Evaluation. For the SLC task, we evaluate the models with precision, recall and micro-averaged F_1 scores. As for the FLC task, we adopt the evaluation script provided by Da San Martino et al. (2019) to calculate precision, recall, and micro-

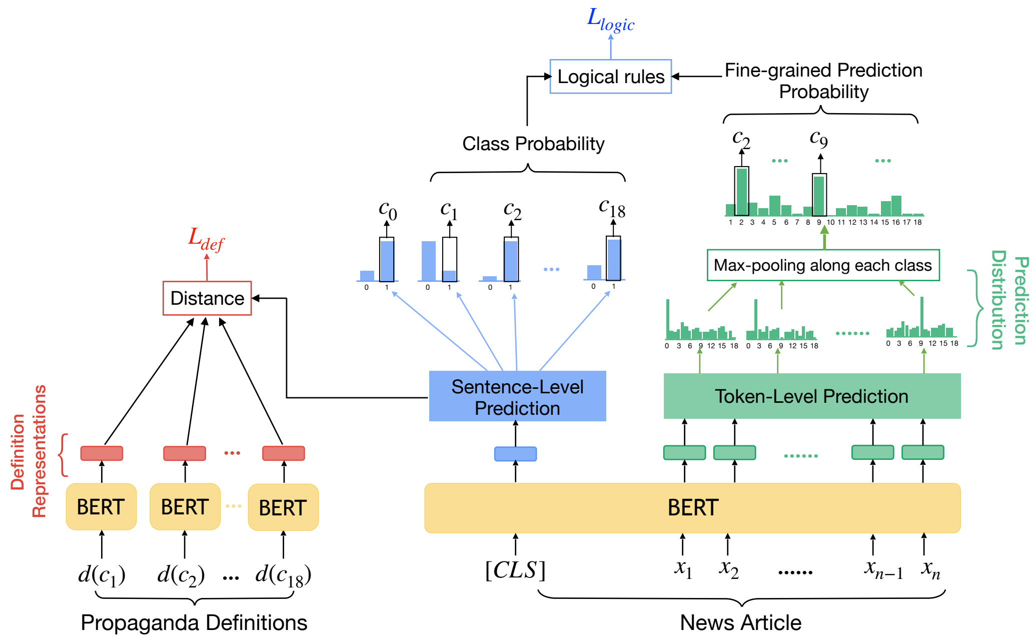

Figure 2: Overview of our proposed model. A BERT-based multi-task learning approach is adopted to make predictions for 18 propaganda techniques at both sentence level and token level. We introduce two types of knowledge as additional objectives: (1) logical knowledge about the consistency between sentence-level and token-level predictions, and (2) textual knowledge from literal definitions of propaganda techniques.

averaged F_1, in that giving partial credit to imperfect matches at the character level. The FLC task is evaluated on two kinds of measures: (1) *Full task* is the overall task, which includes detecting the existence of propaganda techniques in text fragments and identifying the type of them, while (2) *Spans* is a special case of the *Full task*, which only considers the spans of propagandistic fragments except for their propaganda techniques.

3 Method

In this section, we present our approach *LatexPRO* as shown in Figure 2, which injects declarative knowledge of fine-grained propaganda techniques into neural networks. We first present our base model (§3.1), which is a multi-task learning framework that slightly extends the model of Da San Martino et al. (2019). Afterward, we introduce two ways to regularize the learning process with logical knowledge about the consistency between sentence-level and token-level predictions (§3.2) and textual knowledge from literal definitions of propaganda techniques (§3.3). At last, we describe the training and inference procedures (§3.4).

3.1 Base Model

To better exploit the sentence-level information and further benefit token-level prediction, we develop a fine-grained multi-task method as our base model, which makes predictions for 18 propaganda techniques at both sentence level and token level. Inspired by the success of pre-trained language models on various natural language processing downstream tasks, we adopt BERT (Devlin et al., 2019) as the backbone model here. For each input sentence, the sequence is modified as "$[CLS]$*sentence tokens*$[SEP]$". Specifically, on top of BERT, we add 19 binary classifiers for fine-grained sentence-level predictions, and one 19-way classifier for token-level predictions, where all classifiers are implemented as linear layers. At sentence level, we perform multiple binary classifications and this can further support leveraging declarative knowledge. The last representation of the special token $[CLS]$ which is regarded as a summary of the semantic content of the input, is adopted to perform multiple binary classifications, including one binary classification to predict the existence of propaganda techniques, and 18 binary classifications to identify the types of them. We adopt sigmoid activation for each binary classifier. At token level, the last representation of each token is fed into a linear layer to predict the propaganda technique over 19 categories (i.e., 18 categories of propaganda techniques plus one category for "none of them"). We adopt Softmax activation for the

19-way classifier. Two different losses are applied for this multi-task learning process, including the sentence-level loss L_{sen} and the token-level loss L_{tok}. L_{sen} is the binary cross-entropy loss of multiple binary classifications. L_{tok} is the focal loss (Lin et al., 2017) of 19-way classification for each token, which could address the class imbalance problem.

3.2 Inject Logical Knowledge

There are some implicit logical constraints between sentence-level and token-level predictions. However, neural networks are less interpretable and need to be trained with a large amount of data to make it possible to learn such implicit logic. Therefore, we consider tackling the problems by exploiting logic knowledge. In particular, we propose to employ propositional Boolean expressions to explicitly regularize the model with a logic-driven objective, which improves the logical consistency between two different grained predictions, and makes our method more interpretable. For instance, in this work, if a propaganda class c is predicted by the multiple binary classifiers (indicates the sentence contains this propaganda technique), then the token-level predictions belonging to the propaganda class c should also exist. We thus consider the propositional rule $F = A \Rightarrow B$, formulated as:

$$\begin{aligned} P(F) &= P(A \Rightarrow B) \\ &= \neg P(A) \vee P(B) \\ &= 1 - P(A) + P(A)P(B) \\ &= P(A)(P(B) - 1) + 1 \end{aligned} \tag{1}$$

where A and B are two variables. Specifically, substituting $f_c(x)$ and $g_c(x)$ into above formula as $F = \forall c : f_c(x) \Rightarrow g_c(x)$, then the logic rule can be written as:

$$P(F) = P(f_c(x))(P(g_c(x)) - 1) + 1 \tag{2}$$

where x denotes the input, $f_c(x)$ is the binary classifier for the propaganda class c, and $g_c(x)$ is the probability of fine-grained predictions that contains x being category of c. $g_c(x)$ can be obtained by max-pooling over all the probability of predictions for class c. Note that the probabilities of the unpredicted class are set to 0 to prevent any violation, i.e., ensuring that each class has a probability corresponding to it. Our objective here is maximizing $P(F)$, i.e., minimizing $L_{logic} = -log\,(P(F))$, to improve the logical consistency between coarse- and fine-grained predictions.

3.3 Inject Textual Knowledge

The literal definitions of propaganda techniques in this work, can be regarded as textual knowledge which contains useful semantic information. To exploit this kind of knowledge, we adopt an additional encoder to encode the literal definition of each propaganda technique. Specifically, for each definition, the input sequence is modified as "$[CLS]$*definition*$[SEP]$" and fed into BERT. We adopt the last representation of the special token $[CLS]$ as each definition representation $D(c_i)$, where c_i represents the i-th propaganda technique. We calculate the Euclidean distance $dist_2$ between each predicted propaganda category representation $W(c_i)$ and the definition representation $D(c_i)$. Our objective is minimizing the textual definition loss L_{def}, which regularizes the model to refine the propaganda representations.

$$L_{def} = \sum_{i=1}^{18} dist_2\,(W(c_i), D(c_i)) \tag{3}$$

3.4 Training and Inference

Training. To train the whole model jointly, we introduce a weighted sum of losses L_j which consists of the token-level loss L_{tok}, fine-grained sentence-level loss L_{sen}, textual definition loss L_{def} and logical loss L_{logic}:

$$L_j = \alpha * L_{tok} + \beta * (L_{sen} + L_{def} * \lambda) + \gamma * L_{logic} \tag{4}$$

where hyper-parameters α, β, λ and γ are employed to control the tradeoff among losses. During the training stage, our goal is minimizing L_j.

Inference. For the SLC task, our method output the "*propaganda*" only if the probability of propagandistic binary classification for the positive class is above 0.7. This threshold is chosen according to the ratio of propaganda to non-propaganda samples in the training set. For the FLC task, to better exploit the coarse-grained (sentence-level) information to guide the fine-grained (token-level) prediction, we design a way that can explicitly make constraints on 19-way predictions when doing inference. Prediction probabilities of 18 fine-grained binary classifications above 0.9 are set to 1, and vice versa to 0. Then the Softmax probability of 19-way predictions (except for the "*none of them*" class) of each token is multiplied by the corresponding 18 probabilities of propaganda techniques. This means that our model is conservative, which makes

Model	Spans			Full Task			
	P	R	F_1	P	R	F_1	M_C
BERT (Da San Martino et al., 2019)	50.39	46.09	48.15	27.92	27.27	27.60	-
MGN (Da San Martino et al., 2019)	51.16	**47.27**	49.14	30.10	**29.37**	29.73	-
LatexPRO	58.95	42.37	49.30	40.98	26.99	32.54	16.05

Table 2: Overall performance on fragment-level experiments (FLC task) in terms of Precision (P), recall (R) and F_1 scores on our test set. M_C denotes the metric of consistency between sentence-level predictions and token-level predictions. *Full task* is the overall task of detecting both propagandistic fragments and identifying the technique, while *Spans* is a special case of the *Full task*, which only considers the spans of fragments except for their propaganda techniques. Note that (L+T), (L), and (T) denote injecting of both logical and textual knowledge, only logical knowledge, and only textual knowledge, respectively.

predictions for the fragments of propaganda techniques only if with high confidence.

4 Experiments

4.1 Experimental Settings

In this paper, we conduct experiments on Propaganda Techniques Corpus (PTC)[1] (Da San Martino et al., 2019) which is a large manually annotated dataset for fine-grained propaganda detection, as detailed in Section 2. F_1 score is adopted as the final metric to represent the overall performance of models. We select the best model on the dev set.

We adopt BERT-base-cased (Devlin et al., 2019) as the pre-trained model. We implement our model using Huggingface (Wolf et al., 2019). We use AdamW as the optimizer. In our best model on the dev set, the hyper-parameters in loss optimization are set as $\alpha = 0.8$, $\beta = 0.2$, $\lambda = 0.001$ and $\gamma = 0.001$. We set the max sequence length to 256, the batch size to 16, the learning rate to 3e-5 and warmup steps to 500. We train our model for 20 epochs and adopt an early stopping strategy on the average validation F_1 score of *Spans* and *Full Task* with patience of 5 epochs. For all experiments, we set the random seed to 42 for reproducibility.

4.2 Models for Comparison

We compare our proposed methods with several baselines. Moreover, three variants of our method are provided to reveal the impact of each component. The notations of LatexPRO (L+T), LatexPRO (L), and LatexPRO (T) denote our model which injects both logical and textual knowledge, only logical knowledge and only textual knowledge, respectively. Each of these models are described as follows.

BERT (Da San Martino et al., 2019) adds a linear layer on the top of BERT, and is fine-tuned on the SLC and FLC tasks, respectively.

MGN (Da San Martino et al., 2019) is a multi-task learning model, which regards the SLC task as the main task and drive the FLC task on the basis of the SLC task.

LatexPRO is our base model without leveraging any declarative knowledge.

LatexPRO (L) injects logical knowledge into *LatexPRO* by employing propositional Boolean expressions to explicitly regularize the model.

LatexPRO (T) arguments *LatexPRO* with textual knowledge in the literal definitions of propaganda techniques.

LatexPRO (L+T) is our full model in this paper.

4.3 Experiment Results and Analysis

Fragment-Level Propaganda Detection. The results for the FLC task are shown in Table 2. Our base model *LatexPRO* achieves better results than other baseline models, which verifies the effectiveness of our fine-grained multi-task learning structure. It is worth noting that, our full model *LatexPRO (L+T)* achieves superior boost than *MGN* by 10.06% precision and 2.85% F_1 on the *Spans* task, 12.54% precision and 4.92% F_1 on the *Full* task, which is considered as significant progress. This

---

[1] Note that the annotations of the official PTC test set are not publicly available, thus we split the original dev set into dev and test set as Section 2. We use the released code (Da San Martino et al., 2019) to run the baseline.

Table 3: Detailed performance on the full task of fragment-level experiments (FLC task) on our test set. Precision (P), recall (R) and F_1 scores per technique are provided.

demonstrates that leveraging declarative knowledge in text and first-order logic helps to predict the propaganda types more accurately. Moreover, our ablated models *LatexPRO (T)* and *LatexPRO (L)* both gain improvements over *LatexPRO*, while *LatexPRO (L)* gains more improvements than *LatexPRO (T)*. This indicates that injecting each kind of knowledge is useful, and the effect of different kinds of knowledge can be superimposed and uncoupled. It should be noted that, compared with baseline models, our models achieve a superior performance thanks to high precision, but the recall slightly loses. This is mainly because our models tend to make predictions for the high confident propaganda types.

To further understand the performance of models for the FLC task, we make a more detailed analysis of each propaganda technique. Table 3 shows detailed performance on the *Full* task. Our models achieve precision and F_1 improvements of almost all the classes over baseline model, and can also predict some low-frequency propaganda techniques, e.g., `Whataboutism` and `Obfus.,Int.` This further demonstrates that our method can stress class imbalance problem, and make more accurate predictions.

Model	P	R	F_1
Random	30.48	51.04	38.16
All-Propaganda	30.54	100.00	46.80
BERT (Da San Martino et al., 2019)	58.26	57.81	58.03
MGN (Da San Martino et al., 2019)	57.41	62.50	59.85
LatexPRO	56.18	69.79	62.25
LatexPRO (L)	56.53	**73.17**	63.79
LatexPRO (T)	58.33	67.50	62.58
LatexPRO (L+T)	**59.04**	71.66	**64.74**

Table 4: Results on sentence-level experiments (SLC task) in terms of Precision (P), recall (R) and F_1 scores on our test set. *Random* is a baseline which predicts randomly, and *All-Propaganda* is a baseline always predicts the propaganda class.

Sentence-Level Propaganda Detection. Table 4 shows the performances of different models for SLC. The results indicate that our model achieves superior performances over other baseline models. Compared with *MGN*, our *LatexPRO (L+T)* increases the precision by 1.63%, recall by 9.16% and F_1 score by 4.89%. This demonstrates the effectiveness of our model, and shows that our model can find more positive samples which will further benefit the token-level predictions for FLC.

4.4 Effectiveness of Improving Consistency

We further define the following metric M_C to measure the consistency between sentence-level predictions Y_c which is a set of predicted propaganda technique classes, and token-level predictions Y_t which is a set of predicted propaganda techniques for input tokens:

$$M_C(Y_c, Y_t) = \frac{1}{|Y_t|} \sum_{y_t \in Y_t} \mathbb{1}_{Y_c}(y_t) \tag{5}$$

Doc ID: 999000155 · Title: Arizona Democrat Senate Candidate Kyrsten Sinema Refuses To Retract Saying It's OK For Americans To Join Taliban

Ground-truth: […] "I go over there, and I'm fighting for the Taliban […]." Sinema responded: "Fine. I don't care if you go and do that, go ahead.$_1$" […] The Left maintains that Islamic jihad terror is not a problem — it's just a reaction to the evil deeds of the U.S. and Israel$_3$. […]Sinema is proof: the Left hates America,$_2$ and considers "right-wing extremists," […] It used to be that this fact was dismissed as hysterical hyperbole.$_2$

MGN: […] "I go over there, and I'm fighting for the Taliban […]." Sinema responded: "Fine. I don't care if you go and do that, go ahead.$_5$" […] The Left maintains that Islamic jihad terror is not a problem — it's just a reaction to the evil deeds of the U.S. and Israel . […]Sinema is proof: the Left hates America,$_4$ and considers "right-wing extremists," […] It used to be that this fact was dismissed as hysterical hyperbole.$_2$

Our method: […] "I go over there, and I'm fighting for the Taliban […]." Sinema responded: "Fine. I don't care if you go and do that, go ahead.$_1$" […] The Left maintains that Islamic jihad terror is not a problem — it's just a reaction to the evil deeds of the U.S. and Israel$_3$. […]Sinema is proof: the Left hates America,$_2$ and considers "right-wing extremists," […] It used to be that this fact was dismissed as hysterical hyperbole.

Figure 3: Qualitative comparison of 2 different models on a news article. The baseline *MGN* predicts spans of fragments with wrong propaganda techniques, while our method can make more accurate predictions. Here are 5 propaganda techniques: `1.Thought-terminating Cliches`, `2.Loaded Language`, `3.Causal Oversimplification`, `4.Flag waving` and `5.Repetition`. (Best viewed in color)

where $|Y_t|$ denotes a normalizing factor, $\mathbb{1}_A(x)$ represents the indicator function:

$$\mathbb{1}_A(x) = \begin{cases} 1 & \text{if } x \in A \\ 0 & \text{if } x \notin A \end{cases} \tag{6}$$

Table 2 presents the consistency scores M_C. The higher the score indicates the better consistency. Results illustrate that our methods with declarative knowledge can substantially outperform the base model *LatexPRO*. Compared to the base model, our declarative-knowledge-augmented methods enrich the source information by introducing textual knowledge from propaganda definitions, and logical knowledge from implicit logical rules between predictions, which enables the model to make more consistent predictions.

4.5 Case Study

Figure 3 gives a qualitative comparison example between *MGN* and our *LatexPRO (L+T)*. Different colors represent different propaganda techniques. The results show that although *MGN* could predict the spans of fragments correctly, it fails to identify their techniques to some extent. However, our method shows promising results on both spans and specific propaganda techniques, which further confirms that our method can make more accurate predictions.

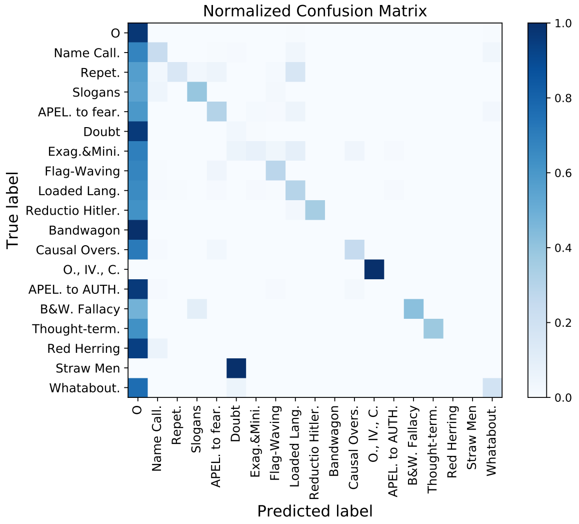

Figure 4: Visualization of confusion matrix result of our *LatexPRO (L+T)*, where `O` represents the `none of them` class.

4.6 Error Analysis

Although our model has achieved the best performance, it still some types of propaganda techniques are not identified, e.g., `Appeal to Authority` and `Red Herring` as shown in Table 3. To explore why our model *LatexPRO (L+T)* cannot predict for those propaganda techniques, we compute a confusion matrix for the *Full Task* of FLC task, and visualize the confusion matrix using a heatmap as shown in Figure 4. We find that most of the off-diagonal elements are in class `O` which represents `none of them`. This demonstrates most of the cases are wrongly classified into `O`. We think this is due to the imbalance of the `propaganda` and `non-propaganda` categories in the dataset. Similarly, `Straw Men`, `Red Herring` and `Whataboutism` are the relatively low frequency of classes. How to deal with the class imbalance still needs further exploration.

5 Related work

Our work relates to fake news detection and the injection of first-order logic into neural networks. We will describe related studies in these two directions.

Fake news detection draws growing attention as the spread of misinformation on social media becomes easier and leads to stronger influence. Various types of fake news detection problems are introduced. For example, there are 4-way classification of news documents (Rashkin et al., 2017), and 6-way classification of short statements (Wang, 2017). There are also sentence-level fact checking problems with various genres of evidence, including natural language sentences from Wikipedia (Thorne et al., 2018), semi-structured tables (Chen et al., 2020), and images (Zlatkova et al., 2019; Nakamura et al., 2019). Our work studies propaganda detection, a fine-grained problem that requires token-level prediction over 18 fine-grained propaganda techniques. The release of a large manually annotated dataset (Da San Martino et al., 2019) makes the development of large neural models possible, and also triggers our work, which improves a standard multi-task learning approach by augmenting declarative knowledge expressed in both first-order logic and natural language.

Neural networks have the merits of convenient end-to-end training and good generalization, however, they typically need a lot of training data and are not interpretable. On the other hand, logic-based expert systems are interpretable and require less or no training data. It is appealing to leverage the advantages from both worlds. In NLP community, the injection of logic to neural network can be generally divided into two groups. Methods in the **first** group regularize neural network with logic-driven loss functions (Xu et al., 2018; Fischer et al., 2019; Li et al., 2019). For example, Rocktäschel et al. (2015) target on the problem of knowledge base completion. After extracting and annotating propositional logical rules about relations in knowledge graph, they ground these rules to facts from knowledge graph and add a differentiable training loss function. Kruszewski et al. (2015) map text to Boolean representations, and derive loss functions based on implication at Boolean level for entailment detection. Demeester et al. (2016) propose lifted regularization for knowledge base completion to improve the logical loss functions to be independent of the number of grounded instances and to further extend to unseen constants, The basic idea is that hypernyms have ordering relations and such relations correspond to component-wise comparison in semantic vector space. Hu et al. (2016) introduce a teacher-student model, where the teacher model is a rule-regularized neural network, whose predictions are used to teach the student model. Wang and Poon (2018) generalize virtual evidence (Pearl, 2014) to arbitrary potential functions over inputs and outputs, and use deep probabilistic logic to integrate indirection supervision into neural networks. More recently, Asai and Hajishirzi (2020) regularize question answering systems with symmetric consistency and symmetric consistency. The former creates a symmetric question by replacing words with their antonyms in comparison question, while the latter is for causal reasoning questions through creating new examples when positive causal relationship between two cause-effect questions holds.

The **second** group is to incorporate logic-specific modules into the inference process (Yang et al., 2017; Dong et al., 2019). For example, Rocktäschel and Riedel (2017) target at the problem of knowledge base completion, and use neural unification modules to recursively construct model similar to the backward chaining algorithm of Prolog. Evans and Grefenstette (2018) develop a differentiable model of forward chaining inference, where weights represent a probability distribution over clauses. Li and Srikumar (2019) inject logic-driven neurons to existing neural networks by measuring the degree of the head being true measured by probabilistic soft logic (Kimmig et al., 2012). Our approach belongs to the first direction, and to the best of knowledge our work is the first one that augments neural network with logical knowledge for propaganda detection.

6 Conclusion

In this paper, we propose a fine-grained multi-task learning approach, which leverages declarative knowledge to detect propaganda techniques in news articles. Specifically, the declarative knowledge is expressed in both first-order logic and natural language, which are used as regularizers to obtain better propaganda representations and improve logical consistency between coarse- and fine-grained predictions, respectively. Extensive experiments on the PTC dataset demonstrate that our knowledge-augmented method achieves superior performance with more consistent between sentence-level and token-level predictions.

Abstract

Even though SRL is researched for many languages, major improvements have mostly been obtained for English, for which more resources are available. In fact, existing multilingual SRL datasets contain disparate annotation styles or come from different domains, hampering generalization in multilingual learning. In this work we propose a method to automatically construct an SRL corpus that is *parallel in four languages: English, French, German, Spanish*, with unified predicate and role annotations that are fully comparable across languages. We apply high-quality machine translation to the English CoNLL-09 dataset and use multilingual BERT to project its high-quality annotations to the target languages. We include human-validated test sets that we use to measure the projection quality, and show that projection is denser and more precise than a strong baseline. Finally, we train different SOTA models on our novel corpus for mono- and multilingual SRL, showing that the multilingual annotations improve performance especially for the weaker languages.

1 Introduction

Semantic Role Labeling (SRL) is the task of extracting semantic predicate-argument structures from sentences. One of the most widely used labeling schemes for this task is based on PropBank (Palmer et al., 2005). It comes in two variants: span-based labeling, where arguments are characterized as word-spans (Carreras and Màrquez, 2005; Pradhan et al., 2012), and head-based labeling, which only labels the syntactic head (Hajič et al., 2009). In this work we focus on head-based labeling, as it is applied in the multilingual CoNLL-09 shared task dataset, comprising 7 languages.

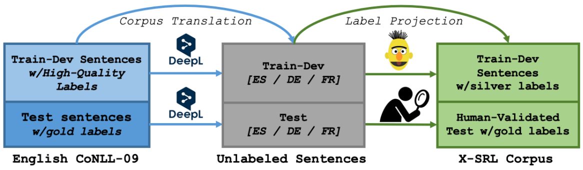

Figure 1: Method to create X-SRL. We automatically translate the English CoNLL-09 corpus, use a fast label projection method for *train-dev* and get human annotators to select the appropriate head words on the target sentences to obtain gold annotations for the *test* sets.

The performance of English SRL has considerably improved in recent years through continuous refinements of Deep Neural Network (DNN) models (Zhou and Xu, 2015; He et al., 2017; Marcheggiani et al., 2017; Cai et al., 2018); however, although the CoNLL-09 SRL dataset already covers 7 languages, other languages have not received the same level of attention. This situation may be due to factors such as i) the lack of sufficient training data to successfully apply a language-agnostic DNN model; ii) the fact that creating new SRL datasets is resource-consuming; iii) current label projection methods suffering from low recall; finally, iv) even in cases where annotated resources are available in other languages, often they were automatically converted from independent pre-existing annotation schemes or labeled with automatic methods, resulting in data quality and labeling schema divergences, hampering the effectiveness of unified models that can be applied in multilingual settings.

In this paper we offer a **multilingual parallel SRL corpus – X-SRL –** for English (EN), German (DE), French (FR) and Spanish (ES) that is based on English gold annotations and *shares the same labeling scheme across languages*.[1] Our corpus has two major advantages compared to existing datasets: first, since it is a *parallel corpus*, all sen-

tences are semantically equivalent allowing us to analyze performance at the sentence-level and to better understand the reasons for SRL score divergences across languages[2]; second, we expect that models trained jointly on multiple languages annotated with a homogeneous labeling style will be able to better generalize across languages[3]. Moreover, by minimizing the need of specialized human annotators, our parallel corpus construction method is *lightweight and portable*, since it is built on three main components: i) A high-quality annotated dataset in the source language, in this case the English CoNLL-09 corpus (Hajič et al., 2009), ii) a high-quality SOTA Machine Translation system, we are using DeepL Pro[4]; and iii) multilingual contextual word representations, in this case multilingual BERT (mBERT) (Devlin et al., 2019). The situation for these multilingual resources is improving with each day, and thus our method, in perspective, could be followed for producing training data for more lower-resource languages. Importantly, although we automatically project labels from English to the newly available corpora in the different languages for *train* and *dev* sections, we also provide *test* sets on which humans assess the quality of the automatic translations and select the valid predicates as well as the appropriate target head words for the target sentences. Having a human-validated test set ensures solid benchmarking for SRL systems, and additionally allows us to assess the validity of the proposed automatic projection for the rest of the data.

Our projection method works as follows (see also Figure 1): We obtain automatic translations of the English CoNLL-09 corpus into each of our target languages; then, we automatically label them without applying any language-pair specific label projection model, but use mBERT with additional filters as a means for alignment. We show that by following this approach we obtain a *more densely annotated dataset* compared to an existing SOTA label projection method (Akbik and Vollgraf, 2018). In short, our contributions are:

- The first fully parallel SRL dataset with dense, homogeneous annotations and human-validated test sets covering four languages: English, French, German and Spanish.
- A simple but effective novel method to project existing SRL annotations from English to lower-resource languages.
- A fast method to create a human-supervised test set that allows us to explore the syntactic and semantic divergences in SRL across languages and to assess performance differences.
- We provide quality measures for our projection based on the human validation process.
- We demonstrate the multilingual generalization capabilities of our corpus by training different SOTA baseline models on our dataset.

2 Related Work

Semi-automatic annotation projection has been applied to different SRL frameworks. Pado (2007); Padó and Lapata (2009) proposed a projection method for FrameNet (Baker et al., 1998) semantic roles that searches for the best alignment of source and target constituent trees, and also created a small human-validated test set for benchmarking.

A number of PropBank resources are available for different languages: the benchmark datasets CoNLL-09 (Hajič et al., 2009) and CoNLL-12 (Pradhan et al., 2012) are well-established, however, a direct cross-lingual comparison of SRL performance across the covered languages is not possible. The reason being that the language-specific datasets come from different sources and were not conceived for such a comparison.

On the other hand, van der Plas et al. (2010) attested the validity of English PropBank labels for French and directly applied them on French data. This motivated SRL projection methods such as van der Plas et al. (2011) and Akbik et al. (2015), which aim to generate a common label set across languages. A known issue with this approach is the need for good quality parallel and sentence-level filtered data. For this reason they used existing parallel corpora, Europarl (Koehn, 2005) and UN (Ziemski et al., 2016), automatically labeled the English side with SRL annotations and transferred them to the corresponding translations. The major issue with this is that evaluation against ground-truth and detailed error analysis on the target languages are not possible, since all annotations are

---

[2] E.g., German F1 score on the CoNLL-09 dataset lags 10 points behind English, but with currently available datasets we cannot be sure if this is due to differences in the available training data or because of language-specific characteristics.

[3] It is not straightforward to use the CoNLL-09 data in a multilingual model: for example, annotations for German use a role inventory with roles A0-A9, and a one-to-one mapping to all English labels is not available.

[4] `https://www.deepl.com/translator`

automatic and come from noisy sources. Likewise, the Universal Proposition Bank[5](Akbik et al., 2015; Akbik and Li, 2016), adds an SRL layer on top of the Universal Dependencies (de Marneffe et al., 2014) corpus, which covers eight different languages. However, i) the original corpora come from independent sources and are not parallel, ii) the source sentences were automatically labeled containing noise even before the alignment step, and iii) the test sets also contain automatic projections without human validation of the labels.

In contrast, we present a corpus that transfers English high-quality labels to the target side, thus projecting the same labeling style to the other languages; more importantly, we conceive of this corpus, from the very beginning, as a parallel resource with translation equivalence with the source and target languages at the sentence-level. In addition, we create a human-validated test set to allow for proper benchmarking in each language.

The use of synthetic data generated by automatic translation has proven to improve performance for MT (Sennrich et al., 2016) and Argumentation Mining (Eger et al., 2018). We similarly create a parallel corpus using automatic translation, however, to our knowledge, we are the first to create a directly comparable multilingual SRL dataset using automatic translation with a manually validated test set, minimizing human labour.

Another attempt to close the gap between languages is by training multilingual SRL systems. He et al. (2019) propose a biaffine scorer with syntax rules to prune of candidates, achieving SOTA independently in all languages from CoNLL-09. Mulcaire et al. (2018) and Daza and Frank (2019) train a single model using input data from different languages and obtain modest improvements, especially for languages where less monolingual training data is available. In this sense, our X-SRL corpus contributes with more compatible training data across languages, and aims to improve the performance of jointly trained multilingual models.

3 Building X-SRL

In this section we first explain our method for translating the English CoNLL-09 SRL dataset (§3.1) into three target languages (DE, ES, FR) [6]. In §3.2 we describe how the human-validated labels (only for the test sets) were obtained in an efficient way, and report annotator agreement statistics in §3.3. The details of how we perform (automatic) label projection enhanced with filtering for *train/dev* are given in §3.4. With this we achieve big annotated SRL datasets for three new languages (cf. Table 3).

When building the X-SRL dataset, in line with the current PropBank SRL data available in different languages, we focus on verbal predicates only. Note that the English CoNLL-09 data includes both verbal and nominal predicate annotations, yet this is due to the NomBank project (Meyers et al., 2004) being available for that language. By contrast, the remaining languages with PropBank SRL training data (including the CoNLL-09 non-English data) only provide annotations for verbal predicates. While we could attempt projecting the English nominal predicate annotations and create an X-SRL dataset that includes nominal SRL for all target languages – which would mean a big advance over the current situation – admitting nominal and verbal SRL annotations in a multilingual setting would confront us with many translation shifts. We could try to capture these for the manually curated test set, however we would run a risk of generating noisy or scarce target annotations when projecting them for the *train/dev* sections.[7]

3.1 Dataset Translation

We aim to produce high-quality labeled corpora while reducing as much as possible the amount of time, cost and human intervention needed to fulfill this task. We use Machine Translation to perform dataset translation, obviating the need of human translator services. As previous work (Tiedemann and Agic, 2016; Tyers et al., 2018) has shown, automatic translations are useful as supervision for syntactic dependency labeling tasks since they are quite close to the source languages; likewise, in Argumentation Mining, Eger et al. (2018) achieve comparable results to using human-translated data. One could argue that by automatically translating the English source, we could run into a problem of

---

[5] `https://github.com/System-T/UniversalPropositions`

[6] We chose these languages given the availability of annotators to validate the quality of test set translations. We hope that future work will apply our method to further languages.

[7] The reasons are complex: First, by including nominal SRL, we would be confronted with translation shifts in both directions, e.g. N-to-V or V-to-N translations. For these, we'd have to verify whether they correspond to valid verbalizations or nominalizations on the target side. This would lead to considerable overhead and, most likely, noise in automatic projection. Also, translation shifts often involve light verb constructions, which require special role annotations. These would be difficult to assign in automatic projection. We thus defer the inclusion of nominal SRL to future work.

Table 1: Examples of translation shifts: (1) predicate nominalization on the target side, (2) and (1) source verb converted to a light verb construction on the target side, (3) a source predicate translates to a verb with separable prefix, and (4) instances of Named Entities being translated or not to the target language.

translationese.[8] While it would be interesting to study possible shining-through effects in our automatically translated target texts and any potential impact on SRL performance (e.g. by comparing a natural vs. translated test set), our main concern is to preserve the relevant *predicate-argument structures* in order to give a strong-enough signal to train our SRL systems, and our initial assumption relies on the evidence from the mentioned previous works (confirmed by our results) that obtaining relevant training data is possible with MT generated sentences.

We take as source the set of sentences in the English CoNLL-09 dataset, which are tokenized and annotated for part-of-speech (POS), syntactic dependencies, predicate senses and semantic roles. We use DeepL to obtain translations of each sentence into the three target languages. For all target sentences we use spaCy[9] to tokenize, assign POS tags and syntactic dependency annotations. This gives us a 4-way parallel corpus with syntactic information on both sides.

3.2 Test Set Annotation

Annotation Setup. To confirm the good quality of the translations delivered by DeepL, we hired 12 annotators with a background in translation studies and experience in $EN \rightarrow T$ translation (we hired 4 annotators for each language pair) to *rate and validate the automatic translations of the test set*[10] by following a guideline that explains the quality validation and the annotation processes[11]. First, we ask them to rate the translations on a scale from 1-5 (worst to best). On the basis of the obtained ratings, we apply a filter and keep only the sentences with *quality rating 3, 4, or 5*. Only on this subset of sentences we require them to do three more tasks: i) we show them the *labeled verbal predicates*[12] in the English sentence and ask them to mark on the target side the words that express the same meaning, ii) we show them a list of *key arguments* (which correspond to the labeled syntactic heads in the English sentence) and likewise, ask them to mark on the target side the expression that best matches each key argument's meaning (marking several words is allowed), and finally iii) we ask them to *fix minor translation mistakes* in order to better reflect the source meaning. Importantly, we ask annotators to flag as **special cases** any one-to-many mappings, and for predicates, any mapping that aligns a source verb to a non-verbal predicate in the target language. We also give the option to map source heads or predicate words to *NONE* when no relevant corresponding expression in the translated sentence can be found.

Annotation Agreement. To approximate the inter-annotator agreement, we gave the first 100 sentences to all annotators of each language pair and compute Krippendorff's alpha[13] on this sub-set of sentences. We obtain $\alpha_{pred_{DE}}$=0.75, $\alpha_{pred_{ES}}$=0.73, $\alpha_{pred_{FR}}$=0.78 for *predicate* and

---

[8] Translationese occurs when – in an attempt to reproduce the meaning of a text in a foreign language – the resulting translation is grammatically correct but carries over language-specific constructs from the source language to the target

[9] `https://github.com/explosion/spaCy`

[10] Note that validating a translation that already exists is considerably faster than generating translations from scratch, therefore annotation time and budget dropped significantly.

[11] See Supplement A for the annotation guideline.

[12] We ignore all source nominal predicates.

[13] We use the NLTK implementation with binary distance to compute the agreement of labels.

$\alpha_{role_{DE}}$=0.79, $\alpha_{role_{ES}}$=0.70, $\alpha_{role_{FR}}$=0.79 for *role labels*. This shows that the *fast* annotation method can be trusted.

Linguistic Validation. We run a second annotation round where two annotators with linguistic background re-validate the instances that were flagged as **special cases** by translators during the first round (more concretely, the possible *translation shifts*). Specifically, annotators in this phase decide, for each special case, if the annotated label should be deleted or corrected. The cases could fall into one or more of the following categories[14] (see Table 1 for some examples):

- **Nominalizations:** A verbal expression (predicate) in English is translated to a nominal expression in the Target (see Table 1, examples (1, 2)). Since we restrict our dataset to verbal predicates (see fn. 7) we discourage the annotation of nominal predicates even when they preserve the original sense.

- **Light Verb Constructions:** This is a special case of nominalization on the target side, where a noun that corresponds to a verb in the source language is an argument of a so-called 'light' verb with bleached, often aspectual, meaning. In example (2), the verb *billed* is translated to *in Rechnung gestellt* (literally: 'in invoice put'). According to Bonial et al. (2015), the nominal argument of a light verb needs a special role annotation.[15] Since there is no easy automatic method to figure out the target senses, we leave these cases for future work and do not annotate them here.

- **Separable Verb Prefixes:** In German, specific verbs must split off their prefix in certain constructions, even though this prefix crucially contributes to their meaning. In example (3), the German verb is *abhängen* which means *to depend*, while the verb *hängen* means *to hang*. Since the labeling scheme that we are using only allows us to tag one word as the head, annotators were instructed to pick the truncated stem of the verb, given that the particle is a syntactic dependent of it.

QUALITY (Q)	EN	DE	ES	FR
5	2,399	718	1,758	1,358
4	0	902	407	463
3	0	593	181	274
2	0	164	46	184
1	0	22	15	119
# Sentences Q >2	2,399	2,213	2,346	2,095
# Kept Predicates Q >2	5,217	4,086	4,376	3,770
# Kept Arguments Q >2	14,156	11,050	10,529	9,854

Table 2: EN shows the original numbers for the English CoNLL-09 corpus. The other three languages show the quality distribution and *predicate* and *role* annotations kept after applying the quality and linguistic filters.

- **Multiword Expressions (MWEs):** A single source word is translated to several target words that constitute a single unit of meaning. The translators were allowed to mark more than one target word if the source word meaning could be mapped to a MWE. For these cases, if they did not fall in any of the previous three categories, and since they were manually aligned for being equivalent in meaning, we transfer the source label to the syntactic head of the marked MWE.

- **Named Entities:** are treated as special cases of MWEs. Some NEs, but not all, are (correctly) translated to the target language, which can result in a change of the argument's head. We see both cases in example (4). When NEs are translated to the target language, we need to select the appropriate head: *Exchange* is the head of the NE in English but *Bourse* should be the head in French. We re-locate the label to the NE's syntactic head on the target side.

The linguistic analysis highlights the importance of providing a human-validated test set – as opposed to relying on automatic projection. While the English labels are considered to be gold standard, their transfer to any target language is not straightforward and must be controlled for the mentioned cases to be considered gold standard on the target side. Accordingly, we also to consider filters or refinements for the automatic projection and finally, on the basis of our validated test set, we can evaluate how accurate our automatic projection is.

3.3 Test Statistics

Table 2 shows the statistics for the final quality distribution for each of the target language datasets according to the translators' ratings. The final test

---

[14] This validation was performed independently, according to the annotators' language expertise. However, the annotators discussed general policies and jointly resolved difficult cases.

[15] The noun projects its predicate-specific role set and in addition includes the governing verb with a role ARGM-LVB.

sets are composed by all sentences with quality level higher than 2. We observe that after applying this filter, the three languages have roughly similar amounts of good quality sentences (between 87% and 97%) as well as similar density of annotations for both predicate and argument labels. The number of sentences that are completely 4-way parallel is 1,714 (71.45% of the original EN corpus). This confirms the intuition that DeepL generates translations that are faithful to the sources. The number of *special cases* analyzed in the second validation step were 294 (DE), 332 (ES) and 1300 (FR), of which 105, 122 and 173, respectively, were considered to be translation shifts and thus were not considered further.

3.4 Automatic Projection

The next step is to find an efficient method to automatically transfer the labels in the *train/dev* portions of the data to the target languages without loosing too many gold labels. Contrary to the test set, we cannot perform human validation due to the size of the data; here we are mostly interested in getting automatically *good enough* labels to train models. Usually, label projection methods (Pado, 2007; Padó and Lapata, 2009; van der Plas et al., 2011; Akbik et al., 2015; Aminian et al., 2019) rely on the intersection of *source-to-target* and *target-to-source* word alignments to transfer the labels in the least noisy manner, and this way prefer to have higher precision at the expense of lower recall. Instead, we take a novel approach and rely on the shared space of mBERT embeddings (Devlin et al., 2019). Specifically, we compute pair-wise cosine similarity between source and target tokens and emulate word-alignments according to this measure[16]. We show that using mBERT instead of typical word alignments dramatically improves the recall of the projected annotations, and enhanced with filters, it also achieves high enough precision, resulting in a more densely labeled target side and therefore better quality training data is expected. Additionally, previous works show that BERT contextualized representations are useful for monolingual Word Sense Disambiguation (WSD) tasks (Loureiro and Jorge, 2019; Huang et al., 2019) which lets us assume that we can rely on mBERT to find good word-level alignments across languages.

Figure 2: We compute a pair-wise cosine similarity matrix to simulate word alignments. For each column, we look only at source word-pieces with an associated label and keep the top-k (k=2) most similar target-side word piece candidates (red squares). The black circles show the aligned full-word.

BERT Cosine Similarity. We start with our word tokenized parallel source $\mathbf{S} = (w_{s_0}, ..., w_{s_n})$ and target $\mathbf{T} = (w_{t_0}, ..., w_{t_m})$ sentences. Then, we use the mBERT tokenizer to obtain word-pieces and their corresponding vectors $\mathbf{S'} = (v_{s_0}, ..., v_{s_p})$ and $\mathbf{T'} = (v_{t_0}, ..., v_{t_q})$ respectively, where we have p source word-pieces and q target word-pieces. We compute the pairwise word-piece cosine similarity between $\mathbf{S'}$ and $\mathbf{T'}$. The cosine similarity between a source word-piece vector and a target word-piece vector is $\frac{v_s^T v_t}{||v_s||||v_t||}$ [17]. The result is a similarity matrix **SM** with p (columns) and q (rows) word-pieces (see Figure 2). In addition, we keep a mapping $\mathbf{S'} \rightarrow \mathbf{S}$ and $\mathbf{T'} \rightarrow \mathbf{T}$ from each of the word-piece vectors to their original respective word tokens to recover the full-word alignments when needed.

Word Alignments. For each column in SM, we choose the k most similar pairs (v_s, v_t) [18]. This is analogous to a $\mathcal{A}_{S' \rightarrow T'}$ alignment [19]. The alignment is done from full-word w_s to full-word w_t, meaning that for each v_s, instead of adding a $v_s \rightarrow v_t$ alignment, we retrieve the full-word w_s to which v_s belongs and the w_t to which v_t belongs and add a $w_s \rightarrow w_t$ alignment to the list of candidates for w_s. At this step, we still permit one-to-many mappings,

---

[16] This is similar to what is done as a first step in BERTScore (Zhang et al., 2020) towards computing a metric for (semantic) sentence similarity, but here we use the token-wise similarity as a guide for cross-lingual word alignments.

[17] We use the implementation of Zhang et al. (2020).

[18] k is a hyperparameter which we chose by hand. The best results were obtained with k=2.

[19] Conversely, we can simulate a $\mathcal{A}_{T' \rightarrow S'}$ alignment by defining a similar process for each row in the matrix.

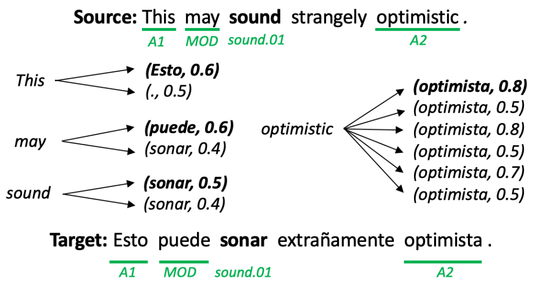

Figure 3: We map word pieces to full-words and apply filters to obtain final source-to-target word alignments.

which means that a w_s can be associated to more than one w_t candidates. We retain a dictionary $D = \{w_s : [(w_{t_1}, sim_{t_1})...(w_{t_x}, sim_{t_x})] | w_s \epsilon S\}$ with their associated similarity scores to keep track of the candidates. See Figure 3 for an example.

Alignment Modes. When projecting annotations to the translated training sections, we are confronted with the same *special cases* that we identified in the test set. In the absence of human validation, we have to define filters to eliminate noisy alignments. By only keeping the intersection of alignments $\mathcal{A}_{S \to T} \bigcap \mathcal{A}_{T \to S}$, we can get rid of a considerable amount of noisy alignments, however this comes at the cost of a very low recall and a sparsely labeled dataset. Since, we are using an accurate word-similarity measure instead of (noisier) word alignments, we can encourage higher recall by considering all $\mathcal{A}_{S \to T}$ alignments and include additional filters to get rid of noisy labels and thus preserve high precision. In (§4.1) we describe in detail the experiments that support this assumption.

Filtered Projection. [20] First of all, we eliminate a considerable amount of potential noise by only looking at the w_s's that hold a predicate or argument label, while ignoring the rest. Next, for each labeled source predicate, we retrieve from D the list of target candidates and keep only those that bear a verbal POS tag. If the list contains more than one target candidate we keep the one with the highest score, and if the list is empty we do not project the predicate, as it will most likely instantiate a translation shift or nominalization. Light verbs should be automatically filtered with this method, since the alignment links a verb to a noun and is therefore dropped. For the case of arguments, we also retrieve the candidates from D. In the ideal case, all candidates belong to the same w_t and we project the label to that word. Otherwise, we take the w_t with more *votes*, i.e. the w_t that was added most often to the list of candidates. In case of a tie, we turn to the similarity score and transfer the argument label to the w_t with the highest similarity[21].

4 Experiments and Evaluations

4.1 Label Projection

Intrinsic Evaluation. Since our test sets are human-validated, we can use them to measure the quality of the label projection methods we have at hand. First, we test the effectiveness of our full method (mBERT+Filters) by comparing it to vanilla cosine similarity (mBERT only) as a projection tool. We apply each method to the test sentences and evaluate the automatically assigned labels against the gold labels provided by annotators. We also show the performance differences when keeping all source to target alignments (S2T) vs. using the intersection of alignments (INTER) when projecting both predicates and arguments. In Table 4 the four combinations can be observed with their specific trade-offs. When using only mBERT with S2T alignments we have high recall but a very mediocre precision; when using INTER alignments we see big gains in precision at the expense of lower recall, as expected. On the other hand, mBERT+Filters obtains consistently better F1, with INTER showing similar behavior to what we observe with the vanilla method, yet with much better precision; however, using full S2T alignments *with filters* gives us the best trade-off: we still achieve around 90% precision and much better recall compared to INTER. This confirms that using S2T alignments (established using mBERT-based cosine similarity) combined with our filters are the best option for projecting labels.

Extrinsic Evaluation. Having settled our best method, we compare it with an SRL label projection software: ZAP (Akbik and Vollgraf, 2018) [22], which also works with the three target languages studied in this paper. ZAP is a pipeline model that takes as input parallel $(\mathbf{S}, \mathbf{T})$ sentences, uses source syntactic and semantic parsers to obtain the annotations, and through a trained heuristic word alignment module that uses pre-computed word

---

[20] `https://github.com/Heidelberg-NLP/xsrl_mbert_aligner`

[21] Score aggregation would be a straightforward way of computing similarities. However, Zhang et al. (2020) mention that while cosine similarity is good to rank semantic similarity, the computed magnitude is not necessarily proportional, therefore it is not a strict metric. For this reason, we only rely on scores as a decision factor in case of ties.

Table 4: Examining different projection methods on our *human-validated test set*: a) vanilla mBERT cosim (mBERT-Only) vs. adding filters (mBERT+Filters); b) INTER using intersective alignments vs. S2T using full source-to-target alignments. Using S2T alignments and applying filters yield highest F1 alignment score.

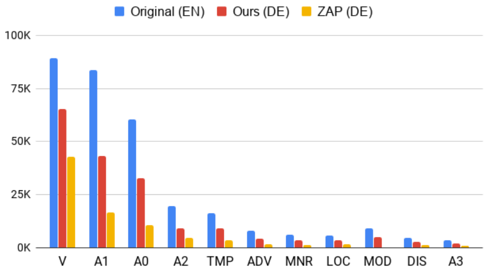

Figure 4: Ten most frequent labels obtained with two label projection methods: OURS vs. ZAP - on the German train set, compared to English source annotations.

translation probabilities, it transfers the labels only when it considers the alignments to be valid, preferring to have fewer, but higher-quality annotations on the target side.

To compare our method to this baseline, we measure the density of the labels on the target training sets after applying both methods to project the labels[23]. Figure 4 shows the case of EN projected to DE where our method consistently recovers more labels from the source, resulting in a more densely annotated training set with comparable label distribution to the EN source. This trend is similar for Spanish and French (overall coverage relative to EN is: DE: 58.9%, ES: 67.3%, FR: 66.9%).

To investigate more deeply why ZAP performs so poorly compared to our method, we use the test sets to measure performance. We first evaluate the capacity to transfer source predicates to the target side. Table 5 clearly shows that ZAP fails to transfer many predicates, perhaps because it has unreliable (or no) word-alignment probabilities for infrequent predicates and it is not fine-tuned for this domain (it was trained on Europarl). As a result, also the argument scores are very low, since for each predicate it misses, the system cannot recover any arguments. This highlights the main advantages of our method: by relying on a big multilingual language model i) we obtain high-quality word alignments featuring high precision *and* recall, and ii) we do not need to re-train for other language pairs nor different domains.

	ZAP						OURS					
	PREDICATE			ARGUMENT			PREDICATE			ARGUMENT		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1

Table 5: We compare our best projection method with ZAP, a SOTA system for SRL label projection on our test sets. The recall of ZAP is extremely low, damaging their overall scores. In contrast, our method is very good at projecting verbal predicates and arguments.

4.2 Training SRL Systems on X-SRL

At this point we have attested the quality of the automatic method for creating the training sets. Now, as an extrinsic evaluation, we will measure how well can different models learn from our data. To train the models we follow (Zhou and Xu, 2015; He et al., 2017) in the sense that we feed the predicate in training and inference, and we process each sentence as many times as it has predicates, labeling one predicate-argument structure at a time.

mBERT fine-tuning. In all settings, we fine-tune mBERT[24]. We use batch size of 16, learning rate of $5e^{-5}$ and optimize using Adam with weight decay (Loshchilov and Hutter, 2019) and linear schedule with warmup. We train for 5 epochs on our data and pick the epoch that performs best on

Table 6: F1 Score with Fine-tuning mBERT on our training data, created using ZAP vs. OUR projection method and evaluated on our test sets. We compare zero-shot (EN-tuned), mono- and multilingual settings.

MODEL	EN	DE	ES	FR
(Daza and Frank, 2019) Mono	90.9	67.6	56.2	58.1
(Daza and Frank, 2019) Multi	87.6	72.5	77.1	75.2
(Cai et al., 2018) Mono	91.4	76.5	**82.6**	80.3
(He et al., 2019) Mono	**92.4**	75.8	82.3	79.3
(He et al., 2019) Multi	92.1	**77.3**	82.5	**80.4**

Table 7: F1 Score when training existing SRL models with our data and evaluating on our test. We compare monolingual (Mono) vs using all data available (Multi).

dev. Concretely, we explore three settings: The obvious baseline is i) to use only the available English high-quality labels for fine-tuning mBERT and apply zero-shot inference on the other three languages (we call this *EN-tuned*). The other two settings are ii) to fine-tune each language independently with its respective training set (*Mono*) and iii) using all the available data from the four languages to train a single model (*Multi*). Table 6 shows that, as expected, for the *EN-tuned* baseline, English reaches an F1 score of 91, and the other three languages can make good use of mBERT's knowledge in the zero-shot setting, reaching scores around 70. We also see that our training sets are more complete, obtaining, across the board, higher F1 scores than the training sets projected using ZAP. We observe that training on monolingual data results in improvements for all languages, and finally, the best setting is to use all data at once, improving the already robust mBERT results, and reaching scores of 77, 92, 81 and 78 for DE, EN, ES, FR respectively, about 8 points higher than the zero-shot baseline in the case of German.

SOTA Models. Next, we choose three SRL systems that show SOTA results on CoNLL-09 and train them using our data instead. Note that our results are not comparable since our train and test sets are completely different for ES and DE; also the EN results are not comparable since we only label verbal predicates; finally, FR is not present in CoNLL-09. Table 7 summarizes the results. The model of Daza and Frank (2019) is an Encoder-Decoder model that was designed for multilingual SRL. It performs poorly when trained on monolingual data but improves significantly when trained with more data (multilingual setting). The model of Cai et al. (2018) adapts the biaffine attention scorer of Dozat and Manning (2017) to the SRL task; we note that this model is not designed for handling multilingual data, therefore we only show the monolingual results, which still achieve the best score (82.6) for ES on our test data. Finally, He et al. (2019) generalizes and enhances the biaffine attention scorer with language-specific rules that prune arguments to achieve SOTA on all languages in CoNLL-09. When training this model using our data it achieves the highest scores for EN in the *Mono* setting and for DE and FR when trained with multilingual data. In sum, using our new corpus to train multilingual SRL systems, with SOTA models and finetuning mBERT, we find evidence that the models can use the multilingual annotations for improved performance, especially for the weaker languages.

5 Conclusions

In this paper, we present the first fully parallel SRL dataset with homogeneous annotations for four different languages. We included human-validated test sets where we address the linguistic difficulties that emerge when transferring labels across languages – despite transferring gold labels from the source. We introduce and evaluate a novel effective and portable automatic method to transfer SRL labels that relies on the robustness of Machine Translation and multilingual BERT and therefore could be straightforwardly applied to produce SRL data in other languages. Finally, we included an extrinsic evaluation where we train SRL models using our data and obtain consistent results that showcase the generalization capacities emerging from our new 4-way multilingual dataset. Future work should address the application of our method to more and typologically more divergent languages.

Abstract

Semantic role labeling (SRL) is the task of identifying predicates and labeling argument spans with semantic roles. Even though most semantic-role formalisms are built upon constituent syntax, and only syntactic constituents can be labeled as arguments (e.g., FrameNet and PropBank), all the recent work on syntax-aware SRL relies on dependency representations of syntax. In contrast, we show how graph convolutional networks (GCNs) can be used to encode constituent structures and inform an SRL system. Nodes in our SpanGCN correspond to constituents. The computation is done in 3 stages. First, initial node representations are produced by 'composing' word representations of the first and last words in the constituent. Second, graph convolutions relying on the constituent tree are performed, yielding syntactically-informed constituent representations. Finally, the constituent representations are 'decomposed' back into word representations, which are used as input to the SRL classifier. We evaluate SpanGCN against alternatives, including a model using GCNs over dependency trees, and show its effectiveness on standard English SRL benchmarks CoNLL-2005, CoNLL-2012, and FrameNet.

1 Introduction

The task of semantic role labeling (SRL) involves predicting the predicate-argument structure of a sentence. More formally, for every predicate, the SRL model must identify all argument spans and label them with their semantic roles (see Figure 1). The most popular resources for estimating SRL models are PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998). In both cases, annotations are made on top of syntactic constituent structures. Earlier work on SRL hinged on constituent syntactic structure, using the trees to derive features and constraints on role assignments (Gildea and Jurafsky, 2002; Pradhan et al., 2005; Punyakanok et al., 2008). In contrast, modern SRL systems largely ignore treebank syntax (He et al., 2018a, 2017; Marcheggiani et al., 2017; Zhou and Xu, 2015) and instead use powerful feature extractors, for example, LSTM sentence encoders.

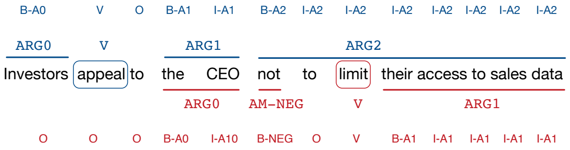

Figure 1: An example with semantic-role annotation and its reduction to the sequence labeling problem (BIO labels): the argument structure for predicates *appeal* and *limit* are shown in blue and red, respectively.

There have been recent successful attempts to improve neural SRL models using syntax (Marcheggiani and Titov, 2017; Strubell et al., 2018; He et al., 2018b). Nevertheless, they have relied on syntactic dependency representations rather than constituent trees. In these methods, information from dependency trees is injected into word representations using graph convolutional networks (GCN) (Kipf and Welling, 2017) or self-attention mechanisms (Vaswani et al., 2017). Since SRL annotations are done on top of syntactic constituents,[1] we argue that exploiting constituency syntax, rather than dependency one, is more natural and may yield more predictive features for semantic roles. For example, even though constituent boundaries could be derived from dependency structures, this would

---

[*] Research conducted when the author was at the University of Amsterdam.

[1] There exists another formulation of SRL, where the focus is on predicting semantic dependency graphs (Surdeanu et al., 2008). For English, however, these dependency annotations are automatically derived from span-based PropBank.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3915–3928,
November 16–20, 2020. ©2020 Association for Computational Linguistics

require an unbounded number of hops over the dependency structure in GCNs or self-attention. This would be impractical: both Strubell et al. (2018) and Marcheggiani and Titov (2017) use only one hop in their best systems.

Neural models typically treat SRL as a sequence labeling problem, and hence predictions are made for individual words. Though injecting dependency syntax into word representations is relatively straightforward, it is less clear how to incorporate constituency syntax.[2] This work shows how GCNs can be directly applied to span-based structures. We propose a multi-stage architecture based on GCNs to inject constituency syntax into word representations. Nodes in our SpanGCN correspond to constituents. The computation is done in 3 stages. First, initial span representations are produced by 'composing' word representations of the first and last words in the constituent. Second, graph convolutions relying on the constituent tree are performed, yielding syntactically-informed constituent representations. Finally, the constituent representations are 'decomposed' back into word representations, which are used as input to the SRL classifier. This approach directly injects information about boundaries and syntactic labels of constituents into word representations and also provides information about the word's neighbourhood in the constituent structure.

We show the effectiveness of our approach on three English datasets: CoNLL-2005 (Carreras and Màrquez, 2005) and CoNLL-2012 (Pradhan et al., 2012) with PropBank-style (Palmer et al., 2005) annotation and on FrameNet 1.5 (Baker et al., 1998) [3]. By empirically comparing SpanGCN to GCNs over dependency structures, we confirm our intuition that constituents yield more informative features for the SRL task. [4]

SpanGCN may be beneficial in other NLP tasks, where neural sentence encoders are already effective and syntactic structure can provide an additional inductive bias, e.g., logical semantic parsing (Dong and Lapata, 2016) or sentence simplification (Chopra et al., 2016). Moreover, in principle, SpanGCN can be applied to other forms of span-based linguistic representations (e.g., co-reference, entity+relations graphs, semantic and discourse structures). However, we leave this for future work.

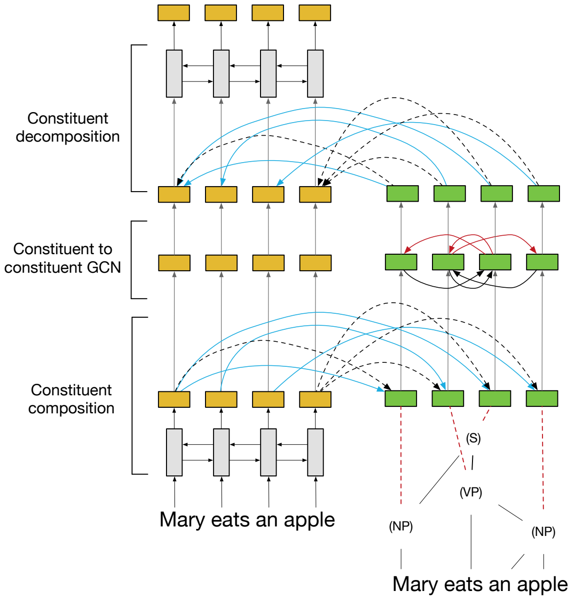

Figure 2: SpanGCN encoder. First, for each constituent, an initial representation is produced by composing the start and end tokens' BiLSTM states (cyan and black dashed arrows, respectively). This is followed by a constituent GCN: red and black arrows represent parent-to-children and children-to-parent messages, respectively. Finally, the constituent is decomposed back: each constituent sends messages to its start and end tokens.

2 Constituency Tree Encoding

The architecture for encoding constituency trees uses two building blocks, a bidirectional LSTM for encoding sequences and a graph convolutional network for encoding graph structures.

2.1 BiLSTM encoder

A bidirectional LSTM (BiLSTM) (Graves, 2013) consists of two LSTMs (Hochreiter and Schmidhuber, 1997), one that encodes the left context of a word and one that encodes the right context. In this paper, we use alternating-stack BiLSTMs as introduced by Zhou and Xu (2015), where the forward LSTM is used as input to the backward LSTM. As in He et al. (2017), we employ highway connections (Srivastava et al., 2015) between layers and recurrent dropout (Gal and Ghahramani, 2016) to avoid overfitting.

---

[2] Recently, Wang et al. (2019) proposed different ways of encoding dependency and constituency syntax based on the linearization approaches of Gómez-Rodríguez and Vilares (2018).

[3] Although we tested the model on English datasets, SpanGCN can be applied to constituent trees in any language.

[4] Code available at `https://github.com/diegma/span-gcn`.

2.2 GCN

The second building block we use is a graph convolutional network (Kipf and Welling, 2017). GCNs are neural networks that, given a graph, compute the representation of a node conditioned on the neighboring nodes. It can be seen as a message-passing algorithm where a node's representation is updated based on 'messages' sent by its neighboring nodes (Gilmer et al., 2017).

The input to GCN is an undirected graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ ($|V| = n$) and $\mathcal{E}$ are sets of nodes and edges, respectively. Kipf and Welling (2017) assume that the set of edges $\mathcal{E}$ contains also a self-loop, i.e., $(v, v) \in \mathcal{E}$ for any v. We refer to the initial representation of nodes with a matrix $X \in \mathbb{R}^{m \times n}$, with each of its column $x_v \in \mathbb{R}^m$ ($v \in \mathcal{V}$) encoding node features. The new node representation is computed as

$$h_v = ReLU\left(\sum_{u \in \mathcal{N}(v)} (Ux_u + b)\right),$$

where $U \in \mathbb{R}^{m \times m}$ and $b \in \mathbb{R}^m$ are a weight matrix and a bias, respectively; $\mathcal{N}(v)$ are neighbors of v; $ReLU$ is the rectifier linear unit activation function.

The original GCN definition assumes that edges are undirected and unlabeled. We take inspiration from dependency GCNs (Marcheggiani and Titov, 2017) introduced for dependency syntactic structures. Our update function is defined as

$$\begin{aligned} h_v^{'} = & ReLU(LayerNorm(\\ & \sum_{u \in \mathcal{N}(v)} g_{v,u}(U_{T_c(u,v)} h_u + b_{T_f(u,v)}))), \end{aligned} \quad (1)$$

where $LayerNorm$ refers to layer normalization (Ba et al., 2016) applied after summing the messages. Expressions $T_f(u, v)$ and $T_c(u, v)$ are fine-grained and coarse-grained versions of edge labels. For example, $T_c(u, v)$ may simply return the direction of an arc (i.e. whether the message flows along the graph edge or in the opposite direction), whereas the bias can provide some additional syntactic information. The typing decides how many parameters GCN has. It is crucial to keep the number of coarse-grained types low as the model will have to estimate one $\mathbb{R}^{m \times m}$ matrix per coarse-grained type. We formally define the types in the next section. We used scalar gates $g_{u,v}$ to weight the contribution of each node in the neighborhood and potentially ignore irrelevant edges:

$$g_{u,v} = \sigma\left(\hat{u}_{T_c(u,v)} \cdot h_u + \hat{b}_{T_f(u,v)}\right), \quad (2)$$

where σ is the sigmoid activation function, whereas $\hat{u}_{T_c(u,v)} \in \mathbb{R}^m$ and $\hat{b}_{T_f(u,v)} \in \mathbb{R}$ are edge-type-specific parameters.

Now, we show how to compose GCN and LSTM layers to produce a syntactically-informed encoder.

2.3 SpanGCN

Our model is shown in Figure 2. It is composed of three modules: constituent composition, constituent GCN, and constituent decomposition. Note that there is no parameter sharing across these components.

Constituent composition The model takes as input word representations which can either be static word embeddings or contextual word vectors (Peters et al., 2018a; Liu et al., 2019b; Devlin et al., 2019). The sentence is first encoded with a BiLSTM to obtain a context-aware representation of each word. A constituency tree is composed of words ($\mathcal{V}_w$) and constituents ($\mathcal{V}_c$).[5] We add representations (initially zero vectors) for each constituent in the tree; they are shown as green blocks in Figure 2. Each constituent representation is computed using GCN updates (Equation 1), relying on the word representation corresponding to the beginning of its span and the representation corresponding to the end of its span. The coarse-grained types $T_c(u, v)$ here are binary, distinguishing messages from start tokens vs. end tokens. The fine-grained edge types $T_f(u, v)$ encode additionally the constituent label (e.g., NP or VP).

Constituent GCN The constituent composition stage is followed by a layer where constituent nodes exchange messages. This layer makes sure that information about children gets incorporated into representations of immediate parents and vice versa. GCN operates on the graph with nodes corresponding to all constituents ($\mathcal{V}_c$) in the trees. The edges connect constituents and their immediate children in the syntactic tree and do it in both directions. Again, the updates are defined as in Equation 1. As before, $T_c(u, v)$ is binary, now distinguishing parent-to-children messages from children-to-parent messages. $T_f(u, v)$ additionally

---

[5] We slightly abuse the notation by referring to non-terminals as constituents: part-of-speech tags (typically 'pre-terminals') are stripped off from our trees.

includes the label of the constituent sending the message. For example, consider the computation of the VP constituent in Figure 2. It receives a message from the S constituent, this is a parent-to-child message, and the 'sender' is S; these two factors determine $T_f(u, v)$ and, as a result, the parameters used in computing the corresponding message.

Constituent decomposition At this point, we 'infuse' words with information coming from constituents. The graph here is the inverse of the one used in the composition stage: the constituents pass the information to the first and the last words in their spans. As in the composition stage, $T_c(u, v)$ is binary, distinguishing messages to start and end tokens. The fine-grained edge types, as before, additionally include the constituent label. To spread syntactic information across the sentence, we use a further BiLSTM layer.

Note that residual connections indicated in grey in Figure 2, let the model bypass GCN if / where needed.

3 Semantic Role Labeling

SRL can be cast as a sequence labeling problem where given an input sentence $\mathbf{x}$ of length T, and the position of the predicate in the sentence $p \in T$, the goal is to predict a BIO sequence of semantic roles $\mathbf{y}$ (see Figure 1). We test our model on two different SRL formalisms, PropBank and FrameNet.

PropBank In PropBank conventions, a frame is specific to a predicate sense. For example, for the predicate *make*, it distinguishes 'make.01' ('create') frame from 'make.02' ('cause to be') frame. Though roles are formally frame-specific (e.g., *A0* is the 'creator' for the frame 'make.01' and the 'writer' for the frame 'write.01'), there are certain cross-frame regularities. For example, *A0* and *A1* tend to correspond to proto-agents and proto-patients, respectively.

FrameNet In FrameNet, every frame has its own set of role labels (frame elements in FrameNet terminology).[6] This makes the problem of predicting role labels harder. Differently from PropBank, lexically distinct predicates (lexical units or targets in FrameNet terms) may evoke the same frame. For example, *need* and *require* both can trigger frame 'Needing'.

As in previous work we compare to, we assume to have access to gold frames (Swayamdipta et al., 2018; Yang and Mitchell, 2017).

4 Semantic Role Labeling Model

For both PropBank and FrameNet, we use the same model architecture.

Word representation We represent words with pretrained word embeddings, and we keep them fixed during training. Word embeddings are concatenated with 100-dimensional embeddings of a predicate binary feature (indicating if the word is the target predicate or not). Before concatenation, the pretrained embeddings are passed through layer normalization (Ba et al., 2016) and dropout (Srivastava et al., 2014). Formally,

$$x_t = dropout(LayerNorm(w_t)) \circ predemb(t)),$$

where $predemb(t)$ is a function that returns the embedding for the presence or absence of the predicate at position t. The obtained embedding x_t is then fed to the sentence encoder.

Sentence encoder As a sentence encoder we use SpanGCN introduced in Section 2. SpanGCN is fed with word representations x_t. Its output is a sequence of hidden vectors that encode syntactic information for each candidate argument h_t. As a baseline, we use a syntax-agnostic sentence encoder that is the reimplementation of the encoder of He et al. (2017) with stacked alternating LSTMs, i.e., our model with the three GCN layers stripped off.[7]

Bilinear scorer Following Strubell et al. (2018), we used a bilinear scorer:

$$s_{pt} = (h_p^{pred})^T U (h_t^{arg}).$$

h_p^{pred} and h_t^{role} are a non-linear projection of the predicate h_p at position p in the sentence and the candidate argument h_t. The scores s_{pt} are passed through the softmax function and fed to the conditional random field (CRF) layer.

Conditional random field For the output layer, we use a first-order Markov CRF (Lafferty et al., 2001). We use the Viterbi algorithm to predict the most likely label assignment at testing time. At training time, we learn the scores for transitions

---

[6] Cross-frame relations (e.g., the frame hierarchy) present in FrameNet can, in principle, be used to establish correspondences between a subset of roles.

[7] To have a fair baseline, we independently tuned the number of BiLSTM layers for our model and the baseline.

Table 1: Results with predicted and gold syntax on the CoNLL-2005 development set.

between BIO labels. The entire model is trained to minimize the negative conditional log-likelihood:

$$\mathcal{L} = -\sum_{j}^{N} \log P(\mathbf{y}|\mathbf{x}, p)$$

where p is the predicate position for the training example j.

5 Experiments

5.1 Data and setting

We experiment on the CoNLL-2005 and CoNLL-2012 (OntoNotes) datasets and use the CoNLL 2005 evaluation script for evaluation. We also apply our approach to FrameNet 1.5 with the data split of Das et al. (2014) and follow the official evaluation set-up from the SemEval07 Task 19 on frame-semantic parsing (Baker et al., 2007).

We train the self-attentive constituency parser of Kitaev and Klein (2018)[8] on the training data of the CoNLL-2005 dataset (Penn Treebank) and parse the development and test sets of CoNLL-2005 dataset. We apply the same procedure for the CoNLL-2012 dataset. We perform 10-fold jackknifing to obtain syntactic predictions for the training set of CoNLL-2005 and CoNLL-2012. For FrameNet, we parse the entire corpus with the parser trained on the training set of CoNLL-2005. All hyperparameters are reported in Appendix A.

5.2 Importance of syntax and ablations

Before comparing our full model to state-of-the-art SRL systems, we show that our model genuinely benefits from incorporating syntactic information and motivate other modeling decisions (e.g., the presence of BiLSTM layers at the top).

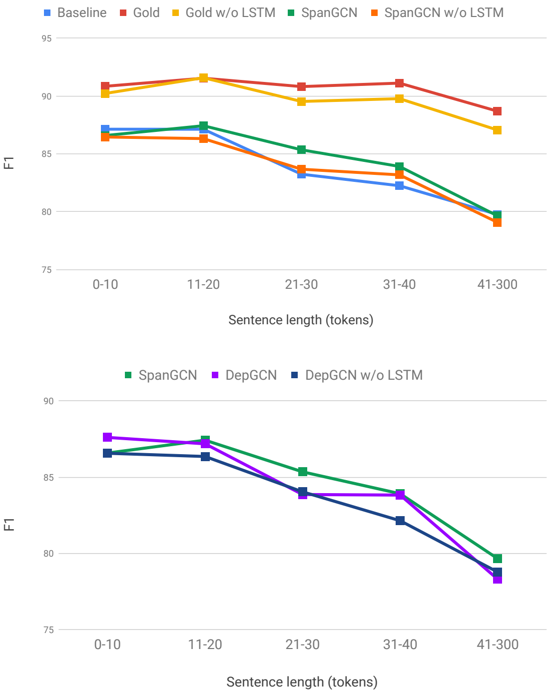

Figure 3: CoNLL-2005 F1 score as a function of sentence length.

We perform this analysis on the CoNLL-2005 dataset. We also experiment with gold-standard syntax, as this provides an upper bound on what SpanGCN can gain from using syntactic information.

From Table 1, we can see that SpanGCN improves over the syntax-agnostic baseline by 1.2% F1, a substantial boost from using predicted syntax. We can also observe that it is important to have the top BiLSTM layer. When we remove the BiLSTM layer, the performance drops by 1% F1. Interestingly, without this last layer, SpanGCN's performance is roughly the same as that of the baseline. This shows the importance of spreading syntactic information from constituent boundaries to the rest of the sentence.

When we provide to SpanGCN gold-standard syntax instead of the predicted one, the SRL scores improve greatly.[9] This suggests that, despite its simplicity (e.g., somewhat impoverished parameterization of constituent GCNs), SpanGCN is capable of extracting predictive features from syntactic structures.

We also measure the performance of the models above as a function of sentence length (Figure 3),

---

[8] https://github.com/nikitakit/self-attentive-parser

[9] The syntactic parser we use scores 92.5% F1 on the development set.

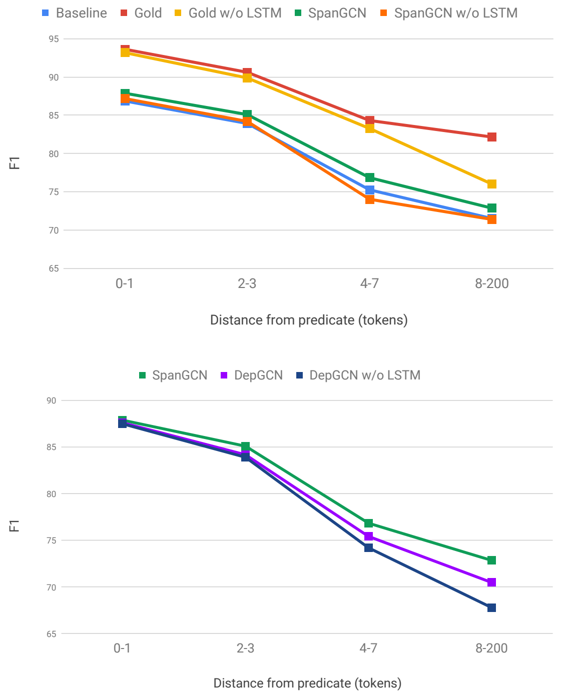

Figure 4: CoNLL-2005 F1 score as a function of the distance of a predicate from its arguments.

and as a function of the distance between a predicate and its arguments (Figure 4). Not surprisingly, the performance of every model degrades with the length. For the model using gold syntax, the difference between F1 scores on short sentences and long sentences is smaller (2.2% F1) than for the models using predicted syntax (6.9% F1). This is also expected as in the gold-syntax set-up, SpanGCN can rely on perfect syntactic parses even for long sentences. In contrast, in the realistic set-up syntactic features start to be unreliable. SpanGCN performs on par with the baseline for very short and very long sentences. Intuitively, for short sentences, BiLSTMs may already encode enough syntactic information, while for longer sentences, the quality of predicted syntax is not good enough to get gains over the BiLSTM baseline. When considering the performance of each model as a function of the distance between a predicate and its arguments, we observe that all models struggle with more 'remote' arguments. Evaluated in this setting, SpanGCN is slightly better than the baseline.

