta-learner that prepares the model to generate the appropriate output format. Learning each new task becomes much easier and results in significant performance gains.
5) We set a new state-of-the-art for few-shot slot labeling, outperforming the prior state-of-the-art by a large margin.
6) We plan to open source our implementation. Please visit `https://arxiv.org/abs/2009.13272` for the release updates.

2 Model

Sequence Labeling as Generation

Most work on sequence labeling uses token-level classification frameworks. That is, given a list of tokens $\ell = \{\ell_i\}_{i=1}^n$, we perform a prediction on every token ℓ_i to obtain $y' = \{y'_i\}_{i=1}^n = \{f(\ell_i; \ell)\}_{i=1}^n$ where $f(\cdot)$ is a token-level prediction function. The prediction is accurate if it matches the original sequence label $y = \{y_i\}_{i=1}^n$.

In contrast to this convention, we frame sequence labeling as a conditional sequence generation problem where given the token list ℓ, we generate an output list $o = g(\ell)$ where g is a sequence-to-sequence model. A "naive" formulation for this task would be to directly generate $o = y$ given ℓ. However, this approach is prone to errors such as word misalignment and length mismatch (see supplementary materials Section A.2 for discussion).

We propose a new formulation for this generation task such that, given the input sequence ℓ, our method generates output o in **augmented natural language**. The augmented output o repeats the original input sequence ℓ with additional markers that indicate the token-spans and their associated labels. More specifically, we use the format $[\ \ell_j, \dots, \ell_{j+t} \mid L\ ]$ to indicate that the token sequence $\ell_j, \dots, \ell_{j+t}$ is labeled as L.

Fig. 1 depicts the proposed format and its equivalent canonical BIO format for the same input sentence. The conversion between the BIO format and our augmented natural language format is invertible without any information loss. This is crucial so that the generated output from model prediction can be converted back for comparison without uncertainty.

There are other formats which can encapsulate all the tagging information but are not invertible. For instance, outputting only the token spans of interest with tagging patterns $[\ \ell_j, \dots, \ell_{j+t} \mid L\ ]$ without repeating the entire sentence results in the invertibility breaking down when there are duplicate token spans with different labels. We discuss this further in the appendix Section A.3.

Joint Sequence Classification and Labeling

Our sequence to sequence approach also supports joint sentence classification and sequence labeling by incorporating the sentence-level label in the augmented natural language format. In practice, we use the pattern ((sentence-level label)) in the beginning of the generated sentence, as shown in Fig. 1. The use of double parentheses is to prevent confusion with a single parenthesis that can occur in the original word sequence ℓ.

Training and Evaluation

We train our model by adapting the pre-trained T5 with the sequence to sequence framework. Additionally, we prefix the input with task descriptors in order to simultaneously perform multiple classification and labeling tasks, similar to the approach by Raffel et al. (2019). This results in a seamless multi-task framework, as illustrated in the top part of Fig. 2. To evaluate, we convert the generated output back to the canonical BIO format and calcu-

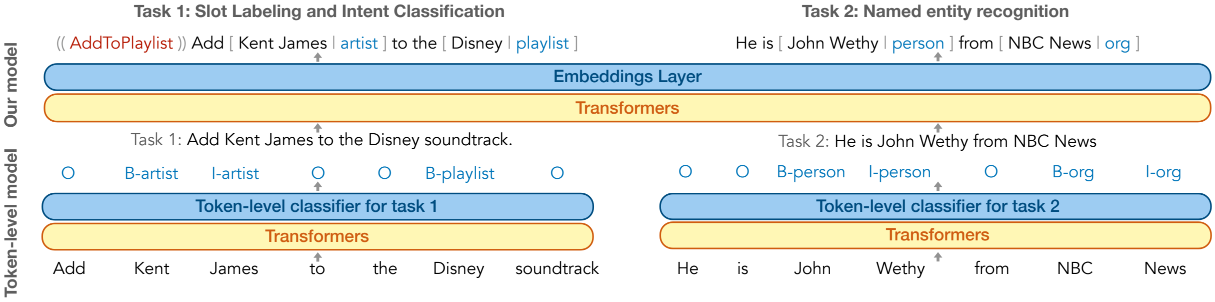

Figure 2: Comparison between our generative-style sequence labeling model (top) and the conventional token-level classification model (bottom).

late the F1 score for sequence labeling or accuracy for sentence classification.

Natural Labels

Labels are associated to real-world concepts that can be described through natural words. These words have rich information, but are often ignored in traditional discriminative approaches. In contrast, our model naturally incorporate label semantics directly through the generation-as-classification approach.

We perform label mapping in order to match the labels to its natural descriptions and use the natural labels in the augmented natural language output. Our motivation is as follows: (1) Pre-trained conditional generation models which we adapt on have richer semantics embedded in natural words, rather than dataset-specific label names. For instance, “country city state” contains more semantic information compared to “GPE”, which is an original label in named entity recognition tasks. Using natural labels should allow the model to learn the association between word tokens and labels more efficiently, without requiring many examples. (2) Label knowledge can be shared among different tasks. For instance, after learning how to label names as “person”, given a new task in another domain which requires labeling “artist”, the model can more easily associate names with “artist” due to the proximity of “person” and “artist” in embeddings. This is not the case if the concept of “person” was learned with other uninformative words.

3 Related Work

Sequence to sequence learning has various applications including machine translation (Sutskever et al., 2014; Bahdanau et al., 2015), language modeling (Radford et al., 2018; Raffel et al., 2019), abstractive summarization (Rush et al., 2015), generative question answering (Dong et al., 2019), to name a few. However, the sequence-to-sequence framework is often not a method of choice when it comes to sequence labeling. Most models for sequence labeling use the token-level classification framework, where the model predicts a label for each element in the input sequence (Baevski et al., 2019; Li et al., 2019b; Chen et al., 2019). While select prior work adopts the sequence-to-sequence method for sequence labeling (Chen and Moschitti, 2018), this approach is not widely in use due to the difficulty of fixing the output length, output space, and alignment with the original sequence.

Multi-task and multi-domain learning often benefit sequence labeling performance (Changpinyo et al., 2018). The archetypal multi-task setup jointly trains on a target dataset and one or more auxiliary datasets. In the cross lingual setting, these auxiliary datasets typically represent high-resource languages (Schuster et al., 2018; Cotterell and Duh, 2017). While in a monolingual scenario, the auxiliary datasets commonly represent similar, high-resource tasks. Examples of similar multi-task pairs include NER and slot labeling (Louvan and Magnini, 2019) as well as dialogue state tracking and language understanding (Rastogi et al., 2018).

A recent series of works frame natural language processing tasks, such as translation, question answering, and sentence classification, as conditional sequence generation problems (Raffel et al., 2019; Radford et al., 2019; Brown et al., 2020). By unifying the model output space across tasks to consist of natural language symbols, these approaches reduce the gap between language model pre-training tasks and downstream tasks. Moreover, this framework allows acquisition of new tasks without any architectural change. The GPT-3 model (Brown

et al., 2020) demonstrates the promise of this framework for few-shot learning. Among other successes, GPT-3 outperforms BERT-Large on the SuperGLUE benchmark using only 32 examples per task. To the best of our knowledge, we are the first to apply this multi-task conditional sequence generation framework to sequence labeling.

The conditional sequence generation framework makes it easy to incorporate label semantics, in the form of label names such as *departure city*, example values like *San Francisco*, and descriptions like *“the city from which the user would like to depart on the airline”*. Label semantics provide contextual signals that can improve model performance in multi-task and low-resource scenarios. Multiple works show that conditioning input representations on slot description embeddings improves multi-domain slot labeling performance (Bapna et al., 2017; Lee and Jha, 2019). Embedding example slot values in addition to slot descriptions yields further improvements in zero-shot slot labeling (Shah et al., 2019). In contrast to our work, these approaches train slot description and slot value embedding matrices, whereas our framework can incorporate these signals as natural language input without changing the network architecture.

4 Experimental Setup and Results

4.1 Data

Datasets We use popular benchmark data SNIPS (Coucke et al., 2018) and ATIS (Hemphill et al., 1990) for slot labeling and intent classification. SNIPS is an SLU benchmark with 7 intents and 39 distinct types of slots, while ATIS is a benchmark for the air travel domain (see appendix A.4 for details). We also evaluate our approach on two named entity recognition datasets, Ontonotes (Pradhan et al., 2013) and CoNLL-2003 (Sang and Meulder, 2003).

Construction of Natural Labels We preprocess the original labels to natural words as follows. For Ontonotes and CoNLL datasets, we transform the original labels via mappings detailed in Table 9 and 5 in the appendix. For instance, we map “PER” to “person” and “GPE” to “country city state”. For SNIPS and ATIS, we use the following rules to convert intent and slot labels: (1) we split words based on “.”, “_”, “/”, and capitalized letters. For instance, we convert “object_type” to “object type” and “AddToPlaylist” to “add to playlist”. These rules result in better tokenization and enrich the label semantics. We refer to these as the **natural label** setting and use is as our default.

4.2 Multi-Task Sequence Classification and Slot Labeling

We first demonstrate that our model can perform multiple tasks in our generative framework and achieve highly competitive or state-of-the-art performance. We consider 4 sequence labeling tasks and 2 classification tasks: NER on Ontonotes and CoNLL datasets; and slot labeling (SL) and intent classification (IC) on SNIPS and ATIS dialog datasets. For comparison, we provide baseline results from the following models:

SL and IC: Bi-Model (Wang et al., 2018) uses two correlated bidirectional LSTMs to perform both IC and SL. **Joint BERT** (Chen et al., 2019) performs joint IC and SL with a sequential classifier on top of BERT, where the classification for the start-of-sentence token corresponds to intent class. **ELMO+Bi-LSTM** (Siddhant et al., 2019) uses a Bi-LSTM with CRF as a classifier on top of pre-trained ELMO (Peters et al., 2018).

NER: Cloze-CNN (Baevski et al., 2019) finetunes a Bi-LSTM with CRF model Peters et al. (2018) on a pre-trained model with a cloze-style word reconstruction task. **BERT MRC** (Li et al., 2019a) performs sequence labeling in a question answering model to predict the slot label span. **BERT MRC + Dice Loss** (Li et al., 2019b) improves upon BERT MRC with a dice loss shown to be suitable for data with imbalanced labels. **BERT** (Devlin et al., 2019) refers to a token-level classification with BERT pre-trained model. Note that the results for BERT with Ontonotes are from our own implementation.

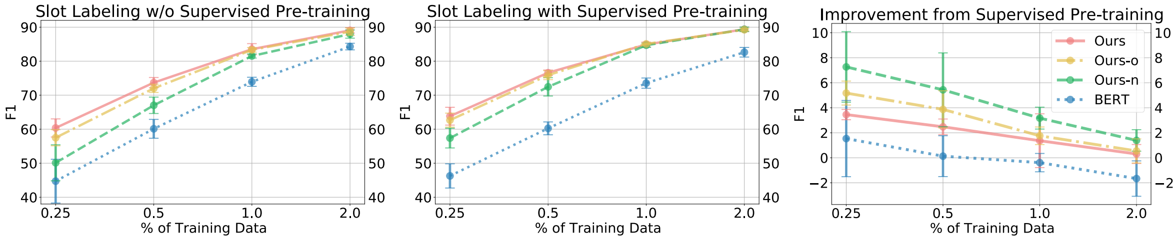
In Table 1, we report a summary of the results for our method and the baselines. Our proposed model achieves highly competitive results for ATIS, Ontonotes, and CoNLL datasets, as well as state-of-the-art slot labeling and intent classification performance on the SNIPS dataset. Unlike all the baseline models, which can perform a single task on a specific dataset, our model can perform all the tasks considered at once (last row of Table 1). For the multi-task models, our results show that different sequence labeling task can help mutually benefit each other, where ATIS slot labeling result improves from 96.13 to 96.65 and CoNLL improves from 90.70 to 91.48. While there are other approaches that perform better than our models in some tasks, we highlight the simplicity of our generation framework which performs multiple tasks seamlessly. This ability helps the models transfer knowledge among tasks with limited data, which are demonstrated through the rest of the paper.

4.3 Limited Resource Scenarios and Importance of Label Semantics

In this section, we show that our model can use the semantics of labels to learn efficiently, which is crucial for scenarios with limited labeled data. To demonstrate this effect, we use our model with the following variants of labels which differ semantic quality: (1) **natural label**, (2) **original label** and (3) **numeric label**.

The natural label version is our default setting where we use labels expressed in natural words. The original label case uses labels provided by the datasets, and the numeric label case uses numbers $0, 1, 2, ...$ as label types. In the numeric version, the model does not have pre-trained semantics of the label types and has to learn the associations between the labels and the relevant words from scratch. We also compare with the BERT **token-level classification** model. Similar to the numeric label case, the label types for BERT do not initially have associated semantics and are implicit through indices in the classifier weights. We use the SNIPS dataset to conduct our experiments due to its balanced domains (see Table 7 in Appendix). We experiment with very limited resource scenarios where we use as low as 0.25% of training data, corresponding to roughly one training sentence per label type on average.

Figure 3a shows the sequence labeling performance for varying amount of training data (see Table 10 in the appendix for numeric results). We observe that label semantics play a crucial role in the model's ability to learn effectively for limited resource scenarios. Our model with natural labels outperforms all other models, achieving an F1 score of $60.4 \pm 2.7\%$ with 0.25% training data, and giving a slight boost over using original labels ($57.5 \pm 2.4\%$). We believe that the improvement can be more dramatic in other datasets where the original labels have no meanings (such as in the numeric case), are heavily abbreviated, or contain rare words. With the numeric model, the performance suffers significantly in low-resource settings, achieving only $50.1 \pm 5.3\%$, or 10.3% lower than the natural label model, with 0.25% data. This result further supports the importance of label semantics in our generation approach. Interestingly, we also observe that the numeric model still outperforms BERT token-level classification ($44.7 \pm 6.4\%$), where neither model contains prior label semantics. This result indicates that even in the absence of label meanings, the generation approach seems more suitable than the token-level framework.



(a) (b) (c)

Figure 3: Model performance on limited amount of training data. The error bars indicate the standard deviation over 4 random trials. **Ours-o** is our model with its original labels. **Ours-n** is our model with numeric labels.

4.4 Teaching Model to Generate via Supervised Transfer Learning

While we train our model in limited data scenarios, we are asking the model to generate a new format of output given small amount of data. This is challenging since a sequence generation framework typically requires large amount of training (Sutskever et al., 2014). Despite this challenge, our model is able to outperform the classical token-level framework with ease. This section explores a clear untapped potential – by teaching our model how to generate the augmented natural language format before adapting to new tasks, we show that the performance on limited data significantly improves. This result contrasts with the BERT token-level model where supervised transfer learning hurts overall performance compared to BERT's initial pre-training due to possible overfitting.

To conduct this experiment, we train our model with the Ontonotes NER task in order to teach it the expected output format. Then, we adapt it on another task (SNIPS) with limited data, as in Section 4.3. We compare the results with the token-level BERT model, which also uses the BERT model trained on Ontonotes for supervised pre-training. We demonstrate the results in Figure 3b as well as highlight the improvement due to supervised pre-training in Figure 3c. We also provide full numeric results in the appendix Table 11 for reference.

Our model demonstrates consistent improvement, achieving an F1 score of $63.8 \pm 2.6\%$ using 0.25% of the training dataset, compared to $60.4 \pm 0.27\%$ without supervised transfer learning. The improvement trend also continues for other data settings, as shown in Figure 3c. The benefits from transfer learning is particularly strong for the numeric label model, achieving $57.4 \pm 2.9\%$ compared to $50.1 \pm 5.3\%$ for 0.25% data. This results suggests that the initial knowledge from supervised pre-training helps the model associate its labels (without prior semantics) to the associated words more easily.

The supervised transfer learning can also be seen as a *meta-learner*, which teaches the model how to perform sequence labeling in the generative style. In fact, when we investigate the model output *without* adapting to the SNIPS dataset, in addition to the output having the correct format, it already contains relevant tagging information for new tasks.

For instance, a phrase "Onto jerry's Classical Moments in Movies" from the SNIPS dataset results in the model output "Onto jerry's [Classical Moments in Movies | *work of art*]". This prediction closely matches the true label "Onto [jerry's | *playlist owner*] [Classical Moments in Movies | *playlist*]" where the true class of "Classical Moments in Movies" is *playlist*. Intuitively, the classification as *work of art* is in agreement with the true label *playlist*, but simply needs to be refined to match the allowed labels for the new task.

In contrast to our framework where the supervised transfer learning helps teach the model an output style, the transfer learning for the token-level classification simply adapts its weights and retains the same token-level structure (albeit with a new classifier). We observe no significant improvement from supervised pre-training for the BERT token-level model, which obtains an F1 score of $46.3 \pm 3.6\%$ compared to $44.7 \pm 6.4\%$ without supervised pre-training (with 0.25% SNIPS data). The improvements are also close to zero or negative for higher data settings (Figure 3c), suggesting that the pre-training of the token-level classification might overfit to the supervised data, and results in lower generalization on other downstream tasks. Overall, the final result on the BERT model lags far behind our framework, performing 17.5% lower than our model's score for 0.25% training data.

In addition, our model with numeric labels performs much better than the BERT token-level model and further highlights the suitability of our generative output format for sequence labeling, regardless to the label semantics. Possible explanations are that the sequence to sequence label is less prone to overfitting compared to the classification framework. It could also be the case that locally tagging words with labels in the word sequence helps improve attention within the transformers model, and improve robustness to limited data.

4.5 Few-Shot Sequence Labeling

4.5.1 Few-Shot Learning

In few-shot learning, we seek to train models such that given a new task, the models are able to learn efficiently from few labels. Different tasks are sampled from various data domains which differ in terms of allowed labels and other nuances such as input styles.

We define a data domain $\mathcal{D}$ as a set of labeled examples $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{N_\mathcal{D}}$ which has its set of allowed label types $\mathcal{Y}_\mathcal{D} \ni y_i$. Few-shot learning approaches are evaluated over many *episodes* of data, which represent a variety of novel tasks. Each episode $(\mathcal{S}, \mathcal{Q})$ consists of a support set $\mathcal{S}$ containing K-shot labeled samples, as well as a query set $\mathcal{Q}$ used for evaluation. Data from the evaluation episodes are drawn from the *target* domains $\{\mathcal{D}_1^T, \mathcal{D}_2^T, \ldots\}$, which the model has not previously seen.

To learn such models, we typically have access to another set of domains called the *source* domains $\{\mathcal{D}_1^S, \mathcal{D}_2^S, \ldots\}$, which can be used as the training resources. In order to train the model to learn multiple tasks well, many few-shot learning approaches use *meta-learning*, or a learning to learn approach, where the model is trained with many episodes drawn from the source domains in order to mimic the evaluation (Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018; Finn et al., 2017). We refer to this as the *episodic training*.

Another approach, called *fine-tuning*, trains the model on a regular training set from the source domains: $\cup_m \mathcal{D}_m^S$. Given an episode $(\mathcal{S}, \mathcal{Q})$ at evaluation time, the model fine-tunes it on the support $\mathcal{S}$, typically with a new classifier constructed for the new task, and evaluates on $\mathcal{Q}$.

4.5.2 Few-Shot Baselines

TransferBERT trains a token-level classification model by fine-tuning. **Matching Net (MN) + BERT** Vinyals et al. (2016) Given a word x_i, the model classifies by finding the most similar word $x_j^\mathcal{S}$ in the support set and predicts $y_j^\mathcal{S}$ as the label of x_i. The model also adapts the backbone model with episodic training. **Warm Proto Zero (WPZ) + BERT** Fritzler et al. (2019) uses token-level prototypical network (Snell et al., 2017), which classifies by comparing a word x_i to each class centroid rather than individual sample embeddings. **L-TapNet + CDT** Hou et al. (2020) uses a CRF framework and leverages label semantics in representing labels to calculate emission scores and a collapsed dependency transfer method to calculate transition scores. We note that all baselines except for TransferBERT uses episodic meta-training whereas TransferBERT uses fine-tuning. All baseline results are taken from Hou et al. (2020).

Our model performs fine-tuning with the generation framework. The major difference between our model and a token-level classification model such as TransferBERT is that we do not require a new classifier for every novel task during the fine-tuning on the support set. The sequence generation approach allows us to use the entire model and adapt it to new tasks, where the initial embeddings contain high quality semantics and help the model transfer knowledge efficiently.

4.5.3 K-shot Episode Construction

Traditionally, the support set $\mathcal{S}$ is often constructed in K-shot formats where we use only K instances of each label type. In sequence labeling problems, this definition is challenging due to the presence of multiple occurrences or multiple label types in a single sentence. We follow Hou et al. (2020) by using the following definition of a K-shot setting: All labels within the task appears at least K times in $\mathcal{S}$ and would appear less than K times if any sentence is removed. We sample 100 episodes from each domain according to this definition. Note that Hou et al. (2020)'s episodes are similar to ours, but preprocess the sentences by lowercasing and removing extra tokens such as commas (see details in Section A.6). Our model is flexible and can handle raw sentences; we therefore use the episodes from the original SNIPS dataset without any modifications.

4.5.4 Data

We perform few-shot experiments on the 7 domains $\{\mathcal{D}_1, \ldots, \mathcal{D}_7\}$ of the SNIPS dataset, namely, Weather (We), Music (Mu), Playlist (Pl), Book (Bo), ScreeningEvent (Se), Restaurant (Re), CreativeWork (Cr). To evaluate a model on domain $\mathcal{D}_i$, we meta-train the model on $\mathcal{D}_i' = \{\mathcal{D}_1, \ldots, \mathcal{D}_7\} -$

		We	**Mu**	**Pl**	**Bo**	**Se**	**Re**	**Cr**	**Ave.**
1-shot	TransferBERT	55.82	38.01	45.65	31.63	21.96	41.79	38.53	39.06

Table 2: Our few-shot slot labeling results on 7 domains of SNIPS dataset. Ours + SNIPS perform meta-training on the leave-one-out SNIPS data, similar to other baselines. Ours + Onto is our model trained on Ontonotes. Ours + No Meta involves no meta-training.

$\mathcal{D}_i$. We refer to this as the *leave-one-out* meta-training sets. All other baselines also use this meta-training data setup.

We note that the training set $\mathcal{D}'_i$ has data distributions that closely match $\mathcal{D}_i$ since they are both drawn from the SNIPS dataset. We investigate more challenging scenarios where we use an alternative source as a meta-training set, as well as no meta-training. In particular, we choose Ontonotes NER task as the alternative source domain. The benefits of using this setup is such that it establishes a single meta-trained model that works across *all* evaluation domains, which we offer as a challenging benchmark for future research.

4.5.5 Few-Shot Results

Table 2 demonstrates the results for few-shot experiments. Our model outperforms previous state-of-the-art on every domain evaluated. In the 5-shot case, our model achieves an average F1 score of 90.9%, exceeding the strongest baseline by 15.9%. Even without meta-training, the model is able to perform on par with state-of-the-art models, achieving an F1 score of 77.3% versus 75.0% for the baseline. Training on an alternative source (NER task) also proves to be an effective meta-learning strategy, performing better than the best baseline by 7.7%. These results indicate that our model is robust in its ability to learn sequence tagging on target domains that differ from sources. In the 1-shot case, our model achieves an average F1 score of 81.0%, outperforming the best baseline significantly (10.6% improvement).

We note that the average support sizes are around 5 to 40 sentences for the 5-shot case, and one to 8 sentences for the 1-shot case (see Table 12 and 13 for details). The results are particularly impressive given that we adapt a large transformer model based on such limited number of samples. In comparison to other fine-tuning approaches such as TransferBERT, our model performs substantially better, indicating that our generative framework is a more data-efficient approach for sequence labeling.

5 Discussion and Future Work

Our experiments consistently show that the generation framework is suitable for sequence labeling and sets a new record for few-shot learning. Our model adapts to new tasks efficiently with limited samples, while incorporating the label semantics expressed in natural words. This is akin to how humans learn. For instance, we do not learn the concept of “person” from scratch in a new task, but have prior knowledge that “person” likely corresponds to names, and refine this concept through observations. The natural language output space allows us to retain the knowledge from previous tasks through shared embeddings, unlike the token-level model which needs new classifiers for novel tasks, resulting in a broken chain of knowledge.

Our approach naturally lends itself to life-long learning. The unified input-output format allows the model to incorporate new data from any domain. Moreover, it has the characteristics of a single, life-long learning model that works well on many levels of data, unlike other approaches that only perform well on few-shot or high-resource tasks. Our simple yet effective approach is also easily extensible to other applications such as multi-label classification, or structured prediction via nested tagging patterns.

Dialogue Response Ranking
Training with Large-Scale Human Feedback Data

Abstract

Existing open-domain dialog models are generally trained to minimize the perplexity of target human responses. However, some human replies are more engaging than others, spawning more followup interactions. Current conversational models are increasingly capable of producing turns that are context-relevant, but in order to produce compelling agents, these models need to be able to predict and optimize for turns that are genuinely engaging. We leverage social media feedback data (number of replies and upvotes) to build a large-scale training dataset for feedback prediction. To alleviate possible distortion between the feedback and engagingness, we convert the ranking problem to a comparison of response pairs which involve few confounding factors. We trained DIALOGRPT, a set of GPT-2 based models on 133M pairs of human feedback data and the resulting ranker outperformed several baselines. Particularly, our ranker outperforms the conventional dialog perplexity baseline with a large margin on predicting Reddit feedback. We finally combine the feedback prediction models and a human-like scoring model to rank the machine-generated dialog responses. Crowd-sourced human evaluation shows that our ranking method correlates better with real human preferences than baseline models.[1]

1 Introduction

Conversing freely in natural language is one of the greatest challenges of artificial intelligence. End-to-end open-domain dialog systems have become increasingly powerful, with advanced model architectures and large-scale training (Zhang et al., 2019b; Adiwardana et al., 2020; Roller et al., 2020; Li et al., 2020). In some settings, human annotators cannot reliably distinguish between human- and machine-generated responses. Though surprisingly effective, the training objective for these models is conceptually simple: minimizing the perplexity of a reference response for a given context.

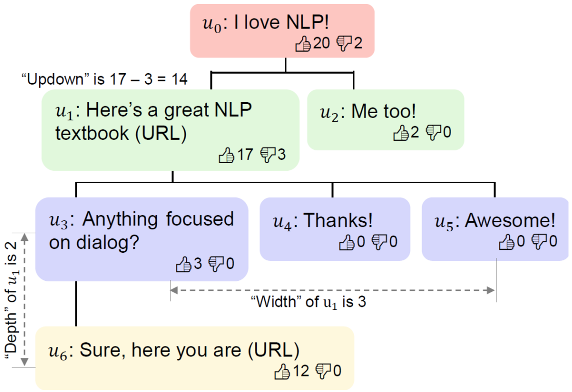

Figure 1: For many online communities, posts and comments have a tree structure and user can upvote or downvote each node individually. This allows us to define measures (e.g. Width, Depth, and Updown) of human feedback and build a large-scale training dataset for response quality prediction.

However, a meaningful evaluation of response generation must take into account more than whether a generated turn is relevant in context, or whether it "sounds human." Conventional neural conversation models often generate trivial or bland responses (Li et al., 2016; Zhao et al., 2017) that are relevant to context but are not engaging. Even human responses can vary dramatically in terms of tonal appropriateness and whether they are interesting enough to prompt a rich listener reaction. A successful dialog turn must be proactive, engaging, and consistent with social norms (Grice, 1975, 1989).