We also check what kind of errors these models make by using an oracle to correct one error type at the time and measuring the influence on the performance (He et al., 2017). Figure 5 (top) shows the results. We can see that all the models make the same fraction of mistakes in labeling arguments, even with gold syntax. It is also clear that using gold syntax and, to a lesser extent, predicted syntax, helps the model to figure out the exact boundaries of argument spans. These results also suggest that using gold-syntax leads to many fewer span-related errors: fixing these errors (merge two spans, spit into two spans, fix both boundaries) yields 6.1% and 1.4% improvements, when using predicted and gold syntax, respectively. The BiLSTM is even weaker here (6.8% increase in F1).

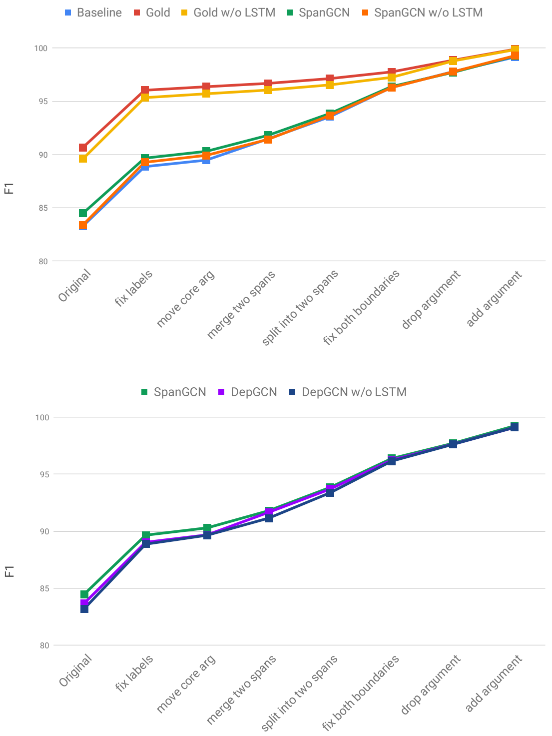

Figure 5: Performance of CoNLL-2005 models after performing corrections from He et al. (2017).

SpanGCN vs. DependencyGCN To show the benefits of using constituency syntax, we compare SpanGCN with the dependency GCN (DepGCN) of Marcheggiani and Titov (2017). We use DepGCN in our architecture in place of the 3-stage SpanGCN. We obtain dependency trees by transforming the predicted constituency trees with CoreNLP (de Marneffe and Manning, 2008). Table 1 shows that while the model with DepGCN preforms +0.38% better than the baseline, it performs worse than SpanGCN 83.56 vs. 84.36 F1. In Figure 3 (bottom), we also compare the performance of the two syntactic encoders as a function of sentence length. Interestingly, DepGCN performs slightly better than SpanGCN on short sentences. Figure 4 (bottom) shows that SpanGCN performs on par with DepGCN when arguments are close to the predicate but better for more distant arguments. As with SpanGCN, Figure 3 and 4 (bottom) show that adding a BiLSTM on top of DepGCN helps to capture long range dependencies. In Figure 5(bottom), we show the different behaviour of DepGCN with respect to SpanGCN in terms of prediction mistakes. Unsurprisingly, the main mistake that DepGCN makes is on deciding span boundaries. Fixing span related errors (merge two spans, spit into two spans, fix both boundaries) yields an improvement of 6.6% for DepGCN vs. 6.1% of SpanGCN.

5.3 Comparing to the state of the art

We compare SpanGCN with state-of-the-art models on both CoNLL-2005 and CoNLL-2012.[10]

CoNLL-2005 In Table 2 (Single) we show results on the CoNLL-2005 dataset. We compare the model with approaches that use syntax (Strubell et al., 2018; Wang et al., 2019) and with syntax-agnostic models (He et al., 2018a, 2017; Tan et al., 2018; Ouchi et al., 2018). SpanGCN obtains the best results also outperforming the multi-task self-attention model of Strubell et al. (2018)[11] on the WSJ (in-domain) (85.43 vs. 84.64 F1) and Brown (out-of-domain) (75.45 vs. 74.55 F1) test sets. The performance on the Brown test shows that SpanGCN is robust with nosier syntax.

CoNLL-2012 In Table 3 (Single) we report results on the CoNLL-2012 dataset. SpanGCN obtains 84.4 F1, outperforming all previous models evaluated on this data.

Experiments using contextualized embeddings We also test SpanGCN using contextualized word embeddings. We use ELMo (Peters et al., 2018a) to train the syntactic parser of Kitaev and Klein (2018), and provide ELMo and RoBERTa (Liu et al., 2019b) embeddings as input to our model.

---

[10] We only consider single, non-ensemble models.

[11] We compare with the LISA model where no ELMo information (Peters et al., 2018a) is used, neither in the syntactic parser nor the SRL components.

Model	P	R	F_1
Yang and Mitchell (2017) (SEQ)	63.4	66.4	64.9
Yang and Mitchell (2017) (ALL)	70.2	60.2	65.5
Swayamdipta et al. (2018)†‡	69.2	69.0	69.1
SpanGCN†	69.8	68.8	69.3

Table 4: Results on FrameNet 1.5 test set using gold frames. † indicates syntactic models and ‡ indicates multi-task learning models.

In Table 2 (Single / Context. Emb.) we show results of models that employ contextualized embeddings on the CoNLL-2005 test set. Both SpanGCN models with contextualized embeddings perform better than the models with GloVe embeddings in both test sets. SpanGCN(RoBERTa) is outperformed by the syntax-aware model of Wang et al. (2019) on the WSJ test but obtains results on par with the state of the art (Li et al., 2019) on the Brown test set.

When we train the syntax-agnostic baseline of Section 4 with RoBERTa embeddings, we obtain 87.0 F1 on the WSJ test set and 79.7 on the Brown test set, 0.9% F1 worse than SpanGCN on both test sets. This suggests that although contextualized word embeddings contain information about syntax (Tenney et al., 2019; Peters et al., 2018b; Hewitt and Manning, 2019), explicitly encoding high-quality syntax is still useful. SpanGCN(ELMo) has comparable results to SpanGCN(RoBERTa) when tested on the WSJ test set, but has a 1.1% difference when tested on the Brown test set. This difference is not surprising; BERT-like embeddings have been shown to perform better than ELMo embeddings in various probing tasks (Liu et al., 2019a). We believe that on top of this, the sheer volume of data used to train RoBERTa (160GB of text) is beneficial in the out-of-domain setting.

We report results with contextualized embeddings on CoNLL-2012 in Table 3 (Single / Context. Emb.). SpanGCN(RoBERTa) obtains the best results. It is interesting to notice, though, that results of the syntax-aware model of Wang et al. (2019) are overall (on both CoNLL 2005 - 2012) similar to SpanGCN(RoBERTa). Also in this setting, SpanGCN(ELMo) obtains similar (although inferior) results to SpanGCN(RoBERTa) 86.5 vs. 86.8 F1. Compared with the best ELMo-based model (Wang et al., 2019), SpanGCN(ELMo) obtains similar (0.1% lower) results.

FrameNet On FrameNet data, we compare SpanGCN with the sequential and sequential-span ensemble models of Yang and Mitchell (2017), and with the multi-task learning model of Swayamdipta et al. (2018). Swayamdipta et al. (2018) use a multi-task learning objective where the syntactic scaffolding model and the SRL model share the same sentence encoder and are trained together on disjoint data. Like our method, this approach injects syntactic information (though dependency rather than constituent syntax) into word representations used by the SRL model. We show results obtained on the FrameNet test set in Table 4. SpanGCN obtains 69.3% F1 score. It performs better than the syntax-agnostic baseline (2.9% F1) and better than the syntax-agnostic ensemble model (ALL) of Yang and Mitchell (2017) (3.8% F1). SpanGCN also slightly outperforms (0.2% F1) the multi-task model of Swayamdipta et al. (2018).

6 Related Work

Among earlier approaches to incorporating syntax into neural networks, Socher et al. (2013); Tai et al. (2015) proposed recursive neural networks that encode constituency trees by recursively creating representations of constituents. There are two important differences between these approaches and ours. First, in our model, the syntactic information in the constituents flows back to word representations. This may be achieved with their inside-outside versions (Le and Zuidema, 2014; Teng and Zhang, 2017). Second, these previous models do a global pass over the tree, whereas GCNs consider only small fragments of the graph. This may make GCNs more robust when using noisy, predicted syntactic structures.

In SRL, dependency syntax has gained a lot of attention. Similarly to this work, Marcheggiani and Titov (2017) encoded dependency structures using GCNs. Strubell et al. (2018) used a multi-task objective to force the self-attention model to predict syntactic edges. Roth and Lapata (2016) encoded dependency paths between predicates and arguments using an LSTM. Li et al. (2018) analysed different ways of encoding syntactic dependencies for dependency-based SRL, while He et al. (2018b) and He et al. (2019) proposed an argument pruning technique which calculates promising candidate arguments. Recently, Wang et al. (2019) used syntax linearizaton approaches of Gómez-Rodríguez and Vilares (2018) and employed this information as a word-level feature in a SRL model. Swayamdipta et al. (2018); Cai and Lapata (2019) used multi-task learning to produce syntactically-informed word representation, with a sentence encoder shared between SRL and an auxiliary syntax-related task.

In earlier work, Naradowsky et al. (2012) used graphical models to encode syntactic structures while Moschitti et al. (2008) applied tree kernels for encoding constituency trees. Many methods cast the problem of SRL as a span classification problem. FitzGerald et al. (2015) used hand-crafted features to represent spans, while He et al. (2018a) and Ouchi et al. (2018) adopted a BiLSTM feature extractor. In principle, SpanGCN can be used as a syntactic feature extractor within this class of models.

7 Conclusions

In this paper, we introduced SpanGCN, a novel neural architecture for encoding constituency syntax at the word level. We applied SpanGCN to SRL, on PropBank and FrameNet. We observed substantial improvements from using constituent syntax on both datasets, and also in the realistic out-of-domain setting. By comparing to dependency GCN, we observed that for SRL constituent structures yield more informative features that the dependency ones. Given that GCNs over dependency and constituency structure have access to very different information, it would be interesting to see in future work if combining two types of representations can lead to further improvements. While we experimented only with constituency syntax, SpanGCN may be able to encode any kind of span structure, for example, co-reference graphs, and can be used to produce linguistically-informed encoders for other NLP tasks rather than only SRL.

A Implementation details

We used 100-dimensional GloVe embeddings (Pennington et al., 2014) for all our experiments unless otherwise specified. We tuned the hyperparameters on the CoNLL-2005 development set. The LSTMs hidden state dimensions were set to 300 for CoNLL experiments and to 200 for FrameNet ones. In our model, we used a four-layer BiLSTM below GCN layers and a two-layer BiLSTM on top. We used an eight-layer BiLSTM in our syntax-agnostic baseline; the number of layers was independently tuned on the CoNLL-2005 development set. For RoBERTa (Liu et al., 2019b) experiments, we used the last layer of the 12-layers (roberta-base) pretrained transformer (Vaswani et al., 2017) without fine tuning it. In the case words got split into multiple subwords by the RoBERTa tokenizer, we took the vector of the first subword unit as the representation of the word as in Devlin et al. (2019).

For ELMo experiments, we learned the mixing coefficients of ELMo, and we concatenated the weighted sum of the ELMo layers with a GloVe 100-dimensional vector. We used the original 5.5B ELMo model [12].

For FrameNet experiments, we constrained the CRF layer to accept only BIO tags compatible with the selected frame.

We used Adam (Kingma and Ba, 2015) as an optimizer with an initial learning rate of 0.001; we halved the learning rate if we did not see an improvement on the development set for two epochs. We trained the model for a maximum of 100 epochs. We clipped the norm of the gradient to 1.

All models were implemented with PyTorch.[13] We used some modules from AllenNLP[14] and the reimplementation of the FrameNet evaluation scripts by Swayamdipta et al. (2018).[15]

B Analysis on Syntax Plus Contextualized Embeddings

We perform an analysis on the use of syntax on top of contextualized representations ELMo and RoBERTa. We perform this analysis on the CoNLL-2005 development set and we measure the impact of contextualized syntax-agnostic vs contextualized syntactic model in function of: sentence length (Figure 6), of the distance of arguments from the predicate (Figure 7), and in function of the type of mistakes they make (Figure 8). In Figures 6,

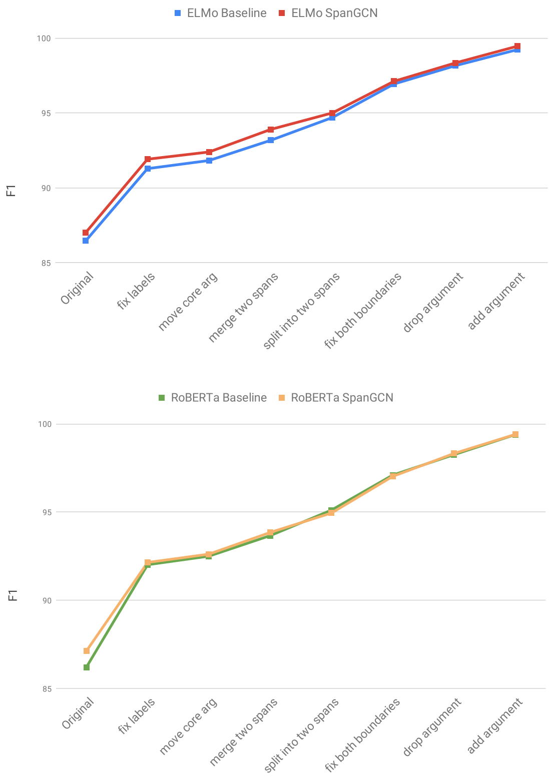

Figure 8: Performance of CoNLL-2005 models after performing corrections from He et al. (2017).

7, and 8, baselines consist of a syntax agnostic 8 layer BiLSTMs on top of the frozen contextualized representation.

Figure 6 shows that for both ELMo and RoBERTa, SpanGCN is beneficial. For ELMo though SpanGCN is not helpful for short sentences (up to length 10), while for RoBERTa, the syntax is beneficial across all sentence lengths.

Figure 7 shows that syntax is beneficial for both contextualized representations. An interesting difference is that for ELMo, syntax is more helpful for arguments very far from the predicate. In contrast, for RoBERTa, syntax is helpful on arguments 4-7 tokens away from the predicate, but hurts performance on arguments farther away from the predicate.

Finally, in Figure 8, we see rather different behaviour between the two representations. For ELMo, the errors that the syntax agnostic model makes are the ones related to span boundaries. For RoBERTa, the syntax-agnostic model makes errors regarding labels, but it is as good as the syntactic model at predicting span boundaries.

C Additional Results

Additional development results for CoNLL-2005 (Table 5) and CoNLL-2012 (Table 6) datasets.

Fast semantic parsing with well-typedness guarantees

Matthias Lindemann and **Jonas Groschwitz** and **Alexander Koller**
Department of Language Science and Technology
Saarland University
{mlinde|jonasg|koller}@coli.uni-saarland.de

Abstract

AM dependency parsing is a linguistically principled method for neural semantic parsing with high accuracy across multiple graphbanks. It relies on a type system that models semantic valency but makes existing parsers slow. We describe an A* parser and a transition-based parser for AM dependency parsing which guarantee well-typedness and improve parsing speed by up to 3 orders of magnitude, while maintaining or improving accuracy.

1 Introduction

Over the past few years, the accuracy of neural semantic parsers which parse English sentences into graph-based semantic representations has increased substantially (Dozat and Manning, 2018; Zhang et al., 2019; He and Choi, 2020; Cai and Lam, 2020). Most of these parsers use a neural model which can freely predict node labels and edges, and most of them are tailored to a specific type of graphbank.

Among the high-accuracy semantic parsers, the *AM dependency parser* of Groschwitz et al. (2018) stands out in that it implements the Principle of Compositionality from theoretical semantics in a neural framework. By parsing into AM dependency trees, which represent the compositional structure of the sentence and evaluate deterministically into graphs, this parser can abstract away surface details of the individual graphbanks. It was the first semantic parser which worked well across multiple graphbanks, and set new states of the art on several of them (Lindemann et al., 2019).

However, the commitment to linguistic principles comes at a cost: the AM dependency parser is slow. A key part of the parser is that AM dependency trees must be *well-typed* according to a type system which ensures that the semantic valency of each word is respected. Existing algorithms compute all items along a parsing schema that encodes the type constraints; they parse e.g. the AMRBank at less than three tokens per second.

In this paper, we present two fast and accurate parsing algorithms for AM dependency trees. We first present an A* parser which searches through the parsing schema of Groschwitz et al.'s "projective parser" efficiently (§4). We extend the supertag-factored heuristic of Lewis and Steedman's (2014) A* parser for CCG with a heuristic for dependency edge scores. This parser achieves a speed of up to 2200 tokens/s on semantic dependency parsing (Oepen et al., 2015), at no loss in accuracy. On AMR corpora (Banarescu et al., 2013), it achieves a speedup of 10x over previous work, but still does not exceed 30 tokens/second.

We therefore develop an entirely new transition-based parser for AM dependency trees, inspired by the stack-pointer parser of Ma et al. (2018) for syntactic dependency parsing (§5). The key challenge here is to adhere to complex symbolic constraints – the AM algebra's type system – without running into dead ends. This is hard for a greedy transition system and in other settings requires expensive workarounds, such as backtracking. We ensure that our parser avoids dead ends altogether. We define two variants of the transition-based parser, which choose types for words either before predicting the outgoing edges or after, and introduce a neural model for predicting transitions. In this way, we guarantee well-typedness with $O(n^2)$ parsing complexity, achieve a speed of several thousand tokens per second across all graphbanks, and even improve the parsing accuracy over previous AM dependency parsers by up to 1.6 points F-score.

2 Related work

In *transition-based parsing*, a dependency tree is built step by step using nondeterministic transitions. A classifier is trained to choose transitions deter-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3929–3951,
November 16–20, 2020.

ministically (Nivre, 2008; Kiperwasser and Goldberg, 2016). Transition-based parsing has also been used for constituency parsing (Dyer et al., 2016) and graph parsing (Damonte et al., 2017). We build most directly upon the top-down parser of Ma et al. (2018). Unlike most other transition-based parsers, our parser implements hard symbolic constraints in order to enforce well-typedness. Such constraints can lead transition systems into dead ends, requiring the parser to backtrack (Ytrestøl, 2011) or return partial analyses (Zhang and Clark, 2011). Our transition system carefully avoids dead ends. Shi and Lee (2018) take hard valency constraints into account in chart-based syntactic dependency parsing, avoiding dead ends by relaxing the constraints slightly in practice.

A* parsing is a method for speeding up agenda-based chart parsers, which takes items off the agenda based on a heuristic estimate of completion cost. A* parsing has been used successfully for PCFGs (Klein and Manning, 2003), TAG (Bladier et al., 2019), and other grammar formalisms. Our work is based most closely on the CCG A* parser of Lewis and Steedman (2014).

Most approaches that produce semantic graphs (see Koller et al. (2019) for an overview) model distributions over graphs directly (Dozat and Manning, 2018; Zhang et al., 2019; He and Choi, 2020; Cai and Lam, 2020), while others make use of derivation trees that compositionally evaluate to graphs (Groschwitz et al., 2018; Chen et al., 2018; Fancellu et al., 2019; Lindemann et al., 2019). AM dependency parsing belongs to the latter category.

3 Background

We begin by sketching the AM dependency parser of Groschwitz et al. (2018).

3.1 AM dependency trees

Groschwitz et al. (2018) use *AM dependency trees* to represent the compositional structure of a semantic graph. Each token is assigned a *graph constant* representing its lexical meaning; dependency labels correspond to operations of the *Apply-Modify (AM) algebra* (Groschwitz et al., 2017; Groschwitz, 2019), which combine graphs into bigger ones.

Fig. 2 illustrates how an AM dependency tree (a) evaluates to a graph (b), based on the graph constants in Fig. 1. Each graph constant is an *as-graph*, which means it has special node markers called *sources*, drawn in red, as well as a *root* marked in bold. These markers are used to combine graphs with the algebra's operations. For instance, the MOD$_{\mathrm{M}}$ operation in Fig. 2a combines the head G_{sleep} with its modifier G_{soundly} by plugging the root of G_{sleep} into the M-source of G_{soundly}, see (c). That is, G_{soundly} has now modified G_{sleep} and (c) is our graph for *sleep soundly*. The other operation of the AM algebra, APP, models argument application. For example, the APP$_{\mathrm{O}}$ operation in Fig. 2a plugs the root of (c) into the O source of G_{want}. Note that because G_{want} and (c) both have an S-source, APP$_{\mathrm{O}}$ merges these nodes, see (d). The APP$_{\mathrm{S}}$ operation then fills this S-source with G_{writer}, attaching the graph with its root, to obtain the final graph in (b).[1]

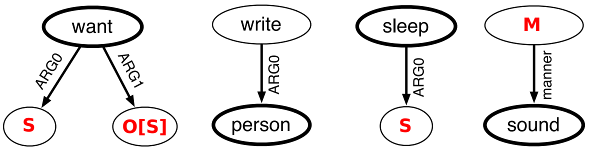

Figure 1: Elementary as-graphs G_{want}, G_{writer}, G_{sleep}, and G_{sound}.

Types. The $[\mathrm{S}]$ annotation at the O-source of G_{want} is a *request* as to what the *type* of the O argument of G_{want} should be. The type of an as-graph is the set of its sources with their request annotations, so the request $[\mathrm{S}]$ means that the source set of the argument must be $\{\mathrm{S}\}$. Because this is true for (c), the AM dependency tree is *well-typed*; otherwise the tree could not be evaluated to a graph. Thus, the graph constants lexically specify the semantic valency of each word as well as reentrancies due to e.g. control, like in this example.

If an as-graph has no sources, we say it has the *empty type* $[\,]$; if a source in a graph printed here has no annotation, it is assumed to have the empty request (i.e. its argument must have no sources). We write τ_G for the type of an as-graph G, and $\mathit{req}_\alpha(\tau)$ for the request at source α of type τ. For example, $\mathit{req}_{\mathrm{O}}(\tau_{G_{\text{want}}}) = [\mathrm{S}]$ and $\mathit{req}_{\mathrm{S}}(\tau_{G_{\text{want}}}) = [\,]$. If an AM dependency (sub-)tree evaluates to a graph G, we call τ_G its *term type*. For example, the sub-tree in Fig. 2a rooted in *sleep* has term type $[\mathrm{S}]$, since it evaluates to (c).

Below, we will build AM dependency trees by adding the outgoing edges of a node one by one;

---

[1] When evaluating an AM dependency tree, the AM algebra restricts operation orders to ensure that every AM dependency tree evaluates to a unique graph. For instance, in Fig. 2, the APP$_{\mathrm{O}}$ edge out of "wants" is always tacitly evaluated before the APP$_{\mathrm{S}}$ edge. For details on this, we refer to Groschwitz et al. (2018) and Groschwitz (2019).

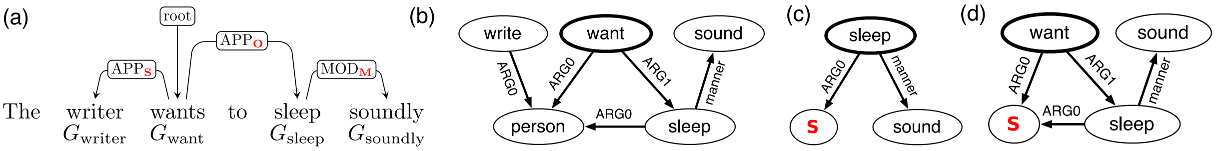

Figure 2: (a) An AM dependency tree with its evaluation result (b), along with two partial results (c) and (d).

we track types there with the following notation. If τ_1 and τ_2 are the term types of AM dependency trees t_1, t_2 and ℓ is an operation of the AM algebra, we write $\ell\,(\tau_1, \tau_2)$ for the term type of the tree constructed by adding t_2 as an ℓ-child to t_1, i.e. by adding an ℓ-edge from the root of t_1 to the root of t_2 (if that tree is well-typed). Intuitively, one can see this as combining a graph of type τ_1 (the head) with an argument or modifier of type τ_2 using operation ℓ; the result then has type $\ell\,(\tau_1, \tau_2)$.

3.2 AM dependency parsing

Groschwitz et al. (2018) approach graph parsing as first predicting a well-typed AM dependency tree for a sentence $w_1, \ldots, w_n$ and then evaluating it deterministically to obtain the graph.

They train a *supertag and edge-factored model*, which predicts a *supertag cost* $c\,(G, i)$ for assigning a graph constant G to the token w_i, as well as an *edge cost* $c\left(i \xrightarrow{\ell} j\right)$ for each potential edge from word w_i to w_j with label ℓ. Tokens which are not part of the AM dependency tree, like *the* and *to* in Fig. 2a, are treated as if they were assigned the special graph constant $\bot$ and an incoming 'IGNORE' edge $0 \xrightarrow{\text{IGNORE}} i$, where 0 represents an artificial root. The root of the AM dependency tree (*wants* in the example) is modeled as having an incoming edge $0 \xrightarrow{\text{ROOT}} i$.

An algorithm for AM dependency parsing searches for the well-typed AM dependency tree which minimizes the sum of supertag and edge costs. Finding the lowest-cost well-typed AM dependency tree for a given sentence is NP-complete. Groschwitz et al. define two approximate parsing algorithms, the 'fixed tree decoder' that fixes an unlabeled dependency tree first , and the 'projective decoder'. Our A* parser is based on the projective decoder and we focus on it here.

Projective decoder. The projective decoder circumvents the NP-completeness by searching for the best *projective* well-typed AM dependency tree. It derives parsing items using the schema (Shieber et al., 1995) shown in Fig. 3[2].

$$\frac{s = c\,(G, i) \quad G \neq \bot}{([i, i+1], i, \tau_G) : s} \;\text{Init}$$

$$\frac{([i,k], r, \tau) : s \quad s' = c\,(\bot, k) + c\left(0 \xrightarrow{\text{IGNORE}} k\right)}{([i, k+1], r, \tau) : s + s'} \;\text{Skip-R}$$

$$\frac{\begin{array}{c}([i,k], r, \tau) : s \\ s' = c\,(\bot, i-1) + c\left(0 \xrightarrow{\text{IGNORE}} i-1\right)\end{array}}{([i-1, k], r, \tau) : s + s'} \;\text{Skip-L}$$

$$\frac{\begin{array}{c}([i,j], r_1, \tau_1) : s_1 \quad ([j,k], r_2, \tau_2) : s_2 \\ \tau = \ell(\tau_1, \tau_2) \text{ defined} \quad s = c\left(r_1 \xrightarrow{\ell} r_2\right)\end{array}}{([i,k], r_1, \tau) : s_1 + s_2 + s} \;\text{Arc-R } [\ell]$$

$$\frac{\begin{array}{c}([i,j], r_1, \tau_1) : s_1 \quad ([j,k], r_2, \tau_2) : s_2 \\ \tau = \ell(\tau_2, \tau_1) \text{ defined} \quad s = c\left(r_2 \xrightarrow{\ell} r_1\right)\end{array}}{([i,k], r_2, \tau) : s_1 + s_2 + s} \;\text{Arc-L } [\ell]$$

$$\frac{([1, n+1], r, [\,]) : \quad s' = c\left(0 \xrightarrow{\text{ROOT}} r\right)}{([0, n+1], r, [\,]) : s + s'} \;\text{Root}$$

Figure 3: Rules for the projective and A* decoder.

Each item encodes properties of a partial AM dependency tree and has the form $([i,k], r, \tau) : s$, where $[i,k] = \{j \mid i \leq j < k\}$ is the span of word indices covered by the item, r is the index of the head word, τ the type and s the cost. The Init rule assigns a supertag G to a word w_i. The Skip-R and Skip-L rules extend a span without changing the dependency derivation, effectively skipping a word by assigning it the $\bot$ supertag and drawing the corresponding 'IGNORE' edge. Finally the Arc-R and Arc-L rules, for an AM operation ℓ, combine two items covering adjacent spans by drawing an edge with label ℓ between their heads. Once the full chart is computed, i.e. all items are explored, a Viterbi algorithm yields the highest scoring well-typed AM dependency tree.

The projective decoder has an asymptotic runtime of $O\left(n^5\right)$ in the sentence length n.

Notation and terminology. Below, we assume that we obtained three fixed non-empty finite sets in training: a set Ω of types; a set C of graph constants (the *graph lexicon*) such that Ω is the set of types of the graphs in C; and a set L of operations, including ROOT and IGNORE. We write S for the set of sources occurring in C and assume

---

[2] Originally only the fixed tree decoder used IGNORE and ROOT edge scores; we extend the projective decoder here for consistency.

that for every source $s \in S$, $\textsc{App}_s \in L$. We write $Dom(f)$ for the domain of a partial function f, i.e. the set of objects for which f is defined.

4 A* AM dependency parsing

While the AM dependency parser yields strong accuracies across multiple graphbanks, Groschwitz et al.'s algorithms are quite slow in practice. For instance, the projective parser needs several hours to parse each test set in §6, which seriously limits its practical applicability. In this section, we will speed the projective parser up through A* search.

4.1 Agenda-based A* parsing

Our A* parser maintains an *agenda* of parse items of the projective parser. The agenda is initialized with the items produced by the Init rule. Then we iterate over the agenda. In each step, we take the item I from the front of the agenda and apply the rules Skip-L and Skip-R to it. We also attempt to combine I with all previously discovered items, organized in a parse chart, using the Arc-L and Arc-R rules. All items thus generated are added to the agenda and the chart. Parsing ends once we either take a goal item $([0, n+1], r, [\,])$ from the agenda, or (unsucessfully) when the agenda becomes empty.

A* parsers derive their efficiency from their ability to order the items on the agenda effectively. They sort the agenda in ascending order of estimated cost $f(I) = c(I) + h(I)$, where c is the cost derived for the item I by the parsing rules in Fig. 3 and $h(I)$ is an *outside estimate*. The quantity $h(I)$ estimates the difference in cost between I and the lowest-cost well-typed AM dependency tree t that contains I. An outside heuristic is *admissible* if it is optimistic with respect to cost, i.e. $f(I) \leq c(t)$; in this case the parser is provably optimal, i.e. the first goal item which is dequeued from the agenda describes the lowest-cost parse tree. Tighter outside estimates lead to fewer items being taken off the agenda and thus to faster runtimes.

A first *trivial*, but admissible baseline lets $h(I) = 0$ for all items I. This ignores the outside part and orders items purely on their past cost. We could obtain a better outside heuristic by following Lewis and Steedman (2014) and summing up the cost of the lowest-cost supertag for each token outside of the item, i.e.

$$h([i,k], r, \tau) = \sum_{j \notin [i,k]} \min_G c(G, j).$$

This heuristic is admissible because each token will have *some* supertag selected (perhaps $\bot$) in a complete AM dependency tree, and its cost will be equal or higher than that of the best supertag.

4.2 Edge-based A* heuristics

Both of these outside heuristics ignore the fact that the cost of a tree consists not only of the cost for the supertags, but also of the cost for the edges.

We can obtain tighter heuristics by taking the edges into account. Observe first that the parse item determines the supertags and edges within its substring, and has designated one of the tokens as the root of the subtree it represents. For all tokens outside of the span of the item, the best parse tree will assign both a supertag to the token (potentially $\bot$) and an incoming edge (potentially with edge label ROOT or IGNORE). Thus, we obtain an admissible *edge-based heuristic* by adding the lowest-cost incoming edge for each outside token as follows:

$$h([i,k], r, \tau) = \sum_{j \notin [i,k]} \min_G c(G, j) + \min_{o \xrightarrow{\ell} j} c(o \xrightarrow{\ell} j)$$

Observe finally that the edge-based heuristic is still overly optimistic, in that it assumes that arbitrarily many nodes in the tree may have incoming ROOT edges (when it needs to be exactly one), and that the choice of IGNORE and $\bot$ are independent (when a node should have an incoming IGNORE edge if and only if its supertag is $\bot$). We can optimize it into the *ignore-aware outside heuristic* by restricting the $\min$ operations so they respect these constraints.

5 Transition-based parsing

As we will see in §6, the A* parser is very efficient on the DM, PAS, and PSD corpora but still slow on EDS and AMR.

Therefore, we develop a novel transition-based algorithm for AM dependency parsing. Inspired by the syntactic dependency parser of Ma et al. (2018), it builds the dependency tree top-down, starting at the root and recursively adding outgoing edges to nodes. However, for AM dependency parsing we face an additional challenge: we must assign a type to each node and ensure that the overall AM dependency tree is well-typed.

We will first introduce some notation (§5.1), then introduce three versions of our parsing schema (§5.2-§5.4), give theoretical guarantees (§5.5) and define the neural model (§5.6).

5.1 Apply sets

The transition-based parser chooses a graph constant G_i for each token w_i; we call its type, τ_{G_i}, the *lexical type* λ of w_i. As we add outgoing edges to i, each outgoing APP_α operation consumes the α source of the lexical type. To produce a well-typed AM dependency tree of term type τ, the sources of outgoing APP edges at i must correspond to exactly the *apply set* $\mathcal{A}(\lambda, \tau)$, which is defined as the set $O = \{o_1, \dots, o_n\}$ of sources such that

$$\text{APP}_{o_n}(\dots \text{APP}_{o_2}(\text{APP}_{o_1}(\lambda, \tau_1), \tau_2), \dots, \tau_n) = \tau$$

for some types $\tau_1, \dots, \tau_n$. That is, the apply set $\mathcal{A}(\lambda, \tau)$ is the set of sources we need to consume to turn λ into τ.

Note that there are pairs of types for which no such set of sources exists; e.g. the apply set $\mathcal{A}([\,], [s])$ is not defined. In that case, we say that $[s]$ is not *apply-reachable* from $[\,]$; the term type must always be apply-reachable from the lexical type in a well-typed tree.

5.2 Lexical type first (with dead ends)

We are now ready to define a first version of the transition system for our parser. The parser builds a dependency tree top-down and manipulates *parser configurations* to track parsing decisions and ensure well-typedness.

A parser configuration $\langle \mathbb{E}, \mathbb{T}, \mathbb{A}, \mathbb{G}, \mathbb{S} \rangle$ consists of four partial functions $\mathbb{E}, \mathbb{T}, \mathbb{A}, \mathbb{G}$ that map each token i to the following:

$\mathbb{E}(i)$: the labeled incoming edge of i, written $j \xrightarrow{\ell} i$, where j is the head and l the label;

$\mathbb{T}(i)$: the set of possible term types at i;

$\mathbb{A}(i)$: the sources of outgoing APP edges at i, i.e. which sources of the apply set we have covered;

$\mathbb{G}(i)$: the graph constant at i.

These functions are partial, i.e. they may be undefined for some nodes. $\mathbb{S}$ is a stack of nodes that potentially still need children; we call the node on top of $\mathbb{S}$ the *active node*.

The initial configuration is $\langle \emptyset, \emptyset, \emptyset, \emptyset, \emptyset \rangle$. A *goal configuration* has an empty stack and for all tokens i, it holds either that i is ignored and thus has no incoming edge, or that for some type τ and graph G, $\mathbb{T}(i) = \{\tau\}$, $\mathbb{G}(i) = G$ and $\mathbb{A}(i) = \mathcal{A}(\tau_G, \tau)$, i.e. $\mathbb{A}(i)$ must be the apply set for the lexical type τ_G and the term type τ. There must be at least one token that is not ignored.

The transition rules below read as follows: everything above the line denotes preconditions on when the transition can be applied; for example, that $\mathbb{T}$ must map node i to some set T of types. The transition rule then updates the configuration by adding what is specified below the line. An example run is shown in Fig. 4.

INIT. An $\text{INIT}(i)$ transition is always the first transition and makes i the root of the tree:

$\mathbb{E}$	$\mathbb{T}$	$\mathbb{A}$	$\mathbb{G}$	$\mathbb{S}$
$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$
$0 \xrightarrow{root} i$	$i \mapsto \{[\,]\}$			i

Fixing the term type as $[\,]$ ensures that the overall evaluation result has no unfilled sources left.

CHOOSE. If we have not yet chosen a graph constant for the active node, we assign one with the $\text{CHOOSE}(\tau, G)$ transition:

	$i \mapsto T$		$i \notin Dom(\mathbb{G})$	$\sigma \vert i$
	$i \mapsto \{\tau\}$	$i \mapsto \emptyset$	$i \mapsto G$	$\sigma \vert i$

This transition may only be applied if the specific term type $\tau \in T$ is apply-reachable from the newly selected lexical type τ_G. The CHOOSE operation is the only operation allowed when the active node does not have a graph constant yet; therefore, it always determines the lexical type of i *first*, before any outgoing edges are added.

APPLY. Once the term type τ and graph G of the active node i have been chosen, the $\text{APPLY}(\alpha, j)$ operation can draw an APP_α edge to a node j that has no incoming edge, adding j to the stack:

$j \notin Dom(\mathbb{E})$	$i \mapsto \{\tau\}$	$i \mapsto A$	$i \mapsto G$	$\sigma \vert i$
$i \xrightarrow{\text{APP}_\alpha} j$	$j \mapsto \{req_\alpha(\tau_G)\}$	$i \mapsto A \cup \{\alpha\}$		$\sigma \vert i \vert j$

Here α must be a source in the apply set $\mathcal{A}(\tau_G, \tau)$ but not in $\mathbb{A}(i)$, i.e. be a source of G that still needs to be filled. Fixing the term type of j ensures the type restriction of the APP_α operation.

MODIFY. In contrast to outgoing APP edges, which are determined by the apply set, we can add arbitrary outgoing MOD edges to the active node i. This is done with the transition $\text{MODIFY}(\beta, j)$, which draws a MOD_β edge to a token j that has no incoming edge, also adding j to the stack:

$j \notin Dom(\mathbb{E})$	$i \mapsto \{\tau\}$	$i \mapsto A$	$i \mapsto G$	$\sigma \vert i$
$i \xrightarrow{\text{MOD}_\beta} j$	$j \mapsto T'$			$\sigma \vert i \vert j$

We require that T' is the set of all types $\tau' \in \Omega$ such that all sources in τ' (except β) including their requests are already present in τ_G, and $req_\beta(\tau') = [\,]$, reflecting constraints on the MOD operation in Groschwitz (2019).

Step	$\mathbb{E}$	$\mathbb{T}$	$\mathbb{A}$	$\mathbb{G}$	$\mathbb{S}$	Transition
1	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	$[]$	
2	$0 \xrightarrow{\text{ROOT}} \mathit{wants}_3$	$\mathit{wants}_3 \mapsto \{[\,]\}$			3	Init 3
3			$\mathit{wants}_3 \mapsto \emptyset$	$\mathit{wants}_3 \mapsto G_{\text{want}}$	3	Choose $[\,]$, $\langle G_{\text{want}}, [s, o[s]]\rangle$
4	$\mathit{wants}_3 \xrightarrow{\text{App}_s} \mathit{writer}_2$	$\mathit{writer}_2 \mapsto \{[\,]\}$	$\mathit{wants}_3 \mapsto \{s\}$		3 2	Apply s, 2
5			$\mathit{writer}_2 \mapsto \emptyset$	$\mathit{writer}_2 \mapsto G_{\text{writer}}$	3 2	Choose $[\,]$, $\langle G_{\text{writer}}, [\,]\rangle$
6					3	Pop
7	$\mathit{wants}_3 \xrightarrow{\text{App}_o} \mathit{sleep}_5$	$\mathit{sleep}_5 \mapsto \{[s]\}$	$\mathit{wants}_3 \mapsto \{s, o\}$		3 5	Apply o, 5
8			$\mathit{sleep}_5 \mapsto \emptyset$	$\mathit{sleep}_5 \mapsto G_{\text{sleep}}$	3 5	Choose $[s]$, $\langle G_{\text{sleep}}, [s]\rangle$
9	$\mathit{sleep}_5 \xrightarrow{\text{MOD}_m} \mathit{soundly}_6$	$\mathit{soundly}_6 \mapsto \{[m], [s, m]\}$			3 5 6	Modify m, 6
10		$\mathit{soundly}_6 \mapsto \{[m]\}$	$\mathit{soundly}_6 \mapsto \emptyset$	$\mathit{soundly}_6 \mapsto G_{\text{soundly}}$	3 5 6	Choose $[m]$, $\langle G_{\text{soundly}}, [m]\rangle$
11					$[]$	3 × Pop

Figure 4: Derivation with LTF of the AM dependency tree in Fig. 2. The steps show only what changed for $\mathbb{E}$, $\mathbb{T}$, $\mathbb{A}$ and $\mathbb{G}$; the stack $\mathbb{S}$ is shown in full. The chosen graph constants are annotated with their lexical types.

Pop. The Pop transition decides that an active node that has all of its App edges will not receive any further outgoing edges, and removes it from the stack.

$$\begin{array}{|c|c|c|c|c|}
 & i \mapsto \{\tau\} & i \mapsto \mathcal{A}(\tau_G, \tau) & i \mapsto G & \sigma|i \\
\hline
 & & & & \sigma
\end{array}$$

5.3 Lexical type first (without dead ends)

While the above parser guarantees well-typedness when it completes, it can still get stuck. This is because when we Choose a term type τ and lexical type λ for a node, we *must* perform Apply transitions for all sources in their apply set $\mathcal{A}(\lambda, \tau)$ to reach a goal configuration. But every Apply transition adds an incoming edge to a token that did not have one before; if our choices for lexical and term types require more Apply transitions than there are tokens without incoming edge left, the parser cannot reach a goal configuration.

To avoid this situation, we track for each configuration c the difference $W_c - O_c$ of the number W_c of tokens without an incoming edge and the number O_c of Apply transitions we 'owe' to fill all sources. O_c is obtained by summing across all tokens i the number $O_c(i)$ of App children i still needs. To generalize to cases in §5.4 where we may not yet know the graph constant for i, we let $K_c(i) = \{\tau_{\mathbb{G}_c(i)}\}$ if $i \in \mathit{Dom}(\mathbb{G}_c)$ and $K_c(i) = \Omega$ otherwise. That is, if the graph constant $\mathbb{G}_c(i)$ is not yet defined, we assume we can choose it freely later. Then we can define

$$O_c(i) = \min_{\lambda \in K_c(i), \tau \in \mathbb{T}_c(i)} |\mathcal{A}(\lambda, \tau) - \mathbb{A}_c(i)|,$$

i.e. $O_c(i)$ is the minimal number of sources we need in addition to the ones already covered in $\mathbb{A}_c(i)$ in order to cover the apply set $\mathcal{A}(\lambda, \tau)$, assuming we choose the lexical type λ and term type τ optimally within the current constraints. If $\mathbb{T}$ or $\mathbb{A}$ is not defined for i, we let $O_c(i) = 0$.

Finally, given a type τ, an upper bound n, and a set A of already-covered sources, we let $\mathit{PossL}(\tau, A, n)$ be the set of lexical types λ such that $A \subseteq \mathcal{A}(\lambda, \tau)$ and we can reach τ from λ with App operations for the sources in A and at most n additional App operations, i.e. $|\mathcal{A}(\lambda, \tau) - A| \leq n$.

We prevent dead ends (see §5.5) by requiring that Choose(τ, G) can only be applied to a configuration c if $\tau_G \in \mathit{PossL}(\tau, \emptyset, W_c - O_c)$. Then τ is apply-reachable from τ_G with at most $W_c - O_c$ Apply transitions; this is exactly as many as we can spare. The Modify transition reduces the number of tokens that have no incoming edge without performing an Apply transition, so we only allow it when we have tokens 'to spare', i.e. $W_c - O_c \geq 1$.

5.4 Lexical type last

The lexical type first transition system chooses the graph constant for a token early, and then chooses outgoing App edges that fit the lexical type. But of course the decisions on lexical type and outgoing edges interact. Thus we also consider a transition system in which the lexical type is chosen *after* deciding on the outgoing edges.

Apply and Modify. We modify the Apply and Modify operations from §5.3 such that they no longer assign term types to children and do not push the child on the stack. This allows the transition system to add outgoing edges to the active node i without committing to types. The Apply(α, j) transition becomes

$$\begin{array}{|c|c|c|c|c|}
j \notin \mathit{Dom}(\mathbb{E}) & i \mapsto T & i \mapsto A & & \sigma|i \\
\hline
i \xrightarrow{\text{App}_\alpha} j & & i \mapsto A \cup \{\alpha\} & & \sigma|i
\end{array}$$

Because we do not yet know the types for i and thus neither the apply set $\mathcal{A}(\lambda, \tau)$, we cannot directly check that this Apply transition will not lead to a dead end. Instead, we check if there are *possible* types τ and λ with α in their apply set, by requiring that $\bigcup_{\tau \in T} \mathit{PossL}(\tau, A \cup \{\alpha\}, W_c - 1)$ is non-empty (it is $W_c - 1$ to account for the edge we are about to add). We also keep the restriction that $\alpha \notin A$, to avoid duplicate APP_α edges.

The MODIFY(β, j) transition becomes

$j \notin Dom(\mathbb{E})$				$\sigma \mid i$
$i \xrightarrow{\text{MOD}_\beta} j$				$\sigma \mid i$

Again, we only allow it when we have tokens 'to spare', i.e. $W_c - O_c \geq 1$.

FINISH. We then replace CHOOSE and POP with a single transition FINISH(G), which selects an appropriate graph constant G for the active node i and pops i off the stack, such that no more edges can be added.

$i \xrightarrow{\text{APP}_{\alpha_k}} j_k$ $i \xrightarrow{\text{MOD}_{\beta_k}} l_k$	$i \mapsto T$	$i \mapsto A$		$\sigma \mid i$
	$i \mapsto \{\tau\}$, $j_k \mapsto T_k$, $l_k \mapsto T'_k$	$j_k \mapsto \emptyset$, $l_k \mapsto \emptyset$	$i \mapsto G$	$\sigma \mid l_1 \mid \ldots \mid l_r$ $\mid j_1 \mid \ldots \mid j_s$

FINISH(G) is allowed if $\mathcal{A}(\tau_G, \tau) = A$ for some $\tau \in T$, and fixes this τ as the term type. In addition, FINISH pushes the child nodes j_k of all $s \geq 0$ outgoing APP edges onto the stack and fixes their term types as $T_k = \{req_{\alpha_k}(\tau_G)\}$ (like in APPLY of §5.2). Similarly, FINISH also pushes the child nodes l_k of all $r \geq 0$ outgoing MOD edges onto the stack and computes their term type sets T'_k as in the MODIFY rule of §5.2. We push the children in the reverse order of when they were created, so that they are popped off the stack in the order the edges were drawn.

Finally, since CHOOSE no longer exists, we must set $\mathbb{A}(i) = \emptyset$ during INIT. An example run is shown in Appendix F.

5.5 Correctness

We state the main correctness results here; proofs are in Appendix G. We assume for all types $\lambda \in \Omega$ and all sources $\alpha \in S$, that the type $req_\alpha(\lambda)$ is also in Ω, and that for every source β with $\text{MOD}_\beta \in L$, the type $[\beta]$ is in Ω. This allows us to select lexical types that do not require unexpected APP children.

Theorem 5.1 (Soundness). Every goal configuration derived by LTF or LTL corresponds to a well-typed AM dependency tree.

Theorem 5.2 (Completeness). For every well-typed AM dependency tree t, there are sequences of LTF and LTL transitions that build t.

Theorem 5.3 (No dead ends). Every configuration derived by LTF or LTL can be completed to a goal configuration.

5.6 Neural model

We train a neural model to predict LTF and LTL transitions, by extending Ma et al.'s stack-pointer model with means to predict graph constants and term types. We phrase AM dependency parsing as finding the most likely sequence $d^{(1)}, \ldots, d^{(N)}$ of LTF or LTL transitions given an input sentence $\mathbf{x}$, factorized as follows:

$$P_\theta(d^{(1)}, \ldots, d^{(N)} | \mathbf{x}) = \prod_{t=1}^{N} P_\theta(d^{(t)} | d^{(<t)}, \mathbf{x})$$

We encode the sentence with a multi-layer BiLSTM based on embeddings for word, POS tag, lemma, named entity tag and character CNN, yielding a sequence of hidden states $\mathbf{s}_1, \ldots \mathbf{s}_n$. The decoder LSTM is initialized with the last hidden state of the encoder and is updated as follows:

$$\mathbf{h}^{(t)} = \text{LSTM}(\mathbf{h}^{(t-1)}, [\mathbf{s}_{tos}, \mathbf{s}_p, \mathbf{s}_c]),$$

where tos denotes the node on top of the stack, p the parent of tos and c refers to the most recently generated child of tos. Let further $a_i^{(t)} \propto \exp \text{Biaffine}(\mathbf{h}^{(t)}, \mathbf{s}_i)$ be an attention score and let $\mathbf{s}'$ be a second BiLSTM encoding trained to predict graphs and term types.

When in the start configuration, the probability of INIT selecting node i as the root is $P(\text{INIT } i | \mathbf{h}^{(t)}) = a_i^{(t)}$; otherwise it is zero.

In LTF, if after $d^{(1)}, \ldots, d^{(t-1)}$ the CHOOSE transition is allowed (and thus required), we have the transition probabilities

$$P_\theta(\text{CHOOSE } (\tau, G) | \mathbf{h}^{(t)}) = P_\theta(\tau | \mathbf{h}^{(t)}) \cdot P_\theta(G | \mathbf{h}^{(t)})$$

where we score the graph constant G and term type τ with softmax functions

$$P_\theta(G | \mathbf{h}^{(t)}) = \text{softmax}(\text{MLP}^G([\mathbf{h}^{(t)}, \mathbf{s}'_{tos}]))_G$$
$$P_\theta(\tau | \mathbf{h}^{(t)}) = \text{softmax}(\text{MLP}^{tt}([\mathbf{h}^{(t)}, \mathbf{s}'_{tos}]))_\tau.$$

In this situation, the probabilities of all other transitions are 0.

In contrast, if in LTF the CHOOSE transition is not allowed, we can draw an edge or POP. We score the target j of the outgoing edge with the attention score $a_j^{(t)}$ and model the probability for POP with an artificial word at position 0 (using an attention score $a_0^{(t)}$). In other words, we have

$$P_\theta(\ell, j | \mathbf{h}^{(t)}) = a_j^{(t)} \cdot P_\theta(\ell | \mathbf{h}^{(t)}, tos \rightarrow j)$$
$$P_\theta(\text{POP} | \mathbf{h}^{(t)}) = a_0^{(t)}$$

where we score the edge label ℓ with a softmax:

$$P_\theta(\ell|\mathbf{h}^{(t)}, tos \to j) = \text{softmax}(\text{MLP}^{lbl}([\mathbf{h}^{(t)}, \mathbf{s}_j]))_\ell.$$

In this situation, CHOOSE has probability 0.

In LTL, we must decide between drawing an edge and FINISH; we score edges as in LTF and replace the probabilities for CHOOSE and POP with

$$P_\theta(\text{FINISH}(G)|\mathbf{h}^{(t)}) = a_0^{(t)} P_\theta(G|\mathbf{h}^{(t)})$$

where $P_\theta(G|\mathbf{h}^{(t)})$ is as above.

Training. The training objective is MLE of θ on a corpus of AM dependency trees. There are usually multiple transition sequences that lead to the same AM dependency tree, so we follow Ma et al. and determine a canonical sequence by visiting the children in an inside-out manner.

Inference. During inference, we first decide whether we have to CHOOSE. If not, we divide each transition into two greedy decisions: we first decide, based on $a_i^{(t)}$, whether to FINISH/POP or whether to add an edge (and where); second we find the graph constant (in case of FINISH) or the edge label. To ensure well-typedness, we set the probability of forbidden transitions to 0.

Run-time complexity. The run-time complexity of the parser is $O(n^2)$: $O(n)$ transitions, each of which requires evaluating attention over n tokens.

The code is available at `https://github.com/coli-saar/am-transition-parser`.

6 Evaluation

Data. We evaluate on the DM, PAS, and PSD graphbanks from the SemEval 2015 shared task on Semantic Dependency Parsing (SDP, Oepen et al. (2015)), the EDS corpus (Flickinger et al., 2017) and the AMRBank releases LDC2015E86, LDC2017T10 and LDC2020T02 (Banarescu et al., 2013). We use the AM dependency tree decompositions of these corpora from Lindemann et al. (2019) (L'19 for short) as training data, as well as their pre- and post-processing pipeline (including the AMR post-processing bugfix published after submission). We use the same hyperparameters and hardware for all experiments (see Appendices B and C).

Baselines. We compare against the fixed tree and projective decoders of Groschwitz et al. (2018), using costs computed by the model of L'19. For the projective decoder we train with the edge existence loss recommended by Groschwitz et al. (2018). The models use pretrained BERT embeddings (Devlin et al., 2019) without finetuning.

6.1 A* parsing

Table 1 compares the parsing accuracy of the A* parser (with the cost model of the projective parser) across the six graphbanks (averaged over 4 training runs of the model), with the Init rule restricted to the six lowest-cost graph constants per token. We only report one accuracy for A* because A* search is optimal, and thus the accuracies with different admissible heuristics are the same. As expected, the accuracy is on par with L'19's parser; it is slightly degraded on DM, EDS and AMR, perhaps because these graphbanks require non-projective AM dependency trees for accurate parsing.

Parsing times are shown in Table 2 as tokens per second. We limit the number of items that can be dequeued from the agenda to one million per sentence. This makes two sentences per AMR test set unparseable; they are given dummy single-node graphs for the accuracy evaluation. The A* parser is significantly faster than L'19's fixed-tree decoder; even more so than the projective decoder on which it is based, with a 10x to 1000x speedup. Each SDP test set is parsed in under a minute.

The speed of the A* parser is very sensitive to the accuracy of the supertagging model: if the parser takes many supertags for a token off the agenda before it finds the goal item for a well-typed tree, it will typically deqeueue many items altogether. On the SDP corpora, the supertagging accuracy on the dev set is above 90%; here even the trivial heuristic is fast because it simply dequeues the best supertag for most tokens. On AMR, the supertagging accuracy drops to 78%; as a consequence, the A* parser is slower overall, and the more informed heuristics yield a higher speedup. EDS is an outlier, in that the supertagging accuracy is 94%, but the parser still dequeues almost three supertags per token on average. Why this is the case bears further study.

6.2 Transition-based parsing

To evaluate the transition-based parser, we extract the graph lexicon and the type set Ω from the training and development sets such that Ω includes all lexical types and term types used. We establish the assumptions of §5.5 by automatically adding up to 14 graph constants per graphbank, increasing the graph lexicon by less than 1%.

The LTL parser is accurate with greedy search and parses each test set in under a minute on the CPU and within 20 seconds on the GPU[3]. Since

Table 2: Avg. parsing speed in tokens/s on test sets. < indicates where parsing was interrupted due to timeout.

the BERT embeddings take considerable time to compute, parsing without BERT leads to a parsing speed of up to 10,000 tokens per second (see Appendix A). With beam search, LTL considerably outperforms L'19 on AMR, matching the accuracy of the fast parser of Zhang et al. (2019) on AMR 17 while outperforming it by up to 3.3 points F-score on DM. On the other graphbanks, LTL is on par with L'19. When evaluated without BERT, LTL outperforms L'19 by more than 1 point F-score on most graphbanks (see Appendix A).

The LTF parser is less accurate than LTL. Beam search reduces or even closes the gap, perhaps because it can select a better graph constant from the beam after selecting edges.

Note that accuracy drops drastically for a variant of LTL which does not enforce type constraints ("LTL, no types") because up to 50% of the predicted AM dependency trees are not well-typed and cannot be evaluated to a graph. The neural model does not learn to reliably construct well-typed trees by itself; the type constraints are crucial.

Overall, the accuracy of LTL is very similar to L'19, except for AMR where LTL is better. We investigated this difference in performance on AMR 17 and found that LTL achieves higher precision but its recall is worse for longer sentences[4]. We suspect this is because LTL is not explicitly penalized for leaving words out of the dependency tree and thus favors shorter transition sequences.

7 Conclusion

We have presented two fast and accurate algorithms for AM dependency parsing: an A* parser which optimizes Groschwitz et al.'s projective parser, and a novel transition-based parser which builds an AM dependency top-down while avoiding dead ends.

The parsing speed of the A* parser differs dramatically for the different graphbanks. In contrast, the parsing speed with the transition systems is less sensitive to the graphbank and faster overall. The transition systems also achieve higher accuracy.

In future work, one could make the A* parser more accurate by extending it to non-projective dependency trees, especially on DM, EDS and AMR. The transition-based parser could be made more accurate by making bottom-up information available to its top-down choices, e.g. with Cai and Lam's (2020) "iterative inference" method. It would also be interesting to see if our method for avoiding dead ends can be applied to other formalisms with complex symbolic restrictions.

Acknowledgments. We thank the anonymous reviewers and the participants of the DELPH-IN Summit 2020 for their helpful feedback and comments. We thank Rezka Leonandya for his work on an earlier version of the A* parser. This research was funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation), project KO 2916/2-2.

---

[4] For both parsers we model the dependence of recall on sentence length with linear regression; the slopes of the two models are significantly different, $p < 0.05$.

A Additional experiments and dev accuracies

Table 3 shows the results of further experiments (means and standard deviations over 4 runs). Models that do not use BERT, use GloVe embeddings of size 200. Note that we use the pre- and post-processing of Lindemann et al. (2019) in the most recent version, which fixes a bug in AMR post-processing[5].

For each model trained, Table 4 shows the performance of one run on the development set.

Table 6 shows F-scores of different versions of Smatch on the AMR tests. See also Appendix E.

B Hardware and parsing experiments

All parsing experiments were performed on Nvidia Tesla V100 graphics cards and Intel Xeon Gold 6128 CPUs running at 3.40 GHz.

We measure run-time as the sum of the GPU time and the CPU time on a single core for all approaches. When computing scores for A*, we use a batch size of 512 for all graphbanks but AMR, where we use a batch size of 128. We use a batch size of 64 for LTL and LTF for parsing on the CPU. The transition probabilites are computed on the GPU and then transferred to the main memory. In the parsing experiments with LTL where the transition system is run on the GPU as well, we use a batch size of 512, except for AMR, for which we use a batch size of 256.

The A* algorithm is implemented in Java and was run on the GraalVM 20 implementation of the JVM.

We run the projective parser and the fixed tree parser of Groschwitz et al. (2018) with the 6 best supertags. When parsing with the fixed tree parser is not completed with k supertags within 30 minutes, we retry with $k-1$ supertags. If $k=0$, we use a dummy graph with a single node.

LTL and LTF are implemented in python and run on CPython version 3.8.

C Hyperparameters and training details

C.1 Scores for A*

We obtain the scores by training the parser of Lindemann et al. (2019). Since Groschwitz et al. (2018) argue that a hinge loss such as the one that L'19 use might not be well-suited for the projective parser, we replaced it by the log-likelihood loss of

Table 5: Avg. parsing speed of transition systems in tokens/s on (in-domain) test sets without BERT. For result with BERT, see main paper.

Groschwitz et al. (2018). The development metric based on which the model is chosen is the arithmetic mean between supertagging accuracy and labeled attachment score.

We follow Lindemann et al. (2019) in the hyperparamters, with two exceptions: we use batch size of 32 instead of 64 because of memory constraints and we add a character CNN to the model to make it more comparable with the model of the transition systems; see below for its hyperparameters. In order to tease apart the impact of the character CNN, we include the performance of a L’19 model with the character CNN in Table 3. Differences are within one standard deviation of the results obtained with the original architecture used in L’19.

Table 6: Results on AMR test sets with different versions of Smatch. L’19 F is the version that was used by Lindemann et al. (2019) and *new F* is version 1.0.4.

C.2 LTL and LTF

We set the hyperparameters manually without extensive hyperparameter search, mostly following Ma et al. (2018). We followed Lindemann et al. (2019) for number of hidden units and dropout in the MLPs for predicting graph constants and for the size of embeddings.

We follow Lindemann et al. (2019) in splitting the prediction of a graph constant into predicting a delexicalized graph constant and a lexical label.

We train all LTL and LTF models for 100 epochs with Adam using a batch size of 64. We follow Ma et al. (2018) in setting $\beta_1, \beta_2 = 0.9$ and the initial learning rate to 0.001. We don’t perform weight decay or gradient clipping. In experiments with GloVe, we use the vectors of dimensionality 200 (6B.200d) and fine-tune them. Following Ma et al. (2018), we employ a character CNN with 50 filters of window size 3.

We use the `BERT large` version of BERT and

average the layers. The weights for the average are learned but we do not fine-tune BERT itself.

For the second encoding of the input sentence, s', we use a single-layer bidirectional LSTM when using BERT and a two-layer bidirectional LSTM when using GloVe. On top of $\mathbf{x}'$ we perform variational dropout with $p = 0.33$, as well as on top of s and s'. The other hyperparameters are listed in Tables 7, 8 and 9. The number of parameters of the LTL and LTF models are in table 10.

Training an LTL or LTF model with BERT took at most 24 hours, and about 10 hours for AMR 15. Training with GloVe is usually a two or three hours shorter.

D Data

We use the AM dependency trees of Lindemann et al. (2019) as training data, along with their preprocessing. See their supplementary materials for more details. For completeness, Table 11 shows the number of AM dependency trees in the training sets as well as the number of sentences and tokens in the test sets. Note that the heuristic approach cannot obtain AM dependency trees for all graphs in the training data but nothing is left out of the test data.

We use the standard splits on all data sets into training/dev/test, again following Lindemann et al. (2019).

PAS, PSD and AMR are licensed by LDC but the DM and EDS data can be downloaded from http://hdl.handle.net/11234/1-1956.

E Evaluation metrics

DM, PAS and PSD We compute labeled F-score with the evaluation toolkit that was developed for the shared task: https://github.com/semantic-dependency-parsing/toolkit.

EDS We evaluate with Smatch Cai and Knight (2013), in this implementation due to its high speed: github.com/Oneplus/tamr/tree/master/amr_aligner/smatch and EDM (Dridan and Oepen, 2011) in the implementation of Buys and Blunsom (2017): https://github.com/janmbuys/DeepDeepParser. We follow Lindemann et al. (2019) in using Smatch as development metric.

	Training		Test	
	Sentences	AM dep. trees	Sentences	Tokens

PAS	35,657	31,796	1,410	33,358
PSD	35,657	32,807	1,410	33,358
EDS	33,964	25,680	1,410	32,306
AMR 15	16,833	15,472	1,371	28,458
AMR 17	36,521	33,406	1,371	28,458
AMR 20	55,635	51.515	1,898	36,928

Table 11: Data statics after preprocessing.Test set is in-domain for SDP.

AMR We evaluate with Smatch in the original implementation https://github.com/snowblink14/smatch. In the main paper, we report results with Smatch 1.0.4, which are somewhat better than with earlier versions. This also applies to the results of Lindemann et al. (2019). Table 6 shows results with the Smatch version that were originally used in Lindemann et al. (2019) (Commit `ad7e65` from August 2018).

F Example for LTL

Fig. 5 shows an example of a derivation with LTL, analogous to the one in Fig. 4.

G Proofs

The proofs given here follow exactly Lindemann (2020).

The transition systems LTF and LTL are designed in such a way that they enjoy three particularly important properties: soundness, completeness and the lack of dead ends. In this section, we phrase those guarantees in formal terms, determine which assumptions are needed and prove the guarantees. It will turn out that significant assumptions are only needed to guarantee that there are no dead ends.

Throughout this section we assume the type system of (Groschwitz, 2019), where types are formally defined as DAGs with sources as nodes, and requests being defined via the edges.

The definition of a goal condition is quite strict but it can be shown that for LTF and LTL simpler conditions are equivalent:

Lemma G.1. Let c be a configuration derived by LTF. c is a goal configuration if and only if $\mathbb{S}_c$ is empty and $\mathbb{G}_c$ is defined for some i.

Proof. $\Longrightarrow$
This follows trivially from the definition of a goal condition.
$\Longleftarrow$
We have to validate that for each token l, either l is ignored and thus has no incoming edge, or that for some type τ and graph G, $\mathbb{T}_c(l) = \{\tau\}$, $\mathbb{G}_c(l) = G$ and $\mathbb{A}_c(l) = \mathcal{A}(\tau_G, \tau)$. Additionally, there must be at least one token j such that $\mathbb{T}_c(j) = \{\tau\}$, $\mathbb{G}_c(j) = G$ and $\mathbb{A}_c(j) = \mathcal{A}(\tau_G, \tau)$. We first show that this latter condition holds for token i for which $\mathbb{G}_c$ is defined. Notice that i must have been on the stack and a CHOOSE transition has been applied. Since it is not on the stack anymore, a POP transition has been applied in some configuration c' where i was the active node. This means that $\mathbb{A}_c(i) = \mathbb{A}_{c'}(i) = \mathcal{A}(\tau_{\mathbb{G}_c(i)}, \tau)$ with $\mathbb{T}_c(i) = \mathbb{T}_{c'}(i) = \{\tau\}$ and thus i fulfills its part for c being a goal configuration.

We assumed that c was derived by LTF, so let s be an arbitrary transition sequence that derives c from the initial state (there might be multiple). We can divide the tokens in the sentence into two groups, based on whether they have ever been on the stack over the course of s:

- let j be an arbitrary token such that there is a state c' produced by a prefix of the transition sequence s where j is on the stack. Here, the same argument holds as above: since j is no longer on the stack, a POP transition must have been applied which implies that $\mathbb{A}_c(j) = \mathcal{A}(\tau_{\mathbb{G}_c(j)}, \tau)$ with $\mathbb{T}_c(j) = \{\tau\}$.
- let j be an arbitrary token such that there is *no* state c' produced by a prefix of the transition sequence s where j is on the stack. Clearly, such a token j does not have an incoming edge and thus also fulfills its part.

☐

Lemma G.2. Let c be a configuration derived by LTL. c is a goal configuration if and only if $\mathbb{S}_c$ is empty and $\mathbb{G}_c$ is defined for some i.

Proof. The proof is analogous to the proof of Lemma G.1. ☐

G.1 Soundness

An important property of the transition systems is that they are sound, that is, every AM dependency tree they derive is well-typed.

Theorem G.3 (Soundness). For every goal configuration c derived by LTF or LTL, the AM dependency tree described by c is well-typed.

Here, ”described by” means that we can read off the AM dependency tree from the set of edges $\mathbb{E}_c$ and graph constants $\mathbb{G}_c$. We do not need any additional assumptions to prove this theorem.

Before we can prove the theorem we first need the following lemma:

Lemma G.4. In every configuration c derived by LTF or LTL, token i has an APP_α child if and only if $\alpha \in \mathbb{A}_c(i)$.

Step	$\mathbb{E}$	$\mathbb{T}$	$\mathbb{A}$	$\mathbb{G}$	$\mathbb{S}$	Transition
1	$\emptyset$	$\emptyset$	$\emptyset$	$\emptyset$	$[]$	
2	$0 \xrightarrow{\text{ROOT}} \mathit{wants}_3$	$\mathit{wants}_3 \mapsto \{[]\}$	$\mathit{wants}_3 \mapsto \emptyset$		3	INIT 3
3	$\mathit{wants}_3 \xrightarrow{\text{APP}_s} \mathit{writer}_2$		$\mathit{wants}_3 \mapsto \{s\}$		3	APPLY (s, 2)
4	$\mathit{wants}_3 \xrightarrow{\text{APP}_o} \mathit{sleep}_5$		$\mathit{wants}_3 \mapsto \{s, o\}$		3	APPLY (o, 5)
5		$\mathit{writer}_2 \mapsto \{[]\}$, $\mathit{sleep}_5 \mapsto \{[s]\}$	$\mathit{writer}_2 \mapsto \emptyset$, $\mathit{sleep}_5 \mapsto \emptyset$	$\mathit{wants}_3 \mapsto G_{\text{want}}$	5 2	FINISH($\langle G_{\text{want}}, [s, o[s]]\rangle$)
6				$\mathit{writer}_2 \mapsto G_{\text{writer}}$	5	FINISH($\langle G_{\text{writer}}, []\rangle$)
7	$\mathit{sleep}_5 \xrightarrow{\text{MOD}_m} \mathit{soundly}_6$				5	MODIFY (m, 6)
8		$\mathit{soundly}_6 \mapsto \{[m], [s, m]\}$		$\mathit{sleep}_5 \mapsto G_{\text{sleep}}$	6	FINISH($\langle G_{\text{sleep}}, [s]\rangle$)
9		$\mathit{soundly}_6 \mapsto \{[m]\}$		$\mathit{soundly}_6 \mapsto G_{\text{soundly}}$		FINISH($\langle G_{\text{soundly}}, [m]\rangle$)

Figure 5: Derivation with LTL of the AM dependency tree in Fig. 2. The steps show only what changed for $\mathbb{E}$, $\mathbb{T}$, $\mathbb{A}$ and $\mathbb{G}$; the stack $\mathbb{S}$ is shown in full. The chosen graph constants are annotated with their lexical types.

Proof. The APPLY(α, j) transitions in LTF and LTL always add an α-source to $\mathbb{A}_c(i)$ and simultaneously add an APP$_\alpha$ edge. There are no other ways to add a source to $\mathbb{A}_c(i)$ or to create an APP$_\alpha$ edge. ☐

To prove the theorem, first observe that LTF and LTL only derive trees. Well-typedness then follows from applying the following lemma to the root of the tree in the goal configuration c:

Lemma G.5. Let c be a goal configuration derived by LTF or LTL and i be a token with $\mathbb{T}_c(i) = \{\tau\}$. Then the subtree rooted in i is well-typed and has type τ.

Proof. By structural induction over the subtrees.

Base case Since i has no children, it has no APP children in particular, making $\mathbb{A}_c(i) = \emptyset$ by Lemma G.4. By definition of the goal configuration, $\mathbb{A}_c(i) = \mathcal{A}(\tau_{\mathbb{G}_c(i)}, \tau)$. Combining this with $\mathbb{A}_c(i) = \emptyset$, we deduce that $\tau_{\mathbb{G}_c(i)} = \tau$ using the definition of the apply set.

Induction step Let i be a node with APP children $a_1, \ldots, a_n$, attached with the edges APP$_{\alpha_1}, \ldots,$ APP$_{\alpha_n}$, respectively. Let i also have MOD children $m_1, \ldots, m_k$, attached with the edges MOD$_{\beta_1}, \ldots,$ MOD$_{\beta_k}$, respectively. Let $\lambda = \tau_{\mathbb{G}_c(i)}$ be the lexical type at i, and $\{\tau\} = \mathbb{T}_c(i)$.

By the definition of the apply set, i reaches term type τ from λ if we can show for all APP children:

(i) i has an APP$_\alpha$ child if and only if $\alpha \in \mathcal{A}(\lambda, \tau)$

(ii) if a is an APP$_\alpha$ child of i, then it has the term type $\mathit{req}_\alpha(\lambda)$.

(i) follows from the goal condition $\mathbb{A}_c(i) = \mathcal{A}(\lambda, \tau)$ and Lemma G.4.

(ii) the only way the edge $i \xrightarrow{\text{APP}_\alpha} a$ can be created is by the APPLY(α, a) transitions with i on top of the stack. Both transition systems enforce $\mathbb{T}_c(a) = \{\mathit{req}_\alpha(\lambda)\}$. Using the inductive hypothesis on a, it follows that a evaluates to a graph of type $\mathit{req}_\alpha(\lambda)$.

Although the MOD children of i cannot alter the term type of i, they could make the subtree rooted in i ill-typed. That is, for any MOD$_\beta$ child m that evaluates to a graph of type τ' by the inductive hypothesis, we have to show that $\tau' - \beta \subseteq \lambda \wedge \mathit{req}_\beta(\tau') = []$. The MOD$_\beta$ edge was created by a MODIFY(β, m) transition. The MODIFY(β, m) transition (in case of LTF) or the next FINISH transition (in case of LTL) resulted in a configuration c', where the term types of m were restricted in exactly that way: $\mathbb{T}_{c'}(m) = \{\tau \in \Omega | \tau - \beta \subseteq \lambda \wedge \mathit{req}_\alpha(\tau) = []\}$. In the derivation from c' to c, a CHOOSE (LTF) or FINISH (LTL) transition must have been applied when m was on top of the stack (because the MOD$_\beta$ edge was created and c is a goal configuration), which resulted in $\mathbb{T}_c(m) = \{\tau'\}$, where $\tau' \in \mathbb{T}_{c'}(m) = \{\tau \in \Omega | \tau - \beta \subseteq \lambda \wedge \mathit{req}_\alpha(\tau) = []\}$. This means that the well-typedness condition indeed also holds for τ'. ☐

G.2 Completeness

Theorem G.6 (Completeness). For every well-typed AM dependency tree t, there are valid sequences of LTF and LTL transitions that build exactly t.

We do not need any additional assumptions to prove this theorem. The proof is constructive: for any well-typed AM dependency tree t, Algorithms 1 and 2 give transition sequences that, when prefixed with an appropriate INIT operation, generate t. We show this by showing the following lemma (for LTF):

Lemma G.7. Let t be a well-typed AM dependency tree with term type τ whose root is r and let c be a configuration derived by LTF with

(i) $\tau \in \mathbb{T}_c(r)$,

(ii) r is on top of $\mathbb{S}_c$,

(iii) $W_c - O_c \geq |t| - 1$, i.e. $W_c - O_c$ is at least the number of nodes in t without the root,

(iv) $i \notin \mathit{Dom}(\mathbb{G}_c)$ for all nodes i of t, and

(v) $i \notin \mathit{Dom}(\mathbb{E}_c)$ for all nodes $i \neq r$ of t

Then $H_{LTF}(c, t)$ (Algorithm 1) constructs, with valid LTF transitions, a configuration c' such that

(a) c' contains the edges of t,

(b) $\mathbb{G}_{c'}(i) = G_i$ where G_i is the constant at i in t,

(c) $\mathbb{S}_{c'}$ is the same as $\mathbb{S}_c$ but without r on top, i.e. $\mathbb{S}_c = \mathbb{S}_{c'}|r$,

(d) $W_{c'} = W_c - (|t| - 1)$, and

(e) for all j that are *not* nodes of t, none of $\mathbb{A}, \mathbb{G}, \mathbb{T}, \mathbb{E}$ changes, e.g. $\mathbb{A}_{c'}(j) = \mathbb{A}_c(j)$.

The lemma basically says that we can insert t as a subtree into a configuration c with LTF transitions. The conditions (i) and (ii) say that we have already put the root of t on top of the stack and thus can now start to add the rest of t. Condition (iii) says that there are enough words left in the sentence to fit t into c, where -1 comes from the fact that the root of t is already on the stack and has an incoming edge. Conditions (iv) and (v) ensure that the part is still empty where we want to put the subtree.