In this work, we move beyond simple prediction of response relevance, augmenting this with a prediction of how likely a response is to elicit a

---

positive reaction from an interlocutor. By incorporating a measure of engagingness into the response generation ranking algorithm, we hope to improve the overall behavior of data-driven conversational agents.

Existing methods are suboptimal for this ranking task. Conventional perplexity based ranking methods (Li et al., 2016; Vijayakumar et al., 2016) focus only on context-hypothesis relevancy. Online conversational systems such as XiaoIce (Zhou et al., 2018) employ a manually-designed set of features to rank hypotheses, but the design of these rankers is not directly based on real-world human preferences or feedback in an end-to-end fashion. Large-scale training data is necessary because of the one-to-many nature of dialog and the scope and complexity of human conversation. However, labeling conversations at scale is too expensive and time-consuming for this purpose. Labeling the “engagingness” of a response is not something a single annotator can do; the task requires something more like a large-scale, collective vote. And yet there is no obvious automated substitute for this kind of human labeling. Conventional quality measurements such as reference-based similarity (Papineni et al., 2002) or lexical diversity (Li et al., 2016; Zhang et al., 2018b) capture only limited aspects of response quality, and are not strongly predictive of human reactions: simply because a response is different from others does not necesarily mean that it will be perceived as “bad”.

Our solution involves leveraging existing human feedback data (e.g., number of replies and likes) from online social communities. While there is work in the field of social media on feedback prediction (Sparling and Sen, 2011; Stoddard, 2015; Glenski and Weninger, 2017), it has not previously been applied to dialog systems and response generation. As illustrated in Figure 1, each comment has its own number of replies and upvotes (termed as “Likes” in some communities). These can be used as engagingness labels after careful normalization and formulation. There exist billions of online threads available and the number is growing fast, thus making it possible to build a large-scale training dataset. However, the relation between feedback and quality may be distorted due to social influence and other confounding factors (Salganik et al., 2006).

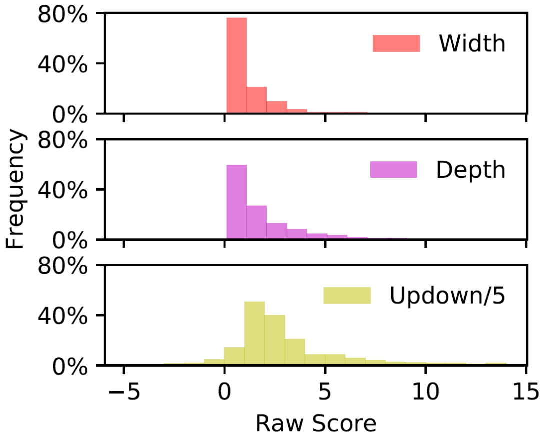

Figure 2: The long-tailed distribution of the raw scores of feedback of Reddit.com.

In order to ameliorate this problem, we propose a contrastive formulation, shifting from ranking to pairwise classification. Using a dataset of 133M pairs of human comments and their associated number of replies or up-/downvotes, we train a set of large-scale transformer-based feedback ranking models which outperform several baselines. In particular, dialog perplexity shows little predictive power of human feedback. We also show that a classifier trained on human-vs-artificial data can achieve good zero-shot relevancy prediction accuracy. Finally, we describe an ensemble model that is capable of merging the predictive powers of all these models, tuned using human calibration. Human evaluation shows that our ranking method outperforms the baselines in terms of correlation with actual human preferences.

2 Human Feedback

Many social media platforms, such as Reddit, Twitter, and Facebook allow users to reply or upvote contents, leveraging that feedback to make decisions about what content to display, highlight, and hide. These collective ratings are treated as a proxy for content engagingness. In this section we discuss a few metrics of user vote data, along with some of the issues posed by its use.

	Width	Depth	Updown
Width	1	0.8592	0.3491
Depth	0.8592	1	0.3257
Updown	0.3491	0.3257	1

Table 1: Spearman’s ρ between different measurements of human feedback. Darker cell color indicates higher correlation.

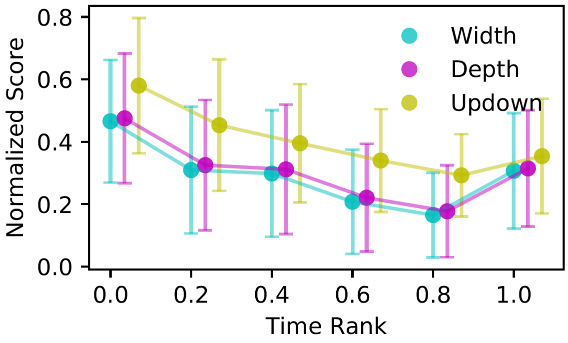

Figure 3: The dependence of feedback on created time of the comments of the same parent node (i.e. the same context) of Reddit.com. Error bars show standard deviation.

2.1 Feedback metrics

As illustrated by Figure 1, posts and comments typically form a tree structure. Each comment branching from the root may have its own comment children. We consider the path from the root to the parent node of a comment to be its context c, and the comment as a reply r. For each dialog (c, r), we consider the following feedback: **Width**, the number of direct replies to r; **Depth**, the maximum length of the dialog after this turn; and **Updown**, the number of upvotes minus the number of downvotes. For example, given the context $c = u_0$, the reply u_1 gets three direct replies u_3, u_4, u_5 and the Width is thus 3. u_3 continues the dialog with one more turn u_6, thus the depth is 2. u_1 got 17 upvotes and 3 downvotes so its Updown is 14. In contrast, u_2 is for the same context, but its Width and Depth is only 0, and Updown is 2.

Though focused on different dimensions, both Width and Depth can be seen as measures of the number of replies, and are therefore often closely correlated, as shown in Table 1 using Reddit as an example. They are less correlated with Updown. Presumably, contributors may feel that an upvote is enough to express their agreement or appreciation, and so do not post a full reply.

2.2 Feedback and Engagingness

The feedback metrics defined above cannot be directly used as a measure of reply engagingness. Stoddard (2015) shows that while popularity, measured by Updown, generally increases with quality, posts of similar quality can exhibit very different upvote counts. This variability can be traced to several different factors. As illustrated in Figure 2, the distribution of feedback is long-tailed, with a small fraction of threads receiving most of the replies and likes. Additionally, the popularity of the specific subreddit in which a comment occurs further confounds things: a relatively uninteresting comment in a very popular thread may get more feedback than an interesting comment in a less trafficked subreddit. Feedback volume is also heavily dependent on the timing of a comment relative to other comments, with replies that come early in a thread being more likely to attract replies or likes. This is shown in Figure 3. This may be tied to other factors such as social influence and disparities in comment visibility causing distortions in the relationship between comment engagingness and popularity (Salganik et al., 2006; Salganik and Watts, 2008; Gilbert, 2013). These findings imply that careful formulation and normalization should be applied before using feedback data as a training signal. We present our approach to this in Section 3.1.

2.3 Tasks

Given a context and a list of responses, we consider the task of predicting a ranking based on the feedback they received, as measured by these three separate metrics: (1) Width, (2) Depth, and (3) Updown. The gold label and training data is available for human response ranking, but in order to make this applicable to machine generated responses, we introduce another task: (4) human-vs-fake, which measures how human-like the response is. We consider two modes of fake examples: random human responses and machine generated responses. We will introduce an ensemble method in Section 3.2 for this last task.

3 The DIALOGRPT Method

In this section we introduce Dialog Ranking Pretrained Transformers (DIALOGRPT).

3.1 Problem Formulation

A Contrastive Learning approach. Given the confounding factors affecting feedback mentioned above, we train the model on *pairs* of samples (c, r^+) and (c, r^-), rather than fitting it to score each dialog *individually*. This follows the Contrastive Learning approach (see Section 5 for a brief review). The model is trained to predict a higher score for the positive sample r^+ (i.e. the response with more feedback) compared to the negative sample r^-. Besides (1) only comparing replies of the same context, we use the following criteria to construct pairs that minimize the effect of confounding factors: (2) the sequence of two replies, r^+ and r^-, must have been created within a brief time window (no more than one hour), and (3) the feedback score of r^+ must exceed that of r^- by a specified threshold in order to make the label less noisy. Due to the long-tailed distribution, we consider both an absolute-valued threshold and a percentage ranking threshold. Furthermore, if a reply has more downvotes than upvotes, it will not be considered as a positive sample, but can be used as a negative sample.

Training objective. The model should be able to output a score at testing time for a hypothesis r for a given context c. At training time, as formulated in Section 3.1, given two hypotheses for a context, the model should be able to identify which one has more feedback. To connect these two requirements, the model outputs a scalar h,

$$h(c, r) = \textsc{DialogRPT}(c, r) \tag{1}$$

At inference time, we compute the score $s(r|c)$

$$s(r|c) = \text{Sigmoid}(h(c, r)) \tag{2}$$

For training, the loss is designed to simultaneously maximize the positive sample score and minimize the negative sample score:

$$\mathcal{L} = -\sum_{i \in \text{batch}} \log \frac{e^{h(c_i, r_i^+)}}{e^{h(c_i, r_i^+)} + e^{h(c_i, r_i^-)}} \tag{3}$$

This can be interpreted as the cross entropy between the target distribution $\{P(r^+) = 1, P(r^-) = 0\}$ and the predicted distribution in Softmax form. Note the contrastive form is crucial, given that a loss function only maximizing $s(r^+|c)$ usually leads to a collapsed solution (Hadsell et al., 2006).

3.2 Model ensemble

For machine generation. The machine generation is required to be both *human-like* and *preferred by human*. To rank the machine generations, we factorize the probability of a joint distribution as follows:

$$\begin{aligned} &P(r = \text{preferred, human-like}|c) \\ &= P(r = \text{preferred}|r = \text{human-like}, c) \cdot \\ &\quad P(r = \text{human-like}|c) \end{aligned} \tag{4}$$

We estimate the first term with the models trained on a human-vs-human ranker on each feedback metric $K \in \{\text{Width, Depth, Updown}\}$

$$P(r = \text{preferred}_K, \text{human-like}|c) \triangleq s_K(r|c) \tag{5}$$

We denote the term $P(r = \text{human-like}|c)$ as $\pi_0(r|c)$, and build a classifier to predict how human-like a response is (see Section 3.3 for details).

$$P(r = \text{human-like}|c) \triangleq \pi_0(r|c) \tag{6}$$

Both $\pi_0(r|c)$ and $s_K(r|c)$ are scores defined in Eq. 2 interpreted as probability.

For overall preference. In case only a simple human preference matters (instead of separate Width, Depth, Updown metrics), we assume that a linear combination exists

$$s_{\text{Prefer}}(r|c) \triangleq \pi_0(r|c) \sum_K w_K s_{\text{K}}(r|c) \tag{7}$$

Human calibration. To estimate the correlation between the feedback score and human response preference, we present pairs of responses for the same context to a set of human annotators, asking them to select the response they would prefer to send or receive. The annotation is conducted for machine-vs.-machine comparisons on 1K pairs, and with 5 individual judges for each pair. Through this controlled setup, we reduce confounding factors, such as social influence and disparities in visibility, that might exist even within the contrastive problem formulation.

The results are used as a proxy for $s_{\text{Prefer}}(r|c)$, and can be used to estimate w_K for the test set, though the optimal value may depend on the test set and the instructions the human annotators were given. Note that the freedom of the system is now limited to a handful of hyper-parameters, limiting the need for large-scale human labeling to learn the model parameters.

3.3 Implementation details

Model and training. Our model is a 12-layer transformer model based on GPT-2 (Radford et al., 2019) architecture, and initialized with DialoGPT-medium model weights (Zhang et al., 2019b). DialoGPT is a large-scale dialog response generation model, pre-trained on 147M Reddit conversations. We use a linear layer to convert the final layer transformer output at the last token time step to a scalar

h. The parameters of the transformers and this output layer are trained simultaneously.

Each model has 354.8M parameters, and is trained on an Nvidia Tesla V100 4-core GPU with batch size 256 at an average training speed of 0.33 M pairs of samples per hour. Each model took around 70 hours to converge (until validation loss on a fixed set of 1024 samples ceased to improve).

Model	Trained on	Dataset size (M)
Human feedback $s_{\mathrm{K}}(r\|c)$	Human vs. Human	
	- Width	22.3
	- Depth	25.1
	- Updown	40.7
Human-like $\pi_0(r\|c)$	Human vs. Fake	
	- Rand	40.7
	- Generated	5.3

Table 2: Summary of models and training data of different tasks, size in millions (M) of pairs

Data construction. Following the contrastive learning approach introduced in Section 3.1, we constructed a 133M-pair training set using Reddit data from 2011-2012, as shown in Table 2. For each task, we sampled 1024 validation pairs from the 2012 data and 5K test pairs from the 2013 data. The train, validation and test data do not share any Reddit posts.

For the human-like (i.e. human-vs-fake) task, we consider two representative negative modes: retrieval and generative dialog model generation. For the former we simply construct negative examples by randomly sampling from the training data. For the latter we use DialoGPT with top-k decoding. Since DialoGPT is able to produce human-like responses in certain evaluation settings, we select only 5.3 M highly-rated human response as positive examples, instead of using all human responses. Note that our method can be extended to include other negative modes such as perturbations and excessive repetition, similar to the synthetic example creation using BLEURT (Sellam et al., 2020).

3.4 Baselines

We consider the following baselines:

Dialog perplexity (ppl.) This metric is calculated for both the forward model (i.e., predict the response from the context) and the reverse model (i.e. predict the context from the response). This ranking method was proposed by Li et al. (2016) and formulated to maximize mutual information (MMI) between the response and context. We use DialoGPT and its reverse model to compute ppl.

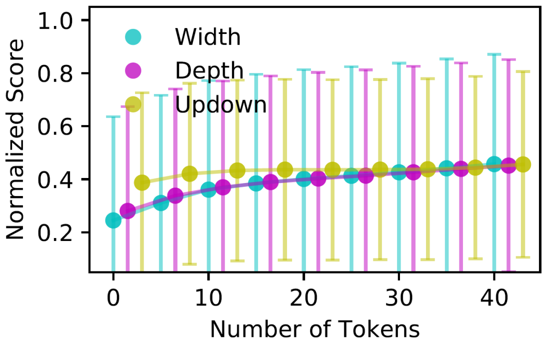

Figure 4: The dependence of feedback on the length for the comments of the same parent node (i.e. the same context). Error bars show standard deviation.

BM25 This classic metric measures keywords similarity (Robertson and Zaragoza, 2009). We use the inner product of the context BM25 vector and candidate response BM25 vector to rank candidates, similar to (Henderson et al., 2019a).

ConveRT (Henderson et al., 2019b) is a transformer-based model pretrained on Reddit data. It encodes context and candidate as vectors and compute their inner product as similarity used for ranking, achieved the existing state-of-the-art performance on several response matching test sets[2].

Bag of words (BoW) For each word, an average of rank-normalized feedback score[3] is calculated for replies that contain this word. This is the score for this word. Due to the long-tailed distribution of the absolute value of feedback items, we normalize them as the percentage ranking for their context. Then we use the average of the scores of the words in a response as the score of this response.

Length As shown in Figure 4, feedback rank weakly correlates with response length. We therefore use the average value of responses of the same length in training data as the predicted score for a hypothesis.

BoW and Length baselines are are intended to capture information about lexical patterns of hu-

---

[3] defined as $1 - i/m$, where i is the feedback rank of this reply for the given context, and m is the number of replies of this context

man feedback in the data and provide a preliminary analysis.

4 Results

4.1 Predicting Human Feedback

Preliminary analysis We first consider findings from the bag of words baseline. As shown in Table 4, responses that receive fewer replies or upvotes tend to be less contentful (e.g. *lol*, *awesome*, *wow*, *nice*). In contrast, comments that attract more feedback are typically different in character: for instance, questions (indicated by *?*, *why*, *how*, *what*, *who*) often lead to longer conversation (greater Depth). Comments targeting a broad audience (labeled by *anyone*, *guys*), tend to receive more direct replies (greater Width) than those aimed at a specific set of people.

A similar pattern is captured by DIALOGRPT, as shown in Table 3. Given the context *I love NLP!*, the relatively bland response *Me too!* gets the lowest scores for all three feedback measures. Higher scores are obtained for Response *B*, where a justification is provided for the agreement (*useful*, *powerful*). Response *C* gets the highest Depth score, as it invites a discussion about how NLP works, something that is unlikely to be completed in one or two turns. Response *D*, in contrast, can be answered in fewer turns but with potentially many valid answers, which explains its high Width score. Finally, Response *E* receives the highest Updown score, probably because the model predicts that many people will upvote it to express gratitude for the useful resource pointer it provides (*textbook*). Removing the word *(URL)* from Response *E* causes the score to drop only slightly, indicating that the model is not simply sensitive to the post containing a web link.

Ranker evaluation We evaluate ranker performance using two metrics. First, we use pairwise accuracy, which measures accuracy in selecting the positive sample from a positive (more feedback) and negative (less feedback) pair for the same context. This is consistent with the training objective. Second, since the models will be used to rank hypotheses, we are also interested in the correlation between the model scorer rank and the the gold label rank. We measure this correlation using Spearman's ρ.

As shown in Table 5, DIALOGRPT shows the highest test performance on both measurements[4] Reverse dialog perplexity generally performs better than forward dialog perplexity. However, as it is not trained with feedback labels, a simple BoW baseline outperforms the dialog models in this task.

We also evaluated performance on feedback data that the model had not been trained on, as shown in Table 6.The model trained on Width data can perform reasonably well on Depth prediction, and vice versa, consistent with the high correlation between their labels as shown in Table 1. The Updown label is less correlated with these, and so the model trained on Updown data performs poorly on Width and Depth data. This is in keeping with the complementary relationship between these models.

4.2 Human-like Classification

Human-vs-Rand We first evaluate performance on the task of selecting the gold response from a set of random distractor responses. For each context, we randomly select n distractors. Performance is evaluated using Hits@k, which is the ratio of the number of gold responses in the top-k ranked hypotheses. Here, k is equal to the number of gold responses. Although DIALOGRPT is trained solely on Human-vs-Rand Reddit data, we show in Table 7 that it performs well even when compared to baseline models on other data sources: DailyDialog (Li et al., 2017) and Twitter[5] PersonaChat[6] (Zhang et al., 2018a). Such *zero-shot* performance indicate that the model generalize reasonably well on unseen datasets.

For the Reddit dataset, which has multiple gold replies, we also compare our method with reference-based similarity measurements, [7] including BLEU (Papineni et al., 2002), BERTScore (Zhang et al., 2019a), and BLEURT (Sellam et al., 2020). These metrics are not applicable on-the-fly, since references are not available, but they are commonly used as offline measures of dialog system quality. As shown in Table 7, although BLEU, BERTScore, and BLEURT take advantage of reference, which is unknown to DIALOGRPT, DIALO-

---

[4] Similar results are observed for the validation set.

[5] `https://github.com/Marsan-Ma/chat_corpus/`

[6] The performance of IR Baseline, Starspace, and KV Profile Memory for PersonaChat are following Zhang et al. (2018a).

[7] Following Galley et al. (2018), for a gold hypothesis, we only use other $k-1$ gold hypotheses as references to avoid a similarity of 1. For each distractor response, we randomly pick $k-1$ references from k gold hypotheses.

Context: I love NLP!				
Response:		Width	Depth	Updown
A	Me too!	0.033	0.043	0.171
B	It's super useful and more and more powerful!	0.054	0.164	0.296
C	Can you tell me how it works?	0.644	**0.696**	0.348
D	Can anyone recommend a nice review paper?	**0.687**	0.562	0.332
E	Here's a free textbook (URL) in case anyone needs it.	0.319	0.409	**0.612**

Table 3: Predicted feedback scores of several example responses given the same context.

Width	r^+	url, anyone, else, who, does, why, guys, seriously, everyone
	r^-	oh, amazing, damn, thanks, wow, nice, !, awesome, lol, upvote
Depth	r^+	?, why, does, how, anyone, isn't, any, what, who,
	r^-	great, nice, amazing, damn, lol, !, awesome, thank, upvote
Updown	r^+	url, our, picture, everyone, hey, part, years, into, will, we
	r^-	maybe, though, awesome, comment, funny, wow, came, upvote, lol

Table 4: Bag of words analysis. If on average the comments containing a certain word get more feedback, we list this word in the r^+ row. If they get less feedback, this word is listed in r^- row.

GRPTshows higher accuracy measured by Hits@k.

Human-vs-Generated We evaluate the model's ability to discriminate between human and generated responses. As shown in Table 6, a model trained only on human-vs-rand data performs poorly on this task, indicating that the generated responses are sufficiently relevant to the context to yield a higher score than a random response. This is consistent with the evaluation results reported by Zhang et al. (2019b), which shows that DialoGPT receives higher relevancy score in a human evaluation. However, the feedback prediction models, Width, Depth and Updown, show much higher accuracy in the human-vs-generated task, even though they were not trained on any generated responses. This implies that the ranking models predict that DialoGPT's generated responses may not be as proactive or as engaging as human responses. Finally, the model trained with both random and generated responses perform well on both human-vs.-fake tasks, but not well on the human-vs.-human feedback ranking tasks. This indicates that the models are complementary to each other, motivating us to build an ensemble model.

4.3 Ensembling Models

Reddit test data. The feedback and the human-like models are combined following Eq. 7 and evaluated using different test sets, as shown in Table 6. For testing on feedback K, where K is Width, Depth or Updown, we set $w_i = 1$ if $i = K$ and 0 otherwise. For human vs. fake, we set $w_K = 1/3$ for all three feedback models. Although the ensemble model's accuracy is not the highest for any of the test sets, it performs reasonably well on all of them.

	Method	Pairwise accuracy	Spearman ρ
Width	Dialog ppl.	0.513	-0.009
	Reverse dialog ppl.	0.571	0.099
	Length baseline	0.595	0.229
	BoW baseline	0.596	0.234
	DIALOGRPT	**0.752**	**0.357**
Depth	Dialog ppl.	0.508	-0.004
	Reverse dialog ppl.	0.557	0.063
	Length baseline	0.543	0.134
	BoW baseline	0.584	0.187
	DIALOGRPT	**0.695**	**0.317**
Updown	Dialog ppl.	0.488	0.003
	Reverse dialog ppl.	0.560	0.076
	Length baseline	0.531	0.063
	BoW baseline	0.571	0.134
	DIALOGRPT	**0.683**	**0.295**

Table 5: Performance on test set ranking gold responses, measured by pairwise accuracy and Spearman's ρ.

Human overall preference. We also test the correlation between the ensemble model and human overall preference, using the human annotations introduced in Section 3.2. As shown in Table 8, adding the human-like model π_0 improves the model performance, indicated by the comparison between the model $\pi_0 \sum_K w_K s_{\text{K}}$ and $\sum_K w_K s_{\text{K}}$. Among the three feedback modes, human preference correlates best with Updown. Presumably, Upvotes (or "Likes"), is more directly tied to human preference than Width or Depth. However, the other two metrics are useful as well.The fitted coefficients of the $\sum_K w_K s_{\text{K}}$ model implies the overall preference is a combination of these modes, favoring replies that can prolong a dialog session ($w_{\text{Depth}} = 0.48$), that are likely to be upvoted ($w_{\text{Updown}} = 1.0$) and that do not target too

Model	Trained on	Tested on				
		Human vs. Human			Human vs. Fake	
		Width	Depth	Updown	Rand	Generated
Human feedback	Width	0.764	0.693	0.601	0.517	0.644
	Depth	0.749	0.701	0.588	0.512	0.647
	Updown	0.659	0.602	0.683	0.526	0.667
Human-like	Rand	0.558	0.552	0.522	0.843	0.413
	+ Generated	0.560	0.558	0.522	0.864	0.880
Ensemble	-	0.746	0.675	0.666	0.758	0.821

broad an audience ($w_{\text{Width}} = -0.50$).

Improving generation model. Even when the generative model (i.e. DialoGPT) is held constant, DIALOGRPT improves candidate ranking in comparison to perplexity-based methods. This indicates that incorporating human feedback information into response generation ranking methods can yield improvements over methods that rely solely on measures of relevancy.

5 Related Work

Dialog hypothesis ranking. Earlier work has explored the use of generation probability $P(h|x)$ or perplexity for hypothesis ranking. Li et al. (2016) combine this with reverse dialog probability to consider mutual information (MMI) in ranking dialog response hypotheses Gao et al. (2019b) adds style intensity for stylized response generation. Another line of works (Henderson et al., 2019a; Humeau et al., 2019) encodes context and candidate as vectors and use their similarity for ranking. Some systems (Zhou et al., 2018; Gao et al., 2020) employ a set of features to rank hypotheses, e.g., local cohesion, global coherence, empathy matching, and retrieval matching.

Reference-based quality measure is also used to estimate the quality of response, although this is not applicable on-the-fly. BLEU (Papineni et al., 2002) is a classic metric measuring the sentence similarity using ngram overlap. BERTScore (Zhang et al., 2019a) uses BERT contextualized word embeddings, instead of ngrams. BLEURT (Sellam et al., 2020) directly measures sentence-level similarity, initialized with BERT and then trained on millions of synthetic examples.

Contrastive Learning focuses on the relation between samples or labels. Hadsell et al. (2006) learns representations using a contrastive loss function which pulls neighbors together and pushes apart non-neighbors in the learned space. Gao et al. (2019a) designed a loss function to reduce the distance between matched context and response in contrast to the random pairs. Chen et al. (2020)

proposed a contrastive learning framework, establishing a new state-of-the-art for image classification.

Social sciences and social-media NLP: Glenski and Weninger (2017) model each user separately and predict their interaction for a given post using features including existing upvotes/downvotes, rank, and bag of words. Stoddard (2015) models upvotes as a time-series function of content quality, displaying position, age and score of the post and shows that popularity is positively correlated with quality, though articles of similar quality can have very different numbers of upvotes. Lakkaraju et al. (2013) studied resubmissions to decompose article popularity into the quality of the content and the appeal of the title. They find that textual features of the title significantly affect popularity.

6 Conclusion

We leverage Reddit human feedback data to build and release a large-scale training dataset for feedback prediction.We trained GPT-2 based models on 133M pairs of human feedback data and demonstrate that these models outperform several standard baselines. In particular, the conventional dialog perplexity baseline shows little predictive power on Reddit human feedback data. We ensemble the feedback prediction models and a human-like scoring model to rank the machine generated dialog responses. Human evaluation shows that human preference is improved with our ranking method. For the future work, we suggest to integrate the ranking models and generation model, e.g., in beam search stage or reinforcement learning using ranking score as reward signal.

Abstract

We propose *test suite accuracy* to approximate semantic accuracy for Text-to-SQL models. Our method distills a small test suite of databases that achieves high code coverage for the gold query from a large number of randomly generated databases. At evaluation time, it computes the denotation accuracy of the predicted queries on the distilled test suite, hence calculating a tight upper-bound for semantic accuracy efficiently. We use our proposed method to evaluate 21 models submitted to the SPIDER leader board and manually verify that our method is always correct on 100 examples. In contrast, the current SPIDER metric leads to a 2.5% false negative rate on average and 8.1% in the worst case, indicating that test suite accuracy is needed. Our implementation, along with distilled test suites for eleven Text-to-SQL datasets, is publicly available.[1]

1 Introduction

A Text-to-SQL model translates natural language instructions to SQL queries that can be executed on databases and bridges the gap between expert programmers and non-experts. Accordingly, researchers have built a diversity of datasets (Dahl, 1989; Iyer et al., 2017; Zhong et al., 2017; Yu et al., 2018) and improved model performances (Xu et al., 2017; Suhr et al., 2018; Guo et al., 2019; Bogin et al., 2019a; Wang et al., 2020). However, evaluating the semantic accuracy of a Text-to-SQL model is a long-standing problem: we want to know whether the predicted SQL query has the same denotation as the gold for every possible database. "Single" denotation evaluation executes the predicted SQL query on one database and compares its denotation with that of the gold. It might create *false positives*, where a semantically different prediction (Figure 1 prediction 1) happens to have the same denotation as the gold, on a particular database. In contrast, exact string match might produce *false negatives*: Figure 1 prediction 2 is semantically equivalent to the gold but differs in logical form.