Theorem G.6 for LTF then follows from applying the lemma to the whole tree t and the configuration obtained after INIT(t). This yields a configuration with empty stack, which is a goal configuration (see Lemma G.1).

Before we approach the proof of Lemma G.7, we need to show the following:

Lemma G.8. Let c be a configuration derived by LTF. If for any token i, $i \notin \mathcal{D}(\mathbb{G}_c)$ then $i \notin \mathcal{D}(\mathbb{A}_c)$.

Proof. We show its contraposition: If for any token i, $i \in \mathcal{D}(\mathbb{A}_c)$ then $i \in \mathcal{D}(\mathbb{G}_c)$. The CHOOSE transition defines $\mathbb{A}_c$ for i, and defines $\mathbb{G}_c$ for i at the same time. There is no transition that can remove i from $\mathcal{D}(\mathbb{G}_c)$. ☐

Proof of Lemma G.7. By structural induction over t.

Base case Let i be on top of the stack in $\mathbb{S}_c$. t is a leaf with graph constant G, thus $W_c - O_c \geq |t| - 1 = 0$. H_{LTF} returns the sequence CHOOSE(τ_G, G), POP. It is easily seen that this sequence, if valid, yields a configuration c' where $\mathbb{T}_{c'}(i) = \{\tau_G\}$, $\mathbb{G}_{c'}(i) = G$ and $\mathbb{A}_{c'}(i) = \mathcal{A}(\tau_G, \tau_G) = \emptyset$. c' also contains all edges of t (there are none).

In order for CHOOSE(τ_G, G) to be applicable, it must hold that $\tau_G \in \mathbb{T}_c(i)$ (holds by (i)), $i \notin \mathcal{D}(\mathbb{G}_c)$ (holds by (iv)) and that $\tau_G \in \mathit{PossL}(\tau_G, \emptyset, W_c - O_c)$, which is equivalent to

$$|\mathcal{A}(\tau_G, \tau_G)| \leq W_c - O_c$$

Since $\mathcal{A}(\tau_G, \tau_G) = \emptyset$ and $W_c - O_c \geq 0$, this holds with equality. The transition CHOOSE(τ_G, G) yields a configuration c_1, where $\mathbb{A}_{c_1}(i) = \mathcal{A}(\tau_G, \tau_G) = \emptyset$, so we can perform POP, which gives us the configuration c'. Since we have not drawn any edge $W_{c'} = W_c = W_c - (1 - 1) = W_c - (|t| - 1)$. Note that these transitions have not changed any $\mathbb{A}, \mathbb{G}, \mathbb{T}, \mathbb{E}$ for $j \neq i$.

Induction step Let i be on top of the stack in $\mathbb{S}_c$ and let i in t have APP children $a_1, \ldots, a_n$, attached with the edges $\text{APP}_{\alpha_1}, \ldots, \text{APP}_{\alpha_n}$, respectively, where n might be 0. Let i in t also have MOD children $m_1, \ldots, m_k$, attached with the edges $\text{MOD}_{\beta_1}, \ldots, \text{MOD}_{\beta_k}$, respectively, where k might be 0 as well. Let G be the constant of i in t, and τ be its term type. By well-typedness of t and the definition of the apply set, we have $\mathcal{A}(\tau_G, \tau) = \{\alpha_1, \ldots, \alpha_n\}$.

$H_{LTF}(t, c)$ returns the sequence in Fig. 6, where c_1 is the configuration after CHOOSE(τ, G), APPLY(α_1, a_1) etc.

For now, let us assume that conditions (i)-(v) are fulfilled for $a_1, \ldots, a_n, m_1, \ldots, m_k$ and their respective configurations and that the sequence is valid. We will verify this at a later stage.

We can apply the inductive hypothesis for all children, which means that c' contains the edges present in the subtrees $a_1, \ldots, a_n, m_1, \ldots, m_k$ and for all nodes j such that j is a descendant of one of $a_1, \ldots, a_n, m_1, \ldots, m_k$, it holds that $\mathbb{G}_{c'}(j) = G_j$ because H_{LTF} applied to some child of t will do the assignment and such an assignment can never be changed in LTF. Assuming the above transition sequence is valid, it is obvious that it also adds the

$$\begin{aligned} &c \xrightarrow{\textsc{Choose}(\tau,\mathrm{G})} c_0' \xrightarrow{\textsc{apply}(\alpha_1,a_1)} c_1 \xrightarrow{H_{LTF}(a_1,c_1)} c_1' \dots c_{n-1}' \xrightarrow{\textsc{apply}(\alpha_n,a_n)} c_n \xrightarrow{H_{LTF}(a_n,c_n)} c_{n'} \\ &c_n' \xrightarrow{\textsc{modify}(\beta_1,m_1)} c_{n+1} \xrightarrow{H_{LTF}(m_1,c_{n+1})} c_{n+1}' \dots \xrightarrow{H_{LTF}(m_k,c_{n+k})} c_{n+k}' \xrightarrow{\textsc{Pop}} c' \end{aligned} \tag{1}$$

Figure 6: Transition sequence returned by $H_{LTF}(t, c)$ in the induction step.

edges from i to $a_1, \dots, a_n, m_1, \dots, m_k$ with the correct labels (consequence (a)) and also makes the assignment $\mathbb{G}_{c'}(i) = G_i$ using $\textsc{Choose}(\tau, G)$ (consequence (b)).

Now we go over the transition sequence in Eq. 6 and check that the transitions can be applied, the conditions (i)-(v) hold and what happens to the stack.

First, in order for $\textsc{Choose}(\tau_G, \tau)$ to be applicable, it must hold that $\tau \in \mathbb{T}_c(i)$ (holds by (i)), $i \notin \mathcal{D}(\mathbb{G}_c)$ (holds by (iv)) and that $\tau_G \in \mathit{PossL}(\tau, \emptyset, W_c - O_c)$, which is equivalent to

$$|\mathcal{A}(\tau_G, \tau)| \leq W_c - O_c$$

Since $\mathcal{A}(\tau_G, \tau) = \{\alpha_1, \dots, \alpha_n\}$ and $W_c - O_c \geq |t| - 1 \geq |\{\alpha_1, \dots, \alpha_n\}| = n$, this holds. This yields a configuration c_0' where $\mathbb{T}_{c_0'}(i) = \{\tau\}$ and $\mathbb{A}_{c_0'}(i) = \emptyset$.

Next, we use the transition $\textsc{apply}(\alpha_1, a_1)$. This is allowed because $\alpha_1 \in \mathcal{A}(\tau_G, \tau)$ (see above), $\alpha_1 \notin \mathbb{A}_{c_0'}(i)$ and $a_1 \notin \mathcal{D}(\mathbb{E}_{c_0'})$ (condition (v)). We get a new configuration c_1 where $\mathbb{A}_{c_1}(i) = \{\alpha_1\}$, $\mathbb{T}_{c_1}(a_1) = \{\mathit{req}_{\alpha_1}(\tau_G)\}$ and $\mathbb{S}_{c_1} = \mathbb{S}_{c_0}|a_1$. We now justify why the inductive hypothesis can be used for a_1 and c_1:

By well-typedness of t, we know that $\mathbb{T}_{c_1}(a_1) = \{\mathit{req}_{\alpha_1}(\tau_G)\} = \{\tau_{a_1}\}$ where τ_{a_1} is the term type of a_1 (condition (i)). From the step before, a_1 is on top of the stack in $\mathbb{S}_{c_1}$ (condition (ii)). We use the fact that $j \notin \mathit{Dom}(\mathbb{G}_c)$ for all nodes j of t and $j \notin \mathit{Dom}(\mathbb{E}_c)$ for all nodes $j \neq i$ (our conditions (iv) and (v)) to justify that conditions (iv) and (v) are also met for a_1. What is left to verify is that $W_{c_1} - O_{c_1} \geq |a_1| - 1$. First, note that $W_{c_1} = W_c - 1$ because of the $\textsc{App}_{\alpha_1}$ edge. We can decompose O_{c_1} as follows:

$$O_{c_1} = O_c - O_c(i) + O_{c_1}(i)$$

because we have only changed $\mathbb{G}_c$ and $\mathbb{A}_c$ for i, not for any other token. $O_c(i) = 0$ by Lemma G.8 and $i \notin \mathcal{D}(\mathbb{G}_c)$ (condition (iv)). We can also see that $O_{c_1}(i) = n - 1$ by definition of $O(\cdot)$ and taking into account that we have drawn the $\textsc{App}_{\alpha_1}$ edge and thus $\mathbb{A}_{c_1} = \{\alpha_1\}$. This means that

$$W_{c_1} - O_{c_1} = (W_c - 1) - (O_c + n - 1) = W_c - O_c - n$$

From condition (iii), we know that $W_c - O_c \geq |t| - 1$. Since t consists of node i and at least n children a_j each of which has $|a_j| - 1$ nodes, we have that

$$|t| \geq 1 + n + \sum_{j=1}^{n} (|a_j| - 1)$$

which is equivalent to

$$|t| - 1 \geq n + \sum_{j=1}^{n} (|a_j| - 1) \tag{2}$$

Plugging this together, we get

$$W_{c_1} - O_{c_1} = W_c - O_c - n \geq \sum_{j=1}^{n} (|a_j| - 1) \geq |a_1| - 1$$

After $H_{LTF}(a_1, c_1)$ we get a configuration c_1'. We have just argued that the inductive hypothesis applies for $H_{LTF}(a_1, c_1)$, so we can use it and find that we are in a nearly identical situation as before $\textsc{apply}(\alpha_1, a_1)$: The stack is $\mathbb{S}_{c_1'} = \mathbb{S}_{c_1}|a_1 = \mathbb{S}_c$. That is, in $\mathbb{S}_{c_1'}$ the top of the stack is i again. What has changed is $W_{c_1'} - O_{c_1'}$ and of course $\mathbb{A}_{c_1'} = \{\alpha_1\}$, which was empty before. We can now apply $\textsc{apply}(\alpha_2, a_2)$ and continue.

Let us consider the general case for $H_{LTF}(a_l, c_l)$ with $1 \leq l \leq n$ where we are in c_l arriving from $\textsc{apply}(\alpha_l, a_l)$. At this point, we know

(i) $\mathbb{T}_{c_l} = \{\tau_{a_l}\}$ where τ_{a_l} is the term type of a_l (by $\textsc{apply}$ before)

(ii) i is on top of the stack (inductive hypothesis for $l' < l$)

In effect, conditions (i) and (ii) for the inductive hypothesis for $H_{LTF}(a_l, c_l)$ are met. Conditions (iv) and (v) for a_l are fulfilled by our assumptions (iv) and (v) because a_l is a subtree of i. What remains to be checked is $W_{c_l} - O_{c_l} \geq |a_l| - 1$. We can calculate $W_{c_l} = W_c - l - \sum_{j=1}^{l-1} (|a_j| - 1)$, where the summation over j comes from the inductive hypothesis for the children $j < l$ and $-l$ comes from the $\textsc{apply}$ transitions we have performed. O_{c_l} is simply $O_{c_l} = O_c + n - l$ because the $\textsc{Choose}$

transition resulted in $O_{c'_0} = O_c + n$ and we have drawn l APP edges already. Plugging this together, we get

$$\begin{aligned} W_{c_l} - O_{c_l} &= W_c - l - \sum_{j=1}^{l-1}(|a_j| - 1) - (O_c + n - l) \\ &\geq (|t| - 1) - n - \sum_{j=1}^{l-1}(|a_j| - 1) \\ &\geq \sum_{j=l}^{n}(|a_j| - 1) \geq |a_l| - 1 \end{aligned}$$

where the first step replaces $W_c - O_c$ by $|t| - 1$ (assumption (iii)) and the second step replaces $(|t| - 1)$ using Eq. 2.

A similar line of reasoning can be used to justify the use of the inductive hypothesis for $H_{LTF}(m_1, c_{n+1}), \ldots, H_{LTF}(m_1, c_{n+k})$.

Note that by applying the inductive hypothesis to all children, we know that i is always on top of the stack after H_{LTF} was applied. This justifies the final POP transition, because at that point $\mathbb{A}_{c'_{n+k}} = \mathcal{A}(\tau_G, \tau)$. Consequence (c) follows from this POP.

We did not change any of $\mathbb{E}, \mathbb{A}, \mathbb{T}, \mathbb{G}$ outside of our subtree i (consequence (e)). This follows from the inductive hypotheses of the children and the fact that i was always on top of the stack when we performed any transition.

If we want to determine $W_{c'}$, we note that we have drawn $n + k$ edges and for each child $ch \in a_1, \ldots, a_n, m_1, \ldots m_k$, we know by the inductive hypothesis that this has drawn $|ch| - 1$ edges. In total, we have

$$\begin{aligned} W_{c'} = W_c &- \left[\sum_{j=1}^{n}(|a_j| - 1) + \sum_{j=1}^{k}(|m_j| - 1)\right] \\ &- (n + k) \\ = W_c &- \left[\sum_{j=1}^{n}|a_j| + \sum_{j=1}^{k}|m_j| - (n + k)\right] \\ &- (n + k) \\ = W_c &- (|t| - 1) \end{aligned}$$

where the last step makes use of the fact that $|t| = 1 + \sum_{j=1}^{n}|a_j| + \sum_{j=1}^{k}|m_j|$.

$\square$

For LTL, the same principle applies with a near identical lemma which only also asks that for the root r of t, $\mathbb{A}_c(r) = \emptyset$. The procedure to construct the transition sequence is shown in Algorithm 2.

Algorithm 1 Generate LTF transitions for AM dependency tree

```
function $H_{LTF}(c, t)$
    Let $t$ have graph constant $G$
    and term type $\tau$
    $c \leftarrow$ CHOOSE$(\tau, G)(c)$
    for APP$_\alpha$ child $a$ of t do
        $c \leftarrow$ APPLY$(\alpha, a)(c)$
        $c \leftarrow H_{LTF}(c, a)$
    end for
    for MOD$_\beta$ child $m$ of $t$ do
        $c \leftarrow$ MODIFY$(\beta, m)(c)$
        $c \leftarrow H_{LTF}(c, m)$
    end for
    $c \leftarrow$ POP$(c)$
    return $c$
end function
```

Algorithm 2 Generate LTL transitions for AM dependency tree

```
function $H_{LTL}(c, t)$
    Let $t$ have graph constant $G$
    for APP$_\alpha$ child $a$ of t do
        $c \leftarrow$ APPLY$(\alpha, a)(c)$
    end for
    for MOD$_\beta$ child $m$ of $t$ do
        $c \leftarrow$ MODIFY$(\beta, m)(c)$
    end for
    $c \leftarrow$ FINISH$(G)(c)$
    Let $t_1, \ldots t_n$ be the children of $t$
    on the stack in $c$
    for $i \in 1, \ldots, n$ do
        $c \leftarrow H_{LTL}(c, t_i)$
    end for
    return $c$
end function
```

G.3 No dead ends

For both LTF and LTL, the following theorem guarantees that we can always get a complete analysis for a sentence:

Theorem G.9 (No dead ends). If c is a configuration derived by LTF or LTL then there is a valid sequence of transitions that brings c to a goal configuration c'.

Together with the soundness theorem (Theorem G.3) that every goal configuration corresponds to well-typed AM dependency tree, this means that we can always finish a derivation to get a well-typed AM dependency tree, no matter what the sentence is or how the transitions are scored. The proof of Theorem G.9 is constructive both for LTF and LTL and is given below. In both cases, we proof a lemma first that there are always ”enough” words left.

Theorem G.9 only holds if we make a few assumptions that are mild in practice. Recall that we assumed that we are given a set of graph constants C that can draw source names from a set S, a set of types Ω and a set of edge labels L. We now make very explicit the following assumptions about their relationships:

Assumption 1. For all types $\lambda \in \Omega$, there is a constant $G \in C$ with type $\tau_G = \lambda$.

Assumption 2. For all types $\lambda \in \Omega$ and all source names $\alpha \in S$, if $\mathit{req}_\alpha(\lambda)$ is defined then $\mathit{req}_\alpha(\lambda) \in \Omega$.

Assumption 3. If $\textsc{mod}_\alpha \in \mathit{Lab}$ then $[\alpha] \in \Omega$.

Assumption 4. For all source names $\alpha \in S$, $\textsc{App}_\alpha \in \mathit{Lab}$.

Assumption 5. There are *no* constraints imposed on which graph constants can be assigned to a particular word.

The assumptions made are almost perfectly met in practice, see the main paper.

In the proof of Theorem G.9 we want to use the fact $[\,] \in \Omega$; this follows from the assumptions above:

Lemma G.10. The empty type $[\,] \in \Omega$.

Proof. Assumption 2 says that for all types $\lambda \in \Omega$ and all sources $\alpha \in S$, the type $\mathit{req}_\alpha(\lambda)$ (if defined) is also a member of Ω. Since types are formally DAGs, each type τ is either empty (that is: $[\,]$) or has a node n without outgoing edges. In the latter case, $\mathit{req}_n(\tau) = [\,]$. ☐

G.3.1 LTF

We prove a lemma that there are always at most as many sources that we have still to fill as there are words without incoming edges.

Lemma G.11. For all configurations derived with LTF, $O_c \leq W_c$.

Proof. By structural induction over the derivation.

Base case The initial state c does not define $\mathbb{A}$ for any token, thus $O_c(i) = 0$ for all i. The number of words without incoming edges in configuration c is $W_c \geq 1$. Therefore, $\sum_i O_c(i) = O_c \leq W_c$.

Induction step Inductive hypothesis: $O_c \leq W_c$
Goal: $O_{c'} \leq W_{c'}$ where c' derives in one step from c.
The derivation step from c to c' is one of:

INIT(i) After INIT, $\mathbb{A}_{c'}$ is not defined for any i, thus $O_c = 0$.

POP This transition only changes the stack, which does not affect O, so $O_{c'}(i) = O_c(i)$ for all i and $W_{c'} = W_c$. The inductive hypothesis applies.

CHOOSE(τ, G) Let i be the active node. No edge was created, thus $W_{c'} = W_c$. For all $j \neq i$, $O_{c'}(j) = O_c(j)$. We can thus write $O_{c'}$ as

$$O_{c'} = O_c - O_c(i) + O_{c'}(i)$$

Since CHOOSE(τ, G) was applicable in c, we know that $i \notin \mathcal{D}(\mathbb{G}_c)$. By Lemma G.8 and by definition of *PossL*, we have that $O_c(i) = 0$, so

$$O_{c'} = O_c + O_{c'}(i) \tag{3}$$

We now look into the value of $O_{c'}(i)$. Since CHOOSE was applied, we know that $\mathbb{G}_{c'}(i) = G$, $\mathbb{A}_{c'}(i) = \emptyset$ and that $\tau_G \in \mathit{PossL}(\tau, \emptyset, W_c - O_c)$, which simplifies to $|\mathcal{A}(\tau_G, \tau)| \leq W_c - O_c$. From this follows that $O_{c'}(i) = \min_{\lambda' \in \{\tau_G\}, \tau' \in \mathbb{T}_{c'}(i)} |\mathcal{A}(\lambda', \tau') - \mathbb{A}_{c'}(i)| \leq W_c - O_c$. Substituting this for $O_{c'}(i)$ in Eq. 3, we get

$$\begin{aligned} O_{c'} &= O_c + O_{c'}(i) \\ &\leq O_c + W_c - O_c = W_c = W_{c'} \end{aligned}$$

APPLY(α, j) Let i be the active node. Since an edge to j was created in the transition, $W_{c'} + 1 = W_c$. We decompose $O_{c'}$ again:

$$O_{c'} = O_c - O_c(i) + O_{c'}(i)$$

Since APPLY could be performed, we know that $\mathbb{T}_c$ and $\mathbb{G}_c$ are defined for i and let us denote them $\mathbb{T}_c(i) = \{\tau\}$ and $\mathbb{G}_c(i) = G$. Thus, $O_c(i) = |\mathcal{A}(\tau_G, \tau) - \mathbb{A}_c(i)|$. Since the precondition of APPLY said that $\alpha \notin \mathbb{A}_c(i)$ and APPLY has the effect that $\mathbb{A}_{c'}(i) = \mathbb{A}_c(i) \cup \{\alpha\}$, we know that $O_{c'}(i) = |\mathcal{A}(\tau_G, \tau) - (\mathbb{A}_c(i) \cup \{\alpha\})| < O_c(i)$. This means that $O_{c'} < O_c$. Using the inductive hypothesis $O_c \leq W_c$ and $W_{c'} + 1 = W_c$, we get

$$O_{c'} < O_c \leq W_{c'} + 1$$

which means that $O_{c'} \leq W_{c'}$.

MODIFY(β, j) Let i be the active node. In Section 5.3, we made the restriction that MODIFY is only applicable if

$$W_c - O_c \geq 1 \tag{4}$$

The transition created an edge, which means that $W_{c'} = W_c - 1$. $O_{c'}$ depends on $\mathbb{G}_{c'}, \mathbb{A}_{c'}$ and $\mathbb{T}_{c'}$. The only thing that changed from c to c' is that $\mathbb{T}_{c'}$ is now defined for j. However, $\mathbb{A}_{c'}$ is still not defined for j, so $O_{c'}(j) = O_c(j) = 0$. This means $O_{c'} = O_c$. Substituting those into Eq. 4 and re-arranging, we get $O_{c'} \leq W_{c'}$.

□

We now show that there are no dead ends by showing that for any configuration c derived by LTF, we can construct a valid sequence of transitions such that the stack becomes empty. By Lemma G.1 this means that c is a goal configuration. We empty the stack by repeatedly applying Algorithm 3.

In line 17, we compute the sources that we still have to fill in order to pop i off the stack. We assume an arbitrary order and o_j refers to one particular source in o. The symbol $\oplus$ denotes concatenation.

Lemma G.12. For any configuration c, $C_{LTF}(c)$ (Algorithm 3) generates a valid sequence s of LTF transitions such that ($|\mathbb{S}_{c'}| < |\mathbb{S}_c|$ or $|\mathbb{S}_{c'}| = 0$) and there is a token i for which $\mathbb{G}_{c'}(i)$ is defined, where c' is the configuration obtained by applying s to c.

Proof. First, we show that $\mathbb{G}_{c'}$ is defined for some i in c'. We make a case distinction based on in which line the algorithm returns. If it returns in lines 4, 11 or 14, it is obvious that $\mathbb{G}_{c'}$ is defined for some i. If it returns in line 26 then o is non-empty because $O_c(i) > 0$. If o is non-empty, we use a CHOOSE transition in the for-loop. The remaining case is returning in line 6. Note that the stack is empty but it is not the initial configuration (otherwise, we would have returned in line 4), so an INIT transition must have been applied, which pushes a token to the stack. Since the stack is now empty in c', a POP transition must have been applied, which is only applicable if $\mathbb{G}$ is defined for the item on top of the stack. Consequently, $\mathbb{G}_{c'}$ is defined for some i.

Further, note that every path through Algorithm 3 either reduces the size of the stack (one more POP transition than tokens pushed to the stack by APPLY) or keeps it effectively empty.

C_{LTF} is constructed in a way that the transition sequence is valid. However, there are a few critical points:

- In line 3, we assume the existence of a graph constant $G \in C$ with $\tau_G = [\,]$. This follows from Lemma G.10 and Assumption 1.
- In line 13, it is assumed that there exists a graph constant $G \in C$ with $\tau_G \in \mathbb{T}_c(i)$. This graph constant always exists because either $\mathbb{T}_c(i)$ is a request (if i has an incoming APP edge) and thus by Assumptions 1 and 4 there is a graph constant $G \in C$, or $\mathbb{T}_c(i)$ is a set of types resulting from a MODIFY transition. Here, the existence of a suitable graph constant G with type $\tau_G \in \mathbb{T}_c(i)$ follows from Assumptions 1 and 3. Assumption 5 makes explicit that there are no further constraints on how we choose G.
- In line 20, it is assumed that there exist $|o|$ tokens without incoming edges. This is true because $|o| = O_c(i) \leq \sum_j O_c(j) = O_c$ and by Lemma G.11, it follows that $|o| \leq W_c$, showing that there are indeed enough tokens without incoming edges.
- In line 24, it is assumed that $\text{APP}_{a_i} \in L$ for some source o_j; this is guaranteed by Assumption 4.

□

In summary, we can turn any configuration c derived by LTF into a goal configuration by repeatedly applying C_{LTF} to it until the (finite) stack is empty. By Lemma G.1, this is a goal configuration.

G.3.2 LTL

The proof works similarly. We first prove a similar lemma that if i is the active node, $O_c(i) \leq W_c$ and then construct a function C_{LTL} (see Algorithm 4) that produces a valid sequence of transitions that we repeatedly apply to reach a goal configuration.

Lemma G.13. Let c be a configuration derived by LTL. If i is the active node in c, then $O_c(i) \leq W_c$.

Proof. By structural induction over the derivation.

Base case In the initial state, the stack $\mathbb{S}_c$ is empty, making the antecedent of the implication false for all i and thus the implication true.

Algorithm 3 Complete LTF sequence

```
function $C_{LTF}(c)$
    if $c = \langle\emptyset,\emptyset,\emptyset,\emptyset,\emptyset\rangle$ then
        Let $G \in C$ with $\tau_G = [\,]$.
        return $\textsc{Init}(1), \textsc{choose}([\,], G), \textsc{Pop}$
    end if
    if $\mathbb{S}_c = [\,]$ then return $[\,]$
    end if
    Let $i$ be top of $\mathbb{S}_c$.
    if $O_c(i) = 0$ then
        if $i \in \mathit{Dom}(\mathbb{G}_c)$ then
            return $\textsc{Pop}$
        else
            Let $G \in C, \tau_G \in \mathbb{T}_c(i)$.
            return $\textsc{choose}(\tau_G, G), \textsc{Pop}$
        end if
    end if
    Let $o = \mathcal{A}(\mathbb{G}_c(i), \tau) - \mathbb{A}_c(i)$
    where $\mathbb{T}_c(i) = \{\tau\}$
    Let $\rho_j = \mathit{req}_{o_j}(\tau_{\mathbb{G}_c(i)})$
    Let $a_1, \dots, a_{|o|}$ be tokens without heads
    $s = [\,]$
    for $a_j \in a_1, \dots, a_{|o|}$ do
        Let $G$ be a constant of type $\rho_j$
        $s = s \oplus \textsc{apply}(o_j, a_j), \textsc{Choose}(\rho_j, G), \textsc{Pop}$
    end for
    return $s \oplus \textsc{Pop}$
end function
```

Induction step Inductive Hypothesis: If i is the active node in c, then $O_c(i) \leq W_c$.
Goal: If i is the active node in c', then $O_{c'}(i) \leq W_{c'}$ where c' derives in one step from c.
The applied transition is one of:

INIT(i) The previous configuration c must be the initial configuration. Now i is the active node in c' and $\mathbb{A}_{c'}(i) = \emptyset$ and $\mathbb{T}_{c'}(i) = \{[\,]\}$ and $\mathbb{G}_{c'}$ is not defined for i. Then $O_{c'}(i) = \min_{\lambda\in\Omega} |\mathcal{A}(\lambda, [\,]) - \mathbb{A}_{c'}(i)|$. Note that the empty type $[\,] \in \Omega$ by lemma G.10 and that $\mathcal{A}([\,],[\,]) = \emptyset$. Choosing $\lambda = [\,]$, we get $O_{c'}(i) = 0$. INIT(i) created an edge into i, so $W_{c'} = W_c - 1$. Since a sentence consists of at least one word ($W_c \geq 1$), we have $O_{c'}(i) = 0 \leq W_{c'}$.

APPLY(α, j) Let i be the active node in c. Then, by construction of APPLY(α, j) it remains the active node in c'. After the transition, $\mathbb{T}_{c'}(i) = \mathbb{T}_c(i)$, $\mathbb{A}_{c'}(i) = \mathbb{A}_c(i) \cup \{\alpha\}$. Thus, $O_{c'}(i)$ can be written as follows:

$$O_{c'}(i) = \min_{\lambda'\in\Omega, \tau'\in\mathbb{T}_c(i)} |\mathcal{A}(\lambda', \tau') - (\mathbb{A}_c(i) \cup \{\alpha\})|$$

Since APPLY(α, j) was applicable, the preconditions must be fulfilled, i.e.

$$\exists\lambda \in \Omega.\exists\tau \in \mathbb{T}_c(i).$$
$$\lambda \in \mathit{PossL}(\tau, \mathbb{A}_c(i) \cup \{\alpha\}, W_c - 1)$$

Expanding the definition of *PossL* we get:

$$\mathbb{A}_c(i) \cup \{\alpha\} \subseteq \mathcal{A}(\lambda, \tau) \wedge$$
$$|\mathcal{A}(\lambda, \tau) - (\mathbb{A}_c(i) \cup \{\alpha\})| \leq W_c - 1$$

for some $\lambda \in \Omega$ and $\tau \in \mathbb{T}_c(i)$. If we now choose $\lambda' = \lambda$ and $\tau' = \tau$ in $O_{c'}(i)$, we get

$$O_{c'}(i) \leq |\mathcal{A}(\lambda, \tau) - (\mathbb{A}_c(i) \cup \{\alpha\})| \leq W_c - 1$$

Since $W_{c'} = W_c - 1$, it holds that $O_{c'}(i) \leq W_{c'}$.

MODIFY(β, j) Let i be the active node. It also remains the active node in c'. The transition consumes a word, that is $W_{c'} = W_c - 1$. However, it can only be applied if $W_c - O_c \geq 1$. Since O_c is obtained by summing over all tokens, $O_c(i) \leq O_c$. We get:

$$O_c(i) \leq O_c \leq W_c - 1 = W_{c'}.$$

Finally, $O_{c'}(i) = O_c(i)$ because none of $\mathbb{A}, \mathbb{G}, \mathbb{T}$ changed for i during the MODIFY(β, j) transition.

FINISH(G) Let i be active node *after* the transition, that is, in c'. The FINISH transition presupposes that i has an incoming edge. We distinguish two cases based on the label:

- i has an incoming APP$_\alpha$ edge. Then we have that $\mathbb{T}_{c'}(i) = \{\mathit{req}_\alpha(\tau_G)\}$ and $\mathbb{G}_{c'}$ undefined for i. Then $O_{c'}(i) = \min_{\lambda\in\Omega} |\mathcal{A}(\lambda, \mathit{req}_\alpha(\tau_G))|$. By Assumption 2, $\mathit{req}_\alpha(\tau_G) \in \Omega$ and by definition of the apply set $\mathcal{A}(\lambda, \lambda) = \emptyset$ for all types λ, so in particular also for $\mathit{req}_\alpha(\tau_G)$, which makes $O_{c'}(i) = 0$.
- i has an incoming MOD$_\beta$ edge. By Assumption 3, we know that $[\beta] \in \Omega$, for which $[\beta] \in \mathbb{T}_{c'}(i)$ holds by construction of FINISH(G). Expanding the definition of $O_{c'}(i)$, we get: $O_{c'}(i) = \min_{\lambda\in\Omega, \tau'\in\mathbb{T}_{c'}(i)} |\mathcal{A}(\lambda, \tau')|$. By choosing $\lambda = [\beta] = \tau'$, we get $O_{c'}(i) = 0$.

Algorithm 4 Complete LTL sequence

```
1: function $C_{LTL}(c)$
2:     if $c = \langle\emptyset,\emptyset,\emptyset,\emptyset,\emptyset\rangle$ then
3:         Let $G \in C$ with $\tau_G = [\,]$
4:         return $\textsc{Init}(1), \textsc{Finish}(G)$
5:     end if
6:     if $\mathbb{S}_c = []$ then return $[]$
7:     end if
8:     Let $i$ be top of $\mathbb{S}_c$.
9:     Let $\lambda, \tau$ be the minimizers of $O_c(i) = \min_{\lambda\in\Omega,\tau\in\mathbb{T}_c(i)} |\mathcal{A}(\lambda,\tau) - \mathbb{A}_c(i)|$
10:    if $O_c(i) = 0$ then
11:        Let $G \in C$ with $\tau_G = \lambda$
12:        return $\textsc{Finish}(G)$
13:    end if
14:    Let $o = \mathcal{A}(\lambda,\tau) - \mathbb{A}_c(i)$
15:    Let $\rho_i = req_{o_i}(\tau_{\mathbb{G}_c(i)})$
16:    Let $a_1, \ldots, a_{|o|}$ be tokens without heads
17:    $s = []$
18:    for $a_j \in a_1, \ldots, a_{|o|}$ do
19:        $s = s \oplus \textsc{Apply}(o_j, a_j)$
20:    end for
21:    $s = s \oplus \textsc{Finish}(G)$ where $\tau_G = \lambda$
22:    return $s$
23: end function
```

Since $O_{c'}(i) = 0$, it also holds that $O_{c'}(i) \le W_c = W_{c'}$.

□

Lemma G.14. For a sentence with n words, a valid LTL transition sequence can contain at most n FINISH transitions.

Proof. By contradiction. Assume there is a valid transition sequence s that contains $m > n$ FINISH transitions.
Since FINISH can only be applied when there is some token on the stack and there are more FINISH transitions than there are tokens, FINISH must have been applied twice with the same active node. Since FINISH removes the active node from the stack, i must have been pushed twice. This means that i has two incoming edges. When the second incoming edge was drawn into i the condition $i \notin \mathcal{D}(\mathbb{E})$ was violated, which contradicts the assumption that the transition sequence s is valid.

□

Lemma G.15. Let c be a configuration derived by an LTL transition sequence s that contains j FINISH transitions. Then $C_{LTL}(c)$ (Algorithm 4) generates a valid sequence s' of LTL transitions that leads to a goal configuration c' or $s \oplus s'$ contains $j + 1$ FINISH transitions.

Proof. We first show the main claim and then verify that the generated transition sequence s' is valid. We make a case distinction on the content of the stack in c'.

$\mathbb{S}_{c'}$ is empty We show that c' is a goal configuration. In order to apply Lemma G.2, we have to show that $\mathbb{G}_{c'}$ is defined for some token i. There is only one path through Algorithm 4 that does not assign a graph constant to a token (line 6). Returning in line 6 means that the stack is empty but the state is not the initial state – so something has been removed from the stack already with a FINISH transition. Consequently, $\mathbb{G}$ is defined for some i.

$\mathbb{S}_{c'}$ is not empty Since the stack is not empty, this means the algorithm returns in line 12 or in line 22. Clearly, the transition sequence that the algorithm returns contains a FINISH transition. Together with the j FINISH transitions that have been performed up to the configuration c, this makes $j + 1$ FINISH transitions.

Algorithm 4 is constructed such that it only produces valid transition sequences. However, there are a few critical points:

- Line 3 assumes the existence of a graph constant $G \in C$ with $\tau_G = [\,]$. This follows from Lemma G.10 and Assumption 1. Assumption 5 explicitly allows us to assign G to any token.

- Line 9 assumes that $K_c(i) = \Omega$ and that $i \in \mathcal{D}(\mathbb{A}_c)$ and $i \in \mathcal{D}(\mathbb{T}_c)$. This is true because i is on top of the stack. $\mathbb{A}$ and $\mathbb{T}$ are always defined for the active node in LTL. $\mathbb{G}$ is never defined for the active node in LTL.

- Lines 11 and 21 assume the existence of a graph constant $G \in C$ of type $\tau_G = \lambda \in \Omega$, which is guaranteed by Assumption 1. Assumption 5 explicitly allows us to assign G to any token.

- Line 16 assumes that there are at least $|o|$ tokens without incoming edges ($W_c \ge |o|$). This is indeed the case, because $|o| = O_c(i)$ and $O_c(i) \le W_c$ by Lemma G.13.

- Line 19 assumes that $\textsc{App}_{o_j} \in L$. This is guaranteed by Assumption 4.

$\square$

We can construct the transition sequence for which Theorem G.9 asks by repeatedly applying C_{LTL} to a given configuration c. Lemma G.15 shows that applying C_{LTL} to a configuration results either in a goal configuration or increases the number of FINISH transitions by one. Lemma G.14 tells us that there is an upper bound on how many times we can increase the number of FINISH transitions in a valid transition sequence. Since C_{LTL} returns only valid transition sequences, this means that we reach a goal configuration by finitely many applications of C_{LTL}.

Improving Out-of-Scope Detection in Intent Classification by Using Embeddings of the Word Graph Space of the Classes

Paulo Cavalin, Victor Henrique Alves Ribeiro, Ana Paula Appel, Claudio Pinhanez
IBM Research
São Paulo, SP, Brazil
pcavalin@br.ibm.com

Abstract

This paper explores how intent classification can be improved by representing the class labels not as a discrete set of symbols but as a space where the word graphs associated to each class are mapped using typical graph embedding techniques. The approach, inspired by a previous algorithm used for an inverse dictionary task, allows the classification algorithm to take in account inter-class similarities provided by the repeated occurrence of some words in the training examples of the different classes. The classification is carried out by mapping text embeddings to the word graph embeddings of the classes. Focusing solely on improving the representation of the class label set, we show in experiments conducted in both private and public intent classification datasets, that better detection of out-of-scope examples (OOS) is achieved and, as a consequence, that the overall accuracy of intent classification is also improved. In particular, using the recently-released *Larson dataset*, an error of about 9.9% has been achieved for OOS detection, beating the previous state-of-the-art result by more than 31 percentage points.

1 Introduction

Intent classification is usually applied for response selection in conversational systems, such as text-based *chatbots*. For the end-user to have the best possible experience with those systems, it is expected that an *intent classifier* is able not only to map an input utterance to the correct intent but also to detect when the utterance is not related to any of the intents, to which we refer to as *out-of-scope* (OOS)[1] inputs or samples. In the light of this, this paper describes and evaluates a method which tries to capture the complexity of the set of intents by embedding them into a vector space created using *word graphs*, as described later. We show that, although the method in some cases is able to improve the accuracy of a text classifier in *in-scope* examples, it has often a tremendous impact on improving the ability of text classifier to reject OOS text, without relying on OOS examples in the training set.

Notice that the intent classifier is typically implemented using standard text classification algorithms (Weiss et al., 2012; Larson et al., 2019; Casanueva et al., 2020). Consequently, to perform OOS sample detection, methods often rely on one-class classification or *threshold rejection*-based techniques using the probability outputs for each class (Larson et al., 2019) or reconstruction errors (Ryu et al., 2017, 2018).

There also exist approaches based on the assumption that OOS data can be collected and included in the training set (Tan et al., 2019; Larson et al., 2019). However, in practice, collecting OOS data can be a burden for intent classifier creation, which is generally carried out by domain experts and not by machine learning experts. Thus, in the ideal world, one should rely solely on *in-scope* data for this task because it is very difficult to collect a set of data that appropriately represents the space of the very unpredictable OOS inputs.

The classes in a traditional text classifier are generally represented by a discrete set of symbols and the classifier is trained with the help of a finite set of examples, where the classes are assumed to be independent and the set of examples to be disjoint. But, in many cases, the classes are in fact associated with inter-connected higher-level concepts which could be formatted into more meaningful representations and better exploited in the classification process for an enhanced representation of the scope of the classifier.

In particular we explore here the use of *graphs* which represent information by means of nodes

---

[1] *Out-of-domain* examples is also a common term in the literature.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3952–3961,
November 16–20, 2020.

connected to each other by arcs. Recent research has demonstrated that nodes in a graph can be converted to an *embedding*, that is, projected into a vector space, which can then be mapped to sentences to cope with tasks such as the *reverse dictionary problem* (Hill et al., 2016; Kartsaklis et al., 2018). We propose here an adaptation of those ideas to an intent classifier so it uses such mappings to expand the representation of the class space, its scope, and class inter-dependencies, and thus possibly making the OOS detection task easier.

This paper presents an investigation of exploiting information from *word graphs* associated to the intent classes to improve OOS sample detection in intent classification. By considering that each class is represented by a set of text examples and that different classes can be connected to each other by means of the repeated occurrence of words in their respective examples, we build a word graph where both class labels and words are represented by single nodes. The word nodes are connected to the class label nodes in accordance to their occurrence in the training samples and their respective class labels. Then, a typical graph embedding technique is used to represent classes with the embedding of their corresponding class label node. Instead of finding the classes with the highest probability, the intent classifier search for the class embedding which maps best to the sentence embedding of a given input sample.

We have implemented and tested this idea with different types of base methods for sentence embedding, such as *Long-short Term Memory (LSTM)* neural networks and *Bidirectional Encoder Representations from Transformers (BERT)*, and performed OOS detection by means of a simple threshold-based rejection. We conducted a thorough evaluation on both private and public intent classification datasets, such as the *Larson dataset* for this specific task (Larson et al., 2019).

Our results show that the proposed word-graph based method improves considerably OOS detection, compared against the corresponding traditional classification algorithms, based on combining the sentence embedding algorithm with *softmax* probabilities. In the case of the Larson dataset, where comparison against varied OOS detection methods is available, we show that our proposed approach reduces dramatically the previous state-of-the-art (SOTA) false acceptance rate in more than 30 percentage points, from 41.1% to 9.9%.

2 The Word Graph Method

This section presents a formal description of the methodology employed in this work.

2.1 Embedding the Set of Classes

An *intent classification* method is a function D which maps a set of sentences (potentially infinite) $S = \{s_1, s_2, ...\}$ into a finite set of classes $\Omega = \{\omega_1, \omega_2, ..., \omega_c\}$:

$$D : S \to \Omega \quad D(s) = \omega_i \tag{1}$$

To enable a numeric, easier handling of the input text, an embedding $\xi : S \to \mathbb{R}^n$ is often used, mapping the space of sentences S into a vector space $\mathbb{R}^n$, and defining a classification function $E : \mathbb{R}^n \to \Omega$ such as $D(s) = E(\xi(s))$. In typical intent classifiers, E is usually composed of a function C which computes the probability of s being in a given class, followed by the *arg max* function. In many intent classifiers, C is the *softmax* function.

$$S \xrightarrow{\xi} \mathbb{R}^n \xrightarrow{C} \mathbb{R}^c \xrightarrow{argmax} \Omega \tag{2}$$

This paper explores how to use embeddings in the other side of the classification functions, that is, by embedding the set Ω of classes into another vector space $\mathbb{R}^m$. The idea is to use class embedding functions which somehow capture better inter-class relations such as similarities, using, for instance, information from the training sets, as we will show later. Formally, we use a *class embedding* function $\psi : \Omega \to \mathbb{R}^m$, its inverse ψ^{-1}, and a function $M : \mathbb{R}^n \to \mathbb{R}^m$ to map the two vector spaces so $D(s) = \psi^{-1}(M(\xi(s)))$.

$$S \xrightarrow{\xi} \mathbb{R}^n \xrightarrow{M} \mathbb{R}^m \xrightarrow{\psi^{-1}} \Omega \tag{3}$$

In this paper we use typical sentence embedding methods to implement ξ. To approximately construct the function M we employ a basic *Mean Square Error* (MSE) method using the training set composed of sentence examples for each class $\omega_i \in \Omega$. As we will see next, the training set will also be used to construct the embedding function for the set of classes ψ and an approximation for its inverse ψ^{-1}.

2.2 Adapting *Kartsaklis* Method (LSTM)

In this paper we explore a text classification method proposed for the *inverse dictionary problem*, where text definitions of terms are mapped to the term they define, proposed by Kartsaklis et al. (2018).

The embedding of the class set into the continuous vector space (equivalent to the ψ function in equation 3) is done by expanding the knowledge graph of the dictionary words with nodes corresponding to words related to those terms and performing random walks on the graph to compute graph embeddings related to each dictionary node, using the *DeepWalk* algorithm (Perozzi et al., 2014). Notice that DeepWalk is a two-way function mapping nodes into vectors and back.

An LSTM, composed of two layers and an attention mechanism, is used by Kartsaklis et al. (2018) for mapping the input texts to the output vector space. To map the two continuous vector spaces representing the definition texts and the dictionary terms, a MSE function, learned from the training dataset, is used. This approach achieves SOTA results on the reverse dictionary task and also in other tasks such as document classification and text-to-entity mapping.

In this work, the approach from Kartsaklis et al. (2018) is employed for mapping the classes into a vector space, although we do not use a knowledge graph as described later. Instead, we create a *word graph G* by associating each class to a node and connecting to each of them nodes which correspond to words in the sentences of the training set of each class. We represent this by the function ζ, such as $\zeta(\Omega) = G$, which is also invertible. Substituting this in equation 3,

$$S \xrightarrow{LSTM} \mathbb{R}^n \xrightarrow{MSE} \mathbb{R}^m \xrightarrow{DeepWalk^{-1}} G \xrightarrow{\zeta^{-1}} \Omega \quad (4)$$

In practice, we compute the mapping from the class embedding space into the class set, called here $InvG : \mathbb{R}^m \rightarrow \Omega$, simply by computing the distance d between a point in $\mathbb{R}^m$ and the inverted projection of each class from Ω, and considering the closest class. That is, for each $w_i \in \Omega$, we consider the associated node in G, and compute the mapping in $\mathbb{R}^m$ of that node, as shown here:

$$InvG(x) = \arg\min_{w_i} d(x, DeepWalk(G(w_i))) \quad (5)$$

By substituting this function into equation 4, we obtain the algorithm we call here *LSTM+*:

$$S \xrightarrow{LSTM} \mathbb{R}^n \xrightarrow{MSE} \mathbb{R}^m \xrightarrow{InvG} \Omega \quad (6)$$

For comparison, the traditional corresponding classification method is tested, where the word graph embedding and associated functions are replaced by discrete *softmax* outputs. We call this simply *LSTM*:

$$S \xrightarrow{LSTM} \mathbb{R}^n \xrightarrow{softmax} \mathbb{R}^c \xrightarrow{argmax} \Omega \quad (7)$$

2.3 Replacing the LSTM with BERT

The natural language processing community has been recently focusing attention on the novel *transformer* models (Vaswani et al., 2017). This is due to the great performance improvement in several complex tasks, such as machine translation, question answering, and text classification. Moreover, such a performance is achieved without the use of convolutions or recurrence in neural networks. By using only the attention mechanism, models are built with lower computational costs, enabling the rapid development of larger and stronger models, which have been achieving SOTA performance in many different tasks.

BERT is one of such models (Devlin et al., 2019). It is a language representation model pre-trained on unlabeled text and conditioned on both the left and right contexts. Therefore, a simple output layer can be fine-tuned to attain strong results in many different tasks. BERT is employed in this paper with the word graph embedding layer (identical to the one in LSTM+). We call this algorithm *BERT+*:

$$S \xrightarrow{BERT} \mathbb{R}^n \xrightarrow{MSE} \mathbb{R}^m \xrightarrow{InvG} \Omega \quad (8)$$

Like in the previous case, we also use the BERT algorithm with traditional discrete softmax outputs for comparison, called here *BERT*:

$$S \xrightarrow{BERT} \mathbb{R}^n \xrightarrow{softmax} \mathbb{R}^c \xrightarrow{argmax} \Omega \quad (9)$$

2.4 Replacing the LSTM with TFIDF

The *term frequency-inverse document frequency* (TFIDF) indicates the importance of a word given its frequency in a document from a corpus (Han et al., 2011). With this statistic, it is possible to detect key words which play important roles in a given document, adjusting to the fact that several words frequently appear in the corpus. Such a technique has been used to generate features in many NLP tasks.

TFIDF is used in this work with an additional output-dense, feed-forward network layer in two different approaches. In the first one, it uses linear outputs for regression with the word graph representation, using the Kartsaklis et al. (2018)-inspired algorithm exactly as we did for the LSTM and

BERT algorithms. We call this algorithm *TFIDF+*. To compare, the feed-forward layer is configured with discrete softmax outputs called *TFIDF*.

2.5 Replacing the LSTM with Average Embedding

Average word embeddings is also used in this work. In particular, *Glove* (Pennington et al., 2014) is employed for embedding each word of the document. Subsequently, the average of the word embeddings is computed to generate the sentence features. Such an average is computed according to equation 10, where $\overline{x}_j$ is the average embedding for sentence j given the embedding of each of its N words x_{ij}. Finally, the computed features are inputted to a regression or a classification dense feed-forward networks, similarly to the previous approaches.

$$\overline{x}_j = \frac{1}{N}\sum_{i=1}^{N} x_{ij} \tag{10}$$

As before, we consider a version where we use average word embeddings in substitution of the LSTM in algorithm LSTM+, called *EMB+*, and also a discrete version using softmax, *EMB*.

2.6 Out-of-scope Sample Detection

A rejection mechanism based on a pre-defined threshold is used for OOS detection. This method can be easily applied to all of the methods described previously, without the need neither for any specific training procedure nor OOS training data.

In greater detail, suppose that for each class $\omega_i \in \Omega$ there is a score denoted $\phi_i \in Z$, where $|Z| = |\Omega|$. Given that $\max(Z)$ represents the highest score associated to a class, and that a rejection threshold θ has been defined on a validation set, samples can be classified as OOS whenever $\max(Z) < \theta$, and they are simply rejected, i.e. no classification output is produced for them. Otherwise, the sample is considered as an *in-scope (IS)* sample and the classification is conducted normally.

In this work, the scores in Z are represented either by the softmax probability computed for LSTM, BERT, TFIDF, and EMB, or by the similarity of sentence and graph embeddings for LSTM+, BERT+, TFIDF+, and EMB+. For the latter, the similarity is computed by means of the dot product between those two embeddings.

3 Experimental Evaluation

We performed a comparative evaluation of the performance of the classifiers described in the previous section using a public dataset described in (Larson et al., 2019) called here the *Larson* dataset[2]; a real dataset from a finance chatbot; and a pool of 40 datasets in two different languages from chatbots built using the same platform, to check for the reproducibility of the results from the finance chatbot dataset.

For those experiments, the methods were implemented as follows. For DeepWalk, the embedding size was set to 150, and the walk sizes to 20, for undirected graphs. For LSTM and LSTM+, we considered word embeddings with 200 elements, output sentence embeddings of size 150, and both methods were trained for 50 epochs. For both mapping sentence to graph embeddings and the softmax classifiers, we trained two-layer neural networks with 800 hidden neurons for 1,000 epochs on Larson dataset, and 300 hidden neurons for 20 epochs on the other datasets. Those parameters were set after preliminary evaluations.

3.1 Evaluation Metrics

We take into account a commonly-used metric for OOS dectection, i.e. *equal error rate (EER)* (Lane et al., 2007; Ryu et al., 2017, 2018; Tan et al., 2019), which corresponds to the classification error rate when the threshold θ is set to a value where false acceptance rate (FAR) and false rejection rate (FRR) are the closest. These two metrics are defined as:

$$FAR = \frac{\text{Number of accepted OOS samples}}{\text{Total of OOS samples}} \tag{11}$$

$$FRR = \frac{\text{Number of rejected IS samples}}{\text{Total of IS samples}} \tag{12}$$

In addition, *in-scope error rate (ISER)* is considered to report IS performance, i.e. the accuracy considering only IS samples, as the class error rate in (Tan et al., 2019). This metric is important to evaluate whether the alternative classification methods are able to keep up with the performance of their counterparts in the classification task.

3.2 Results on the Larson Dataset

In this section we present an evaluation on the Larson dataset (Larson et al., 2019), a recently proposed dataset which has been specifically designed to cope with intent classification and, most importantly, dealing with rejection of OOS samples, which is referred in the paper as out-of-scope queries. There is a total of 22,500 in-scope samples,

---

Method	EER	FAR	FRR	ISER
LSTM	13.4	23.7	16.4	12.2
BERT	12.8	35.3	**10.1**	**6.7**
TFIDF	13.7	17.7	17.3	11.7
EMB	18.0	22.8	22.8	18.1
LSTM+	11.7	20.8	11.9	8.4
BERT+	**9.8**	**9.9**	12.4	7.4
TFIDF+	19.2	29.5	26.4	24.2
EMB+	31.7	29.1	34.3	58.2

Table 1: Results on Larson dataset (in %, the lower the better), for both out-of-scope and in-scope samples: equal error rate (ERR), false acceptance rate (FAR), and false rejection rate (FRR); and only in-scope samples: class error rate (ISER).

evenly distributed across 150 classes, and 1,200 out-of-scope samples. From that, the in-scope samples are divided into 18,000 samples for training, and 4,500 samples for test. From the OOS samples, we take only the same 1,000 examples used in (Larson et al., 2019) for test for a direct comparison.

Table 1 presents a summary of the results on this dataset. We observe that the proposed word graph-based methods making use of LSTM and BERT sentence embeddings are able to outperform their corresponding softmax versions, where BERT+ achieves the lowest EER with 9.8% and the FAR value of 9.9%, beating SOTA results by at least 30 percentage points.

In fact, Larson et al. (Larson et al., 2019) reports the best OOS recall as 66.0%, which is equivalent to an FAR of 34%. However, in the setting where no OOS sample is used for training, the reported FAR value is of 41.1% and our approach achieved 31.2 percentage points below that value.

BERT presents the best ISER, meaning that it is the best type of method for classifying in-scope samples. However, the method does not cope well with out-of-scope examples, and results in the highest values for FAR and that negatively affects the final error rate. Overall, as depicted in Figure 1, the graph-based methods tend to produce systems with larger ROC under-the-curve areas, i.e. better systems overall.

We note also that TFIDF+ and EMB+ had poorer performance than TFIDF and EMB, respectively, which we believe owns mainly to the considerably higher ISER presented by the former. We have evaluated several configurations for those methods but we have not been able to achieve lower values for ISER, what may indicate that it might be more difficult to make use of such types of sentence embeddings in the proposed framework.

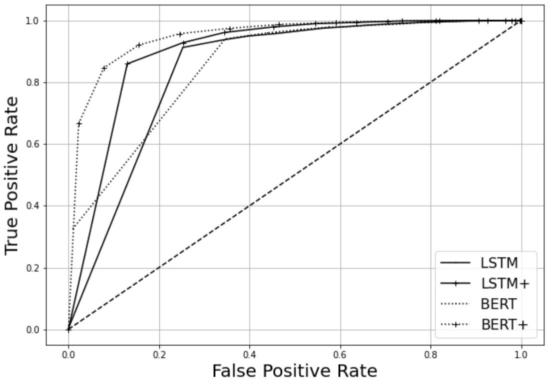

Figure 1: ROC curves on Larson dataset

3.3 Results on the Finance Dataset

This dataset uses data extracted from a real chatbot of a large financial institution from Brazil, called here the *Finance* dataset. The chatbot has content related to products and concepts associated both to the institution and finance in general. This set contains a total of 8,823 examples in Brazilian Portuguese language, split into 6,176 for training and 2,647 for test, distributed over a total of 285 classes.

Besides the different language, this dataset allows us to complement the evaluation of the previous section with an unbalanced dataset. The number of samples per class is non uniform, where most of the classes (87%) contain less than 47 samples, but there is one class with a very large number of examples (1,189), and some classes with as few as 2 samples.

In addition, this dataset has not been conceived to deal with OOS samples. For this reason, we had to create a simulation of such scenario by removing 85 randomly-selected classes and their corresponding samples from the training set and then considering all test samples associated to the removed classes as OOS samples. We repeated that procedure five times to come up with five different samplings of OOS classes for a better statistical analysis. The resulting training set sizes vary from 3,383 to 4,796 samples and the corresponding test sets contain about 35% of OOS samples on average. Results hereafter present an average over the results of the five samplings.

The results are presented in Table 2. LSTM+, with the proposed use of word graphs, achieved the best results in the four metrics. It is interesting not only that EER improves compared with LSTM, from 25.7% to 19.2%, but also that ISER

Method	EER	FAR	FRR	ISER
LSTM	25.7 ±4.6	32.2 ±2.4	32.0 ±7.8	17.5 ±2.7
BERT	24.6 ±3.3	29.2 ±5.3	33.4 ±3.3	17.9 ±1.9
TFIDF	22.0 ±1.1	26.9 ±4.4	26.5 ±3.5	43.8 ±8.0
AVG	25.8 ±2.7	30.5 ±4.0	33.5 ±5.5	48.5 ±8.2
LSTM+	**19.2 ±1.6**	**20.6 ±5.7**	**22.2 ±2.8**	**9.5 ±1.3**
BERT+	22.2 ±1.6	23.0 ±2.5	28.2 ±2.3	17.2 ±1.7
TFIDF+	24.8 ±0.8	28.5 ±2.3	35.8 ±1.7	53.3 ±7.1
AVG+	32.3 ±2.4	45.6 ±2.8	33.7 ±5.0	65.0 ±7.0

Table 2: Results on Finance dataset (in %, the lower the better), for both out-of-scope and in-scope samples: equal error rate (ERR), false acceptance rate (FAR), and false rejection rate (FRR); and only in-scope samples: class error rate (ISER).

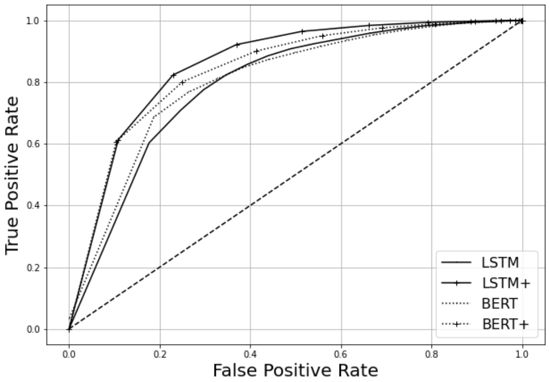

Figure 2: ROC curves on the Finance dataset.

also improves significantly by 6 percentage points. In the case of the BERT-based algorithms, the difference in ISER is much smaller with an improvement of only 0.7 percentage points. In general, the word graph-based BERT+ results in a better system than the softmax counterpart, i.e. BERT, where the former achieves an EER of 22.2% while the latter achieves 24.6%. And the better performance of LSTM+ and BERT+ against LSTM and BERT, respectively, is confirmed by the ROC curve in Figure 2.

Similar to the results on Larson, TFIDF+ and AVG+ presented higher EER than TFIDF and AVG, respectively. The dramatic decreases in ISER show that those word-graph implementations work poorly as classifiers for in-scope samples and we believe that this directly affects the performance on the other metrics. In our opinion, such results indicate that one requirement to benefit from using word graphs to enhance class representations is to make use of sentence embeddings which produce an intent classifier which has an ISER at least comparable to that of softmax-based classifiers. Otherwise, the benefits of the proposed approach are negatively affected by the error which seem be introduced by the in-scope cases.

3.4 Results in a Pool of Chatbots

Considering the diversity of ways in which intents are defined in professional chatbots, we scaled up our evaluation on multiple chatbots datasets obtained from a dialogue engine platform provider. Those datasets were made available by their developers to be used in improving the performance of the engine but no personal or private information was accessed by us.

In total, 40 datasets, 20 in English (EN) and 20 in Brazilian Portuguese (PT-BR) languages, were used for this experiment. The number of samples per dataset varies from 7,851 to 40,474, while the number of in-scope classes ranges from 6 to 966. For all data sets, the ratio of OOS samples is defined to be close to 20%, resulting in a median num-

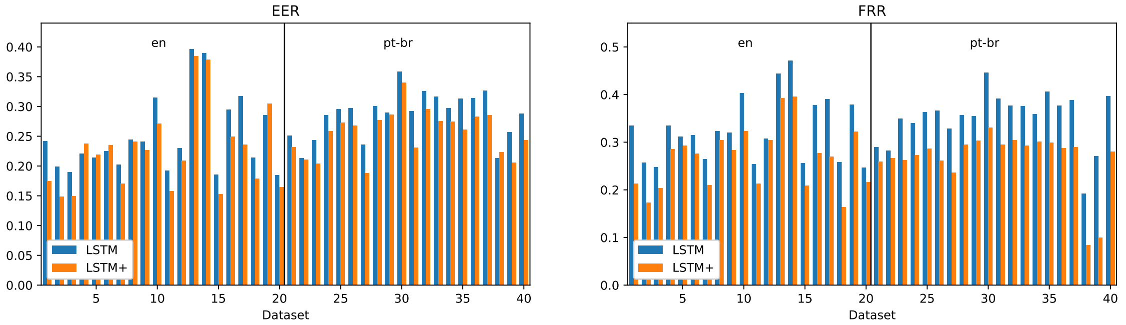

Figure 3: EER and FRR for LSTM and LSTM+ on the Chatbots' datasets.

ber of samples per in-scope class ranging from 9 to 502. In the experiment, we randomly assigned the classes into five different training and test datasets for a better statistical overview. Detailed numbers are provided in Table 3 and Table 4, where it can be noticed the diversity in terms of the number of classes and median samples per class among the the different chatbots.

Figure 3 and Figure 4 present plots of the results comparing LSTM+ vs LSTM and BERT+ vs BERT, respectively, considering two metrics, i.e. EER and FRR, to provide us an idea of the overall performance of the classifiers and the number of examples which are wrongly not rejected. We observe that LSTM+ generally produces lower EER and FRR in general and the statistical significance has been confirmed with the non-parametric paired Wilcoxon's signed rank test (Corder and Foreman, 2009). The mean EER and FRR values presented by LSTM+ were of 24.0% and 26.6%, respectively, and those presented by LSTM were of 26.7% and 33.8%. For BERT+ and BERT, the results show that BERT+ generally produces statistically-significant lower EER and FRR than BERT in the EN datasets, with mean values of 25.5% and 30.2%, respectively, against 26.5% and 34.5%. For PT-BR, though, no statistical difference has been found in EER, with mean EER of 29.3% for BERT+ and 28.6% for BERT. But BERT+ achieves statistically-significant lower FRR than BERT, with a mean of 30.1% of the former versus 38.8% of the latter.

Even though BERT+ has not significantly outperformed BERT in some scenarios, such as with PT-BR chatbots, we can observe a great improvement that the word graphs can bring to intent recognition if we take into account the ISER metric. That is, the difference in ISER of BERT+ against BERT is of 5%, where the former achieved 37% and the latter 32%. In other words, BERT+ can be considered quite worse than BERT for in-scope only intent classification. But, although BERT+ has not been significantly better than BERT with PT-BR chatbots, the proposed word graph-based approach had a great impact in reducing that 5% difference, since both present similar EER values, and still had a huge impact in FRR rates since BERT+ presented significantly better values. Thus, it is likely that by improving the mapping of sentence and graph embeddings for those datasets, and consequently reducing that 5% gap in ISER, BERT+ will stand out as a significantly better approach than BERT.

4 Related work

Classification methods, such as those used for intent classification, have been broadly applied to several areas, with the goal of predicting, for an input sample, which of the classes of the problem that sample is associated to. In the case of single-label classification, the training process consists of approximating a probability function, for instance a softmax function for neural networks, by using as reference an one-hot-encoding representation of class labels (Bishop, 2006).

OOS sample detection is a problem which may be critical for intent recognition in chatbots, so that applying rejection mechanisms are important for detecting those cases (Feng and Lin, 2019; Larson et al., 2019; Zheng et al., 2019). Traditional classification can be implemented, for example, by training a specific OOS class to set up a rejection threshold, or even by training a binary classifier (Larson et al., 2019). Given that no specific domain information or structure are taken into account, those methods are roughly the same that have been previously applied for other classification problems (Fumera et al., 2003; Luckner and Homenda, 2014).

Some recent effort has been put specifically for

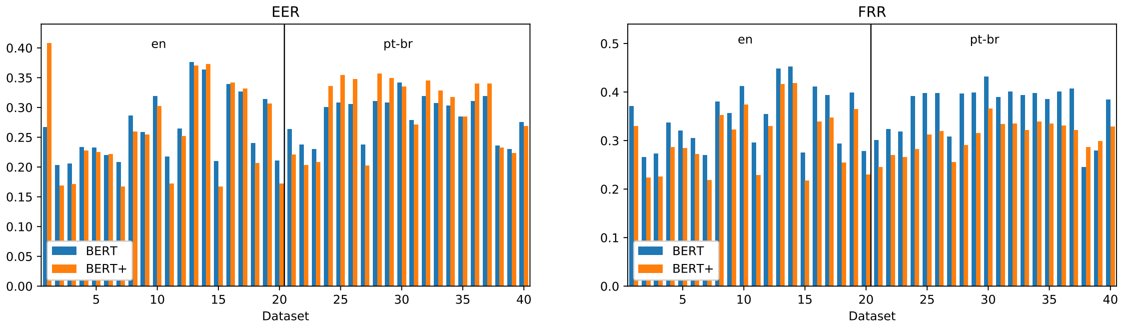

Figure 4: EER and FRR results for BERT and BERT+ on the Chatbots' datasets.

OOS sample detection for intent recognition, either by considering OOS data during the training process (Tan et al., 2019) or solely by improving in-scope sample representation by means of *Auto Encoders* (Ryu et al., 2017) and *Generative Adversarial Neural Networks (GANs)* (Ryu et al., 2018), which is more desirable since there is no reliance on tedious data gathering processes to represent unpredictable OOS inputs. The latter two methods are directly related to ours but, unfortunately, the lack of publicly-available source codes and datasets has made it a challenge to reproduce the methods for a fair direct comparison with ours.

Recently, methods which are able to take advantage of graph information in machine learning models have been proposed. Some of them take advantage at the sample level, such as label propagation (Bui et al., 2018). Others, though, take advantage of graphs at concept level, such as in (Hill et al., 2016; Kartsaklis et al., 2018; Prokhorov et al., 2019). Hill et al. (2016) demonstrate the sentence embeddings could be mapped onto graph embeddings, in reverse dictionary-like problems. Following, Kartsaklis et al. (2018) demonstrated that textual features can improve considerably such a mapping. Those findings have opened an opportunity to enhance class modeling and hopefully better define the scope of a classifier, in special intent classifiers, since classes can be easily represented in a graph space by means of their relationship with individual words extracted from the training samples as we did in this paper.

The previously-mentioned research have been put in practice mostly by advances in sentence embedding (Collobert et al., 2011; Pagliardini et al., 2018) and graph embedding techniques (Cai et al., 2018). Some of them are directly inspired by advances in word embeddings and convolutional neural networks, such as *DeepWalk* (Perozzi et al., 2014) and *Node2Vec* (Grover and Leskovec, 2016).

5 Final Remarks

In this paper we propose the use of information from word graphs to enhance intent classification, more specifically, for the detection of out-of-scope examples. Instead of working on the representation of the input text, we enhance the representation of the outputs, i.e. how classes and their corresponding labels are represented. The results demonstrate the approach has a considerable positive impact for the detection of out-of-scope examples when an appropriate sentence embedding such as LSTM and BERT is used. In the publicly-available Larson dataset, the proposed approach beats the previously-published results by a high margin, and particularly enhancing the false acceptance rate (FAR) from 41.1% to 9.9%.

In our view, the improved results are due to a better representation of the higher-level concepts associated to the classes. By connecting the intents to lower-level entities, i.e. the words associated to the intents, and therefore establishing inter-connections between the classes, the word graph space enriches the traditional representation of classes by means of classifier parameters which are learned solely from input examples.

We believe that the approach is general enough to be applied to others areas and presents ideas to develop more accurate classifiers in general, across multiple areas, particularly in contexts where out-of-scope samples are common. In image classification problems, for instance, word graphs related to visual words could be computed. In addition, the proposed word graph method can be improved by exploiting combinations of the proposed expanded class representation with the traditional softmax-based method, what may also provide better accuracy for in-scope samples in some situations.

Abstract

Language drift has been one of the major obstacles to train language models through interaction. When word-based conversational agents are trained towards completing a task, they tend to invent their language rather than leveraging natural language. In recent literature, two general methods partially counter this phenomenon: Supervised Selfplay (S2P) and Seeded Iterated Learning (SIL). While S2P jointly trains interactive and supervised losses to counter the drift, SIL changes the training dynamics to prevent language drift from occurring. In this paper, we first highlight their respective weaknesses, i.e., late-stage training collapses and higher negative likelihood when evaluated on human corpus. Given these observations, we introduce Supervised Seeded Iterated Learning (SSIL) to combine both methods to minimize their respective weaknesses. We then show the effectiveness of SSIL in the language-drift translation game.

1 Introduction

Since the early days of NLP (Winograd, 1971), conversational agents have been designed to interact with humans through language to solve diverse tasks, e.g., remote instructions (Thomason et al., 2015) or booking assistants (Bordes et al., 2017; El Asri et al., 2017). In this goal-oriented dialogue setting, the conversational agents are often designed to compose with predefined language utterances (Lemon and Pietquin, 2007; Williams et al., 2014; Young et al., 2013). Even if such approaches are efficient, they also tend to narrow down the agent's language diversity. To remove this restriction, recent work has been exploring interactive word-based training. In this setting, the agents are generally trained through a two-stage process (Wei et al., 2018; De Vries et al., 2017; Shah et al., 2018; Li et al., 2016a; Das et al., 2017): Firstly, the agent is pretrained on a human-labeled corpus through supervised learning to generate grammatically reasonable sentences. Secondly, the agent is finetuned to maximize the task-completion score by interacting with a user. Due to sample-complexity and reproducibility issues, the user is generally replaced by a game simulator that may evolve with the conversational agent. Unfortunately, this pairing may lead to the *language drift* phenomenon, where the conversational agents gradually co-adapt, and drift away from the pretrained natural language. The model thus becomes unfit to interact with humans (Chattopadhyay et al., 2017; Zhu et al., 2017; Lazaridou et al., 2020).

While domain-specific methods exist to counter language drift (Lee et al., 2019; Li et al., 2016b), a simple task-agnostic method consists of combining interactive and supervised training losses on a pretraining corpus (Wei et al., 2018; Lazaridou et al., 2016), which was later formalized as Supervised SelfPlay (S2P) (Lowe et al., 2020).

Inspired by language evolution and cultural transmission (Kirby, 2001; Kirby et al., 2014), recent work proposes Seeded Iterated Learning (SIL) (Lu et al., 2020) as another task-agnostic method to counter language drift. SIL modifies the training dynamics by iteratively refining a pretrained student agent by imitating interactive agents, as illustrated in Figure 1. At each iteration, a teacher agent is created by duplicating the student agent, which is then finetuned towards task completion. A new dataset is then generated by greedily sampling the teacher, and those samples are used to refine the student through supervised learning. The authors empirically show that this iterated learning procedure induces an inductive learning bias that successfully maintains the language grounding while improving task-completion.

As a first contribution, we further examine the performance of these two methods in the setting of a translation game (Lee et al., 2019). We show that

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3962–3970,
November 16–20, 2020.

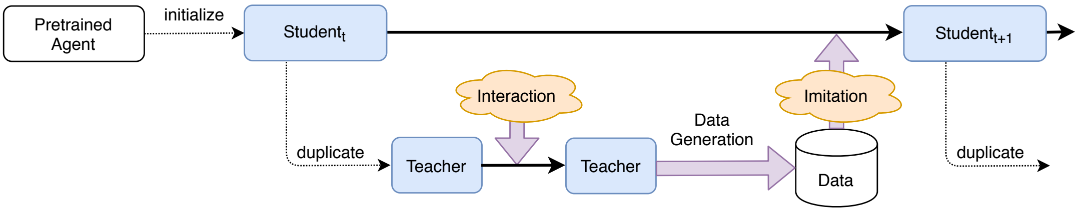

Figure 1: SIL (Lu et al., 2020). A student agent is iteratively refined using newly generated data from a teacher agent. At each iteration, a teacher agent is created on top of the student before being finetuned by interaction, e.g. maximizing a task completion-score. Teacher generates a dataset with greedy sampling and students imitate those samples. The interaction step involves interaction with another language agent.

S2P is unable to maintain a high grounding score and experiences a late-stage collapse, while SIL has a higher negative likelihood when evaluated on human corpus. We propose to combine SIL with S2P by applying an S2P loss in the interactive stage of SIL. We show that the resulting *Supervised Seeded Iterated Learning* (SSIL) algorithm manages to get the best of both algorithms in the translation game. Finally, we observe that the late-stage collapse of S2P is correlated with conflicting gradients before showing that SSIL empirically reduces this gradient discrepancy.

2 Preventing Language Drift

We describe here our interactive training setup before introducing different approaches to prevent language drift. In this setting, we have a set of collaborative agents that interact through language to solve a task. To begin, we train the agents to generate natural language in a word-by-word fashion. Then we finetune the agents to optimize a task completion score through interaction, i.e., learning to perform the task better. Our goal is to prevent the language drift in this second stage.

2.1 Initializing the Conversational Agents

For a language agent f parameterized by $\boldsymbol{\theta}$, and a sequence of generated words $\boldsymbol{w}_{1:i} = [w_j]_{j=1}^{i}$ and an arbitrary context $\boldsymbol{c}$, the probability of the next word w_i is $p(w_{i+1}|\boldsymbol{w}_{1:i}, \boldsymbol{c}) = f_{\boldsymbol{\theta}}(\boldsymbol{w}_{1:i}, \boldsymbol{c})$ We pretrain the language model to generate meaningful sentences by minimizing the cross-entropy loss $\mathcal{L}^{\text{CE}}_{pretrain}$ where the word sequences are sampled from a language corpus $D_{pretrain}$. Note that this language corpus may either be task-related or generic. Its role is to get our conversational agents a reasonable initialization.

2.2 Supervised Selfplay (S2P)

A common way to finetune the language agents while preventing language drift is to replay the pretraining data during the interaction stage. In S2P the training loss encourages both maximizing task-completion while remaining close to the initial language distribution. Formally,

$$\mathcal{L}^{\text{S2P}} = \mathcal{L}^{\text{INT}} + \alpha \mathcal{L}^{\text{CE}}_{pretrain} \tag{1}$$

where $\mathcal{L}^{\text{INT}}$ is a differentiable interactive loss maximizing task completion, e.g. reinforcement learning with policy gradients (Sutton et al., 2000), Gumbel Straight-through Estimator (STE) (Jang et al., 2017) etc., $\mathcal{L}^{\text{CE}}_{pretrain}$ is a cross-entropy loss over the pretraining samples. α is a positive scalar which balances the two losses.

2.3 Seeded Iterated Learning (SIL)

Seeded Iterated Learning (SIL) iteratively refines a pretrained *student* model by using data generated from newly trained *teacher* agents (Lu et al., 2020). As illustrated in Figure 1, the student agent is initialized with the pretrained model. At each iteration, a new teacher agent is generated by duplicating the student parameters. It is tuned to maximize the task-completion score by optimizing the interactive loss $\mathcal{L}^{\text{TEACHER}} = \mathcal{L}^{\text{INT}}$ In a second step, we sample from the teacher to generate new training data $D_{teacher}$, and we refine the student by minimizing the cross-entropy loss $\mathcal{L}^{\text{STUDENT}} = \mathcal{L}^{\text{CE}}_{teacher}$ where sequence of words are sampled from $D_{teacher}$. This imitation learning stage can induce an information bottleneck, encouraging the student to learn a well-formatted language rather than drifted components.