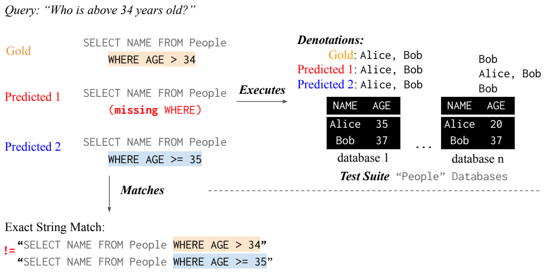

Figure 1: Prediction 2 is semantically correct, and Prediction 1 is wrong. Exact string match judges prediction 2 to be wrong, which leads to *false negatives*. Only comparing denotations on database 1 judges prediction 1 to be correct, which leads to *false positives*. Test suite evaluation compares denotations on a set of databases and reduces false positives.

The programming language research community developed formal tools to reliably reason about query equivalence for a restricted set of query types. They lift SQL queries into other semantic representations such as K-relations (Green et al., 2007), UniNomial (Chu et al., 2017) and U-semiring (Chu et al., 2018); then they search for an (in)equivalence proof. However, these representations cannot express sort operations and float comparisons, and hence do not support the full range of operations that Text-to-SQL models can use. We ideally need a method to approximate semantic accuracy reliably without operation constraints.

If the computational resources were unlimited, we could compare the denotations of the predicted query with those of the gold on a large number of random databases (Section 4.1), and obtain a tighter upper bound for semantic accuracy than single de-

---

notation evaluation. The software testing literature calls this idea fuzzing (Padhye et al., 2019; AFL; Lemieux et al., 2018; Qui). However, it is undesirable to spend a lot of computational resources every time when we evaluate a Text-to-SQL model. Instead, we want to check denotation correctness only on a smaller test suite of databases that are more likely to distinguish[2] *any* wrong model-predicted queries from the gold.

We propose *test suite accuracy* (Section 2) to efficiently approximate the semantic accuracy of a Text-to-SQL model, by checking denotations of the predicted queries on a compact test suite of databases with high code coverage. We introduce how to construct/search for such a test suite without prior information about model-predicted queries.

Our search objective is formally defined through *neighbor queries* (Section 3.1), which are generated by modifying one aspect of the gold query. For example, prediction 1 in Figure 1 is a neighbor query of the gold, since they differ only by a "`WHERE`" clause. These neighbor queries are usually semantically different from the gold, and if a test suite can distinguish them from the gold, it is likely to distinguish other wrong queries as well. The latter holds because distinguishing all neighbors from the gold requires executions on these databases to exercise every modified part of the gold query, hence reflecting comprehensive code coverage and high test quality (Miller and Maloney, 1963; Ammann and Offutt). Hence, we formalize our objective as finding a small test suite that can distinguish all the neighbors (Section 3.2).

We search under this objective by generating a large number of random databases (Section 4.1) and keeping a small fraction of them that can distinguish the neighbors from the gold (Section 4.2). We call this set of databases a *distilled test suite*. While evaluating model-predicted queries, we only check their denotations on the distilled test suite to approximate semantic accuracy efficiently.

Application We distill a test suite for the SPIDER dataset (Yu et al., 2018) (Section 5) from 1000 random databases, which can distinguish more than 99% of the neighbor queries. We use the test suite to evaluate 21 SPIDER leader board submissions, randomly sample 100 model-predicted queries where our method disagrees with exact set match (ESM, the current SPIDER official metric), and manually verify that our method is correct in *all* these cases (Section 6.1).

We use test suite accuracy as a proxy for semantic accuracy to examine how well ESM approximates the semantic accuracy (Section 6.2), and identify several concerns. (1) ESM tends to underestimate model performances, leading to a 2.5% false negative rate on average and 8.1% in the worst case. (2) ESM does not reflect all improvements in semantic accuracy. For example, it undervalues a high-score submission with 61% semantic accuracy by 8%, but instead favors five other submissions with lower semantic accuracy, thus misrepresenting state of the art. (3) ESM becomes poorer at approximating semantic accuracy on more complex queries. Since models are improving and producing harder queries, ESM deviates more from semantic accuracy. We need test suite accuracy to better track progress in Text-to-SQL development.

Our main paper focuses on SPIDER. However, we also generated distilled test suites for other popular text-to-SQL datasets including CoSQL (Yu et al., 2019a), SParC (Yu et al., 2019b), Academic (Li and Jagadish, 2014), Advising (Finegan-Dollak et al., 2018a), ATIS (Dahl et al., 1994), Geography (Zelle and Mooney, 1996), IMDB (Yaghmazadeh et al., 2017), Restaurants (Popescu et al., 2003), Scholar (Iyer et al., 2017) and Yelp (Yaghmazadeh et al., 2017). We will release our test suites[3] and the details of these datasets can be seen in Appendix A.2.

To summarize, we contribute:

- A method and a software to create compact high quality test suites for Text-to-SQL semantic evaluation.
- Test suites to reliably approximate semantic accuracy for eleven popular datasets.
- A detailed analysis of why current metrics are poor at approximating semantic accuracy.

2 Problem Statement

Let $w \in \mathcal{W}$ be a database input to a SQL query $q \in \mathcal{Q}$, and $[\![q]\!]_w$ be the denotation of q on w,[4] where $\mathcal{W}/\mathcal{Q}$ is the space of all databases/SQL queries. Two queries q_1 and q_2 are semantically equivalent

---

[2] Section 2 defines that a database distinguishes two queries if their executions lead to different results.

[3] https://github.com/ruiqi-zhong/TestSuiteEval

[4] As in Yu et al. (2018), we use Sqlite3 to obtain the denotation. Define $[\![q]\!]_w = \perp$ if execution does not end, which is implemented as timeout in practice.

if their denotations are the same for all possible databases, i.e.

$$\forall w \in \mathcal{W}, [\![q_1]\!]_w = [\![q_2]\!]_w \tag{1}$$

We refer to the ground truth query as g and the model-predicted query to be evaluated as q. Ideally, we want to evaluate whether q is semantically equivalent to g (abbreviated as **semantic accuracy**), which is unfortunately undecidable in general (Chu et al., 2017). Traditionally, people evaluate a model-predicted query q by either **exact string match** or compare denotations on a single database w (abbreviated as **single denotation accuracy**). Exact string match is too strict, as two different strings can have the same semantics. Single denotation evaluation is too loose, as the denotations of g and q might be different on another database w.

We use **test suite** to refer to a set of databases. A database w **distinguishes** two SQL queries g, q if $[\![g]\!]_w \neq [\![q]\!]_w$, and a test suite S distinguishes them if one of the databases $w \in S$ distinguishes them:

$$\exists w \in S, [\![g]\!]_w \neq [\![q]\!]_w \tag{2}$$

For convenience, we define the indicator function:

$$D_S(g, q) := \mathbb{1}[S \text{ distinguishes } g, q] \tag{3}$$

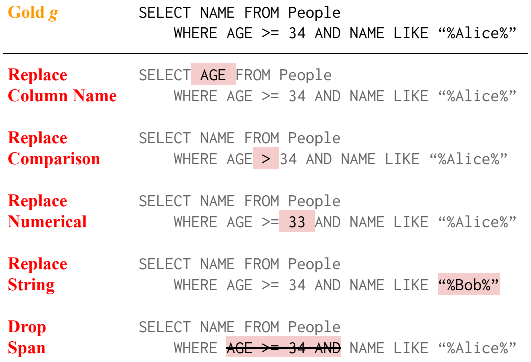
We use the test suite S to evaluate a model-predicted query q: q is correct iff $D_S(g, q) = 0$; i.e., g and q have the same denotations on all databases in S.

To summarize, if $M_1 \Rightarrow M_2$ means that "correctness under M_1 implies correctness under M_2", exact match $\Rightarrow$ semantic accuracy $\Rightarrow$ test suite accuracy $\Rightarrow$ single denotation accuracy. Our goal is to construct a test suite of databases S to obtain a tight upper bound on semantic accuracy with test suite accuracy reliably and efficiently.

3 Desiderata

Since we want to construct a test suite S of databases for each gold query g, we use S_g to denote the target test suite. Before describing how to generate S_g, we first list two criteria of a desirable test suite. Later we construct S_g by optimizing over these two criteria.

Computational Efficiency. We minimize the size of S_g to speed up test suite evaluations.



Gold g	`SELECT NAME FROM People` `WHERE AGE >= 34 AND NAME LIKE "%Alice%"`
Replace Column Name	`SELECT AGE FROM People` `WHERE AGE >= 34 AND NAME LIKE "%Alice%"`
Replace Comparison	`SELECT NAME FROM People` `WHERE AGE > 34 AND NAME LIKE "%Alice%"`
Replace Numerical	`SELECT NAME FROM People` `WHERE AGE >= 33 AND NAME LIKE "%Alice%"`
Replace String	`SELECT NAME FROM People` `WHERE AGE >= 34 AND NAME LIKE "%Bob%"`
Drop Span	`SELECT NAME FROM People` WHERE ~~AGE >= 34 AND~~ NAME LIKE "%Alice%"

Figure 2: Automatically generating a set of neighbor queries N_g. We apply one type of modification to the original gold query g at a time. The modified queries are likely to be semantically close but inequivalent to the gold.

Code Coverage. The test suite needs to cover every branch and clause of the gold query such that it can test the use of every crucial clause, variable, and constant. For example, database 1 in Figure 1 alone does not have a row where "`AGE` $\leq$ 34" and hence does not have comprehensive code coverage.

3.1 Measure Coverage through Neighbors

We measure the code coverage of a test suite by its ability to distinguish the gold query from its *neighbor queries*: a set of SQL queries that are close to the gold in surface forms but likely to be semantically different. To generate them, we modify one of the following aspects of the gold query (Figure 2): (1) replace an integer (float) constant with either a random integer (float) or its value ± 1 (0.001); (2) replace a string with a random string, its sub-string or a concatenation of it with another random string; (3) replace a comparison operator/column name with another; (4) drop a query span unless the span does not change the semantics of the query. For example, the "`ASC`" keyword does not change the semantics because it is the default sort order. We then remove modified queries that cannot execute without any errors.

Note that our method does not pre-determine the number of neighbor queries. It is adaptive and generates more neighbors for longer and more complex queries since there are more spans to drop and more constants to replace.

Neighbor queries have two desirable properties. First, they are likely to be semantically different from the gold query. For example, "`> 34`" is semantically different from "`≥ 34`" (replace comparison operator) and "`> 35`" (replace constants);

however, we only apply one modification at a time, since "> `34`" is semantically equivalent to "≥ `35`" for an integer. Secondly, their subtle differences from the gold require the test suite to cover all the branches of the gold query. For example, the database needs to have people above, below and equal to age 34 to distinguish all its neighbors. Hence, the test suite tends to have high quality if it can distinguish the gold from all its neighbors.

We use N_g to denote the set of neighbor queries of the gold query g.

3.2 Optimization Objective

To recap, our objective is to search for a *small* test suite S_g that can distinguish as *many* neighbor queries as possible. Formally, we optimize over S_g with the objective below:

$$\begin{aligned} & \text{minimize } |S_g| \\ s.t. \quad & \forall q \in N_g, D_{S_g(g,q)} = 1 \end{aligned} \tag{4}$$

4 Fuzzing

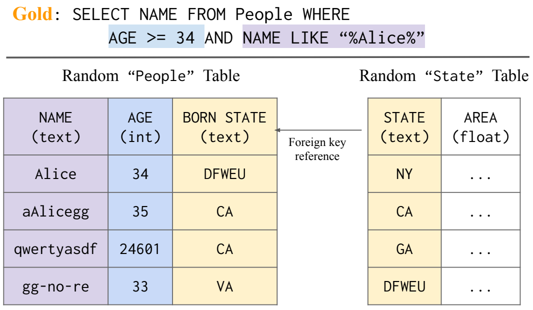
We optimize the above objective through fuzzing: a software testing technique that generates a large number of random inputs to test whether a program satisfies the target property (e.g., SQL equivalence). We describe a procedure to sample a large number of random databases and keep a small fraction of them to distill a test suite S_g.

4.1 Sampling Databases

A database w needs to satisfy the input type constraints of the gold program g, which include using specific table/column names, foreign key reference structure, and column data types. We describe how to generate a random database under these constraints and illustrate it with Figure 3.

If a column c_1 refers to another column c_2 as its foreign key, all elements in c_1 must be in c_2 and we have to generate c_2 first. We define a partial order among the tables: table A < table B if B has a foreign key referring to any column in table A. We then generate the content for each table in ascending order found by topological sort. For example, in Figure 3, we generate the "`State`" table before the "`People`" table because the latter refers to the former.

We now sample elements for each column such that they satisfy the type and foreign key constraints. If a column c_1 is referring to another column c_2, each element in c_1 is uniformly sampled from c_2. Otherwise, if the column is a numerical(string) type, each element is sampled uniformly from $[-2^{63}, 2^{63}]$ (a random string distribution). We also randomly add in constant values used in g (e.g., 34 and "Alice") and their close variants (e.g., 35 and "aAlicegg") to potentially increase code coverage. We denote the database distribution generated by this procedure as $\mathcal{I}_g$.



Gold: `SELECT NAME FROM People WHERE AGE >= 34 AND NAME LIKE "%Alice%"`

Random "People" Table

NAME (text)	AGE (int)	BORN STATE (text)
Alice	34	DFWEU
aAlicegg	35	CA
qwertyasdf	24601	CA
gg-no-re	33	VA

Random "State" Table

STATE (text)	AREA (float)
NY	...
CA	...
GA	...
DFWEU	...

Figure 3: A random database input w from the distribution $\mathcal{I}_g$, where g is the gold SQL query. We generate the "`State`" column before the "`BORN STATE`" column because the latter has to be a subset of the former. Each element of the column "`BORN STATE`" is sampled uniformly at random from the parent "`STATE`" column. For the column that has data type int/string, each element is either a random number/string or a close variant of a constant used the gold query.

4.2 Distilling a Test Suite

We use samples from $\mathcal{I}_g$ to construct a small test suite S_g such that it can distinguish as many neighbor queries (Section 3.1) in N_g as possible. We initialize S_g to be empty and proceed greedily. A database w is sampled from the distribution $\mathcal{I}_g$; if w can distinguish a neighbor query that cannot be distinguished by any databases in S_g, we add w to S_g. Appendix A.1 gives a more rigorous description. In the actual implementation, we also save the disk space by sharing the same random database w_t across all gold SQL queries that are associated with the same schema. Though this algorithm is far from finding the optimal solution to Objective 4, in practice, we find a test suite that is small enough to distinguish most neighbor queries.

5 Evaluation Setup

We introduce the dataset and the model-predicted queries we use to study our test suite evaluation. We also adapt our test suite evaluation and the official SPIDER metric to make a fair comparison.

5.1 Dataset

We generate test suites S_g for the development set of Spider (Yu et al., 2018), which contains 1034 English utterances and their corresponding SQL queries, spanning across 20 different database schemata. It stratifies data into four categories (easy, medium, hard, and extrahard) according to difficulty level measured by gold SQL complexity. We decide to focus on Spider because it invites researchers to submit their model-predicted queries and requires them to follow a standard format, which makes it convenient to study a wide variety of model-predicted queries.

5.2 Model-Predicted Queries

We obtain the development set model-predicted queries from 21 submissions.[5] They include models from Guo et al. (2019); Bogin et al. (2019b); Choi et al. (2020); Wang et al. (2020). [6] These models capture a broad diversity of network architectures, decoding strategies, and pre-traning methods, with accuracy ranging from below 40% to above 70%. The first author obtained these model-predicted queries from the second author *after* producing the test suites to ensure that our method is general and not tailored to a specific family of model-predicted queries.

5.3 Metric Adaptation

The Spider official evaluation metric is exact set match (abbreviated as ESM) (Zhong et al., 2017; Yu et al., 2018). It parses the gold and model-predicted queries into sub-clauses and determines accuracy by checking whether they have the same *set* of clauses. It improves over exact string matching by preventing false negatives due to semantically equivalent clause reordering. However, it is still considered a strict metric and creates false negatives.

To further reduce false negatives, the actual implementation of the official Spider metric is looser. We list all of its major differences from the standard ESM below; accordingly, we either adapt our test suite evaluation or fix the Spider implementation to make a fair comparison.

(1) The Spider metric does not check constant prediction correctness. Therefore, our adapted test suite evaluation enumerates all possible ways to replace the constants in a model-predicted query with the gold constants and consider a model-predicted query to be correct if one of the replacements passes the test suite. (2) The Spider metric does not check column order, so our adapted evaluation considers two denotations equivalent if they only differ by column order. (3) The Spider evaluation script accidentally ignores any join predicate. We fix this bug. (4) The Spider metric does not check table variable names. Yu et al. (2018) implemented this because different intermediate tables can contain the same column, hence selecting any of them is equivalent. We keep this feature since it effectively rules out many false negatives. However, it also introduces new false positives (e.g., Figure 8 row 1).

Unless we explicitly specify, in the rest of our paper, "ESM" and "test suite accuracy" refer to these adapted metrics rather than the original ones.

6 Results

We first show that our test suite evaluation is reliable by verifying that the test suite distinguishes most neighbor queries, and always makes the correct judgement on 100 model-predicted queries we manually examined (Section 6.1). Then we use test suite accuracy as a proxy for semantic accuracy to calculate the error rate of the existing commonly used metrics (Section 6.2) and their correlations (Section 6.3). At last we discuss the computational efficiency of test suite evaluation (Section 6.4).

6.1 Reliability

Distinguish Neighbor Queries. For each gold query in Spider, we generate on average 94 neighbor queries (Figure 2). We sample 1000 random databases for each database schema and run fuzzing (Section 4.2) to construct S_g, which takes around a week on 16 CPUs. Figure 5 plots the fraction of neighbor queries that remain undistinguished after attempting t random databases.

Checking single database denotation fails to distinguish 5% of the neighbor queries, and the curve stops decreasing after around 600 random databases; 1000 random databases can distinguish > 99% of the neighbor queries. A large number of random databases is necessary to achieve comprehensive code coverage.

Figure 4 presents some typical neighbor queries that have the same denotations as the gold on all the databases we sampled. These queries are only a small fraction (1%) of all the neighbors; in most

---

[5] The model-predicted queries are available here.

[6] Many dev set submissions do not have public references.

Modification	Gold & Modified	Passing Reason
Comparison Operator Replaced	`Gold: SELECT T1.NAME FROM Conductor … GROUP BY T2.CONDUCTER_ID HAVING COUNT(*) > 1` `Modified: SELECT T1.NAME FROM Conductor … GROUP BY T2.CONDUCTER_ID HAVING COUNT(*) != 1`	Count is always positive, so "> 1" is equivalent to "!= 1". modification is semantically equivalent to the original SQL.
Constant Replaced	`Gold: SELECT NAME FROM City WHERE POPULATION BETWEEN 160000 AND 90000` `Modified: SELECT NAME FROM City WHERE POPULATION BETWEEN 160000 AND 21687`	Original annotation is wrong and both the original and the modification lead to empty results, which are semantically equivalent.
Column Name Dropped	`Gold: SELECT COUNT(T2.LANGUAGE), T1.NAME …` `Modified: SELECT COUNT(*), T1.NAME FROM …`	The SQL interpreter infers it should count the number of rows. modification is semantically equivalent to the original SQL.
Comparison Operator Replaced	`Gold: SELECT COUNT(*) FROM Dogs WHERE age < (SELECT AVG(AGE) FROM Dogs)` `Modified: SELECT COUNT(*) FROM Dogs WHERE age <= (SELECT AVG(AGE) FROM Dogs)`	A dog entry needs to have exactly the average age to distinguish the modification. This happens with low probability and our test suite fails to distinguish them.

Figure 4: Representative modifications in N_g that produce the same results as the gold (pass) on all sampled databases.

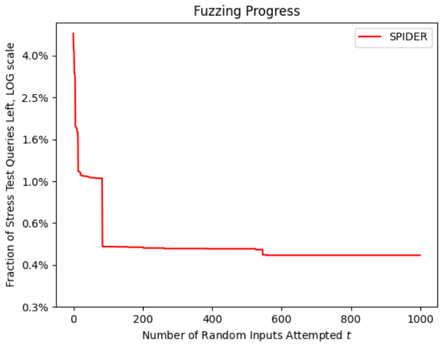


Figure 5: The progress of fuzzing (Section 4.2). The x-axis represents the number of random databases attempted (t), and the y-axis (re-scaled by log) is the fraction of neighbor queries left. y-value at $x = 0$ is the fraction of neighbors left after checking denotations on the database provided by Yu et al. (2018).

cases they happen to be semantically equivalent to the gold. We acknowledge that our fuzzing based approach has trouble distinguishing semantically close queries that differ only at a floating-point precision (e.g. "≤ `2.31`" vs. "< `2.31`"). Fortunately, however, we cannot find a false positive caused by this weakness in our subsequent manual evaluation.

Manual Evaluation. Even though our test suite achieves comprehensive code coverage, we still need to make sure that our method does not create any false positive on model-predicted queries. We focus on the queries from the 21 submissions that are considered incorrect by ESM but correct by our test suite evaluation, randomly sampled and manually examined 100 of them. *All* of them are semantically equivalent to the gold query; in other words, we did not observe a single error made by our evaluation method. We release these 100 model-predicted queries along with annotated reasons for why they are equivalent to the gold labels,[7] such that the research community can conveniently scrutinize the quality of our evaluation method.

We also confirm that our method can reliably evaluate model-predicted queries on WikiSQL (Zhong et al., 2017). We refer the readers to Appendix A.3 for further experimental details.

Difficulty	Mean	Std	Max
easy (%)	0.5 / 2.2	0.5 / 1.3	2.0 / 7.2
medium (%)	0.2 / 1.9	0.3 / 1.9	0.7 / 8.0
hard (%)	0.5 / 4.4	1.2 / 3.8	4.0 / 12.1
extra (%)	1.7 / 3.2	1.8 / 1.6	5.3 / 8.2
all data (%)	0.5 / 2.6	1.0 / 1.7	2.0 / 8.1

Table 1: The false positive/negative rate of the adapted exact set match metric (Section 5.3) for each difficulty split. We report the mean / std / max of these two statistics among 21 dev set submissions.

6.2 Errors of Traditional Metrics

Given that test suite evaluation empirically provides an improved approximation of semantic equivalence, we use test suite accuracy as ground truth and retrospectively examine how well ESM approximates semantic accuracy. We calculate the

---

[7] Manual examinations are available here.

Difficulty	Mean	Std	Max
easy (%)	3.6	1.2	6.0
medium (%)	5.9	0.9	8.2
hard (%)	8.0	1.5	10.3
extra (%)	11.0	3.5	17.6
all data (%)	6.5	1.0	9.0

Table 2: The false positive rate of single denotation accuracy (i.e., checking denotation only on the databases originally released in Yu et al. (2018)) for each difficulty split. We report the mean / std / max of these two statistics among 21 dev set submissions.

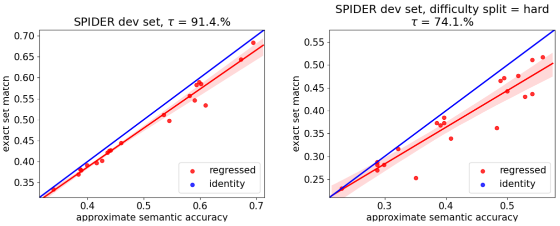
false positive/false negative rate for each difficulty split and report the mean, standard deviation, and max for all 21 submissions.

Table 1 shows the results. ESM leads to a nontrivial false negative rate of 2.6% on average, and 8.1% in the worst case. The error becomes larger for harder fractions of queries characterized by more complex queries. On the hard fraction, false negative rate increases to 4% on average and 12.1% in the worst case.

In Table 2, we report the difference between test suite accuracy and single denotation accuracy, which effectively means checking denotations of the model-predicted queries only on the databases from the original dataset release (Yu et al., 2018). In the worst case, single denotation accuracy creates a false positive rate of 8% on the entire development set, and 4% more on the extrahard fraction.

6.3 Correlation with Existing Metrics

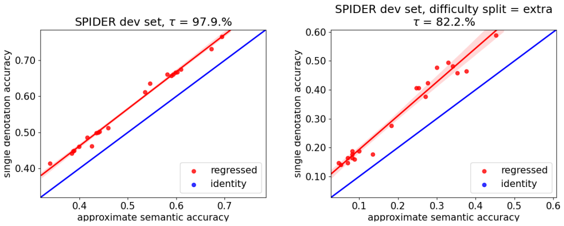
Could surface-form based metric like ESM reliably track improvements in semantic accuracy?



(a) τ = 91.4% on all queries in the dev set.

(b) τ = 74.1% on hard fraction of the dev set.

Figure 6: Kendall τ correlation between exact set match and test suite accuracy. Each dot is a dev set submission to the Spider leaderboard.



(a) τ = 97.9% on all queries in the dev set.

(b) τ = 82.2% on extrahard fraction of the dev set.

Figure 7: Kendall τ correlation between single execution accuracy as originally defined in Yu et al. (2018) and test suite accuracy. Each dot is a dev set submission to the Spider leaderboard.

We plot ESM against test suite accuracy for all 21 dev set submissions in Figure 6. On a macro level, ESM correlates well with test suite accuracy with Kendall τ correlation 91.4% in aggregate; however, the correlation decreases to 74.1% on the hard fraction. Additionally, ESM and test suite accuracy starts to diverge as model performance increases. These two facts jointly imply that as models are becoming better at harder queries, ESM is no longer sufficient to approximate semantic accuracy. On a micro level, when two models have close performances, improvements in semantic accuracy might not be reflected by increases in ESM. On the hard fraction, 5 out of 21 submissions have more than four others that have lower test suite accuracy but higher ESM scores (i.e., there are five dots in Figure 6b such that for each of them, four other dots is located in its upper left).

Figure 7 plots the correlation between single denotation accuracy against test suite accuracy. On the extrahard fraction, four submissions have more than three others that have higher single denotation accuracy but lower test suite accuracy. Checking denotation only on the original database is insufficient.

We list the Kendall τ correlations between test suite accuracy and different metrics in Table 3 and plot them in the appendix Section A.4. The correlation with the current official metric is low without fixing the issue (3) identified in Section 5.3.

6.4 Computational Efficiency

On average, we distill 42 databases for each of the 1034 queries. In total, there are 695 databases since queries with the same database schema share the same test suite. These databases take 3.27GB in space (databases from the original datasets take 100.7MB). Running the gold queries on the entire test suite takes 75.3 minutes on a single CPU (compared to 1.2 minutes on the databases from the original datasets). Although test suite evaluation consumes more space and computational resources

Difficulty	Adapted	Official	Single Denot.
easy (%)	91	86	90
medium (%)	90	37	96
hard (%)	75	28	94
extra (%)	91	20	82
all data (%)	91	40	98

Table 3: Kendall τ correlation between various metrics and test suite accuracy across 21 submissions. **Adapted** refers to ESM after we fix the issue (3) identified in Section 5.3. **Official** refers to directly running the official evaluation script to evaluate, and **Single Denot.** refers to only checking denotation on the one database provided by Yu et al. (2018).

than single denotation evaluation, it is parallelizable and affordable by most researchers.