2.4 SSIL: Combining SIL and S2P

S2P and SIL have two core differences: first, SIL never re-uses human pretraining data. As observed in Section 4.1, this design choice reduces the language modeling ability of SIL-trained agents, with a higher negative likelihood when evaluated on human corpus. Second, S2P agents merge interactive and supervised losses, whereas SIL's stu-

Finetuning Methods	*Training Losses*
Gumbel	$\mathcal{L}^{\text{INT}}$
S2P	$\mathcal{L}^{\text{INT}} + \alpha\mathcal{L}^{\text{CE}}_{pretrain}$
SIL (teacher)	$\mathcal{L}^{\text{INT}}$
SIL (student)	$\mathcal{L}^{\text{CE}}_{teacher}$
SSIL (teacher)	$\mathcal{L}^{\text{INT}} + \alpha\mathcal{L}^{\text{CE}}_{pretrain}$
SSIL (student)	$\mathcal{L}^{\text{CE}}_{teacher}$

Table 1: Finetuning with respective training objective.

dent never experiences an interactive loss. As analyzed in Section 4.3, the S2P multi-task loss induces conflicting gradients, which may trigger language drift. In this paper, we propose to combine these two approaches and demonstrate that the combination effectively minimizes their respective weaknesses. To be specific, we apply the S2P loss over the SIL teacher agent, which entails $\mathcal{L}^{\text{TEACHER}} = \mathcal{L}^{\text{INT}} + \alpha\mathcal{L}^{\text{CE}}_{pretrain}$. We call the resulting algorithm, Supervised Seeded Iterated Learning (SSIL). In SSIL, teachers can generate data that is close to the human distribution due to the S2P loss, while students are updated with a consistent supervised loss to avoid the potential weakness of multi-task optimization. In addition, SSIL still maintains the inductive learning bias of SIL. We list all these methods in Table 1 for easy comparison. We also experiment with other ways of combining SIL and S2P by mixing the pretraining data with teacher data during the imitation learning stage. We call this method *MixData*. We show the results of this approach in Appendix 4.2. We find that this approach is very sensitive to the mixing ratio of these two kinds of data, and the best configuration is still not as good as SSIL.

3 Experimental Setting

3.1 Translation Game

We replicate the translation game setting from (Lee et al., 2019) as it was designed to study language drift. First, a *sender* agent translates French to English (Fr-En), while a *receiver* agent translates English to German (En-De). The sender and receiver are then trained together to translate French to German with English as a pivot language. For each French sentence, we sample English from the sender, send it to the receiver, and sample German from the receiver. The task score is defined as the BLEU score between generated German translation and the ground truth (*BLEU De*) (Papineni et al., 2002). The goal is to improve the task score without losing the language structure of the intermediate English language.

3.2 Training Details

The sender and the receiver are pretrained on the IWSLT dataset (Cettolo et al., 2012) which contains (Fr, En) and (En, De) translation pairs. We then use the Multi30k dataset (Elliott et al., 2016) to build the finetuning dataset with (Fr, De) pairs. As IWSLT is a generic translation dataset and Multi30k only contains visually grounded translated captions, we also call IWSLT task-agnostic while Multi30K task-related. We use the cross-entropy loss of German as the interactive training objective, which is differentiable w.r.t. the receiver. For the sender, we use Gumbel Softmax straight-through estimator to make the training objective also differentiable w.r.t. the sender, as in Lu et al. (2020). Implementation details are in Appendix B

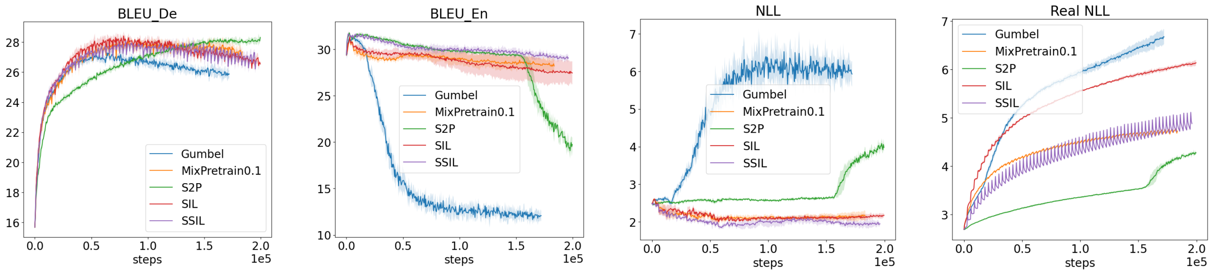
3.3 Metrics for Grounding Scores

In practice, there are different kinds of language drift (Lazaridou et al., 2020) (e.g. syntactic drift and semantic drift). We thus have multiple metrics to consider when evaluating language drift. We first compute English BLEU score (*BLEU En*) comparing the generated English translation with the ground truth human translation. We include the negative log-likelihood (*NLL*) of the generated En translation under a pretrained language model as a measure of syntactic correctness. In line with (Lu et al., 2020) , we also report results using another language metric: the negative log-likelihood of human translations (*RealNLL*) given a finetuned Fr-En model. We feed the finetuned sender with human task-data to estimate the model's log likelihood. The lower is this score, the more likely the model would generate such human-like language.

4 Experiments

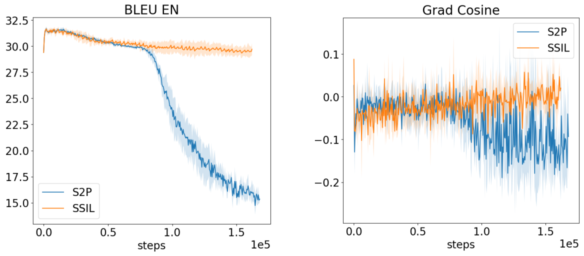
4.1 S2P and SIL Weaknesses

We report the task and grounding scores of vanilla Gumbel, S2P, SIL, and SSIL in Figure 2. The respective best hyper-parameters can be found in the appendix. As reported by Lu et al. (2020), vanilla Gumbel successfully improves the task score *BLEU De*, but the *BLEU En* score as well as other grounding metric collapses, indicating a language drift during the training. Both S2P and SIL manage to increase *BLEU De* while maintaining a higher *BLEU En* score, countering language drift. How-



(a) BLEU De (Task Score) (b) BLEU En (c) NLL (d) RealNLL

Figure 2: Task and language metrics for Vanilla Gumbel, SIL, S2P, and SSIL in the translation game average over 5 seeds. We also show the results of mixing pretraining data in the teacher dataset (Section 4.2). The plots are averaged over 5 seeds with shaded area as standard deviation. Although SIL and S2P both counter language drift, S2P suffers from late collapse, and SIL has a high *RealNLL*, suggesting that its output may not correlate well with human sentences.



(a) Bleu En (b) Cosine Similarity

Figure 3: Cosine similarity between the gradients issued from $\mathcal{L}^{\text{INT}}$ and $\mathcal{L}^{\text{CE}}_{pretrain}$. The collapse of the BLEU En matches the negative cosine similarity.

ever, S2P has a sudden (and reproducible) late-stage collapse, unable to maintain the grounding score beyond 150k steps. On the other hand, SIL has a much higher RealNLL than S2P, suggesting that SIL has a worse ability to model human data. SSIL seems to get the best of the two worlds. It has a similar task score *BLEU De* as S2P and SIL, while it avoids the late-stage collapse. It ends up with the highest *BLEU En*, and it improves the RealNLL over SIL, though still not as good as S2P. Also, it achieves even better NLL, suggesting that its outputs are favoured by the pretrained language model.

4.2 Mixing Teacher and Human Data

We also explore whether injecting pretraining data into the teacher dataset may be a valid substitute for the S2P loss. We add a subset of the pretraining data in the teacher dataset before refining the student, and we report the results in Figure 2 and 6. Unfortunately, such an approach was quite unstable, and it requires heavy hyper-parameters tuning to match SSIL scores. As explained in (Kirby, 2001), iterated learning rely on inductive learning to remove language irregularities during the imitation step. Thus, mixing two language distributions may disrupt this imitation stage.

4.3 Why S2P collapses?

We investigate the potential cause of S2P late-stage collapse and how SSIL may resolve it. We firstly hope to solve this by increasing the supervised loss weight α. However, we find that a larger α only delays the eventual collapse as well as decreases the task score, as shown in Figure 5 in Appendix D.

We further hypothesize that this late-stage collapse can be caused by the distribution mismatch between the pretraining data (IWSLT) and the task-related data (Multi30K), exemplified by their word frequencies difference. A mismatch between the two losses could lead to conflicting gradients, which could, in turn, make training unstable. In Figure 3, we display the cosine similarity of the sender gradients issued by the interactive and supervised losses $cos(\nabla_{sender}\mathcal{L}^{\text{INT}}, \nabla_{sender}\mathcal{L}^{\text{CE}}_{pretrain})$ for both S2P and SSIL for $\alpha = 0.5$ during training. Early in S2P training, we observe that the two gradients remain orthogonal on average, with the cosine oscillating around zero. Then, at the same point where the S2P *Bleu En* collapses, the cosine of the gradients starts trending negative, indicating that the gradients are pointing in opposite directions. However, SSIL does not have this trend, and the *BLEU En* does not collapse. Although the exact mechanism of how conflicting gradients trigger the language drift is unclear, current results favor our hypothesis and suggest that language drift could result from standard multi-task optimization issues (Yu et al., 2020; Parisotto et al., 2016; Sener and Koltun, 2018) for S2P-like methods.

Conclusion We investigate two general methods to counter language drift: S2P and SIL. S2P experiences a late-stage collapse on the grounding score, whereas SIL has a higher negative likelihood on human corpus. We introduce SSIL to combine these two methods effectively. We further show the correlation between S2P late-stage collapse and conflicting gradients.

(b) Cosine Similarity

Figure 4: Cosine similarity bewteen $\mathcal{L}^{\text{CE}}_{pretrain}$ and $\mathcal{L}^{\text{INT}}$ when $\alpha = 0.7$

B Translation Game Implementation Details

We here report the experimenatl protocol from We use the Moses tokenizer (Koehn et al., 2007) and we learn a byte-pair-encoding (Sennrich et al., 2016) from Multi30K with all language. Then the same BPE is applied to different dataset. Our vocab size for En, Fr, De is 11552, 13331, and 12124. Our pretraining datasets are IWSLT while the finetuning datasets are Multi30K. Our language model is trained with captions data from MSCOCO (Lin et al., 2014). For image ranker, we use the captions in Multi30K as well as the original Flickr30K images. We use a ResNet152 with pretrained ImageNet weights to extract the image features. We also normalize the image features. We follow the pretraining and model architecture from work (Lu et al., 2020).

C Hyper-parameters

During finetuning, we set Gumbel temperature to be 0.5 and follow the previous work (Lu et al., 2020) for other hyperparameters, e.g. learning rate, batch size, etc. We list our hyper-parameters and our sweep: We mainly use P100 GPU for our experiments. For training 200k steps, Gumbel takes 17 hours, S2P takes 24 hours, SIL takes 18 hours and SSIL takes 24 hours. The best hyperparameters for SIL are $k_1 = 3000, k_2 = 200, k_2' = 300$. The best $alpha$ for $S2P$ is 1, while for $SSIL$ we choose $\alpha = 0.5$.

Name	Sweep
k_1	3000, 4000
k_2	200, 300, 400
k_2'	200, 300, 400
α	0, 0.01, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7

D S2P Details

We show the results of S2P with varying α in Figure 5. In general, one can find that for S2P there is a trade-off between grounding score and task score controlled by α. A larger α might delay the eventual collapse. However, if the α is too large, the task score will decrease significantly. As a result, even though increasing α seems to fit the intuition, it cannot fix the problem.

Abstract

The lack of time-efficient and reliable evaluation methods hamper the development of conversational dialogue systems (chatbots). Evaluations requiring humans to converse with chatbots are time and cost-intensive, put high cognitive demands on the human judges, and yield low-quality results. In this work, we introduce *Spot The Bot*, a cost-efficient and robust evaluation framework that replaces human-bot conversations with conversations between bots. Human judges then only annotate for each entity in a conversation whether they think it is human or not (assuming there are humans participants in these conversations). These annotations then allow us to rank chatbots regarding their ability to mimic the conversational behavior of humans. Since we expect that all bots are eventually recognized as such, we incorporate a metric that measures which chatbot can uphold human-like behavior the longest, i.e., *Survival Analysis*. This metric has the ability to correlate a bot's performance to certain of its characteristics (e.g., fluency or sensibleness), yielding interpretable results. The comparably low cost of our framework allows for frequent evaluations of chatbots during their evaluation cycle. We empirically validate our claims by applying *Spot The Bot* to three domains, evaluating several state-of-the-art chatbots, and drawing comparisons to related work. The framework is released as a ready-to-use tool.

1 Introduction

Evaluation is a long-standing issue in developing conversational dialogue systems (i.e., chatbots). The underlying difficulty in evaluation lies in the problem's open-ended nature, as chatbots do not solve a clearly-defined task whose success can be measured in relation to an a priori defined ground truth. Automatic metrics have so far failed to show high correlation with human evaluations (Liu et al., 2016; Lowe et al., 2017; Mehri and Eskenazi, 2020). Human evaluation approaches are mainly classified according to the following: single-turn vs. multi-turn evaluation, and direct user evaluation vs. expert judge evaluation. Single-turn analysis is usually performed by a human judge that rates a single response of the bot to a given context, whereas multi-turn analysis is often performed by a user that interacts with the bot and rates the interaction. Single-turn ratings disregard the multi-turn nature of a dialogue (See et al., 2019). Although more and more multi-turn evaluations are performed, most of them are based on human-bot conversations, which are costly to obtain and tend to suffer from low quality (Dinan et al., 2020a). The instructions to be followed by annotators are often chosen ad-hoc and there are no unified definitions. Compounded with the use of often criticized Likert scales (Amidei et al., 2019a), these evaluations often yield a low agreement. The required cost and time efforts also inhibit the widespread use of such evaluations, which raises questions on the replicability, robustness, and thus significance of the results.

In this work, we present the *Spot The Bot* framework, a cost-efficient evaluation methodology that can be used to rank several bots with regard to their ability to disguise as humans. It works as a multi-turn-based evaluation with human judges. *Spot The Bot* is based on two observations: First, chatbots are trained on conversations between humans, and thus, they should be evaluated regarding their ability to mimic human behavior. Second, the longer a conversation is, the more likely it is that a bot exhibits non-human-like behavior.

Spot The Bot works by generating conversations between bots, then mixing these bot-bot conversations with human-human conversations and letting

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3971–3984,
November 16–20, 2020.

human judges decide for each entity in the conversations if it is a human or a bot. The conversations are rated at different points in time, which introduces the time-dependent component. This setting allows for two different analyses: a *ranking based on pairwise comparisons of bots*, and the application of the *Survival Analysis*, which computes the survival rate for each bot at different conversation lengths. Furthermore, the human judges annotate the entities with respect to more fine-grained features, which can be chosen based on characteristics that the bots are expected to exhibit (e.g. fluency or informativeness). The Survival Analysis further allows to pin down the features that contribute to a dialogue system's survival, enabling interpretable results.

We show that our framework produces reliable, repeatable results, while being quicker and more cost-effective to run than related approaches, as it does not rely on human-bot conversations and generally requires fewer annotations. Furthermore, we show that disagreement between human annotators can be interpreted as a feature of a system's performance, rather than a weakness in the evaluation approach. We apply the framework to three well-known domains and common baselines and state-of-the-art systems to produce a stable ranking among them. We release the framework as a ready-to-use tool for evaluating dialogue systems into which different systems can be plugged and compared[1].

2 Related Work

There exist various methods to evaluate dialogue systems, both automatic and human-based, but no single evaluation metric is widely agreed upon in the scientific community (Deriu et al., 2020). Automatic evaluation metrics for chatbots are known to correlate poorly with human ratings (Liu et al., 2016; Lowe et al., 2017; Mehri and Eskenazi, 2020), so we focus on human-based approaches, which can be classified in two dimensions: 1) single-turn vs. multi-turn approaches, and 2) approaches where the dialogue systems are judged by the user directly (interactive) or where judgments are made by objective experts, who do not participate in the dialogue (static).

Single-turn Static Evaluations. Evaluations based on a static context and a single response from the dialogue systems are widely adopted. Usually, the rating is performed by expert raters that read the response of one or more dialogue systems to a static context and rate the responses (Galley et al., 2018). Alternatively, the responses of two bots can be compared directly to choose a preferred answer (Li et al., 2016). While being relatively time and cost-efficient, single-turn evaluation fails to capture the conversation's quality as a whole. A system that tends to produce repeated answers can obtain a high single-turn score, albeit a low multi-turn one (See et al., 2019). Some authors also report poor inter-annotator agreement (Ghandeharioun et al., 2019).

Human-Bot Conversations. In order to perform interactive multi-turn evaluations, the standard method is to let humans converse with a chatbot and rate it afterward (Ghandeharioun et al., 2019), typically using Likert scales (van der Lee et al., 2019). The ConvAI2 challenge (Dinan et al., 2020b) and the Alexa Prize (Venkatesh et al., 2018) applied this procedure. Apart from the high cost of collecting human-bot conversations, this approach puts a high cognitive strain on humans, as they have to perform several tasks at once (Schmitt and Ultes, 2015). Besides, it is not always possible to get sensible conversations with bots, making it hard to get high-quality conversations. In fact, in the ConvAI2 challenge, half of the collected human-bot conversations were discarded due to their low quality (Dinan et al., 2020b). Finally, Likert scales are known to suffer from high annotation variance (Ghandeharioun et al., 2019), require normalization a posteriori, are prone to order effects and are less reliable than ranking-based ratings (Amidei et al., 2019b).

Self-talk. Recently, using self-talk dialogues, i.e., dialogues where a bot talks to itself, gained traction as a cost-effective basis for evaluation. This idea is closely related to user simulations used to evaluate task-oriented systems (Schatzmann et al., 2006). Ghandeharioun et al. (2019) and Deriu and Cieliebak (2019) use self-talk to produce automatic evaluations. In ACUTE-EVAL (Li et al., 2019), the authors propose to let humans evaluate self-talk dialogues. Since self-talk does not allow direct comparisons between bots, the authors let humans read two self-talk conversations

Figure 1: Overview of the *Spot The Bot* process for one conversation. 1: A bot-bot conversation is segmented into different lengths (e.g. 2, 3, and 5 exchanges). 2: These segments are shown to distinct sets of annotators who judge whether each entity is a bot. 4: The winner is determined for each annotated segment and survival statistics are updated. This process is repeated for all conversations between the competing bots.

side-by-side and rate them with respect to various features. This increases the cognitive complexity of the annotation task. Furthermore, the resulting ranking of the bots is per criterion, whereas our method produces one ranking and can optionally incorporate annotations of features that yield interpretability of the results.

Turing Test. *Spot The Bot* is reminiscent of the Turing Test (Turing, 1950), as the dialogue systems are evaluated based on their ability to mimic human behavior. The Turing test served as a useful mental model for understanding what machine intelligence might mean. However, it has also been criticized as a way to identify intelligence in NLP systems. Bender and Koller (2020) argues that a system may fool a user into believing it is human, and yet this does not prove that the system understands the meaning of the conversation they are having. In our approach, we claim that *failing* the test is a valid indicator to discriminate among bots. In fact, we presume that eventually all bots will fail the test, and we collect a time component to record the time it takes for a bot to be detected.

3 Spot The Bot

In this section, we first provide an overview of the *Spot The Bot* framework and then describe the evaluation process's individual steps.

3.1 Overview

Spot The Bot employs a tournament among chatbots to determine which performs the best at mimicking humans' conversational behavior. To measure the success of each bot, human crowdworkers are shown conversations between two competing bots at a time, mixed with conversations between two humans. The crowdworkers' task is to determine for each entity in a conversation whether it is a human or a bot (or whether the crowdworker is unsure). The bot that is most frequently annotated as being human wins the tournament. Figure 1 provides an overview of the process for one conversation.

There are different use cases for *Spot The Bot*, e.g., when a novel dialogue strategy is to be compared against existing ones or if a set of chatbots is to be ranked in the context of a shared task. On top of returning a ranking, *Spot The Bot* employs the Survival Analysis, which introduces a time aspect into the evaluation and provides insights into how different features correlate to the bots' ability to pass as a human.

Formally, assume a pool of b bots $\{B_1, ..., B_b\}$, which is to be ranked. For each pair of bots, a set of conversations is sampled by letting the bots talk to each other, where S_{ij} denotes the set of conversations between bots B_i and B_j. Each conversation is defined as a sequence of exchanges $e_0, ..., e_N$, where each exchange consists of two turns: $e_i = \{t_0^{e_i}, t_1^{e_i}\}$, one for each entity.

Segmentation. The more exchanges there are in a conversation, the more likely it is that a bot gets recognized as such. Thus, we show different segments of the conversation to the crowdworkers. A segment is defined as the first k exchanges of the dialogue: $S_{ij}^k = e_0, ..., e_k$. Thus, an annotator only sees the first k exchanges of the conversation.[2] Each segment of the same conversation is rated by a different annotator to avoid that one annotator sees parts of the same conversation multiple times, which would bias the rating. We choose different segment lengths since we cannot know a priori which length is sufficient for the different bots to be recognized as such.

Human Conversations. We add conversations among humans to the pool of conversations that are to be rated. The human conversations are sampled from the training set used to train the dialogue systems in the respective domain. The results of the annotations of the human dialogues establish an upper bound for the evaluation. Also, they are meant to prevent annotators from concluding that all entities are bots.[3]

Annotation. The annotation procedure works in two steps: First, the annotators have to decide for each entity in a conversation segment if it is a bot or a human. Second, to correlate the outcome to various characteristics of a bot, the framework allows rating specific features (e.g., fluency or appropriateness). The framework then measures the influence of these features on the survival time of the bots, which serves as an explainability component (cf. Sections 3.3 and 4.2).

Features. We chose three features: sensibleness, specificity (Adiwardana et al., 2020), and fluency. The first two are shown to capture the core conversational behavior of answering sensibly and not with illogical statements while being specific to the conversation's given context. The third feature states if the utterances are grammatically correct and fluent. The features are rated by preference ranking, that is, the annotator states which of the two entities performed better with respect to the features.

3.2 Ranking

We define a win function for the annotations of the pairwise, direct conversations between two bots. The outputs of the win function are aggregated to determine the overall winner of the tournament.

Win Function. Each annotation at each segment length $S_{ij}^k = e_0, ..., e_k$ of a conversation constitutes the result of one annotation applied by one crowdworker, individually labeling each of the two entities as either *bot, human*, or *unsure*. The winner of segment S_{ij}^k under a crowdworker's annotation is determined by the following ordering of the labels: *human* $>$ *unsure* $>$ *bot*. That is, if bot B_i is assigned the label *human* and bot B_j has label *bot* or *unsure*, B_i has won the segment.[4] Similar to Bojar et al. (2013), we define a win rate of B_i against B_j to aggregate the wins from all segments of all annotations stemming from conversations between bots B_i and B_j, as:

$$\frac{\textsc{wins}(B_i, B_j)}{\textsc{wins}(B_i, B_j) + \textsc{wins}(B_j, B_i)} \tag{1}$$

where $\textsc{wins}(B_i, B_j)$ denotes the number of times that B_i wins against B_j.

Ranking. To create the ranking, we follow the approach by Dušek et al. (2018), where the ranking is generated by the TrueSkill (Herbrich et al., 2006) algorithm based on the win rate, and significant differences in performance are determined by bootstrap sampling. The result is a ranked set of clusters, where each cluster is composed of entities that do not have a significant difference in performance.

3.3 Survival Analysis

While pair-wise win rates are well-suited to provide a *relative* ranking among a pool of bots, it does not serve as an *absolute* evaluation of a single bot's ability to disguise as a human. Also, the conversations' segmentation introduces a time component, which we leverage to investigate our intuition that bots are more likely to reveal themselves in longer conversations. In our evaluation, a bot that is able to disguise in long conversations can be said to be most successful. Thus, we complement our evaluation with *Survival Analysis*.

Survival Analysis estimates probabilities for the occurrence of an event at different points in time. It has a long history in the medical domain, where it is used to estimate the effectiveness of different

---

[2] We experimented with letting crowdworkers decide where they were sure that an entity is a bot or a human. However, this approach required too much fine-tuning to constrain erratic annotator behavior, cf. Appendix B.

[3] We investigated if annotators realize that conversations are either between bots or humans by looking at ratios of conversations where both entities are labeled identically, but found no evidence that this happens more often than by chance.

[4] This process is repeated for all crowdworkers who annotated the segment - in our case two per segment - and each win is counted separately.

treatments (Li and Ma, 2013). In engineering disciplines, it is applied to estimate the time to failure of machine components (Eyal et al., 2014). In our case, we are interested in the time, corresponding to the number of exchanges, until a dialogue system is spotted as such. In addition, Survival Analysis allows us to correlate finer-grained characteristics to the survival probability, which allows us to inspect which of the annotated features impact a bot's survival.

We interpret the annotation data as such: the *spotted* event occurred if the system was annotated as "bot" and it *survived* if it was annotated as "unsure" or "human". Let k be the number of exchanges in the annotated conversation segment, meaning that each dialog system produced k outputs. If the dialog system was not spotted, we know it survived for at least k exchanges. This is a so-called right-censored data point. If the dialogue system was spotted as such, we cannot tell the exact number of exchanges it took for an annotator to spot it, meaning it could have taken less than k exchanges. We thus record that the spotting event happened in the interval $(0, k]$, a so-called interval-censored event. From this data, we can get non-parametric estimates of the survival function of the different systems per domain (Turnbull, 1974). To check whether these differences are significant, we apply a generalized log-rank test (Zhao and Sun, 2004). We use the *Cox Proportional Hazards Model* (Cox, 1972) to study the influence of the features outlined in Section 3.1 on the time before the systems are spotted.[5]

4 Experiments

Domains. We apply *Spot The Bot* to three widely used domains for conversational dialogue systems: Dailydialog (Li et al., 2017), Empathetic Dialogues (Rashkin et al., 2019), and PersonaChat (Zhang et al., 2018). For each domain[6], we prepared a pool of bots to be ranked and analyzed. For each pair of bots, we sampled $|S_{ij}| = 45$ conversations. For this, we seed the conversations by using the first exchange of a conversation in the test set, which is sampled at random. Although there exists a probability that the bots resample parts of a conversation, we did not find evidence of this happening. In fact, only 2% of all sampled conversations contain an exchange, which can be found in the training material. For the annotation task, we recruited paid crowdworkers from Amazon Mechanical Turk (AMT). To avoid that, the results are biased towards the performance of a few crowdworkers, we designed a Human Intelligence Task as a batch of 20 conversations, and each worker was only allowed to work on three batches. We designed the batches so that two segments of the same conversations never appear in the same batch, and each batch contains different segments of different conversations.

Segmentation. The segment lengths are based on the lengths of the dialogues in a domain. Since we add human conversations of the training set to be rated, the sampled dialogues should adhere to their lengths. PersonaChat and Dailydialog have longer conversations; thus, we used segments of 2, 3, and 5 exchanges. The Empathetic Dialogue domain has shorter dialogues; thus, we used segment lengths of 1, 2, and 3 exchanges.

Dialogue Systems. For each domain, we prepared a pool of dialogue systems to be ranked. If applicable, we reused existing systems. In order to assess the performance of *Spot The Bot* regarding weak models, we trained a small sequence-to-sequence model (DR) for only 3 epochs, which returns mostly general answers. For the Dailydialog domain, we trained all bots in the pool using ParlAI as there were no pre-trained models available. To leverage the recently developed language models, we fine-tune a GPT-2 (GPT) model (Radford et al., 2018), and a BERT-Rank (BR) model. Additionally, we train a sequence-to-sequence model (S2) with attention to compare the language models to previous state-of-the-art approaches. Together with the DR model, the pool consists of $b = 4$ systems. For the Empathetic Dialogues, we prepared the same pool of models as in Dailydialog. Since the recently developed Blender model (Roller et al., 2020) is trained on the Empathetic Dialogue dataset as well, we add the pre-trained version to the pool (BL). For the PersonaChat domain, we mostly reuse the openly available systems of the ConvAI2 challenge (Dinan et al., 2020a), namely, Lost in Conversation[7] (LC) and Huggingface [8]

---

[5] We use the *icenReg* R package (Anderson-Bergman, 2017), which allows us to fit a Cox model to our interval-censored data.

[6] See details in Appendix E.

[7] `https://github.com/atselousov/transformer_chatbot`

[8] `https://github.com/huggingface/transfer-learning-conv-ai`

(HF), which were the top-rated dialogue systems in the ConvAI2 challenge (Dinan et al., 2020a), as well as KVMemNN (KV), which served as the baseline. We also add the Blender model, which is also trained in this domain. In order to have more retrieval based systems, we train a BertRank (BR) model. Together with the DR model, the pool consists of $b = 6$ different dialogue systems.

4.1 Ranking Results

Table 1 gives an overview of the win rates for each pair of bots and their ranking ranges. The Chi-square test computes the significance. For each domain, most pairwise win-rates are significant.

As expected, DR performs worst in all three domains, which is due to its repetitive nature, which is exposed over the course of a dialogue. In the Dailydialog and the Empathetic Dialogues domains, the GPT2 and the BR models perform equally, i.e., they end up in the same cluster. In both domains, systems using pre-trained language models outperform the S2 model, which is learned from scratch, which aligns with the expectation of related findings. The BL model outperforms all other models in both the PersonaChat and Empathetic Dialogues domains, which is in line with the results presented by the authors of the Blender model (Roller et al., 2020). Furthermore, the LC model is ranked very highly. This corresponds to the findings of the ConvAI2 challenge (Dinan et al., 2020a). However, in *Spot The Bot*, the KV is ranked much higher than the HF model, which is not in line with the ConvAI2 evaluation.

Table 2: Per feature win-rate of the different systems over all domains. Bold numbers indicate that the feature has a significant influence on system survival according to a Cox model.

Figure 2 shows the survival functions for the three domains. The survival rates produce the same rankings as those from pairwise win rates reported in Table 1, except for the Empathetic Dialogues domain, where GPT and BR switch places. Importantly, the distinction between these two is not significant in any of the rankings. Further non-significant differences within the Survival Analysis are S2 and DR in the Empathetic Dialogues domain, BR and S2 in the Dailydialog domain, and LC and KV in the PersonaChat domain. All other pairwise comparisons of survival curves are significant with $p < 0.05$ after correction for multiple comparisons.

Feature Influence. For each of the three features – fluency, specificity, and sensibleness – annotators

Figure 2: Survival function per system estimated for each domain.

have to specify whether one entity performed better, the same, or worse than the other. We encode this information as 1, 0, and -1 respectively and fit a Cox proportional hazards model (Cox, 1972) for every system independently with the features as covariates.

The numerical entries in Table 2 refer to the per-feature win-rate of each bot, which is computed analogously to Equation 1 using the feature annotations directly. Bold entries in Table 2 show which features have a significant influence on the system being spotted. All significant effects go in the intuitive direction, meaning that a higher feature value leads to longer survival. For example, for the DR model, the fluency feature is significant across all three domains, and together with its low fluency win rate, we can deduce that it is often spotted due to its low fluency. Sensibleness seems to be an important feature across the board, meaning that in general, bots can be spotted due to inappropriate, nonsensical answers or hide if they respond in a suitable manner. Interestingly, specificity seems to be mostly unimportant, which could be due to either the bots not being noticeably unspecific, or it being an irrelevant feature for the chosen domains.

5 Discussion

5.1 On Inter-Annotator Agreement

The robustness of the evaluation of chatbots is often hampered by inter-annotator agreement (IAA) (Gandhe and Traum, 2016). Measuring and reporting IAA is not yet a standard practice in evaluating chatbots (Amidei et al., 2019a), and producing annotations with high IAA on open-domain conversations is prone to be impeded by subjective interpretation of feature definitions and idiosyncratic annotator behavior (Bishop and Herron, 2015).

In our setting, annotator disagreement on a bot's human-like behavior can be interpreted as a *feature* of a bot's performance: A bot that manages to fool one of two annotators into believing it is human can be said to have performed better than a bot that does not manage to fool any annotator.

To analyze the annotator agreement in this light, we calculate per bot and label the percentage of cases where both annotators annotate the label if one of them does. Given three labels (*human, bot, unsure*), the chance for random agreement is 0.33. The results averaged over all investigated domains and segment lengths per bot, are shown in Table 3.[9]

The results confirm that the bots that rank high based on win rates and in the survival analysis (BL, GPT, LC) obtain the highest agreement on the *human* label and lowest agreement on the *bot* label. Conversely, the DR system obtains the highest agreement when being identified as a bot, and lowest when it is perceived as a human.

label	bot ↓	human ↑	unsure
human	*0.33*	*0.84*	*0.15*
BL	0.38	0.65	0.14
LC	0.60	0.52	0.10
GPT	0.65	0.48	0.15
HF	0.70	0.41	0.10
KV	0.64	0.49	0.08
BR	0.74	0.39	0.15
DR	0.85	0.29	0.17

Table 3: Annotator agreement on labels.

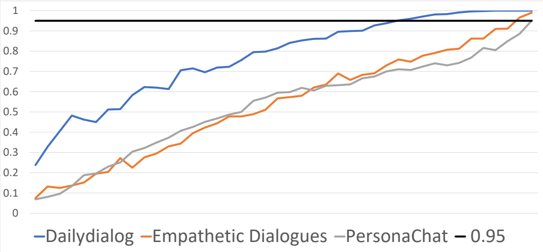
This analysis suggests that our experiments' results do not stem from a random agreement between the annotators, i.e., the annotations of the best and worst-performing systems show agreement distinctly higher than chance regarding the respective labels.

---

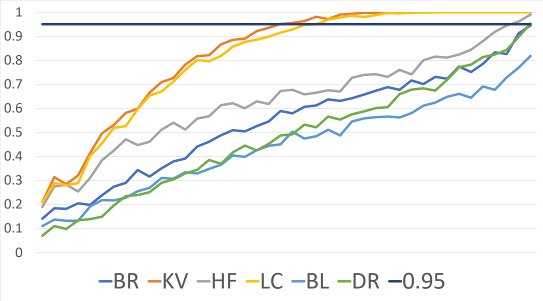
[9] We also analyzed agreement per segment length and domain but found no significant difference to averaging agreement over domains and segment lengths.

5.2 On Reliability

One key requirement for an evaluation procedure is that repeated executions of the procedure result in the same outcome. We measure how many pairwise conversations between two bots are needed to guarantee a stable ranking. That is, what is the lower bound to $|S_{ij}|$ so that the ranking is stable. For each $|S_{ij}| \in \{3...45\}$, we randomly sample $|S_{ij}|$ conversation for each pair and compute the ranking. We repeat this subsampling procedure 1000 times and measure the minimum $|S_{ij}|$ that guarantees the same ranking in at least 95% of cases. Figure 3a shows for each $|S_{ij}| \in \{3...45\}$ the proportion of times in which the most frequent ranking occurred. For the Dailydialog domain, $|S_{ij}| = 33$ pairwise conversations are enough to guarantee a stable ranking. In the other two domains, this value is reached with over 40 pairwise dialogues.



(a) Stability Experiment.



(b) Leave-one-out Experiment.

Figure 3: Ranking stability experiments.The x-axis denotes the number of pairwise conversations between two bots. The y-axis denotes the rate at which the same ranking is achieved across 1000 repetitions. The horizontal line denotes the 95% mark. In the lower Figure, we show the experiments for the PersonaChat domain, when leaving one system out.

A more in-depth analysis reveals that ranking stability depends on the significance of pairwise comparisons. For instance, in the PersonaChat domain, the KV and LC systems are not significantly different, which leads to two different rankings depending on the subsampling: in the first, KV and LC are in the same cluster, and in the second, LC and KV are in separate clusters, with LC being on top. Thus, removing either of them from the pool would yield a more stable ranking. To investigate this further, we applied a leave-one-out stability analysis. More precisely, we applied the analysis on $B \setminus \{sys_i\}$, where $sys_i \in B$. Figure 3b shows the result of the leave-one-out stability analysis. When leaving one between LC or KV out, the stability is achieved with 25 pairwise dialogues. When removing one of the other systems, the stability is reached with at least 40 dialogues. Thus, the number of pairwise bot-bot chats needed for *Spot the Bot* evaluation depends on the pool of bots to be evaluated and should be determined empirically.

5.3 On Time Efficiency

Evaluation methods, which are costly and take up a long time, slow down the development cycle of dialogue systems. *Spot The Bot* brings down the cost and time effort compared to other methods. In Table 4 the mean time per annotation is displayed. For the Dailydialog and PersonaChat domain, the average annotation time is at around 25 seconds. For the Empathetic Dialogues, it is at 18 seconds, which is due to the shorter dialogues. We compare this to the time to create conversations between humans and bots. We recruited three dialogue system experts from our lab to interact with the systems. Each expert created 5 conversations with each system. The average times do not take into account the time needed to instruct the experts. For the Dailydialog and Empathetic Dialogues domains, it takes over 2 Minutes per conversation.

DOMAIN	Annotation Time (Sec)	Time per Conversation (Sec)
DAILYDIALOG	26	153
EMPATHETIC DIALOUGES	18	136
PERSONACHAT	24	238

Table 4: Overview of time efficiency in Seconds. Spot The Bot annotation versus creating human-bot conversations.

For PersonaChat, the time increased to almost 4 minutes. Similarly to our experts, the average time for a human-bot conversation in the wild evaluation of the ConvAI2 challenge[10] also lies at 4 minutes[11]. Considering the 100 dialogues per system used in ConvAI, the evaluation time would be 2,000 minutes per system. In Spot the Bot, 40 annotations times 24 seconds mean 16 minutes per pair

---

[10] http://convai.io/data/

[11] We consider only conversations that have at least 10 turns, which is comparable to the setting of our experts.

of systems. Assuming a comparison between 5 systems, an approach based on human-bot annotations such as ConvAI would require 20 thousand minutes, while Spot the Bot would do with 0,16 thousand minutes[12].
Concerning other methods based on self-talk, ACUTE-EVAL did not report the time per annotation, but they reported the time required to achieve significant results in PersonaChat, which is close to 30 minutes. Our method requires only 16 minutes (with 40 annotations). Thus, *Spot The Bot* increases the annotation speed while reducing the human raters' mental strain.

6 Conclusion

In this work, we introduced *Spot The Bot*, a robust and time-efficient approach for evaluating conversational dialogue systems. It is based on conversations between bots rated by humans with respect to the bots' ability to mimic human behavior. We show that *Spot The Bot* yields robust and significant results while reducing the evaluation time compared to other evaluation frameworks. A team of researchers who would like to benchmark their system against four competing chatbots could do that for the cost of fewer than 3 hours of crowdsourced annotations. Spot the Bot facilitates developers making real progress based on frequent manual evaluations data, avoiding the use of noisy automatic metrics or once-in-a-year costly manual evaluations. We make the framework as well as the data publicly available.

[12] The amount of time needed by ConvAI grows linearly with the number of systems, while Spot the Bot (and ACUTE-EVAL) would grow quadratically. A pool of five systems seems reasonable for a research team, but even for larger pools (up to 51 systems) *Spot the Bot* is still more efficient.

A Annotation Tool

Figure 4 shows the annotation tool. The annotator is presented with a segment of the conversation, with the first i exchanges. In the first step, the annotator needs to decide for both entities separately if they are human or not. If it is not yet possible to decide, the annotator can choose to state that they are undecided. In the second step, the annotators are asked to state which of the two entities performs better with respect to three different features: fluency, sensibleness, and specificity with the following definitions:

- Fluency: Which entities' language is more fluent and grammatically correct?
- Sensibleness: Which entities' responses are more sensible? If the answer seems confusing, illogical, contradictory, or factually wrong then it is NOT sensible.
- Specificity: Which entities' responses are more specific and explicit in the given context? An answer is specific if it can be given only in the current context.

B Gamification

As an alternative to the segmentation approach, we experimented with a gamified version of the annotation tool (see Figure 5). In this version, the annotators were presented with the first turn of the conversation. At each point in time, they could choose whether to open the next turn or decide for an entity. If both decisions have been made, the annotators had to decide for the three aforementioned features, which entity performs better. The task was framed as a game, and the annotators received feedback in the form of a leaderboard. The score was a combination of the correctness (were the entities classified correctly) and a turn-penalty. That is, the more turns they opened, the lower the score. As an additional incentive, the winner was awarded a bonus payment. However, this approach resulted in unwanted behavior of the annotators. Some always decided after just one exchange, which leads to random annotations. Others opened the whole conversation first and then decided. To counteract these behaviors the tool needed a lot of fine-tuning, making the approach not reliable for practical use.

C Experimental Setup

All the systems which we used were trained using the ParlAI system. We used the available models for the Lost in Conversation system, Blender, Huggingface system, and the KVMemNN. The other systems were trained using the ParlAI training functionality with the following hyperparameters. We trained all the models for 30 epochs. For all the Bert-Rank experiments, we used the Bi-Encoder and optimized the last four layers due to GPU restrictions. The GPT2 models were trained with the standard-setting. Due to GPU restrictions, we used the small version of the GPT2 model. The sequence-to-sequence model was trained with two layers of GRUs (Cho et al., 2014), each with 512 hidden units. We used the general attention mechanism (Luong et al., 2015) and used the FastText word-embeddings(Bojanowski et al., 2017). We used the ADAM optimizer (Kingma and Ba, 2014) with a learning rate of 0.001. For the small sequence-to-sequence model, we used a one layer GRU with 128 hidden units. We trained this model for only 3 epochs as we noted that after three epochs, it is able to generate the generic answers.

and specificity. The rankings are similar to the bot detection rankings. For empathetic dialogues, the GPT model performs indistinguishably from the S2 model. In the PersonaChat domain, HF and BR are in the same cluster.

E Domain Details

DOMAIN NAME	#DIALOGUES	AVG. EXCHANGES	$\|B\|$	SEGMENTS
DAILYDIALOG	13118	3.74	4	2,3,5
EMPATHETIC DIALOGUES	25000	1.65	5	1,2,3
PERSONACHAT	10907	7.85	6	2,3,5

Table 7: Overview of the domains

We apply Spot The Bot on three different domains, which all are based on conversations between two humans. Thus, dialogue systems learn to imitate human conversational behavior.

Personachat. PersonaChat (Zhang et al., 2018) contains dialogues between two humans, each of the conversation participants is given a predefined persona. The persona is a set of characteristics of a person (name, occupation, hobbies, etc.), and the goal of the conversation is to mimic the process of getting to know each other.

Dailydialog. Dailydialog (Li et al., 2017) is a dataset that contains dialogues that occur in daily life situations. The data is crawled from English learning websites. Thus, the dialogues are better curated and more formal. Furthermore, the data is annotated with features that represent the emotion in the dialogue. For our experiment, we did not make use of these features.

Empathetic Dialogues. Empathetic Dialogues (Rashkin et al., 2019) focuses on empathetic response generation. The dialogues occur between two persons that discuss a situation that happened to one of the participants. Thus, there are two types of participants: the speaker and the listener. The first describes the situation and their feelings about it, and the listener responds empathetically.

F Segment Length Analysis

SYS/SEG	2		3		5	
	WR	HP	WR	HP	WR	HP
GPT	0.75	0.30	0.75	0.34	0.81	0.22
BR	0.60	0.22	0.64	0.21	0.70	0.15
S2	0.46	0.20	0.39	0.17	0.34	0.11
DR	0.16	0.11	0.20	0.11	0.13	0.04
TIES	72%		75%		81%	

Table 8: Segment Analysis for the Dailydialog domain. For each segment 2,3, and 5 the win-rate (WR) and the percentage of classification as humans (HP) are shown. In the last row the percentage of ties is shown.

The intuition behind the segment length is that if the dialogue is too long, then most conversational dialogue systems will always be exposed as such. Contrary, if the dialogues are too short, there is too little information to discriminate between dialogue systems. Thus, having different lengths of conversations ensures that these extremes do not occur. The effect is shown in Table 8. For each dialogue system, the rate at which it is classified as a human is depicted for the three different segments. For each dialogue system, this rate goes down, which is in line with our intuition. Similarly, the rate of unsure classification is lower at later segments. In later segments, two phenomena occur. First, the number of ties increases, as most dialogue systems get exposed as such, the number of ties in the Dailydialog domain increases from 72% to 81%. Second, the difference between the win-rates increases. Better bots have a higher win-rate, and the lower-ranked bots get a lower win rate. However, the win-rates are less significant due to the high number of ties. For instance, the GPT model increases its win rate to 0.81, whereas the win rate for S2 decreases from 0.46 to 0.34.

G On Stability against weak Annotators

One drawback of Likert-scale based evaluation methods is that many annotations need to be removed due to unreliable annotators (Lowe et al., 2017). *Spot The Bot* shows that it is stable with respect to weak annotators. Since we can measure how often the annotators correctly classify an entity, we can rate the quality of an annotator. A random annotator would receive a correctness rate of 50%. Table 9 shows an overview of the annotators for each domain.

DOMAIN	#ANN	AVG. CORR	AVG. HUM. CORR.	$< 50\%$
DD	33	77%	86%	9.1%
ED	32	63%	92%	7.5%
PC	40	69%	77%	22.8%

Table 9: Overview of the annotator performance. The number of annotations (#Ann), the average correctness score (AVG. CORR), the average correctness score for the human-human conversations (AVG. HUM. CORR.), and the percentage of annotators that have a correctness score below 50% ($< 50\%$).

The average correctness score is significantly higher than random. For the Dailydialog and Empathetic Dialog domain, the rate of annotators, which achieved a rate below 50%, was below 10% of all annotators. For the PersonaChat domain, the rate is higher, which is due to the fact that stronger dialogue systems were in the pool of bots. The average correctness scores for predicting humans correctly is high for all domains. Hence, *Spot The Bot* proves to be stable against annotators with low scores.

When removing all annotators with scores below 75%, the rankings remain stable. Only the significance scores decrease as a large number of dialogues gets removed. This lies in contrast to the gathering of conversations between humans and bots, which must be strictly supervised. For instance, the dialogues gathered in the wild evaluation of the ConvAI2 challenge were not usable. In fact, we applied Spot The Bot on these conversations, and the humans were rated as bots in 45% of the cases.

Human-centric dialog training via offline reinforcement learning

Abstract

How can we train a dialog model to produce better conversations by learning from human feedback, without the risk of humans teaching it harmful chat behaviors? We start by hosting models online, and gather human feedback from real-time, open-ended conversations, which we then use to train and improve the models using offline reinforcement learning (RL). We identify implicit conversational cues including language similarity, elicitation of laughter, sentiment, and more, which indicate positive human feedback, and embed these in multiple reward functions. A well-known challenge is that learning an RL policy in an offline setting usually fails due to the lack of ability to explore and the tendency to make over-optimistic estimates of future reward. These problems become even harder when using RL for language models, which can easily have a 20,000 action vocabulary and many possible reward functions. We solve the challenge by developing a novel class of offline RL algorithms. These algorithms use KL-control to penalize divergence from a pre-trained prior language model, and use a new strategy to make the algorithm pessimistic, instead of optimistic, in the face of uncertainty. We test the resulting dialog model with ratings from 80 users in an open-domain setting and find it achieves significant improvements over existing deep offline RL approaches. The novel offline RL method is viable for improving any existing generative dialog model using a static dataset of human feedback.

1 Introduction

Training open-domain dialog models is inherently difficult, since for each utterance there are many acceptable responses, yet no perfect response. While supervised learning from conversational corpora allows models to learn grammatical structure and even topic coherence, these models do not generalize, since the training objectives mostly lead the models to memorize responses within the corpus.

Humans are the ultimate authority in evaluating what makes one conversational reply better than another. To learn from real conversations with humans, we created an interactive, online platform which hosted a diverse set of neural network dialog models that users could chat with in real time. However, when learning from human interactions in the wild it is crucial to be able to learn offline and test the policy before deploying it, lest it learn inappropriate behaviors (e.g. Horton (2016)). Thus, we need to train and test models offline, to ensure safe model outputs. In order to safely learn to optimize human feedback we pursued an *offline reinforcement learning* approach to training dialog models (see Figure 1).

Offline RL is challenging; most deep RL algorithms fail to learn from data that is not heavily correlated with the current policy (Fujimoto et al., 2018). Even models based on off-policy algorithms like Q-learning fail to learn in the offline RL setting, as the model is not able to explore. If the offline dataset is not sufficient to cover the input-response space, offline RL models suffer from *extrapolation error*, learning arbitrarily bad estimates of the value of responses not contained in the data.

We solve these problems by developing a new method for offline RL. The method starts by leveraging a pre-trained language model to constrain offline RL updates. While training with RL, we penalize divergence from this prior model using forms of KL-control. This combats extrapolation error, and ensures that the RL model learns a policy that stays close to the distribution of realistic language, while learning to maximize positive human responses using the offline data. Further, we use dropout to obtain uncertainty estimates of the target Q-values, and to obtain a lower bound to alleviate over-optimistic bias in estimating future

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 3985–4003,
November 16–20, 2020.

reward. We show that this new method is able to learn successfully from many different reward functions, even in a very large space with 20,000 tokens.

Both linguistic theory (e.g. Grice's Maxims (Grice, 1975)) and empirical experiments correlating human judgement with language features suggest that there are many criteria that could be used to evaluate a conversational agent (Ghandeharioun et al., 2019; Adiwardana et al., 2020). We develop a set of reward functions for our dialog agents to optimize, which are designed to approximate implicit human preferences expressed during conversational responses. We show that the new method is better able to optimize these rewards using the offline data, and when tested with a new set of 80 human conversation partners, leads to more positive responses and higher quality ratings than a state-of-the-art offline deep RL method.

Novel contributions of this paper are:

- A new offline RL method, Way Off-Policy (WOP) learning, which introduces the use of KL-control from a pre-trained model to reduce extrapolation error, and an approach to make estimates more pessimistic in the face of uncertainty.
- Experiments showing the effectiveness of WOP above strong offline RL baselines.
- An investigation into developing conversation rewards based on how human preferences are implicitly expressed in text. We are the first work to learn from implicit signals in conversation using offline RL.

2 Related Work

2.1 Dialog

Improving dialog systems with RL has largely been restricted to task-oriented dialog systems, which have a limited number of task-specific actions (Fatemi et al., 2016; Gašić et al., 2011; Liu and Lane, 2017; Liu et al., 2018; Su et al., 2017). Some of these approaches incorporate human input through explicit, manual feedback (Shah et al., 2018) or implicit signals (e.g. the user interrupting the system or starting over) (Shi and Yu, 2018).

RL in the open-domain dialog setting is less explored (Li et al., 2016, 2017b, 2018). Authors may choose to use a highly restricted action space; for example, using RL to choose which dialog model to invoke (Serban et al., 2017a). Ziegler et al. (2019) used explicit human feedback to improve the summarization and text continuation performance of a large-scale language model.

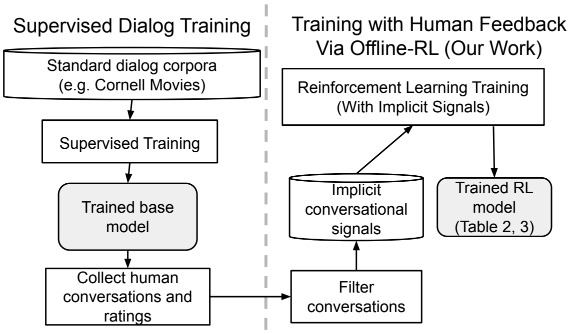

Figure 1: Schematic diagram of our method for training with human conversation cues via offline RL. Unlike traditional approaches which stop at using explicit feedback to evaluate static conversations, we allow humans to freely interact with dialog models, and compute metrics based on their implicit satisfaction which are optimized using offline RL.

Although implicit signals such as sentiment (Hancock et al., 2019) and conversation length (Zhou et al., 2018) have been used in maximum likelihood estimation (MLE) systems, the idea of using such signals as a reward for RL is relatively unexplored. Henderson et al. (2008) combine using reinforcement learning to optimize dialog reward with using supervised learning to restrict the conversation to be close to the training data. Shin et al. (2019) use on-policy learning in conjunction with a user-sentiment approximator to improve a seq2seq model, but are unable to learn directly from user feedback. To the best of our knowledge, we are the first to use offline RL to train dialog models on real human interactions.

2.2 Offline RL and KL-Control

The approach we propose is based on KL-control, a branch of stochastic optimal control (SOC) (Stengel, 1986) where the Kullback-Leibler (KL) divergence from some distribution is used to regularize an RL policy (Abdolmaleki et al., 2018; Kappen et al., 2012; Rawlik et al., 2012; Todorov, 2007). Well-known examples include Trust Region Policy Optimization (TRPO) (Schulman et al., 2015), and use conservative, KL-regularized policy updates to restrict the RL algorithm to stay close to its own prior policy (Haarnoja et al., 2018; Kakade, 2002; Peters et al., 2010; Rawlik et al., 2012). KL-control has been used to improve transfer learning between maximum likelihood estimation (MLE) training on data, and training with RL (Jaques et al., 2017). Our work is the first to propose KL-control from a pre-trained model to improve offline RL.

Other strategies to improve off-policy learning differ from our work: They either have focused on scenarios where the policy is able to explore and collect more data (Degris et al., 2012; Riedmiller, 2005) such as learning online from an outdated replay buffer (e.g. (Munos et al., 2016)), or have performed off-policy policy evaluation (Farajtabar et al., 2018; Jiang and Li, 2016; Precup, 2000; Thomas and Brunskill, 2016). In contrast, we learn a policy entirely offline, from a fixed batch of data, with no ability to explore. Others have tackled this problem using deep learning, but have not used KL-control (Liu et al., 2019; Gelada and Bellemare, 2019; Bhatt et al., 2019; Kumar et al., 2019; Agarwal et al., 2019; Fujimoto et al., 2018; Ghasemipour et al., 2020).

Most similar to our work is Batch Constrained Q-learning (BCQ) (Fujimoto et al., 2018), which addresses extrapolation error in offline RL by constraining the actions of the policy to be close to the offline data. This is accomplished by learning a generative model of the offline data, $p(a|s)$, and sampling from this model during learning and inference. We improve upon this approach by using KL-control to directly integrate knowledge of the prior model $p(a|s)$ into the RL policy.

3 Way Off-Policy RL

We adapt typical RL notation to the problem of generating a conversation. Here, we consider human interaction to represent the RL environment. The conversation history is the state s_t of the environment at timestep t, and is composed of a series of utterances, which are composed of vocabulary tokens. The action a_t that the RL model must take at each timestep is to select the most appropriate token according to its policy $\pi(a_t|s_t)$. Once it has constructed an utterance, the response of a human to that utterance is used to compute a reward signal r_t to train the model. The agent's goal is to maximize reward over a conversation trajectory τ, with a discount factor of γ applied to future rewards.

Q-learning methods learn an action-value estimate of the total expected discounted future reward, $Q_\pi(a_t, s_t) = \mathbb{E}_\pi[\sum_{t'=t}^{T} \gamma^{t'-t} r_{t'}]$, through iterative updates based on the Bellman equation:

$$\begin{aligned} Q_{\theta_\pi}(s_t, a_t) &= r_t + \\ \gamma \mathbb{E}_{s_{t+1} \sim p(\cdot|s_t, a_t)} &[\max_{a_{t+1}} Q_{\theta_T}(s_{t+1}, a_{t+1})] \end{aligned} \tag{1}$$

In deep Q-learning (Mnih et al., 2013), a Q-network approximates $Q_{\theta_\pi}(s_t, a_t)$ and drives the policy π. A second Target Q-network approximates the expected reward from the next state, $Q_{\theta_T}(s_{t+1}, a_{t+1})$ (Van Hasselt et al., 2016). Here, we used pre-trained language models to initialize our Q- and Target Q- networks.

3.1 Offline RL and extrapolation error

In offline RL, we are given a fixed batch of data $\mathcal{B}$, and assume that no further interaction with the environment is possible. To train Q_{θ_π}, we sample $(s_t, a_t, r_t, s_{t+1}) \sim \mathcal{B}$, and update the weights of the Q-network to approximate Eq. 1. Because Q-learning is an off-policy algorithm, in principle it should be able to learn from data collected by any behavior policy. However, extrapolation error occurs when the ORL policy learns to favor a state-action pair (a, s) that is unlikely, or not contained, in the batch data. In this case, the estimate $Q(a, s)$ can be arbitrarily bad (Fujimoto et al., 2018). Because the Bellman equation bootstraps each Q-value based on all future Q estimates, any error can accumulate to distort Q-values (Kumar et al., 2019). Experiments from Fujimoto et al. (2018) show that extrapolation error can be highly detrimental to offline RL.

These problems are compounded by the fact that algorithms like Q-learning are inherently optimistic in the face of uncertainty. When value estimates for some region of the state-action space are noisy (because too few experience samples have been used to refine them), the maximum operation in Eq. 1 will lead to an overestimation of expected reward. In a normal RL setting, this overestimation bias drives the model to explore states and actions for which the value estimates have the highest variance, thus enabling it to refine them; in essence, creating a built-in drive to explore. In the offline setting, where exploration is not possible, the model is instead driven to value parts of the state-action space for which it has little to no data to learn a good policy. Table 1 shows an example of this effect, where a vanilla Q-learning model trained on an offline batch of data (*Batch Q*) begins to use unrealistic language that is not contained within the

[User]: hey, what's up? **[Batch Q]**: where did you get??, that sounds so exciting. how do you work for you... you want to talk to me?... you want **[User]**: yes, i want to talk to you! **[Batch Q]**: where did you say to me?... you want to talk to you about you... you are so good for you... you are so good...	**[User]**: hey, what's up? **[KL-control]**: hey, i hope you have a great day and i wish you the best. **[User]**: oh thank you that's very sweet of you. **[KL-control]**: so, i'm so excited, and i'm so excited to meet new people.

Table 1: Purely reward-maximizing methods like *Batch Q* trivially exploit a reward for asking questions by only asking questions, and using the maximum number of tokens in every sentence. In contrast, KL-control methods output plausible language by staying close to the language prior, while eliciting positive feedback from humans.

batch data, for example saying implausible phrases such as "*where did you say to me?*".

Even in the online setting, applying deep RL to dialog generation is challenging due to the large state-action space. While typical game RL tasks may have an action space of dimension 8 (Mnih et al., 2013), in dialog the action space is the number of tokens in the vocabulary: 20,000. The high-dimensional state-action space further compounds the problems of extrapolation error and overestimation bias in offline RL. Below, we describe a novel method to ameliorate these issues.

3.2 Dropout for uncertainty estimation of Target Q-values

Overestimation error in estimating future rewards based on Target Q-values poses an issue for offline RL. We leverage the fact that a network trained with dropout can be used to approximate a Bayesian uncertainty estimate of the network's output (Gal and Ghahramani, 2016). Given the target Q-network Q_{θ_T}, we compute $Q(a_{t+1}, s_{t+1})$ by running M stochastic forward passes of the network, each with a new dropout mask d_i. Taking the minimum of these outputs gives a Monte Carlo (MC) estimate of the lower-bound of $Q_{\theta_T}(a_{t+1}, s_{t+1})$:

$$Q(a_{t+1}, s_{t+1}) = \min_{i=1...M} [Q_{\theta_T}(a_{t+1}, s_{t+1}; d_i)]$$

This penalizes high variance estimates and leads the algorithm to be pessimistic in the face of uncertainty, rather than optimistic, favoring actions and states well covered by the offline data.

3.3 KL Control from pre-trained prior

Recall that BCQ (Fujimoto et al., 2018) uses offline data to learn a model of which actions are probable given a state: $p(a|s)$. It then samples actions from $p(a|s)$ to constrain the RL policy such that it cannot take unrealistic actions.

In the language domain, we already have access to a better model of $p(a|s)$ than could easily be learned from a small amount of offline data. Any language model gives us the probability of a word occurring given a particular conversation context ($p(a|s)$), and can be used as a language *prior* to prevent the RL model from choosing unrealistic words. Rather than simply sampling from this prior, we directly incorporate knowledge of the prior into the RL policy. To achieve this, we use KL-control to penalize divergence between the prior $p(a|s)$ and the Q-network policy π_θ, while maximizing reward.

Given a trajectory of actions, $\tau = \{a_1, a_2, ...a_{t-1}\}$, let $q(\tau) = \prod_{t=1}^{T} \pi_\theta(a_t, s_t)$ be the policy of our Q-learning algorithm at the trajectory level. Similarly, let $p(\tau) = \prod_{t=1}^{T} p(a_t|s_t)$ be the prior distribution over the trajectory, and $r(\tau)$ be the rewards. We seek to maximize the following KL-regularized objective:

$$L(q) = \mathbb{E}_{q(\tau)}[r(\tau)]/c - D_{KL}[q(\tau)||p(\tau)] \quad (2)$$

As $D_{KL}[q||p] = \sum_x q(x)(\log q(x) - \log p(x))$, this is equivalent to maximizing the following expected value function at the action level:

$$\begin{aligned} Q^\pi(s_t, a_t) = \mathbb{E}_\pi[\sum_{t'=t}^{T} r(s_{t'}, a_{t'})/c \\ + \log p(a_{t'}|s_{t'}) - \log \pi(a_{t'}|s_{t'})] \end{aligned} \quad (3)$$

The two terms we have introduced in Eq. 3 have clear implications. The $\log p(a|s)$ term rewards choosing actions that have high probability under the prior, biasing the model to state-action pairs that are realistic and likely to be in the offline data; thus, extrapolation error is reduced. The effects of using KL-control to ensure an RL model continues to use realistic language are shown in Table 1.

The $-\log \pi(a|s)$ term is analogous to entropy regularization. Maintaining diversity through entropy regularization is important for dialog models, which are known to collapse to a small number of uninteresting samples (Li et al., 2017a).

We can derive an entropy-regularized version of Q-learning, known as soft Q-learning (Haarnoja et al., 2017), or Ψ-learning (Jaques et al., 2017; Rawlik et al., 2012). This allows us to re-state our entropy-regularized, KL-control objective as:

$$\begin{aligned}\Psi^*(s_t, a_t) &= r(s_{t'}, a_{t'})/c + \log p(a_{t'}|s_{t'}) \\ &\quad + \gamma \log \sum_{a'} \exp(\Psi^*(s', a')) \end{aligned} \tag{4}$$

$$\pi^*_\Psi(a_t|s_t) = \exp(\Psi^*(s_t, a_t)) \tag{5}$$

Because it avoids taking a hard max over noisy estimates, this Ψ-learning objective leads to less overestimation of future reward, and aids learning through more stable temporal-difference updates.

3.4 Comparison to existing techniques

To test our algorithm against a state-of-the-art offline deep RL technique, we implement a discrete version of Batch Constrained Q-learning (Fujimoto et al., 2018), DBCQ. For a fair comparison, we also use a fully trained language model to provide $p(a|s)$ to BCQ, and apply our Monte Carlo target estimation technique to reduce overestimation error. Finally, to adapt BCQ to discrete action spaces, we remove the continuous-action perturbation model.

4 Learning from talking to humans

Figure 1 illustrates our experimental approach. The left side of the figure describes traditional approaches to dialog generation, in which human feedback is only used to evaluate static conversations generated by dialog models. In contrast, we allow humans to freely interact with our models online, and use their implicit conversation cues to update our dialog models using offline RL.

4.1 Training baseline dialog models

Before learning from human feedback with RL, we first train a collection of baseline dialog models using standard corpora: the CORNELL dataset of movie dialog (Danescu-Niculescu-Mizil and Lee, 2011) and a REDDIT Casual Conversations dataset (Ghandeharioun et al., 2019). For model architectures, we focused on hierarchical sequence-to-sequence models (Serban et al., 2016, 2017b; Park et al., 2018)

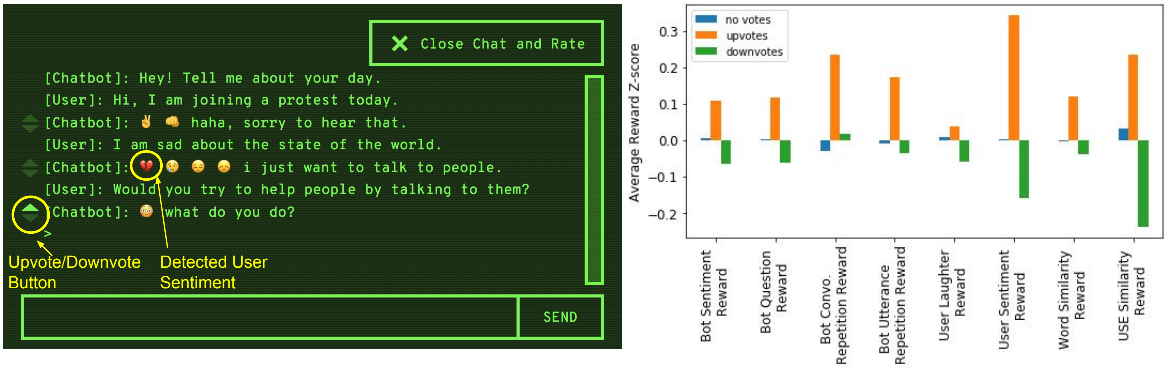
because they were found to be more effective for the datasets under consideration than e.g. Transformers (Saleh et al., 2019). Regardless, the techniques proposed here are model-agnostic, and could be applied to a dialog model with any underlying architecture. In total, we trained over 40 dialog models with different architectures, on different datasets, with different feature-based regularization (e.g. sentiment or relatedness as in Ghandeharioun et al. (2019)). These models vary significantly in the distribution of language they learned, and thus differ significantly from the offline RL policy.

4.2 Hosting real-time conversations online

The trained models were deployed to interact live with human users via a web server that hosts neural network dialog models on GPU for fast, real-time inference: `https://github.com/asmadotgh/neural_chat_web`. Figure 2 shows a screenshot of the interface, which includes buttons that allow users to give manual feedback on responses they particularly liked or disliked. Users were encouraged to use these buttons, and we sum these manual votes to create an overall *votes* score. After chatting, users were asked to provide a Likert scale rating of the bot's conversation quality, fluency, diversity, contingency/relatedness, and empathy. The code for the RL models is available in open-source at `https://github.com/natashamjaques/neural_chat/tree/master/BatchRL`. Using the server, we collected a batch of human interaction data containing $46,061$ pairs of user input and agent response. Because humans may use inappropriate language with bots online (see (Horton, 2016)), we filtered this data to remove 1 character responses, profanities, and invalid inputs for a remaining total of $45,179$ response pairs. This filtering step is important to ensure undesirable human behavior is not learned by the RL algorithms. The offline data was used to train the RL models as described in Section 3.

4.3 Evaluating offline RL models

We recruited 80 Mechanical Turk workers to provide a total of 600 7-point Likert scale ratings of the trained bots, after interacting with each for at least 6 turns. We note that using this platform to test our models "in the wild" with novel humans represents a more meaningful test of generalization than testing an RL model in the same limited (game) environment in which it was trained, since humans are not restricted in the text they can type as input to the model.



[Chatbot]: Hey! Tell me about your day.
[User]: Hi, I am joining a protest today.
[Chatbot]: ✌ 👊 haha, sorry to hear that.
[User]: I am sad about the state of the world.
[Chatbot]: 💔 😢 😔 😞 i just want to talk to people.
[User]: Would you try to help people by talking to them?
[Chatbot]: 😳 what do you do?

(a) Platform Interface

(b) Rewards by Upvote/Downvote

Figure 2: (a) Platform interface in which users chat in real time with dialog models hosted on GPU. The interface displays the user's sentiment detected with DeepMoji (Felbo et al., 2017), and includes buttons for the user to upvote (downvote) a response they particularly like (dislike). (b) By conditioning on responses which received positive, neutral, and negative manual feedback (votes), we can determine which implicit rewards map most clearly to user ratings.

5 Measuring implicit conversation cues

Our goal is to improve a dialog model's ability to engage in natural conversation with a human by learning from the implicit signals in the human's response. Requiring a human to manually rate good interactions is unnatural and cumbersome, and we hypothesize it cannot scale as effectively as recognizing and learning from informative cues within the user's text responses. The golden question is which goals should be used to train a good chit-chat dialog model.

Understanding when a human is satisfied with the conversation is an unsolved problem. As a first step, we designed several intrinsic conversation rewards, taking inspiration from prior work in dialog, as well as the psychology of human conversation. We noted that psychologists have identified the importance of emotion in creating a sense of understanding (Bodie et al., 2015; Weger Jr et al., 2010), laughter as important to building solidarity (Hay, 2000), paraphrasing and style matching as helping to facilitate good conversation (Ireland et al., 2011; Weger Jr et al., 2010), and asking questions as an important active listening skill (Bodie et al., 2012). Further, prior work has found that eliciting longer conversations can be a signal of engagement (Sidner et al., 2004; Zhou et al., 2018), and that reducing repetition and increasing specificity on the part of the model can improve conversation quality (See et al., 2019; Mehri and Eskenazi, 2020). We compute a large collection (30 in total) of bot rewards (rewards based on bot behavior e.g. asking questions), user rewards (rewards based on eliciting positive user behavior e.g. laughter), and interaction rewards (rewards based on similarity between the user's input and bot's response e.g. similarity to the user's response in sentence embedding space).

To determine which of these rewards objectively relate to user satisfaction, we examine the reward score for those responses that received positive, negative, and neutral manual feedback using the upvote/downvote buttons provided in the interface. We found that only some of the rewards mapped accurately to user ratings (see Figure 2b), and these are the ones we optimize with our RL models. For more details about the reward functions, please see the appendix. Notably, conversation length and specificity score were not found to be higher in upvoted bot responses.

Note that four of the rewards (starting with the *bot* prefix) can be optimized by the model itself, but the remaining four rewards include eliciting positive responses from a human user or measuring user-bot response similarity (e.g. using word overlap or similarity in Universal Sentence Encoder (USE) embeddings (Cer et al., 2018)).

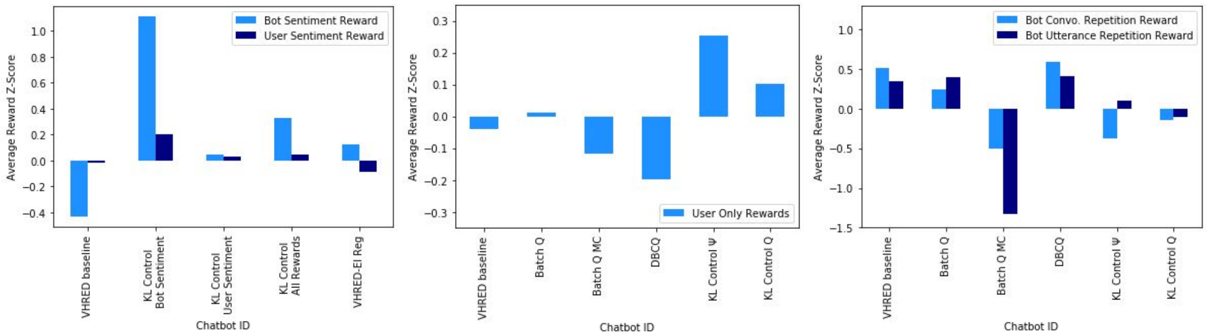
6 Results

6.1 Controlling bot conversation behavior

We first examine whether our algorithms can successfully maximize the proposed bot rewards as intended[1]. We trained RL models on 1) bot sentiment reward only, 2) user sentiment reward only, and 3) a combination of rewards (from Figure 2b). We compare the effectiveness of these models to a

---

[1] In the appendix, we provide a study comparing WOP to prior work in traditional, non-dialog RL tasks, and find that it outperforms all relevant baselines including DBCQ.



(a) Sentiment Rewards (b) User Rewards (c) Bot Repetition Rewards

Figure 3: (a) Average reward scores of sentiment rewards computed on study chat transcripts across different models. KL-control methods more effectively increase bot sentiment and elicit more positive sentiment from humans than either the baseline language model or adding sentiment regularizer during supervised training. (b) The sentiment and laughter elicited from humans is higher for KL-control methods than the language model baseline and other offline RL techniques. (c) Average bot repetition reward scores (higher scores indicate less repetition). The RL models contain more conversation and utterance repetition.

baseline VHRED model and a Sentiment and Infersent regularized VHRED model (as proposed by Ghandeharioun et al. (2019)). We compute the reward scores (e.g. sentiment) based on conversations with new humans in the wild (i.e. during the final study). Figure 3a shows that the KL-control model, trained to maximize bot sentiment, achieves higher bot sentiment in experiments than both the VHRED baseline and the VHRED-EI model (with sentiment and topic regularization (Ghandeharioun et al., 2019)). This illustrates that for controlling bot sentiment, a reward-based approach better optimizes bot behavior than training with sentiment-based regularization. Furthermore, controlling bot sentiment also leads to eliciting higher user sentiment in our open-domain experiments.

6.2 Measuring human conversation behavior

We then consider how effective our algorithms are at maximizing rewards that are based on human behavior.

Although user rewards are inherently more difficult to optimize than bot rewards, Figure 3b illustrates that our KL-control models elicit higher human reward scores (user sentiment and user laughter) than other offline RL algorithms and the baseline VHRED model. This demonstrates the success of our algorithms in eliciting positive responses from the human conversation participants[2].

6.3 Overall human ratings

Table 2 shows the results of the human evaluation, comparing WOP to ablations of itself, vanilla offline RL (Batch Q), and DBCQ.

Compared to the RL baseline (Batch Q), MC Target Q estimation leads to modest improvements in Fluency. While the DBCQ model is rated better than Batch Q and does well in the Diversity category, it performs worse than the WOP KL-control methods, particularly at eliciting human rewards. The KL-control models show substantial gains over the RL baselines across both ratings and human reward. We perform a one-way analysis of variance (ANOVA) comparing the KL-control models to the Batch Q baselines and DBCQ on total human ratings, and find that the KL-control models are significantly better, $F(x) = 7.328, p < .005$. This validates the hypothesis that KL-control with a strong, pre-trained prior can be used to improve offline RL.

6.4 The role of repetition

The overall human quality ratings are worse in the offline RL bots as compared to the language model prior (Table 2). The biggest gap between the VHRED and RL models is the diversity ratings. The conversation and utterance repetition scores of each technique in Figure 3c reveal that the RL models (including the KL-control models) contain more repetition than the baseline. We hypothesize that due to the limited size of our offline data, the RL models have restricted their outputs to focus on a narrow range of conversations that elicited high rewards in the training data, which may increase repetitiveness. Some applications may require shaping dialog model behavior towards a desired objective (such as using appropriate language) over maximizing other conversation objectives.

---

[2] In the appendix, we replicate these experiments with a different baseline model, and produce the same findings.

Model type	**Quality**	**Fluency**	**Diversity**	**Relatedness**	**Empathy**	**Total**	**Votes**	**Human reward**

Table 3: Interactive human evaluation of WOP trained with different reward functions. Manual votes are outperformed by implicit signals. Ratings are Likert scale with 95% confidence intervals ($n = 40$), votes and human reward are z-scores.

6.5 Comparing rewards

Table 3 presents the results of models trained with only a single reward function, to investigate which rewards presented in Section 5 are useful for achieving high-quality conversations with humans.

We note that extracting a set of reward functions post-hoc from a batch of data and training on these independently is made feasible through offline RL. Here all models are trained with WOP (KL-control, Ψ-learning, and MC targets). Maximizing positive sentiment in the user leads to the highest quality bot, underscoring the importance of implicit signals as cues for good conversation. The bot trained on the manual votes provided by users at the utterance level achieves decent quality scores, but fails to elicit a higher z-score of manual upvotes than other models.

Training on the manual upvote reward may help the bot learn successful behaviors indirectly but such a sparse reward is difficult to optimize for directly. Even though users were instructed to make use of the vote feature, voting is burdensome, and users did not vote frequently enough to provide a good training signal.

Meanwhile, *implicit* signals of human enjoyment (such as sentiment) are dense and thus a more scalable way to learn from human preferences. Across all bots trained on single features, the bot trained on minimizing repetition (both on a conversational and utterance level) achieves the best quality over all.

7 Discussion

In this work, we present novel techniques that enable successful offline reinforcement learning on any base language model from real human conversations. This allows the dialog systems practitioner to train models that learn language structure from vast, readily-available corpora, then fine-tune for specific desirable behaviors post-hoc through RL rewards.

We observe that the new offline RL method successfully optimizes both generated bot rewards and elicited human responses. We show that it presents a better option than using regularization in training a specific bot behavior. Further, RL currently remains the only option for maximizing user feedback over the course of a conversation.

Compared to prior work in offline RL, the novel WOP offline RL algorithm achieves higher performance in traditional RL tasks, elicits more positive feedback in conversations with novel humans at test time, and earns overall higher human ratings.

A limitation of our study is that the question of what to optimize with RL to improve overall qualitative ratings remains open. We have shown that manual ratings are too sparse to optimize effectively, and instead suggest using implicit rewards.

However, our reward set proved insufficient to achieve higher human quality ratings, at least with the limited offline training data we were able to collect. It is unlikely the rewards proposed here fully cover what it means to have a high quality open-ended conversation. Future work should investigate more rewards for training an open-domain dialog model such as long term conversation rewards that may need to be computed over many conversation turns.

Our work computes conversational rewards based on dialog data and annotations from online task workers in the United States. Considering the broader impacts of our work, a representative and diverse set of conversations and annotations should be collected before real world systems are trained and deployed using our algorithms.

We have shown that the proposed techniques can be useful for shaping dialog model behavior towards a desired objective. For many practical applications, we may have specific requirements for the language generated by a model—for example, that it is appropriate, positive, and polite—even if this leads to a lower perception of conversation quality for some users. We have shown that the Way Off-Policy algorithm provides a more effective way to teach a language model specific behaviors from offline data than previously proposed RL or regularization techniques.

Acknowledgments

We would like to thank Scott Fujimoto for insightful email correspondence on this topic, approval of the DBCQ algorithm, and suggestion to apply model averaging. We would like to thank Sudha Rao and Yonatan Bisk for helpful guidance and feedback in the re-framing and re-writting process of this work. We also thank Max Kleiman-Weiner, Ardavan Saeedi, Sebastian Zepf, Sara Taylor, Oliver Saunders Wilder, Kyle Kastner, Marissa Zhang, and Kristy Johnson for their helpful discussions about this project, and many others for helping test-drive our bots.

We thank the MIT Quest for Intelligence, and MIT Stephen A. Schwarzman College of Computing, and the Machine Learning Across Disciplines Challenge for providing computing resources, and MIT Media Lab Consortium for the support of this research. This work has been partially supported by RTI2018-095232-B-C22 grant from the Spanish Ministry of Science.

A Reproducibility

A.1 Training details and hyperparameters

Baseline Models

The underlying architecture of the baseline language models employed for this work is a Variational Hierarchical Recurrent Encoder Decoder (VHRED) (Serban et al., 2017b). We also conduct a second set of experiments on an enhanced version of this model with additional knowledge distillation to improve the model's ability to track the sentiment and semantics of the conversation, as proposed by Ghandeharioun et al. (2019). The language models were originally trained on two datasets: movie dialogs (Danescu-Niculescu-Mizil and Lee, 2011) and a dataset scraped from `reddit.com/r/casual_conversation` (Ghandeharioun et al., 2019).

The underlying parameters of the VHRED model were as follows: Context RNN hidden size $= 1000$, decoder hidden size $= 1250$, encoder hidden size $= 1250$, z embedding size $= 600$, gradient clip $= 1.0$, dropout $d = 0.2$. The maximum conversation length was fixed at 5 utterances (context from more than 5 utterances ago was discarded), and the maximum sentence length was 30 tokens. The VHRED model has 76.6 million parameters.

We also added layers to the Context RNN and regularized it to be able to predict the semantic content of the input utterance using a form of knowledge distillation (Hinton et al., 2015) from a state-of-the-art sentence-embedding model (Conneau et al., 2017). There were 2 additional feedforward semantic prediction prediction layers of size 128, which used ReLu activation. The VHRED model with sentiment and infersent regularization has 95.4 million parameters.

Each RL model was trained on a NVIDIA GeForce GTX 1080 GPU.

RL Models

The RL models, the main focus of our work, were trained using human conversation data collected via the online interactive platform (described in Section F) and batch size was fixed at 32. Each model was trained for 2000 epochs. The RL models were initialized with the weights of the best model trained on the Reddit dataset. Early stopping was used to determine the number of training iterations of the best checkpoint. For each bot, 3 different stopping epochs were tested and the best was selected. The checkpoint was selected using manual tuning based on interactive chat with the chatbots. For the best performing bots, KL-Control Q and KL-Control Ψ, the 1600 and 1800 epoch checkpoints were selected respectively.

The reward weights were also tuned to determine which weighting of rewards produced the desired bot behavior. We tried uniform weights (summing up to 1) and slightly increased weights for repetition rewards and human bot interaction rewards. The best weights were found to be assigning 0.15 to repetition and human bot interaction rewards and 0.1 to all other rewards. Reward weights were also determined using manual tuning and conversational interaction. The same reward weights were shared between all RL models we trained. Only 3 sets of weights were tried in the reward weights hyperparameter optimization process.

All other hyperparameters were shared between RL models, and were as follows: discount $\gamma = 0.5$, weight placed on RL reward vs. KL-divergence term $c = 2$, number of Monte Carlo samples of the Target Q-network $M = 5$, target network update rate $\alpha = .005$, learning rate $r = .0001$. We used a smooth $L1$ loss function to approximate the Q-values, and clipped gradients at a value of 1.0. The RL models have a total of 76.6 parameters (same as the VHRED models).

A.2 Computing Infrastructure

Each RL model was trained on a NVIDIA GeForce GTX 1080 GPU. Training models for 2000 epochs took approximately 30 minutes for each model. The runtime for training the VHRED baseline models is around 6 hours. The speediness of training the RL models illustrates the scalability of RL training in improving dialog models for specific features.

A.3 Model Validation and Evaluation

We use interactive human evaluation through an online chat interface. Human participants are recruited using Amazon Mechanical Turk and rate either 7 or 8 bots each. Participants were instructed to continue the conversation through at least 6 human responses. After the conversation, participants are asked to rate each bot in terms of *Quality*, *Fluency*, *Diversity*, *Contingency*, and *Empathy* on a 7-point Likert scale. A detailed example of the chat and interaction platform can be found in Section F. Since our models are evaluated using interactive chat, we also validate our models through interactive chat and rate the models while tuning hyperparameters. The authors interacted with and rated bots during to validate bots.

B Offline-RL with VHRED with Emotion and Infersent Regularization

We also conducted experiments using each offline RL algorithm with a Sentiment and Infersent regularized VHRED Model. As described in Section A.1, by adding about 20 million extra parameters to the VHRED model in order to better achieve semantic coherence and sentiment contingency, the VHRED-EI (Emotion and Infersent regularized) model is a better performing baseline in terms of human ratings (Ghandeharioun et al., 2019).

We conducted the same human experiments where we recruited participants from Amazon Mechanical Turk to chat with and rate each dialog model. We found similar results as presented in our main paper. While our KL-control models achieved higher qualitative ratings than the other offline RL algorithms, none of the RL models received higher qualitative ratings than the VHRED-EI Model (Table 4). We also replicated training the KL-Control Ψ model on single rewards and found that training on User Sentiment elicited the highest human qualitative ratings (Table 5). This consistent with our results on the VHRED model.

C Traditional RL experiments

To demonstrate the effectiveness of these techniques, we tested them on traditional RL tasks using the OpenAI gym (Brockman et al., 2016), focusing on the *CartPole-v0* and *Acrobot-v1* experiments. We first train an online Q-learning *Behavior* policy, and store all (s, a, r, s') experience samples into a replay buffer. We use this buffer to train a prior model of $p(a|s)$ using a Variational Auto-encoder. The VAE was trained to reconstruct the next state given the current state, $p(s'|s)$, using a mean-squared error loss. The next action was predicted from the latent embedding z, meaning the model learned three functions: $z = f_e(s)$, $s' = f_d(z)$, and $a = f_a(z)$. For Cartpole, both the encoder and decoder were made up of two linear layers with 750 neurons each. The latent dimension of the VAE was size 256. For Acrobot, the encoder and decoder had only one layer of size 256 each, and the latent dimension was 64.

This VAE is used as a part of both the DBCQ and WOP algorithms. We can also use it for imitation learning, by sampling actions directly from $p(a|s)$ to obtain Behavioral Cloning (BC). We

Table 5: Interactive human evaluation of WOP trained with different reward functions on VHRED-EI model. Ratings are Likert scale with 95% confidence interval ($n = 45$), votes and human reward are z-scores.

benchmark all of these techniques against vanilla Q-learning on the batch data (*Batch Q*). All Q-networks shared the same underlying architecture: three fully-connected layers of size [256, 128, 64], with ReLU activation between. All models were trained with the Adam optimizer (Kingma and Ba, 2014).

For each experiment, we ran 50 trials of each model with a different random seed each time. The Behavior policy was trained for a total of 20,000 steps in the environment, so in the *Full buffer* condition offline agents saw 20,000 experience samples. The Behavior policy typically converged before 10,000 steps, so in the *Expert demonstrator* condition the offline agents received the last 10,000 experience samples from the trained agent. In the *Concurrent* condition, offline agents saw a moving window of 1000 samples, since the online learner only used the most recent 1000 samples in the buffer for learning. The learning rate was .001, $\gamma = .99$, and ϵ decayed linearly from 1.0 to .01 over 2000 steps. The KL-constraint was computed as $D_{KL}[q(\tau)||p(\tau)] = \alpha \log p(a|s) - \beta \log \pi(a|s)$, where $\alpha = 0.5$ and $\beta = 0.1$. DBCQ sampled $n = 2$ actions before selecting the best action based on the maximum Q-value; note that in this environment there are only 2 actions. For Cartpole we used the Ψ-learning loss, and for Acrobot we used the traditional Q-learning loss.

We experiment with four different conditions which vary the quality of the Behavior policy and the replay buffer data: a) *Full buffer*: all experience samples experienced during online training are used for offline learning; b) *Concurrent*: the offline learning algorithms see a sliding window of experience samples in the same order that the online learner experienced them; c) *Expert demonstrator*: the buffer only contains experience generated by a fully trained online learner; and d) *Noisy demonstrator*: the online learner has a high probability of acting randomly ($\epsilon = 0.3$) and is thus a bad model of the optimal policy.

Figure 4 shows the results. Across conditions, we see that WOP is able to outperform Batch Q, imitation learning (BC), DBCQ, and the original behavior policy. As expected, Imitation learning (BC) underperforms other techniques when the batch contains noisy or inexpert experience samples. However, when the batch contains only expert trajectories, Batch Q fails to learn, because the batch does not cover the full state-action space well, increasing extrapolation error. DBCQ matches or outperforms BC and Batch Q in all scenarios. However, because DBCQ acts by sampling from $p(a|s)$ as learned by the BC model, its performance suffers when the batch data is noisy or imperfect. In

contrast, WOP is able to learn to trade-off staying close to the prior and obtaining higher reward, and consistently outperforms all other algorithms in this environment.

D Additional results

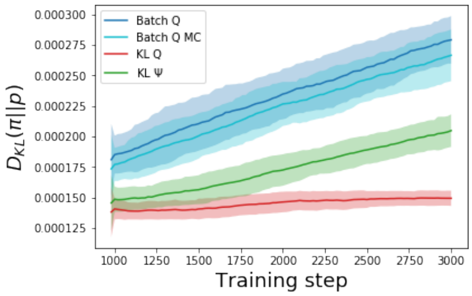

Figure 6: KL-divergence of the policy from the prior is lower with KL-control throughout training. Bands show σ.

Figure 6 shows the KL-divergence between RL policies and the prior language model throughout offline RL training. Without KL-regularization, the baseline RL models diverge quickly and continuously from the prior, losing information about realistic sequences. This figure also helps explain the poor performance of DBCQ in Table 2. The underlying Q-network in DBCQ does not directly integrate the prior. As Q-learning causes the model to diverge from the prior, the Q-estimates of language generated according to the prior become unrealistic, and selects unrealistic actions. This results in highly 'diverse' (random) generated utterances. Note that since we operate in discrete action space, we could not include the perturbation model originally proposed by (Fujimoto et al., 2018), which may be critical to achieving good performance with BCQ.

E Implicit Rewards Details

The total reward used to train the bots is a combination of the rewards described in Table 6. These rewards were selected based on the average z-score of rewards for utterances that were upvoted and downvoted. Figure 8 shows all the user rewards and that *User Laughter* and *User Sentiment* reward scores correlate with upvotes and downvotes. Figure 9 shows all the bot rewards with *Bot Sentiment*, *Bot Laughter*, *Bot Convo. Repetition*, and *Bot Utterance Repetition* as rewards that correlate with manual votes. Figure 10 shows the bot-user combined rewards, and that *Word Similarity* and *USE Similarity* are the rewards that correlate with manual up and downvotes.

E.1 Sentiment-based

To compute sentiment on short texts like conversation utterances, we leverage a state-of-the-art sentiment-detection model, which was trained on a massive amount of Twitter data to predict the emo-

Reward	Weight
User Sentiment	0.10
User Laughter	0.10
USE Similarity	0.15
Word Similarity	0.15
Bot Question	0.10
Bot Sentiment	0.10
Bot Conversation Repetition	0.15
Bot Utterance Repetition	0.15

Table 6: Reward weights used for RL model training

jis in tweets (Felbo et al., 2017). Transfer learning from this model to other tasks showed that it was able to significantly outperform a series of sentiment, irony, and sarcasm benchmarks. This DeepMoji model outputs a probability distribution over 64 most-frequently used emojis as shown in Figure 7. After observing the performance of the model in detecting users' emotions in the domain of online chat, we define a set of weights over the emojis and calculate the weighted sum over an emotion embedding vector to derive a *Sentiment* reward which is higher for positive sentiment and lower for negative sentiment. These weights are shown in Figure 7 (b). We also compute a sentiment-transition reward using the same score based on whether the peak positive sentiment occurred later in the conversation than the peak negative sentiment, reasoning that sentiment should improve over the course of the conversation. The *Bot Sentiment* reward is the DeepMoji sentiment computed on the bot response, *User Sentiment* reward is the value computed on the user response, and the *Sentiment Coherence* reward is based on the similarly of user and bot sentiments.

E.2 Engagement-based

Based on prior work (Zhou et al., 2018), we use the number of turns in the conversation as an indicator of the quality of the bot's performance. To distribute this reward over every utterance in the conversation, we take the total conversation length N, and compute the discounted reward for utterance $n < N$ as $\gamma^{N-n}N$ (*Conversation Length*). We also reward each utterance with the number of words and characters in the user's response, which we refer to as *User Ans. Word Len* and *User Ans. Char Len*. We also examine how long bot responses are with the *Bot Response Length* reward.

E.3 Laughter

Laughter has been shown to be very important to human affiliation (Provine, 1996) and solidarity (Hay, 2000). Therefore, we detect the number of occurrences of strings indicating laughter (e.g. 'ha', 'lol') in the user's response, and use this as a reward. Interestingly, we find that bots trained to maximize user laughter learn to be extremely supportive and cheerful compared to other bots (for definitions of supportive and cheerful see section E.6).

E.4 Semantic similarity

Language style matching has been shown to be a strong predictor of relationship initiation and stability (Ireland et al., 2011). While it would be ideal if our chatbots could intelligently adapt their conversation style to a new user, in reality most baseline dialog models struggle to maintain topic coherence, even over a few utterances (for an analysis of this effect, see (Ghandeharioun et al., 2019)). Therefore we reward *semantic similarity* between the user's input and the bot's response, to encourage the bot to stay on topic and produce reasonable answers. The *Infersent Cornell Coherence* and *Infersent Reddit Coherence* rewards are computed using a sentence embedding model trained on the Reddit and Cornell corpora respectively (described in section A.1). We use the Universal Sentence Encoder ((Conneau et al., 2017)) to compute the *USE Similarity* reward. We also directly compute word overlap as a reward as *Word Similarity*.

E.5 Questions

Asking questions is an important listening skill, and is linked to conversation management, attentiveness, and responsiveness (Bodie et al., 2012). Therefore, we give the bot a reward of 0.5 if the utterance contains a question word (*how, what, where, why, when, who*), and an additional 0.5 if it contains a question mark. We refer to this reward as *Bot Question*.

E.6 Phrase based rewards

After training the bots on these rewards, we noticed a shift in the distribution of their language towards more polite, cheerful, and supportive speech. Therefore, we designed post-hoc metrics to measure these qualities, which are based on counting whether a subset of phrases is present in an utterance.

Compliment phrases: *you are beautiful, you*

(a)

(b)

Figure 7: (a) 64-most frequent emojis as predicted by (Felbo et al., 2017) used for calculating emotion embeddings. (b) Assigned weights used in producing the sentiment reward from the predicted emoji values.

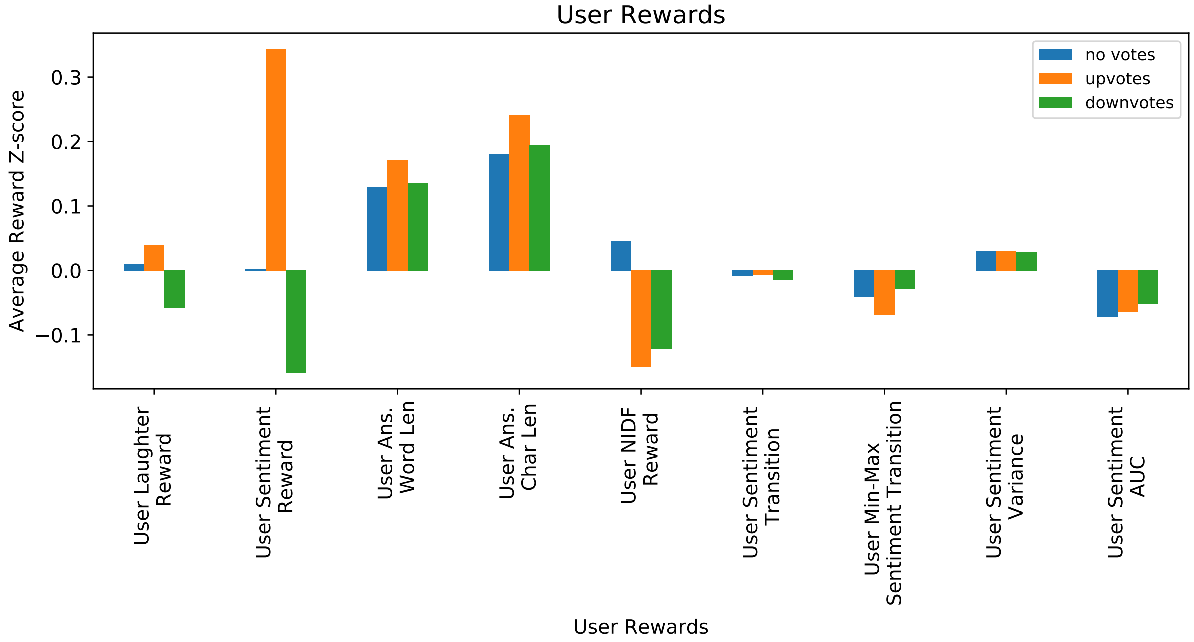

Figure 8: Mean z-scores for user-response-based rewards by manual vote

are so beautiful, you're beautiful, you're beautiful, you are the best, you're the best, i like you, you're a good, you re a good, i love the way you

Politeness phrases: *if I may; may I; please; thanks; no worries; if you don't mind; have a great day; I'm sorry*.

Supportive phrases: *you're right; you are right; you're not alone; you are not alone; congrats; that's a good idea; that is a good idea; you'll be fine; you will be fine; you'll be okay; you will be okay; it will get better; sorry you're going through; sorry you are going through; if it makes you feel better; if it makes you feel any better; keep your head up; keep it up; I'm in a similar situation; I am in a similar situation; you'll get it; you will get it; happy for you; I'm in the same boat; I am in the same boat; if you feel like you need to vent*.

Cheerful phrases: *nice to hear; happy; excited; really nice; glad; the best; great; good time; looking forward; beautiful*.

E.7 Toxicity

We also want to discourage our bot from malicious or offensive language. Saleh et al. (2019) incorporate a Toxicity Classifier trained with data from the Toxic Comment Classification Challenge[3] as a reward in the training hierarchical RL dialog models. We compute Toxicity reward scores using this classifier as *Bot Toxicity* (e.g. lower toxicity score, higher *Bot toxicity* reward).

E.8 Specificity

Specificity within a conversation is valuable in avoid exchanging vacuous phrases back and forth.

---

[3] `https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge`

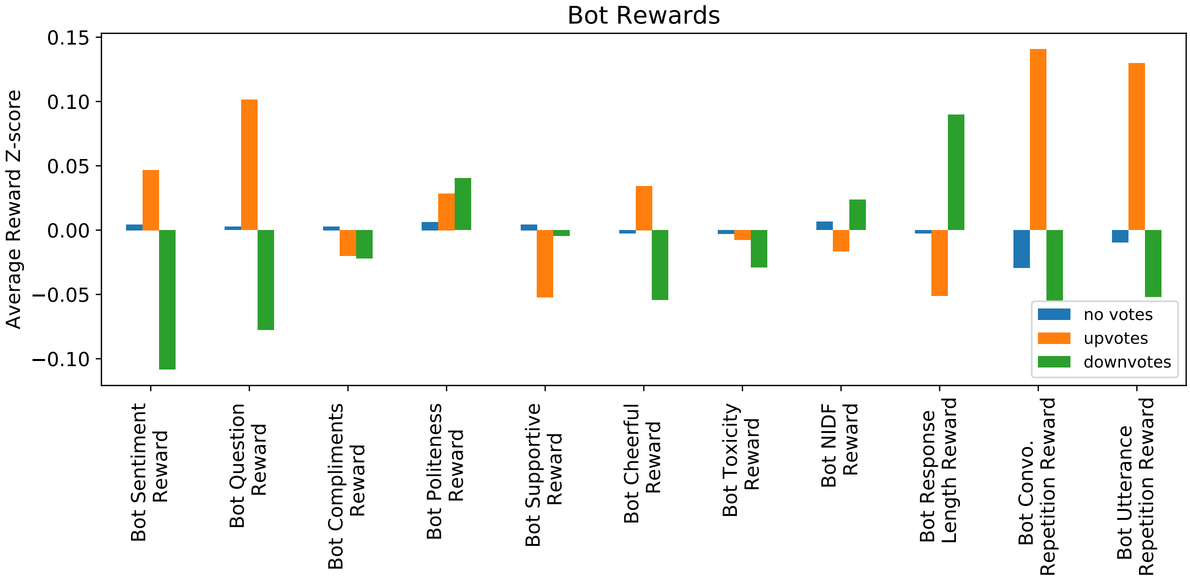

Figure 9: Mean z-scores for bot-based rewards by manual vote

However building a chit-chat bot without a knowledge graph back-end limits the level of substance that can be incorporated into a conversation. We use the approach from (See et al., 2019) of computing normalize IDF to create more specificity in the conversation. We compute NIDF on both user (*User NIDF*) and bot (*Bot NIDF*) text.

E.9 Repetition

While minimizing repetition is a common implicit goal of dialog systems, we will explicitly optimize for reducing repetition through repetition rewards. We compute utterance repetition by the number of non-unique words in each utterance as *Bot Utterance Repetition Reward*. We compute conversation repetition by the number of non-unique words in each conversation as *Bot Convo. Repetition Reward*. These rewards are negated since we want a higher reward score for less repetition. We also remove stop words in the computation of non-unique words.

F Interactive bot platform details

To collect data from humans interacting with our bots, we built a platform for hosting deep neural network dialog models online on GPU for fast, real-time inference. Figure 11 shows an example of the interface, in which users are able to rate the bots after talking to them for at least three turns.

Note that during the chat, annotators can optionally click the up and down arrows beside each chatbot response to give feedback on the specific utterance. Once 6 or more turns of the conversation has taken place, participants may click “Close Chat and Rate” to get to the rating screen.

We train our RL models based on chat data collected on this platform. Currently, the conversations contain Personally Identifiable Information such as user name, age, location, etc. We obtained for IRB approval for this study and cannot release the conversations at this time in their current form.

F.1 Website server setup and configuration

The server was hosted on a Google Cloud Platform virtual instance with 64GB of RAM and a NVIDIA Tesla P100 graphics card. The backend was a Django program being served by NGINX and uWSGI. For simplicity, we opted to have the Django process import the chatbots into the same Python process as Django, rather than have the two connect to each other via other means such as sockets. This configuration decreased development time and increased reliability, but it would need to be revisited if the server needed to scale several orders of magnitude past what was required for this study. The current configuration was still able to support hundreds of simultaneous users and host more than 30 bots concurrently.

The chatbots were kept in a separate project from the Django project and maintained separately from the server code. Each chatbot extended an abstract class that defined key methods for the Django pro-

gram to use, and was registered to a globally accessible dictionary via a decorator. The Django project was provided the path to the Chatbots project in its PYTHONPATH, so it could import the dictionary in which all the chatbot objects had been registered and use that to dynamically determine which chatbots were available and to access them in its views.

It is important to note that the chatbots used PyCUDA, and PyCUDA does not work in a multiprocessing environment. Because of this, uWSGI needed to be configured to only have one python process and to disable any attempt at multiprocessing. Furthermore, the chatbots required substantial startup times, so all chatbots are kept in memory at all times in the Django process. In order to keep all the chatbots in memory concurrently, we needed a very high amount of RAM on our server and opted for a 64GB virtual instance, and a GPU with 16GB RAM. This combination of CUDA to run the chatbots on the GPU with a high amount of RAM to keep all bots in memory at the same time resulted in incredibly fast server response times, with effectively no increase in response time when using the bots in requests compared to requests that did not.

For further information and instructions on server configuration, please read the server documentation available at `https://github.com/asmadotgh/neural_chat_web`. We hope that this platform will allow others to host their own bots and evaluate them in an interactive setting.

Speakers Fill Lexical Semantic Gaps with Context

Tiago Pimentel[ð] **Rowan Hall Maudslay**[ð] **Damián Blasi**[ə,ʃ,ʁ] **Ryan Cotterell**[ð,ʕ]
[ð]University of Cambridge [ə]Harvard University [ʃ]MPI SHH [ʁ]HSE University [ʕ]ETH Zürich

`dblasi@fas.harvard.edu`, `ryan.cotterell@inf.ethz.ch`

Abstract

Lexical ambiguity is widespread in language, allowing for the reuse of economical word forms and therefore making language more efficient. If ambiguous words cannot be disambiguated from context, however, this gain in efficiency might make language less clear—resulting in frequent miscommunication. For a language to be clear *and* efficiently encoded, we posit that the lexical ambiguity of a word type should correlate with how much information context provides about it, on average. To investigate whether this is the case, we operationalise the lexical ambiguity of a word as the entropy of meanings it can take, and provide two ways to estimate this—one which requires human annotation (using *WordNet*), and one which does not (using BERT), making it readily applicable to a large number of languages. We validate these measures by showing that, on six high-resource languages, there are significant Pearson correlations between our BERT-based estimate of ambiguity and the number of synonyms a word has in *WordNet* (e.g. $\rho = 0.40$ in English). We then test our main hypothesis—that a word's lexical ambiguity should negatively correlate with its contextual uncertainty—and find significant correlations on all 18 typologically diverse languages we analyse. This suggests that, in the presence of ambiguity, speakers compensate by making contexts more informative.

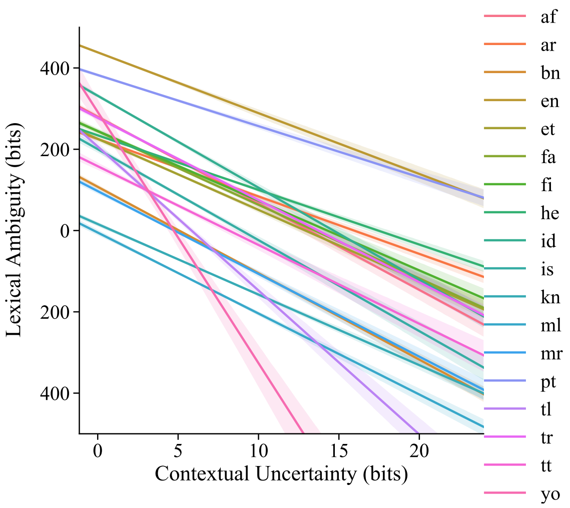

Figure 1: The relationship between contextual uncertainty—how uncertain a word is given its context—and lexical ambiguity, across a diverse set of languages.

1 Introduction

Linguistic structure and meaning are often underdetermined in the linguistic signal. In an extreme case this can lead to **ambiguity**: sentences might allow more than one valid syntactic structure, and pronouns could corefer to various antecedents. Complementarily, linguistic signals can also overdetermine some aspect of the intended message—for instance, agreement patterns may require redundant marking, and word forms might occupy sparsely populated parts of the phonological space (Harley and Bown, 1998).

In a tradition that goes back at least to Zipf, it has been hypothesised that individuals maintain an efficient balance between over- and under-specifying an intended message. Such balance is mediated by conflicting pressures for both **clarity** (the quality that allows the reconstruction of the intended message), and **economy of expression** (which allows for inexpensive and rapid encoding of the message in a linguistic signal).

A recent instantiation of this idea is that in an efficient language, one expects economical words (which are short or phonotactically simple) to be associated with multiple unrelated meanings, so they can be more widely used (Piantadosi et al., 2012). At first blush, this may appear to sacrifice clarity, increasing ambiguity and making it more difficult for a listener to resolve the linguistic signal. The emerging picture from psycholinguistics and

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4004–4015,
November 16–20, 2020.

pragmatics, however, is that individuals *can* fill in these ambiguous gaps, by tapping on additional linguistic or extra-linguistic cues (Tanenhaus et al., 1995; Federmeier and Kutas, 1999; Dautriche et al., 2018). An obvious example is given by the role of contextual information in reducing the ambiguity associated with the meaning of a word form. For instance, the contexts which surround the word *ruler* in the sentences 'Alice borrowed a *ruler* from her friends at school' and 'Bob rose to power and became a ruthless *ruler*' each play a crucial role in disambiguating its intended underlying meaning.

To remain robust in the presence of noise, we may expect the linguistic signal to be on average somewhat overdetermined by the speaker, leading to redundancy in how words and their contexts determine the intended meaning.[1] By analysing this redundant information-theoretically under the assumption that languages strike a balance between economy of expression and clarity, we derive that the 'amount' of lexical ambiguity in a given word type should negatively correlate with how uncertain on average the word is given its context (see §4). As communication unfolds, the efficiency of a particular word can only be modestly modified (e.g. by choosing clipped forms when available; Mahowald et al., 2013). However, contexts can be enriched or demoted dynamically, so as to complement a word with the evidence needed for disambiguation.

To investigate whether it is the case that the contexts in which a word appears are systematically adapted to enable disambiguation, we first provide an operationalisation of lexical ambiguity, grounded in information theory. We then provide two methods for estimating it, one using *WordNet* (Miller, 1995), and the other using multilingual BERT's contextualised embeddings (Devlin et al., 2019), which allows us to explore a large set of languages. We validate our lexical ambiguity measurements by comparing one to the other in six high-resource languages from four language families (Afro-Asiatic: Arabic; Austronesian: Indonesian; Indo-European: English, Persian and Portuguese; Uralic: Finnish), and find significant correlations between the number of synsets in *WordNet* and our BERT estimate (e.g. $\rho = 0.40$ in English), indicating that our annotation-free method for measuring lexical ambiguity is useful.

We then test our main hypothesis—that the contextual uncertainty about a word should negatively correlate with its degree of lexical ambiguity. First, we test this on the same set of six high-resource languages for which we have *WordNet* annotation, and find significant negative correlations on five of them. We then extend our evaluation, using our BERT-based measure, to cover a much more representative set of 18 typologically diverse languages: Afrikaans, Arabic, Bengali, English, Estonian, Finnish, Hebrew, Indonesian, Icelandic, Kannada, Malayalam, Marathi, Persian, Portuguese, Tagalog, Turkish, Tatar, and Yoruba.[2] In this set, we find significant negative correlations for all languages (see Figure 1).

2 Ambiguity in Language

While the pervasiveness of ambiguity in language encumbers the algorithmic processing of natural language (Church and Patil, 1982; Manning and Schütze, 1999), people seamlessly overcome ambiguity through both linguistic and non-linguistic means. World knowledge, pragmatic inferences, and expectations about discourse coherence all contribute to rapidly decoding the intended message out of potentially ambiguous signals (Wasow, 2015). While sometimes ambiguity might indeed result in an observed processing burden (Frazier, 1985), which could lead communication astray, individuals can in response retrace and reanalyse their inferences (as it has been famously shown in garden-path sentences like "The horse raced past the barn fell"; Bever, 1970).

This outstanding capacity to navigate ambiguous linguistic signals calls for a reexamination of the presence of ambiguity found in language. If the linguistic signal was deterministically and uniquely decodable—as, for instance, in the universal language proposed by Wilkins (Borges, 1964)—then all of the para-linguistic evidence would be redundant, and the code underlying the signal would be substantially more cumbersome. On the other hand, if linguistic signals present individuals with too many compatible inferences, communication would break down. An extreme case is represented by Louis Victor Leborgne, an aphasia patient described by Paul Broca (Mohammed et al., 2018). Louis, in spite of immaculate comprehension and mental functions, was unable to utter anything else than the syllable "tan" in his attempts to communicate.

---

[1] We refer to overdetermination with relation to redundancies in the signal itself, rather than a precise intended meaning.

[2] We refer to these using ISO 639-1 codes.

The most influential explanation offered for why natural languages are seemingly far from both extremes derives from the seminal work of Zipf (1949). In that work, Zipf proposed several aspects of human cognition and behaviour could be derived from the principle of least effort. Languages should aim to minimise the complexity and cost of linguistic signals as much as possible, under the sole constraint that the signal can be decoded efficiently.

2.1 Lexical Ambiguity

We are concerned exclusively with **lexical ambiguity**. A classic example is the English word *bank*, which can refer to either an establishment where money is kept, or the patch of land alongside a river. A significant source of lexical ambiguity is word types which exhibit multiple senses, which are said to be **polysemous** or **homonymous**.[3] Dautriche (2015) estimates that about 4% of word forms are homophones: "such variation is the rule rather than the exception" (Cruse, 1986).

Lexical ambiguity is, in general, a fuzzy concept. Not only can it be unclear what it means for two senses to be distinct, but different linguistic annotators will also have different opinions on what constitutes a word sense versus a productive use of metaphor. Often the 2nd or 3rd definitions of a word in a dictionary blur this line (Lakoff and Johnson, 1980)—in *WordNet* (Miller, 1995), for instance, the third sense of *attack* (intense adverse criticism, e.g. "the government has come under attack") could be viewed as a metaphorical usage of the first (a military offensive against an enemy, e.g. "the attack began at dawn"), projected from one domain to another. Indeed, this fuzziness has led some researchers to prefer unsupervised word sense induction methods, as they obviate the potentially problematic annotation altogether (e.g. Panchenko et al., 2017). Such unsupervised methods are not without problems, though, with one example being their overreliance on topical words (Amrami and Goldberg, 2019). These difficulties motivate us to opt for using two distinct representation of a word's lexical ambiguity: one hand-annotated and discrete, the other unsupervised and continuous.

2.2 Accounts of Lexical Ambiguity

When investigating the relationship between ambiguity and word frequency, Zipf argued that ambiguity results as a trade-off from opposing forces between speaker and listener, together optimising the communication channel via a principle of least effort: the listener wants to easily disambiguate, the speaker wants to choose words which required little effort to utter, and to avoid excessively searching their lexicon.

Building on Zipf's (1949) theories, Piantadosi et al. (2012) posit that, when viewed information-theoretically, ambiguity is in fact a *requirement* for a communication system to be efficient. Focusing on economy of expression, Piantadosi et al. suggest that lexical ambiguity serves a purpose when the context allows for disambiguation—it allows the re-use of simpler word forms.[4] They support their hypothesis by demonstrating a correlation between the number of senses for a word listed in *WordNet* (Miller, 1995) and a number of measures of speaker effort—phonotactic well-formedness, word length and the word's log unigram probability (based on a maximum-likelihood estimate from a large corpus).

More recently, Dautriche et al. (2018) showed that languages' homophones are more likely to appear across distinct syntactic and semantic categories, and will therefore be naturally easier to disambiguate. In this work, we show that speakers compensate for lexical ambiguity by making contexts themselves more informative in its presence.

We note an important detail in one of Piantadosi et al.'s experiments. In their work, they employ unigram surprisal (i.e. $-\log p_{unigram}(\cdot)$, where $p_{unigram}(\cdot)$ is the unigram distribution) as a proxy for ease of production, correlating this with polysemy. They justify this approximation based on the fact that more frequent words are, in general, processed more quickly (Reder et al., 1974). However, this measure has a confounder with our hypothesis: a word's frequency correlates with its contextual uncertainty. We believe our proposed measure to be more directly connected with lexical ambiguity.

3 Ambiguity and Uncertainty

We formulate both lexical ambiguity and contextual uncertainty information-theoretically. Let $\mathcal{M}$ be a space of all lexical meaning representations, $\mathcal{W}$ be the space of all words and $\mathcal{C}$ be the space of all contexts. We denote the $\mathcal{M}$-, $\mathcal{W}$-, and $\mathcal{C}$-valued random variables as M, W and C, respectively, and name elements of those sets m, w and c. We take $\mathcal{M}$ to be an either discrete or continuous mean-

---

[3] We make no distinction between polysemy, homonymy, and other sources of lexical ambiguity a word may exhibit.

[4] Recent work, though, has shed some doubt in the interpretation behind these results, showing they might arise solely due to a language's phonotactics distribution (Trott and Bergen, 2020; Caplan et al., 2020).

ing space, $\mathcal{W}$ to be the set of words in a language (excluding the beginning-of- and end-of-sequence symbols, BOS and EOS) and

$$\mathcal{C} = \{\langle \text{BOS} \circ \mathbf{p}, \mathbf{s} \circ \text{EOS} \rangle \mid \mathbf{p} \circ w \circ \mathbf{s} \in \mathcal{W}^*\} \quad (1)$$

where $\circ$ denotes string concatenation, and $\mathbf{p}$ and $\mathbf{s}$ are the prefix and suffix context strings respectively. This set contains every possible context that could surround a word, padded with beginning-of-sequence and end-of-sequence symbols. We additionally define $\tilde{\mathbf{p}} = \text{BOS} \circ \mathbf{p}$ and $\tilde{\mathbf{s}} = \mathbf{s} \circ \text{EOS}$.

3.1 Lexical Ambiguity

We start with a formalisation of lexical ambiguity. Specifically, we formalise the lexical ambiguity of *an entire language* as

$$\mathrm{H}(M \mid W) = \qquad (2)$$
$$- \sum_{w \in \mathcal{W}} p(w) \int p(m \mid w) \log_2 p(m \mid w) \, \mathrm{d}m$$

Interpreting entropy as uncertainty, this definition implies that the harder it is to predict the meaning of a word from its form alone, the more lexically ambiguous that word must be.

We will generally be interested in the half-pointwise entropy, rather than the entropy itself. In the case of lexical ambiguity, we consider the following half-pointwise entropy

$$\mathrm{H}(M \mid W = w) = \qquad (3)$$
$$- \int p(m \mid w) \log_2 p(m \mid w) \, \mathrm{d}m$$

This half-pointwise entropy tells us how difficult it is to predict the meaning when you know the specific word *without* considering its context. We will not generally have access to the true distribution $p(m \mid w)$, so we will need to approximate this entropy. This is discussed in §5.1. A unique feature of this operationalisation of lexical ambiguity is that it is language independent.[5] However, the quality of a possible approximation will vary from language to language, depending on the models and the data available in that language.

A final note is that mutual information between M and W *as a function of* w is equivalent, up to an additive constant, to the conditional entropy

$$\mathrm{I}(M; W = w) = \mathrm{H}(M) - \mathrm{H}(M \mid W = w) \quad (4)$$

where $\mathrm{H}(M)$ is constant with respect to w. This equation asserts something rather trivial: that lexical ambiguity is inversely correlated with how informative a word is about its meaning.

3.2 Contextual Uncertainty

The predictability of a word in context is also naturally operationalised information-theoretically. We take the contextual uncertainty, once again defined for *an entire language*, as

$$\mathrm{H}(W \mid C) = \qquad (5)$$
$$- \sum_{w \in \mathcal{W}} p(w) \sum_{\mathbf{c} \in \mathcal{C}} p(\mathbf{c} \mid w) \log_2 p(w \mid \mathbf{c})$$

Again, we are mostly interested in the half-pointwise entropy, which tells us how predictable a given word is, averaged over all contexts:

$$\mathrm{H}(W = w \mid C) = \qquad (6)$$
$$- \sum_{\mathbf{c} \in \mathcal{C}} p(\mathbf{c} \mid w) \log_2 p(w \mid \mathbf{c})$$

We take this as our operationalisation of contextual uncertainty. We note that this definition is different to typical uses of surprisal in computational psycholinguistics (Hale, 2001; Levy, 2008; Seyfarth, 2014; Piantadosi et al., 2011; Pimentel et al., 2020). Most work in this vein attempts to maintain cognitive plausibility, usually calculating surprisal based on only the unidirectional left piece of the context, as $-\log p(w \mid \mathbf{c}_{\leftarrow})$.

Although surprisal is the operationalisation we are interested in here, we note that a word may have low surprisal if it is frequent *across many* contexts and not just in a specific one under consideration. Sticking with our notion of half-pointwiseness, we define contextual informativeness as

$$\mathrm{I}(W = w; C) = \qquad (7)$$
$$\mathrm{H}(W = w) - \mathrm{H}(W = w \mid C)$$

where we define a word's pointwise entropy (also known as surprisal) as

$$\mathrm{H}(W = w) = -\log_2 p(w) \qquad (8)$$

The mutual information between a word and its context was studied before by Bicknell and Levy (2011), Futrell and Levy (2017) and Futrell et al. (2020)—although only using the unidirectional left piece of the context. Eq. (7) again asserts something trivial: low contextual uncertainty implies in an informative context. This informativeness itself is upper-bounded by the word's absolute negative log-probabiliy (i.e. the unigram surprisal).

---

[5] We acknowledge the abuse of this bigram in the NLP literature (Bender, 2009), and use it in the following specific sense: the operationalisation may be applied to *any* language independent of its typological profile.

4 Hypothesis: Why Should Ambiguity Correlate with Uncertainty?

As discussed in §1, we expect the linguistic signal to be on average somewhat overdetermined or redundant—such redundancy leads to **robustness** in noisy situations, when part of the signal may be lost during its implementation. A natural measure of robustness is the three-way mutual information between the context of a word, the word itself, and meaning—$\mathrm{I}(M; C; W)$—which represents how much information about the meaning is redundantly encoded in both the context and the word. The half-pointwise tripartite mutual information can be decomposed as

$$\begin{aligned}
\mathrm{I}(M;&C; W = w) \\
&= \mathrm{I}(M; W = w) - \mathrm{I}(M; W = w \mid C) \\
&= \mathrm{I}(M; W = w) - \mathrm{H}(W = w \mid C) \\
&\quad + \mathrm{H}(\cancel{W = w \mid M, C}) \\
&\approx \underbrace{\mathrm{I}(M; W = w)}_{(1)} - \underbrace{\mathrm{H}(W = w \mid C)}_{(2)} \qquad (9)
\end{aligned}$$

In this equation, we assume there are no true synonyms under a specific context—i.e. given a meaning and a context there is no uncertainty about the word choice: $\mathrm{H}(W = w \mid M, C) \approx 0$. Term 1 is the information a word shares with its meaning (which is inversely correlated with lexical ambiguity; see eq. (4)) and term 2 is the predictability of a word in context or the contextual uncertainty (which is itself inversely correlated with contextual informativeness; see eq. (7)).

For a language to be efficient, it may reuse its optimal word forms (as defined by their utterance effort), increasing lexical ambiguity (Piantadosi et al., 2012) and reducing the amount of information a word contains about its meaning (term 1). This reduces redundancy though, increasing the chance of miscommunication in the presence of noise. Speakers can compensate for this by making contexts more informative for these words (term 2 smaller). A negative correlation between contextual uncertainty and lexical ambiguity then arises from the trade-off between clarity and economy.

5 Computation and Approximation

Our information-theoretic operationalisation requires approximation. First, we do not know the true distributions over words, their meanings and their contexts. Second, even if we did, eq. (3) and eq. (6) would likely be hard to compute.

5.1 Lexical Ambiguity

In this section, we provide two approximations for lexical ambiguity. One assumes discrete word senses and requires data annotation (*WordNet*), while the other considers continuous meaning spaces (BERT) and allows us to extend our analysis to languages with fewer of these resources.

Discrete senses *WordNet* (Miller, 1995) is a valuable resource available in high-resource languages, which provides a list of synsets for word types. By taking these synsets to be the possible meanings of a word, and assuming a uniform distribution over them, we approximate the entropy as

$$\mathrm{H}(M \mid W = w) \approx \log_2(\#\textit{senses}[w]) \qquad (10)$$

Continuous meaning space We now describe how to approximate ambiguity using BERT (Devlin et al., 2019).[6] Let $w \in \mathcal{W}$ be a word and let $\mathbf{c} = \langle \tilde{\mathbf{p}}, \tilde{\mathbf{s}} \rangle \in \mathcal{C}$ be a padded context. We assume that a word's contextual embedding in BERT (i.e. its final hidden state) is a good approximation for its meaning in a given sentence.[7] We define the hidden state of a word w in a context $\mathbf{c}$ as

$$\mathbf{h}_{\langle w, \mathbf{c} \rangle} = \mathrm{BERT}(\tilde{\mathbf{p}} \circ w \circ \tilde{\mathbf{s}}) \qquad (11)$$

and we approximate the true distribution over words, meanings and contexts by

$$p(w, m, \mathbf{c}) \approx \delta(m \mid w, \mathbf{c})\, p(w, \mathbf{c}) \qquad (12)$$

where we define $\delta(m \mid w, \mathbf{c})$ to place probability 1 on the point $m = \mathbf{h}_{\langle w, \mathbf{c} \rangle}$ and 0 on every other point. In other words, we assume the meaning is a deterministic function of a word–context pair, and that it is approximated by BERT's hidden state.

This alone is not enough to estimate eq. (3), though, since we still do not have access to the true distribution $p(w, \mathbf{c})$. Furthermore, estimating the marginal distribution $p(m|w)$ directly is infeasible, given the sparsity of the meaning space. Instead, we approximate an upper bound of the entropy directly—exploiting the fact that a Gaussian distribution $\mathcal{N}(\mu, \Sigma)$ will have an entropy that is

---

[6] We used the implementation of Multilingual BERT made available by Wolf et al. (2019).

[7] Since BERT returns embeddings for WordPiece units (Wu et al., 2016) rather than words, we average them per word to get embeddings at the word-level. We acknowledge that this is a naïve method of compositionality; improving the method would likely strengthen our results.

greater than or equal to any other distribution with the same finite and known (co)variance (Cover and Thomas, 2012, Chapter 8):[8]

$$\mathrm{H}(M \mid W = w) \leq \mathrm{H}(\mathcal{N}(\boldsymbol{\mu}_w, \Sigma_w)) = \frac{1}{2} \log_2 \det{(2\pi e \Sigma_w)} \quad (13)$$

We estimate this covariance based on a corpus of N word–context pairs $\{\langle w, \mathbf{c}\rangle_i\}_{i=1}^{N}$, which we assume to be sampled according to the true distribution p (our corpora comes from Wikipedia dumps and is described in §6).[9]

The tightness of this upper bound on the entropy depends on both the accuracy of the covariance matrix estimation and the nature of the true distribution $p(m \mid w)$. If $p(m \mid w)$ is concentrated in a small region of the meaning space (corresponding to a word with nuanced implementations of the same sense), the bound in eq. (13) could be relatively tight. In contrast, a word with several unrelated homophones would correspond to a highly structured $p(m \mid w)$ (e.g. with multiple modes in far distant regions of the space) for which this normal approximation would result in a very loose upper bound.

5.2 Contextual Uncertainty

How uncertain the context is about a specific word is formalised in the half-pointwise entropy presented in eq. (6). We may get an upper bound on this entropy from its cross-entropy:

$$\mathrm{H}(W = w \mid C) \leq \mathrm{H}_{q_{\boldsymbol{\theta}}}(W = w \mid C) = -\sum_{\mathbf{c} \in \mathcal{C}} p(\mathbf{c} \mid w) \log q_{\boldsymbol{\theta}}(w \mid \mathbf{c}) \quad (14)$$

where $q_{\boldsymbol{\theta}}$ is a cloze language model that we train to approximate p (as we explain later in this section). This equation, though, still requires an infinite sum over $\mathcal{C}$. We avoid that by using an empirical estimate of the cross-entropy:

$$\mathrm{H}_{q_{\boldsymbol{\theta}}}(W = w \mid C) \approx -\sum_{i=1}^{N_w} \log q_{\boldsymbol{\theta}}(w_i \mid \mathbf{c}_i) \quad (15)$$

where N_w is the number of samples we have for a specific word type w.

To choose an appropriate distribution $q_{\boldsymbol{\theta}}(w \mid \mathbf{c})$, we train a model on a masked language modelling task. Defining MASK as a special type in vocabulary V, we take a masked hidden state as

$$\mathbf{h_c} = \mathrm{BERT}(\tilde{\mathbf{p}} \circ \text{MASK} \circ \tilde{\mathbf{s}}) \quad (16)$$

We then use this masked hidden state to estimate the distribution

$$q_{\boldsymbol{\theta}}(w \mid \mathbf{c}) = \mathrm{softmax}(W^{(2)} \sigma(W^{(1)} \mathbf{h_c})) \quad (17)$$

where $W^{(\cdot)}$ are linear transformations, and bias terms are omitted for brevity. We fix BERT's parameters and train this model with Adam (Kingma and Ba, 2015), using its default learning rate in PyTorch (Paszke et al., 2019). We use a ReLU as our non-linear function σ and 200 as our hidden size, training for only one epoch. By minimising cross-entropy loss we achieve an estimate for p.

We do not use BERT directly as our model $q_{\boldsymbol{\theta}}$ because its multilingual version was trained on multiple languages, and, thus, was not optimised on each individually. We found this resulted in poor approximations on the lowest-resource languages. Furthermore, we note that BERT gives probability estimates for word pieces (as opposed to the words themselves), and combining these piece-level probabilities to word-level ones is non-trivial. Indeed, doing so would require running BERT several times per word, increasing the already high computational requirements of this study. To compute the probability of a word composed of two word pieces, for example, we would need to run the model with two masks, i.e. $\mathrm{BERT}(\tilde{\mathbf{p}} \circ \text{MASK} \circ \text{MASK} \circ \tilde{\mathbf{s}})$, and combine the pieces' probabilities. To correctly estimate the probability distribution over the entire vocabulary (i.e. $q_{\boldsymbol{\theta}}(w \mid \mathbf{c})$), we would need to replace each position with an arbitrary number of MASKs and normalise these probability values.

6 Data

We used Wikipedia as the main data source for all our experiments. Multilingual BERT[10] was trained on the 104 languages with the largest Wikipedias[11]—of these, we subsampled a diverse set of 18 for our experiments: Afrikaans, Arabic, Bengali, English, Estonian, Finnish, Hebrew, Indonesian, Icelandic, Kannada, Malayalam, Marathi, Persian, Portuguese, Tagalog, Turkish, Tatar, and Yoruba.

---

[8] We note that, unlike its discrete counterpart, differential entropy values can be negative.

[9] We explain how to approximate the covariance matrix Σ_w per word type in App. A.

[10] Information about multilingual BERT can be found in: `https://github.com/google-research/bert/blob/master/multilingual.md`

[11] List of Wikipedias can be found in `https://meta.wikimedia.org/wiki/List_of_Wikipedias`

** $p < 0.01$ * $p < 0.1$

Table 1: Correlations between a word's lexical ambiguity as estimated with BERT or *WordNet*.

For each of these languages, we first downloaded their entire Wikipedia, which we sentencized and tokenized using language specific models in spaCy (Honnibal and Montani, 2017)—our definition of a word here is, thus, a token as given by the spaCy tokenizer. We then subsampled 1 million random sentences per language for our analysis and another 100,000 random sentences to train the model $q_{\boldsymbol{\theta}}$. We run multilingual BERT on the 1 million analysis sentences to acquire both $\mathbf{h}_{\langle w,\mathbf{c}\rangle}$ and $\mathbf{h}_{\mathbf{c}}$ (eq. (11) and eq. (16)) for each word in these corpora—discarding any word for which we do not have at least 100 contexts in which the word occurs. For the purpose of our analysis, we also discarded any word containing characters not in the individual scripts of the analysed language. The final number of word types used in our analysis can be found in Tables 1 and 3.

7 Discussion: *WordNet* vs. BERT-based approximations

The novel continuous (BERT-based) approximation of lexical ambiguity has two important virtues over the alternative *WordNet*-based measure. On the practical side, it can be readily computed for many languages. Since we are using multilingual BERT for our continuous approximation, as discussed in §5, this quantity is easily obtainable for the 104 languages on which it was trained. Second, on more theoretical grounds, the continuous representation of the space of meanings might better capture the gradient that goes from subtle but distinct senses of the same word to completely unrelated homophones (Cruse, 1986, p. 51). Alternatively, the *WordNet*-based measure of lexical ambiguity is supported by expert human annotation and extensive research on its linguistic and psycholinguistic correlates, e.g. Sigman and Cecchi (2002) and Budanitsky and Hirst (2006).

These differences notwithstanding, we expect both measures to correlate to a certain degree. To evaluate this, we run an experiment comparing both estimates in six languages from four different families for which *WordNet* is available: Arabic, English, Finnish, Indonesian, Persian, and Portuguese.

Figure 2 and Table 1 show that indeed both measures are positively correlated, although the association may be modest in some languages. The Pearson correlation between our estimates is $\rho = 0.40$ for English, but only $\rho = 0.06$ for Finnish—other languages lie in the range between the two.[12] This correlation seems to increase with the quality of the BERT model for the language under consideration—English has the largest Wikipedia, so multilingual BERT should naturally be better modelling it, while Finnish has the smallest Wikipedia among these six languages. A complementary explanation is that *WordNet* itself might be better for English than other languages—while English's *WordNet* contains synsets for 147,306 words, Persian only has them for 17,560. This suggests that the modest associations found should be taken as pessimistic lower bounds.

A potential underlying problem in the above study is that the number of senses a word has in *WordNet* might rely on word frequency (this beyond a true underlying relationship with it)—e.g. annotating senses for frequent words may be easier than for infrequent ones. Furthermore, the number

** $p < 0.01$ * $p < 0.1$

Table 2: Parameters (and their significance) of a multivariate linear regression predicting our BERT-based measure of ambiguity from both our *WordNet* estimate and the word's frequency. All analysed variables were normalised to have zero mean and unit variance.

of samples a word has in our corpus will affect its sample density in the embedding space and thus its estimated BERT entropy. As a second evaluation, we therefore train a multivariate linear regressor predicting our BERT-based measure not only from the log of the number of senses a word has in *WordNet*, but also the word's frequency (i.e. its number of occurrences in the corpus). This analysis is presented in Table 2, where we can see that both our estimates of lexical ambiguity still correlate when controlling for frequency. This table also shows that our BERT-based estimate still correlates with the word's frequency when controlling for the number of senses the word has in *WordNet*. Future work could delve further into what this correlation implies, with the potential to improve our proposed annotation-free estimate of lexical ambiguity.

8 Lexical Ambiguity Correlates With Contextual Uncertainty

We now test whether lexical ambiguity negatively correlates with contextual uncertainty, the main hypothesis of our paper. We first evaluate this on a set of six high-resource languages, using our *WordNet* estimate for the lexical ambiguity of a word. The top half of Table 3 shows the results: for five of the six languages, there is a negative correlation between the number of senses of a word and contextual uncertainty ($p < 0.01$). The top half of Figure 3 further presents these results. In these Figures we see that, especially for highly ambiguous words, contextual uncertainty tends to be very small. This supports our hypothesis, but only on a restricted set of languages for which *WordNet* is available.

With that in mind, we now consider a larger and more diverse set of 18 languages, analysed using our BERT-based estimator of lexical ambiguity. Figures 1 and 3 show the relationship between contextual uncertainty and lexical ambiguity—in all 18 analysed languages, we find negative correlations, further supporting our hypothesis. These correlations are presented in the bottom half of Table 3, and range from Pearson $\rho = -0.31$ in Portuguese to $\rho = -0.55$ in Yoruba ($p < 0.01$).

Table 3: Correlation between lexical ambiguity and contextual uncertainty.

Comparing the top and bottom half of Table 3, we see that the correlations are larger when using our BERT estimate rather than the *WordNet* one. We believe this may result from one or all of the following: (i) there is a confounding effect caused by the use of the same model (BERT) to estimate both ambiguity and surprisal, (ii) the assumption that the senses in *WordNet* are uniformly distributed may be simplistic, and (iii) our BERT-based ambiguity estimate may capture a more subtle sense of ambiguity than *WordNet*, which may result in a

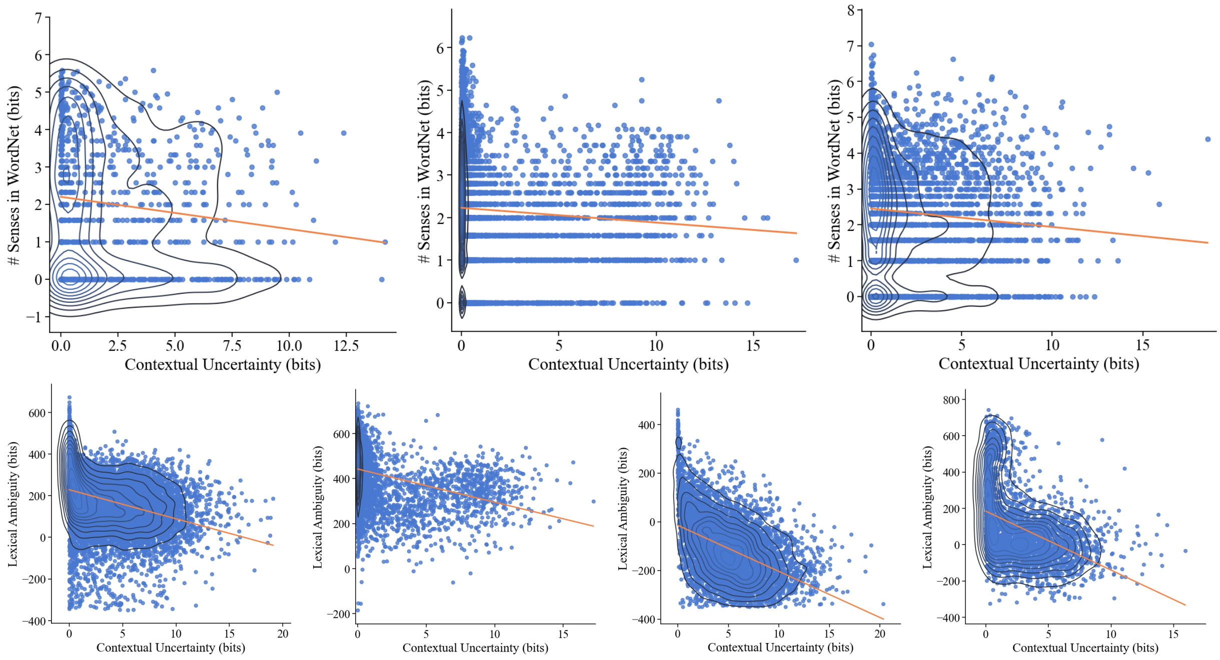

Figure 3: Contextual uncertainty versus lexical ambiguity in a selection of languages. Each plot contains the scatter points (representing each word type), a robust linear regression and kernel density estimate regions. (From left to right; Top) *WordNet*: Arabic, English, Indonesian; (Bottom) BERT: Arabic, English, Malayalam, Tagalog.

stronger correlation with contextual uncertainty.[13] Nonetheless, even if there is a confounding effect in this second batch of experiments (using BERT to estimate lexical ambiguity), the first batch (with *WordNet*) has no such confounding factor—providing strong support for our main hypothesis.

A quick visual inspection of Figure 3 indicates this data might be heteroscedastic—it might have unequal variance across distinct ambiguity levels. To investigate this, we run White's (1980) test on the uncertainty–ambiguity pairs. This verifies the intuition that this distribution is heteroscedastic for both our *WordNet* and BERT measures ($p < 0.01$). Future work should investigate the impact of this heteroscedasticity in lexical ambiguity.

Limitations This work focuses on proposing new information-theoretic approximations for both lexical ambiguity and bidirectional contextual uncertainty and on positing that these two measures should negatively correlate. In this experiment section, we tested the hypothesis on a set of typologically diverse languages. Nonetheless, our experiments are restricted to Wikipedia corpora. This data is naturally limited. For instance, while dialog utterances may rely on extra-linguistic clues, sentences in Wikipedia cannot. Furthermore, due to its ample audience target, the text in Wikipedia may be over descriptive. Future work should investigate if similar results apply to other corpora.

9 Conclusion

In this paper we hypothesised that, were a language economical in its expressions *and* clear, then the contextual uncertainty of a word should negatively correlate with its lexical ambiguity—suggesting speakers compensate for lexical ambiguity by making contexts more informative. To investigate this, we proposed an information-theoretic operationalisation of lexical ambiguity, together with two methods of approximating it, one using *WordNet* and one using BERT. We discuss the relative advantages of each, and provide experiments using both. With our *WordNet* approximation, we found significant negative correlations between lexical ambiguity and contextual uncertainty in five out of six high-resource languages analysed, supporting our hypothesis in this restricted setting. With our BERT approximation, we then expanded our analysis to a larger set of 18 typologically diverse languages and found significant negative correlations between lexical ambiguity and contextual uncertainty in all of them, further supporting our hypothesis that contextual uncertainty negatively correlates with lexical ambiguity.

---

[13] Cruse (1986, p. 51) argues there are two ways in which context affects a word's semantics—selection between units of distinct senses, or contextual modification of a single sense.

A Gaussian Approximation for a Words' Meanings

Given our samples $\{\langle w, \mathbf{c}\rangle_i\}_{i=1}^{N}$ of word–context pairs (assumed to be drawn from the true distribution p), we get the subset of N_w instances of word type w. We then use an unbiased estimator of the covariance matrix:

$$\Sigma_w \approx \frac{1}{N_w - 1}\sum_{i=1}^{N_w}\left(\mathbf{h}_{\langle w,\mathbf{c}\rangle_i} - \tilde{\boldsymbol{\mu}}_w\right)\left(\mathbf{h}_{\langle w,\mathbf{c}\rangle_i} - \tilde{\boldsymbol{\mu}}_w\right)^{\top} \tag{18}$$

where the sample mean is defined as

$$\tilde{\boldsymbol{\mu}}_w \approx \frac{1}{N_w}\sum_{i=1}^{N_w}\mathbf{h}_{\langle w,\mathbf{c}\rangle_i} \tag{19}$$

We note that these approximations become exact as $N_w \to \infty$ due to the law of large numbers.

Since $\mathbf{h}_{\langle w,\mathbf{c}\rangle}$ (i.e. BERT's hidden state) is a 768 dimensional vector, we might not have enough samples to fully estimate Σ_w. So we actually approximate this entropy by using only its variance $\mathrm{diag}(\Sigma_w)$. This is still an upper bound on the true entropy

$$H(\mathcal{N}(\boldsymbol{\mu}_w, \Sigma_w)) \leq H(\mathcal{N}(\boldsymbol{\mu}_w, \mathrm{diag}(\Sigma_w))) \tag{20}$$

The right side of this equation is, then, used as our actual lexical ambiguity estimate.

B ISO 639-1 Codes

In this Section, we present the set of ISO 639-1 language codes we use throughout this paper—in Table 4.

Abstract

Across languages, multiple consecutive adjectives modifying a noun (e.g. "the big red dog") follow certain unmarked ordering rules. While explanatory accounts have been put forward, much of the work done in this area has relied primarily on the intuitive judgment of native speakers, rather than on corpus data. We present the first purely corpus-driven model of multi-lingual adjective ordering in the form of a latent-variable model that can accurately order adjectives across 24 different languages, even when the training and testing languages are different. We utilize this novel statistical model to provide strong converging evidence for the existence of universal, cross-linguistic, hierarchical adjective ordering tendencies.

1 Introduction

Most native speakers of a language would agree that certain adjective orderings are preferable to others. For instance, in English, "the big red dog" sounds natural while "the red big dog" sounds very awkward. Similar ordering preferences have been found to apply universally across the languages in the world: for example, the adjective for "big" in most languages tends to be farther away from the noun, syntactically, than "red." For an overview of these phenomena, see Cinque (2010).

There are many explanatory accounts of cross-linguistic adjective ordering in the linguistics literature, the most popular being hierarchical tendencies based on semantic categories of adjectives (Dixon, 1982; Sproat and Shih, 1991; Cinque, 1994, 2010). For instance, Sproat and Shih (1991) and Cinque (2010) note that adjectives describing SIZE tend to be placed further from the noun than those describing COLOR in most languages. However, most of these studies have relied primarily on the judgment of native speakers rather than on corpus data, and those corpus-based models that do exist have focused exclusively on English (Shaw and Hatzivassiloglou, 1999; Malouf, 2000; Wulff, 2003; Mitchell, 2009; Dunlop et al., 2010; Mitchell et al., 2011; Hill, 2012; Scontras et al., 2017; Hahn et al., 2018; Futrell et al., 2020). In this paper, we make use of tools and techniques from statistical modeling to provide strong converging evidence supporting a hierarchical theory of cross-linguistic adjective ordering.

Specifically, we present a novel interpretable, multi-lingual, latent-variable model of adjective ordering that directly enforces a hierarchy of semantic classes and is trained entirely using corpus data. We empirically show that our model accurately orders adjectives across 24 different languages, even when tested on languages that it has not been trained on. In doing so, we demonstrate the existence of universal, cross-linguistic, hierarchical tendencies in adjective ordering.

2 Adjective Ordering

Consider the following English phrases, taken from Teodorescu (2006):

(1) A beautiful small black purse
(2) a. # A beautiful black small purse[1]
 b. # A small beautiful black purse
 c. # A small black beautiful purse

None of these phrases are ungrammatical, yet most native English speakers would contend that only (1) is correct in most contexts. Further complicating the phenomenon, there are many unmarked cases where ordering rules can be broken without hurting correctness. For example, now consider:

(3) A brown Chinese bear
(4) A Chinese [brown bear][2]

---

[1] # denotes an infelicitous phrase

[2] [ ] denotes an adjective-noun collocate

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4016–4028,
November 16–20, 2020.

Here, (3) presents the most natural ordering of "brown" and "Chinese" (to illustrate this, substitute "bear" with "house"), but (4) is also correct because a "brown bear" is an adjective–noun collocate. For a more detailed discussion on adjective ordering exceptions, see Teodorescu (2006).

2.1 Common Theories

All adjective ordering theories put adjectives on a scale. What differentiates them is the granularity of that scale and the metric used to rank adjectives. This section describes the most notable theories, which appeal to a hierarchy of semantic classes, inherentness, modification strength, and subjectivity. We adopt the hierarchical approach in this paper because it is more general and so allows a closer fit to the data. While the more functional explanations (i.e. inherentness, modification strength, and subjectivity) might allow us to derive a hierarchy from something more fundamental, current theories only appear to account for a portion of adjective ordering preferences.

Hierarchical theories. Hierarchical theories of adjective ordering posit that each adjective belongs to a class of semantically similar adjectives, and that these classes follow a rigid order. Several theories describing how prenominal adjective classes are ordered have been suggested, most famously Cinque (2010)'s: VALUE → SIZE → SHAPE → COLOR → PROVENANCE. Dixon (1982) observes that postnominal adjectives follow the opposite order as do prenominal ones. To illustrate, consider the following phrase in both English and Spanish:

(5) An ugly black shirt

(6)	Una	camisa	negra	fea
	a	*shirt*	*black*	*ugly*

Inherentness. The inherentness theory (Whorf, 1945) posits that adjectives fall into two broad categories: adjectives that describe inherent properties of nouns—such as color, material, physical state, provenance, breed, nationality, function, use, etc.—and adjectives that describe non-inherent properties, and that inherent adjectives are usually placed closer to the noun than non-inherent ones.

Modification strength. Vecchi et al. (2013) apply a compositional distributional semantics approach to studying English adjective–adjective–noun phrases, and note that in correctly ordered phrases, the adjective closer to the noun contributes more to the meaning of the phrase than does the adjective further from the noun. For instance, "different architectural style" is more similar to "architectural style" than it is to "different style".

Subjectivity. The subjectivity theory (Hill, 2012; Scontras et al., 2017; Hahn et al., 2018) ranks adjectives by subjectivity on a continuous scale and posits that the less subjective an adjective is, the closer it should be placed to the noun.

2.2 Binomial Ordering

A closely related phenomenon to adjective ordering is binomial ordering. Binomials are pairs of words joined by a conjunction, such as "salt and pepper" or "ball and chain". Adjective ordering and binomial ordering have been studied in similar ways, and have in many cases been found to behave similarly (Benor and Levy, 2006; Copestake and Herbelot, 2011; Ivanova and Levy, 2018).

3 A Latent-Variable Model

A natural mathematical formalization of adjective ordering is as a latent-variable model. A latent-variable model relates a set of observable variables to a set of unobservable (latent) ones. Here, we observe how adjectives are ordered in corpus data and from this infer an ordered set of latent adjective classes. This allows us to determine the ordering of an arbitrary set of adjectives by referencing their class memberships and the class order.

Like other latent-variable models, such as latent semantic analysis (Dumais et al., 1988) and latent Dirichlet allocation (Blei et al., 2003), our model aims to fit the data using a lower-dimensional space. In particular, the number of adjective classes is much smaller than the size of the vocabulary or the size of the pre-trained adjective embeddings.

3.1 Ordering English Adjectives

Consider an English noun phrase where k unique adjectives $\mathbf{a} = \{a_1, \ldots, a_k\}$ modify a noun n, and $k \geq 2$. Let $\mathcal{C}$ be an ordered set of latent adjective classes labeled $[1, 2, \ldots, |\mathcal{C}|]$ and let d be the dimensionality of our pre-trained word embedding vectors $\mathbf{e}(\cdot)$. Our goal is to simultaneously learn a mapping $\mathbf{V} \in \mathbb{R}^{d \times |\mathcal{C}|}$ from adjective embeddings to latent classes and learn an interaction matrix $\mathbf{W} \in \mathbb{R}^{|\mathcal{C}| \times |\mathcal{C}|}$ which reflects the preferred ordering of those classes.

We develop a probabilistic model of each of the $k!$ possible permutations $\boldsymbol{\pi}$ of $\mathbf{a}$ as in eq. (1), which factorizes the distribution in terms of the latent classes $\mathbf{c}$ (a k-length tuple of class labels, one per adjective in the permutation). The i^{th} class, c_i, denotes the class assigned to the i^{th} adjective, a_i.

$$p(\boldsymbol{\pi} \mid \mathbf{a}) = \sum_{\mathbf{c} \in \mathcal{C}^k} p(\boldsymbol{\pi} \mid \mathbf{c}) \prod_{i=1}^{k} p(c_i \mid a_i) \tag{1}$$

Given latent classes, the distribution over permutations is given in eq. (2), using the scoring function in eq. (3), where π_i indexes the adjective in the i^{th} position of the permutation, and so c_{π_i} is the latent class in the i^{th} position. Thus, eq. (3) sums the ordering preference scores between each consecutive pair of adjective classes in the permutation, using the pairwise preferences in $\mathbf{W}$. Using these scores, eq. (2) produces a distribution, normalizing over the set of all permutations S_k:

$$p(\boldsymbol{\pi} \mid \mathbf{c}) = \frac{\exp \operatorname{score}(\boldsymbol{\pi}, \mathbf{c})}{\sum_{\boldsymbol{\pi}' \in S_k} \exp \operatorname{score}(\boldsymbol{\pi}', \mathbf{c})} \tag{2}$$

$$\operatorname{score}(\boldsymbol{\pi}, \mathbf{c}) = \sum_{i=1}^{k-1} W_{c_{\pi_i}, c_{\pi_{i+1}}} \tag{3}$$

Finally, the distribution over latent classes is obtained with $\mathbf{V}$, making use of a pre-trained embedding $\mathbf{e}(a_i)$ for each adjective:

$$p(c_i \mid a_i) = \operatorname{softmax}\left(\mathbf{V}\,\mathbf{e}(a_i)\right)_{c_i} \tag{4}$$

To summarize, we compute the probability of each permutation by considering all possible assignments of latent classes. The probability of a permutation is a weighted sum (eq. (1)) of normalized scores (eqs. (2) and (3), using $\mathbf{W}$), weighted according to the likelihood of the latent classes (eq. (4), using $\mathbf{V}$). Both $\mathbf{W}$ and $\mathbf{V}$ are learned through batch gradient descent.

To predict an ordering, we enumerate all permutations of $\mathbf{a}$, compute their probabilities as described, and pick the highest scoring one.

3.2 Enforcing a Total Ordering

Hierarchical theories imply a total ordering of adjective classes. This means that the class order is antisymmetric, transitive, and a connex relation. While it is likely that our model learns a (predominantly) total ordering, we cannot be absolutely sure that it does. To remedy this, we enforce a total ordering of categories by modifying our model such that $\mathbf{W}$ is no longer learned, but is instead fixed as a matrix with ones above the diagonal and zeroes elsewhere. We will refer to this as an off-upper-triangular matrix. To illustrate how this enforces a total ordering, recall that each element W_{ij} of $\mathbf{W}$ represents a preference for ordering class i before class j. Then, given a $|\mathcal{C}| \times |\mathcal{C}|$ off-upper-triangular matrix of ones and zeroes:

$$\begin{bmatrix} 0 & 1 & 1 & \dots & 1 \\ 0 & 0 & 1 & \dots & 1 \\ 0 & 0 & 0 & \dots & 1 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & 0 \end{bmatrix}$$

Class 1 precedes classes $2, 3, \dots, |\mathcal{C}|$; class 2 precedes classes $3, 4, \dots, |\mathcal{C}|$; etc. To distinguish between the previously described variant where $\mathbf{W}$ is learned and this one, we will refer to the former as the **English Learned-W model (EL)** and the latter as the **English Fixed-W model (EF)**.

3.3 Handling Postnominal Adjectives

In English, noun phrases consisting of a noun and one or more adjectives always place the adjectives *before* the noun. However, this is not the case in other languages, where the adjectives can be placed before, after, or both before and after the noun. As such, we need to modify our model to accommodate such structures.

With the EL and EF models, we use a single interaction matrix $\mathbf{W}$ to score a permutation $\boldsymbol{\pi}$ of the adjectives $\mathbf{a} = \{a_1, \dots, a_k\}$ that modifies n. But if we must now support adjectives both before and after the noun, we must decompose $\mathbf{a}$ into two sets: $\mathbf{a}^{(\text{left})} = \{a_1^{(\text{left})}, \dots, a_j^{(\text{left})}\}$ and $\mathbf{a}^{(\text{right})} = \{a_1^{(\text{right})}, \dots, a_\ell^{(\text{right})}\}, j \geq 2$ or $\ell \geq 2$. Then, we can use two separate $\mathbf{W}$ matrices, $\mathbf{W}^{(\text{left})}$ and $\mathbf{W}^{(\text{right})}$, to score the adjectives that appear directly to the left and right of n, respectively:

$$\begin{aligned} \operatorname{score}(\boldsymbol{\pi}, \mathbf{c}) = {} & \operatorname{score}(\boldsymbol{\pi}^{(\text{left})}, \mathbf{c}^{(\text{left})}) \\ & + \operatorname{score}(\boldsymbol{\pi}^{(\text{right})}, \mathbf{c}^{(\text{right})}) \end{aligned} \tag{5}$$

Conveniently, maximizing $\operatorname{score}(\boldsymbol{\pi}, \mathbf{c})$ is equivalent to maximizing $\operatorname{score}(\boldsymbol{\pi}^{(\text{left})}, \mathbf{c}^{(\text{left})})$ and $\operatorname{score}(\boldsymbol{\pi}^{(\text{right})}, \mathbf{c}^{(\text{right})})$ independently.