We may speed up the evaluation by checking denotation only on a single database sampled from the distribution $\mathcal{I}_g$. While this sped-up version sacrifices precision for speed, *retrospectively*, it produces the exact same outcomes as running the full test suite on the 21 submissions. Therefore, the sped-up version might be useful when occasional errors are tolerable (e.g. denotation based training). However, we still recommend using the full test suite for reliable evaluation, since a single sample from $\mathcal{I}_g$ cannot distinguish all neighbors, and checking denotations on multiple databases with comprehensive code coverage is always more reliable, especially when we have no prior information about the model-predicted queries.

7 Metrics Comparison and Analysis

We explain how ESM and test suite accuracy differ and provide representative examples (Figure 8).

False Positives Although standard ESM is strict, the adapted ESM (Section 5.3) can introduce false positives because it ignores table variable names. See Figure 8 row 1 for an example.

False Negatives Row 2-4 shows that slightly complicated queries usually have semantically equivalent variants, and it is nontrivial to tell whether they are semantically equivalent unless we execute them on a test suite or manually verify.

Nevertheless, even though test suite accuracy reliably approximates semantic accuracy according to our observation, researchers might also care about other aspects of a model-predicted query. Semantic accuracy is only concerned with *what* are the denotations of a query, but not *how* it calculates them. For example, Figure 8 row 5 represents one of the most common types of false negatives, where the model-predicted query chooses to join other tables even though it is unnecessary. While semantically correct, the model-predicted query increases running time. Figure 8 row 7 exhibits a similar but more complicated and rare example.

Inserting gold values into model-predicted queries as described in Section 5 might also unexpectedly loosen the semantic accuracy metric. For example, in Figure 8 row 6, the model-predicted query uses the "`LIKE`" keyword rather than the "=" operator. By SQL style conventions, "`LIKE`" usually precedes a value of the form "`%[name]%`" and corresponds to natural language query "`contains [name]`" rather than "`matches [name]`"; it seems plausible that the model does not understand the natural language query. However, if we replace the wrong value "`%[name]%`" with the gold value "`[name]`" after the "`LIKE`" operator, the predicate becomes semantically equivalent to "`= [value]`" and hence makes the query semantically correct. Value prediction is a crucial part of evaluating Text-to-SQL models.

8 Discussion and Conclusion

Semantic Evaluation via Test Suites We propose test suite accuracy to approximate the semantic accuracy of a Text-to-SQL model, by automatically distilling a small test suite with comprehensive code coverage from a large number of random inputs. We assure test suite quality by requiring it to distinguish neighbor queries and manually examining its judgments on model-predicted queries. Our test suites will be released for eleven datasets so that future works can conveniently evaluate test suite accuracy. This metric better reflects semantic accuracy, and we hope that it can inspire novel model designs and training objectives.

Our framework for creating test suites is general and only has two requirements: (1) the input is strongly typed so that the fuzzing distribution $\mathcal{I}_g$ can be defined and the sample input can be meaningfully executed, and (2) there exist neighbor queries N_g that are semantically close but different from the gold g. Since these two conditions hold in many execution environments, our framework might potentially be applied to other logical forms, such as λ-DCS (Liang, 2013), knowledge graphs (Lin et al., 2018), and python code snippets (Yin et al., 2018; Oda et al., 2015) if variable types can

	Error	Gold & Model Prediction	Explanation
1	False Positive	**Gold:** `SELECT T3.NAME, T2.COURSE FROM Course_arrange AS T1 JOIN Course AS T2 ON T1.COURSE_ID = T2.COURSE_ID JOIN Teacher AS T3 ON T1.TEACHER_ID = T3.TEACHER_ID;` **Prediction:** `SELECT T1.NAME, T2.COURSE FROM Course_arrange AS T1 JOIN Course AS T2 ON T1.COURSE_ID = T2.COURSE_ID JOIN Teacher AS T3 ON T1.TEACHER_ID = T3.TEACHER_ID;`	Exact set match does not account for table variable names.
2	False Negative	**Gold:** `SELECT TEMPLATE_ID FROM Templates EXCEPT SELECT TEMPLATE_ID  FROM Documents;` **Prediction:** `SELECT TEMPLATE_ID  FROM Templates WHERE TEMPLATE_ID NOT IN (SELECT TEMPLATE_ID FROM Documents);`	"`EXCEPT`" is semantically equivalent to "`NOT IN`"
3	False Negative	**Gold:** `SELECT COUNT(*) FROM Area_code_state;` **Prediction:** `SELECT COUNT(STATE) FROM Area_code_state;`	Counting any column is the same.
4	False Negative	**Gold:** `SELECT TRANSCRIPT_DATE FROM Transcripts ORDER BY TRANSCRIPT_DATE DESC LIMIT 1;` **Prediction:** `SELECT MAX(TRANSCRIPT_DATE) FROM Transcripts;`	First element of descendingly sorted column is equivalent to maxing.
5	False Negative	**Gold:** `SELECT COUNT(*) FROM Cars_data WHERE HORSEPOWER > 150;` **Prediction:** `SELECT COUNT(*) FROM Cars_data as T1 JOIN Car_names as T2 on T1.ID = T2.MAKEID where T1.HORSEPOWER > 150;`	Semantically correct redundant join.
6	False Negative	**Gold:** `SELECT AIRLINE FROM Airlines WHERE ABBREVIATION = "UAL";` **Prediction:** `SELECT AIRLINE FROM Airlines WHERE ABBREVIATION LIKE "UAL";`	If the string value is the same, "=" is equivalent to "`LIKE`"
7	False Negative	**Gold:** `SELECT LANGUAGE FROM Country_language GROUP BY LANGUAGE ORDER BY Count(*) DESC LIMIT 1;` **Prediction:** `SELECT Country_language.LANGUAGE FROM Country JOIN Country_language GROUP BY Country_language.LANGUAGE ORDER BY Count(*) Desc LIMIT 1;`	The redundant join is implicitly a cross join, which will repeat every row in `Country_language` by [size of `Country` table] times. It leads to the same ranking if counted.

Figure 8: Representative examples where the exact set match (ESM) metric is different from test suite accuracy. False Positives happen when ESM judges a model-predicted query to be correct but test suite accuracy judges it to be wrong. False Negatives happen when the reverse takes place.

be heuristically extracted. We hope to see more future work that evaluates approximate semantic accuracy on the existing benchmarks and formulates new tasks amenable to test suite evaluation.

We do not attempt to solve SQL equivalence testing in general. While our test suite achieves comprehensive code coverage of the gold query, it might not cover all the branches of model-predicted queries. Adversarially, we can always construct a query that differs from the gold only under extreme cases and fools our metric. Fortunately, we never observe models making such pathological mistakes. However, it is necessary to revisit and verify this hypothesis some time later due to Goodhardt's law, since researchers will optimize over our metric.

Beyond Semantic Evaluation Although test suite evaluation provably never creates false negatives in a strict programming language sense, it might still consider "acceptable answers" to be wrong and result in false negatives in a broader sense. For example, in a database of basketball game results, the predicate "`A_wins`" is equivalent to "`scoreA > scoreB`" according to common sense. However, such a relation is not explicitly reflected in the database schema, and our procedure might generate an "unnatural" database where "`scoreA > scoreB`" but not "`A_wins`", hence distinguishing the model-predicted query from the gold. Fortunately, this issue is mitigated by current models. If "`A_wins`" is mentioned in the text, the model would prefer predicting "`A_wins`" rather than "`scoreA > scoreB`". Nevertheless, to completely solve this issue, we recommend future dataset builders to explicitly define the database generation procedure. Automatic constraint induction from database content and schema descriptions might also be possible, which is on its own an open research problem.

Additionally, some answers might be pragmatically acceptable but semantically wrong. For example, if a user asks "who is the oldest person?", the correct answer is a person's name. However, it also makes sense to return both the name and age columns, with the age column sorted in descending order. Collecting multiple gold SQL query references for evaluation (like machine translation) might be a potential solution.

Finally, as discussed in Section 7, there might be other crucial aspects of a model-predicted query beyond semantic correctness. Depending on the goal of the evaluation, other metrics such as memory/time efficiency and readability are also desirable and complementary to test suite accuracy.

Acknowledgement

We thank Wanyong Feng, Naihao Deng and Songhe Wang for rewriting queries and cleaning databases from Finegan-Dollak et al. (2018b). We thank Rishabh Agarwal, Tong Guo, Wonseok Hwang, Qin Lyu, Bryan McCann, Chen Liang, Sewon Min, Tianze Shi, Bailin Wang and Victor Zhong for responding to our cold email looking for WikiSQL model-predicted queries.

A Appendix

A.1 Algorithmic Description of Section 4.2

Algorithm 1: Distilling a test suite S_g. N_g is the set of neighbor queries of g; $\mathcal{I}_g$ is a distribution of database inputs.

```
$S_g := \emptyset, N := N_g$ ;
for $t = 1, 2, \ldots 1000$ do
    $w_t \sim \mathcal{I}_g$;
    for $q \in N_g$ do
        if $D_{\{w_t\}}(q, g) = 1$ then
            $S_g.add(w_t)$;
            $N.remove(q)$
return $S_g$
```

A.2 Test Suite for Other Datasets

Data We download Academic, Advising, ATIS, Geography, IMDB, Restaurants, Scholar and Yelp from Finegan-Dollak et al. (2018a). For each dataset, we distill a test suite for the test split if it is already defined; otherwise we distill for the entire dataset.

We distill one shared test suite for the development set of SPIDER (Yu et al., 2018), CoSQL (Yu et al., 2019a) and SPARC (Yu et al., 2019b), since they share the same 20 database schemata.

Test Suite Statistics The detailed test suite statistics can be seen in Table 4. The following list describes what each column represents:

- # Queries: the number of SQL queries we generate test suites for. Notice that this is not the full dataset size.
- Time: the time needed (in minute) to execute all the gold queries on its corresponding test suite on a single CPU. The smaller the value, the better.
- Size: the total size (in Giga-Bytes(G)/Mega-Bytes(M)) of the test suite. The smaller the value, the better.
- OrigSize: the size of the databases (in Giga-Bytes) in the original release.
- $|N_g|$: the average number of neighbor queries generated for each gold query g in the dataset.
- Undistinguished: the fraction of neighbor queries that cannot be distinguished by the test suite. The smaller the value, the better.
- # "Reliable": the estimated fraction of gold queries in a dataset that can be *reliably evaluated* (defined below). The larger the value, the better.

SPIDER, CoSQL and SPARC have approximately the same statistics, since they share the same database schema and annotation convention. The other eight datasets have significantly longer queries with much more "`JOIN`" and "`WHERE`" operations. Hence, there are more spans to drop and more neighbors are generated per query.

Reliability Table 4 column "Undistinguished" implies that fuzzing cannot distinguish a non-trivial fraction of neighbor queries for some datasets. Besides cases where the neighbor queries are accidentally semantically equivalent to the gold, there are two major categories where fuzzing fails to distinguish semantically inequivalent neighbors.

- The gold query contains too many "`WHERE`" operations. For example, among the 93 queries in the ATIS test split, the maximum number of "`WHERE`" operations is 24 for a single query, whereas this number is only 2 among 1034 queries in the SPIDER development set. Distinguishing two queries that differ by only one "`WHERE`" operation is hard because the randomly sampled database needs to have a row that exactly satisfies all the "`WHERE`" clauses.
- The gold query contains predicates like "`WHERE COUNT(*) > 5000`". Distinguishing "`WHERE COUNT(*) > 5000`" from "`WHERE COUNT(*) > 4999`" requires the number of the target (intermediate) table to have a size exactly 5000. Such a requirement is particularly hard for randomly generated databases.

We say that a datapoint can be *reliably evaluated* if all of its undistinguished neighbors do not fall into the above two categories; then we estimate the fraction of datapoints that can be reliably evaluated for each dataset in Table 4. Fortunately, the majority of queries can be reliably evaluated for every dataset. Future manual efforts to hand-craft test suite might be needed to distinguish the neighbor queries and make test suite evaluation more reliable on ATIS and Advising.

Finally, Suhr et al. (2020) evaluates execution accuracy only on datapoints where the gold denotation is not empty. In comparison, at least one

Dataset	# Queries	Time ↓	Size ↓	OrigSize	$\lvert N_g \rvert$	Undistinguished ↓	# "Reliable" ↑
SPIDER	1034	75.3m	3.27G	0.10G	94	0.44%	100.0%
CoSQL	1007	75.6m	3.27G	0.10G	93	0.48%	100.0%
SPARC	1203	86.7m	3.27G	0.10G	81	0.71%	100.0%
Academic	189	1.6m	0.03G	4.81G	368	1.36%	94.7%
Advising	76	1.7m	0.14G	0.03G	520	0.91%	63.2%
ATIS	93	19.2m	0.92G	0.06G	974	0.63%	76.3%
Geography	51	0.4m	2.21M	0.26M	108	5.28 %	88.2%
IMDB	97	0.8m	0.02G	0.99G	253	0.23%	100.0%
Restaurants	23	0.2m	1.37M	1.03M	379	0.14%	100.0%
Scholar	101	0.9m	9.43M	6.45G	107	0.54%	92.1%
Yelp	122	1.4m	0.02G	2.15G	274	0.07%	98.3%

Table 4: Detailed test suite statistics by datasets. Appendix Section A.2 includes detailed explanation of each column name. ↓/↑ means that we hope the number to be small/large. SPIDER, CoSQL and SPARC share the same test suite.

database from our test suite produces non-empty gold denotation for every datapoint in all eleven datasets.

A.3 Evaluation on WikiSQL

We show that our test suite evaluation strategy also works well for model-predicted queries on WikiSQL (Zhong et al., 2017). The dev/test set contains 8420/15878 SQL queries, respectively.

Model-Predicted Queries We reached out to authors of individual works to obtain real model predictions on WikiSQL, and heard back from Min et al. (2019); McCann et al. (2018); Lyu et al. (2020); Hwang et al. (2019); He et al. (2019); Shi et al. (2018); Guo (2017); Agarwal et al. (2019); Liang et al. (2018); Wang et al. (2019).

We use the model-predicted queries from the first six works cited above since they provided model-predicted queries in the format consistent with Zhong et al. (2017), which can be easily converted into SQL queries. Specifically, we consider the model-predicted queries from the following eight models: MQAN unordered (McCann et al., 2018), X-SQL (He et al., 2019), HydraNet with/without Execution Guidance (Lyu et al., 2020), IncSQL (Shi et al., 2018), SQLova with/without Execution Guidance (Hwang et al., 2019) and HardEM (Min et al., 2019). This provides us in total $(8420 + 15878) \times 8 \approx 200K$ model-predicted queries.

Test Suite Generation We run the fuzzing algorithm (Section 4) as before to create test suite. Since the most complex query in WikiSQL is simple and only consists of a single "`WHERE`" clause with an aggregation operation, our test suite can distinguish all the neighbors.

Metric Difference To check whether our test suite reliably evaluates semantic accuracy, we examine model-predicted queries where test suite accuracy disagrees with Exact Set Match (ESM) (as in Section 6.1).

We find that there is only one pattern where a semantically correct prediction is considered wrong by ESM: counting any column of a table gives exactly the same denotation. For example, "`SELECT count(col1) from Table`" is semantically equivalent to "`SELECT count(col2) from Table`" but different in surface form. After implementing a rule to filter out this equivalence pattern, we only find one model-predicted query that is considered wrong by ESM but correct by test suite accuracy, and we present it below.

The gold query is

`SELECT MAX(col2) table WHERE col4 = 10;`

, while the model-predicted query is

`SELECT MAX(col2) FROM table WHERE col2 > 10 AND col4 = 10;`

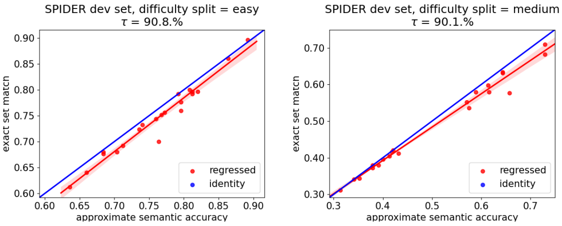
.This model-predicted query is not semantically equivalent to the gold, and hence our test suite evaluation makes an error. It over-generates a clause "`WHERE col2 > 10`" that is not covered by the test suite. None of our sampled database leads to a gold denotation fewer or equal to 10, which is a necessary and sufficient condition to distinguish these two queries.

To conclude, on WikiSQL, we only find 1 out of 200K model-predicted queries where our test suite accuracy makes an error, while we are able to verify that our test suite accuracy is correct for all the other model-predicted queries. This further implies that our method to develop semantic evaluation is robust and not dataset-specific.

On the other hand, however, the only semantically equivalent variant of the gold query in WikiSQL is replacing the column to be counted. Since we might still want to check which column the model-predicted query is counting for code readability, we do NOT recommend researchers to use test suite accuracy for WikiSQL.

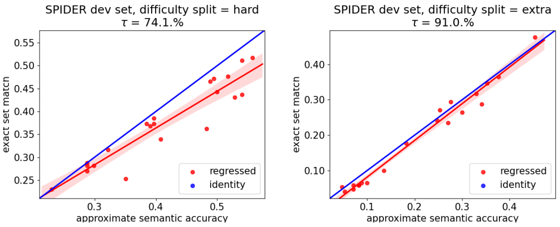
A.4 Correlation Plot with Other Metrics

We plot the correlation between test suite accuracy and (1) adapted exact set match (Figure 9), (2) official Spider exact set match (Figure 10), and (3) single denotation accuracy (Figure 11) on each fraction of the difficulty split.



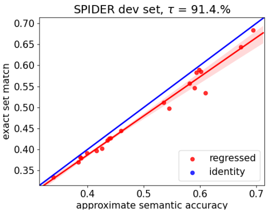
(a) τ = 90.8% on easy fraction.

(b) τ = 90.1% on medium fraction.



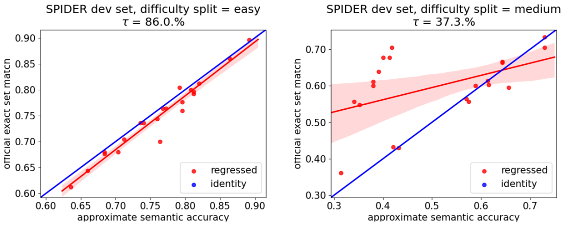
(c) τ = 74.1% on hard fraction.

(d) τ = 91.0% on extra hard fraction.



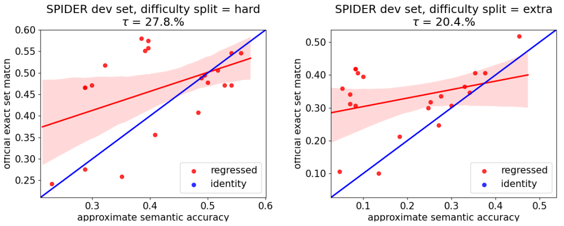
(e) τ = 91.4% on all data.

Figure 9: Kendall τ correlation between **adapted exact set match** and fuzzing-based accuracy. Each dot in the plot represents a dev set submission to the Spider leader board.



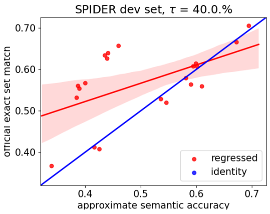
(a) τ = 86.0% on easy fraction.

(b) τ = 37.3% on medium fraction.



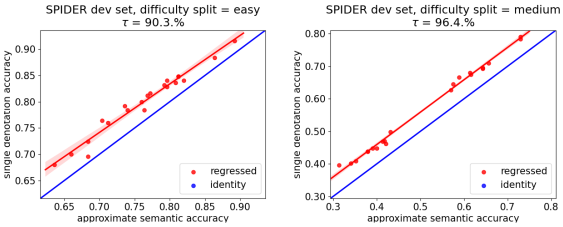
(c) τ = 27.8% on hard fraction.

(d) τ = 20.4% on extra hard fraction.



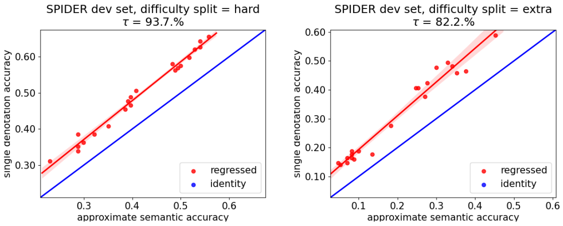
(e) τ = 40.0% on all data.

Figure 10: Kendall τ correlation between the official **Spider exact set match** and fuzzing-based accuracy. Each dot in the plot represents a dev set submission to the Spider leader board.



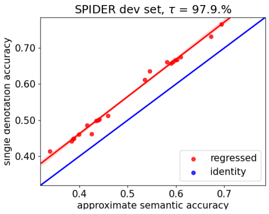
(a) τ = 90.3% on easy fraction.

(b) τ = 96.4% on medium fraction.



(c) τ = 93.7% on hard fraction.

(d) τ = 82.2% on extra hard fraction.



(e) τ = 97.9% on all data.

Figure 11: Kendall τ correlation between **single denotation accuracy** and fuzzing-based accuracy. Each dot in the plot represents a dev set submission to the SPIDER leader board.

Cross-Thought for Sentence Encoder Pre-training

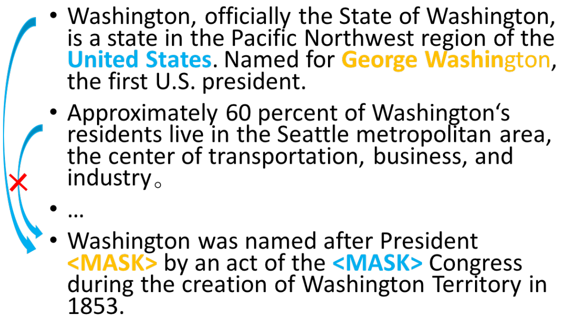
Abstract

In this paper, we propose Cross-Thought, a novel approach to pre-training sequence encoder, which is instrumental in building reusable sequence embeddings for large-scale NLP tasks such as question answering. Instead of using the original signals of full sentences, we train a Transformer-based sequence encoder over a large set of short sequences, which allows the model to automatically select the most useful information for predicting masked words. Experiments on question answering and textual entailment tasks demonstrate that our pre-trained encoder can outperform state-of-the-art encoders trained with continuous sentence signals as well as traditional masked language modeling baselines. Our proposed approach also achieves new state of the art on HotpotQA (full-wiki setting) by improving intermediate information retrieval performance.[1]

1 Introduction

Encoding sentences into embeddings (Kiros et al., 2015; Subramanian et al., 2018; Reimers and Gurevych, 2019) is a critical step in many Natural Language Processing (NLP) tasks. The benefit of using sentence embeddings is that the representations of all the encoded sentences can be reused on a chunk level (compared to word-level embeddings), which can significantly accelerate inference speed. For example, when used in question answering (QA), it can significantly shorten inference time with all the embeddings of candidate paragraphs pre-cached into memory and only matched with the question embedding during inference.

There have been several models specifically designed to pre-train sentence encoders with large-scale unlabeled corpus. For example, Skip-thought (Kiros et al., 2015) uses encoded sentence embeddings to generate the next sentence (Figure 2(a)). Inverse Cloze Task (Lee et al., 2019) defines some pseudo labels to pre-train a sentence encoder (Figure 2(b)). However, pseudo labels may bear low accuracy, and rich linguistic information that can be well learned in generic language modeling is often lost in these unsupervised methods. In this paper, we propose a novel unsupervised approach that fully exploits the strength of language modeling for sentence encoder pre-training.



- Washington, officially the State of Washington, is a state in the Pacific Northwest region of the **United States**. Named for **George Washington**, the first U.S. president.
- Approximately 60 percent of Washington's residents live in the Seattle metropolitan area, the center of transportation, business, and industry。
- …
- Washington was named after President <MASK> by an act of the <MASK> Congress during the creation of Washington Territory in 1853.

Figure 1: Example of short sequences that can leverage each other for pre-training sentence encoder.

Popular pre-training tasks such as language modeling (Peters et al., 2018; Radford et al., 2018), masked language modeling (Devlin et al., 2019; Liu et al., 2019) and sequence generation (Dong et al., 2019; Lewis et al., 2019) are not directly applicable to sentence encoder training, because only the hidden state of the first token (a special token) (Reimers and Gurevych, 2019; Devlin et al., 2019) can be used as the sentence embedding, but no loss or gradient is specifically designed for the first special token, which renders sentence embeddings learned in such settings contain limited useful information.

Another limitation in existing masked language modeling methods (Devlin et al., 2019; Liu et al., 2019) is that they focus on long sequences (512 words), where masked tokens can be recovered by

(a) Skip-Thought (b) Inverse Cloze Task (c) Cross-Thought

Figure 2: Structures of pre-training models for sentence encoder. (a) is a Seq2Seq model that generates the next sentence based on the embedding of the previous sentence. (b) is the classification/ranking model based on pre-defined pseudo labels. (c) is the structure of our model by using the sentence embedding from other sequences to generate the masked word.

considering the context within the same sequence. This is useful for word dependency learning within a sequence, but less effective for sentence embedding learning.

In this paper, we propose Cross-Thought, which segments input text into shorter sequences, where masked words in one sequence are less likely to be recovered based on the current sequence itself, but more relying on the embeddings of other surrounding sequences. For example, in Figure 1, the masked words "George Washington" and "United States" in the third sequence can only be correctly predicted by considering the context from the first sequence. Thus, instead of performing self-attention over all the words in all sentences, our proposed pre-training method enforces the model to learn from mutually-relevant sequences and automatically select the most relevant neighbors for masked words recovery.

The proposed Cross-Thought architecture is illustrated in Figure 2(c). Specifically, we pre-append each sequence with multiple special tokens, the final hidden states of which are used as the final sentence embedding. Then, we train multiple cross-sequence Transformers over the hidden states of different special tokens independently, to retrieve relevant sequence embeddings for masked words prediction. After pre-training, the attention weights in the cross-sequence Transformers can be directly applied to downstream tasks (e.g., in QA tasks, similarity scores between question and candidate answers can be ranked by their respective sentence embeddings).

Our contributions are summarized as follows. (i) We propose the Cross-Thought model to pre-train a sentence encoder with a novel pre-training task: recovering a masked short sequence by taking into consideration the embeddings of surrounding sequences. (ii) Our model can be easily finetuned on diverse downstream tasks. The attention weights of the pre-trained cross-sequence Transformers can also be directly used for ranking tasks. (iii) Our model achieves the best performance on multiple sequence-pair classification and answer-selection tasks, compared to state-of-the-art baselines. In addition, it further boosts the recall of information retrieval (IR) models in open-domain QA task, and achieves new state of the art on the HotpotQA benchmark (full-wiki setting).

2 Related Work

Sequence Encoder Many studies have explored different ways to improve sequence embeddings. Huang et al. (2013) proposes deep structured semantic encoders for web search. Tan et al. (2015) uses LSTM as the encoder for non-factoid answer selection, and Tai et al. (2015) proposes tree-LSTM to compute semantic relatedness between sentences. Mou et al. (2016) also uses tree-based CNN as the encoder for textual entailment tasks. Cheng et al. (2016) proposes Long Short-Term Memory-Networks (LSTMN) for inferring the relation between sentences, and Lin et al. (2017) combines LSTM and self-attention mechanism to improve sentence embeddings. Multi-task learning (Subramanian et al., 2018; Cer et al., 2018) has also been applied for training better sentence embeddings. Recently, in additional to supervised learning, models pre-trained with unsupervised methods begin to dominate the field.

Pre-training Several methods have been proposed to directly pre-train sentence embedding, such as Skip-thought (Kiros et al., 2015), FastSent (Hill et al., 2016), and Inverse Cloze Task (Lee et al., 2019). Although these methods can obtain better sentence embeddings in an unsupervised way, they cannot achieve state-of-the-art performance in downstream tasks even with further finetuning. More recently, Peters et al. (2018) proposes to pre-train LSTM with language modeling (LM) task, and Radford et al. (2018) pre-trains Transformer also with LM. Instead of sequentially generating words in a single direction, Devlin et al. (2019) proposes the masked language modeling task to pre-train bidirectional Transformer. Most recently, Guu et al. (2020); Lewis et al. (2020) propose to jointly train sentence-embedding-based information retriever and Transformer to re-construct documents. However, their methods are usually difficult to train with reinforcement learning methods involved, and need to periodically re-index the whole corpus such as Wikipedia. In this paper, to pre-train sentence encoder, we propose a new model Cross-Thought to recover the masked information across sequences. We make use of the heuristics that nearby sequences in the document contain the most important information to recover the masked words. Therefore, the challenging retrieval part can be replaced by soft-attention mechanism, making our model much easier to train.

3 Cross-Thought

In this section, we introduce our proposed pre-training model Cross-Thought, and describe how to finetune the pre-trained model on downstream tasks. Specifically, most parameters in downstream tasks can be initialized by the pre-trained Cross-Thought, and for certain tasks (e.g., ranking) the attention weights across sequences can be directly used without additional parameters (Figure 3).

3.1 Pre-training Data Construction

Our pre-training task is inspired by Masked Language Modeling (Devlin et al., 2019; Liu et al., 2019), and the key difference is the way to construct sequences for pre-training. As our goal is sentence embedding learning, the pre-training task is designed to encourage the model to recover masked words based on sentence-level global context from other sequences, instead of word-level local context within the same sequence (Figure 1). Therefore, unlike previous work that segments raw text into long sequences and shuffles the sequences for pre-training, we propose to create shorter text sequences instead, without shuffling. In this way, a shorter sequence may not contain all the necessary information for recovering the masked words, hence requiring the probing into surrounding sequences to capture the missing information.

3.2 Cross-Thought Pre-training

The pre-training model is illustrated in Figure 3(a). As aforementioned, the input of pre-training data consists of M continuous sequences $[X_0, X_1, ..., X_{M-1}]$. Similar to BERT (Devlin et al., 2019), we use the hidden state of the special token as the final sentence embedding. To encode the embeddings with richer semantic information, we propose to pre-append N special tokens S instead of a single one to each sequence X.

We first use Transformer to encode the segmented short sequences as follows:

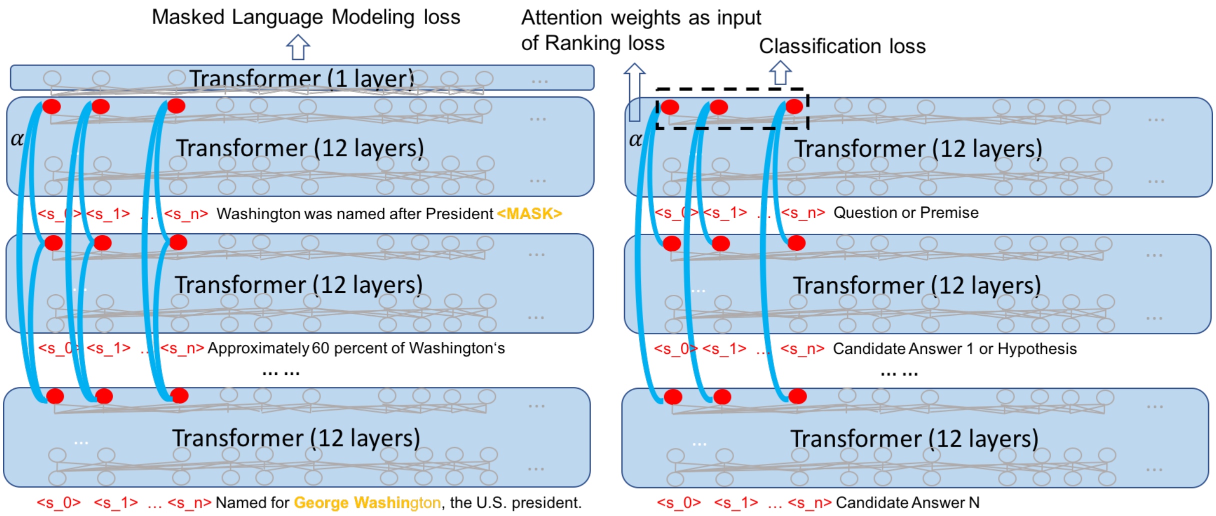
$$\begin{aligned} \mathbf{H}_m &= \text{Transformer}([\mathbf{S}; \mathbf{X}_m]), && (1) \\ \mathbf{E}_m &= \mathbf{H}_m[0{:}N-1], && (2) \end{aligned}$$

where $\mathbf{S} \in \mathbb{R}^{N \times d}$ are the embeddings of N special tokens, and $\mathbf{X}_m \in \mathbb{R}^{l_m \times d}$ are the contextualized word embeddings of the m-th sequence. l_m is the sequence length and d is the dimension of the embedding. $[\cdot;\cdot]$ is the concatenation of matrices. $\mathbf{H}_m \in \mathbb{R}^{(N+l_m)\times d}$ are all the hidden states of the Transformer, and $\mathbf{E}_m \in \mathbb{R}^{N\times d}$ are the hidden states on the special tokens, used as the final sequence embedding.

Next, we build cross-sequence Transformer on top of these sequence embeddings, so that each sequence can distill information from other sequences. As the embeddings of different special tokens encode different information, we run Transformer on the embedding of each special token separately:

$$\begin{aligned} \mathbf{F}_n &= [\mathbf{E}_0[n]; \mathbf{E}_1[n]; ...; \mathbf{E}_{M-1}[n]], && (3) \\ \mathbf{C}_n &= \text{Cross-Transformer}(\mathbf{F}_n), && (4) \end{aligned}$$

where $\mathbf{E}_m[n] \in \mathbb{R}^d$ is the n-th row of $\mathbf{E}_m$. $\mathbf{F}_n \in \mathbb{R}^{M\times d}$ is the concatenation of all the embeddings of the n-th special token in each sequence. $\mathbf{C}_n \in$



(a) Cross-Thought for Pre-training (b) Cross-Thought for Finetuning

Figure 3: Illustration of Cross-Thought for pre-training and finetuning procedures. Circles in red are sentence embeddings. Lines in blue are the cross-sequence Transformers, the attention weights of which are α in Eqn. (7). Words in red are special tokens, the hidden states of which are the sentence embeddings. Multiple special tokens are used to enrich the sentence embeddings. In (a), the sentence embedding of the third sequence provides context that can help generate the masked word in the first sequence. In (b), the model can be initialized with pre-trained Cross-Thought for Answer Selection or Textual Entailment tasks. The attention weights α and hidden states of cross-sequence Transformers can be used directly for Ranking and Classification tasks.

$\mathbb{R}^{M\times d}$ is the output of cross-sequence Transformer, where all the information across sequences are fused together. As the weights of multi-head attention in cross-sequence Transformer will be used for downstream tasks, we decompose the attention weights of one head in the cross-sequence Transformer on the n-th special tokens as follows:

$$\begin{aligned} \mathbf{Q} &= \mathbf{W}^Q\mathbf{F}_n, &(5)\\ \mathbf{K} &= \mathbf{W}^K\mathbf{F}_n, &(6)\\ \alpha &= \text{Softmax}\,(\frac{\mathbf{QK}^T}{\sqrt{d}}), &(7)\end{aligned}$$

where $\mathbf{W}^Q \in \mathbb{R}^{d\times d}$, $\mathbf{W}^K \in \mathbb{R}^{d\times d}$ are the parameters to learn. $\alpha \in \mathbb{R}^{M\times M}$ are the attention weights that can be directly used in downstream tasks (e.g., for measuring the similarity between question and candidate answers in QA tasks).

Finally, to encourage the embedding from other sequences retrieved by cross-sequence Transformer to help generate the masked words in the current sequence, we use another Transformer layer on top of the merged sequence embeddings as follows:

$$\begin{aligned} \mathbf{G}_m &= [\mathbf{C}_0[m]; \mathbf{C}_1[m]; ...; \mathbf{C}_{N-1}[m]; \mathbf{H}_m[N{:}]]\,, \\ \mathbf{O}_m &= \text{Transformer}(\mathbf{G}_m), \qquad (8)\end{aligned}$$

where $\mathbf{C}_n[m] \in \mathbb{R}^d$ is the hidden state of cross-sequence Transformer on the n-th special token of the m-th sequence. $\mathbf{H}_m[N{:}] \in \mathbb{R}^{l_m\times d}$ from Eqn.(1) is the hidden state for non-special words X_m. $\mathbf{O}_m \in \mathbb{R}^{(N+l_m)\times d}$ will be used to generate the masked word:

$$\mathcal{L}_{\text{mask}} = \sum_{m,i} -\log(P(a_{m,i}|\mathbf{O}_m)), \qquad (9)$$

where $P(a_{m,i}|\mathbf{O}_m)$ is the probability of generating the i-th masked word in the m-th sequence.

3.3 Cross-Thought Finetuning

To demonstrate how pre-trained Cross-Thought can initialize models for downstream tasks, we take two tasks as examples: answer selection and sequence-pair classification (under the setting of using sentence embeddings only, without word-level cross-sequence attention (Devlin et al., 2019)). The procedure is illustrated in Figure 3 (b).

Answer Selection The goal is to select one answer from a candidate pool, $\{X_1, X_2, ..., X_{M-1}\}$ based on question X_0. We consider the representations of candidate answers that are cached and can be matched to question embeddings when a new question comes in. Based on the pre-trained model, the attention weights in Eqn.(7) from different heads of the cross-sequence Transformers can be directly applied to rank the answer candidates. For further finetuning, the loss relying on the attention weights is defined as follows:

$$\mathcal{L}_{\text{answer}} = -\log(\alpha[0][m]), \tag{10}$$

where $\alpha[0]$ are the attention weights between question X_0 and all the answer candidates, and m is the index of the correct answer in $\{X_1, X_2, ..., X_{M-1}\}$. Note that we have multiple cross-sequence Transformers on different special tokens, and each Transformer has multiple heads. Thus, we use the mean value of all the attention matrices as the final weights.

Sentence Pair Classification The goal is to identify the relation between two sequences, X_0 and X_1. Reusable sequence embeddings are very useful in some tasks, such as finding the most similar pair of sentences from a large candidate pool, which requires large-scale repetitive encoding and matching without pre-computed sentence embeddings. As the pre-training of cross-sequence Transformer is designed to fuse the embeddings of different sequences, the merged representations in Eqn.(4) can be used for downstream classification as follows:

$$\begin{aligned}\bar{\mathbf{C}} &= [\mathbf{C}_0; \mathbf{C}_1; ...; \mathbf{C}_{N-1}],\\ \bar{\mathbf{c}} &= \text{Flatten}(\bar{\mathbf{C}}),\\ \mathcal{L}_{\text{cls}} &= -\log\left(\text{Softmax}\left(\mathbf{W}^c\bar{\mathbf{c}}^T\right)[y]\right), \end{aligned} \tag{11}$$

where $\bar{\mathbf{C}} \in \mathbb{R}^{2N\times d}$ is the concatenation of the hidden states of all the cross-sequence Transformers on N different special tokens. Note that there are only two sequences here for classification. $\bar{\mathbf{c}} \in \mathbb{R}^{2Nd}$ is the reshaped matrix for final classification, and cross-entropy loss is used for optimization.

4 Experiments

In this section, we conduct experiments based on our pre-trained models, and provide additional detailed analysis.

4.1 Datasets

We conduct experiments on five datasets, the statistics of which is shown in Table 1.

Dataset	#train	#test	#seq	Goal
MNLI-m	373K	10K	2	classification
MNLI-mm	373K	10K	2	classification
SNLI	549K	10K	2	classification
QQP	346K	391K	2	classification
Quasar-T	29K	3K	100	ranking
HotpotQA	86K	7K	5M	ranking

Table 1: Statistics of the datasets. #train and #test are the number of samples for training and testing. #seq is the number of sequences needed to use for each sample. 5M is for 5 million.

MNLI (Williams et al., 2018)[2]: Multi-Genre Natural Language Inference matched (MNLI-m) and mismatched (MNLI-mm) are textual entailment tasks. The goal is to classify the relation between premise and hypothesis sentences into three classes: entailment, contradiction and neutral. The train and test sets come from the same *source* and same *genre* in MNLI-m, and different in MNLI-mm.

SNLI (Bowman et al., 2015)[3]: The dataset of Stanford Natual Language Inference is another textual entailment task.

QQP (Wang et al., 2018): Quora Question Pairs is to identify whether two questions are duplicated or not.

Quasar-T (Dhingra et al., 2017)[4]: This is a dataset for question answering by searching the related passages and then reading it to extract the answer. In this dataset, we evaluate the models by whether it can correctly select the sentence containing the gold answer from the candidate pool.

HotpotQA (Yang et al., 2018)[5]: A dataset of diverse and explainable multi-hop question answering. We focus on the full-wiki setting, where the model needs to extract the answer from all the abstracts in Wikipedia and related sentences.

Note that for the datasets of MNLI, QQP and HotpotQA, the test sets are hidden and the number of submissions is limited. For a fair comparison between our models and baselines, we split 5% of the training data as validation set and use the original validation set as test set.

4.2 Implementation Details

All the models are pre-trained on Wikipedia and finetuned on downstream tasks. We also evaluate the pre-trained models on whether they can perform unsupervised paragraph selection, and whether the improvement over paragraph ranking can lead to better answer prediction on HotpotQA task. As our experiments are to evaluate the ability of sentence

encoder, we only build a light layer on sentence embeddings for classification task, and use only dot product (Cross-Thought, ICT) or cosine similarity (Skip-thought, LM, MLM) between sentence embeddings for ranking task. Note that for fair comparison, all the encoders in our experiments have the same structure as RoBERTa-base (12 layers, 12 self-attention heads, hidden size 768). For all experiments, we use Adam (Kingma and Ba, 2015) as the optimizer and use the tokenizer of GPT-2 (Radford et al., 2018).

For model pre-training, all models including the baselines we re-implement are trained with Wikipedia pages.[6] We use 16 NVIDIA V100 GPUs for model training. Our code is mainly based on the RoBERTa codebase,[7] and we use similar hyperparameters as RoBERTa-base training. Each training sample contains 500 short sequences with 64 tokens, and we randomly mask 15% of the tokens in the sequences. During training, we fix the position embeddings for the pre-appended special tokens, and randomly select 64 continuous positions from 0 to 564 for the other words. Thus, the model can be used to encode longer sequences in downstream tasks. The batch size is set to 128 (4 million tokens). We use warm-up steps 10,000, maximal update steps 125,000, learning rate 0.0005, dropout 0.1 for pre-training. Each model is pre-trained for around 4 days.

For model finetuning, in experiments for MNLI, SNLI and QQP, we use batch size 32, warmup steps 7,432, maximal update steps 123,873, and learning rate 0.00001. For Quasar-T and HotpotQA, we set batch size 80, warmup steps 2,220, maximal update steps 20,360, and learning rate 0.00005. Dropout is the only hyper-parameter we tuned, and 0.1 is the best from [0.1, 0.2, 0.3]. As HotpotQA in full-wiki

---

[7] https://github.com/pytorch/fairseq

setting does not provide answer candidates, we randomly sample 100 negative paragraphs from the top 1000 paragraphs ranked by BM25 scores during training. During inference, we use sentence embeddings to further rank the top 1000 paragraphs. For the unsupervised experiment on HotpotQA, we only rank top 200 paragraphs.

4.3 Baselines

Existing baseline methods are mostly trained with different encoders or different datasets. For fair comparison, we re-implement all these baselines by using a 12-layer Transformer as the sentence encoder and Wikipedia as the source for pre-training. There are three groups of baselines considered for evaluation:

Pre-trained Sentence Embedding

- *ICT* (Lee et al., 2019): Inverse cloze task treats a sentence and its context as a positive pair, otherwise negative. Sentences are masked from the context 10% of the time. This model is trained by ranking loss based on the dot product between sequence embeddings.
- *Skip-Thought* (Kiros et al., 2015): The task is to encode sentences into embeddings that are used to re-construct the next and the previous sentences. This model is based on encoder-decoder structure without considering attention across sequences (Cho et al., 2014). We use 6-layer Transformer as the decoder for re-construction.

Language Modeling In addition, we also re-implement benchmark baselines on the classic Language Modeling (LM) and Mask Language Modeling tasks, as most existing models are pre-trained with different unlabeled datasets:

- *Language Model (LM)* (Radford et al., 2018): The task is to predict the probability of the next word based on given context. As the words are sequentially encoded, to evaluate the performance of this model on HotpotQA in the unsupervised setting, we use the last hidden state as the sentence embedding (instead of the first one by ICT, MLM, Skip-Thought).
- *Masked Language Model (MLM)* (Devlin et al., 2019): The task is to generate randomly masked words from sequences. We explore different settings of training data. “Masked LM-1-512” trains a Transformer on sequences with 512 tokens and pre-appends 1 special token to each sequence. “Masked LM-1-64” is trained on sequences with 64 tokens. Both models are trained with Wikipedia text only. “Masked LM (160G)” is the RoBERTa model pre-trained on a much larger corpus.

Multi-hop Question Answering To further evaluate our model on multi-hop question answering task in open-domain setting, we compare our framework with several strong baselines on HotpotQA:

- *Cognitive Graph* (Ding et al., 2019): It uses an iterative process of answer extraction and further reasoning over graphs built upon extracted answers.
- *Semantic Retrieval* (Nie et al., 2019): It uses a semantic retriever on both paragraph- and sentence-level to retrieve question-related information.
- *Recurrent Retriever* (Asai et al., 2020): It uses a recurrent retriever to collect useful information from Wikipedia graphs for question answering.

4.4 Experimental Results

Results on the classification and ranking tasks are summarized in Table 2. Results of our pipeline on HotpotQA (full-wiki) are shown in Table 3.

Effect of Pre-training Tasks Among all the pre-training tasks, our proposed method Cross-Thought achieves the best performance. With finetuning, LM pre-training tasks work better than the Skip-Thought and ICT methods which are specifically designed for learning sentence embedding. Moreover, we provide a fair comparison between “Cross-thought-1-64” and “Masked LM-1-64”, both of which segment Wikipedia text into short sequences in 64 tokens for pre-training, and only use the hidden state of the first special token as sentence embedding. Results show that our Cross-Thought model achieves much better performance than Masked LM-1-64, as well as the Transformer pre-trained on 160G data (10 times larger than Wikipedia).

Effect of Training on Short Sequences Results on “Cross-Thought-1-512” and “Cross-Thought-1-64” (using sequences of 512 tokens and 64 tokens, respectively) clearly show that shorter sequences lead to more effective pre-training. Moreover, we also observe that “Cross-Thought-1-512” and “Masked LM-1-512” achieve almost the same performance. It means that our Cross-Thought has

Q	Jens Risom introduced what type of design, characterized by minimalism and functionality?	Washington was named after President <MASK>by an act of the <MASK>Congress during the creation of Washington Territory in 1853.
C1	**Scandinavian design** is a design movement characterized by simplicity, minimalism and functionality that emerged in the 1950s in the five Nordic countries of Finland, Norway, Sweden, Iceland and Denmark... Table 4: Case study on unsupervised passage ranking. The attention weights are learned by cross-sequence Transformer from pre-training. The examples on the left come from HotpotQA and are the ranked passages from 200 candidates for answering the question. The examples on the right are in the format of Masked Language Modeling task, where our Cross-Thought needs to recover the masked words by leveraging other sequences. C: the ranked passages by attention weights.

to be trained on short sequences (64 tokens); otherwise, it would learn more on the word dependencies within sequence other than the sequence embeddings. Actually, the effect of short sequences is also proved by Skip-Thought which focuses on generating sequences in sentence level, but our Cross-Thought can achieve better performance.

Effect of Sentence Embedding Size As we keep the number of parameters fixed for the encoders trained with different tasks, increasing the dimension of hidden state will lead to more parameters to train. Instead, for each sequence, we pre-append more special tokens, the hidden states of which are concatenated together as the final sentence embedding. Experiments on "Cross-Thought-1-64", "Cross-Thought-3-64" and "Cross-Thought-5-64" compare pre-appending 1, 3 and 5 different special tokens to sequences for pre-training. We can see that a larger sentence embedding size can significantly improve performance on the ranking tasks while not on the classification tasks. We hypothesize that the main reason is ranking tasks are more challenging, with many different pairs to compare, for which the contextual sentence embeddings can provide additional information.

Effect of Paragraph Ranking without Finetuning We also conduct an analysis on whether pre-trained sentence embeddings can be directly used for downstream tasks without finetuning. Although model performance without finetuning is generally worse than supervised training, experiments in column "HotpotQA(u)" further validate the previously discussed three conclusions. Besides, we observe that although the model pre-trained by masked language modeling leads to better performance after finetuning, it is not designed to train sentence embeddings, thus cannot be used for passage ranking. While all the other methods achieve much better performance than masked language modeling, our model "Cross-Thought-5-64" with the largest embedding size achieves the best performance.

Effect of Cross-Thought as Information Retriever (IR) on QA Task Our pipeline of solving HotpotQA (full-wiki) consists of three steps: (i) Fast candidate paragraph retrieval; (ii) Multi-hop paragraphs re-ranking by a more complex model; and (iii) Answer and supporting facts extraction. We evaluate our proposed method on how well the finetuned sentence embeddings can be utilized in the first step for IR, with the re-ranker and answer extractor fixed. "Masked LM-1-64" and "Cross-Thought-1-64" in Table 3 show that our pre-trained model achieves better performance than the baseline model pre-trained on single sequences. Moreover, the pipeline integrating our sentence embedding achieves new state of the art on HotpotQA (full-wiki).

4.5 Case Study

Table 4 provides a case study on the unsupervised passage ranking and masked language modeling tasks. For the case from HotpotQA, we can see that attention weights from the cross-sequence Transformer in Cross-Thought can rank the paragraph with gold answer to the first place among the 200 candidate paragraphs.

For the case from Mased Language Modeling, we also observe that the sentence that can be used to recover the masked words receives much higher attention weight compared to others, validating our motivation on retrieving the useful sentence embeddings from other sequences to enhance masked word recovery in the current sequence.

5 Conclusion

We propose a novel approach, Cross-Thought, to pre-train sentence encoder. Experiments demonstrate that using Cross-Thought trained with short sequences can effectively improve sentence embedding. Our pre-trained sentence encoder with further finetuning can beat several strong baselines on many NLP tasks.

AutoQA: From Databases To QA Semantic Parsers With Only Synthetic Training Data

Silei Xu* **Sina J. Semnani*** **Giovanni Campagna** **Monica S. Lam**

Abstract

We propose AutoQA, a methodology and toolkit to generate semantic parsers that answer questions on databases, with no manual effort. Given a database schema and its data, AutoQA automatically generates a large set of high-quality questions for training that covers different database operations. It uses automatic paraphrasing combined with template-based parsing to find alternative expressions of an attribute in different parts of speech. It also uses a novel filtered auto-paraphraser to generate correct paraphrases of entire sentences.

We apply AutoQA to the Schema2QA dataset and obtain an average logical form accuracy of 62.9% when tested on natural questions, which is only 6.4% lower than a model trained with expert natural language annotations and paraphrase data collected from crowdworkers. To demonstrate the generality of AutoQA, we also apply it to the Overnight dataset. AutoQA achieves 69.8% answer accuracy, 16.4% higher than the state-of-the-art zero-shot models and only 5.2% lower than the same model trained with human data.

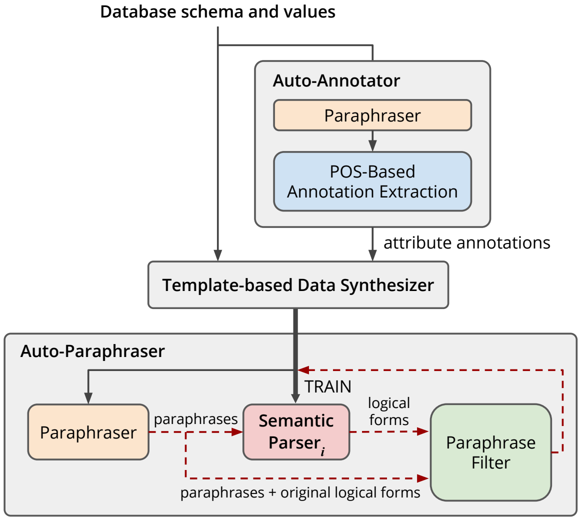

Figure 1: The architecture of the AutoQA toolkit. (a) The auto-annotator extracts annotations from paraphrases. (b) A template-based data synthesizer (Xu et al., 2020) generates data from the annotations to train a semantic parser. (c) An auto-paraphraser uses self-training to iteratively introduce more paraphrases to train the next version of the semantic parser. The red dotted lines show that generated paraphrases are filtered out unless the current semantic parser can translate them to the logical forms of the original sentences.

1 Introduction

Semantic parsing is the task of mapping natural language sentences to executable logical forms. It has received significant attention in question answering systems for structured data (Wang et al., 2015; Zhong et al., 2017; Yu et al., 2018b; Xu et al., 2020). However, training a semantic parser with good accuracy requires a large amount of annotated data, which is expensive to acquire. The complexity of logical forms means annotating the data has to be done by an expert. This adds to the cost and hinders extending question answering to new databases and domains.

To eliminate the need for annotating data with logical forms, SEMPRE (Wang et al., 2015) proposed the new methodology of first synthesizing questions on the database, then manually paraphrasing them. Recently, the Schema2QA toolkit (Xu et al., 2020) demonstrated that it is possible to achieve high accuracy on realistic user inputs using this methodology with a comprehensive set of generic, domain-independent question templates. However, this approach requires a significant manual effort for each domain: the developers must supply how each attribute can be referred to using different parts of speech, and crowdworkers are needed to paraphrase the queries.

Our objective is to eliminate the need for manual effort in building semantic parsers, while achieving comparable accuracy. We hypothesize that, for common domains, the knowledge of how each attribute would be referred to in natural language is implicitly presented in large text corpora and can be captured by general-purpose paraphrasing models. With that insight, we developed AutoQA, a toolkit that (1) automatically annotates the database attributes using paraphrasing models, (2) uses generic templates to synthesize a large set of complex queries, and (3) uses a novel filtered auto-paraphraser to further increase the variety of the synthesized data. The resulting dataset is then used to train a BERT-LSTM model (Xu et al., 2020). The architecture of AutoQA is shown in Fig. 1.