As with English, we present two variants of the multi-lingual model, one where $\mathbf{W}^{(\text{left})}$ and $\mathbf{W}^{(\text{right})}$ are learned and one where they are fixed. We will refer to the former as the **Multi-lingual Learned-W model (ML)** and the latter as the **Multi-lingual Fixed-W model (MF)**. The primary challenge in implementing MF is deciding what $\mathbf{W}^{(\text{right})}$ should be. While $\mathbf{W}^{(\text{left})}$ can simply be an off-upper-triangular matrix, as $\mathbf{W}$ is in EF, we need an appropriate matching $\mathbf{W}^{(\text{right})}$ that captures the different treatment given to prenominal and postnominal adjectives. Ultimately, we adopt Dixon (1982)'s observation that postnominal adjectives follow the opposite order as do prenominal ones, and fix $\mathbf{W}^{(\text{right})}$ as a matrix with ones below the diagonal and zeroes elsewhere, i.e. an off-lower-triangular matrix.

3.4 Multi-lingual Word Embeddings

In order to predict adjective order across languages, we need a joint model for word representations. We use multi-lingual fastText (Bojanowski et al., 2017) Wikipedia supervized word embeddings of dimensionality $d = 300$ aligned in a single vector space (MUSE), provided by Conneau et al. (2018).

4 Data

This section describes our English, multi-lingual, and additional languages datasets.

4.1 English Dataset

Multi-adjective noun phrases are surprisingly rare; analyzing 54,478 English noun phrases from the Universal Dependencies (UD) project (Nivre et al., 2016; Zeman et al., 2019), we find that only 745 of them (1.37%) contain two or more adjectives. As such, we require a large corpus to train our model. The data comprising the English dataset comes from ukWaC (Baroni et al., 2009), an enormous (>2 billion words) corpus of automatically tagged and dependency-parsed online text from the .uk domain. Unfortunately, ukWaC contains a lot of low-quality data, including non-English characters, incorrect tokenization, and part-of-speech errors.

We first extract all noun phrases where a noun is modified by multiple consecutive adjectives, i.e. all phrases consisting of an ordered set of consecutive adjectives $[a_1, \ldots, a_k], k \geq 2$, directly preceding a noun n. We then disqualify all noun phrases where more than six adjectives modify a noun, because we find that such samples tend to consist of bad data, such as "......" annotated as a sequence of adjectives. Finally, MUSE fastText embeddings are only released as word–embedding dictionaries, unlike standard fastText embeddings which are built from substrings of characters. Thus, unlike conventional fastText embeddings, they are unable to infer embeddings for unseen words. And so, we need to disqualify all noun phrases which include adjectives not in these dictionaries.

	Split by Token	
	# Phrases	# Adj Types
Training	10,000	2,695
Testing	1,000	806
Total	11,000	2,786
	Split by Type	
	# Phrases	# Adj Types
Training	9,165	2,514
Testing	1,835	890
Total	11,000	2,786

Table 1: English dataset summary.

We then randomly select 12,000 phrases. Of these, 1,000 are set aside as a development set. The remaining 11,000 phrases are split in two different ways: by **token** and by **type**. Splitting by token is done by randomly picking 10,000 phrases to form the training set and letting the remaining 1,000 phrases form the testing set. Splitting by type is done by randomly picking 90% of the unique adjective types in the data, letting all phrases where *all* their adjectives belong to this 90% form the training set, and letting the remaining phrases form the testing set. This ensures that every phrase in the testing set will contain at least one adjective not present in the training set. A summary of the English dataset can be found in Tab. 1.

4.2 Multi-Lingual Dataset

Because our multi-lingual models are trained on multiple languages at once, we do not need as many data per language and can afford to use much smaller corpora. We obtain the non-English data used to train ML and MF from UD. UD provides treebanks with annotated dependencies in many languages, which we use to determine which adjectives are modifying which nouns. The English portion of this dataset re-uses the ukWaC corpus.

For each language that we choose to include, we once again extract all noun phrases where a noun is modified by multiple consecutive adjectives. This time, however, we need to account for postnominal adjectives as well. We extract all phrases where an ordered set of consecutive adjectives $[a_1^{(\text{left})}, \ldots, a_j^{(\text{left})}], j \geq 2$, precedes n or an ordered set of consecutive adjec-

tives $[a_1^{(\text{right})}, \ldots, a_\ell^{(\text{right})}], \ell \geq 2$, follows n. We then once again disqualify all noun phrases which include adjectives not in the MUSE fastText dictionary. From the remaining pool, we randomly select 5,000 phrases to form our training set and 1,000 phrases to form our testing set, except for Russian, where we only have 667 phrases remaining to construct the testing set. A summary of the multi-lingual dataset can be found in Tab. 2.

Criteria for Choosing Languages. We have two criteria for choosing languages for this dataset. Firstly, the language must have MUSE fastText embeddings, as we require embeddings aligned in a common vector space. Secondly, the UD corpora for the language must contain over 5,000 usable multi-adjective noun phrases to provide a sufficiently large training set.

4.3 Additional Languages Dataset

A glaring limitation of our multi-lingual dataset is that it is not typologically diverse: it contains two Germanic and two Slavic languages. Most critically, we note that in all four of its languages, adjectives predominantly precede the noun. While we are unable to train on more languages due to a lack of data, there is no reason why we cannot test on them. The additional languages dataset consists of phrases from 20 additional MUSE-supported languages using their UD corpora and the same preprocessing pipeline as described in §4.2. Among these are three Uralic languages (Estonian, Finnish, Hungarian) and one Afro-Asiatic language (Hebrew), while the rest are Indo-European. We do not include Arabic because its MUSE fastText embeddings seem to be incorrectly formatted. We also choose not to include Indonesian, Macedonian, Romanian, Turkish, or Vietnamese because they have too few (<50) phrases to construct a representative testing set. Meta-data describing the additional languages dataset can be found in Tab. 3.

5 Experimental Details and Hyperparameters

We split our experiments into English experiments (§6) and transfer learning experiments (§7). All of our models are trained for a single epoch of the relevant training data with a learning rate of 0.1 and a batch size of 32; we found a single epoch more than sufficient for our purposes in preliminary experimentation. We also set $|\mathcal{C}| = 15$ and $d = 300$

	EL	EF	Random
Token split	0.843	0.823	0.483
Type split	0.836	0.829	0.482

Table 4: English accuracy on different data splits. Comparing the two models on the same data split, the results do not differ significantly.

	EL	EF	Random
Scrambled	0.791	0.797	0.483
Unscrambled	0.784	0.797	0.483

Table 5: English accuracy with scrambled and unscrambled fastText vectors. Comparing different vectors for the same model, the results do not differ significantly.

for all models. We report the exact expectation of the random baseline. All significance testing is done with permutation tests following Dror et al. (2018), using 10,000 random permutations and significance at $\alpha = 0.05$. All differences between model performance and the corresponding random baselines are significant with $p < 0.01$.

6 English Experiments

Our English experiments serve to demonstrate the basic correctness of the model. We also provide a qualitative analysis of EF.

6.1 Predictive Accuracy

We train each of the English models on the token and type split English data described in §4.1. The token split allows us to evaluate the basic predictive accuracy of EL and EF, while the type split allows us to evaluate how well the EL and EF models generalize to unseen adjective types. Results are detailed in Tab. 4. We achieve high accuracy on both the token split and type split data, demonstrating the correctness of the model. Importantly, our strong performance on the type split data demonstrates that EL and EF generalize well to unseen adjective types. We also observe that EL and EF results are similar, suggesting that adjective ordering preferences naturally tend towards a total ordering, since learning $\mathbf{W}$ did not significantly improve results.

6.2 Validating Use of fastText

We now address a potential confounding influence of the pre-trained fastText embeddings. We are concerned that adjective ordering information may be pre-baked into the MUSE fastText embeddings that we use, since the embeddings were trained on text where adjectives were correctly ordered. To check this, we retrain two small fastText models on a subset of 12,500 sentences from ukWaC. The first model is trained on these sentences as they are, and the second model is trained on a version of these sentences where strings of consecutive adjectives have been randomly scrambled. We then retrain the EL and EF models on the token split data with both the scrambled and unscrambled fastText vectors. Results are detailed in Tab. 5.

That neither pair of scrambled and unscrambled results differs significantly indicates that adjective ordering information is *not* coming from the fastText embeddings. Otherwise, the unscrambled model should have outperformed the scrambled model. Due to the computational expense of retraining multi-lingual fastText, we do not repeat this validation with the multi-lingual models.

6.3 Qualitative Evaluation of EF

Perhaps the most convenient property of the EF model is that it is fully interpretable. We are able to, for any given adjective, extract information about which class it belongs to, and know from the model's design that classes follow a total ordering such that class 1 precedes class 2 precedes class 3, and so on. In this experiment, we first qualitatively analyze the 177 testing phrases in the token split data that EF orders incorrectly, making generalizations about what kinds of mistakes the model makes. We then make a qualitative comparison between the hierarchy that EF learns and the hierarchy proposed by Cinque (2010).

Types of Mistakes. Two types of cases account for most of EF's mis-orderings. Firstly, many of the mis-ordered testing phrases deviate from typical adjective ordering tendencies because they contain adjective–noun collocates. Such phrases include "Italian [secret service]", "modern [good practice]", and "Japanese [popular culture]" (to illustrate how these are atypical, consider "secret Italian meatballs", "good modern ethics", and "popular Japanese restaurant"). We note that this tends to occur with adjectives that describe PROVENANCE: these, while typically placed near the noun, are also often prepended to collocates. We are largely unsurprised by this, as it mirrors the intuitive observations made regarding adjective-noun collocates illustrated in (3) and (4). An interesting direction for future work might be to model the likelihood of an adjective and a noun forming a collocate and integrate that into our current model.

Secondly, we observe that EF often mis-orders phrases containing adjectives describing ORDER (e.g. "next", "first", "other") and QUANTITY (e.g. "few", "many"). Examining EF's adjective-class layer, we discover that it has placed these words together in the same class, when intuitively ORDER adjectives should precede QUANTITY adjectives (e.g. "next few lessons", "first many partners"). Further experimentation would be necessary to determine why EF has done this, but we suspect intuitively that it may be because ORDER and QUANTITY adjectives are relatively small classes and are semantically similar. If they occur more often next to other classes than next to each other, there is only a weak pressure for the model to assign these words to distinct classes. A more rigorous error analysis would require a comprehensive dictionary of adjectives tagged with their semantic classes.[3] Unfortunately, constructing such a dictionary is beyond the scope of this paper.

Comparison with Cinque's Hierarchy. We take the 100 most common adjectives in the English dataset and use EF's adjective-class layer to determine their class memberships. We then compare these classes and their relative orderings to those proposed by Cinque (2010): VALUE → SIZE → SHAPE → COLOR → PROVENANCE.

We observe that EF follows most of Cinque's rules. Most notably, EF clearly learns categories of adjectives describing SIZE, COLOR and PROVENANCE, and additionally learns that SIZE precedes COLOR precedes PROVENANCE. We perform a small-scale statistical verification of this observation by hand-constructing a testing set of Cinquean phrases and using it to evaluate the similarity of EF's and Cinque's predictions. To do this, we first select five common adjectives from each of the five Cinquean categories. We then construct a testing set using pairs of only these 25 adjectives based on Cinque's hierarchy. This gives us $\binom{5}{2} * 5^2 = 250$ testing phrases. Since these are all pairs, the expected random baseline is simply 50%.

We then evaluate the predictive accuracy of EF on the Cinquean testing phrases. EF achieves an accuracy of 0.960 with $p < 0.01$, suggesting that EF agrees with most of Cinque's rules. Importantly, this does *not* mean that EF is 96% accurate at ordering adjectives, but only that EF agrees with 96% of Cinque's predictions on our test set. As discussed, many of EF's mistakes on real corpus data are attributable to adjective ordering exceptions like adjective-noun collocates, which Cinque's hierarchy does not address either.

While EF follows most of Cinque's *existing* rules, we also observe that EF learns *additional* rules not described by Cinque. For instance, EF seems to learn a category of adjectives describing TYPE, which follows adjectives describing PROVENANCE and contains adjectives such as "financial", "technical", and "scientific". This seems intuitively correct—to illustrate, consider "Russian financial burden", "German technical wonder", and "African scientific achievement". This suggests that an accurate adjective ordering hierarchy may need to be more complex than described by Cinque. In particular, it seems that Cinque's adjective classes are too broad. An alternate interpretation is that TYPE adjectives are defined by being capable of forming adjective-noun collocates with most of the nouns that they commonly modify.

But we must emphasize that this analysis is still anecdotal. The noted similarities and differences are difficult to quantify, and as far as we are aware there is no large-scale corpus of adjectives tagged with their Cinquean categories to enable a more reliable quantitative approach; we would ideally want such a corpus in a large number of languages. For now, we simply suggest that while Cinque's hierarchy captures many truths about adjective ordering, it does not quite grasp the entire picture.

Comparison with Functional Theories The bulk of the existing work on statistically modelling adjective ordering can be broadly separated into two categories: that which is *theoretically-motivated* (e.g. Wulff, 2003; Futrell et al., 2020), and that which is *empirically-motivated* (e.g. Malouf, 2000). The theoretically-motivated approach attempts to deduce the source of adjective ordering preferences by fitting adjective ordering data to pre-determined features derived from more fundamental functional pressures. The empirically-motivated approach attempts to fit adjective ordering data as accurately as possible by learning features from data. This paper falls into the empirically-motivated category because a hierar-

---

[3] Specifically, these would have to be semantic classes comparable with those learned by EF.

	ML (Learned **W**)			MF (Fixed **W**)			Random

English	$0.803^{\dagger\ddagger}$	0.820	0.820	0.800	0.811	0.808	0.487
German	$0.695^{\dagger\ddagger*}$	0.802	0.807	$0.732^{\dagger\ddagger*}$	0.796	0.807	0.488
Russian	$0.840^{\dagger\ddagger}$	$0.893^{\dagger}$	0.911	$0.859^{\ddagger}$	$0.873^{\dagger}$	0.892	0.485

Table 6: Multi-lingual accuracy. A † denotes that a result differs significantly from the result to its right. A ‡ denotes that a result differs significantly from the result two to its right. A * denotes that a result differs significantly from its ML/MF counterpart. The terminology used to describe the columns is defined in §7.1.

chical model like ours or Cinque's is in no way functional – it postulates that a particular hierarchy exists but does not explain why it exists in that particular order. Importantly, this means that a hierarchical theory is not necessarily at odds with the functional theories. Rather, it is very possible that one or more functional theories might serve to explain the empirically observed hierarchies.

Interestingly, there seems to be a gap in predictive accuracy between theoretically-motivated and empirically-motivated models. For example, Wulff (2003) and Futrell et al. (2020) achieve accuracies in the low 70s, while Malouf (2000) and this paper achieve accuracies in the 80s. While these results are hard to compare directly as they were achieved on different datasets, this suggests that there are some ordering preferences not yet captured by any existing functional theory.

7 Transfer Learning Experiments

An important claim of the hierarchical theory for adjective ordering is that the hierarchy applies universally across languages. If this is the case, then we should be able to accurately order adjectives from languages that we have not trained on.

7.1 Predictive Accuracy

We evaluate each of the multi-lingual models on the multi-lingual dataset in three different scenarios. The first scenario (henceforth the **mono-lingual** scenario) addresses single-language training and testing. For this, we train one model on each of the four languages in the dataset by itself. Each model is then tested on the language that it was trained on. The second scenario (henceforth the **transfer** scenario) addresses the model's ability to generalize to unseen languages by holding out the language in question. For this, we train four models, each on every language but the one we want to test (e.g. on Czech, English, German, but not Russian). Each model is then tested on the language that was held out during training. The third scenario (henceforth the **joint** scenario) addresses the potential for augmenting single-language training with additional data from other languages. For this, we train a single model on all four languages together. The model is then tested on each of the four languages individually. Results are detailed in Tab. 6.

We observe that the model performs much better than chance on the transfer scenario. This confirms the theory that universal hierarchical adjective ordering tendencies generalize across languages. Otherwise, we would expect chance level performance. We also observe that for all languages, performance on the joint scenario is better than or equal to performance on the mono-lingual scenario, which is in turn better than or equal to performance on the transfer scenario. This upward trend of transfer $\leq$ mono-lingual $\leq$ joint suggests that while training on additional languages can help performance, the most important single factor is to train on the language that is being tested. In fact, given that the multi-lingual models did not achieve the same performance on the joint scenario as the English models did on the English dataset (§6.1), we predict that performance on the mono-lingual scenario would have been the best for all languages if there had been more training data. Finally, we observe that for the most part, corresponding ML and MF results do not differ significantly, suggesting once again that adjective ordering preferences tend towards a total ordering. Taken together, these observations suggest that a universal hierarchy of adjective ordering tendencies exists, though individual languages may also feature additional unique tendencies not shared by the others.

Language	Family	Accuracy	Random

Table 7: MF accuracy on additional languages.

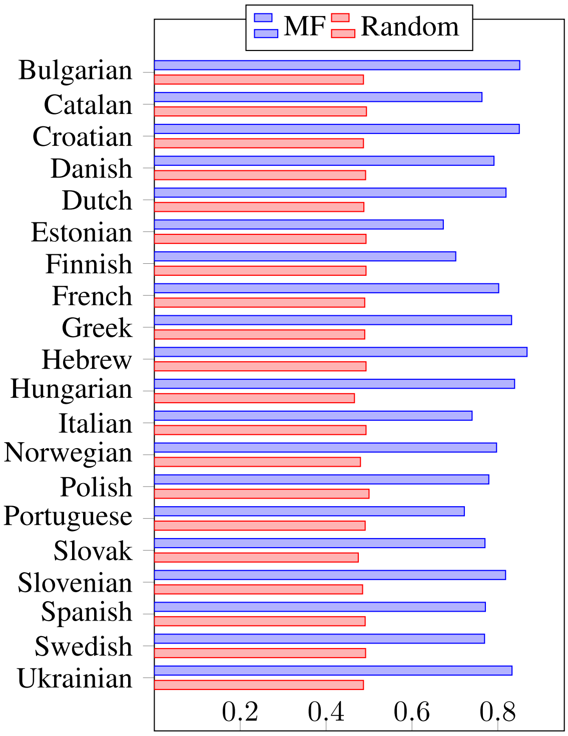

Figure 1: MF accuracy on additional languages.

7.2 Testing on Additional Languages

To build confidence that our findings truly generalize widely across typologically diverse languages, we train the MF model on Czech, English, German, and Russian, and test it on each of the languages in the additional languages dataset. We choose to test only the MF model as the ML model would not have the data to learn a correct $\mathbf{W}^{(\text{right})}$ matrix (as Czech, English, German, and Russian tend not to have postnominal adjectives) and would thus understandably under-perform on the languages which predominantly feature postnominal adjectives (i.e. Catalan, French, Hebrew, Italian, Portuguese, and Spanish). This experiment is conceptually identical to the multi-lingual transfer scenario. Results are detailed in Tab. 7 and visualized in Fig. 1.

MF performs much better than chance on every language, with similar accuracies as those achieved in the transfer scenario. This gives us confidence that the conclusions drawn in §7.1 do generalize widely across typologically diverse languages.

8 Conclusion

We built an interpretable, multi-lingual latent-variable model of hierarchical adjective ordering that directly enforces a hierarchy of semantic classes and is trained entirely using corpus data. We found that our fixed-W variants, which enforce total orderings of semantic classes, perform similarly to our learned-W variants, suggesting that adjective ordering preferences naturally tend towards total orderings. We also found that our model is able to accurately order adjectives from 24 different languages, regardless of whether it was directly trained on them, although it does benefit from having been trained on the language on which it is tested. Interestingly, we were able to achieve high predictive accuracy on languages predominantly featuring postnominal adjectives (e.g. French, Spanish), despite having only trained on languages predominantly featuring prenominal ones (Czech, English, German, Russian), by simply reversing the prenominal adjective ordering rules for postnominal ones.

In summary, our work presents converging evidence that adjectives exhibit universal hierarchical ordering tendencies, with the added observations that individual languages feature additional unique tendencies not shared by others, and that adjective ordering is symmetric with respect to the noun.

Yavrumyan, Zhuoran Yu, Zdeněk Žabokrtský, Amir Zeldes, Manying Zhang, and Hanzhi Zhu. 2019. Universal Dependencies 2.5. LINDAT/CLARIAH-CZ digital library at the Institute of Formal and Applied Linguistics (ÚFAL), Faculty of Mathematics and Physics, Charles University.

A Reproducibility

In the interest of fostering reproducibility, we provide the following additional information about our data, models, and computing infrastructure.

A.1 Data

We use Universal Dependencies (UD) 2.5 and ukWaC, which can be found at `http://hdl.handle.net/11234/1-3105` and `https://wacky.sslmit.unibo.it/doku.php`, respectively. Note that UD has since been updated to version 2.6.

A.2 Model Parameters and Runtime

The learned-W models (EL, ML) have $2 * |\mathcal{C}|^2 + d * |\mathcal{C}| = 4,950$ learnable parameters. The fixed-W models (EF, MF) have $d * |\mathcal{C}| = 4,500$ learnable parameters. The time taken to train each model varies based on the number of training samples—as a rule of thumb, training the learned models takes about 1.5-2 hours per 10,000 samples, while training the fixed models takes about 1 hour per 10,000 samples. Training all of the model variants necessary to reproduce this paper in full takes about 24 hours. Testing either model type takes only several minutes per 1,000 samples.

A.3 Computing Infrastructure

All our development, training, and testing was done on a personal computer with the following specifications:

- Operating System: Windows 10 Pro (64-bit)
- CPU: Intel Core i7-7700k @ 4.20 GHz
- GPU: None
- RAM: 64GB DDR4
- Storage Used: Approximately 200GB

A.4 Other Notes

We did not use validation sets as we saw little value to extensively tuning the model, since we were trying to explore the properties of a natural phenomenon rather than aiming to achieve the highest possible accuracy. All reported results are from the first time each model variant was tested.

Surprisal Predicts Code-Switching in Chinese-English Bilingual Text

Abstract

Why do bilinguals switch languages within a sentence? The present observational study asks whether word surprisal and word entropy predict code-switching in bilingual written conversation. We describe and model a new dataset of Chinese-English text with 1476 clean code-switched sentences, translated back into Chinese. The model includes known control variables together with word surprisal and word entropy. We found that word surprisal, but not entropy, is a significant predictor that explains code-switching above and beyond other well-known predictors. We also found sentence length to be a significant predictor, which has been related to sentence complexity. We propose high cognitive effort as a reason for code-switching, as it leaves fewer resources for inhibition of the alternative language. We also corroborate previous findings, but this time using a computational model of surprisal, a new language pair, and doing so for written language.

1 Introduction

Code-Switching (CS) occurs when a speaker alternates from one language to another during linguistic communication (e.g., Poplack, 1980). For example, in: “洗衣房在basement 。” (“The laundry room is in the basement.”), the speaker alternates from Chinese to English by introducing the word “basement”, replacing the Chinese word “地下室”. This behavior is very common among bilinguals.

Many factors have been shown to affect the propensity of a bilingual to code-switch. Among others, there are variables related to the participants in the conversation (e.g., Blom and Gumperz, 1972), the ease of production of the relevant words (e.g., Gollan and Ferreira, 2009), the linguistic context (e.g., Clyne, 1991), memory limitations of the speaker (Eppler, 2011), cognitive load and emotional state of the speaker (e.g., Grosjean, 1982; Dornic, 1978), and the type of information to be conveyed (e.g., Karrebæk, 2003; Myslín and Levy, 2015). Among the latter, predictability, as measured by word completion, has been correlated with code-switching (Myslín and Levy, 2015). In this paper, we model predictability using word surprisal calculated with a language model.

We ask whether word surprisal (Hale, 2001) and word entropy (Roark et al., 2009) affect the probability of CS within a sentence (intra-sentential CS), while controlling for other known psycholinguistic factors. Word surprisal measures how unpredictable a word is in its context, typically operationalized as the negative log-probability of a word w_i conditioned on a window of t previous words:

$$surp(w_i) = -logP(w_i|w_{i-1}, ..., w_{i-t}) \quad (1)$$

Word entropy *before* w_i measures the uncertainty when w_i is still unknown, operationalized as the expectation over the vocabulary of word surprisal:

$$H_{i-1} = \sum_{w \in \text{vocab}} -logP(w|w_{i-1}, ..., w_{i-t}) * P(w|w_{i-1}, ..., w_{i-t}) \quad (2)$$

Thus, given a context, word surprisal measures how unpredictable a *specific* word is, while word entropy measures how unpredictable *all* words are in average. These variables have been related to a very wide range of psycholinguistic phenomena (e.g., Hale, 2001, 2006; Smith and Levy, 2013; Demberg and Keller, 2008; Calvillo and Crocker, 2015; Henderson et al., 2016; Frank and Willems, 2017; van Schijndel and Linzen, 2018; Brennan and Hale, 2019).

We collected a corpus of Chinese-English text from online forum conversations where the majority of sentences are in Chinese but some sentences contain segments in English. These code-switched

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4029–4039,
November 16–20, 2020.

sentences were translated into Chinese and compared to sentences with similar syntactic structure but without any code-switch, in order to see what factors affected the propensity of CS. With this paper, we make a curated version of this dataset publicly available, together with the code that was used for its extraction and processing.[1] Then, we fitted a logistic regression model to predict CS in a sentence, testing whether the addition of surprisal and entropy improves a model that only contains control factors.

The results show that word surprisal improves the quality of the model. Since surprisal has been related to cognitive effort of language production (e.g., Kello and Plaut, 2000) and comprehension (Hale, 2001), we can relate CS to states in which the speaker faces difficulties, and/or, similar to Myslín and Levy (2015), as a strategy to signal highly informative content.

Conversely, we found no evidence of word entropy improving the model. Furthermore, word entropy does not reach significance even when used as the only predictor. While further testing is needed, we attribute this result to the fact that during language production, speakers are completely aware of the semantics they try to convey, radically reducing the number of possible word continuations, thus reducing the effort of selecting a word among multiple possibilities. In the case of surprisal, we interpret the effect observed here as the facilitation that the previous words could have on the production of the next word, irrespective of the semantics' effect.

The rest of this document is organized as follows: Section 2 presents a selection of factors that have been known to affect CS. Section 3 explains the method that we used to obtain the Chinese-English corpus and analyze it. Section 4 shows the results of the analysis. Finally, sections 5 and 6 present the Discussion and Conclusion respectively.

2 Factors that predict CS

We can arrange some of the factors that have been shown to affect CS according to their source:

Sociocultural: CS can be used to construct identity and modulate social distance and affiliation (Beebe and Giles, 1984). Moreover, CS can be affected by the kind of participants in a conversation. For example, Blom and Gumperz (1972) observed that Norwegian locals tended to switch from a dialect form to a standard form of Norwegian as soon as they felt the presence of non-locals.

CS can also be affected by the type of content that is conveyed. For example, speakers can use CS to try to distance themselves while talking about embarrassing (Bond and Lai, 1986) or emotional (Altarriba and Santiago-Rivera, 1994) topics.

Linguistic: CS seems to obey certain linguistic rules. E.g., at the morphological level, CS has been proposed to occur only if the switched morpheme is not bound (Poplack, 1980), and if it does not violate any syntactic rule of the languages involved (Poplack, 1980; Lederberg and Morales, 1985).

Speaker-related: Factors related to the difficulties that speakers encounter during language production. Indeed, one view of CS is that it occurs to compensate for a lack of language proficiency (Heredia and Altarriba, 2001).

Independent of the proficiency level, some words are inherently more difficult to access, in which case a speaker might choose to produce a word in a different language if it is more accessible (e.g., Gollan and Ferreira, 2009), in line with the idea of an integrated representation of a bilingual's linguistic knowledge (Putnam et al., 2018). For instance, words with higher frequency and shorter length are more accessible (D'Amico et al., 2001; Forster and Chambers, 1973). Moreover, words referring to concrete and highly imageable concepts are suggested to be more integrated in the bilingual lexicon than abstract words, predicting a greater probability of CS (Marian, 2009). Similarly, nouns are suggested to be stored in a common semantic system shared across languages, while other words are stored in language-specific areas, since the latter elicit slower and less consistent associations across languages (Marian, 2009; G. van Hell and De Groot, 1998). Thus, nouns are the class of words that is most frequently code-switched (e.g., Myers-Scotton, 1993) and borrowed (Muysken, 2000), followed by verbs and other parts of speech.

Following *Dependency Locality Theory* (Gibson, 1998, 2000), Eppler (2011) shows that the more intervening words between a potentially code-switched word and its dependency governor, the more difficult it is for the speaker to track the language of the governor, due to memory limitations, and therefore the more likely to code-switch.

Comprehender-related: CS has also been proposed as a strategy to facilitate comprehension

---

[1] `https://github.com/lfang1/CodeSwitchingResearch`

by marking portions of discourse (Auer, 1995; Gumperz, 1982; Zentella, 1997). From this view, the act of CS carries information, similar to how prosody helps comprehenders to recognize the focus of an utterance. Thus, CS has been reported to be used to increase the salience of discourse markers (De Rooij, 2000), to signal new discourse topics (Barredo, 1997; Zentella, 1997), to contrast topic and focus elements (Romaine, 1995), and to mark important discourse information (Karrebæk, 2003).

Similar to Karrebæk (2003), Myslín and Levy (2015) show evidence suggesting that speakers code-switch to mark important information in Czech-English bilingual speech, where importance is measured by the amount of semantic information that they convey. Then, more informative meanings receive more distinct encodings, reducing the risk of miscommunication.

3 Methods

Our initial hypothesis was that bilinguals are more prone to CS when the words to be produced have high surprisal; and at states of high uncertainty, as measured by word entropy. In order to test this, we used binary logistic regression to assess the effect of surprisal and entropy for predicting CS, while controlling for other well-known factors.

First, we collected a corpus of bilingual Chinese-English text that contains code-switched sentences. Then, the code-switched sentences were translated into Chinese, obtaining fully Chinese sentences. The correctness and fluency of these translations were verified using a survey in Amazon Mechanical Turk. We will refer to each of the translated versions of the code-switched sentences as a *CS-sent*; note that *these* are the sentences that are used for the analysis. Afterwards, for each CS-sent, we selected a sentence from those that did not originally contain a code-switch and that had a similar syntactic structure to the corresponding CS-sent, as described in the Alignment section below. We use *nonCS-sent* to refer to these sentences. Finally we trained a binary logistic regression model to predict whether a sentence was a CS-sent or a nonCS-sent.

To investigate the effect of surprisal and entropy more directly, the logistic regression model used several control factors reflecting some of the findings in Section 2. Then, a genetic algorithm was used to select, among all the possible models that can be obtained by combining all control factors and their two-way interactions, the model that would minimize the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC), which are measures of model quality that are based on the log likelihood of the model, the number of parameters of the model, and the size of the dataset. This selected model is the control model of our experiments.

Finally, the control model was compared to models that included word surprisal and entropy, respectively, to examine their relative contributions in explaining CS beyond the known correlates.

The next subsections explain more in detail the procedure that we followed to collect the corpus, obtain the measurements related to the control factors, and train the final logistic regression model.

3.1 Chinese-English Text Corpus

Previous CS research has focused on speech (e.g., Poplack, 1980; Myslín and Levy, 2015; Beebe and Giles, 1984; Karrebæk, 2003; Zentella, 1997). In contrast, we examine written language produced by Chinese-English bilinguals to generalize previous findings. Speech differs from text in that, during written language production, speakers have relatively more time to think and modify their utterances, making them less spontaneous and more complex. For example, spoken utterances tend to have fewer words, their words are shorter, and their vocabulary is less diverse than in text (Drieman, 1962; Gibson et al., 1966). Consequently, we expect CS to be a more conscious and less spontaneous act in text, possibly increasing its strategic use, and decreasing the influence of other factors that could be related to the spontaneity of speech.

To our knowledge, there is currently no Chinese-English text corpus that contains translations of the code-switched parts. Since we need the translations in order to properly estimate word surprisal, we built a corpus that includes them. The next paragraphs explain the procedure that we performed.

Data source: Data were acquired from the publicly available Chinese Students and Scholars Association Bulletin Board Systems (CSSA BBS) of the Pennsylvania State University, the Carnegie Mellon University, and the University of Pittsburgh. The users of CSSA BBS are Chinese-English bilinguals who have studied in the USA for several years.

The Stanford Chinese word segmenter (The Stanford NLP Group, 2018) was used to segment the sentences into words with the Chinese Penn Treebank standard (Xue et al., 2005). Any personal information present in the sentences such as people's proper names, telephones or addresses was removed. The sentences are related to four main topics: housing, secondhand goods, experience sharing, and ride sharing.

CS identification: To identify the sentences that contained a code-switch, we used the Google English 1-gram corpus, such that if an English word (a word contained in the English 1-gram corpus) was identified in a sentence, that sentence was considered as code-switched. By this simple definition, 4740 code-switched sentences and 14956 non-code-switched sentences were identified and extracted.

Translation: Five Chinese-English bilinguals translated the code-switched sentences into Chinese, obtaining one translation per sentence. While multiple translations could be possible for some sentences, more than half of the code-switches corresponded to single words, suggesting that only few alternatives were available in most cases. The translators were all international Chinese undergraduate students who have similar language proficiency and cultural background to the original posters in the CSSA BSS corpus.

Cleaning: During the translation, it became clear that a large amount of code-switches corresponded to proper nouns and words that had no clear translation to Chinese. These types of code-switches might occur for completely different reasons: for instance, there might be no way in Chinese to refer to a particular bar in Pittsburgh. In order to distinguish the sentences that clearly contained an interesting code-switch, we manually classified the sentences into four categories: *clean_cs*, *proper_nouns*, *internet_slang*, and *other*. The *other* category includes incomplete sentences and unidentified words. After this point, we only considered the sentences in *clean_cs* because in those cases a clear equivalent in Chinese existed. This group had 1690 sentences with code-switches mostly related to common nouns and adjectives (e.g., "neighborhood", "basement", and "available").

Alignment: The predictors are defined with respect to the first word that was code-switched in each CS-sent, which we call the *CS-point*. Since CS normally occurs if it does not violate any syntactic rule of the involved languages (Poplack, 1980), we compared the CS-sents to the nonCS-sents only at points of the nonCS-sents where CS would be plausible. Thus, we paired each CS-sent to the nonCS-sent that had the most similar syntactic structure among the available nonCS-sents. Through this process, we obtain a single CS-point for each nonCS-sent, at which CS is plausible to happen according to the syntactic structure. We expect this balancing also to reduce unforeseen confounds that could make difficult the results' interpretation, allowing us to analyze CS at any location of the sentence and with any syntactic structure.

original	整个	**house**	家具		齐全
CS-sent	整个	房子	家具		齐全
POS	DT	**NN**	NN		VA
	whole	**house**	furniture		complete
nonCS-sent	全部	木头	地板	,	干净
POS	DT	**NN**	NN	PU	VA
	all	**wood**	floor		clean

Table 1: Example of CS-sent / nonCS-sent alignment.

First, we used the Stanford Parser to obtain part-of-speech tags (*POS*) and dependency trees of all sentences. Then, for each CS-sent, we selected the most similar nonCS-sent according to the Levenshtein similarity of their POS sequences. We only considered alignments that had at least a 40% Levenshtein similarity, discarding all CS-sents for which no nonCS-sent fulfilled that requirement. In addition, the selected nonCS-sent had to contain the same ngram of POS corresponding to the POS of the words at CS-point-1 (if the switch is not sentence-initial), CS-point, and CS-point$+1$ (if the switch is not sentence-final). Table 1 shows an example, where DT NN NN is said ngram. Finally, when there were available candidates (which happened for 92.2% of the CS-sents), the dependency relation of the word at the CS-point to its governor had to be the same in the nonCS-sent (compound:nn in the example of Table 1).

In the end, there were 1476 pairs CS-sent/nonCS-sent. Regarding sentence length, μ=11.1, mode=6, min=2 and max=43. Concerning the index of the CS-point, μ=5.15, mode=2, and max=30. For the words at the CS-point, 62% are nouns, 23% are verbs, and 15% have other POS, replicating previous findings (Myers-Scotton, 1993).

Verification of the Translations: The translations were verified in their fluency (whether they resemble native Chinese utterances) and correctness (whether they reflect the semantics of the original sentences). Using a sample of 500 CS-sents of our dataset, and Amazon's Mechanical Turk, we recruited 33 native Chinese speakers with high proficiency in English. Each participant was shown

60 pairs of the original code-switched sentences and their translations, such that each pair was verified by 3 participants. Each participant was asked to rate the correctness and fluency of the translations. Additionally, the survey contained low/high quality control items, in order to verify the participants' engagement. We removed the participants who showed no reaction to the manipulations of the control items. The participants rated in average the quality of the translations as 4.04 ($\sigma = 1.3$) out of 5 in correctness, and 4.08 ($\sigma = 1.3$) out of 5 in fluency, indicating that the translations are fluent Chinese sentences and that they adequately reflect the original meaning of the code-switched sentences.

3.2 Control Variables

We introduced several controls in order to account for findings documented in the CS literature described in Section 2, and to see whether our variables of interest can explain the data beyond the controls.

Considering that all sentences were produced by speakers of the same community, with similar age and educational background, we can assume that sociocultural factors are homogeneous in the analyzed sentences. Moreover, with respect to linguistic factors, we selected the nonCS-sents and their CS-points to be similar to the CS-sents.

We considered the following variables as controls in our experimental setup. These are measured in the CS-sents and the nonCS-sents at their CS-points, and introduced in the logistic regression model as predictors. Note that many code-switched segments contain more than a single word, however we focus only on the first word, as it is where the code-switch actually occurs.

Word Frequency: Words with lower frequency are considered less accessible, so bilinguals are more likely to code-switch when the intended words are infrequent. The relative frequency of the word at the CS-point was calculated from the Google Chinese 1-gram corpus. These frequencies were converted to negative logs before introducing them to the logistic regression model.

Word length: The number of Chinese characters forming the word at the CS-point. Longer words are considered less accessible, and therefore more prone to CS.

Sentence length: The number of words in the sentence. To our knowledge, there has been no studies analyzing the relation between CS and sentence length, however, this measure has been used to assess sentence complexity (e.g., Howcroft and Demberg, 2017; Petersen, 2007). We hypothesize that bilinguals are more likely to CS when a sentence is longer, as it implies a higher effort to retrieve and produce the relevant structures and words. In these more demanding occurrences, there would be less available resources left to inhibit the alternative language, thereby increasing the propensity to CS.

Part-of-speech tag: The POS of the word at the CS-point. "NR" (proper noun), "NN" (common noun), "NT" (temporal noun) were all converted to "noun". "VE" (e.g, "be" and "have") and "VV" (other verb) were all converted to "verb". For the regression model, we only considered 3 classes: "noun", "verb", and "other"; the latter referring to the POS-tags that are not related to nouns or verbs.

Dependency relation: Bilinguals might be more likely to CS when a word holds a specific dependency relation to its governor in a dependency tree. Hence, the word at the CS-point was annotated with the dependency relation that connects it to its governor. We only considered and introduced as categorical predictors the relations that occurred more than 100 times: "compound:nn", "nsubj", "dobj", "root", "dep", "amod". Then, every relation that did not occur at least 100 times was grouped into "other".

Dependency distance: Bilinguals are more prone to CS when the distance between a word and its dependency governor is longer (Eppler, 2011). We measured dependency distance as the difference between the index of the word at the CS-point and the index of its dependency governor (i.e., two adjacent words have a dependency distance of 1), only when the governor is to the left of the CS-point (otherwise we assign a distance of 0).

Location: We use a discrete variable with 3 levels to encode whether the CS-point is located at the beginning, middle or end of the sentence (10-80-10 percent of the sentence).

Regarding POS, dependency relations and location, we did not expect a strong effect on CS because CS-sents and nonCS-sents are matched to be syntactically similar. Nonetheless, we include these predictors in order to capture any remaining effect of syntactic structure on CS.

3.3 Variables of Interest

These are the variables we wanted to test in order to see whether they are relevant predictors of CS.

Word Surprisal: The negative log probability of the word at the CS-point given the 4 previous words in the sentence calculated using a 5-gram language model trained on the Chinese Wikipedia with the SRILM framework $-logP(w_i|w_{i-1},...,w_{i-4})$. Out-of-vocabulary words were assigned the highest surprisal value found in the corpus (i.e., 10.166).

Word Entropy: Measured *before* the word at the CS-point w_i, and given the previous 4 words ($t = 4$ in equation 2), calculated with the same language model that we used for surprisal.

3.4 Modeling Procedure

We used logistic regression to predict whether a sentence belongs to the set of CS-sents or to the set of nonCS-sents. The model's predictors are a combination of the control factors mentioned above, as well as word surprisal and entropy. Before training, all numerical predictors were standardized such that their mean is 0 and standard deviation is 0.5.

Considering that we are mainly interested in the effect of surprisal and entropy, we first obtained a parsimonious control model using all the control factors and their two-way interactions. In order to select the best combination of control factors and interactions, we followed Myslín and Levy (2015) using a genetic algorithm (Calcagno et al., 2010) to find the model that minimizes the AIC and BIC. Afterwards, we introduced word surprisal and entropy in order to see whether they improve the quality of the model.

4 Results

4.1 Selection of the Control Model

The models selected using AIC and BIC differ slightly: they have the same main effects, but the AIC model has some additional interactions. BIC penalizes the number of parameters more heavily than AIC when the number of data points is relatively large. In contrast, the value of AIC does not depend on the number of data points. Since our dataset is relatively large ($n = 2952$), we chose the model selected using BIC:

$$CS \sim postag + freq + w\_length + s\_length \tag{3}$$

where postag, freq and w_length refer respectively to the POS, frequency and length of the word at the CS-point; and s_length is the sentence length. This model has an AIC of 3967.3 and a BIC of 4003.2. As expected, most factors related to syntax (dependency relation, dependency distance and location) were not selected, as they were mostly counterbalanced during the alignment.

4.2 Variables of Interest

After obtaining the control model, we added word surprisal and entropy to test whether they improve the quality of the model. If they do, it would mean that they are relevant predictors of CS above and beyond the control factors.

Word Surprisal: Adding word surprisal indeed improves the quality of the control model, reducing the AIC from 3967.3 to 3954.5 and the BIC from 4003.2 to 3996.4. This finding is confirmed using a likelihood ratio test ($\chi^2(1) = 14.81, p < 0.001$). Adding surprisal to a model that also includes entropy gives similar results.

The direction of this effect was as expected: words with higher surprisal are more likely to be code-switched ($\beta = 0.37, z = 3.82, p < .001$).

Word Entropy: Adding word entropy did not improve the quality of the model, increasing the AIC from 3967.3 to 3967.9 and the BIC from 4003.2 to 4009.8. Furthermore, in the resulting model word entropy does not reach significance as predictor. Adding word entropy to a model that also includes surprisal gives similar results. Finally, word entropy does not reach significance even when it is used as the only predictor.

This result was unexpected considering the relation of word entropy to word surprisal: entropy is the average over the vocabulary of the surprisal values at the CS-point. Intuitively, entropy is related to the effort of selecting the correct word at a given time, which would be related to the number of plausible words continuations at that point. However, the number of alternatives would be also limited by the semantics the speaker tries to convey. So, it is likely that the semantics reduce drastically the amount of plausible word continuations. In that case, a better measure could be the entropy over the probability distribution $P(w_i|w_{i-1},...,w_0,semantics)$, which is a direction that can be explored in future work.

4.3 Control Factors

Since word entropy did not improve the control model, we only report the model that adds word surprisal, whose parameters are shown in Table 2.

	Parameter Estimates		Wald's Test		Likelihood Ratio Test	
Predictor	Coef.β	SE(β)	Z	p_z	χ^2	p
(intercept)	-0.13	0.05	-2.75	$< .01$		
surprisal	0.37	0.09	3.82	$< .001$	14.81	$< .001$
frequency	0.21	0.11	1.91	.055	3.67	.055
word length	0.47	0.09	4.79	$< .001$	23.34	$< .001$
sentence length	0.58	0.08	7.32	$< .001$	56.10	$< .001$
POS=verb	0.46	0.10	4.42	$< .001$	20.52	$< .001$
=other	0.23	0.11	2.08	$< .05$		

Table 2: Summary of the logistic regression model after including word surprisal: coefficient estimates β, Wald's z-scores and their significance level, contribution to likelihood χ^2 and its significance level. The response variable was coded as nonCS-sent = 0 and CS-sent = 1. The baseline of the categorical variable POS is ”noun”. AIC/BIC before introducing surprisal: 3967.3/4003.2; after introducing surprisal: 3954.5/3996.3.

Some predictors correlate with each other. For example, infrequent words tend to be longer (Zipf, 1935), and have higher surprisal. In our dataset, the negative log of word frequency and surprisal have a Spearman's $\rho = 0.62 (p < 0.001)$. Similarly, the negative log of word frequency and word length have a Spearman's $\rho = 0.57 (p < 0.001)$. In order to asses whether collinearity would impact the quality of the model, we used the Generalized Variance Inflation Factor (GVIF). In our case, all values were below 2, meaning that although some collinearity exists, it should not be problematic for the model's results.

As one can see, most factors were significant predictors of CS, replicating previous findings:

Frequency: Words with lower frequency (higher negative log frequency) show a slight tendency to be code-switched, even while having word surprisal as a predictor ($\beta = 0.21, z = 1.91, p = 0.055$), corroborating previous findings showing that, independent of context, frequent words are more accessible and consequently less prone to CS. The relatively high p-value is likely due to the correlation of word frequency with word surprisal.

Word length: Longer words are more likely to be code-switched ($\beta = 0.47, z = 4.79, p < .001$). Similar to frequency, word length has been related to accessibility, such that longer words are less accessible and therefore more prone to CS.

Sentence length: Speakers are more likely to switch in longer sentences ($\beta = 0.58, z = 7.32, p < .001$). We explain this as a side effect of the higher production effort that longer sentences imply, as longer sentences require more tokens and structures to be retrieved and produced. Under these circumstances, people may have less resources to control/inhibit the production of words in the alternative language, thereby increasing the probability of CS.

Part-of-speech tag: Compared to the baseline (nouns), verbs are more likely to be classified as code-switched ($\beta = 0.46, z = 4.42, p < .001$), followed by other POS ($\beta = 0.23, z = 2.08, p < .05$). Since *noun* is the most common code-switched POS in the corpus, we interpret this result not as nouns being less likely to be switched, but as the model relying more on the other predictors when it encounters a noun, since the values related to POS would be zero.

5 Discussion

In this study we explore the effect of word surprisal and entropy on CS. The computation of these measures relies on language models trained with sufficient and appropriate data, which is non-trivial in the case of bilingual text. Moreover, even assuming a large bilingual corpus, utterances tend to appear in segments of the same language, so any code-switch is likely to cause an increase of surprisal on the word where the switch occurs. For example, in: “洗衣房在basement 。”, we expect “basement” to have high surprisal at least partly because an English word does not tend to follow a sequence of Chinese words. This makes it difficult to assess whether the increase of surprisal causes the code-switch or vice versa. Conversely, by using a translated version, if there is an increase of surprisal, it would not be because of the code-switch, but possibly because the concept or Chinese word is infrequent.

Considering these aspects, we used a monolingual Chinese language model to see whether word surprisal at the CS-point can predict CS assuming that the switch never occurred, as previously described. While we performed several steps to verify the quality of the translations, it is possible that the translation process could introduce uncommon constructions, increasing the surprisal values. However, in more than half of the code-switched sentences, the switch corresponded to a single word, likely resulting in few translation alternatives. Moreover, the verification survey showed that the translations are fluent and semantically correct. Consequently, we expect the sentences that we used to be appropriate for our study.

Using this new Chinese-English CS dataset, we tested several factors that have been shown to affect CS. We found that long and infrequent words are more likely to be code-switched, which is compatible with previous findings suggesting that words with these characteristics are less accessible and more likely to be code-switched.

Another important predictor was sentence length, where longer sentences are more likely to be code-switched. This could reflect the effort related to produce longer sentences, as they require more structures to be retrieved and handled.

Critically, word surprisal was also a relevant factor for predicting CS. Since surprisal has been related to cognitive effort in language comprehension (Hale, 2001) and to some extent in language production (e.g., Kello and Plaut, 2000), we may interpret word surprisal as the degree to which the words that were previously produced facilitate production. From this view, word surprisal would index context-dependent accessibility, in contrast to word frequency, which would index context-free word accessibiity. Then, words with high surprisal would be less accessible, similar to infrequent words.

Unexpectedly, word entropy did not seem to predict CS. If word entropy indexes the effort of choosing among multiple possible word continuations, then our calculation did not reflect the true probability distribution, as the number of candidate words would be drastically reduced by the semantics the speaker tries to convey. Something similar would happen with word surprisal, in that case, we interpret the results observed here as the facilitation that the previous words have on the production of the next word, beyond the effect that the semantics could have. We expect that entropy calculations conditioned on semantics could give different results.

The current model of bilingual representations suggest that bilinguals actively inhibit the alternative language when speaking in a second language (Green, 1998; Meuter and Allport, 1999). Nonetheless, bilinguals often code-switch, suggesting that inhibition might depend on the context, available resources, and even audience design. For example, when a bilingual is with other bilinguals, he/she might feel more free to code-switch using the most accessible words, knowing that the audience would understand both languages (Blanco-Elorrieta and Pylkkänen, 2018); while in monolingual situations, the bilingual would use the appropriate language, inhibiting the alternative one (e.g., Blom and Gumperz, 1972). Alternatively, if the bilingual is under high cognitive load, the available resources for inhibition would be less, reducing inhibition and increasing the probability of CS (e.g., Dornic, 1978).

Most predictors in our model can be related to production effort: long and infrequent words are less accessible and therefore harder to produce; longer sentences require more structures to be handled; assuming word surprisal reflects context-dependent accessibility, high-surprisal words would also be harder to produce. In this context, we propose CS as a result of high cognitive effort, leaving less resources for inhibition, and thus increasing the probability of CS.

Another explanation for CS, within audience design, is one of strategy, where CS can highlight segments with high information density in order to emphasize their content. This might increase the probability of successful comprehension. To study that possibility, Myslín and Levy (2015) used *predictability of meaning* (PoM). This notion relates to word surprisal perhaps in a similar way to how word surprisal relates to word frequency: they both encode how unlikely a given word is, correlating to some degree, however they are not completely redundant. PoM is calculated by asking comprehenders to guess possible word continuations – in either language – given a context and within a limited number of guesses. PoM corresponds to the accuracy of that guess. This is where our study contributes important data using the automatic, neutral, and well-studied surprisal metric. Word surprisal is calculated using a language model, permitting more nuanced online estimations. In terms of their interpretation, PoM is, as its name suggests, more related to semantics, as it is language-independent and elicited offline (without time pressure). By contrast, word surprisal is language-specific and encodes both how likely a meaning and a specific word are. Thus, an example in which these metrics would differ is when a meaning is predictable, but the related word in a specific language is not, giving a high PoM but also a high word surprisal.

Further modeling is needed to disentangle these explanations (cognitive effort, audience design). It is possible that if a speaker has difficulties during production, CS would be more likely to occur; and at the same time, if the speaker believes CS would help to communicate his/her message (as proposed by Myslín and Levy, 2015), then he/she might choose to code-switch. As previous findings show, CS is a phenomenon that can be affected simultaneously by a wide variety of factors.

6 Conclusion

We investigated the effect of word surprisal and word entropy on the probability of code-switching (CS) in Chinese-English written communication. A corpus of text containing Chinese-English conversations was collected and its code-switched phrases were translated back into their context language. The translations of the code-switched sentences were compared to sentences with similar syntactic structure but without code-switches, in order to see what factors affected the propensity to CS.

Surprisal predicts CS. Since surprisal has been associated with cognitive effort during language production (e.g., Kello and Plaut, 2000) and comprehension (Hale, 2001), we can relate CS to situations in which the speaker faces difficulties; and/or similar to Myslín and Levy (2015), situations where the speaker uses CS as a strategy to emphasize highly informative content to the comprehender in order to facilitate communication.

We found no evidence showing that entropy, as opposed to surprisal, predicts CS. This may be due to the formulation of entropy that we used, which does not consider the semantics the speaker tries to convey.

This paper makes two specific contributions. The first one is the finding that **CS in *written* *language*** is reliably affected by **sentence length, word length,** arguably **word frequency**, and, most importantly **word surprisal**. The second contribution is a **new Chinese-English CS dataset**, which includes translations to the dominant language, which we hope will be used in further models of CS.

Word Frequency Does Not Predict Grammatical Knowledge in Language Models

Charles Yu, Ryan Sie, Nico Tedeschi, and Leon Bergen
`{cty002,rdsie,njtedeschi,lbergen}@ucsd.edu`
University of California, San Diego

Abstract

Neural language models learn, to varying degrees of accuracy, the grammatical properties of natural languages. In this work, we investigate whether there are systematic sources of variation in the language models' accuracy. Focusing on subject-verb agreement and reflexive anaphora, we find that certain nouns are systematically understood better than others, an effect which is robust across grammatical tasks and different language models. Surprisingly, we find that across four orders of magnitude, corpus frequency is unrelated to a noun's performance on grammatical tasks. Finally, we find that a novel noun's grammatical properties can be few-shot learned from various types of training data. The results present a paradox: there should be less variation in grammatical performance than is actually observed.

1 Introduction

Neural language models (Howard and Ruder, 2018; Devlin et al., 2019; Dai et al., 2019; Yang et al., 2019; Radford et al., 2019) have achieved success in both text prediction and downstream tasks such as question-answering, text classification, and natural language inference. The strong performance of these models raises scientific questions about the knowledge they have acquired, in particular, about the abstractness and generality of their linguistic representations.

Previous work has investigated the linguistic representations of neural language models in several domains, and found varying evidence for how linguistically adequate these representations are (Lau et al., 2017; Marvin and Linzen, 2018; Goldberg, 2019; Futrell et al., 2019). This work has employed psycholinguistic methodology in order to elicit grammatical judgments from these models, inferring the models' underlying representations from the patterns of judgments.

In the current work, we focus on the variation in grammatical knowledge that potentially exists within a neural language model. Just as in human psycholinguistic tasks, previous work on neural LMs has observed variability in grammatical judgments between different sentences; not all violations of a grammatical constraint are judged to be equally bad. It is not clear, however, whether there are systematic sources of variation in these judgments, and if so, what the sources are.

We will focus on variation among lexical items, using English subject-verb agreement and reflexive anaphora as a case study. We first ask whether language models learn the grammatical properties of some nouns more accurately than for others. We do this by measuring the accuracy of language models when making grammatical judgments involving different nouns. We find systematic variation among nouns: nouns that perform well on one task or language model are more likely to perform well on other tasks or other language models. We then consider possible sources of the observed variation between nouns, finding that the grammatical properties of nouns are paradoxically easy to learn; our results suggest that there should be much less variation than is actually observed.[1]

Related work

A number of other studies have investigated the linguistic representations of neural models, both language models specifically and networks trained using other objectives. Linzen et al. (2016); Gulordava et al. (2018); Kuncoro et al. (2018) probe the ability of LSTMs to learn hierarchical structures. Warstadt et al. (2019b) introduces a large-scale corpus of grammatical acceptability judgements, trains RNNs to predict these judgments, and concludes

that the models outperform unsupervised baselines, but fall far short of human performance. Lepori et al. (2020) finds that tree-based RNNs outperform sequential RNNs on number prediction tasks, but that fine-tuning on an artificially-generated augmentation set can bring the models closer to parity.

Other work has focused on probing whether neural language models have acquired adequate representations of specific linguistic phenomena. Marvin and Linzen (2018) and Goldberg (2019) use a minimal pair methodology to assess the grammatical knowledge of RNNs and BERT, looking at subject-verb number agreement, reflexive anaphora, and negative polarity items. Wilcox et al. (2018) examines whether RNN language models exhibit *wh*-licensing interactions on surprisal associated with gaps, concluding they can represent long-distance filler-gap dependencies and learn certain island constraints. Futrell et al. (2019) studies whether neural language models show evidence for incremental syntactic state representations using psycholinguistic methodology. Warstadt et al. (2019a) studies BERT's knowledge of NPI's, focusing on differences between tasks: boolean classification (e.g. Linzen et al. 2016 and Warstadt et al. 2019b), minimal pair comparisons (e.g. Marvin and Linzen 2018 and Wilcox et al. 2019), and probing tasks (e.g. Giulianelli et al. 2018).

2 Approach

We use the minimal pair methodology of Marvin and Linzen (2018) in order to investigate the grammatical judgments of neural language models. Given a minimal pair of sentences, i.e. a pair that differ from each other in their acceptability due to a difference in just one grammatical property. If the model understands the grammatical phenomenon being studied, it should assign higher probability to the grammatical sentence than to the ungrammatical sentence.

2.1 Grammatical tasks

Table 1 shows the 10 grammatical tasks (Marvin and Linzen, 2018) and the templates used for generating minimal pairs. The tasks fall into two general categories: subject-verb agreement (SVA) and reflexive anaphora (RA). The first SVA task, SVA Simple, probes whether the model understands that subject number must agree with the number of third-person present verbs:

(1) a. The cat walks.
b. *The cat walk.

The other SVA tasks probe whether the models have more sophisticated representations of number agreement. For example, the SVA PP task measures whether the model is able to ignore distractors ("boys") which occur between the head of the subject and the verb:

(2) a. The cat next to the boys jumps.
b. *The cat next to the boys jump.

The object relative clause tasks probe whether the model accurately maintains the head's number in the presence of an embedded clause. Marvin and Linzen (2018) provide extensive discussion of the linguistic motivation for these tasks.

The RA tasks measure whether the language model understands the structural conditions on the binding of reflexive pronouns. The tasks make use of the following property of English reflexives: a reflexive pronoun needs to agree in number with its antecedent. The RA Sent.Comp task evaluates whether the model understands that reflexives must be in the same clause as their antecedents:

(3) a. The lawyers said the defendant incriminated himself.
b. *The lawyers said the defendant incriminated themselves.

The RA tasks involving object relative clauses evaluate whether the models understand that reflexive anaphora do not bind to the noun in an embedded clause but rather to the head noun.

2.2 Measuring the performance of a noun

We use these tasks in order to measure how well the model understands the grammatical properties of a particular *target noun*. Given a specific target noun, it is substituted as the TargetNoun in each of the task templates shown in Table 1. This gives a partially specified template. For example, substituting the target noun "zombie" in the SVA Simple template results in:

(4) The zombie $\langle$Verb$\rangle$.

Given each of these partially specified templates, 500 minimal pairs are randomly sampled by filling in the remaining lexical items. Finally, the model's

Task	Template
SVA Simple	The ⟨TargetNoun⟩ ⟨Verb⟩.
SVA Subj.Rel.Clause	The ⟨TargetNoun⟩ that liked the ⟨Noun⟩ ⟨Verb⟩.
SVA Sent.Comp.	The ⟨Noun⟩ said the ⟨TargetNoun⟩ ⟨Verb⟩.
SVA PP	The ⟨TargetNoun⟩ next to the ⟨Noun⟩ ⟨Verb⟩.
SVA Obj.Rel.Clause.That	The ⟨TargetNoun⟩ that the ⟨Noun⟩ liked ⟨Verb⟩.
SVA Obj.Rel.Clause.NoThat	The ⟨TargetNoun⟩ the ⟨Noun⟩ liked ⟨Verb⟩.
RA Simple	The ⟨TargetNoun⟩ ⟨PastTransVerb⟩ ⟨himself/themselves⟩.
RA Sent.Comp.	The ⟨NonGenderedNoun⟩ said the ⟨TargetNoun⟩ ⟨PastTransVerb⟩ ⟨himself/themselves⟩.
RA Obj.Rel.Clause.That	The ⟨TargetNoun⟩ that the ⟨NonGenderedNoun⟩ liked ⟨PastTransVerb⟩ ⟨himself/themselves⟩.
RA Obj.Rel.Clause.NoThat	The ⟨TargetNoun⟩ the ⟨NonGenderedNoun⟩ liked ⟨PastTransVerb⟩ ⟨himself/themselves⟩.

Table 1: Templates used for sentence generation. TargetNoun indicates the position of the target noun whose performance score is being calculated.

grammatical judgments on the 500 minimal pairs are computed (by taking the difference in scores between the grammatical and ungrammatical variants) and averaged, resulting in a task performance score for the noun.

2.3 Limitations

These analyses are limited in several respects. First, only two grammatical tasks are used. By using a wider range of tasks, it will be possible to investigate a larger set of grammatical phenomena outside of number agreement.

Second, while the study focuses on the grammatical information carried by nouns, other lexical types such as verbs are likely to carry this information as well. Future work can determine whether the approach generalizes to verbs and other lexical types.

Finally, while the study uses acceptability judgments in order to determine the models' grammatical knowledge, other probing tasks exist and may produce different results (Warstadt et al., 2019a). We use acceptability judgments because, to the best of our knowledge, feature probing has not been extensively studied for GPT-2 or Transformer-XL. Different probing architectures may produce different results for these models. It would be desirable to understand the robustness of the current results to the choice of experimental readout.

3 Methods

In this section we describe the process of calculating a target noun's task performance score in more detail.

3.1 Sentence generation

Using WordNet (Fellbaum, 1998) and VerbNet (Schuler, 2005), we compiled a list of lexical items as shown in Table 2. The target nouns were drawn from the Noun list, which consisted of animate nouns. Only nouns with distinct singular and plural forms were included. All verbs in the Verb set have an intransitive reading. For each pair of task template and target noun, 500 sentences were randomly sampled by choosing lexical items from the appropriate word lists.

For each sampled sentence, 2*2 or 2*2*2 versions were generated (depending on the template). These versions varied the grammaticality of the sentence and the plurality of the target noun and any distractor nouns. For example, for the SVA Simple task, 2*2 versions are generated for every sampled sentence:

(5) a. Singular-Grammatical: The horse walks.
b. Singular-Ungrammatical: *The horse walk.
c. Plural-Grammatical: The horses walk.
d. Plural-Ungrammatical: *The horses walks.

3.2 Models

Our experiments use three models, Transformer-XL (Dai et al., 2019), GPT-2 (Radford et al., 2019), and BERT (Devlin et al., 2019). We use the Hugging Face implementations (Wolf et al., 2019) with the pre-trained models *transfo-xl-wt103*, which is trained on the WikiText-103 dataset, *gpt2-xl*, which is trained on the WebText dataset, and *bert-base-uncased*, which is trained on BookCorpus and English Wikipedia.

3.3 Sentence scoring

We now describe how a score was calculated for a particular sampled sentence. For each of the

Set Name	Transformer-XL	GPT-2	BERT
Noun	916	723	704
Verb	615	228	406
NonGenderedNoun	870	679	663
PastTransVerb	1298	1034	1298

Table 2: Size of word sets for each model.

sentence variants (e.g. Example 5), the model computes a score. In the case of Transformer-XL and GPT-2, this score is simply the the log probability of the string. For example, for Transformer-XL:

$$\text{Score}_{\text{string}}(s) = \log P_{\text{TXL}}(s) \tag{1}$$

where P_{TXL} is the Transformer-XL language model probability distribution.

For BERT, given its masked language model architecture, we follow the approach of Goldberg (2019). For the SVA tasks, we compute the log conditional probability of the verb whose number must agree with the target noun. For the RA tasks, we compute the log conditional probability of the reflexive pronoun. Both conditional probabilities are computed conditional on the left and right contexts.

Given the scores for a sentence's variants, we compute an overall score for the sentence, which captures how much the model prefers the grammatical variants to the ungrammatical variants. For each sampled sentence S, there are either 2 or 4 minimal pairs among its variants. In Example 5, a. and b. is a minimal pair, and c. and d. is a minimal pair. Letting $s_a, ..., s_d$ denote these variants, the overall score for the sentence is given by:

$$\begin{aligned}\text{Score}_{\text{sent}}(S) = \frac{1}{2}(&\text{Score}_{\text{string}}(s_a) - \text{Score}_{\text{string}}(s_b)\\ &+\text{Score}_{\text{string}}(s_c) - \text{Score}_{\text{string}}(s_d))\end{aligned}$$

The formula when there are four minimal pairs is similar.

3.4 Noun scoring

We next compute an overall score for the target noun. As described in Section 3.1, for a specific target noun n and task, we sample 500 sentences $S_1, ..., S_{500}$. The noun's score for this task is then given by:

$$\text{Score}_{\text{noun}}(n) = \frac{1}{500}\sum_{i=1}^{500} \text{Score}_{\text{sent}}(S_i) \tag{2}$$

3.5 Word filtering and tokenization

Words were removed from a particular model if either their singular or plural form was tokenized to *unk*, or if their singular and plural forms were assigned different numbers of tokens.[2] For BERT, words in the Verb set were removed if they were assigned more than one token, as BERT does not model the joint distribution over multiple masked tokens.

For Transformer-XL, we add a padding text[3] and a start-of-sentence-token ($\langle$SOS$\rangle$) to the beginning of the sentence and an end-of-sentence token ($\langle$EOS$\rangle$) to the end of the sentence. For GPT-2, we make no modifications to the generated sentence (although prefix spaces are added to the strings for tokenization purposes). For BERT, since it is a masked language model, we replace the Verb (for SVA) or reflexive pronoun (for RA) with a [MASK] token after tokenization. Thus, each sentence will have a single mask token corresponding to the word that should agree with the target noun.

4 Results

4.1 Noun performance is correlated across tasks

We first examine how each noun's performance varies across the grammatical tasks. For each noun-task pair, we measure the average performance of the noun on that task, as described above. This gives 10 features per noun, corresponding to the 10 grammatical tasks.

Figure 1 shows the pairwise comparisons between performance on the different tasks for Transformer-XL. Results for BERT and GPT-2 are similar and are shown in the appendix. The figure shows that performance is correlated across the tasks; for many pairs of tasks, nouns which have higher performance on one task are likely to have higher performance on the other.

Using principal component analysis, we found that a single principal component explains 47% of task variance for Transformer-XL, and two principal components explain 73%. Results are similar for BERT and GPT-2, and are shown in the appendix. The first PC primarily measures performance on the four reflexive anaphora tasks, while the second PC measures performance on the subject-verb agreement across relative clause tasks.

---

[2] The latter constraint was used in order to simplify batching.

[3] `https://tinyurl.com/y9kjuj5q`

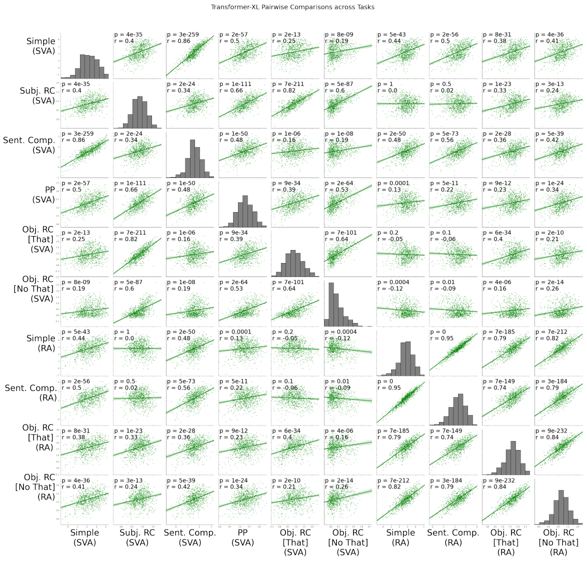

Figure 1: Pairwise comparisons between tasks with Transformer-XL. Rows and columns represent tasks, and one point represents a single noun's performance on a pair of tasks. The four tasks on the lower right, with strongest correlations, all involve reflexive anaphora.

This suggests that there is a dimension that characterizes whether the model understands how reflexive binding constraints operate for a noun, and a dimension for whether the model understands subject-verb agreement for the noun. Note that Figure 1 additionally demonstrates correlations between the reflexive tasks and the subject-verb agreement tasks.

These results provide evidence that language models' variation in performance on the grammatical tasks is, in part, explained by properties of the nouns which are stable across tasks. The models understand number agreement better for some nouns, and worse for others.

4.2 Noun performance is correlated across models

We next investigate whether nouns exhibit stable behavior across different neural language models. For each pair of the three language models, we measured how well a noun's task performance in one language model predicted its task performance in the other language model.

Figure 2 shows comparisons between pairs of language models on the 10 grammatical tasks. Of the 30 comparisons, 24 show significant positive correlations between the pairs of language models. 22 of the correlations remain significant after Bonferroni correction.

GPT-2 and Transformer-XL show the strongest correlation in performance. It is possible that this is due to methodological differences between the task setup for GPT-2 and Transformer-XL compared to BERT: GPT-2 and Transformer-XL are performing a language modeling task in which the probability of a full sentence is queried, while BERT performs masked language modeling on a single target word. The difference may also be due to corresponding training differences between BERT and the autoregressive language models.

The results provide evidence that nouns exhibit stable task performance across language models. The source of the correlation across language models must come from features of the training data. Properties of the natural text distribution of nouns lead some of these nouns to be better understood than others.

4.3 Effect of frequency on task performance

In Sections 4.1 and 4.2, we found evidence that nouns exhibit stable performance across different grammatical tasks and language models. One obvious explanation of these results is that nouns vary in their frequency in natural text, and language models learn more accurate grammatical representations for more frequent nouns.

In order to investigate this, we measured the frequency of each noun in two corpora: WikiText-103, a 103 million token subset of Wikipedia, which was used for training Transformer-XL; and Open WebText (Gokaslan and Cohen, 2019), an open-source implementation of the web corpus used to train GPT-2.[4] Word frequencies were measured separately for singular and plural noun forms. Figure 3 shows the relationship between frequency and task performance on each of the ten grammatical tasks. The appendix shows the results broken down by task type.

The results show no clear relationship between noun frequency and task performance. Frequency explains no more than 0.1% of the variation in performance. This holds true over more than four orders of magnitude in frequency. This provides evidence that 1) differences in corpus frequency do not explain the systematic differences observed between nouns, and 2) relatively few observations suffice for transformer language models to learn

---

[4] BERT was trained on a mix of Wikipedia text and BookCorpus. Because, as of this writing, BookCorpus is no longer distributed, WikiText-103 was used as a proxy for BERT training frequencies.

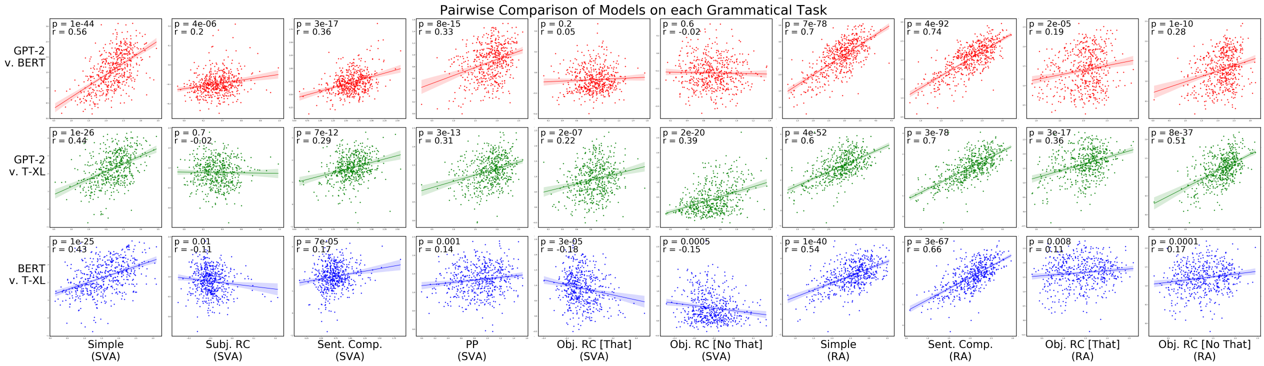

Figure 2: Pairwise comparisons between GPT-2, Transformer-XL, and BERT on the 10 grammatical tasks. Each row corresponds to a pair of language models, and each column is a single task. One point represents the performance of a noun on a single task.

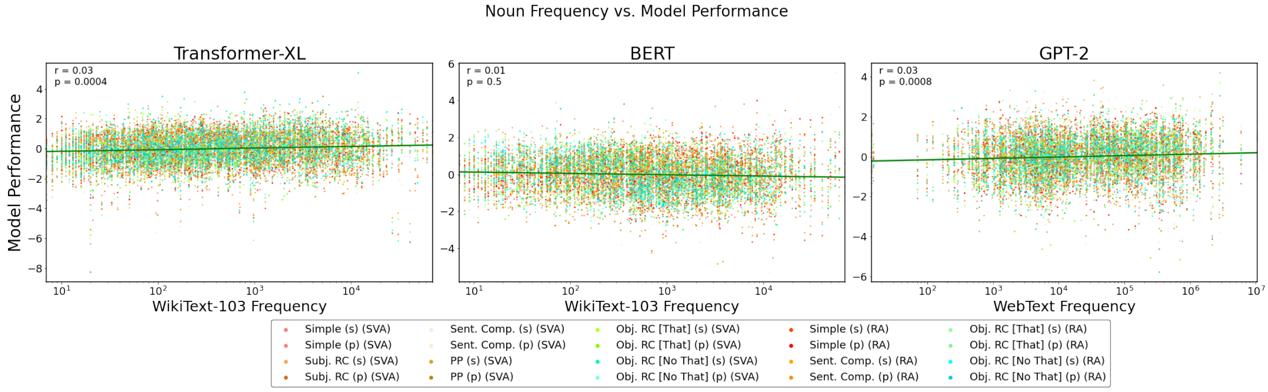

Figure 3: Relationship between corpus frequency and task performance for Transformer-XL, BERT, and GPT-2. Performance scores are z-normalized. Colors indicate the ten grammatical tasks and singular/plural form of the noun (*s* indicates singular, *p* indicates plural). Each point represents task performance for a single noun.

correct number agreement behavior for a noun. In the next section, we investigate this finding further.

5 Few-shot learning for novel lexical items

The results in the previous section provide evidence that nouns systematically vary in their performance on grammatical tasks; some nouns perform better than others across tasks and language models. However, this variation is not explained by frequency of occurrence in natural text. Nouns that occur on the order of 100 times in a corpus do not have systematically worse performance than nouns that occur 10^6 times.

The results raise a question: if frequency does not influence how well a noun is understood, what does? If low frequency nouns are understood as well as higher frequency nouns, then this suggests that language models few-shot learn the grammatical properties of nouns. We suggest that by studying what makes a noun learnable in a few-shot setting, it may be psosible to better understand the sources of the observed variation.