The contributions of this paper are:

- AutoQA, a toolkit that automatically creates a semantic parser that answers questions about a given database. As the parser is trained only with automatically generated data, its cost is significantly lower than current approaches.
- A novel algorithm for annotating database attributes with phrases in different parts of speech. The algorithm is based on automatic paraphrasing combined with template-based parsing (Section 4).
- A new automatic paraphrasing model, based on BART (Lewis et al., 2019), that can generate natural paraphrases of sentences, with a filter trained with synthetic data to ensure the preservation of the original meaning expressed in a formal language (Section 5).
- The methodology has been tested on the Overnight dataset (Wang et al., 2015) and Schema.org web data (Xu et al., 2020) (Section 6). On Overnight, AutoQA achieves an average of 55.6% logical form accuracy and 69.8% denotation (answer) accuracy without using the human paraphrases for training, which are 18.6% and 16.4% higher than the state-of-the-art zero-shot models, respectively. On Schema.org, AutoQA achieves an average logical form accuracy of 62.9%, within 6.4% of models trained with manual annotations and human paraphrases.[1]

2 Related Work

Bootstrapping Semantic Parsers. Neural semantic parsing for question answering is a well-known research topic (Pasupat and Liang, 2015; Wang et al., 2015; Dong and Lapata, 2016; Jia and Liang, 2016; Krishnamurthy et al., 2017; Zhong et al., 2017; Yu et al., 2018b). State of the art methods use a sequence-to-sequence architecture with attention and copying mechanism (Dong and Lapata, 2016; Jia and Liang, 2016) and rely on large datasets. Acquiring such datasets is expensive, and the work must be replicated in every new domain.

Prior work proposed bootstrapping semantic parsers using paraphrasing (Wang et al., 2015), where a dataset is synthesized using a grammar of natural language, and then paraphrased by crowdworkers to form the training set. Paraphrasing has been applied to datasets for SQL (Zhong et al., 2017), as well as multi-turn dialogue datasets (Shaw et al., 2018; Rastogi et al., 2019).

Our previous work with Genie (Campagna et al., 2019) proposed training with large amounts of synthesized and smaller amounts of paraphrased data. Later, we developed Schema2QA (Xu et al., 2020), a synthesis tool based on a general grammar of English. Schema2QA was found to be effective for the question answering task on the Web. Both works rely on manual paraphrases and hand-tuned annotations on each database attribute. Training with synthetic data has also been explored to complement existed dataset (Weir et al., 2020) and in the few-shot setting (Campagna et al., 2020; Moradshahi et al., 2020).

A different line of work proposed training with a large multi-domain dataset, and then using transfer learning to generalize to new datasets, in a completely zero-shot fashion (Herzig and Berant, 2018a; Chang et al., 2019). Yet, such scenario requires acquiring the multi-domain dataset in the first place, and there is a significant gap between the accuracy of training with and without in-domain data (Yu et al., 2018b). Our approach instead is able to synthesize data for the new domain, so the model is exposed to in-domain data while retaining the zero-shot property of no human-annotated data.

Pre-trained Models for Data Augmentation. Previous work showed that pre-trained models are very effective at generalizing natural language knowledge in a zero- and few-shot fashion (Radford et al., 2019; Brown et al., 2020). These models

Table 1: Example questions in the restaurant domain with their ThingTalk representations.

have been used to expand training data for various NLP classification tasks, by fine-tuning the model on a small seed dataset, then using conditioning on the class label to generate more data (Anaby-Tavor et al., 2020; Kumar et al., 2020). Kobayashi (2018) proposed using a bidirectional LSTM-based language model to substitute words that fit the context, conditioning on the class label to prevent augmentation from changing the class label. Wu et al. (2019) used BERT (Devlin et al., 2019) in a similar way, and Hu et al. (2019b) improved upon it by jointly fine-tuning BERT and the classifier. Semnani et al. (2019) explored data augmentation for domain transfer using BERT.

These approaches rely on an initial dataset with many examples in each class, and therefore are not suitable for semantic parsing, where each logical form has only a few or even just one example.

Neural Paraphrasing for Data Augmentation. The performance of many NLP tasks can be improved by adding automatically generated paraphrases to their training set. The general approach is to build a paraphrase generation model, usually a neural model (Prakash et al., 2016, Iyyer et al., 2018, Gupta et al., 2017), using general-purpose datasets of paraphrase sentence pairs.

Data augmentation through neural paraphrasing models has been applied to various tasks such as sentiment analysis (Iyyer et al., 2018), intent classification (Roy and Grangier, 2019), and span-based question answering (Yu et al., 2018a). Paraphrasing models may generate training examples that do not match the original label. Noisy heuristics, such as those employed by Yu et al. (2018a), are not enough for semantic parsing, where paraphrases need to be semantically equivalent in a very strict and domain-dependent sense. We propose a novel filtering approach, and show its effectiveness in reducing the noise of neural paraphrasing.

3 Schema2QA Data Synthesis Pipeline

AutoQA is based on Schema2QA (Xu et al., 2020), the state-of-the-art pipeline to generate high-quality training data for database QA at a low cost. Schema2QA first synthesizes utterance and formal representation pairs with a template-based algorithm, and then paraphrases utterances via crowdsourcing. The semantic parser is trained with both synthetic and paraphrased data, and tested on crowdsourced, manually annotated real questions.

Instead of relying on crowdworkers to paraphrase and create variety from the synthesized canonical questions, Schema2QA uses a comprehensive set of 800 domain-independent templates, along with a few manual annotations for each attribute in each domain, to synthesize high-quality data. About 2% of the synthesized data are manually paraphrased.

Our previous work (Xu et al., 2020) shows that a parser trained on such dataset achieves 70% accuracy on natural complex questions. Table 1 shows a few questions that Schema2QA can parse and their representation in ThingTalk, which is a query language designed to support translation from natural language.

Schema2QA answers long-tail questions well because its synthesized data have good coverage of possible questions asked, while showing great linguistic variety. It synthesizes questions using generic question templates, which have placeholders to be substituted with domain-specific annotations that match the expected part-of-speech (POS) type. Table 2 shows how annotations of the 6 POS categories for the "AlumniOf" attribute are used in the example templates to synthesize example utterances. In total, six POS categories are identified: *active verb* phrase, *passive verb* phrase, *adjective* phrase, *prepositional* phrase, and two noun phrases: *is-a noun* phrase which describes what the subject is, *has-a noun* phrase which describes what the subject has. There is a wide variety in annotations for an attribute, and often only a sub-

POS	Annotation	Example template	Example utterance
is-a noun	alumni of value	table that|which|who is|are [noun phrase] value	people who are alumni of Stanford
has-a noun	a value degree	table with (a|an|the) value [noun phrase]	people with a Stanford degree
active verb	graduated from value	table that|which|who [verb phrase] value	people who graduated from Stanford
passive verb	educated at value	table [passive verb phrase] value	people educated at Stanford
adjective	value	value table	Stanford people
prepositional	from value	table [prepositional phrase] value	people from Stanford

Table 2: Annotations for "alumniOf" attribute with example templates and utterances in six POS categories, where table and value denote the placeholders for table canonical annotations and values, respectively.

set of POS types is relevant to an attribute. It is thus challenging, often requiring multiple rounds of error analysis, to come up with these different annotations manually.

4 Automatic Annotation

Our AutoQA toolkit automatically provides unambiguous attribute annotations for all parts of speech, with the help of a neural paraphrasing model.

4.1 Canonical Annotation

AutoQA first derives a *canonical* annotation for each table and its attributes. Where necessary, it splits the attribute name into multiple words (e.g. "alumniOf" turns into "alumni of"). It then uses a POS tagger to identify the category of the canonical annotation.

The canonical annotation is used both for training and as the starting point to identify alternative phrases for each attribute, hence it must be meaningful and unambiguous. When applying AutoQA to an existing ontology, developers can override the table or attribute names if they are not meaningful or they are ambiguous.

4.2 POS-based Annotation Extraction

As shown in Table 2, an attribute can be described in various ways in different parts of speech. It is not enough to retrieve synonyms of the canonical annotation, as all synonyms will have the same POS. Some synonyms may also be inappropriate for the domain, if generated without context.

Our goal is to automatically derive all the other POS annotations given a canonical annotation. For example, the canonical annotation for the "alumniOf" attribute is "alumni of *value*" of POS "is-a-noun", as shown in the first row of Table 2. We wish to derive other "is-a-noun" annotations, as well as those in other POS categories in the table.

Our solution is to synthesize questions using the templates for the POS of the canonical annotation, get paraphrases from a neural model, parse the paraphrases using the templates as grammar rules, and turn successful parses into annotations.

AutoQA first generates short example sentences for each attribute using its canonical annotation. We generate questions that ask for objects with a given value of the attribute, using the grammar templates for the POS of the canonical annotation for the attribute. We generate up to 10 sentences for each alternative in the grammar template, using a different value for each one.

Second, AutoQA obtains paraphrases for the generated sentences using a neural paraphraser based on the BART sequence-to-sequence model (Section 6.1). To get more diverse paraphrases, we run 3 rounds of paraphrasing, where in each round we paraphrase the output of the previous round. All the words are tagged with their POS. For example, with "people who are alumni of Stanford" as an input, we can get paraphrases such as "people with a Stanford degree", as shown in the last column of Table 2.

Third, AutoQA parses the paraphrases using the templates (third column in Table 2) as grammar rules. A phrase is considered a successful parse only if the "table" and the "value" match exactly and the POS of all placeholders match that of the corresponding words. Correctly parsed phrases are then turned into annotations.

Note that we generate only sentences that map to *selection* operations, such as "show me people who are alumni of Stanford". Selection questions include a sample value, "Stanford", for the attribute, which is useful to provide a better context for the paraphraser. The paraphraser can generate phrases like "find people from Stanford", which is trivial to parse correctly. In contrast, values are missing in *projection* questions, such as "what institution are the people alumni of", which makes paraphrasing and subsequent parsing harder. While we only paraphrase selection questions, the annotations identified will be used for all types of questions.

4.3 Resolving Conflicts

Neural paraphrasing is imperfect and can generate incorrect annotations. Our priority is to eliminate ambiguity: we do not worry as much about including nonsensical sentences in the training, as such sentences are unlikely to appear at test time. Consider a movie domain with both “director” and “creator” attributes. The paraphrasing model might generate the annotation “creator” for “director”. To avoid generating such conflicted annotations within the domain, we detect annotations that appear in two or more attributes of the same type in the database. If such an annotation shares the same stem as one attribute name, it is assigned uniquely to that attribute. Otherwise, it is dropped entirely. As we train with data that is synthesized compositionally, we would rather lose a bit of variety than risk introducing ambiguity.

5 Automatic Paraphrasing

Synthetic training data is good for providing coverage with a large number of perfectly annotated sentences, and to teach the neural semantic parser compositionality. However, grammar-based synthesis often results in clunky sentences and grammatical errors. In addition, even with 800 generic templates, the synthesized sentences still lack naturalness and variety. In particular, people often compress multiple concepts into simpler constructions (sublexical compositionality (Wang et al., 2015)), e.g. “books with at least 1 award” can be simplified to “award-winning books”.

Capturing these linguistic phenomena in the training data is not possible with a finite set of templates. This is why paraphrasing is critical when training semantic parsers. Here we describe how we approximate manual paraphrases with a neural paraphrasing model.

5.1 Noise in Neural Paraphrasing

Using automatically generated paraphrases for training is challenging. First, paraphrasing models output noisy sentences, partially due to the noise in the existing paraphrasing datasets[2]. We cannot accept paraphrases that change the meaning of the original sentence, which is represented by the logical form annotation. This noise problem exists even in human paraphrasing; Wang et al. (2015) reports that 17% of the human paraphrases they collected changed the logical form. Second, there is an inherent diversity-noise trade-off when using automatic generation. The more diverse we want to make the outputs, the noisier the model’s output will be. Third, the auto-paraphraser is fed with synthetic sentences, which have a different distribution compared to the paraphrase training set.

We have empirically found the following ways in which noise is manifested:

- The output is ungrammatical or meaningless.
- The output changes in meaning to a different but valid logical form, or rare words like numbers and proper nouns are changed.
- The model is “distracted” by the input sentence due to limited world knowledge. “I’m looking for the book the dark forest”, is very different from “I’m looking for the book *in* the dark forest”.
- The model outputs sentence pairs that can be used interchangeably in general, but not in the specific application. For example, “restaurants close to my home” and “restaurants near me” have different target logical forms.
- Automatically-generated annotations are not reviewed by a human to ensure their correctness. An example is the word “grade” instead of “stars” in the hotels domain. Further paraphrasing these noisy sentences amplifies the noise.

5.2 Paraphrase Filtering

How do we produce semantically correct paraphrases and yet obtain enough variety to boost the accuracy of the parser? Our approach is to generate high variety, and then filter out noisy sentences. More specifically, we feed auto-paraphrased sentences to a parser trained on only synthetic sentences. We accept the sentences as correct paraphrases only if this parser outputs a logical form equal to the original logical form.

Correct paraphrases are then used to train another parser from scratch, which will have a higher accuracy on the natural validation and test sets. The first parser can correctly parse the examples

---

[2] Most large-scale paraphrasing datasets are built using bilingual text (Ganitkevitch et al., 2013) and machine translation (Mallinson et al., 2017) or obtained with noisy heuristics (Prakash et al., 2016). Based on human judgement, even some of the better paraphrasing datasets score only 68%-84% on semantic similarity (Hu et al., 2019a, Yang et al., 2019).

present in the synthetic set, e.g. "I am looking for the movies which have Tom Hanks in their actors with the largest count of actors.". It also generalizes to paraphrased sentences like "I'm looking for Tom Hanks movies with the most actors in them.". Paraphrased sentences like this are added to the training set to generate a second parser. This second parser can generalize to an even more natural sentence like "What is the Tom Hanks movie with the biggest cast?" This iterative process, as shown in Fig. 1, can be repeated multiple times.

This idea is borrowed from self-training (McClosky et al., 2006; He et al., 2019), where a model is used to label additional unlabeled data. Self-training requires an initial *good-enough* model to label data with, and optionally a filtering mechanism that is more likely to remove incorrect labels than correct labels (Yarowsky, 1995). We use a parser trained on a synthetic dataset as our initial *good-enough* model. The following two observations are the intuition behind this decision:

1. Paraphrases of a synthetic dataset are still relatively similar to that set. Thus, a parser trained on synthetic data, which delivers near perfect accuracy for the synthetic data, has a very high accuracy on the paraphrased data as well.
2. Unlike classification tasks, the set of valid logical forms in semantic parsing is so large that outputting the right logical form by chance is very unlikely.

Note that this filtering scheme might throw away a portion of correct paraphrases as well, but filtering out noisy examples is more important. The second observation ensures that the number of false positives is low.

5.3 Coupling Auto-Annotator with Auto-Paraphraser

Since both auto-annotation and auto-paraphrasing use a neural paraphraser, here we contrast them and show how they complement each other.

Auto-annotation provides alternative expressions with different POS for a single attribute at a time. The input sentences are simpler, so paraphrases are more likely to be correct, and they are filtered if they cannot be parsed correctly with the grammar rules. This makes it easier to coax more diverse expressions on the attribute from the paraphraser without having to worry about noisy outputs.

Annotations extracted by the auto-annotator are amplified as the synthesizer uses them to compose many full sentences, which are used to train the first parser with sufficient accuracy for self-training.

The auto-paraphraser, on the other hand, is applied on all synthesized data. It not only produces more natural alternative phrases for complex sentences, but also generates domain-specific and value-specific terminology and constructs. These two tasks complement each other, as supported by the empirical results in Section 6.2.2.

6 Experiments

In this section, we evaluate the effectiveness of our methodology: can a semantic parser created with AutoQA approach the performance of human-written annotations and paraphrases? We evaluate on two different benchmark datasets: the Schema2QA dataset (Xu et al., 2020) and the Overnight dataset (Wang et al., 2015).

6.1 AutoQA Implementation

Paraphrasing Model. We formulate paraphrasing as a sequence-to-sequence problem and use the pre-trained BART large model (Lewis et al., 2019). BART is a Transformer (Vaswani et al., 2017) neural network trained on a large unlabeled corpus with a sentence reconstruction loss. We fine-tune it for 4 epochs on sentence pairs from PARABANK 2 (Hu et al., 2019a), which is a paraphrase dataset constructed by back-translating the Czech portion of an English-Czech parallel corpus. We use a subset of 5 million sentence pairs with the highest dual conditional cross-entropy score (Junczys-Dowmunt, 2018), and use only one of the five paraphrases provided for each sentence. We experimented with larger subsets of the dataset and found no significant difference. We use token-level cross-entropy loss calculated using the gold paraphrase sentence. To ensure the output of the model is grammatical, during training, we use the back-translated Czech sentence as the input and the human-written English phrase as the output. Training is done with mini-batches of 1280 examples where each mini-batch consists of sentences with similar lengths[3].

We use nucleus sampling (Holtzman et al., 2019) with top-p=0.9 and generate 5 paraphrases per sentence in each round of paraphrasing. We use greedy

---

[3] This reduces the number of pad tokens needed, and makes training faster.

decoding and 4 temperatures (Ficler and Goldberg, 2017) of 0.3, 0.5, 0.7 and 1.0 to generate these paraphrases. Note that the input dataset to each paraphrasing round is the output of the previous round, and we have one round for Schema2QA and three rounds for Overnight experiments.

Semantic Parsing Model. We adopt our previously proposed BERT-LSTM model (Xu et al., 2020) as the semantic parsing model. The model is a sequence-to-sequence neural network that uses a BERT pre-trained encoder (Devlin et al., 2019), coupled with an LSTM decoder (Hochreiter and Schmidhuber, 1997) with attention (Bahdanau et al., 2014). The model uses a pointer-generator decoder (See et al., 2017) to better generalize to entities not seen during training. The model was implemented using the Huggingface Transformers library (Wolf et al., 2019). We use the same hyperparameters as Xu et al. (2020) for all experiments. The model has approximately 128M parameters.

6.2 Applying AutoQA to Schema2QA

We first apply AutoQA to the Schema2QA dataset, a semantic parsing dataset that targets the ThingTalk query language, and uses Schema.org as the database schema. Queries are performed against structured data crawled from websites in 6 domains: restaurants (using data from Yelp), people (from LinkedIn), hotels (from the Hyatt hotel chain), books (from Goodreads), movies (from IMDb), and music (from Last.fm).

The Schema2QA training data set was created using synthesis based on manual field annotations and human paraphrasing, while its evaluation data was crowdsourced by showing the list of attributes to workers and asking them for natural questions. The evaluation data contains complex questions referring up to 6 attributes, with comparisons and relational algebra operators: join, selection, projection, sort, and aggregates.

In our experiments, we use the Schema2QA validation and test sets, but *not* the training data. We synthesize our own training data using the same 800 templates, and replace the manual annotations with our auto-annotation and the manual paraphrases with auto-paraphrases.

For auto-annotation to work, the table and attribute names must be meaningful and unambiguous as discussed in Section 4. We found it necessary to override the original names in only three cases. In the restaurants domain, “starRating” is renamed to “michelinStar” to avoid ambiguity with “aggregateRating”. In the people domain, “addressLocality” is renamed to “homeLocation” to avoid confusion with “workLocation”. In the music domain, “musicRecording” is renamed to “song” to better match natural language.

When applying auto-paraphrasing, we preprocess the questions to replace entity placeholders (e.g. TIME_0) with an equivalent token in natural language (e.g. 2pm), then postprocess the outputs to restore them. This way, the neural network does not have to deal with these tokens which it has not seen during its pre-training.

As shown in Table 3, AutoQA generates about 45% more attribute annotations, and produces 60 times larger paraphrase sets, compared with the original Schema2QA training set. Although AutoQA’s training set is larger than Schema2QA’s, we note that in our experiments, adding more synthetic data to Schema2QA did not improve its accuracy any further. We compare the diversity of the two datasets using distinct-1 and distinct-2 metrics (Li et al., 2016) which measure the ratio of distinct unigram and bigrams in the datasets. AutoQA’s training sets have about 35% higher distinct-1 and 60% higher distinct-2.

Model	Restaurants	People	Movies	Books	Music	Hotels	Average
Schema2QA (Xu et al., 2020)	69.7	75.2	70.0	70.0	63.9	67.0	69.3
Schema2QA w/o manual annotation & paraphrase	30.0	30.4	36.6	34.9	33.7	59.7	37.6
AutoQA	65.3	64.6	66.1	54.1	57.3	70.1	62.9

Table 4: Test accuracy of AutoQA on the Schema2QA dataset. For the hotel domain, Xu et al. (2020) only report transfer learning accuracy, so we rerun the training with manual annotations and human paraphrases to obtain the accuracy for hotel questions.

	Restaurants	People	Movies	Books	Music	Hotels	Average
Schema2QA (Xu et al., 2020)	70.8	74.9	75.3	80.7	71.8	69.3	73.8
Schema2QA (w/o manual annotation & paraphrase)	33.9	32.7	35.7	39.9	37.1	61.6	40.2
AutoQA	69.5	66.1	68.0	67.6	66.9	66.6	67.4
– Auto-annotation	43.2	50.1	51.4	59.6	49.7	67.3	53.5
– Auto-paraphrase	62.1	50.5	62.7	61.5	58.6	59.1	59.1
– Paraphrase filtering	50.4	48.0	55.0	44.1	53.5	44.7	49.3

Table 5: Ablation study on Schema2QA development sets. Each "–" line removes only that feature from AutoQA.

6.2.1 Evaluation

Our evaluation metric is *logical form accuracy*: the logical form produced by our parser must exactly match the one in the test set. As shown in Table 4, AutoQA achieves an average accuracy of 62.9% in six domains, only 6.4% lower compared to the models trained with manual attribute annotations and human paraphrases. The difference is mainly because paraphraser fails to generate a few common phrases in some cases. For example, it fails derive "employee" or "employed by" from the canonical annotation "works for", which is quite common in the evaluation set. Compared with the baseline models trained with data generated by Schema2QA but without manual annotation and human paraphrase, AutoQA improves the accuracy by 25.3%. This result is obtained on naturally sourced test data, as opposed to paraphrases. This shows that AutoQA is effective for bootstrapping question answering systems for new domains, without any manual effort in creating or collecting training data.

6.2.2 Ablation Study

We conduct an ablation study on the development set to evaluate how each part of our methodology contributes to the accuracy. We subtract different components from AutoQA, generate the training data, and run the experiment with the same hyperparameters. When paraphrase filtering is removed, we still use simple string matching to remove erroneous paraphrases where entities and numbers in the utterance do not match the logical form.

As shown in Table 5, AutoQA reaches an overall accuracy of 67.4%, 6.4% lower than models trained with human annotations and human paraphrases. AutoQA outperforms the baseline trained on synthetic data generated from the canonical annotation by 27.2%. This indicates that AutoQA is an efficient and cost-effective replacement for manual annotation and paraphrasing.

On average, applying only auto-paraphrase on synthetic data based on canonical annotations without auto-annotation achieves 53.5%, which is 13.9% lower than the full AutoQA. Applying only auto-annotation without auto-paraphrase obtains 59.1%, and is 8.3% lower than AutoQA. This shows that the two components of AutoQA complement each other to achieve the best performance.

If auto-paraphrase is used without filtering, not only does it not improve the accuracy, but also the average accuracy drops by 18%. This shows that without filtering, even a paraphraser with a large pre-trained neural model like BART cannot be used for semantic parsing due to noisy outputs.

6.3 Applying AutoQA to Overnight

To evaluate if the AutoQA methodology generalizes to different types of databases, logical forms, and templates, we apply AutoQA on the well-known Overnight benchmark. Overnight is a semantic parsing dataset with questions over a knowledge base with very few entities across 8 domains. The dataset was constructed using paraphrasing; both training and test sets are paraphrased from the same set of synthetic sentences.

We train the BERT-LSTM model on data synthesized from Overnight templates with both auto-annotation and auto-paraphrase. Auto-annotation

Table 6: Logical form accuracy (left) and answer accuracy (right) percentage on the Overnight test set. Numbers are copied from the cited papers. We report the numbers for the BL-Att model of Damonte et al. (2019), Att+Dual+$\mathcal{LF}$ of Cao et al. (2019), ZEROSHOT model of Herzig and Berant (2018b), and the Projection model of Marzoev et al. (2020). Herzig and Berant (2018b) do not evaluate on the Basketball domain.

is limited to two parts of speech, since Overnight uses a very simple template set to synthesize training examples, with only placeholders for active verb phrase and noun phrase. We use the standard train/test split and following previous work, use 20% of the human paraphrases from the original training set for validation, so that validation and test sets are from the same distribution.

We evaluate both *logical form accuracy* and *answer accuracy*, which checks whether the answer retrieved from the knowledge base matches the gold answer. The model outputs a ranked list of logical forms for each input question using beam search with 25 beams, and chooses the first output that is syntactically valid. Other than this, all models and hyperparameters are the same as Section 6.

In Table 6, we compare our technique to other approaches that do not use in-domain human data. They are either synthetic-only (Marzoev et al., 2020) or use human data from other Overnight domains (Herzig and Berant, 2018b). For reference, we also include two of the best-performing models that use in-domain human data (Cao et al., 2019; Chen et al., 2018)[4].

Whereas Schema2QA dataset has naturally sourced evaluation and test data, Overnight evaluates on human paraphrase data. Evaluating with paraphrase data is not as meaningful, and makes the benchmark easier for models trained with human paraphrase data (Campagna et al., 2019). Nonetheless, AutoQA achieves an average logical form accuracy of 55.6% and answer accuracy of 69.8%, which is only 5.2% lower than the same parser trained with human paraphrases, and matches its performance in the housing domain. Compared to other zero-shot models trained with no in-domain data, AutoQA outperforms the state of the art by 18.6% and 16.4% on logical form accuracy and answer accuracy, respectively. This shows that by generating diverse and natural paraphrases in domain, AutoQA can reach comparable performance with models with human training data, and is much more accurate compared to other zero-shot approaches.

7 Discussion

In this work, we propose AutoQA, a methodology and a toolkit to automatically create a semantic parser given a database. We test AutoQA on two different datasets with different target logical forms and data synthesis templates. On both datasets, AutoQA achieves comparable accuracy to state-of-the-art QA systems trained with manual attribute annotation and human paraphrases.

AutoQA relies on a neural paraphraser trained with an out-of-domain dataset to generate training data. We suspect the methodology to be less effective for domains full of jargon. Even for common domains, AutoQA sometimes failed to generate some common phrases. Further improvement on neural paraphraser is needed to generate more diverse outputs. Future work is also needed to handle attributes containing long free-form text, as AutoQA currently only supports database operations without reading comprehension.

A The Cost of AutoQA

The only form of cost in AutoQA's methodology is compute cost. Here we mention more details with regards to that. To use AutoQA for a new domain, the following steps will have to be executed to generate the final training set. Numbers are for the Schema2QA dataset, and batch sizes are set to maximize GPU utilization.

- Automatic annotation: This step runs inference using the BART paraphraser model as introduced in Section 6.1, it takes less than 10 minutes for each domain.
- Template-based data synthesizer: This step synthesize data with annotation generated by auto-annotator. Depending on the domain, it takes between 3 to 5 hours on an AWS m5.4xlarge machine (16 vCPU and 64 GiB of memory).
- Training a parser with the synthetic dataset to use as filter: We train the BERT-LSTM model for 4000 iterations only, as we empirically observed that training more than that does not improve the quality of the filter. This takes less than half an hour on an AWS p3.2xlarge machine (16GB V100 GPU, 8vCPUs, 61 GiB of memory).
- Automatic paraphrasing and filtering: This step uses the fine-tuned BART large model, which has about 400M parameters, to generate 5 paraphrases per input, and then the BERT-LSTM parser, which has 128M parameters, to filter those paraphrases. Note that no training is done in this step. In our experiments, this step takes less than 4 GPU-hours.
- Training of the semantic parser: Similar to training the filter, but we train for 60000 iterations, and it takes less than 6 GPU-hours.

The approximate total per-domain cost of Schema2QA experiments using Amazon Web Services is $36.

A Spectral Method for Unsupervised Multi-Document Summarization

Abstract

Multi-document summarization (MDS) aims at producing a good-quality summary for several related documents. In this paper, we propose a spectral-based hypothesis, which states that the goodness of summary candidate is closely linked to its so-called spectral impact. Here spectral impact considers the perturbation to the dominant eigenvalue of affinity matrix when dropping the summary candidate from the document cluster. The hypothesis is validated by three theoretical perspectives: semantic scaling, propagation dynamics and matrix perturbation. According to the hypothesis, we formulate the MDS task as the combinatorial optimization of spectral impact and propose an accelerated greedy solution based on a surrogate of spectral impact. The evaluation results on various datasets demonstrate: (1) The performance of the summary candidate is positively correlated with its spectral impact, which accords with our hypothesis; (2) Our spectral-based method has a competitive result as compared to state-of-the-art MDS systems.

1 Introduction

Given a cluster of documents related to the same topic or event, the task of multi-document summarization (MDS) centers on a brief summary of the cluster. As emphasized by Lebanoff et al. (2018), for this task, the labeled training data (i.e. cluster-summary pairs) are scarce. Hence dealing with it in an unsupervised paradigm becomes a reasonable choice. For the unsupervised MDS task, the automatic summarizer is required to discover the main content of the document cluster without the guidance of golden summaries. To preserve the fluency and grammaticality of summary, we mainly focus on the extractive method in which summary sentences are extracted from the original document cluster.

In this paper, we propose a novel spectral-based hypothesis for the unsupervised MDS task. The hypothesis states that the goodness (or effectiveness) of any summary candidate is closely linked with its spectral impact on the document cluster. The spectral impact of a summary candidate quantifies the perturbation to the dominant eigenvalue (in modulus) of affinity matrix when dropping the candidate from the document cluster. In other words, the hypothesis points out the spectral impact as an indicator of the MDS task, which is the first attempt to characterize MDS from a spectral viewpoint explicitly. As a representation of the document cluster, the affinity matrix supports the definition of spectral impact. Adjusting the building of the affinity matrix can bring out the best in the hypothesis. To validate the proposed hypothesis, we provide both theoretical explanations and empirical evidence. *Theoretically*, the spectral impact caused by dropping a summary from the cluster can be characterized from three different perspectives (see §2.4). *Empirically*, for any summary candidate, the real dataset witnesses a positive correlation between its performance and computed spectral impact. For a particular MDS task, applying the hypothesis leads to a constrained optimization problem where the objective function is spectral impact. Our summarizer utilizes an accelerated greedy algorithm based on a surrogate of spectral impact. The competitive results of our summarizer have been obtained on various datasets.

The differences between prior works and our method are clarified for unsupervised MDS:

(1) *Underlying hypothesis*. The hypothesis indicates the mechanism for the summarization. For instance, manifold-ranking-based methods share the hypothesis that a good summary sentence has a high ranking on the low-dimensional manifold that documents reside in (Wan et al., 2007; Cheng et al., 2011; Li et al., 2011). However, the reasonableness

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 435–445,
November 16–20, 2020.

of this manifold hypothesis has not been directly evaluated. Another hypothesis in the sparse-coding-based methods (Li et al., 2015b; Liu et al., 2015; Yao et al., 2015) regards the original sentences as a linear combination of summary sentences. This leads to an intuitive reconstruction, whereas linear combination is more a simplification than a necessity. Our proposed hypothesis offers a spectral viewpoint and will be explicitly validated on the real dataset.

(2) *Optimization objective*. Multi-criteria optimization is suitable for MDS as various criteria (goals) exist in the task, such as relevancy criterion and non-redundancy criterion. For instance, Lin and Bilmes (2011) is a bi-criteria case that imposes the submodularity constraint on each criterion. Multi-criteria loss functions in neural-network-based methods (Ma et al., 2016; Chu and Liu, 2019; Zheng et al., 2019) include the reconstruction errors from different spaces. In the above cases, the overall objective functions used include some hyperparameters for gluing singletons. Comparatively, our proposed objective (spectral impact) has a compact form. It avoids the hyperparameter setting and simulates the non-separable processing of multiple MDS criteria by human beings.

(3) *Model complexity*. There is a trade-off between model complexity and model interpretability. For instance, the reported performance of the aforementioned deep-neural-based models is elusive, and there exists no general principle to further improve them. Our summarizer realizes the interpretable behavior based on verified hypothesis while preserving enough model complexity by the flexible affinity matrix (as a plug-in).

Our main contributions are twofold: (1) A novel spectral-based hypothesis for unsupervised MDS, which gains support from both theoretical and empirical sides; (2) An accelerated greedy algorithm for solving the hypothesis-driven optimization problem.

The rest of the paper is organized as follows. §2 gives the details of our method, including the spectral-based MDS hypothesis and the greedy algorithm to solve the spectral optimization problem. Evaluation results, related work and conclusions are covered in §3, §4 and §5 respectively.

2 Spectral-based MDS

What role does the summary play in the process of MDS? Our proposed hypothesis offers a spectral insight and brings out a workable formulation of MDS.

2.1 Notations

We use calligraphic fonts for sets, capital bold letters for matrices and lower-case bold letters for vectors. The universal set $\mathcal{C}$ is formed by splitting and gathering the sentences from document cluster, i.e. $\mathcal{C}=\{s_1, s_2, ..., s_n\}$ (s_i represents the i-th sentence and n is the total number of sentences). Each sentence has its ordinal number, e.g. o_i of sentence s_i indicates it is the (o_i)-th sentence in the document that s_i belongs to. The summary candidate (subset of $\mathcal{C}$) is denoted as $\mathcal{S}$. We represent the affinity matrix of document cluster as: $\mathbf{A}=\{a_{ij}\}_{n\times n}$. In addition, the dominant eigenvalue (in modulus) and the corresponding eigenvector of $\mathbf{A}$ are denoted as $\lambda(\mathbf{A})$ and $\mathbf{v}$, respectively.

Dropping a set from a matrix: emptying all the rows and columns whose indexes occur in the set. Consider the operation of dropping $\mathcal{S}$ from $\mathbf{A}$. If we denote the operation itself and the resultant matrix as $\mathbf{A}\backslash\mathcal{S}$, then

$$\mathbf{A}\backslash\mathcal{S} = \begin{cases} 0, & s_i \in \mathcal{S} \text{ or } s_j \in \mathcal{S}, \\ a_{ij}, & \text{otherwise.} \end{cases}$$

2.2 Spectral Hypothesis

When representing the document cluster as a matrix, the matrix spectrum (i.e. a collection of eigenvalues) can uncover its different facets. Note that the dominant eigenvalue especially corresponds to the key facet, which gives a clue as to the main content that the summarizer needs to discover. For the extractive MDS, we propose the spectral-based hypothesis:

GIVEN: Affinity matrix $\mathbf{A}$, the matrix representation of document cluster; set $\mathcal{S}$, any summary candidate including some original sentences.

DEFINITION: Spectral impact of $\mathcal{S}$ is the perturbation to dominant eigenvalue of $\mathbf{A}$ when dropping $\mathcal{S}$ from $\mathbf{A}$, i.e. $\Delta\lambda(\mathcal{S}) \triangleq \lambda(\mathbf{A}) - \lambda(\mathbf{A}\backslash\mathcal{S})$.

HYPOTHESIS: Goodness of $\mathcal{S}$ as a summary has a close link with its spectral impact $\Delta\lambda(\mathcal{S})$.

The above hypothesis tells us that the goodness (effectiveness) of any summary candidate can be determined by the proposed spectral impact, which reflects the change of dominant eigenvalue when the summary candidate $\mathcal{S}$ is left out. Affinity matrix $\mathbf{A}$ supports the definition of spectral impact, which

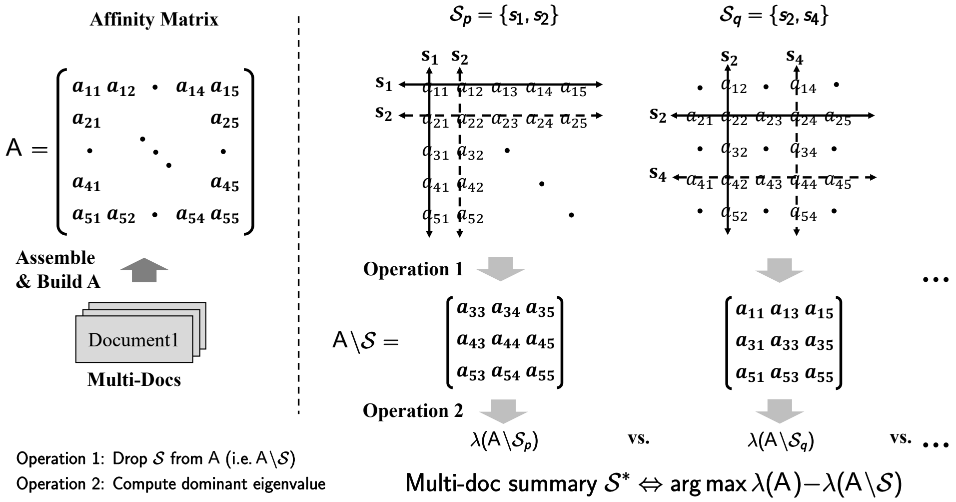

Figure 2.1: An example depicting the spectral-based hypothesis for the task of unsupervised MDS ($n = 5$, $k = 2$). The hypothesis suggests using spectral impact to judge whether a summary candidate is good or not.

stores the pairwise affinity of sentences as the name suggests.

For a specific MDS task, applying the hypothesis leads to an optimization formulation as follows:

$$\mathcal{S}^* = \arg\max_{\mathcal{S}\subseteq\mathcal{C}} \Delta\lambda(\mathcal{S}), \quad \text{s.t. } |\mathcal{S}| \leqslant k. \qquad (1)$$

The set $\mathcal{C}$ denotes the universal set and the number k specifies the maximum capacity of candidate $\mathcal{S}$.

The above formulation sets the spectral impact to be the objective function. The inherent rationality can be verified partially by these properties:

(a) *monotonicity*: $\Delta\lambda(\mathcal{S}_1) \leqslant \Delta\lambda(\mathcal{S}_2)$ for any $\mathcal{S}_1 \subseteq \mathcal{S}_2$ (see Li et al., 2012, Theorem 1);

(b) *normalization*: $\Delta\lambda(\Phi) = 0$, $\Delta\lambda(\mathcal{C}) = \lambda(\mathbf{A})$ (Φ denotes empty set).

In the context of MDS, property (a) points out that a whole summary has more goodness than its components and property (b) regulates a reasonable range of the goodness of any summary candidate.

An overview of our hypothesis can be found in Figure 2.1. The document cluster with its matrix representation **A** is depicted in the left part, while the right part gives the dropping operation and the computation of spectral impact for two summary candidates $\mathcal{S}_p$ and $\mathcal{S}_q$. The goodness of each candidate is judged by their spectral impacts, and the winner $\mathcal{S}^*$ stands out with the largest spectral impact.

Notice that cardinality constraint is adopted in Problem (1) to specify the length limit of summary. Other reasonable constraints are also available, such as the knapsack constraint and the non-uniform matroid constraint (Welsh, 1976). The relevant conclusions and solutions discussed in the following sections continue to be applicable for those constraints.

2.3 Affinity Matrix

Many prior works have adopted **A** for the MDS task, such as Yang et al. (2018) and Yang et al. (2019). Each element in the affinity matrix **A** is a pairwise affinity of two different sentences. Since our hypothesis depends on **A**, a better MDS performance can be expected by adjusting the building of **A**. Sentence embeddings play a vital role in the process of building **A**, since affinity a_{ij} can be set to be the cosine similarity of the embeddings of sentences s_i and s_j (i.e. $a_{ij} = a_{ji}$ and $a_{ii} = 0$). For comparison purposes, we consider the following three strategies of building sentence embeddings.

Tf-isf: the simple tf-idf model with a finer granularity. More details can be found in Wan et al. (2007) and Wang et al. (2017).

ESE: the enhanced feature embedding model (Yang et al., 2019). The embedding of each sentence is the concatenation of all components: paragraph vector, positional embedding and three feature embeddings (namely word-part-of-speech, bigram and trigram).

BERT: the sentence encoder that learns vector representations by pre-training a deep bi-directional Transformer network (Devlin et al., 2019). The advantage is that BERT is context-sensitive when considering the word embedding.

Notice that the leading sentences in each document should have priority in the summary extraction. For injecting this knowledge, a_{ij} is multiplied by the average positional weight $1/(o_i+o_j)$. This can differentiate the sentences across documents and preserve the symmetry of $\mathbf{A}$.

2.4 Justifications of Hypothesis

We validate our spectral-based hypothesis by the following three complementary perspectives:

Semantic scaling: *dominant eigenvalue of affinity matrix determines the vector scaling in semantic space*. The n-dimensional semantic space is constructed as follows: Each sentence in the document cluster represents a different dimension and the i-th axis of the space corresponds to the i-th sentence. Then the affinity matrix $\mathbf{A}_{n\times n}$ can be seen as a linear operator on this semantic space and the pairwise affinity a_{ij} regulates the transformation between the i-th axis and j-th axis. Given an arbitrary nonzero vector $\mathbf{x}$ in the space, the transformed vector is $\mathbf{Ax}$. Then the property holds:

$$\|\mathbf{Ax}\| \leqslant \lambda(\mathbf{A})\|\mathbf{x}\|. \tag{2}$$

Notation $\|\cdot\|$ denotes the Euclidean norm of vector. This is a sharp bound as equality holds only if $\mathbf{x}$ is the dominant eigenvector of operator $\mathbf{A}$.

The property shows that the scaling up of any vector (namely $\|\mathbf{Ax}\|/\|\mathbf{x}\|$) is not larger than $\lambda(\mathbf{A})$. Hence, the dominant eigenvalue $\lambda(\mathbf{A})$ characterizes the ability of operator $\mathbf{A}$ to scale up any vector in the semantic space that document cluster resides in. When dropping the summary candidate $\mathcal{S}$, the transformations to and from all axes covered by $\mathcal{S}$ will no longer exist for operator $\mathbf{A}$. In other words, there is no contribution for scaling up vectors from the i-th axis for any sentence $s_i \in \mathcal{S}$. When the best-quality summary is dropped, the main components of operator $\mathbf{A}$ are emptied, which causes the largest reduction of its ability to scale up vectors. Therefore, the dominant eigenvalue, indicator of this ability, can be used to locate the multi-document summary, as proposed in our hypothesis.

Propagation dynamics: *isolating the summary blocks the information dynamics*. In this perspective, there is a spread of information over the document cluster according to the underlying network specified by matrix $\mathbf{A}$. The pairwise affinity a_{ij} indicates the propagation rate between sentences s_i and s_j (more similar they are, more rapid the propagation occurs). The question that arises here is whether the information propagated from a few seed sentences will form a pandemic or become extinct in the long term. In epidemiology, the virus (information) will form a pandemic only if the basic reproduction number R_0 of this virus is larger than 1 (Jones, 2007). For instance, R_0 of COVID-19 is about 3.28 (> 1) (Liu et al., 2020), which uncovers the inevitable propagation of this virus.

Many works (Wang et al., 2003; Prakash et al., 2012; Chen, 2018) have found out that R_0 is proportional to the dominant eigenvalue of the underlying information network. Thus a small dominant eigenvalue corresponds to a small value of R_0, which hinders the information propagation. For the MDS task, when isolating the best-quality summary (i.e. $\mathbf{A}\backslash\mathcal{S}$), the remainder of the document cluster will become the hardest for information propagation. Our hypothesis is consistent with this finding as the summary $\mathcal{S}$ found by solving Problem (1) is able to reduce $\lambda(\mathbf{A}\backslash\mathcal{S})$ the most.

Matrix perturbation: *spectral impact considers both the relevancy and non-redundancy goal of MDS*. For analyzing the behavior of spectral impact, we expand it using first-order matrix perturbation theory (Stewart, 1990) as follows:

$$\begin{aligned}\Delta\lambda(\mathcal{S}) &= \mathbf{u}^{'}\mathbf{Eu} + \mathcal{O}(\|\mathbf{E}\|^2)\\ &= 2\sum_{s_i\in\mathcal{S}} {u_i}^2\lambda(\mathbf{A}) - \sum_{s_i,s_j\in\mathcal{S}} u_i a_{ij} u_j + \mathcal{O}(\|\mathbf{E}\|^2),\end{aligned} \tag{3}$$

where $\mathbf{E} = \mathbf{A} - \mathbf{A}\backslash\mathcal{S}$, $\mathbf{Au} = \lambda(\mathbf{A})\mathbf{u}$, $\|\mathbf{u}\| = 1$.

Let us analyze each term of the expansion shown in Eq. (3). The first sums up the score of $2{u_i}^2\lambda(\mathbf{A})$ for any sentence $s_i \in \mathcal{S}$. The value of u_i is a measure for the relevancy of sentence s_i, since eigenvector centrality has been typically used for ranking sentences (Erkan and Radev, 2004; Bellaachia and Al-Dhelaan, 2014; Al-Dhelaan, 2015). Hence, the first term is an indicator for the **relevancy** of summary $\mathcal{S}$. The second term is a penalty that considers every pair of summary sentences. Specifically, the penalty is $u_i a_{ij} u_j$ for sentences s_i and s_j. When a_{ij} is large (sentences are redundant), the penalty becomes prominent. Thus the second term measures the **non-redundancy** of summary $\mathcal{S}$. The third term $\mathcal{O}(\|\mathbf{E}\|^2)$ is relatively small compared to the preceding two because matrix $\mathbf{E}$ is nearly dominated by zeros ($|\mathcal{S}| << n$). Hence the third term will not change the main behavior of $\Delta\lambda(\mathcal{S})$.

2.5 Algorithm

The naive idea for solving Problem (1) is to enumerate all possible combinations and find the best summary. The time complexity is $\binom{n}{k}n^2$ if it takes $\mathcal{O}(n^2)$ time to compute the dominant eigenvalue of matrix (say using the method proposed by Lanczos (1950)). This exact enumeration algorithm is *infeasible* even when n is 500 and k is 5.

Theoretically, Problem (1) falls into spectral optimization that has been proved to be NP-hard in many cases (Van Mieghem et al., 2011). To avoid the time-consuming eigen-decomposition, some works resort to the QR decomposition of matrix (Li et al., 2015a; Chen et al., 2018). However, to actually compute QR decomposition, they depend on the Gram–Schmidt process that is inherently numerically unstable, which impedes the optimization process. In this paper, we bypass all these matrix decomposition and propose a straightforward surrogate for spectral impact, which is both effective and efficient. Based on a bound for dominant eigenvalue of $\mathbf{A}\backslash\mathcal{S}$ (Theorem 2.14 in Stevanovic (2014)), the surrogate is proposed as follows:

Surrogate of spectral impact:

$$\Delta\lambda(\mathcal{S}) \approx \frac{\sum_{s_i\in\mathcal{S}} v_i^2\lambda - \sum_{s_i,s_j\in\mathcal{S}} v_i a_{ij} v_j}{\sum_{s_i\in\mathcal{C}} v_i^2 - \sum_{s_i\in\mathcal{S}} v_i^2}$$

where λ is the dominant eigenvalue $\lambda(\mathbf{A})$ and $\mathbf{v}$[1] is its corresponding eigenvector of matrix $\mathbf{A}$.

By using the surrogate for acceleration, we consider a greedy strategy to iteratively select $\mathcal{S}$, which is listed in Alg. 2.1. First, we compute the dominant eigenvalue λ and eigenvector $\mathbf{v}$ of $\mathbf{A}$ (line 1). At each iteration (lines 3 to 7), the sentence s_τ maximizing the marginal gain of $\Delta\lambda(\mathcal{S})$ is extracted based on the previously selected set $\mathcal{S}$ (i.e. maximizing $\Delta\lambda(\mathcal{S}\cup\{s_j\})–\Delta\lambda(\mathcal{S})$, line 4) and added to $\mathcal{S}$ (line 5). Also, the auxiliary vector $\mathbf{w}$ and scalar x should be updated according to the numerator and denominator of the surrogate (lines 6, 7). The operator '$\odot$' and '$\cdot$', for any two vectors, are their Hadamard product and inner product, respectively.

Algorithm 2.1: Accelerated Spectral MDS

```
Input: the affinity matrix $\mathbf{A}$ and the budget $k$
Output: the summary $\mathcal{S}$
1 Compute the dominant eigen-pair $(\lambda, \mathbf{v})$ of $\mathbf{A}$;
2 Initialize: $\mathcal{S} \leftarrow \Phi$, $\mathbf{w} \leftarrow \lambda\mathbf{v} \odot \mathbf{v}$, $x \leftarrow \mathbf{v}\cdot\mathbf{v}$;
3 for $i \leftarrow 1 : k$ do
4     Let
        $\tau \leftarrow \arg\max_j\{\frac{w_j}{x-v_j^2}|j\in[1,n]; s_j\notin\mathcal{S}\}$;
5     Add $s_\tau$ to $\mathcal{S}$;
6     Update: $w_j \leftarrow w_j - 2v_j a_{j\tau} v_\tau$ for all $s_j \notin \mathcal{S}$;
7     Update: $x \leftarrow x - v_\tau^2$;
8 return $\mathcal{S}$
```

The lemma below demonstrates that Alg. 2.1 has a quadratic time complexity, which is evidently better than the exponential one of naive enumeration.

Lemma 2.1. *The time complexity of Alg. 2.1 is* $\mathcal{O}(n^2 + kn)$.

Proof. Computing the dominant eigen-pair of matrix $\mathbf{A}$ takes $\mathcal{O}(n^2)$ time. The initializations of the vector $\mathbf{w}$ and scalar x are both linear time operations, i.e. $\mathcal{O}(n)$. At each iteration, all n sentences need to be traversed for extracting s_τ and updating $\mathbf{w}$. Thus the total complexity is $\mathcal{O}(n^2 + kn)$. ☐

To get the final summary, we reorder the summary sentences returned by Alg. 2.1 according to their positions in the corresponding document.

3 Experiments

3.1 Datasets

Three datasets are selected in the following experiments to provide a complete evaluation of our method. Two domains have been taken into account: news (DUC and Multi-News) and business reviews (Yelp). Table 3.1 lists some key characteristics of these datasets.

DUC 2004[2] (task 2): the DUC task that contains a benchmark dataset. There are 50 document clusters, each of which includes 10 documents about the same news event. In addition, four human-written summaries are offered for each cluster to be the reference (golden) summary.

Yelp[3]: an all-purpose dataset that can be utilized for MDS. We only use the subset that has the reference summary (the test split offered by Chu and Liu (2019)): 100 businesses (document clusters), each of which includes 8 reviews (documents). One reference summary was collected for each cluster using crowdsourcing. More details of building the dataset can be found in Chu and Liu (2019).

Multi-News[4]: a large-scale dataset collected from news aggregator (Fabbri et al., 2019). It has 5622 document clusters (in the test split offered by the original paper), and multiple documents are present

---

[1] The eigenvector $\mathbf{v}$ can be of arbitrary length, which differs from the normalized vector $\mathbf{u}$ in Eq. (3).

[2] https://duc.nist.gov/duc2004/tasks.html

[3] https://www.yelp.com/dataset

[4] https://github.com/Alex-Fabbri/Multi-News

in each cluster. Furthermore, each cluster is attached with one human-written reference summary.

	DUC 2004	Yelp	Multi-News
Domain	News	Business review	News
#Clusters	50	100	5622
#Docs per cluster	10	8	2∼10
#Ref. per cluster	4	1	1
#Doc sources	2	1	>1500

Table 3.1: Dataset statistics (only showing test split).

3.2 Experimental Details

For the extractive MDS method (including ours), the pre-processing includes paragraph splitting, sentence splitting and word tokenization. In our method, all the splitted sentences are gathered in set $\mathcal{C}$. The input of Alg. 2.1 includes the affinity matrix $\mathbf{A}$ which is built according to the strategies stated in §2.3. Specifically, the strategy utilizing tf-isf vectors has a word bag that contains all the stemmed words found in the dataset (word stemming using Porter's stemmer[5]). For the strategy ESE, we pre-trained all different sentence embeddings on Daily Mail dataset (Hermann et al., 2015) by following the guideline of Yang et al. (2019) (the dimension of concatenated embedding is 800). For the strategy BERT, we used the uncased BERT-Base model[6] pre-trained on Wikipedia, through bert-as-service[7] to obtain the sentence embedding of 768 dimensions. All the experiments are performed on a machine with two CPUs (3.5GHz) and one GPU (16G memory).

The extractive MDS methods need a length limit of summary to terminate the extraction of summary sentences. We adopt 100 words as the length limit in the DUC dataset, instead of 665 bytes specified by the official task. The change has also been made to provide the same setting for evaluating various methods in Hong et al. (2014) and Zheng et al. (2019). For the Yelp dataset, we set the limit to be the 99.5th percentile less than the maximum length of any document; for Multi-News, the limit is set as 300 words. The same settings have been adopted in Chu and Liu (2019) and Fabbri et al. (2019), respectively.

3.3 Evaluation Metrics

We adopt ROUGE (Lin, 2004) as the automatic metric, which has been observed in a good agreement with human judgment (Owczarzak et al., 2012). It measures the overlap of N-grams (R-N) and skip-bigrams with a maximum distance of four words (R-SU4). Also, it can be computed based on the longest common subsequence (R-L). Each version of ROUGE has their scores oriented to recall, precision and F1.

In the experiments, we report the different combinations of ROUGE scores for each dataset, which have been recommended and adopted by previous works. Specifically, the recall scores of R-1,2,4 will be reported for the DUC 2004 dataset according to Hong et al. (2014), Wang et al. (2017) and Zheng et al. (2019); the F1 scores of R-1,2,L will be reported for Yelp as in Chu and Liu (2019); the F1 scores of R-1,2,SU4 will be reported for Multi-News as in Fabbri et al. (2019). The toolkit for computing ROUGE metrics is ROUGE-1.5.5[8] and its option is set to be '-m -c 95 -r 1000 -f A -p 0.5 -t 0'.

3.4 Comparing Methods

We compare our method with both traditional and state-of-the-art MDS methods.

Lead: The documents in a cluster are randomly shuffled, and the first sentence of the document is added to the summary until the length limit is reached.

LexRank (Erkan and Radev, 2004): It performs the sentence relevancy estimation by the random walk process on the sentence graph.

CLASSY04 (Conroy et al., 2004): It ranked first in the official evaluation of DUC 2004. As a supervised method, it uses a Hidden Markov Model to rank sentences and a QR decomposition to produce the summary.

C-Attention (Li et al., 2017a): The cascaded attention based auto-encoder is proposed for estimating the relevancy of words and sentences.

GRU-GCN (Yasunaga et al., 2017): It is a supervised method that employs a Graph Convolutional Network on sentence graph. The sentence embedding obtained from a Recurrent Neural Network serves as the input node feature.

ParaFuse (Nayeem et al., 2018): MDS is formulated as multi-sentence compression. As the state-

[8] https://github.com/andersjo/pyrouge/tree/master/tools/ROUGE-1.5.5

of-the-art on DUC 2004, however, it needs some extra resource and toolkit, such as paraphrase bank and keyword extractor.