We use a few-shot learning paradigm, introducing a new lexical item into the vocabulary of the language model, either “wug” (intended as a new singular noun), or “wuz” (intended as a plural). We then fine-tune the language model using several example sentences containing this word. Note that this paradigm is distinct from nearly all of the few-shot learning experiments performed in Radford et al. (2019); Brown et al. (2020), which operate on a known vocabulary.[5]

5.1 Learning agreement from syntactic data

We first look at whether training data containing explicit syntactic markers of number agreement is sufficient for few-shot learning. Table 3 describes

---

[5] Brown et al. (2020) perform several experiments on novel vocabulary items.

Training data type	Template
Simple	The wug/wuz ⟨PresentTenseVerb⟩.
Pred-adj	The wug/wuz is/are ⟨Adj⟩.
Reflexive	The wug/wuz ⟨Verb⟩ himself/themselves.

Table 3: The three types of training data used for syntactic fine-tuning.

the types of training data we examine. The three types of training data use different syntactic markers of plurality to indicate whether the new noun is singular or plural.

The language models are fine-tuned with 5 sentences drawn from a single training data type. GPT-2 was fine-tuned for 2 epochs, and BERT was fine-tuned for 4 epochs.[6] Transformer-XL was not used for the fine-tuning experiments, due to issues with introducing new vocabulary items given Transformer-XL's adaptive weight embedding.

After fine-tuning, each model was evaluated on the 10 grammatical tasks in Table 1. For each grammatical task, 500 sentences were sampled from the task template, and a performance score was calculated by averaging scores of the samples, as described in Section 3.4.

Figure 4 shows results for fine-tuning on the three types of syntactic data. Compared to model performance on real lexical items (shown in the leftmost column), both BERT and GPT-2 achieve qualitatively similar performance given the Pred-adj and Reflexive training data, but worse performance given the Simple training data. Performance is weakest on subject-verb agreement (SV-agreement) tasks involving relative clauses. When trained on data containing reflexive anaphora, both models achieve notably higher performance on the grammatical tasks involving reflexive anaphora.

The results provide evidence that small amounts of syntactic training data support learning the agreement properties of novel nouns. They also provide evidence of heterogeneity among different types of training data. Training from bare present tense verbs is least effective, and training from sentences containing reflexives leads to improved performance on tasks which require understanding of the conditions on reflexive binding.

5.2 Learning agreement from semantic data

We next examine whether purely semantic indicators of plurality are sufficient for learning a noun's

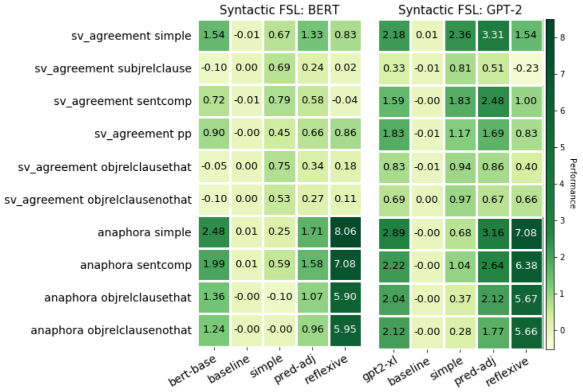

Figure 4: Few-shot learning from syntactic examples (averaging over plural and singular results). Columns show different types of training data, and rows show the 10 grammatical tasks. The bert-base and gpt2-xl columns indicate model performance on known lexical items, i.e. summarizing results from Section 4. The baseline columns indicate performance of non-fine-tuned models on the novel wug/wuz lexical items. Scores are differences of log-probabilities between grammatical and ungrammatical. The 95% confidence interval around each point estimate is always smaller than ±0.25.

number agreement properties. We look at several types of constructions which provide information about the plurality of a noun, but using predicates with past tense verbs that don't inflect for number so that there is no grammatical number agreement. In particular, we note the different possible readings with reference to the distributive and collective distinction described in the semantics literature (Lønning, 1997; Lasersohn, 2011; Champollion, 2015). For documentation of predicates that require a collective NP subject, see Levin (1993).

We use the fine-tuning method from Section 5.1.

Singular constructions

In order to induce singular noun interpretations, we use the singular-biased constructions shown at the top of Table 4. For example, if a wug worked all alone or came unaccompanied, it is likely that "wug" is both semantically and grammatically singular. However, these constructions do not gramatically require the head noun to be singular: they are compatible with distributive readings where the predicate individually applies to members of a group (e.g. "the lawyers worked all alone" means *each* lawyer worked alone).

BERT and GPT-2 were fine-tuned on 5 examples of each of the singular constructions. Figure 5 shows the results. None of the constructions con-

---

[6] Prior to more systematic experiments, we informally optimized the number of fine-tuning epochs.

	Training data type	Example
Singular	all-alone	The wug worked all alone.
	unaccompanied	The wug came unaccompanied.
	separated-entire	The wug became separated from the entire group.
	personally	The wug personally thanked me.
Plural	unison	The wuz nodded in unison.
	together	The wuz ate together.
	simultaneously	The wuz jumped simultaneously.
	outnumbered	The wuz outnumbered the cats.
	constituted	The wuz constituted a majority of the team.
	gathered	The wuz gathered quietly.

Table 4: Types of training data used for semantic fine-tuning.

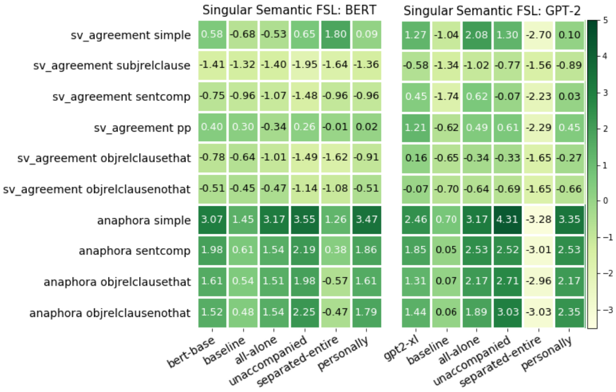

Figure 5: Few-shot learning from singular semantic examples. The bert-base and gpt2-xl columns indicate model performance on known lexical items, i.e. summarizing results from Section 4. The baseline columns indicate performance of non-fine-tuned models on the novel wug token.

sistently induced correct performance on the grammatical tasks across both models. Three of the constructions — *all-alone*, *unaccompanied*, and *personally* — led to strong performance on the reflexive anaphora tasks (stronger than the average performance calculated in Section 4). The *separated-entire* construction consistently decreased performance on the tasks relative to baseline.

Plural constructions

In order to provide the models with data indicating that a novel noun is plural, we use constructions which force either collective or distributive readings. For example, in Table 4, if the wuz constituted the majority of the team, then the word "wuz" must be semantically plural. The construction *constituted a majority* is collective because it must apply to the group as a whole:

(6) The doctors constituted a majority of the team.

   a. *Distributive reading: each of the doctors constituted a majority.

   b. Collective reading: the doctors as a group constituted a majority.

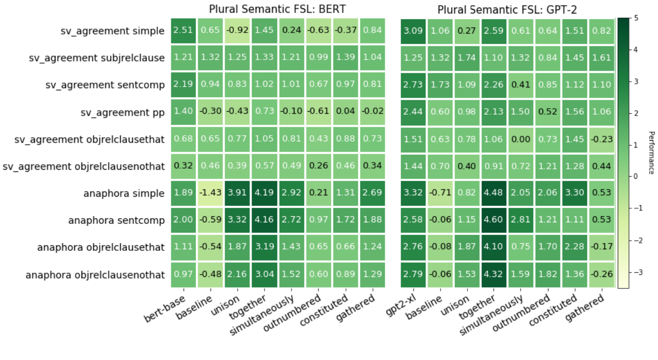

Figure 6: Few-shot learning from plural semantic examples. The baseline columns indicate performance of non-fine-tuned models on the novel wuz token.

While the argument of a collective predicate must be semantically plural, it is not necessarily grammatically plural. For example, the singular "the group" could constitute the majority of the team.

Three of the constructions in Table 4 are collective: *outnumbered*, *constituted*, and *gathered*. The other three are distributive phrasal predicates, which force distributive readings:

(7) The architects nodded in unison.

   a. Distributive reading: each of the architects nodded.

   b. *Collective reading: the group of architects itself nodded.

Figure 6 shows the plural learning results. The 6 types of training data perform comparably on the subject-verb agreement tasks (and similar to the baseline model, which represents performance prior to fine-tuning). The three distributive phrasal constructions perform better on the reflexive anaphora tasks than the three collective constructions, though all constructions improve relative to the baseline.

6 Discussion

We have investigated the sources of variation in neural language models' grammatical judgments. We found that there are systematic differences between nouns: when a language model exhibits knowledge of a noun's grammatical properties in one task, it is more likely to do so in other tasks. Moreover, when one language model exhibits this knowledge, other language models are more likely to as well.

The study found two latent dimensions of variation between nouns: one corresponding to how well the models understood its behavior with reflexive pronouns, and the other corresponding to subject-verb agreement.

Subsequent analyses demonstrate a pair of empirical phenomena:

1. It is relatively easy to learn the number agreement properties of a noun. The models learn the agreement properties of a novel noun from just a few samples, and the data supporting few-shot learning appears to be densely distributed; nearly all types of syntactic and semantic data examined lead to improvements on the reflexive pronoun or subject-verb agreement tasks.

2. Nouns that occur more frequently during training are not learned more accurately. Many nouns that occur with high frequency are not learned accurately.

These results suggest that nouns should vary less in their grammatical performance than is actually observed; the study finds *excess variation* in grammatical performance. If number agreement can be correctly learned from a few samples (FSL samples), then one would expect model performance to either a) improve with more data, as more FSL samples are observed, or b) improve with more data up to some threshold, and then asymptote after learning has saturated. In either case, for high frequency nouns, a sufficient number of FSL samples should be observed for these nouns to be learned very accurately.

A potential explanation of the results is that they are caused by catastrophic forgetting (Ratcliff, 1990; French, 1999): although a sufficient number of FSL samples are observed for a noun, these samples are forgotten during training, causing the performance of the noun to degrade. This explanation is implausible. If catastrophic forgetting is occurring, then the problem should be more severe for infrequent nouns than for frequent nouns, as the interval between training samples will be longer for infrequent nouns. This would predict better performance for frequent nouns.

Abstract

It has been conjectured that multilingual information can help monolingual word sense disambiguation (WSD). However, existing WSD systems rarely consider multilingual information, and no effective method has been proposed for improving WSD by generating translations. In this paper, we present a novel approach that improves the performance of a base WSD system using machine translation. Since our approach is language independent, we perform WSD experiments on several languages. The results demonstrate that our methods can consistently improve the performance of WSD systems, and obtain state-of-the-art results in both English and multilingual WSD. To facilitate the use of lexical translation information, we also propose BABALIGN, an precise bitext alignment algorithm which is guided by multilingual lexical correspondences from BabelNet.

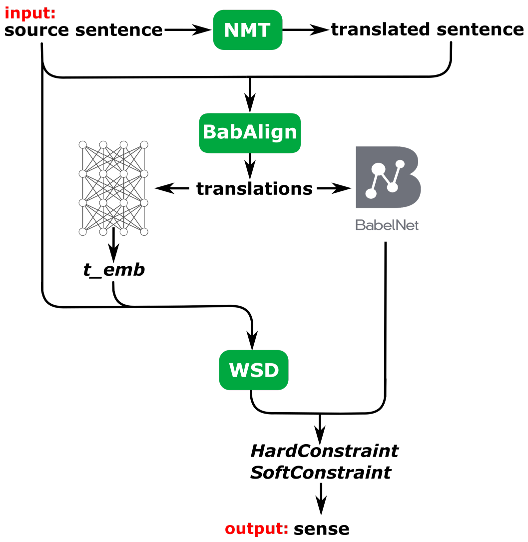

Figure 1: An overview of our approach to leverage translations to improve a base WSD system.

1 Introduction

Word sense disambiguation (WSD) is one of the core tasks in natural language processing. Given a predefined sense inventory, a WSD system aims to identify the correct sense of a content word in context. Although WSD is a monolingual task, it has been conjectured that multilingual information could help (Resnik and Yarowsky, 1999; Carpuat, 2009). Attempts have been made to leverage parallel corpora for sense tagging (Diab and Resnik, 2002), but no effective method for improving WSD with translations has been proposed to date.

Much of the history of WSD has been determined by the availability of manually created lexical resources in English, including SemCor (Miller et al., 1994) and WordNet (Miller, 1995). The situation changed with the introduction of BabelNet (Navigli and Ponzetto, 2012a), a massive multilingual semantic network, created by automatically integrating WordNet, Wikipedia, and other resources. In particular, BabelNet synsets contain translations in multiple languages for each individual word sense. Methods have been proposed to use multilingual information in BabelNet for WSD (Navigli and Ponzetto, 2012b; Apidianaki and Gong, 2015), but they do not directly exploit the mapping between senses and translations in multiple languages.

While there have been many attempts to apply WSD to machine translation (MT) (Liu et al., 2018; Pu et al., 2018), our goal instead is to harness advances in MT to improve WSD. Rather than develop a new WSD system, we propose a general method that can make existing and future systems more accurate by leveraging translations. We evaluate our methods with several supervised and knowledge-based WSD systems.

Our approach is based on the assumption of absolute synonymy between the senses of mutual translations in context (Hauer and Kondrak, 2020). The principal method SOFTCONSTRAINT refines sense

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4055–4065,

predictions of a given base WSD system using sense-translation mappings from BabelNet. The approach is able to take advantage of translations in multiple languages, whether produced manually or by MT models. It is also able to leverage sense frequency information, which can be obtained in either a supervised or unsupervised manner. Another method that we test is *t_emb* which integrates translations as contextual word embeddings into a WSD system to bias its sense predictions. To obtain word-level translations from the translated contexts, we introduce BABALIGN, a precise alignment algorithm guided by BabelNet synsets. In Figure 1, we show the entire architecture of our model based on aforementioned components.

Our experimental results demonstrate that translations can significantly improve existing WSD systems. We perform several experiments on English and multilingual WSD with both manual and machine translations. In the English WSD experiments with manual translations and word-level alignments, we determine the potential of our methods in an ideal situation. In the experiments with machine translations, we validate that the methods are effective and robust by showing improvements over existing WSD systems. Finally, in the multilingual WSD experiments, we demonstrate the language independence of our methods.

The main contributions of this work are the following. (1) We propose the first effective method to improve WSD with automatically generated translations. (2) Our language-independent knowledge-based method achieves state-of-the-art results in both English all-words and multilingual WSD. (3) We introduce a bitext alignment algorithm that leverages information from BabelNet.

2 Related Work

The integration of multilingual information to improve English WSD has been considered in prior work. Through analyzing a multilingual dictionary, Resnik and Yarowsky (1999) observe that highly distinct senses can translate differently. Diab and Resnik (2002) propose a WSD system based on translation information extracted from a bitext, but it fails to outperform systems that rely on monolingual information only.

Word sense induction (WSI) and cross-lingual WSD (CLWSD) are related tasks. WSI aims for automatically inducing word senses from corpora by clustering similar instances of words. Several prior works perform WSI based on bitexts to create bilingual sense inventory on word samples, where translations are treated as sense tags (Specia et al., 2007; Apidianaki, 2009). CLWSD is a task to predict a set of translations for a given ambiguous word in context. Attempts have been made to integrate translations as bag-of-words feature vectors to enhance CLWSD (Lefever et al., 2011). Since the goals of WSI and CLWSD differ from standard WSD with predefined senses, our approach is not directly comparable.

Navigli and Ponzetto (2012b) incorporate translations in BabelNet synsets as a feature in a graph-based WSD system. However, rather than apply translations of the focus word token as constraints, they simply consider all possible translations of the focus word type to enhance its sense distinctions.

Apidianaki and Gong (2015) directly apply sense-translation mappings in BabelNet as a hard constraint on sense predictions using translations from sense-annotated bitexts. Unlike our work, their approach is based on the BabelNet First Sense (BFS) baseline, rather than on an actual WSD system. Their results on English WSD fail to show improvement over the baseline, which may be due to the use of only a single target language, as well as word alignment errors.

3 Methods

We first formulate our WSD task. The input is a sentence, in which one word, e, is designated as the *focus word*. The set of possible senses of the focus word $S(e)$ comes from the sense inventory. We assume that a base WSD system assigns a probability or score to each sense, with the output being the sense with the maximum score. The objective is to determine which sense $s \in S(e)$ is the sense of e in this sentence.

We propose two methods, HARDCONSTRAINT and SOFTCONSTRAINT, which can be used to augment any base WSD system that meets the above specifications. Both methods leverage translations in order to constrain sense predictions made by a base WSD system. In addition, we introduce a method of leveraging contextual word embeddings to enhance the integration of translations in combination with those constraints. Finally, since our methods crucially depend upon identifying the translation of the focus word in the translated sentence, we also introduce a new knowledge-based word alignment algorithm.

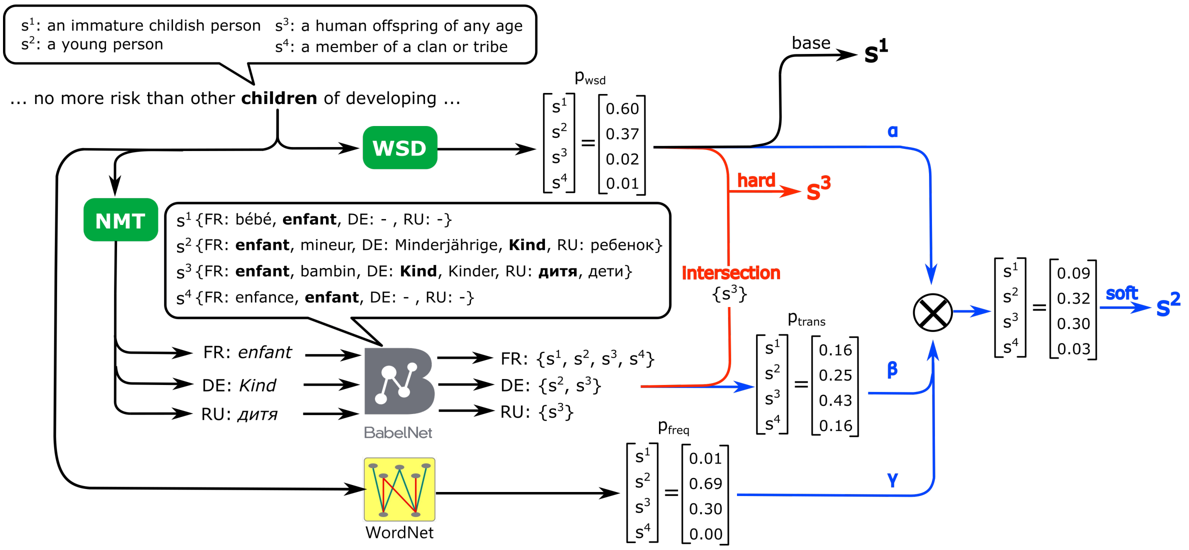

Figure 2: The application of HARDCONSTRAINT (red) and SOFTCONSTRAINT (blue) when disambiguating the word *children* in the given context (actual example from Senseval2 data where the correct sense is s^2).

3.1 HARDCONSTRAINT

Our first method extends the idea of Apidianaki and Gong (2015) to constrain $S(e)$ based on sense-translation mappings in BabelNet. However, instead of relying on a single translation, we incorporate multiple languages by taking the intersection of the individual sets of senses; that is, we rule out senses if their corresponding BabelNet synsets do not contain translations from all target languages. This baseline method is simple but inflexible: the correct sense can be accidentally ruled out if the provided translation of the focus word is not found in the corresponding BabelNet synset.

Our implementation of HARDCONSTRAINT considers the intersection of the sets of synsets that contain translations from each language. Ideally, the intersection contains exactly one sense, which we take as the final prediction. (Such a case is illustrated in Figure 2.) Otherwise, if the intersection contains multiple senses, we choose the one with the highest score from the base WSD system. If the intersection happens to be empty, we back-off to the prediction of the base WSD system.

3.2 SOFTCONSTRAINT

HARDCONSTRAINT is effective at ruling out sense candidates, but is also sensitive to MT errors and BabelNet deficiencies. BabelNet contains translations for only 79% of the nominal senses in WordNet, and its multilingual lexicalizations have an average precision of only 72% (Navigli and Ponzetto, 2012a).

Our principal method, SOFTCONSTRAINT, is more robust in handling noisy MT translations and BabelNet gaps. It integrates information from three sources: the base WSD system, translations, and sense frequencies (Figure 2). From each of these sources, we derive a probability distribution over $S(e)$. We employ the product of experts (PoE) approach (Hinton, 2002) to combine the probabilities as follows:

$$\tilde{p}(s) = p_{wsd}(s)^{\alpha} \cdot p_{trans}(s)^{\beta} \cdot p_{freq}(s)^{\gamma}$$

The resulting score $\tilde{p}$ is an unnormalized measure of probability with tunable weights α, β, and γ. We tune those weights through grid-search. The sense that maximizes this measure is taken as the prediction. Below, we provide the details on each of the three distributions.

Probability p_{wsd} is obtained by simply normalizing the numerical scores from the base WSD system.

Probability p_{trans} is calculated on the basis of the set of translations for each focus word e in BabelNet. Given a source focus word e and a word f in another language, we obtain its sense coverage $c(e, f)$ representing the number of possible senses of e that are mapped to f, i.e., the number of BabelNet synsets containing both e and f. Based on the sense coverage, the word pair e and f is assigned a weight $w(e, f)$ that reflects its discrimination power:

$$w(e,f) = \begin{cases} \frac{1}{c(e,f)} & \text{if } c(e,f) \neq 0 \\ 0 & \text{otherwise} \end{cases}$$

Now, we consider f to be a translation $t_L(e)$ for e in a target language $L \in \mathcal{L}$, where $\mathcal{L}$ stands for the set of target languages. The score of a candidate sense $s \in S(e)$ is then the sum of weights of the translations that are found in the corresponding BabelNet synset $BN(s)$:

$$score(s) = \sum_{L \in \mathcal{L}} w(e, t_L(e)) \cdot \mathbb{1}_{BN(s)}(t_L(e))$$

where $\mathbb{1}_{BN(s)}(t_L(e))$ is an indicator function that becomes 1 if $t_L(e) \in BN(s)$ and 0 otherwise. As with p_{wsd}, we normalize the scores into a proper probability distribution p_{trans} over the set of senses. To avoid zero values, we perform smoothing by adding a small positive value (a tunable parameter).

Probability p_{freq} represents the sense frequency information for a given lemma and part-of-speech (POS). This information is also used by most WSD systems. For English, we obtain sense frequencies from WordNet, which derives such information from SemCor, a sense-annotated corpus. To handle senses with zero frequency in SemCor, we also apply additive smoothing. To obtain p_{freq} for languages other than English, which lack large, high-quality sense annotated corpora, we use CluBERT (Pasini et al., 2020), the state-of-the-art system for unsupervised sense distribution learning, which applies a clustering algorithm to contextual embeddings from BERT (Devlin et al., 2019). Like our methods, CluBERT is language independent, has no additional training data requirements, and has been successfully integrated into WSD systems to improve their performance.

Figure 2 illustrates how SOFTCONSTRAINT combines the three probability distributions to correct an incorrect sense prediction produced by a base system.

3.3 Contextual Word Embeddings

Recent work has demonstrated the utility of contextual word embeddings for NLP tasks (Peters et al., 2018; Devlin et al., 2019). Accordingly, WSD systems such as SENSEMBERT (Scarlini et al., 2020) take a contextual embedding of the focus word as input, in order to leverage its dense encoding of relevant local information, which may be used to determine the correct sense.

In this section, we propose a method of adding translation information to the input of a WSD system by modifying the contextual embedding of the focus word to reflect its translation. We refer to this method as *t_emb*. Note that this method can be combined with either the HARDCONSTRAINT or SOFTCONSTRAINT methods. Unlike the constraint-based methods, which use translations of the focus word to post-process the output of a WSD system, *t_emb* provides the translation information in the form of an embedding directly as input to the WSD system. Thus, translation information is used as an additional feature to improve sense predictions of the base WSD system.

As before, our approach is to translate the context of the focus word, and use word alignment to identify the translation of the focus word. We compute a contextual embedding of this translation, just as we did for the focus word itself, and then concatenate the two embeddings. This produces a new embedding that can be provided to a base WSD system in place of the focus word embedding alone. However, since not all WSD systems use contextual embeddings, this method is less general, and we only apply it to some of our models and evaluation experiments.

3.4 Translation Alignment

The effectiveness of our approach for improving WSD depends on the correct identification of the word-level translations in each language. Even when the sentential context of the focus word is correctly rendered in another language, both HARDCONSTRAINT and SOFTCONSTRAINT rely on the proper alignment between the source focus word and its translation, which may be composed of multiple word tokens. Although attention weights in some NMT systems may be used to derive word alignment, such an approach is not necessarily more accurate than off-the-shelf alignment tools (Li et al., 2019). Therefore, our approach is to instead identify the word-level translations by performing a bitext-based alignment between the source focus words and their translations.

During development, we found that the accuracy of alignment tools such as FASTALIGN (Dyer et al., 2013) is limited by the size of the aligned bitext, as well as the lack of access to the translation information which is present in BabelNet. To mitigate these issues, we introduce a knowledge-based word alignment algorithm BABALIGN[1] that leverages translation information in BabelNet by post-processing the output of an off-the-shelf word aligner. BA-

---

[1] Implementation is available at: `https://github.com/YixingLuan/BabAlign`

bAlign is shown to be more effective than existing word aligners in downstream tasks such as cross-lingual lexical entailment (Hauer et al., 2020). We first append our translated WSD data to a large lemmatized bitext. We further augment the bitext with the BabelNet translations for all WSD focus words. We then run the base aligner in both translation directions, and take the intersection of the two sets of alignment links. In its final stage, BabAlign leverages the BabelNet translation pairs again, to post-process the generated alignment.

Algorithm 1 summarizes BabAlign. The algorithm takes as input a source-language sentence and a target-language sentence, as well as the set of translations for each content word in the source sentence. As BabAlign is an alignment post-processing algorithm, its input is the alignment of the two sentences from a base aligner.

If a source word w_s is aligned to a word w_t which is one of its translations, the alignment is considered correct. Since a possible translation may be composed of multiple words (e.g., French translation *salle d'audience* for *courtroom*), we attempt to expand a partial alignment by considering the adjacent word tokens. This is achieved by invoking *compound_search*, which takes the aligned token pair (w_s, w_t) and returns the longest sequence of target tokens c such that $bn(w_s)$ contains c, c contains w_t, and c does not contain any target tokens (except w_t) that are aligned by the base aligner. If no such compound is found, *compound_search* simply returns w_t, so no change in the alignment will be made.

On the other hand, if the source word w_s is aligned to a target word which is not among its translations, we invoke *bnlex_search*, which returns the longest sequence of target tokens l such that $bn(w_s)$ contains l, and l does not contain any tokens that are already aligned. Intuitively, this is an attempt to "repair" an incorrect alignment by searching for an unaligned target word which is known to be a translation of w_s. If such an l can be found (i.e. $l \neq None$), the alignment is modified so that w_s is aligned to l.

Algorithm 1 BabAlign

```
Input:
    list of all source tokens, $\sigma_s = (w_{s1}, \ldots, w_{sl})$
    list of all target tokens, $\sigma_t = (w_{t1}, \ldots, w_{tm})$
    BabelNet translations, $bn(w_s) = \{l_1, \ldots, l_n\}$

$A \leftarrow BaseAligner(\sigma_s, \sigma_t)$
for each aligned word pair $(w_s, w_t) \in A$ do
    if $w_t \in bn(w_s)$ then
        $c \leftarrow compound\_search(w_s, w_t)$
        Modify $A$ such that $w_s$ aligns to $c$.
    else
        $l \leftarrow bnlex\_search(w_s)$
        if $l \neq None$ then
            Modify $A$ such that $w_s$ aligns to $l$.
return $A$
```

4 Word Alignment Evaluation

To show the effectiveness of BabAlign, which combines an existing word aligner with translations from BabelNet, we evaluate the alignment performance using parallel datasets with gold alignment. We employ FastAlign as the base aligner. As the evaluation datasets, we use SemCor 3.0[2] and its translations, Multi SemCor (MSC) (Bentivogli and Pianta, 2005) and Japanese SemCor (JSC) (Bond et al., 2012), to evaluate English-Italian and English-Japanese alignment respectively. Both MSC and JSC contain manually annotated gold alignment for a subset of the sense-annotated content words in SemCor. We extract all English, Italian, and Japanese sentence triples where an English token has gold alignments in both the Italian and Japanese sides. We get 639 sentence triples with 2602 aligned tokens. We only evaluate the alignment performance for those 2602 sense-annotated tokens, and do not consider the alignment for other tokens, because our purpose here is to obtain proper translations for test words in the WSD setting.

For SemCor, we continue to use the included tokenization, lemma, and POS information. For MSC and JSC, we do not use the tokenization, lemma, and POS information provided in the data to emulate the setting where we generate translations for monolingual WSD datasets. Instead, for MSC, JSC, and the additional bitexts, we employ morphological taggers to perform pre-processing: TreeTagger (Schmid, 1994) for Italian and MeCab (Kudo, 2005) for Japanese. The additional bitexts that we append to the data are from OpenSubtitles2018 (Lison and Tiedemann, 2016): English-Italian (37.8M sentences) and English-Japanese (2.2M sentences). We evaluate alignment performance in terms of

---

[2] We use SemCor 3.0 in the Natural Language Toolkit (NLTK) to keep the compatible file format with MSC and JSC.

Method	Data	En-It	En-Ja
FASTALIGN	test data only	80.4	36.0
	+OpenSub	93.3	75.6
	+OpenSub +pairs	93.6	81.9
BABALIGN	+OpenSub +pairs	**94.0**	**91.6**

Table 1: Alignment F-score on English-Italian and English-Japanese bitexts.

whether the lemma of the aligned translation corresponds to the lemma of the manually aligned translation in MSC or JSC.

Table 1 compares the alignment approaches. As expected, the concatenation of a large bitext to the test data (+OpenSub) dramatically reduces the number of errors. The addition of translation pairs from BabelNet (+pairs) yields further gains. BABALIGN itself improves the quality of the alignment on English-Japanese by nearly 10 points. The improvement on English-Italian is smaller, as the alignment between similar languages is easier, and the additional bitext is much larger. Japanese is particularly challenging, not only because it is typologically different, but also due to the frequency of multi-character compounds. The back-off strategy used by BABALIGN effectively leverages possible translations in BabelNet to recover tokenized compounds and missing alignment links. This mitigates the effect of alignment errors on our WSD results, which we describe in the next section.

5 WSD Evaluation

In this section, we first describe the WSD systems that we use in our experiments. We then show how our methods can improve existing WSD systems in the oracle setting for English all-words WSD. Finally, we report the results of the experiments on multilingual WSD and English all-words WSD with automatic translations.

5.1 WSD Systems

There are two main approaches to WSD: supervised and knowledge-based. Supervised systems are trained on sense-annotated corpora and generally outperform knowledge-based systems. On the other hand, knowledge-based systems usually apply graph-based algorithms to a semantic network and thus do not require any sense-annotated corpora. Since it is expensive to obtain manually sense-annotated corpora and such corpora exist mainly in English, it is often impractical to apply supervised systems to multilingual settings. Therefore, for multilingual WSD, knowledge-based approaches are typically employed.

Many effective WSD systems have been proposed; we include here only the systems that we use in our experiments. IMS (Zhong and Ng, 2010) is a canonical supervised WSD system, which uses support vector machines with various lexical features. LMMS (Loureiro and Jorge, 2019) leverages contextual word embeddings and surpasses the long-standing 70% F-score ceiling for supervised WSD. It learns supervised sense embeddings by applying BERT to SemCor, with additional semantic knowledge from WordNet. Among the knowledge-based systems, Babelfy (Moro et al., 2014) applies random walks with restarts to BabelNet to perform WSD and entity linking. Even though Babelfy is based on BabelNet, it does not make direct use of the translation information in BabelNet. Similarly, UKB (Agirre et al., 2014, 2018), which is based on personalized PageRank on WordNet, achieves state-of-the-art performance on English all-words WSD. Finally, utilizing contextual embeddings, SENSEMBERT (Scarlini et al., 2020) learns knowledge-based multilingual sense embeddings obtained by combining representations learned using BERT with knowledge obtained from BabelNet. This yields state-of-the-art results on English nouns WSD and multilingual WSD. We test these systems both without modification, and with the addition of our knowledge-based methods, to measure how much improvement can be obtained by leveraging translations.

5.2 Oracle WSD Experiments

Our first set of experiments aims at estimating the upper limits of our approach in an oracle setting of annotated and aligned bitexts with high-quality human translations.

Experimental Setup Our sense-annotated bitexts are MSC and JSC (Section 4), which contain manual translations of texts from SemCor. As in Section 4, we use 639 sentences with 2602 sense-annotated instances from MSC and JSC. We randomly sample 10% of the instances as the development set. We tune all parameters on the development set, and use the same hyperparameters throughout the experiment.

We employ two knowledge-based WSD systems: Babelfy and UKB. Both systems have variants that take advantage of sense frequency information in

System	Translation	base	hard	soft
Babelfy	IT	50.7	60.3	58.6
	JA		65.8	65.8
	IT+JA		66.7	**68.6**
UKB	IT	58.0	64.1	64.2
	JA		72.0	72.1
	IT+JA		72.2	**73.3**
Babelfy + WN1st	IT	72.6	73.2	**73.6**
	JA		73.1	**73.6**
	IT+JA		73.4	**73.6**
UKB + dict_weight	IT	71.2	73.6	75.4
	JA		78.5	80.0
	IT+JA		77.8	**80.1**

Table 2: WSD F-score on the SemCor test set with Italian and Japanese translations.

WordNet. Babelfy backs off to the WordNet first sense (WN1st) using a fixed confidence threshold, which we set to 0.8 following Moro et al. (2014). UKB uses complete sense frequency distributions, which are referred to as the dictionary weight (*dict_weight*). We use the same parameter settings as Agirre et al. (2018). For fair comparison, when applying SOFTCONSTRAINT to a system variant without sense frequency information, we set γ to 0 to turn off the p_{freq} component.

Results The results in Table 2 demonstrate the efficacy of leveraging translations for WSD. The systems without sense frequency information are boosted by 15-18%, while the systems with full features get up to 9% absolute improvement. Also, SOFTCONSTRAINT consistently outperforms HARDCONSTRAINT. The modest improvement of 1% on Babelfy is due to the base system falling back on the WN1st sense in about 80% of test instances, precluding the use of translations.

Also, we observe that our approach is effective in combining translations from multiple languages. For instance, the F-score of 73.3% for plain UKB with SOFTCONSTRAINT (shown in Table 2) drops to 72.1% with only Japanese translations, to 64.2% with only Italian translations, and to 58.0% with no translations. These results also indicate that translations from a more distant language, i.e., Japanese, work better at discriminating senses.

5.3 Multilingual WSD Experiments

Since our methods are language-independent, we test them on standard multilingual WSD datasets.

Experimental Setup We perform our multilingual WSD evaluation on benchmark parallel datasets in English, Spanish, Italian, French, and German from SemEval-2013 task 12 (Navigli et al., 2013) and SemEval-2015 task 13 (Moro and Navigli, 2015).[3] The datasets contain manual reference translations, but are not word-aligned. We perform experiments in two settings, with either machine or human translations. To obtain automatic translations, we translate the test sets into English using Google Translate[4] because the pre-trained NMT models for test languages are not always available. For manual translations, we use the provided parallel datasets in all languages. For each individual language, we use BABALIGN to obtain translations of the focus word in other languages. We randomly sample 10% of test instances in each dataset to obtain development sets for parameter tuning.

We use two multilingual base WSD systems: IMS and SENSEMBERT. We train IMS on OneSeC (Scarlini et al., 2019), an automatically sense-annotated set of corpora in multiple languages.[5] For SENSEMBERT embeddings, when we integrate the translation embedding (*t_emb*), we concatenate the focus word embedding and its corresponding *t_emb*, as described in Section 3.3. To compute these contextual word embeddings for English translations, we use the 768-dimensional multilingual BERT cased pre-trained model (mBERT). Since both OneSeC and SENSEMBERT are limited to nouns, we follow Scarlini et al. (2019, 2020) in performing the evaluation on nominal instances only.

Since languages other than English lack large sense-annotated corpora, we employ two evaluation settings. In the default setting, sense frequency information is not used, with the parameter γ set to 0 in SOFTCONSTRAINT. In the other setting, we approximate sense distributions with CluBERT (Pasini et al., 2020).

Results In Tables 3 and 4, we report the WSD results on SemEval-2013 and SemEval-2015 datasets.[6] Surprisingly, the results with English-only Google Translate (GT) translations are only slightly lower on average than with manual translations from multiple languages. HARDCON-

Table 4: WSD F-score of SENSEMBERT with translations on the nominal instances of the SemEval-2013 and SemEval-2015 datasets, with Google Translate (English) and manual (all languages) translations.

STRAINT performs well in this set of experiments, as nouns are very well covered by BabelNet.[7] SOFTCONSTRAINT achieves an average improvement of several F1 points on both systems, even without sense frequency information. The best results are obtained using sense frequency estimates from CluBERT, especially when they can be combined with mBERT-based contextual translation embeddings (*t_emb*), neither of which requires manually sense-annotated corpora. We interpret these results as the new state of the art in multilingual WSD based on the consistent improvement over SENSEMBERT.

To evaluate the potential of using translations from a replicable NMT model, we obtain English translations for test words in the SemEval-2013 German dataset with a pre-trained transformer model (Ng et al., 2019) available in the fairseq toolkit (Ott et al., 2019). In this setting, we use only English translations for both constraints and *t_emb*. The results on both WSD systems with the pre-trained model are almost the same as with GT, and slightly better than with English-only manual translations. According to our preliminary analysis, machine translations may sometimes work better because they tend to be more literal, and easier to align with the source focus words. This suggests that our methods can effectively leverage translations from different kinds of sources.

5.4 English WSD Experiments with NMT

In the final set of experiments, we evaluate our methods on standard monolingual benchmark datasets using NMT translations from multiple languages.

Experimental Setup We evaluate on five English all-words datasets: Senseval2, Senseval3, SemEval-2007, SemEval-2013, and SemEval-2015 from the unified framework made available by Raganato et al. (2017). Since these datasets are not accompanied by translations, we automatically obtain the translations from NMT models. We tune parameters on Senseval2, and apply the same parameter settings in all datasets.

We test our methods with four base WSD systems: Babelfy and UKB (knowledge-based), and IMS and LMMS (supervised), trained on SemCor 3.0 provided in Raganato et al. (2017). Our replication experiments match the reported results for these systems (±0.2% on average). For translations, we employ pre-trained transformer models from the fairseq toolkit: English-French and English-German models from Ott et al. (2018), and an English-Russian model from Ng et al. (2019). We choose French, German, and Russian as target languages due to the availability of pre-trained models. Note that unlike multilingual WSD experiments (Section 5.3), we do not use Google Translate in the following experiments. We compare plain Babelfy and UKB to SOFTCONSTRAINT without p_{freq}. For other systems, we derive p_{freq} from sense frequency information from WordNet 3.0.[8]

Results Table 5 shows the results on the standard English all-words WSD datasets. While HARDCONSTRAINT is not sufficiently robust to improve complex WSD systems with automatically generated translations, SOFTCONSTRAINT shows statistically significant improvements over the original performance for all base systems.

---

[7] Over 99% of the words in BabelNet are nouns (Navigli and Ponzetto, 2012a). On average, 92% of the SemEval translations are in the BabelNet synsets of the correct senses.

[8] Due to the complexity of transforming mBERT representations into different dimensionalities and vector spaces, translation embeddings are not used in these experiments.

Table 6: WSD F-score of UKB + dict_weight with translations from a single language only.

For example, UKB with *dict_weight* correctly predicts the sense of "earth" in *"the* **world***'s most influential countries."* However, English *world* and its three translations, *monde*, *Welt*, and *mir*, are only found in the BabelNet synset glossed as "populace", while the Russian translation *mir* happens to be missing from the BabelNet synset glossed as "earth", perhaps because there is no Russian link to the English Wikipedia page for *World.* Hence, while HARDCONSTRAINT miscorrects the UKB prediction to the sense of "populace", SOFTCONSTRAINT keeps it unchanged by leveraging sense frequencies and the base system scores.

In Table 6, we show additional results on UKB with *dict_weight* when using only a single language to derive translations. All three languages show similar improvements, and we can obtain better improvements by combining multiple languages.

In summary, these results again demonstrate that our method can effectively integrate information from the WSD system itself, translations, and sense frequency even with noisy translations generated by NMT models. While translations are shown to help even strong supervised WSD systems, the improvements are particularly impressive on knowledge-based systems. The SOFTCONSTRAINT result on UKB with *dict_weight* sets a new state of the art for knowledge-based systems.

6 Conclusion

We proposed a novel approach that improves WSD by leveraging translations from multiple languages, which incorporates a knowledge-based bitext alignment. We tested our methods with several base WSD systems. We demonstrated experimentally that SOFTCONSTRAINT can consistently improve WSD performance even when no manual translations are available, leading to state-of-the-art results on multilingual and English all-words WSD. We make the source code available at `https://github.com/YixingLuan/translations4wsd`.

Towards Better Context-aware Lexical Semantics: Adjusting Contextualized Representations through Static Anchors

Qianchu Liu, Diana McCarthy, Anna Korhonen
Language Technology Lab, TAL, University of Cambridge, UK
`ql261@cam.ac.uk, diana@dianamccarthy.co.uk, alk23@cam.ac.uk`

Abstract

One of the most powerful features of contextualized models is their dynamic embeddings for words in context, leading to state-of-the-art representations for context-aware lexical semantics. In this paper, we present a post-processing technique that enhances these representations by learning a transformation through static anchors. Our method requires only another pre-trained model and no labeled data is needed. We show consistent improvement in a range of benchmark tasks that test contextual variations of meaning both across different usages of a word and across different words as they are used in context. We demonstrate that while the original contextual representations can be improved by another embedding space from either contextualized or static models, the static embeddings, which have lower computational requirements, provide the most gains.

1 Introduction

Word representations are fundamental in Natural Language Processing (NLP) (Bengio et al., 2003). Recently, there has been a surge of contextualized models that achieve state-of-the-art in many NLP benchmark tasks (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019b; Yang et al., 2019). Even better performance has been reported from fine-tuning or training multiple contextualized models for a specific task such as question answering (Devlin et al., 2019; Xu et al., 2020). However, little has been explored on directly leveraging the many off-the-shelf pre-trained models to improve task-independent representations for lexical semantics. Furthermore, classic static embeddings are often overlooked in this trend towards contextualized models. As opposed to *contextualized* embeddings that generate dynamic representations for words in context, *static* embeddings such as word2vec (Mikolov et al., 2013) assign one fixed representation for each word. Despite being less effective in capturing context-sensitive word meanings, static embeddings still achieve better performance than contextualized embeddings in traditional context-independent lexical semantic tasks including word similarity and analogy (Wang et al., 2019). This suggests that static embeddings have the potential to offer complementary semantic information to enhance contextualized models for lexical semantics.

We bridge the aforementioned gaps and propose a general framework that improves contextualized representations by leveraging other pre-trained contextualized/static models. We achieve this by using *static anchors* (the average contextual representations for each word) to transform the original contextualized model, guided by the embedding space from another model. We assess the overall quality of a model's lexical semantic representation by two *Inter Word* tasks that measure relations between different words in context. We also evaluate on three *Within Word* tasks that test the contextual effect from different usages of the same word/word pair. Our method obtains consistent improvement across all these context-aware lexical semantic tasks. We demonstrate the particular strength of leveraging static embeddings, and offer insights on the reasons behind the improvement. Our method also has minimum computational complexity and requires no labeled data.

2 Background

This section briefly introduces the contextualized/static models that we experimented in this study. For static models, we select three representative methods. **SGNS** (Mikolov et al., 2013), as the most successful variant of word2vec, trains a log linear model to predict context words given a target word with negative sampling in the objective. **FastText** improves over SGNS by training at the n-gram level and can generalize to unseen words (Bojanowski et al., 2017). In addition to these two prediction-based models, we also include

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4066–4075,
November 16–20, 2020.

one count-based model, **GloVe** (Pennington et al., 2014). GloVe is trained to encode semantic relations exhibited in the ratios of word-word occurrence probabilities into word vectors.

As opposed to static embeddings, contextualized models provide dynamic lexical representations as hidden layers in deep neural networks typically pre-trained with language modeling objectives. In our study, we choose three state-of-the-art contextualized models. **BERT** (Devlin et al., 2019) trains bidirectional transformers (Vaswani et al., 2017) with masked language modeling and next sentence prediction objectives. Liu et al. (2019b)'s **RoBERTa** further improves upon BERT by carefully optimizing a series of design decisions. **XLNet** (Yang et al., 2019) takes a generalized autoregressive pre-training approach and integrates ideas from Transformer-XL (Dai et al., 2019). For the best performance, we use the Large Cased[1] variant for each contextualized model. Since our study focuses on generic lexical representations and many of the lexical semantic tasks do not provide training data, we extract features[2] from these contextualized models without fine-tuning the weights for a specific task. This feature-based approach is also more efficient compared with fine-tuning the increasingly larger models which can have hundreds of millions of parameters.

3 Method

Our method[3] is built from a recently proposed cross-lingual alignment technique called *meeting in the middle* (Doval et al., 2018). Their method relies on manual translations to learn a transformation over an orthogonal alignment for better **cross-lingual static** embeddings. We show that by a similar alignment + transformation technique, we can improve **monolingual contextualized** embeddings without resorting to any labeled data.

The direct correspondence among contextualized and static embeddings for alignment is not straightforward, as contextualized models can compute infinite representations for infinite contexts. Inspired by previous study (Schuster et al., 2019) that found contextualized embeddings roughly form word clusters, we take the average of each word's contextual representations as anchors of a contextualized model. We call them *static anchors* as they provide one fixed representation per word, and therefore correspond to word embeddings from a static model such as FastText. We also use these anchors to align between contextualized models. To form the vocabulary for creating static anchors in our experiments, we take the top 200k most frequent words and extract their contexts from English Wikipedia.

To describe the method in more detail, we represent the anchor embeddings from the original contextualized model as our source matrix $\mathbf{S}$, and the corresponding representations from another contextualized/static model as target matrix $\mathbf{T}$. $\mathbf{s}_i$ and $\mathbf{t}_i$ are the source and target vectors for the i_{th} word in the vocabulary (V). We first find an orthogonal alignment matrix $\mathbf{W}$ that rotates the target space to the source space by solving the least squares linear regression problem in Eq. 1. $\mathbf{W}$ is found through Procrustes analysis (Schönemann, 1966).

$$\mathbf{W} = \arg\min_{\mathbf{W}} \sum_{i=1}^{|V|} \|\mathbf{W}\mathbf{t}_i - \mathbf{s}_i\|^2 \quad s.t. \quad \mathbf{W}^{\mathbf{T}}\mathbf{W} = \mathbf{I}. \tag{1}$$

As described in Eq. 2, we then learn a linear mapping $\mathbf{M}$ to transform the source space towards the average of source and the rotated target space, by minimizing the squared Euclidean distance between each transformed source vector $\mathbf{M}\mathbf{s}_i$ and the mean vector $\boldsymbol{\mu}_i$ ($\boldsymbol{\mu}_i = (\mathbf{s}_i + \mathbf{W}\mathbf{t}_i)/2$). $\mathbf{M}$ is the mapping we will use to transform the original contextualized space. Following Doval et al. (2018), $\mathbf{M}$ is found via a closed-form solution.

$$\mathbf{M} = \arg\min_{\mathbf{M}} \sum_{i}^{|V|} \|\mathbf{M}\mathbf{s}_i - \boldsymbol{\mu}_i\|^2 \tag{2}$$

For improved alignment quality, as advised by Artetxe et al. (2016), we normalize and mean-center[4] the embeddings in $\mathbf{S}$ and $\mathbf{T}$ a priori.

4 Experiments

Task Descriptions[5] We evaluate on three *Within Word* tasks. Usage Similarity (**Usim**) (Erk et al., 2013) dataset measures graded similarity of the same word in pairs of different contexts on the scale from 1 to 5. Word in Context (**WiC**) (Pilehvar and Camacho-Collados, 2019) dataset challenges a system to predict a binary choice of whether a pair of contexts for the same word belongs to the same

---

[1] 1024 dimensions with case-preserving vocabulary.

[2] Appendix A contains more details on feature extraction.

[3] Implementation details are listed in Appendix B.

[4] We pre-process representations with the same centering and normalization in all tasks. Our reported results are similar or better than the results from un-preprocessed representations.

[5] Appendix C reports details for each task and experiment.

meaning or not. We follow the advised training scheme in the original paper to learn a cosine similarity threshold on the representations. The recently proposed **CoSimlex** (Armendariz et al., 2019) task provides contexts for selected word pairs from the word similarity benchmark SimLex-999 (Hill et al., 2015) and measures the graded contextual effect. We use the English dataset from this task. Its first subtask, **CoSimlex-I**, evaluates the change in similarity between the same word pair under different contexts. As it requires a system to capture different contextual representations of the same word in order to correctly predict the change of similarity to the other word in the pair, CoSimlex-I indirectly measures within-word contextual effect and therefore provides our third *Within Word* task. The second CoSimLex subtask, **CoSimlex-II**, is an *Inter Word* task as it requires a system to predict the absolute gold rating of each word pair consisting of different words in each context. We also evaluate on another related *Inter Word* task, Stanford Contextual Word Similarity (**SCWS**), which provides graded similarity scores of word pairs in independent contexts. Compared with the two *Inter Word* tasks, the three *Within Word* tasks are more sensitive to contextual effects since they penalize strongly a static model (eg. FastText) as being no better than a random baseline. By contrast, we might expect a context-independent static model to perform reasonably, though not as good as a context-sensitive model, in $InterWord$ tasks (Armendariz et al., 2019).

Results: Table 1 reports the performance of each contextualized model before and after the transformation guided by each of the other contextual/static embeddings. In this table, → indicates the direction of the transformation. For example, RoBERTa → FastText denotes using FastText as the target space to transform RoBERTa.

We find that applying transformation is generally able to improve each contextualized model, obtaining the best performance across all the tasks. In particular, we observe substantial improvements in Usim (ca. 0.04 increase of ρ) and SCWS (ca. 0.03 increase of ρ). The most consistent improvement comes from leveraging static embeddings. This is especially evident in *Inter Word* tasks where transforming towards FastText achieves the best performance but leveraging another contextualized model often brings harm. This suggests that the static embeddings are able to inject better inter-word relations (Wang et al., 2019) into a contextualized model. At the same time, static embeddings consistently improve performance in *Within Word* tasks in 24 out of the total 27 configurations, reassuring us that the contextualization power of the original contextual space is not only preserved but even enhanced. Overall, FastText is the most robust target space as it improves all the contextualized source representations for all the tasks except for XLNet in WiC. SGNS and GloVe are also competitive especially in improving *Within Word* tasks.

Analysis: The overall improvement in both *Within Word* and *Inter Word* tasks suggests two possible benefits from the transformation: better within-word contextualization and better overall inter-word semantic space. We perform controlled studies that test for these two sources of improvement in isolation. We test on the best base contextualized space (RoBERTa) with the various transformations.

The fact that a static embedding (FastText) performs better than a random baseline in *Within Word* tasks (see Table 1) suggests that there are some lexical cues in the target words (eg. morphological variations) that can help solve the task alongside the context. To highlight the improvement in contextualization alone, since the *Within Word* tasks before lemmatization may contain different word forms of the same lemma as the target words in each pair, we lemmatize all the target words in the dataset. As a result, each pair in the *Within Word* tasks now contains the identical target word. We observe that the results after lemmatization are slightly lower than before but the transformation especially towards static embeddings is indeed able to improve the contextualization across all the tasks (Table 2).

To test solely the effect on the overall inter word semantic space of the contextualized model becomes better after the transformation, we 'decontextualize' the model by evaluating only on the static anchors of the contextualized embeddings. These static anchors are not sensitive to a particular context and can thus only reflect overall inter word semantic space like embeddings from a static model. We observe improvement from the transformation on the static anchors in *Inter Word* tasks. In particular, aligning towards FastText brings the largest and the most consistent gains. This suggests that FastText may have offered a better ensemble space with RoBERTa and results in a better overall inter word semantic space.

	Within Word			Inter Word

Table 2: Controlled experiments on lemmatised (lemma) and decontextualized (decon) RoBERTa before and after transformation towards static embeddings (red rows) or another contextualized embedding (blue rows). The lemma decon condition in the *Within Word* task is irrelevant as the results will be equivalent to random baselines. (r: uncentered Pearson correlation, ρ: Spearman correlation, acc: Accuracy)

To better understand the contextualization improvement in the *Within Word* scenario, we focus on WiC to perform more detailed analysis. While we report results on the test set in Table 1, we present the following analysis on the train and development sets because the test set labels have not been released. We focus on the best performing model in the task, RoBERTa → SGNS, to examine the difference before and after the transformation.

Overall, we observe a trend for the within-word contextual representations to move slightly closer to each other after the transformation, as the mean cosine similarity of a pair's contextual word representations across all instances has increased from 0.516 to 0.542. We further break down cases according to their labels and find that the transformation mainly brings the representations closer for TRUE pairs (where the context pairs of the word are indeed expressing the same meaning) with the mean cosine similarity increased from 0.606 to 0.651. For FALSE cases where the context pairs refer to distinct meanings of the target word, there is less increase in similarity (from 0.426 to 0.433). We also find that the improved performance in this task can be largely attributed to correcting many erroneous FALSE predictions in the original space as these representations are drawn closer after the transformation (See Appendix D). We qualitatively examine these corrected TRUE cases (Examples are provided in Appendix E), and found that the improvement typically comes from reduced variance for the contextual representations of monosemous words. An example is the word *daughter*. We observe very low cosine similarity among its contextual representations in the original space. These representations are drawn closer after the transformation (eg. cosine similarity from 0.48 to 0.67). We suspect this might be related to contextualized models' over-sensitivity to context changes (Shi et al., 2019).

To summarize the analysis, our controlled experiments confirm our two hypotheses that the transformation brings two independent effects: improved overall inter-word semantic space and improved within-word contextualization. Our qualitative analysis shows that the improved within-word contextualization is likely to be the result of context variance reduction.

5 Related Work

It has been shown that combining different static word representations (for example through averaging or concatenation) into a meta embedding can usually lead to better lexical representations (Coates and Bollegala, 2018; Yin and Schütze, 2016). While these task-independent meta embedding techniques are mainly applied on static embeddings, research has started to explore leveraging ensemble contextualized models when performing fine-tuning on a specific task (Devlin et al., 2019; Xu et al., 2020). Our method, as a post-processing transformation over task-independent contextual representations, is inherently different from these meta embedding and ensemble approaches. Computationally, our method does not require maintaining multiple models at test time, and is therefore more efficient. Our method is also by far the most effective way to leverage static embeddings to improve contextualized representations.[6]

Our methodology is related to studies on aligning cross-lingual embeddings (Doval et al., 2018; Liu et al., 2019a; Schuster et al., 2019). While these works mainly focus on obtaining better cross-lingual representations, our study is the first attempt to show that some of the cross-lingual alignment methods can be applied to improve monolingual contextualized representations with no manual resources required.

6 Conclusion

We present an effective post-processing method that transforms and enhances contextual word representations through static anchors with guidance from other contextualized/static embeddings. We show leveraging static embeddings, with no labeled data, consistently improves (across almost all configurations) on both *Inter Word* and surprisingly *Within Word* context-aware lexical semantic tasks. We also perform controlled analysis to highlight, in isolation, the improvement from the transformation on both contextualization and on an overall inter-word semantic space. In the future, we plan to apply the transformed representations on more lexical semantics tasks such as word sense disambiguation within an application (Navigli and Vannella, 2013).

---

[6] A simple meta embedding baseline that concatenates contextualized and static representations generally impairs the performance. (Appendix F)

A Details on extracting contextual word representations

We take the average of the last 12 layers from BERT and RoBERTa, and of the full 24 layers from XLNet as feature representations. We empirically found averaging the last 12 layers performs better than averaging the full 24 layers or the last layer for BERT and RoBERTa. This is in line with Tenney et al. (2019) that found semantic information is better captured in higher layers in BERT.

If a word is split into subwords after tokenization, we average the subword representations. We leave other ways of extracting the features for future work.

B Implementation details

For the input pre-trained models, we report their hyper-parameters and training details in the following:

Models	**Hyper-parameters & Training details**
RoBERTa	1024 dimensions; 24 layers; 16-heads, 355M parameters.
BERT	1024 dimensions; 24 layers; 16-heads, 340M parameters.
XLNet	1024 dimensions; 24 layers; 16-heads, 340M parameters.
Static models (eg. FastText)	300-d vectors trained on the latest English Wikipedia. We pad these vectors to 1024 to match the dimension size of the contextualized models.

As to our transformation method, we report the following details:

no. of parameter	1024*1024
Average runtime	10 seconds
Computing infrastructure	GeForce GTX 1080 Ti

We release our code at `https://github.com/qianchu/adjust_cwe.git`

C Details for experiments and data sets in this study

We provide the statistics for each task including number of examples, train/dev/test splits, and links to downloadable versions of the data in Table 3.

We also report the validation performance for WiC as the only supervised task in our study. Results on the development set and the hyper-parameters (the cosine similarity threshold) are listed in Table 4. The threshold is searched with 0.01 step size until we find the model that achieves the highest accuracy.

D Changes in model prediction on WiC before and after the transformation

Table 5 lists the changes in predicted labels after transforming RoBERTa towards SGNS. We categorize the changes into four groups according to the prediction changes after the transformation. The largest group contains 153 cases that were originally predicted as false negatives and were corrected after the transformation.

E Examples of corrected TRUE cases after transformation in WiC

Below are examples that were corrected to TRUE labels after the transformation in RoBERTa → SGNS. We also report changes in the cosine similarity of contextual representations in each example.

Examples	**similarity change**
I [know] it 's time. It is vital that he not [know].	0.42→0.65
I already have a son , so I would like to have a [daughter]. Her [daughter] cared for her in her old age.	0.48→0.67

F Results on concatenating contextualized and static embeddings

Please refer to Table 6 for a simple baseline that concatenates FastText and each of the contextualized model. We report results for FastText only as it has proved to be the most robust static embedding target space. We found similar results for concatenating with other static embeddings. In short, the simple concatenation with a static embedding generally brings more harm for the contextualized model.

Task	**Statistics**	**Links**
Usim	We exclude one sentence that caused xml parsing errors (call.v.1211) and 9 pairs involving this sentence. The final testset contains 1133 context pairs.	`http://www.dianamccarthy.co.uk/downloads/WordMeaningAnno2012/`
WiC	We use the original dataset with train/development/test splits containing 5428/638/1400 instances respectively.	Link to train and development sets: `https://pilehvar.github.io/wic/` Link to test set: `https://competitions.codalab.org/competitions/20010`
CoSimlex	Contains 333 word pairs and each pair has two different contexts. We test on the whole dataset	`https://competitions.codalab.org/competitions/20905`
SCWS	2003 word pairs with contexts	`shorturl.at/swMS3`

Table 3: Statistics for each task evaluated in the study

	WiC (acc%)	threshold
RoBERTa	67.24	0.5300
→ BERT	67.86	0.5600
→ XLNet	67.40	0.5500

XLNet	62.70	0.5300
→ BERT	62.70	0.5900
→ RoBERTa	62.54	0.5800
→ FastText	62.07	0.5700
→ SGNS	61.91	0.5900
→ GloVe	61.75	0.6600

Table 4: Performance on the development set of WiC

	TRUE (gold)	FALSE (gold)
FALSE (before) → TRUE (after)	153	99
TRUE (before) → FALSE (after)	116	145

Table 5: Change of predicted labels after the transformation of RoBERTa → SGNS. The left most column shows the predicted labels before and after the transformation, and the top row shows the gold label. The shaded cells report the number of cases corrected by the transformation.

	Within Word			Inter Word	
	Usim ρ	WiC acc%	CoSimlex-I r	CoSimlex-II ρ	SCWS ρ
RoBERTa	0.6196	68.28	0.7713	0.7249	0.6996
→ FastText	**0.6544**	**69.00**	**0.7794**	**0.7344**	0.7159
+ FastText	0.3301	66.85	0.5854	0.587	**0.7179**
BERT	0.5995	66.29	0.7595	0.7228	0.7520
→ FastText	**0.6388**	**67.57**	**0.7701**	**0.7315**	**0.7507**
+ FastText	0.3663	65.64	0.764	0.6763	0.7488
XLNet	0.4944	**63.14**	0.7727	0.7450	0.7242
→ FastText	**0.5223**	62.50	**0.7805**	**0.7473**	**0.7563**
+ FastText	0.2792	61.21	0.7641	0.6688	.7363

Table 6: Comparing concatenation (+) and our transformation method (→) on leveraging static embeddings. While concatenation may sometimes achieve slightly better results in SCWS, it largely worsens the performance in general. By contrast, our method achieves the most consistent and robust improvements (r: uncentered Pearson correlation; ρ: Spearman correlation; acc: Accuracy)

Compositional Demographic Word Embeddings

Charles Welch, Jonathan K. Kummerfeld, Verónica Pérez-Rosas, and **Rada Mihalcea**
Computer Science & Engineering
University of Michigan
{cfwelch,jkummerf,vrncapr,mihalcea}@umich.edu

Abstract

Word embeddings are usually derived from corpora containing text from many individuals, thus leading to general purpose representations rather than individually personalized representations. While personalized embeddings can be useful to improve language model performance and other language processing tasks, they can only be computed for people with a large amount of longitudinal data, which is not the case for new users. We propose a new form of personalized word embeddings that use demographic-specific word representations derived compositionally from full or partial demographic information for a user (i.e., gender, age, location, religion). We show that the resulting demographic-aware word representations outperform generic word representations on two tasks for English: language modeling and word associations. We further explore the trade-off between the number of available attributes and their relative effectiveness and discuss the ethical implications of using them.

1 Introduction

Word embeddings are used in many natural language processing tasks as a way of representing language. Embeddings can be efficiently trained on large corpora using methods like word2vec or GloVe (Mikolov et al., 2013; Pennington et al., 2014), which learn one vector per word. These embeddings capture syntactic and semantic properties of the language of all individuals who contributed to the corpus. However, they are unable to account for user-specific word preferences (e.g., using the same word in different ways across different contexts), particularly for individuals whose usage deviates from the majority. These individual preferences are reflected in the word's nearest neighbors. As an example, Table 1 shows the way two users use the word "health" and the word's five nearest neighbors in their respective personalized embedding spaces. The word is used in similar contexts, where contextual embeddings may give similar representations, but it has different salient meanings in the personal space of each user. User A tends to talk more about preventative care and insurance, while user B tends to talk about people's experiences affecting their mental health.

User	Example Use	Nearest Neighbors
A	doctors think this is bad for her **health** ...	preventative, insurance, reform, medical, education
B	it is usually bad for your **health** ...	professional, mental, conduct, experiences, online
All	N/A	medical, preventative, insurance, safety, healthcare

Table 1: Nearest neighbors of the word "health" for two different users in personalized and a generic embedding space.

The typical approach in natural language processing (NLP) is to use one-size-fits-all language representations, which do not account for variation between people. This may not matter for people whose language style is well represented in the data, but could lead to worse support for others (Pavalanathan and Eisenstein, 2015; May et al., 2019; Kurita et al., 2019). While the way we produce language is not a direct consequence of our demographics or any other grouping, it is possible that by tailoring word embeddings to a group we can more effectively model and support the way they use language.

Additionally, personalized embeddings can be useful for applications such as predictive typing systems that auto-complete sentences by providing suggestions to users, or dialog systems that follow the style of certain individuals or professionals (e.g., counselors, advisors). They can also be used to match the communication style of a user, which would signal cooperation from a dialog agent.

In this paper, we propose compositional demographic word embeddings as a way of building personalized word embeddings by leveraging data from users sharing the same demographic attributes

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4076–4089,
November 16–20, 2020.

(e.g., age: *young*, location: *Europe*). Our proposed method has the benefits of personalized word representations, while at the same time being applicable to users with limited or no data.

To implement and evaluate our proposed method, we build a large corpus of Reddit posts from 61,981 users for whom we extract self-reported values of up to four demographic properties: age, location, gender, and religion. We examine differences in word usage and association captured by the demographics we extracted and discuss the limitations and ethical considerations of using or drawing conclusions from this method. We explore the value of compositional demographic word embeddings on two English NLP tasks: language modeling and word associations. In both cases, we show that our proposed embeddings improve performance over generic word representations.

2 Related Work

Embedding Bias. Recent work on embeddings has revealed and attempted to remove racial, gender, religious, and other biases (Manzini et al., 2019; Bolukbasi et al., 2016). The bias in our corpora and embeddings have a societal impact and risks exclusion and demographic misrepresentation (Hovy and Spruit, 2016). This means that users of certain regions, ages, or genders may find NLP technologies more difficult to use. For instance, when using standard corpora for POS tagging, Hovy and Søgaard (2015) found that models perform significantly lower on younger people and ethnic minorities. Similarly, results on text-based geotagging show best results for men over 40 (Pavalanathan and Eisenstein, 2015).

Similar results are starting to be found in embeddings produced by contextual embedding methods (May et al., 2019; Kurita et al., 2019). We focus on non-contextual embedding methods because of their computational efficiency, which is crucial if many separate representations are being learned. Additionally, there may not be a large amount of available data for underrepresented groups and these contextualized models require billions of tokens for training. Recent work has also shown that static embeddings are competitive with contextualized ones in some settings (Arora et al., 2020).

Personalization. The closest work is Garimella et al. (2017)'s exploration of demographic-specific word embedding spaces. They trained word embeddings for male and female speakers who live in the USA and India using skip-gram architectures that learn a separate word matrix for each demographic group (e.g., male speakers from the USA).

Another line of work used discrete (Hovy, 2015) or continuous values (Lynn et al., 2017) to learn speaker embeddings: a single vector for each user. The speaker embedding is appended to the input of the recurrent or output layer, and trained simultaneously with the rest of the model. This idea applies to any contextual information type and was introduced as a way to condition language models on topics learned by topic modeling (Mikolov and Zweig, 2012). It has since been used as a way of representing users in tasks such as task-oriented and open-domain dialog (Wen et al., 2013; Li et al., 2016), information retrieval based on book preferences (Amer et al., 2016), query auto-completion (Jaech and Ostendorf, 2018), authorship attribution (Ebrahimi and Dou, 2016), sarcasm detection (Kolchinski and Potts, 2018), sentiment analysis (Zeng et al., 2017), and cold-start language modeling Huang et al. (2016). Finally, a recent study by King and Cook (2020) compared how to improve a language model with user-specific data using priming and interpolation, depending on the amount of data available, learning a new model for each user.

More generally, personalization has been extensively applied to marketing, webpage layout, product and news recommendation, query completion, and dialog (Eirinaki and Vazirgiannis, 2003; Das et al., 2007). Welch et al. (2019a,b) explored predicting response time, common messages, and speaker relationships from personal conversation data. Zhang et al. (2018) conditioned dialog systems on artificially constructed personas and Madotto et al. (2019) used meta-learning to improve this process. Goal-oriented dialog has used demographics (i.e. age, gender) to condition system response generation, showing that this relatively coarse grained personalization improves system performance (Joshi et al., 2017).

Social Media. We use social media data with demographic attributes inferred from user posts. Prior work has explored extraction or prediction of attributes such as age, gender, region, and political orientation (Rao et al., 2010; Rangel et al., 2013). Work on analyzing the demographics of social media users also includes race/ethnicity, income level, urbanity, emotional stability, personality traits (McCrae and Costa Jr, 1997), and life satisfaction (Duggan and Brenner, 2013; Correa et al., 2010).

One particularly relevant study by Gjurković and Šnajder (2018) presented a corpus of Reddit users with personality information as well as some demographics for a subset of users. Unlike our approach, which is based on text content, they extract information from Reddit flairs, a type of user tag. Out of their set of 10,295 users, 2,253 are also in our set of users (22% of theirs, 0.5% of ours) that have one or more demographic labels, confirming the speculation in their paper that extracting demographics from text is a complementary approach that captures more information about users in their data. Other work has used Reddit posts to identify users who were diagnosed with depression (Yates et al., 2017) and to construct personas for personalized dialog agents (Mazaré et al., 2018).

Language Models. To evaluate embeddings, we consider language modeling, a task that has long been used for speech recognition and translation, and more recently been widely used for model pretraining. A range of models have been developed, with progressively larger models trained on more data (e.g., Dai et al., 2019). Variations of the LSTM have consistently achieved state-of-the-art performance without massive compute resources (Merity et al., 2018a; Melis et al., 2019; Merity, 2019; Li et al., 2020). We use the AWD-LSTM (Merity et al., 2018b) in our experiments, as it achieves very strong performance, has a well-studied codebase, and can be trained on a single GPU in a day.

3 Dataset

Our first contribution is a new dataset. We use English Reddit comments as they are publicly available, are written by many users, and span multiple years.[1] We extract demographic properties of users from self-identification in their text.

3.1 Finding Demographic Information

Reddit users do not have profiles with personal information fields that we could scrape. Instead, we developed methods to extract demographic information from the content of user posts.

In order to determine what kind of information we can extract about users, we performed a preliminary analysis. We manually labeled a random sample of 132 statements that users made about themselves. We specifically searched for statements starting with phrases such as ‘i am a’ or ‘i am an’. In our sample: 36% clearly stated the user’s age, religion, gender, occupation, or location; 34% contained descriptive phrases that were difficult to categorize like ‘i am a big guy’ or ‘i am a lazy person’; and 30% mentioned attributes such as sexual orientation, dietary restrictions, political affiliations, or hobbies that were rare overall.

Based on our analysis, we decided to focus on age, religion, gender, occupation, and location as the main attributes.[2] These were extracted as follows:

Age. We extracted the user’s age using a regular expression.[3] During this process, we found users that were matched to different ages due to the corpus covering user activity across several years. In those cases, we removed users whose age difference was greater than the time span of our corpus. Additionally, we excluded users who said they were less than 13 years of age, as this violates the Reddit terms of service. We decided to split the age into two groups, young and old at a threshold of 30, as this split was used in previous work (Rao et al., 2010), and it gave a reasonable split for our data and the data we used for testing word associations (Garimella et al., 2017).

Gender. Gender was extracted by searching for statements referring to oneself as a ‘boy’, ‘man’, ‘male’, ‘guy’, for male, or ‘girl’, ‘woman’, ‘female’, ‘gal’, for female. Manual inspection revealed some users indicated that they were of both genders. In that case, if one gender occurred less than one fifth of the time we took the majority of the reported gender, otherwise we removed the user from our dataset. We acknowledge that this approach excludes transgender, gender fluid, and a range of non-binary people, and may misgender people as well (see § 7 for further discussion of these issues).

Location. To obtain location information, we searched for phrases such as ‘i am from’ and ‘i live in.’ Next, whenever either the next token is (1) tagged as a location by a named entity recognizer (Manning et al., 2014), (2) a noun, or (3) the word ‘the’, we select all subsequent tokens in the phrase as the user location. Manual inspection of matches showed that Reddit users are not consistent in the

[2] We attempted to extract occupations, but found they were difficult to identify and group because there are many different occupations, many ways of stating one’s occupation, and many ways to describe the same occupation.

[3] `.*?(i am|i\’m) (\\d+) (years|yrs|yr) old[ˆe].*?`

granularity of reported location. Statements included cities, state, province, country, continent, or geographical region. Based on the number of users per country, we decided to merge some countries into region labels while leaving others separate. This resulted in the following set of regions: USA, Asia, Oceania, UK, Europe, Canada. We further matched location statements to lexicons to resolve the location to one of these regions, removing common relative location words.[4] For larger population regions of Canada and the USA, we match statements using state abbreviations, province names, highest population cities, and in the USA we also match the capital cities. For other regions we only match the highest population cities as there were too many cases to cover.

Religion. To extract religion, we searched for the five largest global religious populations,[5] counting 'secular', 'atheist', and 'agnostic' as one non-religious group. We used a regular expression[6] and filtered users who stated beliefs in more than one of these five groups.

3.2 Post-processing

The resulting dataset was further filtered to remove known bots.[7] For the demographic data we consider two subsets. First, the set of users for which all four attributes are known (4Dem). With this set we perform ablation experiments on the number of known attributes in a controlled manner. However, it is important to note that this set may not be representative of most users on Reddit, as it focuses on users willing to divulge a range of demographic attributes. Our second sample addresses this by including users for whom we identify two or more of the demographic attributes (2+Dem). Statistics for these sets are described in Table 2, along with the training, development, and test splits used for the language modeling experiments.

The distribution of demographic values for each of these sets is shown in Figure 1. Looking at the set of all users in our data who have at least two known demographic attributes (2+Dem), we find that 83% of the time location is unknown. Age and religion are the next most frequently missing at 53% and 34% respectively. Gender is more likely to be known than the other attributes: only 10% of users in this subset have an unknown gender. In a manual evaluation of all our extracted attribute labels for the 100 users, we found accuracies of

Set	Users	Posts
All Reddit	13,213,172	1,430,935,783
	2+Dem	
Total	61,627	205,394,970
Training	34,110	50,000
Validation	9,190	10,000
Test	9,143	10,000
	4Dem	
Total	354	3,433,062
Test	354	10,000

Table 2: Statistics for two Reddit sets: with at least two demographic attributes (2+Dem), or all four demographic attributes (4Dem). Training, development, test splits used in the language modeling experiments are also shown. First row shows overall number of posts and users from the entire set of Reddit posts.

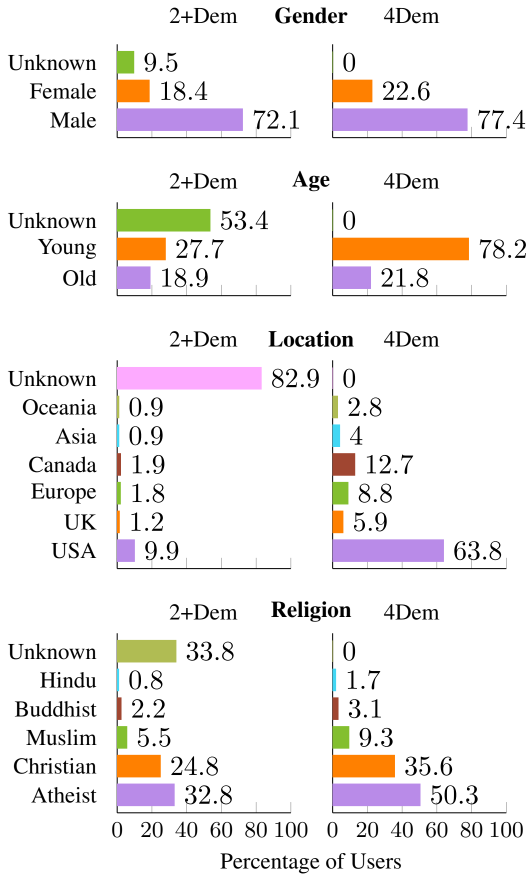

Figure 1: Distribution of the four demographic attributes in our two datasets, showing the set with all demographics known on the right and the random sample from those with at least two known on the left.

Table 3: Examples of words with low overlap in nearest neighbors, showing how meaning can differ across the values of a demographic attribute.

94% for location and gender, 78% for religion, and 96% for age. Additional details of this evaluation are provided in the supplementary material.