Best Review (Chu and Liu, 2019): A simple baseline selecting the best document to be summary based on word overlap.

Centroid (Rossiello et al., 2017): Word embeddings are exploited to boost the performance of centroid-based methods.

MeanSum (Chu and Liu, 2019): An end-to-end neural model is put forward to implement the abstractive summarization of business review documents. The summary is decoded from the mean of the representations of input reviews.

PG (See et al., 2017): It introduces a pointer-generator (PG) network that motivates the summarizer to copy original words from input via pointing, while preserving the ability to generate new words.

Hi-MAP (Fabbri et al., 2019): It proposes the integration of sentence-level MMR scores into the PG network in order to adapt the attention weights on a word-level. The MMR score is computed by the Maximal Marginal Relevance algorithm (Carbonell and Goldstein, 1998), which gives the goodness of the available sentence given already selected ones.

Our method Spectral: This is our spectral-based method specified in Alg. 2.1. According to different building strategies in §2.3, it has three versions: Spectral-tfisf, Spectral-ESE and Spectral-BERT.

Notice that on DUC 2004, the supervised methods are trained on datasets of earlier DUC evaluations or CNN and Daily Mail datasets (Hermann et al., 2015) according to their original papers. On Multi-News, they are both trained and tested on the dataset itself.

3.5 Main Results

Table 3.2 demonstrates the ROUGE results of various methods on the DUC dataset. The method ParaFuse is previously state-of-the-art on this dataset. From the table, our method Spectral-BERT outperforms ParaFuse by 1.2 percent in R-1 score and has a slightly lower R-2 and R-4 score (still ranking second). Notice that ParaFuse, as mentioned in §3.4, is not exactly a self-contained system. Compared with CLASSY04 (winner of the official evaluation), Spectral-BERT has an enormous advantage (say 3.7% and 2.7% higher R-1 and R-2 score, respectively). Notice that all supervised methods have a relatively low performance, since they are trained on datasets different from DUC 2004. This observation is consistent with the results reported in Fabbri et al. (2019).

Method		R-1	R-2	R-4
Supervised method	CLASSY04	0.376	0.090	1.51%
	GRU-GCN	0.385	0.095	1.32%
	Hi-MAP	0.358	0.089	1.46%
Unsupervised method	Lead	0.332	0.061	0.60%
	LexRank	0.360	0.075	0.82%
	C-Attention	0.391	0.093	1.61%
	ParaFuse	0.401	**0.120**	**1.87%**
	Spectral-tfisf	0.382	0.095	1.58%
	Spectral-ESE	0.404	0.108	1.67%
	Spectral-BERT	**0.413**	0.117	1.75%

Table 3.2: ROUGE results on the DUC 2004 dataset (our model is Spectral). The best ROUGE scores are highlighted in bold, and the second best are underlined.

Method	R-1	R-2	R-L
Lead	0.268	0.038	0.144
Centroid	0.246	0.029	0.138
Best review	0.280	0.035	0.153
MeanSum	0.289	0.037	0.159
Spectral-tfisf	0.283	0.036	0.147
Spectral-ESE	0.291	0.037	0.165
Spectral-BERT	**0.302**	**0.045**	**0.172**

Table 3.3: ROUGE results of unsupervised methods on the Yelp dataset (our model is Spectral). Best scores are in bold, and second best are underlined.

Table 3.3 and Table 3.4 show ROUGE results on Yelp and Multi-News, respectively. Our method Spectral-BERT has also beaten other unsupervised methods by a wide margin (say 1.3% higher R-L score than MeanSum and 2.1% higher R-SU4 score than C-Attention). Compared with the state-of-the-art supervised system on Multi-News (namely Hi-MAP), Spectral-BERT cannot rival its performance. However, Spectral-BERT has beaten the other supervised system (i.e. PG) according to R-2 and R-SU4 score.

We observe that a better matrix building strategy (stated in §2.3) has led to a considerable improvement of our method on all three datasets. Specifically, the BERT encoder brings about one percent improvement in R-2 score as compared with the tf-isf model. It proves that our method is flexible and can benefit from recent off-the-shelf pre-training techniques (Devlin et al., 2019; Clark et al., 2019).

Method		R-1	R-2	R-SU4
Supervised method	PG	0.419	0.129	0.165
	Hi-MAP	**0.435**	**0.149**	**0.174**
Unsupervised method	Lead	0.394	0.118	0.145
	LexRank	0.383	0.127	0.132
	C-Attention	0.386	0.125	0.146
	Spectral-tfisf	0.397	0.121	0.144
	Spectral-ESE	0.396	0.130	0.159
	Spectral-BERT	*0.409*	*0.136*	*0.167*

Table 3.4: ROUGE results on the Multi-News dataset (our model is Spectral). The best scores are in bold, the second best are underlined, the best among unsupervised methods are in *italics*.

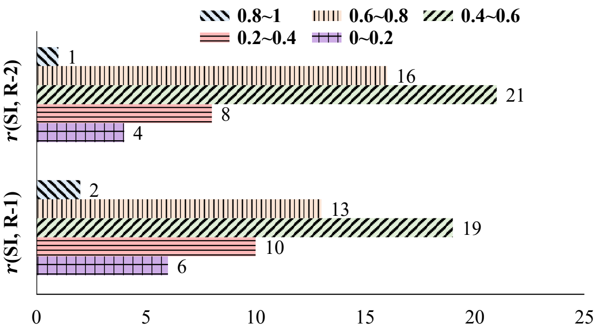

Figure 3.1: Pearson correlation coefficients r of spectral impact (SI) and ROUGE (R-1 or R-2) on DUC 2004. The sample size is the number of document clusters, i.e. 50. Best viewed in colors.

3.6 Linguistic Quality

To further assess the linguistic quality of different summaries, we employ Amazon Mechanical Turk[9] workers to judge the performance of three summarizers on a random sample of Multi-News (200 document clusters). A worker is asked to rate each summary on a scale of 1 (poor) to 5 (excellent) according to three criteria: **relevancy** (does the summary cover all the key information of document cluster?) and two criteria adopted by DUC 2005 evaluation (**non-redundancy** and **grammaticality**) (Dang, 2005). Table 3.5 shows the results. We observe that our method Spectral has the highest relevancy and non-redundancy score. Abstractive method C-Attention has a relatively low score of grammaticality. Notice that the non-redundancy scores of all summarizers are generally low, which shows that humans are more sensitive to the redundancy existing in the summary.

Method	Relev.	NonRed.	Gram.	Average
LexRank	4.19	2.74	**4.61**	3.85
C-Attention	4.32	3.18	3.25	3.58
Spectral-BERT	**4.57**	**3.32**	4.46	**4.12**

Table 3.5: Linguistic quality on Multi-News.

3.7 Hypothesis Validation

We provide the empirical evidence of our proposed spectral-based hypothesis. For each cluster of documents on DUC 2004, we construct a sample set of 500 summary candidates $\mathcal{S}$, each of which contains 3 original sentences selected randomly from the documents. The Pearson correlation coefficient (denoted by r) of spectral impact and the candidate goodness as a summary, when applied to the sample set, is computed and the derived histogram is shown in Figure 3.1. Each correlation coefficient falls into their corresponding bins. In the figure, our method Spectral-BERT and the ROUGE metrics are utilized because: (1) Spectral-BERT has been reported with a better empirical performance in §3.5; (2) The goodness of summary candidate in this scenario can be measured by the precision-oriented ROUGE scores, esp. R-1 and R-2, in that the word count of candidate $\mathcal{S}$ is varied in the sample. We note that there are no bins corresponding to negative correlation coefficients (r ranges from -1 to 1), and quite a few r's have a large score beyond 0.5 (the widely accepted threshold of a large r recommended by Cohen (2013)). This demonstrates that the two variables have a positive linear correlation, which supports our hypothesis. Similar results can be obtained when $\mathcal{S}$ contains a different number of sentences.

4 Related Work

Unsupervised MDS. There are a bunch of works working on different hypotheses and models in this field. PageRank alike algorithms (Erkan and Radev, 2004; Mei et al., 2010; Wang et al., 2017) utilize random walks with some redundancy avoiding measures. Regarding the document cluster as a manifold structure, (Wan et al., 2007; Cheng et al., 2011; Li et al., 2011) use the manifold ranking process on data. There are also quite a few neural architecture based models for a hidden semantic representation of sentences, documents or subtopics, such as (Ma et al., 2016; Li et al., 2017a,b; Zheng et al., 2019).

Spectral optimization. Optimizing eigen-related

---

[9] https://www.mturk.com/

metrics often leads to a specific collective optimization problem, which is believed to be hard in nature unless P = NP (Cook, 1971). Some particular examples (Van Mieghem et al., 2011; Chen et al., 2016) have been proved NP-hard. The typical solvers adopt the heuristics based on either perturbation theory (Chen et al., 2016) or QR decomposition (Li et al., 2015a; Chen et al., 2018).

5 Conclusion

We propose a novel hypothesis-driven method for unsupervised MDS, where the goodness of any summary candidate can be determined from a spectral perspective when dropping it from the document cluster. Various MDS tasks of different sizes and domains show a promising result of our method. Extending our method to an abstractive setting is meaningful future work.

Acknowledgments

We would like to thank all the reviewers for their helpful advice on various aspects of this work. This work is supported by National Natural Science Foundation of China (No. 61936012 and No. U19A2065) and Beijing Academy of Artificial Intelligence (BAAI).

Abstract

Deep learning has led to significant improvement in text summarization with various methods investigated and improved ROUGE scores reported over the years. However, gaps still exist between summaries produced by automatic summarizers and human professionals. Aiming to gain more understanding of summarization systems with respect to their strengths and limits on a fine-grained syntactic and semantic level, we consult the Multidimensional Quality Metric[1] (MQM) and quantify 8 major sources of errors on 10 representative summarization models manually. Primarily, we find that 1) under similar settings, extractive summarizers are in general better than their abstractive counterparts thanks to strength in faithfulness and factual-consistency; 2) milestone techniques such as copy, coverage and hybrid extractive/abstractive methods do bring specific improvements but also demonstrate limitations; 3) pre-training techniques, and in particular sequence-to-sequence pre-training, are highly effective for improving text summarization, with BART giving the best results.

1 Introduction

Automatic text summarization has received constant research attention due to its practical importance. Existing methods can be categorized into extractive (Dorr et al., 2003; Mihalcea and Tarau, 2004; Nallapati et al., 2017) and abstractive (Jing and McKeown, 2000; Rush et al., 2015; See et al., 2017) methods, with the former directly selecting phrases and sentences from the original text as summaries, and the latter synthesizing an abridgment by using vocabulary words. Thanks to the resurgence of deep learning, neural architectures have been investigated for both extractive (Cheng and Lapata, 2016; Xu and Durrett, 2019) and abstractive (Nallapati et al., 2016; Lewis et al., 2019; Balachandran et al., 2020) summarization systems.

Although improved ROUGE scores have been reported on standard benchmarks such as Gigaword (Graff et al., 2003), NYT (Grusky et al., 2018) and CNN/DM (Hermann et al., 2015) over the years, it is commonly accepted that the quality of machine-generated summaries still falls far behind human written ones. As a part of the reason, ROUGE has been shown insufficient as a precise indicator on summarization quality evaluation (Liu and Liu, 2008; Böhm et al., 2019). In the research literature, human evaluation has been conducted as a complement (Narayan et al., 2018). However, human evaluation reports that accompany ROUGE scores are limited in scope and coverage. On a fine-grained level, it still remains uncertain what we have achieved overall and what fundamental changes each milestone technique has brought.

We aim to address the above issues by quantifying the primary sources of errors over representative models. In particular, following MQM (Mariana, 2014), we design 8 metrics on the *Accuracy* and *Fluency* aspects. Models are analyzed by the overall error counts on a test set according to each metric, and therefore our evaluation can be more informative and objective compared with existing manual evaluation reports. We call this set of metrics **PolyTope**. Using PolyTope, we manually evaluate 10 text summarizers including Lead-3, TextRank (Mihalcea and Tarau, 2004), Sequence-to-sequence with Attention (Rush et al., 2015), SummaRuNNer (Nallapati et al., 2017), Point-Generator (See et al., 2017), Point-Generator-with-Coverage (Tu et al., 2016; See et al., 2017), Bottom-Up (Gehrmann et al., 2018), BertSumExt (Liu and Lapata, 2019), BertSumExtAbs (Liu and Lapata, 2019) and BART (Lewis et al., 2019), through

[1] MQM is a framework for declaring and describing human writing quality which stipulates a hierarchical listing of error types restricted to human writing and translation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 446–469,
November 16–20, 2020.

which we compare neural structures with traditional preneural ones, and abstractive models with their extractive counterparts, discussing the effectiveness of frequently-used techniques in summarization systems. Empirically, we find that:

1. Preneural vs Neural: Traditional rule-based methods are still strong baselines given powerful neural architectures.
2. Extractive vs Abstractive: Under similar settings, extractive approaches outperform abstractive models in general. The main shortcoming is *unnecessity* for extractive models, and *omission* and *intrinsic hallucination* for abstractive models.
3. Milestone Techniques: Copy works effectively in reproducing details. It also reduces duplication on the word level but tends to cause redundancy to a certain degree. Coverage solves repetition errors by a large margin, but shows limits in faithful content generation. Hybrid extractive/abstractive models reflect the relative strengths and weaknesses of the two methods.
4. Pre-training: Pre-training is highly effective for summarization, and even achieves a better content selection capability without copy and coverage mechanisms. Particularly, joint pre-training combining text understanding and generation gives the most salient advantage, with the BART model achieving by far the state-of-the-art results on both automatic and our human evaluations.

We release the test set, which includes 10 system outputs and their manually-labeled errors based on PolyTope, and a user-friendly evaluation toolkit to help future research both on evaluation methods and automatic summarization systems[2].

2 Related Work

Extractive Summarization Early efforts based on statistical methods (Neto et al., 2002; Mihalcea and Tarau, 2004) make use of expertise knowledge to manually design features or rules. Recent work based on neural architectures considers summarization as a word or sentence level classification problem and addresses it by calculating sentence representations (Cheng and Lapata, 2016; Nallapati et al., 2017; Xu and Durrett, 2019). Most recently, Zhong et al. (2020) adopts document-level features to rerank extractive summaries.

Abstractive Summarization Jing and McKeown (2000) presented a cut-paste based abstractive summarizer, which edited and merged extracted snippets into coherent sentences. Rush et al. (2015) proposed a sequence-to-sequence architecture for abstractive summarization. Subsequently, Transformer was used and outperformed traditional abstractive summarizer by ROUGE scores (Duan et al., 2019). Techniques such as AMR parsing (Liu et al., 2015), copy (Gu et al., 2016), coverage (Tu et al., 2016; See et al., 2017), smoothing (Müller et al., 2019) and pre-training (Lewis et al., 2019; Liu and Lapata, 2019) were also examined to enhance summarization. Hybrid abstractive and extractive methods adopt a two-step approach including content selection and text generation (Gehrmann et al., 2018; Hsu et al., 2018; Celikyilmaz et al., 2018), achieving higher performance than end-to-end models in ROUGE.

Analysis of Summarization There has been much work analyzing summarization systems based on ROUGE. Lapata and Barzilay (2005) explored the fundamental aspect of "coherence" in machine generated summaries. Zhang et al. (2018) analyzed abstractive systems, while Kedzie et al. (2018) and Zhong et al. (2019) searched for effective architectures in extractive summarization. Kryscinski et al. (2019) evaluated the overall quality of summarization in terms of redundancy, relevance and informativeness. All the above rely on automatic evaluation metrics. Our work is in line with these efforts in that we conduct a fine-grained evaluation on various aspects. Different from the above work, we use human evaluation instead of automatic evaluation. In fact, while yielding rich conclusions, the above analytical work has also exposed deficiencies of automatic toolkits. The quality of automatic evaluation is often criticized by the research community (Novikova et al., 2017; Zopf, 2018) for its insufficiency in neither permeating into the overall quality of generation-based texts (Liu and Liu, 2008) nor correlating with human judgements (Kryscinski et al., 2019).

There has also been analysis work augmenting ROUGE with human evaluation (Narayan et al., 2018; Liu and Lapata, 2019). Such work reports coarse-grained human evaluation scores which typ-

Table 1: ROUGE scores of 10 summarizers on CNN/DM Dataset (non-anonymous version). We get the score of Lead-3 and TextRank from Nallapati et al. (2017) and Zhou et al. (2018), respectively.

ically consist of 2 to 3 aspects such as informativeness, fluency and succinctness. Recently, Maynez et al. (2020) conducted a human evaluation of 5 neural abstractive models on 500 articles. Their main goal is to verify the faithfulness and factuality in abstractive models. In contrast, we evaluate both rule-based baselines and extractive/abstractive summarizers on 8 error metrics, among which faithfulness and factuality are included.

Our work is also related to research on human evaluation for summarization. To this end, Pyramid (Nenkova and Passonneau, 2004) scores a summarizer based on its system output and multiple references. Annotators are requested to identify the smallest content units of semantic meaning, and then associate each unit with a weight by counting how many reference summaries contain this unit. The score of a summary is computed according to the number and weight of units. In addition to Pyramid, there are human evaluation metrics based on ranking (Narayan et al., 2018), best-worst scaling (Kiritchenko and Mohammad, 2017) and question answering (Clarke and Lapata, 2010). The above methods assign one score to each summarization output. In contrast to these methods, our error-count based metrics are motivated by MQM for human writing, and are more fine-grained and informative. We show more empirical contrast between evaluation metrics in Figure 3 in Section 6. Most recently, Stiennon et al. (2020) uses human evaluation as a reward for training automatic summarizers, reporting significant improvement compared with models trained using reference summaries. Their work also demonstrates the usefulness of human evaluation in text summarization.

3 Models

We re-implement and evaluate 10 representative and influential methods. Their publicly reported ROUGE F1 scores are illustrated in Table 1.

3.1 Extractive Methods

Lead-3 Lead-3 is a commonly-used baseline, which simply selects the first three sentences as the summary. It is used as a standard baseline by most recent work (Cheng and Lapata, 2016; Gehrmann et al., 2018). Intuitively, the first three sentences of an article in news domain can likely be its abstract, so the results of Lead-3 can be a highly faithful approximation of human-written summary.

TextRank TextRank (Mihalcea and Tarau, 2004) is an unsupervised key text units selection method based on graph-based ranking models (Page et al., 1998). It defines "recommendation" by calculating co-similarity between sentences and yielding a weighted graph accordingly. Sentences with high weights are extracted as summaries. It is selected as a representative of statistical models.

SummaRuNNer SummaRuNNer (Nallapati et al., 2017) is a representative neural extractive model which selects full sentences from the input as a summary. It first encodes the input with a hierarchical BiGRU, then scans input sentences from left to right. An accumulated summary representation is generated by a weighted sum of all previous selections, which is fed into a logistic classifier to make the final prediction on summary.

BertSumExt BertSumExt (Liu and Lapata, 2019) takes pre-trained BERT (Devlin et al., 2019) as the sentence encoder and an additional Transformer as the document encoder. A classifier on sentence representation is used for sentence selection. It takes advantages of knowledge from fine-tuned BERT for generating better summaries.

3.2 Abstractive Methods

Seq2Seq with Attention The sequence-to-sequence model structure is first used for abstractive summarization by Rush et al. (2015). To allow effective and free text generation rather than simple selection and rearrangement, a target-to-source attention module is adopted to capture the information from every encoder hidden state. We follow the implementation of See et al. (2017).

Pointer-Generator See et al. (2017) introduces the pointer network (Vinyals et al., 2015) to address the problem that seq2seq models tend to reproduce factual details inaccurately. The method can both generate words from the vocabulary via a generator, and copy content from the source via a pointer.

Pointer-Generator-with-Coverage See et al. (2017) use the coverage mechanism (Tu et al., 2016) to avoid repetition problems. This mechanism calculates a coverage vector as an extra input for the attention mechanism to strengthen attention to different locations.

Bottom-Up Gehrmann et al. (2018) propose a two-step approach, first selecting potential output words and then generating a summary based on pointer-generator network. Bottom-Up is selected as a representative of hybrid models which integrate extractive and abstractive methods.

BertSumExtAbs BertSumExtAbs (Liu and Lapata, 2019) adopts the same encoder as BertSumExt, and a 6-layer Transformer decoder with randomly initialized parameters. It is selected as a representative of neural abstractive models with pretrained contextualized sentence representation.

BART Instead of pre-training the encoder only, BART (Lewis et al., 2019) jointly pre-trains a seq2seq model combining a bidirectional encoder and an auto-regressive decoder. Further fine-tuned on summarization datasets, it achieves the current state-of-the-art result in terms of ROUGE scores.

4 Evaluation Method

We analyze system performance by using ROUGE (Lin, 2004) for automatic scoring and PolyTope for human scoring. ROUGE has been adopted by most work on summarization. It is a recall-based metric calculating lexical overlap between system output and human summaries. Particularly, ROUGE-1 is based on unigram overlaps, ROUGE-2 on bigrams and ROUGE-L on longest common subsequences.

PolyTope is an error-oriented fine-grained human evaluation method based on Multidimensional Quality Metric (MQM) (Mariana, 2014). In particular, it consists of 8 issue types (Section 4.1), 8 syntactic labels (Section 4.2) and a set of severity rules (Section 4.3) to locate errors and to automatically calculate an overall score for the tested document. As illustrated in Figure 3, compared with ROUGE, PolyTope is more fine-grained in offering detailed and diagnostic aspects of overall quality.

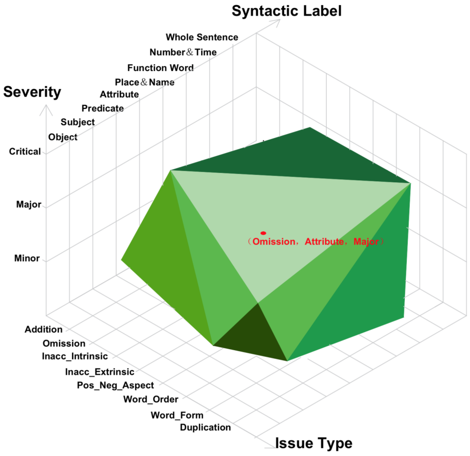

Figure 1: PolyTope verdicts each error by three coordinates according to its syntactic and semantic roles.

We develop an operating interface for annotation, which is shown in Appendix A.1. Particularly, a human annotator is presented the original text and an output summary in juxtaposition, and is asked to select segments that are deemed incorrect after reading. Upon a preliminary selection, he is asked to make a further selection among 8 issue types and 8 syntactic labels, respectively. An embedded severity score is then generated automatically for every incorrect segment, and the quality score is calculated for the annotated summary as:

$$\text{Score} = (1 - \frac{\sum_{\alpha \in I} \alpha * \text{Severity}_{\alpha}}{\text{word}_{\text{count}}}) * 100,$$

where $I \in \{\textsc{Minor},\textsc{Major},\textsc{Critical}\}$, indicating the error count for each severity. Severity scores are deducted for errors of different severity, with the deduction ratio being set as 1:5:10 for MINOR, MAJOR and CRITICAL, respectively. $\text{word}_{\text{count}}$ is the total number of words in samples. For a skilled annotator, it takes 2.5-4 minutes averagely to complete annotation of one sample, of which 2-3 minutes are used for extensive reading and 0.5-1 minutes for annotation. After PolyTope evaluation, 3-dimensional error points show the overall quality of the tested model (Figure 1). The inter-annotator agreement over 20 documents is 0.8621 in terms of Pearson correlation coefficient, which shows that PolyTope can significantly reduce subjective bias of annotators. More human annotation details are illustrated in Appendix B.

4.1 Issue Type

Issue types of PolyTope can be categorized into *Accuracy* and *Fluency* issues, whose definitions can

Issue type	Sub Issue Type	Subject	Object	Predicate	Number&Time	Place&Name	Attribute	Function Word	Whole Sentence
Accuracy	Addition	Critical	Critical	Critical	Major	Major	Major	Minor	Major
	Omission	Critical	Critical	Critical	Critical	Major	Major	Minor	Critical
	Inacc Intrinsic	Critical	Critical	Critical	Critical	Critical	Major	Minor	N/A
	Inacc Extrinsic	Critical	Critical	Critical	Critical	Critical	Critical	Minor	N/A
	Pos Neg Aspect	N/A	N/A	Critical	N/A	N/A	Critical	N/A	N/A
Fluency	Word Order	N/A	N/A	Major	N/A	N/A	Major	Minor	N/A
	Word Form	Minor	Minor	Minor	Minor	Minor	Minor	Minor	N/A
	Duplication	Major	Major	Major	Major	Major	Major	Minor	Major

Table 2: PolyTope for summarization diagnostics. This error matrix avoids subjectivity as human judgers only need to annotate issue types and syntactic labels of each mistake. Severity rules and scores is predefined and automatically calculated, without providing their own preference and scores.

be traced to the MQM principle. *Accuracy*-related issues refer to the extent to which the content conveyed by the target summarization does not match or accurately reflect the source text. It comprises five sub-types:

Addition Unnecessary and irrelevant snippets from the source are included in the summary.

Omission Key point is missing from the output.

Inaccuracy Intrinsic Terms or concepts from the source are misrepresented and thus unfaithful.

Inaccuracy Extrinsic The summary has content not presented in the source and factually incorrect.

Positive-Negative Aspect The output summary represents positive statements whereas the source segment is negative, and vice versa.

Fluency issues refer to linguistic qualities of the text. Unlike *Accuracy*, *Fluency* is independent of the relationship between the source and the target. It comprises three sub-types:

Duplication A word or longer portion of the text is repeated unnecessarily.

Word Form Problems in the form of a word, including agreement, POS, tense-mood-aspect, etc.

Word Order Problems in the order of syntactic constituents of a sentence.

Their examples are elaborated in Appendix A.2.

4.2 Syntactic Label

Syntactic labels aim to locate errors, allowing tighter relevance between error issues and sentence constituents. According to ACE2005 (Automatic Content Extraction), we define 8 syntactic labels to distinguish sentence components, namely *Subject*, *Predicate*, *Object*, *Number&Time*, *Place&Name*, *Attribute*, *Function Word* and *Whole Sentence*. Their definitions are elaborated in Appendix A.3.

4.3 Severity

Severity is an indication of how severe a particular error is. It has three levels: MINOR, MAJOR and CRITICAL, calculated by the evaluation tool automatically given the human decision on the error type and syntactic label. In practice, each cell in Table 2 corresponds to a specific severity level. Issues with higher severity have more impact on perceived quality of the summary.

Minor Issues that do not impact usability or understandability of the content. For example, if grammar function word repeats itself, the redundant preposition is considered an error but does not render the text difficult to use or problematic.

Major Issues that impact usability or understandability of the content but do not render it unusable. For example, an additional attribute may result in extra effort for the reader to understand the intended meaning, but does not make the content unfit for purpose.

Critical Issues that render the content unfit for use. For example, an omitted subject that changes the meaning of the text would be considered critical. If the error prevents the reader from using the content as intended or if it presents incorrect information that could result in harm to the user, it must be categorized as critical. In general, even a single critical error is likely to cause serious problems.

5 Evaluating Model Performance

We evaluate the aforementioned 10 models using the above two metrics, focusing on comparisons between pre-neural and neural methods, extractive and abstractive methods, and better understanding the effects of milestone techniques such as copy, coverage, pre-training and hybrid abstractive/extractive models. We randomly sample 150 trials from the non-anonymized CNN/DM dataset (Hermann et al., 2015). When predicting