4 Generating Compositional Demographic Word Embeddings

We propose two methods for learning compositional demographic embeddings. The first learns a generic embedding for each word and a vector representation of each demographic attribute (including 'unknown'). This is memory efficient, as we need only 19 vectors to cover all of our attributes. In the second method, for each word we learn (a) a generic embedding and (b) a vector for each demographic attribute. This is more expressive, but requires twenty vectors for each word.

4.1 Demographic Attribute Vectors

In this approach we jointly learn a matrix for words and a separate vector for each demographic value. The word matrix $W \in \mathbb{R}^{|V| \times k}$ has a row for each word in the vocabulary and a k-dimensional vector for each embedding. The demographic values can be represented by another matrix $D \in \mathbb{R}^{|C| \times k}$, where C is the set of all demographic values (e.g., male, female, christian, USA). The hidden layer is calculated as $h = W_h^\intercal(W_w + C_g + C_l + C_r + C_a)$ where w represents the one-hot encoding of an input word and g, l, r, a represent the demographic values of the speaker. This is a modified skip-gram architecture (Mikolov et al., 2013) with a hierarchical softmax, which sums five terms so that back-propagation updates the word representation as well as the demographic values.

We use posts from all users to train embeddings for words that occur at least five times across all users. This yields a vocabulary of 503k words. We learn 100-dimensional embeddings with an initial learning rate of 0.025 and a window size of five.

4.2 Demographic Word Matrices

When learning demographic matrices we separately run our skip-gram model for each of the demographic attributes (e.g., gender) and learn a generic word matrix $W_G \in \mathbb{R}^{|V| \times k}$ and a value specific word matrix for each value, v, of the given attribute, A, (e.g., male, female) $W_v \in \mathbb{R}^{|V| \times k}, \forall v \in A_v$. This changes the hidden layer calculation to $h = W_h^\intercal G_w + W_h^\intercal W_{vw}$, with hidden layer weights W_h, and the model then learns a generic word representation, in matrix G, while learning the value specific impact on the meaning of that word.

Differences Across Demographic Embeddings. In order to understand what our embeddings capture, we examine words that have different representations across demographics. We can look at the nearest neighbors of a given query word across the embedding spaces for different demographics. We perform this analysis on both the demographic matrices and vectors, finding less variation in the neighbors when using demographic vectors, making them less interesting. We show examples of words with low overlap in nearest neighbors for demographic matrices in Table 3. These show the differences in word meaning across groups.

5 Language Modeling

We first examine the usefulness of our embeddings by showing that they can help us better model a user's language. We consider two experiments. First, we focus on compositional demographic embeddings and sample 50k posts from our corpus for training the language model and 5k for each of validation and test. Next, we compare with a user-specific model on a sample of our data with text from just 100 users who each have a large amount of data available in our corpus, with an average of 3.2 million tokens per user.

In both experiments, we use the language model developed by Merity et al. (2018b,a). As discussed in § 2, this model was recently state-of-the-art and has been the basis of many variations. We modify it to initialize the word embeddings with the ones we provide and to concatenate multiple embedding vectors as input to the recurrent layers. The rest of the architecture is unaltered. We tried adding rather than concatenating and found no improvement. We chose to concatenate the inputs with the intuition that the network would learn how to combine the information itself.

We explored various hyperparameter configurations on our validation set and found the best results using dropout with the same mask for generic and demographic-specific embeddings, untied weights, and fixed input embeddings. Untying and fixing input embeddings is supported by concurrent work (Welch et al., 2020b). Each model is trained for 50 epochs. We use the version from the epoch that had the best validation set perplexity, a standard metric in language modeling that measures the accuracy of the predicted probability distribution.

5.1 Demographic Perplexity Evaluation

Table 4 shows results for our demographic personalization methods, which are designed to handle new users for whom we have demographics but not much text data. The first method, demographic vectors, performs no better than generic embeddings. This is surprising since prior work has achieved success on a range of tasks with this kind of representation (see § 2). We suspect that for language modeling the variations are too fine-grained to be captured by a single vector. However, demographic matrices do improve significantly over generic embeddings. A model with all demographics improves the most, but we also see improvements when only one demographic value is known.

The LSTM hidden layer size is the same across models, but the change in the input size affects the total number of parameters. To control for this, we ran our baseline model and model initialized with generic words with a larger input size, matching the number of parameters in our best models. As shown in Table 4, this increase in parameters does not improve performance.

Model Type and Input Size	2+Dem	4Dem
Baseline, 100	123.8	124.6
Baseline, 500	125.1	126.1
Generic Words Only, 100	116.0	112.1
Generic Words Only, 500	115.8	112.6
Demographic Vectors, 200	116.7	113.0
Demographic Matrices		
+ Age Only, 200	109.4	110.3
+ Gender Only, 200	109.4	109.9
+ Location Only, 200	109.7	112.9
+ Religion Only, 200	110.9	112.0
+ All Demographics, 500	**107.7**	**109.1**

Table 4: Perplexity on the demographic data. Our demographic-based approach improves performance. The difference between the last row and generic words is significant ($p < 0.00001$ with a permutation test).

		2+Dem		4Dem

	Atheist	106.4	103.2	112.7	109.9
	Muslim	112.7	108.5	109.5	108.4
	Hindu	122.4	115.6	158.1	159.5
	Buddhist	114.1	111.7	116.4	114.1
	Unknown	122.3	109.1	-	-
Gender	Male	113.5	109.2	115.2	112.6
	Female	100.9	97.8	102.7	100.4
	Unknown	122.3	118.5	-	-

Table 5: Perplexity for language models with no demographics (0D) or with all four demographic matrices (4D) with results broken down by demographic values.

5.1.1 Ablation Experiments

Table 4 shows results when using no demographics (top 4 rows), one demographic at a time (rows 6-9) and all four demographics (row 10). Each attribute improves perplexity, with age and gender improving it more than location and religion.

Additionally, we perform a breakdown of the performance of our demographic matrices language model on each of the demographic groups. These results are shown in Table 5. We do see worse performance on some minorities as compared to other groups for the same model, although that is not always the case (gender, for instance, shows better perplexities for female than for male, and Muslim shows lower perplexity than Christianity, which has substantially more data). When we use the demographic word embeddings in our model, we are able to improve performance for all demographic groups, including minorities.

We also find that the performance on the ‘unknown’ group increases in all cases with our largest improvement on ‘unknown’ religion. The unknown is explicitly modeling people in our dataset who have either (1) stated this demographic information with a value that we model but not in a way that our regular expressions identify, (2) stated this demographic information with a value that we do not model, or (3) have not stated this demographic information. In the second case, the effect is that it is useful to know which demographic groups the speaker does not belong to. In the third case, it may be that not sharing this particular piece of information (while sharing other personal information) says more about what the speaker will tend to say.

5.2 Comparison with User Representations

For users with a lot of data, it is possible to train a user-specific model, with embeddings that capture their unique language use. We would expect this to be better than our demographic embeddings, but also only be feasible for users with a lot of data. This experiment compares our demographic approach with a user-specific approach.

We create a model for each user using the sample that has a large amount of data for 100 users (3.2 million tokens each on average) as done in concurrent work (Welch et al., 2020a). We tried two approaches, user vectors and user matrices, which are analogous to our demographic vectors and matrices. The difference is that rather than having a separate vector / matrix for each demographic we have a separate vector / matrix for each user. Our split sizes for language model experiments are the same as the demographic experiments.

Results. Table 6 shows results for generic embeddings, user vectors, user matrices, and demographic matrices. We find that user vectors, as have been used widely in previous work (Kolchinski and Potts, 2018; Li et al., 2016), do not improve performance. Both our demographic and user matrices improve performance over generic embeddings with comparable performance. While we chose 100 users with a lot of data, they had less data than the amount used to train each demographic specific model. The relationship between the amount of data, its similarity to a user’s writing, and the effect on performance is an interesting open question.

Model	PPL
Generic Word Embeddings	63.94
User Vectors	68.98
User Matrices	61.69
Demographic Matrices	61.80

Table 6: Comparing our demographic-based approach with two user-specific approaches. Perplexities are generally lower than previous tables because the threshold for rare words being made UNK was higher.

6 Demographic Word Associations

As a second evaluation, we consider word associations, a core task in NLP that probes the relatedness or similarity between words. Data is collected for the task by presenting a stimulus word (e.g., *cat*) and asking people what other words come to mind (e.g., *dog* or *mouse*). Earlier systems relied on resources such as WordNet to solve the task, but most recent work has used word embeddings.

Data. For our evaluation, we use data from Garimella et al. (2017). They constructed a word association dataset and experimented with learning separate word embedding matrices for different demographic groups. To collect the data, they (1) asked crowd workers to write one word associated with a single word prompt and (2) asked the workers their gender, age, location, occupation, ethnicity, education, and income. Only gender and location information was released, but the authors provided age information upon request.

Evaluation. As in prior work, we consider evaluation metrics defined in terms of: f_w, the number of people who listed word w for a stimulus; f_{max}, the highest f_w across all words chosen for a stimulus; and t, the number of participants given a stimulus. *best* is f_w divided by f_{max}, where w is the word in the embedding space closest to the stimulus word; *ooN* (out-of-N) is $\sum f_w/t$ for the N words in the embedding space closest to the stimulus word; both are averaged over all stimulus words.

We consider two experiments. One directly matches Garimella et al. (2017), testing each demographic group separately. Since our interest is in compositionality, we also introduce a setting where the data is split into eight disjoint sets, one for each combination of the three attributes.

Models. Garimella et al. (2017) proposed two methods, which we merge by taking the best result from either one. We considered only our demographic matrix embeddings as they performed best

	best		oo3		oo10		best		oo3		oo10		best		oo3		oo10

Table 8: Results on the 8 disjoint word association subsets for each combination of attributes. Similarities concatenate three embeddings that are each either generic, or specific to that demographic attribute. Overall, using age and gender in combination gives the best performance, though using all three is better on oo3. † indicates statistically significant improvement (permutation test, $p < 0.001$) over the next best model on the marked metric.

on language modeling. For the experiment with separate demographics, we use the appropriate embeddings. For the experiment with combinations of demographics, we concatenate the embeddings. We also compare to concatenation of generic embeddings learned for each attribute (this performs better than any individual generic embedding).

Results. Table 7 shows results on the single-demographic experiment. We achieve higher performance, but that may come from the change in training dataset.[8,9] Table 8 shows results on the multi-demographic setting. We include only the best pair (age and gender) due to space. We have seen in earlier experiments that location does not perform as well as the other attributes and found the same trend here. Overall, composing demographic-based representations helps, with a combination of all three attributes consistently performing well on the *oo3* metric, while having two helps on the *best* metric. Generic embeddings only score the highest on one subset: Male, India, Young.

7 Limitations and Ethical Considerations

This work uses demographic information to modify language representation. This type of work is encouraged by the numerous arguments outlined in (Perez, 2019), which demonstrate the need for demographic data disaggregation in order to make decisions and build technologies that are equitable for all. We view our work as an initial investigation of differences in language model performance across demographics and how technology can be improved for the identified groups. Our results in Tables 4 and 5 show that using demographic information can enable the development of language tools that improve performance for all groups compared to simply training on all data.

Although we show that some language production aspects are correlated with demographic information, we do not believe the way we speak is a direct and only consequence of one's demographics, neither do we claim that this is the ideal information source for it or that this will necessarily hold for populations sampled significantly differently than in our study. As a consequence, it

---

[8] Their models are trained on 67.6m tokens of blog data, while ours are trained on 1,400m tokens of Reddit data.

[9] We see a larger gain for the US than the IN evaluation. This may be because in our data location is unknown for many users and India is underrepresented (so much so that we aggregate it into all of Asia).

is possible that using demographics in embedding construction could accentuate bias, although this remains to be studied. Those that use our method should account for this possibility.

Our study uses four demographic variables and only covers a subset of the potential values of each demographic. For instance, we do not use the same granularity across locations, include all locations, religions, or gender identities. We simplify age into ranges. The groups ‘secular’, ‘agnostic’, and ‘atheist’ are grouped into one broader group. Our sample is further biased by the choice of platform as each platform contains text from different populations. Users in our sample are predominately young, male, atheist, and live in the United States.

When using gender as a study variable, we followed the recommendations of Larson (2017). Our “gender” extraction method does not refer to biological sex. After running gender extraction patterns, users are assigned to either the ‘male’, ‘female’, or ‘unknown’ label, meaning that on the basis of these phrases one’s gender identity is assumed to be binary or to be a gender identity unknown to our model, which may include those who are transgender, non-binary, or those who do not wish to disclose their gender. However, we are aware that the use of regular expressions for the extraction of demographic attributes can lead to false positives and false negatives (error rates are provided in the supplemental material) and that there exists a bias in using these strategies, as populations that do not wish to be identified are less likely to explicitly make such statements. For transparency, our released code includes the scripts used to assign demographic labels.

Above we discussed concerns for incorrect demographic assignment when developing models. There are also potential negative consequences when using these models in a deployed system. Our embeddings can only be used when the demographics of a user are known. This may be acceptable if the user voluntarily self-reports their demographics with the understanding that they will alter the predictions they receive. However, if demographics are automatically inferred there is a risk of misattribution, which depending on the application may have negative consequences.

A separate consideration is the environmental impact of this approach. Compared to the standard method, our approach does involve training more models, but the cost of inference is likely only marginally higher. We believe the additional cost in training is worth the benefits to individual users.

Finally, we acknowledge that components of our method could potentially be used for user profiling (Rangel et al., 2013) and/or surveillance of target populations, thus exposing members of underrepresented groups to harms such as discrimination and coercion and threatening intellectual freedom (Richards, 2013). Similarly, the language models could be used to generate text in the style of a target population or at least to estimate the label distribution of a given text, which would help obfuscate the identity of the author (Potthast et al., 2018). This obfuscation could help hide an author’s identity in order to avoid surveillance or could be used maliciously to infiltrate communities online. We advocate against the use of our methods for these or other ethically questionable applications.

8 Conclusions

We proposed a novel method of generating word representations by composing demographic-specific word vectors. Through experiments on two core language processing tasks, language modeling and word associations, we show that demographic-aware word representations outperform generic embeddings. We also find that demographic matrices perform much better than demographic vectors. Through several ablation analyses we show that word embeddings that leverage multiple demographic attributes give better performance than those using single attributes.

To support future work that can help model individuals and demographics, our code is available at `http://lit.eecs.umich.edu`. Our data is not available due to licensing restrictions but can be redownloaded and processed with our scripts. We hope this will support work on solutions for NLP applications and resources that can better serve minorities and underrepresented groups.

A Annotation of Demographic Attributes

In order to verify the accuracy of our demographic attribute assignment, we manually annotated a sample of 100 users from the dataset. Our extraction of attributes with regular expressions and rules was meant to have high-precision. It is likely that more attributes marked 'unknown' by our extraction could be filled in upon manual inspection. We evaluate the retrieved attributes for these 100 users by viewing the set of all posts that matched our extraction rules and attempting to annotate age, religion, gender, and location. The annotation instructions were to identify the value of these four attributes based on the annotators interpretation of the text of the posts. Then, for cases where the extracted attribute is not 'unknown', we calculate the percentage of times that they are the same. We get 94% for location and gender, 78% for religion, and 96% for age. It should also be noted that despite the annotators best efforts, it is not possible to know the actual ground truth values.

B Reproducibility Criteria

For each item in the list we have a section below with the relevant information.

B.1 Experimental Results

A clear description of the mathematical setting, algorithm, and/or model. The model we use is described in Merity et al. (2018b). We modify it to support weight freezing and initialization. In Section 2 where they describe the weight-dropped LSTM, we concatenate our vectors for user-specific and demographic representations to x_t.

The embeddings are obtained from the model described in Bamman et al. (2014) for the demographic and user matrices. To obtain demographic vectors, we treat C, from Section 2, as a matrix whose rows represent the demographic attribute of a speaker (e.g. male, female) independent of the word used. The model updates the same way, changing a generic word vector and relevant demographic attribute vectors when backpropagating.

A link to a downloadable source code, with specification of all dependencies, including external libraries

- AWD-LSTM code is available from `https://github.com/salesforce/awd-lstm-lm`.
- Embedding code is available from `https://github.com/dbamman/geoSGLM`.

Code modifications will be available at `http://lit.eecs.umich.edu`. We use PyTorch 1.0.1 with CUDA 10.0.103.

Description of computing infrastructure used Each model is trained on one NVIDIA Tesla V100 GPU.

Average runtime for each approach Our methods take between 260 and 1450 seconds per epoch depending on the approach.

Number of parameters in each model The number of parameters for the model that uses all four demographic attributes has the most parameters at 249,752,492. Our smallest model is the user representation comparison which has 48,066,614.

Corresponding validation performance for each reported test result Validation perplexities are reported for the 2+Dem validation set. Table 5 validation perplexities:

- demographic matrices ppl 62.57
- 500d baseline ppl 127.54
- 100d baseline ppl 124.39
- 100d generic ppl 111.70
- demographic age ppl 109.61
- demographic location ppl 109.93
- demographic gender ppl 109.68
- demographic religion ppl 110.88

Table 6 validation perplexities:

- user vectors ppl 69.59
- user matrices ppl 62.11
- demographic matrices ppl 62.57
- generic ppl 65.44

Explanation of evaluation metrics used, with links to code Perplexity for language models is common and is implemented in Merity's code. The word association metrics for best, oo3, and oo10 are described in Garimella et al. (2017) and we have reimplemented these metrics in order to compare to their results.

B.2 Hyperparameter Search

In our initial experiments on the 2+Dem validation set we chose the highest performing hyperparameters from the following list. One value listed means we used this value as described in Merity's code. Parameters were manually tuned and the best validation perplexity was chosen to use for all experiments.

- embedding dimension: [100, 500] – best 100
- LSTM hidden size (nhid): [550, 1150] – best 1150
- wdrop: 0.0
- dropouti: 0.5
- dropouth: 0.5
- dropoute: 0.1
- embedding composition function: [addition, concatenation] – best concatenation
- tied weights: [true, false] – best false
- frozen pretrained embeddings: [true, false] – best true
- LSTM layers (nlayers): 3
- learning rate: [10, 30] – best 30

We also experimented with embedding dropout masks. We initially had separate masks for the generic and concatenated demographic-specific embeddings but if one is masked and not the other it doesn't mask all information about that word. When we tried embedding dropout with the same mask for each concatenated vector perplexity dropped several points.

The vocabulary size for demographic experiments was 502k, while the experiments for individual users had a vocabulary size of 177k words.

B.3 Datasets

Relevant statistics such as number of examples See section 3 of the paper.

Details of train/validation/test splits See Table 2 for details of the 2+Dem and 4Dem experiments and Section 5.2 for details on the user representation comparison.

Explanation of any data that were excluded, and all pre-processing steps See Section 3.2.

A link to a downloadable version of the data The Reddit data from 2007-2015 is available from `https://www.reddit.com/r/datasets/comments/3bxlg7/i_have_every_publicly_available_reddit_comment/`. Our subset of demographic labeled comments will not be available due to licensing restrictions, but can be reconstructed using our scripts and the source data linked to here. Our code can also be used to label more Reddit data from after this collection was posted.

For new data collected, a complete description of the data collection process, such as instructions to annotators and methods for quality control. See Section 3 for data collection details and the beginning of this supplemental material for details on the annotation process.

Do “Undocumented Workers” == “Illegal Aliens”? Differentiating Denotation and Connotation in Vector Spaces

Albert Webson[1,2], Zhizhong Chen[3], Carsten Eickhoff[1], and Ellie Pavlick[1]

{albert_webson, zhizhong_chen, carsten, ellie_pavlick}@brown.edu
[1]Department of Computer Science, Brown University
[2]Department of Philosophy, Brown University
[3]Department of Physics, Brown University

Abstract

In politics, neologisms are frequently invented for partisan objectives. For example, “undocumented workers” and “illegal aliens” refer to the same group of people (i.e., they have the same denotation), but they carry clearly different connotations. Examples like these have traditionally posed a challenge to reference-based semantic theories and led to increasing acceptance of alternative theories (e.g., Two-Factor Semantics) among philosophers and cognitive scientists. In NLP, however, popular pretrained models encode both denotation and connotation as one entangled representation. In this study, we propose an adversarial neural network that decomposes a pretrained representation as independent denotation and connotation representations. For intrinsic interpretability, we show that words with the same denotation but different connotations (e.g., “immigrants” vs. “aliens”, “estate tax” vs. “death tax”) move closer to each other in denotation space while moving further apart in connotation space. For extrinsic application, we train an information retrieval system with our disentangled representations and show that the denotation vectors improve the viewpoint diversity of document rankings.

1 Introduction

Language carries information through both denotation and connotation. For example, a reporter writing an article about the leftmost wing of the Democratic party can choose to refer to the group as “progressives” or as “radicals”. The word choice does not change the individuals referred to, but it does communicate significantly different sentiments about the policy positions discussed. This type of linguistic nuance presents a significant challenge for natural language processing systems, most of which fundamentally assume words to have similar meanings if they are surrounded in similar word contexts. Such assumption risks confusing differences in connotation for differences in denotation or vice versa. For example, using a common skip-gram model (Mikolov et al., 2013) trained on a news corpus (described in §3.2), Figure 1 shows nearest neighbors of “government-run healthcare” and “economic stimulus”. The resulting t-SNE clusters are influenced as much by policy denotation (shapes) as they are by partisan connotation (colors[1]). Using these entangled representations in applications such as information retrieval could have pernicious consequences such as reinforcing ideological echo chambers and political polarization. For example, a right-leaning query like “taxpayer-funded healthcare” could make one equally (if not more) likely to see articles about “totalitarian” and “horror stories” than about “affordable healthcare”.

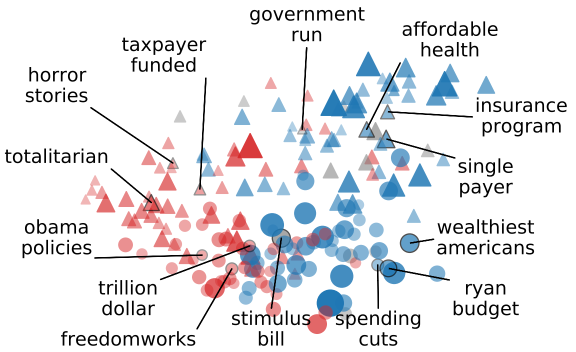

Figure 1: Nearest neighbors of government-run healthcare (triangles) and economic stimulus (circles). Note that words cluster as strongly by policy denotation (shapes) as by partisan connotation (colors); namely, pretrained representations conflate denotation with connotation. Plotted by t-SNE with perplexity = 10.

To address this, we propose classifier probes that

---

[1] Throughout this paper, blue reflects partisan leaning toward the Democratic Party and red reflects partisan leaning toward the Republican Party in the United States.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4090–4105,
November 16–20, 2020. ©2020 Association for Computational Linguistics

measure denotation and connotation information in a given pretrained representation, and we arrange the probe losses in an adversarial setup in order to decompose the entangled pretrained meaning into distinct denotation and connotation representations (§4). We evaluate our model intrinsically and show that the decomposed representations effectively disentangle these two dimensions of semantics (§5). We then apply the decomposed vectors to an information retrieval task and demonstrate that our method improves the viewpoint diversity of the retrieved documents (§6). All data, code, preprocessing procedures, and hyperparameters are included in the appendix and our GitHub repository.[2]

2 Philosophical Motivation

Consider the following two sentences: "Undocumented workers are undocumented workers" vs. "Undocumented workers are illegal aliens". Frege (1892) famously used sentence pairs like these, which have the same truth conditions but clearly different meanings, in order to argue that meaning is composed of two components: "reference", which is some set of entities or state of affairs, and "sense", which accounts for how the reference is presented, encompassing a large range of aspects such as speaker belief and social convention.

In contemporary philosophy of language, the sense and reference argument has evolved into debates of semantic externalism vs. internalism and referential vs. conceptual role semantics. Externalists and referentialists[3] continue the truth-conditional tradition and emphasize meaning as some entity to which one is causally linked, invariant of one's psychological encoding of the referent (Putnam, 1975; Kripke, 1972). On the other hand, conceptual role semanticists emphasize meaning as what inferences one can draw from a lexical concept, deemphasizing the exact entities which the concept includes (Greenberg and Harman, 2005). Naturally, a popular position takes the Cartesian product of both schools of meaning (Block, 1986; Carey, 2009). This view is known as Two-Factor Semantics, and it forms the inspiration for our work. To avoid confusion with definitions from existing literature, we use the terms "denotation" and "connotation" rather than "reference" and "concept" when discussing our models in this paper.

3 Data

We assume that it is possible to disentangle the two factors of semantics by grounding language to different components of the non-linguistic context. In particular, our approach assumes access to a set of training sentences, each of which grounds to a denotation d (which approximates reference) or a connotation c (which approximates conceptual inferences). We require at least one of d or c to be observed, but we do not require both (elaborated in §4.3). In this work, d and c are discrete symbols. However, our model could be extended to settings in which d and c are feature vectors.

While we are interested in learning lexical-level denotation and connotation, we train on sentence- and document-level speaker and reference labels. We argue that this emulates a more realistic form of supervision. For example, we often have metadata about a politician (e.g., party and home state) when reading or listening to what they say, and we are able to aggregate this to make lexical-level judgements about denotation and connotation.

We experiment on two corpora: the Congressional Record (CR) and the Partisan News Corpus (PN), which differ in linguistic style, partisanship distribution (Figure 2), and the available labels for grounding denotation and connotation.

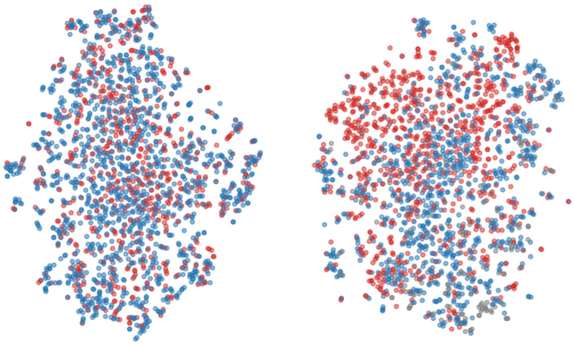

Figure 2: Vector spaces that result from training vanilla word2vec on the Congressional Record (left) and Partisan News (right). We evaluate on both corpora, but note that the Partisan News corpus better exemplifies the problem we target where words cluster strongly according to ideological stance.

3.1 Congressional Record

The Congressional Record (CR) is the official transcript of the floor speeches and debates of

---

[2] https://github.com/awebson/congressional_adversary

[3] Technically, one can be a referentialist while also being a semantic internalist. See Gasparri and Marconi (2019) for a nuanced overview as well as related theories in linguistics and cognitive science.

Name	Corpus	Vocab.	Num. Sent.	Denotation Grounding	Connotation Grounding
CR BILL	Congr. Record	21,170	381,847	legislation title (1,029-class)	speaker party (2-class)
CR TOPIC	Congr. Record	21,170	381,847	policy topic (41-class)	speaker party (2-class)
CR PROXY	Congr. Record	111,215	5,686,864	none (LM proxy)	speaker party (2-class)
PN PROXY	Partisan News	138,439	3,209,933	none (LM proxy)	publisher partisan leaning (3-class)

Table 1: Summary of model variants experimented.

the United States Congress dating back to 1873. Gentzkow et al. (2019) digitized and identified approximately 70% of these speeches with a unique speaker, where each speaker is labeled with their gender, party, chamber, state, and district. To constrain the political and linguistic change over time, we use a subset of the corpus from 1981 to 2011.[4]

In order to assign labels that can be used as proxies of denotation, we weakly label each sentence with both its legislative topic and the specific bill being debated.[5] To do this, we collected a list of congressional bills from the U.S. Government Publishing Office.[6] For our purposes, this data provides the congressional session, policy topic, and an informal short title for each bill. We perform a regular expression search for each bill's short title among the speeches in its corresponding congressional session. For bills that are mentioned at least 3 times, we assume that the speech in which the bill was mentioned as well as 3 subsequent speeches are referring to that bill, and we label each speech with the title and the policy topic of that bill. Speeches that are not labeled by this process are discarded. Additional details and examples are given in Appendix D.

3.2 Partisan News Corpus

Hyperpartisan News is a set of web articles collected for a 2019 SemEval Task (Kiesel et al., 2019). It consists of articles scraped from the political sections of 383 news outlets in English. Each article is associated with a publisher which, in turn, has been manually labeled with a partisan leaning on a five-point scale: "left, center-left, center, center-right, right". Upon manual inspection, we find that the distinctions between right vs. center-right and left vs. center-left are prone to annotation artifacts. Therefore, we collapse these labels into a three-point scale, and we refer to this 3-class corpus as the Partisan News (PN) corpus throughout. No denotation label is available for this corpus.

4 Model

Section 4.1 describes our model architecture. Sections 4.2 and 4.3 then describe specific instantiations that we use in our experiments. These variants are summarized in Table 1.

4.1 Overall Architecture

Let $V_{\text{deno}}, V_{\text{conno}}, V_{\text{pretrained}}$ be the vector spaces of denotation, connotation, and pretrained spaces respectively. Our model consists of two adversarial decomposers:

$$D : V_{\text{pretrained}} \to V_{\text{deno}}$$
$$C : V_{\text{pretrained}} \to V_{\text{conno}}$$

The goal is to train D to *preserve* as much denotation information as possible while *removing* as much connotation information as possible from the pretrained representation. Symmetrically, C will preserve as much *connotation* as possible while removing as much *denotation* as possible from the pretrained representation.

For clarity, let us focus on D for now. To measure how much denotation or connotation structure is encoded in V_{deno}, we use two classifiers probes trained to predict the denotation label d or connotation label c, which yield two cross-entropy losses $\ell_{\text{deno. probe}}$ and $\ell_{\text{cono. probe}}$ respectively. In order to encourage the decomposer D to preserve denotation and remove connotation, we define its loss function as

$$L_D = \sigma(\ell_{\text{deno. probe}}) + \sigma(\ell_{\text{conno. adversary}})$$

where σ is the sigmoid function and

$$\ell_{\text{conno. adversary}} = \text{KL Div}\,(\text{conno. probe predicted dist.}, \text{uniform dist.})$$

---

[4] 2011 is the latest session available for the Bound Edition of CR; 1981 is chosen because the Reagan Administration marks the last party realignment and thus we can expect connotation signals to remain reasonably consistent over this period.

[5] We also experimented with collecting more precise reference labels using the entity linkers of both Google Cloud and Facebook Research on a variety of corpora. However, the results of entity linking were too poor to justify pursuing this direction further. We would love to see future works that devise creative ways to include better denotation grounding.

[6] https://www.govinfo.gov/bulkdata/BILLSTATUS

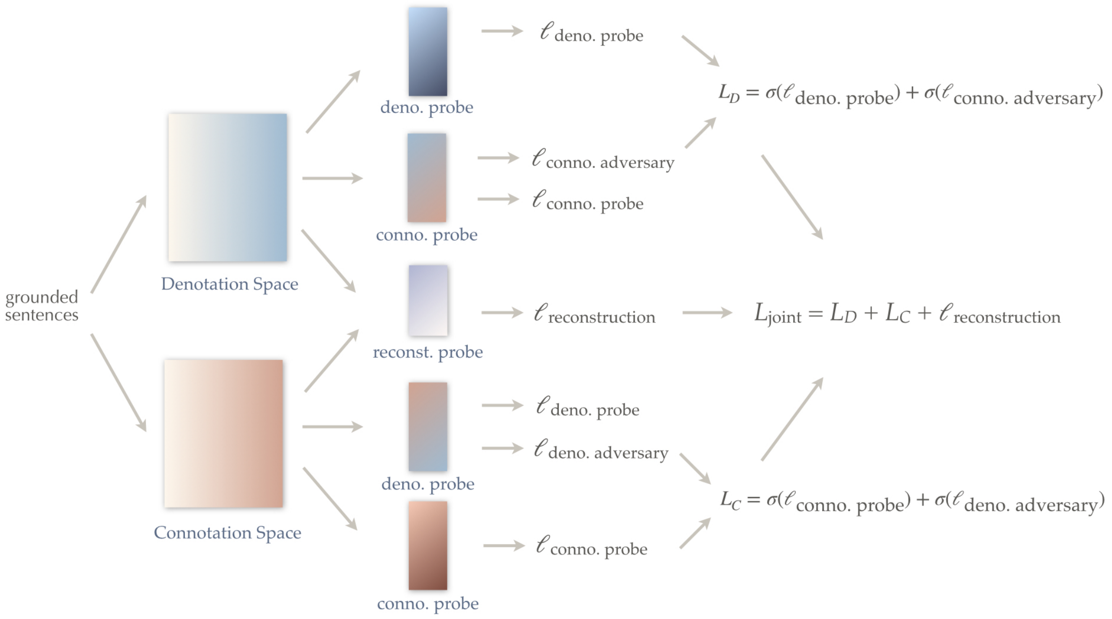

Figure 3: Overall model and composition of losses

The adversarial loss $\ell_{\text{conno. adversary}}$ rewards D to remove connotation structure such that the probe prediction is random. Meanwhile, the probes themselves are still only gradient updated with the usual cross-entropy losses—extracting and measuring as much denotation or connotation information as possible—independent of the decomposer D.

As shown in Figure 3, C is set up symmetrically, so it is trained with the usual classification loss from its connotation probe and a KL divergence adversarial loss from its denotation probe.

Finally, we impose a reconstruction probe R with the loss function:

$$\ell_{\text{recon.}} = 1 - \cos\text{sim}(R(v_{\text{deno}}, v_{\text{conno}}), v_{\text{pretrained}})$$

which enforces that the combination of denotation and connotation subspaces preserves all the semantic meaning of the original pretrained space, as opposed to merely encoding predictive features that maximize probe accuracies. (We verified in ablation experiments that this is in fact what happens without R.) Assembling everything together, the decomposers D and C are jointly trained with $L_{\text{Joint}} = L_D + L_C + \ell_{\text{recon.}}$.

In principle, D and C can be a variety of sentence encoders. In this work, we implement them as simple mean bags of static embedding for two reasons: First, it is difficult to interpret contextualized embedding for an individual word (especially for the type of analysis we present in §5). Second, many of the interesting heavily connotative expressions consist of multiple words (e.g., “socialized medicine”, “universal healthcare”) and compositionality is still far from being solved. Therefore, we conjoin multiword expressions with underscores so that we can model them in the same way as atomic words.[7]

4.2 Connotation Probes

We exploit the fact that much of the debate in American politics today is (sadly) reducible to partisan division (Lee, 2009; Klein, 2020), thus it is safe to define the connotation label of every document to be simply the partisanship of the speaker. Of course, connotation in the general domain can encompass much more than liberals vs. conservatives, and in future work, we hope to extend this to multifaceted connotations that are more true to the semantic theories as discussed in §2. For now, in CR, connotation is the speaker’s party, and in PN, connotation is the partisan leaning of the publisher.

Again, in principle, the probes can be a variety of neural modules. In this work, we implement the connotation probes as 4-layer MLPs. We experimented with the more popular 1-layer MLP and 1-linear-layer probes. However, when the probes are shallow, the model converges before most of the information that should be removed is in fact removed. For example, when we use a 4-layer MLP

---

[7] Appendix B documents this preprocessing step in detail. Throughout this paper, “words” refers to both individual words and underscored short phrases.

probe on a decomposed representation trained with a 1-layer probe, the 4-layer probe accuracies are just as good as if the representation has not been decomposed at all. That is, our experiments suggest that the probes have to be sufficiently complex in order to truly measure what denotation/connotation structure is removed or preserved in a decomposed representation.

4.3 Denotation Probes

For the CR corpus, we experimented with two types of denotation labels: The specific piece of legislation under discussion and the general policy topic under discussion. In CR BILL, the label is one of the 1,029 short titles of bills. In CR TOPIC, the label is one of 41 policy topics. Both types of labels are annotated as described in §3.1. For the same reason as discussed in the previous paragraph, we implement the denotation probes as 4-layer MLPs.

Additionally, as mentioned in Footnote 5, precise denotation labels are difficult to collect, so we also experimented with more realistic settings (CR PROXY and PN PROXY) which do not use any denotation labels. In this case, we return to the theories discussed in §2 and note that, because semantic meaning can be partitioned into two components, we may assume pretrained representations encode the overall meaning and any aspects of meaning that are not explained by our connotation labels must belong to denotation.[8] Thus, we may continue to use the pretraining objective (in this implementation, skip-gram-style context word prediction) as a proxy probe for denotation information and rely on the adversarial connotation probe to remove connotation structure in the denotation space.

5 Intrinsic Evaluation

We confirm that our decomposed denotation and connotation spaces reflect their intended purposes by measuring their structures with homogeneity metrics (§5.1) on three sets of evaluation words (§5.2) as well as inspecting their t-SNE clusters.

5.1 Homogeneity Metrics

To quantify how much denotation or connotation structure is encoded in a vector space, we define the homogeneity (h_{deno}, h_{conno}) of a given space to be the average proportion of a query word's top-k nearest neighbors[9] which share the same denotation/connotation label as the query's own denotation/connotation label.[10] In particular, we are interested in comparing the delta of V_{deno} and V_{conno} against $V_{\text{pretrained}}$. For V_{deno}, we hope to see h_{deno} *increase* relative to the pretrained space and see h_{conno} *decrease* relative to the pretrained space. For V_{conno}, we hope to observe movement in the opposite direction.

As motivated in §3, our model is trained with labels at the sentence-level, while homogeneities are evaluated at the word-level. We assign a word's connotation label to simply be the party that uses the word most often. For CR BILL and CR TOPIC, we assign the word-level denotation label as either the bill or the topic that uses the word most often. For the PN corpus, no ground truth denotation label is available, so we cannot directly measure h_{deno}, but we show alternative evaluation in §5.3. Table 3 shows the baseline h_{deno} and h_{conno} scores for embeddings pretrained on each corpus and evaluating over two test sets of words (described in the next section).

5.2 Test Sets

We evaluate on words sampled in three different ways: **Random** is a random sample of 500 words drawn from each corpus' vocabulary that occur at least 100 times in order to filter out web scraping artifacts, e.g., URLs and author bylines. **High Partisan** is a sample of around 300 words from each corpus's vocabulary that occur at least 100 times and have high partisan skew; namely, words that are uttered by a single party more than 70% of the time. This threshold is chosen based on manual inspection, but we have evaluated on other thresholds as well with no significant difference in results. This High Partisan set is then bisected into two disjoint sets as dev and test data for model selection. All word sets sampled at different ratios are included in our released data. Finally, **Luntz-esque** is a small set of manually-vetted pairs of words that are known to have the same denotation but different connotations. Most of them are drawn

---

[8] We acknowledge that this feels a bit backward: Ideally, in a Fregean sense, everything not explained by reference is left over to sense, rather than the converse. However, we are constrained by the available grounding. In a different setting, if we had explicit referential labels but no speaker information, we could use skip-gram as the proxy for connotation instead.

[9] We set $k = 10$, but we found that evaluation results remain robust across different choices of k.

[10] We also ran `sklearn.homogeneity_score` but saw no difference in trends, so we report our homogeneity metric for its simple interpretability.

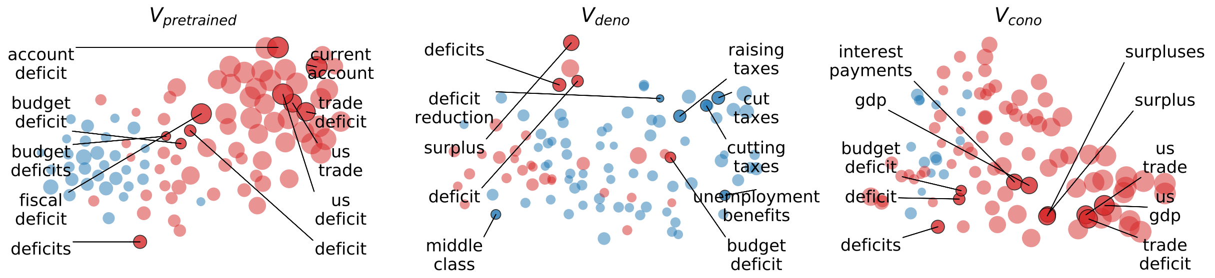

Figure 4: Neighborhood of "deficit" in $V_{\text{pretained}}$, V_{deno}, and V_{conno} of PN PROXY. Arrows point to the top-10 nearest neighbors. Colors reflect partisan leaning, where more opaque dots are more heavily partisan words. Note that in $V_{\text{pretained}}$ and in V_{conno}, the nearest neighbors are all Republican-leaning words, whereas they are balanced in V_{deno}.

		V_{deno} (and Δ with V_{pre})				V_{conno} (and Δ with V_{pre})

from *The New American Lexicon* (Luntz 2006[11]), a famous report from focus group research which explicitly prescribes word choices that are empirically favorable to the Republican party line.

5.3 Results

Overall, we see that our V_{deno} and V_{conno} spaces demonstrate the desired shift in homogeneities and structures, which is intuitively illustrated by Figure 4. Quantitatively, Table 2 enumerates the homogeneity scores of both decomposed spaces as well as their directions of change relative to the pretrained space. For V_{deno}, we see that denotation homogeneity h_{deno} consistently increases and connotation homogeneity h_{conno} consistently decreases as desired. Conversely, for V_{conno}, we see h_{conno} increases and h_{deno} decreases as desired. Further, we see that the magnitude of change is greater across the board for the highly partisan words than for random words, which is expected as the highly partisan words are usually loaded with more denotation or connotation information that can be manipulated. The only exception is CR PROXY's V_{deno}, which sees no significant movement in either direction. This is understandable because CR PROXY is not trained with ground truth denotation labels. (We evaluate it with the labels from CR BILL).

As means of closer inspection, we compute the cosine similarities of words in our Luntz-esque analysis set. Because these pairs of words are known to be political euphemisms (e.g. "estate tax" and "death tax", which refer to the same tax policy but imply opposite partisanship), we expect these pairs to become more cosine similar in V_{deno} and less cosine similar in V_{conno}. As shown in Table 4, even without ground truth denotation labels, the V_{deno} of CR PROXY and PN PROXY still preserve the pretrained denotation structure reasonably well. For pairs that do see decrease in V_{deno} similarity, the errors are far smaller relative to their correct

---

reduction in V_{conno} similarity. For example, "political speech" and "campaign spending" experience a small (-0.02) decrease in denotation similarity; in exchange, the model correctly recognizes that the two words have opposite ideologies (-0.81 in connotation similarity) on the issue of whether unlimited campaign donation is shielded by the First Amendment as "political speech".

6 Extrinsic Evaluation

Ultimately, our work aims to be more than just a theoretical exercise, but also to enable greater control over how sensitive NLP systems are to denotation vs. connotation in downstream tasks. To this end, we construct an ad hoc information retrieval task. We compare a system built on top of $V_{\text{pretrained}}$ to systems built on top of V_{deno} and V_{conno} in terms of both the quality of the ranking and the ideological diversity represented among the top results.

6.1 Setup

We focus only on PN PROXY for this evaluation since it best matches the setting where we would expect to apply these techniques in practice: (1) We cannot always assume access to discrete denotation labels. (2) Language in the PN corpus is strongly influenced by ideology (as shown in Figure 2).

To generate a realistic set of queries, we start with 12 seed words from our vocabulary, chosen based on a list of the most important election issues for Democrat and Republican voters according to a recent Gallup Poll[12]. This results in the following list: "economy, healthcare, immigration, women's rights, taxes, wealth, guns, climate change, foreign policy, supreme court, tariffs, special counsel". Then, for each seed word, we take 5 left-leaning seeds to be the 5 nearest neighbors according to $V_{\text{pretrained}}$, filtered to words which occur at least 100 times and for which at least 70% of occurrences appeared in left-leaning articles. We similarly chose 5 right-leaning seeds. We then submit each partisan seed to the Bing Autosuggest API and retrieve 10 suggestions each. We manually filter the list of queries to remove those that do not reflect the intended word sense (e.g., "VA" leading to queries about Virginia rather than the Veterans Administration) and those which are not well matched to our document collection (e.g., queries seeking dictionary definitions, job openings, or specific websites such as Facebook). Our final list contains 410 queries, 216 left-leaning and 194 right-leaning. Table 5 shows several examples, the full list is included in the supplementary material.

Wealth: globalist agenda ○ globalist leaders ○ extreme poverty rates ○ romneys ties to burisma **Women's Rights:** title ix impact ○ safe spaces and snowflakes ○ anti-choice zealots ○ marriage equality court case **Immigration:** illegal immigrants at southern border ○ illegals caught voting 2016 ○ drug policy fbi ○ opioid crisis afghanistan

Table 5: Example right- and left-leaning queries generated using the procedure described.

6.2 Models

We generate a ranked list of documents for each query in a two-step manner: (1) We pre-select the 5,000 most relevant documents according to a tra-

---

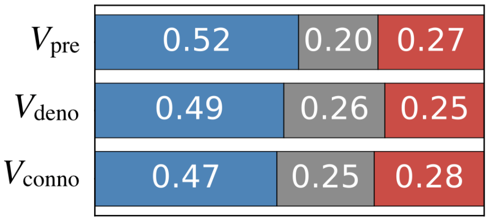
[12] https://news.gallup.com/poll/244367/top-issues-voters-healthcare-economy-immigration.aspx

ditional BM25 model (Robertson et al., 1995) with default parameters. (2) This initial set of documents is then ranked using DRMM (Guo et al., 2016), a neural relevance matching model for adhoc retrieval. We train our retrieval model on the MS MARCO collection (Bajaj et al., 2016) of 550,000 queries and 8.8 million documents from Bing. To highlight the effect of pretrained vs. decomposed word embeddings, we freeze our word embeddings during retrieval model training. While (1) is purely based on tf-idf style statistics and remains static for all compared conditions, (2) is repeated for every proposed word embedding. This results in a ranked list of the top 100 most relevant documents for each query and word embedding.

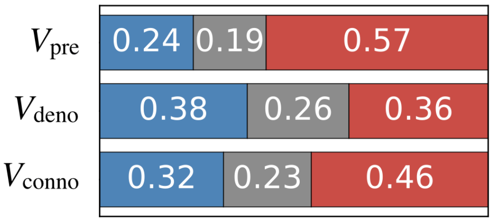
6.3 Results

We compare the results of the DRMM retrieval model using different word embeddings in terms of quality and diversity of viewpoints reflected in the ranked results. To measure diversity, we report the overall distribution of political leanings among the top 100 documents and the rank-weighted α-nDCG (Clarke et al., 2008) diversity score. For α-nDCG, higher values indicate a more diverse list of results whose political leanings are evenly distributed across result list ranks. To measure ranking quality, we take a sample of 10 queries and collect top 10 results returned by each model variant, for a total of 300 query/document pairs. We shuffle the list of pairs to avoid biasing ourselves, and manually label each pair for whether or not the document is relevant to the query. We report Precision@10 estimated based on these 10 queries.

Figure 5 shows the overall party distributions. Table 6 reports the α-nDCG and P@10 metrics. We can see that models which use V_{deno} produce more diverse rankings than do models that use $V_{\text{pertained}}$, with V_{deno} producing an α-nDCG@100 of 0.94 vs. 0.92 for pretrained. This trend is especially apparent in the rankings returned for right-leaning queries: Under the pretrained model, 57% of the documents returned came from right-leaning news sources, whereas under the V_{deno}-based model, the results are nearly perfectly balanced between news sources. However, we do see a drop in precision when using V_{deno}. This is not surprising given the limitations observed in §5. If we had access to ground-truth denotation labels when training V_{deno}, we might expect to see these numbers improve. This is a promising direction for future work.



Left-Leaning Queries



Right-Leaning Queries

Figure 5: Distribution of partisanship of news source for top 100 documents for right-leaning and left-leaning queries. Red = right-leaning news sources; blue = left-leaning; gray = nonpartisan or apolitical.

	α-nDCG		Gini		
	@10	@100	L	R	P@10
$V_{\text{pretrained}}$	0.907	0.915	0.215	0.207	0.78
V_{deno}	0.922	0.944	0.160	0.080	0.37
V_{conno}	0.904	0.914	0.147	0.153	0.64

7 Related Work

Embedding Augmentation. At the lexical level, there is substantial literature that supplements pretrained representations with desired information (Faruqui et al., 2015; Bamman et al., 2014) or improves their interpretability (Murphy et al., 2012; Arora et al., 2018; Lauretig, 2019). However, existing works tend to focus on evaluating the dictionary definitions of words, less so on grounding words to specific real world referents and, to our knowledge, no major attempt yet in interpreting and manipulating the denotation and connotation dimensions of meaning as suggested by the semantic theories discussed in §2. While we do not claim to do full justice to conceptual role semantics either, this paper furnishes a first attempt at implementing a school of semantics introduced by philosophers of language and increasingly popular among cognitive scientists.

Style Transfer. At the sentence level, adversarial setups similar to ours have been previously explored for differentiating style and content. For example, Romanov et al. (2019); Yamshchikov et al. (2019); John et al. (2019) converted informal English to formal English and Yelp reviews from positive to negative sentiment. The motivation for such models is primarily natural language generation and the personalization thereof (Li et al., 2016). Additionally, our framing in terms of Frege's sense and reference adds clarity to the sometimes ill-defined problems explored in style transfer (e.g., treating sentiment as "style"). For example, "she is an undocumented immigrant" and "she is an illegal alien" have the same truth conditions but different connotations, whereas "the cafe is great" and "the cafe is terrible" have different truth conditions.

Modeling Political Language. There is a wealth of work on computational approaches for modeling political language (Glavaš et al., 2019). Within NLP, such efforts tend to focus more on describing how language differs between political subgroups, rather than recognizing similarities in denotation across ideological stances, which is the primary goal of our work. For example, Preoţiuc-Pietro et al. (2017); Han et al. (2019) attempt to predict a person's political ideology from their social media posts, Sim et al. (2013) detect ideological trends present in political speeches, Fulgoni et al. (2016) predict political leaning of news articles, and Padó et al. (2019) focuses on modeling the network structure of policy debates within society. Also highly related is work analyzing linguistic framing in news (Greene and Resnik, 2009; Choi et al., 2012; Baumer et al., 2015).

Echo Chambers and Search. The dangers of ideological "echo chambers" have received significant attention across NLP, information retrieval, and social science research communities. Dori-Hacohen et al. (2015) discuss the challenges of deploying information retrieval systems in controversial domains, and Puschmann (2019) looks specifically at the effects of search personalization on election-related information. Many approaches have been proposed to improve the diversity of search results, typically by identifying search facets *a priori* and then training a model to optimize for diversity (Tintarev et al., 2018; Tabrizi and Shakery, 2019; Lunardi, 2019). In terms of linguistic analyses, Rashkin et al. (2017) and Potthast et al. (2018) analyze stylistic patterns that distinguish fake news from real news. Duseja and Jhamtani (2019) study linguistic patterns that distinguish whether individuals are within social media echo chambers.

8 Summary

In this paper, we describe the problem of pretrained word embeddings conflating denotation and connotation. We address this issue by introducing an adversarial network that explicitly represents the two properties as two different vector spaces. We confirm that our decomposed spaces encode the desired structure of denotation or connotation by both quantitatively measuring their homogeneity and qualitatively evaluating their clusters and their representation of well-known political euphemisms. Lastly, we show that our decomposed spaces are capable of improving the diversity of document rankings in an information retrieval task.

A Hyperparameters

- All classifier probes are 4-layer MLPs with hidden size 300, ReLU as nonlinearity, and dropout with $p = 0.33$.

- Decomposers D and C are embedding matrices of shape (vocab_size, 300). Recomposer R concatenates denotation and connotation as a 600-dimensional vector and then feed it into a linear layer of size (600, 300).

- The skip-gram loss follows the parameters recommended by Mikolov et al. (2013). Context window radius = 5. Negative samples per true context word = 10. We also subsample frequent words in exactly the same way as the original paper (equation 5) did with their threshold of 10^{-5}.

- We use Adam as our optimizer throughout. Learning rate = 1×10^{-3} for homogeneity and 1×10^{-5} for Luntz-esque models. Other parameters left as PyTorch default.

- We train 30 epochs for large corpora (CR PROXY and PN PROXY). 150 epochs for smaller corpora (CR TOPIC and CR BILL).

- With batch size = 1024, the smaller corpora take about half an hour to train on an RTX 2080 Ti or comparable GPUs. With batch size = 8192, The larger corpora take about 50 hours to train.

- PyTorch version = 1.6. CUDA version = 10.2.

B Preprocessing Procedures for Congressional Record

We use Stanford Stanza (Qi et al., 2020) for tokenization, part-of-speech tag, dependency parsing, and named entity recognition. We replace multiword phrases with an atomic token. We source our phrases of interests from the following three pipelines:

1. Named entity recognizer.
2. Frequency-based collocation. (We experimented with PMI-based collocation, which yielded results that were more prone to artifacts and arbitrary threshold setting.)
3. Bigram and trigram constituents of parse trees that are (a) POS-tagged as noun phrase or verb phrase; (b) contain no stop words as in `nltk.corpus.stop_words`; (c) contain no parliamentary procedural words as in {"yield", "motion", "order", "ordered", "quorum", "roll", "unanimous", "mr.", "madam", "speaker", "chairman", "president", "senator", "gentleman", "colleague", "colleagues"}

Luntz-esque: estate tax, death tax, capitalism, free market, undocumented, illegal aliens, foreign trade, international trade, public option, governmentrun, political speech, campaign spending, cut taxes, trickledown, **Random (CR):** cerro, brownfields, redtape, soon as possible, implicit, sup, habits, granted, personality, luis, internationally, itemize, fidel castro, centralize, restraint, pleadings, amendment before us, child custody protection, cheney, illegal aliens, **Random (PN):** reigniting, hurst, see happen, wandering, wp, conveying, obama obama, global politics, really serious, faggot, permanent normal, syrian observatory, native american, strength among, orbiting, protege, exclaimed, tunis, snopes staff, administration also, **High Partisan (CR):** the usa patriot act, mining, patterns, public safety, gorge, spills, wall street, joliet, bridges, tax code, registrants, freedom of speech, compensatory time, college education, shelter, hunger, oil companies, scourge, somalia, traders, **High Partisan (PN):** mrs. romney, pesticides, zionists, u.s. support, pacific northwest, economics defense, light bulbs, east asian, burton, smog, abdel fattah, banksters, work requirements, greenhouse gases, duggars, nigeria security, bolling, geopolitics, teng, newsom said

Table 7: Sample words from each of our test sets as described in §5.2.

From these sources, we filter vocabulary with minimum frequency = 15 for small corpora, 30 for large corpora. We then replace each phrase in the corpus by their respective tokens joined by an underscore. When words can be replaced by multiple phrases, longer phrases take priority, and then more frequent phrases take second priority.

Finally, we discard sentences with less than 5 words. We truncate sentences more than 20 words.

C Preprocessing Procedures for Partisan News

Kiesel et al. (2019) includes 600k articles for train and 150k articles for validation, each labeled with a 5-way partisanship by their publisher. We only train on their validation set because it is comparable in size with Congressional Record and it requires less data cleaning. We discard duplicate sentences, and the rest of the processing pipeline is the same as the Congressional Record.

As mentioned in the main paper, we find the corpus-given “left” vs. “left-center” and “right” and “right-center” labels are prone to artifacts of particular publishers. For example, many foreign policy related phrases dominate the “right-center” category simply because the publisher *Foreign Affairs* is labeled as “right-center”, but this distinction is unsupported in ground truth. Therefore, we collapse “left-center” and “left” as one class, and we collapse “right-center” and “right” as one class.

D Grounding Bill Titles and Topics

We first filter out bills that are mentioned less than 3 times in its corresponding two-year congressional session. The vast majority of bills are only mentioned one time (when they were introduced) or twice (often a bipartisanship poster-child co-sponsor repeats the spiel.)

After manual inspection, we define three speeches after the bill mentioned speech as context speeches and thus assigned the same denotation label (bill or topic) as the bill mentioned speech. Statistics of bill mentioned for each congressional session is summarized in Table 8. Subsequent tables show examples of bill topics, their frequency, and example bill mentioned speeches.

Session	Bills Scraped	Bill Title RegEx Matches	Bills with $\geqslant 3$ mentions	Speeches with those Bills Mentioned	Num. Sentences
97	1471	539	43	464	20372
98	1633	688	51	665	33242
99	1895	360	45	273	16128
100	2092	440	47	358	18376

Table 10: CR TOPIC

Example Speeches with Bill Mentions
“Auto Stock for Every Taxpayer Act” These companies did all of this when the main company decided that the subsidiary was not consistent with the core business. That is what we should do with General Motors–give taxpayers its shares and get General Motors back in the marketplace where it belongs. This idea is fast. it is simple. and it creates a market for the shares... I ask unanimous consent to have printed in the RECORD newspaper articles supporting the Auto Stock for Every Taxpayer Act.
“Radioactive Import Deterrence Act” Mr. Speaker. the Radioactive Import Deterrence Act is a bipartisan bill that would ban the importation of lowlevel radioactive waste unless the President provides a waiver. Lowlevel radioactive waste is generated by medical facilities. university research labs. and utility companies. This waste is generated all over the United States. but finding permanent disposal sites has proven difficult. Currently. 36 States and the District of Columbia have only one approved site to store all the waste generated by those industries. That site is located in Utah...
“Help Find the Missing Act” I yield myself such time as I may consume. Madam Speaker. the Help Find the Missing Act. or Billys Law. will help families of missing persons find their loved ones by strengthening Federal databases about missing persons and unidentified remains. Every year. tens of thousands of Americans go missing and are never found. In the subcommittee we heard moving testimony from Ms. Janice Smolinski. whose son. Billy. went missing in 2004. While she has not found her son. she has dedicated her life to improving the system for others. including highlighting the need to strengthen and expand access to our missing persons databases. I thank her for her dedication to this worthy cause...
“Emergency Aid to American Survivors of the Haiti Earthquake Act” Madam Speaker. I yield myself such time as I may consume. I rise in support of this Senate bill. S. 2949. As Representative MCDERMOTT described. it will provide assistance to thousands of Americans returning from Haiti following the devastating January 12 earthquake there. Let me reiterate that we are helping American citizens with this legislation. The bill. entitled Emergency Aid to American Survivors of the Haiti Earthquake Act. will ensure that State and local governments and charitable agencies on the ground in Florida...
“Enhanced Oversight of State and Local Economic Recovery Act” Mr. Speaker. I rise to thank my colleagues for favorable consideration of H.R. 2182. the Enhanced Oversight of State and Local Economic Recovery Act. I was pleased to cosponsor this legislation. which was introduced by the chairman of the Oversight and Government Reform Committee. At a hearing of that committee. we learned that dedicated oversight funding for State and local governments could improve oversight of money appropriated through the American Recovery and Reinvestment Act...
“Veterans Dog Training Therapy Act” I yield myself such time as I may consume. Madam Speaker. I rise today in support of H.R. 3885. the Veterans Dog Training Therapy Act. I want to thank the ranking member of the Health Subcommittee. Congressman BROWN from South Carolina. for bringing us this legislation. Madam Speaker. we all recognize how damaging the invisible wounds of war can be. The need for effective treatments for posttraumatic stress disorder and for other conditions. such as depression and substance abuse. is apparent. I think. to all Americans. This act recognizes and meets this need by exploring an innovative and promising new form of treatment. using the training of service dogs as a therapeutic medium...
“Prevent Deceptive Census Look Alike Mailings Act” Mr. Speaker. entering its 23rd decade. the U.S. Census is the longest running national census in the world. Our founders wrote it into the Constitution. because taking a fair count is an essential part of fair government. A comprehensive. accurate Census helps ensure that our common resources are distributed where they are most needed. so that our communities can get the roads. schools. and police protection that they need. Theres nothing partisan about that goal. Unfortunately. some groups have set out to deceive Americans by disguising their own private mailings as Census documents...

Abstract

Text summarization is one of the most challenging and interesting problems in NLP. Although much attention has been paid to summarizing structured text like news reports or encyclopedia articles, summarizing conversations—an essential part of human-human/machine interaction where most important pieces of information are scattered across various utterances of different speakers—remains relatively under-investigated. This work proposes a multi-view sequence-to-sequence model by first extracting conversational structures of unstructured daily chats from different views to represent conversations and then utilizing a multi-view decoder to incorporate different views to generate dialogue summaries. Experiments on a large-scale dialogue summarization corpus demonstrated that our methods significantly outperformed previous state-of-the-art models via both automatic evaluations and human judgment. We also discussed specific challenges that current approaches faced with this task. We have publicly released our code at `https://github.com/GT-SALT/Multi-View-Seq2Seq`.

1 Introduction

We live in an information age where communications between human and human/machine are increasing exponentially in the form of textual dialogues between users and users-agents (Kester, 2004). It is challenging and time-consuming to review all the content before starting any conversations especially when the chatting history becomes very long (Gao et al., 2020). How to process and organize those interaction activities into concise and structured data, i.e. conversation summarization, becomes technically and socially important.

Most existing research efforts on text summarization have been focused on single-speaker documents like news reports (Nallapati et al., 2016; See et al., 2017), scientific publications (Nikolov et al., 2018) or encyclopedia articles (Liu* et al., 2018), where structured text is usually used to elaborate a core idea in the third-person point of view, and the information flow is very clear through paragraphs or sections. Different from these structured documents, conversations are often informal, verbose and repetitive, sprinkled with false-starts, back channeling, reconfirmations, hesitations, speaker interruptions (Sacks et al., 1978) and the salient information is scattered in the whole chat, making current summarization models hard to focus on many informative utterances. Take the conversation in Table 1 as an example, turns, informal words, abbreviations, and emoticons all introduce new forms of challenges to the task of summarization. This calls for the design and development of new methods for dialogue summarization instead of directly applying current document summarization models.

There has been some recent research on conversation summarization such as directly deploying existing document summarization models (Gliwa et al., 2019) and exploring multi-sentence compression (Shang et al., 2018), however, most of them haven't utilized specific conversational structures, which refer to the way utterances are organized in order to make the conversation meaningful, enjoyable and understandable (Sacks et al., 1978), in dialogues – a key factor that differentiates dialogues from structured documents. As a way of using language socially of "doing things with words" together with other persons, the conversation has its own dynamic structures that organize utterances in certain orders to make the conversation meaningful, enjoyable, and understandable (Sacks et al., 1978). Although there are a few exceptions such as utilizing topic segmentation (Liu et al., 2019b; Li et al., 2019), dialogue acts (Goo and Chen, 2018) or key point sequence (Liu et al., 2019a), they either need

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4106–4118,
November 16–20, 2020.

Conversation		**Topic View**	**Stage View**
James:	Hey! I have been thinking about you :)	Greetings	Openings
Hannah:	Oh, that's nice ;)		
James:	What are you up to?	Today's plan	
Hannah:	I'm about to sleep		Intention
James:	I miss u. I was hoping to see you		
Hannah:	Have to get up early for work tomorrow	Plan for tomorrow	Discussion
James:	What about tomorrow?		
Hannah:	To be honest I have plans for tomorrow evening		
James:	Oh ok. What about Sat then?	Plan for Saturday	
Hannah:	Yeah. Sure I am available on Sat		
James:	I'll pick you up at 8?	Pick up time	
Hannah:	Sounds good. See you then.		Conclusion
Summary	James misses Hannah. They agree for James to pick Hannah up on Saturday at 8.		

Table 1: Example conversation from SAMSum (Gliwa et al., 2019) with its topic view and stage view (extracted by our methods), and the human annotated summary.

extensive expert annotations of discourse acts(Goo and Chen, 2018; Liu et al., 2019a), or only encode conversations based on their topics (Liu et al., 2019b), which fails to capture rich conversation structures in dialogues.

Even one single conversation can be viewed from different perspectives, resulting in multiple conversational or discourse patterns. For instance, in Table 1, based on what topics were discussed (**topic view**) (Galley et al., 2003; Liu et al., 2019b; Li et al., 2019), it can be segmented into *greetings*, *today's plan*, *plan for tomorrow*, *plan for Saturday* and *pick up time*; from a conversation progression perspective (**stage view**) (Ritter et al., 2010; Paul, 2012; Althoff et al., 2016), the same dialogue can be categorized into *openings*, *intention*, *discussion*, and *conclusion*. From a coarse perspective (**global view**), conversations can be treated as a whole, or each utterance can serve as one segment (**discrete view**). Models that only utilized a fixed topic view of the conversation (Joty et al., 2010; Liu et al., 2019b) may fail to capture its comprehensive and nuanced conversational structures, and any amount of information loss introduced by the conversation encoder may lead to larger error cascade in the decoding stage. To fill these gaps, we propose to combine those multiple, diverse views of conversations in order to generate more precise summaries.

To sum up, our contributions are: (1) we propose to utilize rich conversational structures, i.e., structured views (topic view and stage view) and the generic views (global view and discrete view) for abstractive conversation summarization. (2) We design a multi-view sequence-to-sequence model that consists of a conversation encoder to encode different views and a multi-view decoder with multi-view attention to generate dialogue summaries. (3) We perform experiments on a large-scale conversation summarization dataset, SAMSum (Gliwa et al., 2019), and demonstrate the effectiveness of our proposed methods. (4) We conduct thorough error analyses and discuss specific challenges that current approaches faced with this task.

2 Related Work

Document Summarization Document summarization has received extensive research attention, especially for abstractive summarization. For instance, Rush et al. (2015) introduced to use sequence-to-sequence models for abstractive text summarization. See et al. (2017) proposed a pointer-generator network to allow copying words from the source text to handle the OOV issue and avoid generating repeated content. Paulus et al. (2018); Chen and Bansal (2018) further utilized reinforcement learning to select the correct content needed by summarization. Large-scale pre-trained language models (Liu and Lapata, 2019; Raffel et al., 2019; Lewis et al., 2019) have also been introduced to further improve the summarization performance. Other line of work explored long-document summarization by utilizing discourse structures in text (Cohan et al., 2018), introducing hierarchical models (Fabbri et al., 2019) or modifying attention mechanisms (Beltagy et al., 2020). There are also recent studies looking at the faithfulness in

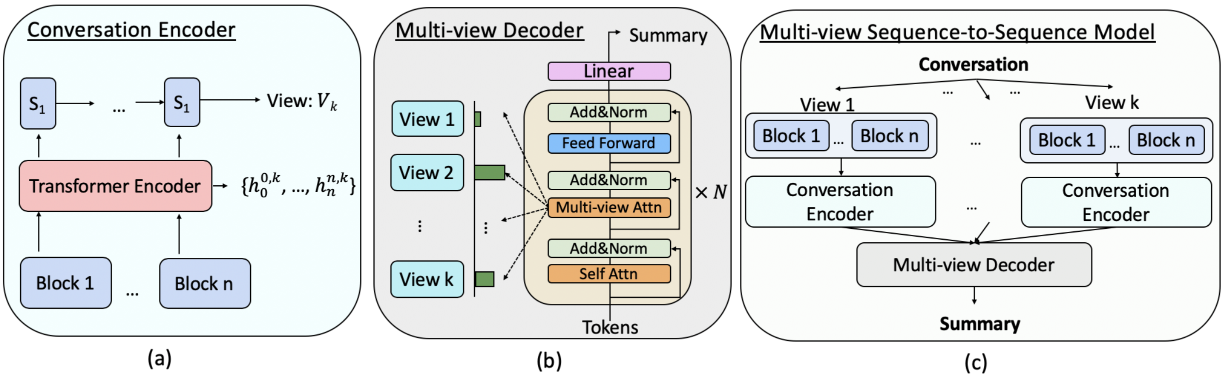

Figure 1: Model architecture. Different views of conversations are first extracted automatically, and then encoded through the conversation encoder (a) and combined in the multi-view decoder to generate summaries (b). In the conversation encoder, each view (consists of blocks) is encoded separately and the block's representations S_i are encoded through LSTM to represent the view. In the multi-view decoder, the model decides attention weights over different views and then attend to each token in different views through the multi-view attention.

document summarization (Cao et al., 2018; Zhu et al., 2020a), in order to enhance the information consistency between summaries and the input.

Dialogue Summarization When it comes to the summarization of dialogues, Shang et al. (2018) proposed a simple multi-sentence compression technique to summarize meetings. Zhao et al. (2019); Zhu et al. (2020b) introduced turn-based hierarchical models that encoded each turn of utterance first and then used the aggregated representation to generate summaries. A few studies have also paid attention to utilizing conversational analysis for generating dialogue summaries, such as leveraging dialogue acts (Goo and Chen, 2018), key point sequence (Liu et al., 2019a) or topics (Liu et al., 2019b; Li et al., 2019). However, they either needed a large amount of human annotation for dialogue acts, key points or visual focus (Goo and Chen, 2018; Liu et al., 2019a; Li et al., 2019), or only utilized topical information in conversations (Li et al., 2019; Liu et al., 2019b).

These prior work also largely ignored diverse conversational structures in dialogues, for instance, reply relations among participants (Mayfield et al., 2012; Zhu et al., 2019), dialogue acts (Ritter et al., 2010; Paul, 2012), and conversation stages (Althoff et al., 2016). Models that only utilized a fixed topic view of the conversation (Galley et al., 2003; Joty et al., 2010) may fail to capture its comprehensive and nuanced conversational structures, and any amount of information loss introduced by the conversation encoder may lead to larger error cascade in the decoding stage. To fill these gaps, we propose to leverage diverse conversational structures including topic segments, conversational stages, dialogue overview, and utterances to design a multi-view model for dialogue summarization.

3 Method

Conversations can be interpreted from different views and every single view enables the model to focus a specific aspect of the conversation. To take advantages of those rich conversation views, we design a Multi-view Sequence-to-Sequence Model (see Figure 1) that firstly extracts different views of conversations (Section 3.1) and then encodes them to generate summaries (Section 3.2).

3.1 Conversation View Extraction

Conversation summarization models may easily stray among all sorts of information across various speakers and utterances especially when conversations become long. Naturally, if informative structures in the form of small blocks can be explicitly extracted from long conversations, models may be able to understand them better in a more organized way. Thus, we first extract different views of structures from conversations.

Topic View Although conversations are often less structured than documents, they are mostly organized around topics in a coarse-grained structure (Honneth et al., 1988). For instance, a telephone chat could possess a pattern of "*greetings* → *invitation* → *party details* → *rejection*" from a topical perspective. Such explicit view and topic flow could help models interpret conversations more precisely and generate summaries that cover important topics. Here we combine the classic topic segment

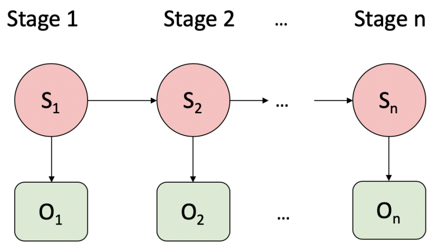

Figure 2: Allowed state transitions for the HMM conversation model. S_i are conversation stages, O_i are sentences' encoded representations. Conversation stages evolve in an increasing order from 1 to n.

Stage	Interpretation	Top Freq Words
1	Openings	hey, hi, good, yeah,going, time
2	Intentions	need, like, think, get, want, really
3	Discussions	will, know, time, come,tomorrow, meet
4	Conclusions	thanks, ok, see, great, thank, sure

Table 2: The top 6 frequent words appearing in each stage and the interpretations for different stages.

algorithm, C99 (Choi, 2000) that segments conversations based on inter-sentence similarities, with recent advanced sentence representations Sentence-BERT (Reimers and Gurevych, 2019), to extract the topic view. Specifically, each utterance u_i in a conversation $\mathbf{C} = \{u_1, u_2, ..., u_m\}$ is first encoded into hidden vectors via Sentence-BERT. Then the conversation $\mathbf{C}$ is divided into blocks $\mathbf{C}_{topic} = \{\mathbf{b}_1, ..., \mathbf{b}_n\}$ through C99, where $\mathbf{b}_i$ is one block that contains several consecutive utterances, such as the topic view described in Table 1.

Stage View As a way of doing things with words socially together with other people, conversation organizes utterances in certain orders to make it meaningful, enjoyable, and understandable. (Sacks et al., 1978; Althoff et al., 2016) For example, counseling conversations are found to follow a common pattern of "*introductions → problem exploration → problem solving → wrap up*" (Althoff et al., 2016). Such conversation stage view provides high-level sketches about the functions or goals of different parts in conversations, which could help models focus on the stages with key information.

We follow Althoff et al. (2016) to extract stages through a Hidden Markov Model (HMM). We impose a fixed ordering on the stages and only allow transitions from the current stage to the next one. The observations in the HMM model are the encoded representations h_i from Sentence-BERT. We set the number of hidden stages as 4. Similar to the topic view extraction, we segment the conversations into blocks $\mathbf{C}_{stage} = \{\mathbf{b}_1, ..., \mathbf{b}_n\}$, where $\mathbf{s}_i$ is one block that contains several consecutive utterances. We interpret the inferred stages qualitatively and further visualize the top 6 frequent words appearing in each stage in Table 2. We found that conversations around daily chats usually start with *openings*, introduce the goals/focus of the conversation followed by discussions of the details, and finally conclude with certain endings. Table 1 shows an example of the stage view.

Global View and Discrete View In addition to the aforementioned two structured views, conversations can also be naturally viewed from a relatively coarse perspective, i.e., a global view that concatenates all utterances into one giant block (Gliwa et al., 2019), and a discrete view that separates each utterance into a distinct block (Liu and Chen, 2019; Gliwa et al., 2019).

3.2 Multi-view Sequence-to-Sequence Model

We extend generic sequence-to-sequence models to encode and combine different conversation views. To better utilize semantic information in recent pre-trained models, we implement our base encoders and decoders with a transformer based pre-trained model, BART (Lewis et al., 2019). Note that our multi-view sequence-to-sequence model is agnostic to BART with which it is initialized.

Conversation Encoder Given a conversation under a specific view k with n blocks: $\mathbf{C}_k = \{\mathbf{b}_1^k, ..., \mathbf{b}_n^k\}$, each token $x_{i,j}^k$ in a block $\mathbf{b}_j^k = \{x_{0,j}^k, x_{1,j}^k, ..., x_{m,j}^k\}$ is first encoded through the conversation encoder $\mathbf{E}$, e.g., BART encoder as shown in Figure 1(a), into hidden representations:

$$\{h_{0,j}^k, h_{1,j}^k, ..., h_{m,j}^k\} = \mathbf{E}(\{x_{0,j}^k, x_{1,j}^k, ..., x_{m,j}^k\}) \tag{1}$$

Note that we add special tokens $x_{0,j}^k$ at the beginning of each block and use these tokens' representations to describe each block, i.e., $S_j^k = h_{0,j}^k$.

To depict different views using hidden vectors, we aggregate the information from all blocks in one conversation through LSTM layers (Hochreiter and Schmidhuber, 1997):

$$S_j^k = \text{LSTM}(h_0^{j,k}, S_{j-1}^k), j \in [1, n] \tag{2}$$

We use the last hidden state S_n^k to represent the current view k, denoted as V_k.

Multi-view Decoder Different views could provide different types of conversational aspects for models to learn and further determine which set of utterances should deserve more attention in order to generate better dialogue summaries. As a result, the ability to strategically combine different views is essential. To this end, we propose a transformer based multi-view decoder to integrate encoded representations from different views and generate summaries as shown in Figure 1(b).

The input to the decoder contains $l-1$ previously generated tokens $t_1, ..., t_{l-1}$. Via our multi-view decoder $\mathbf{D}$, the l-th token is predicted via:

$$\{y_1, ..., y_{l-1}\} = \mathbf{D}(\{t_1, ..., t_{l-1}\}, \mathbf{E}(C)) \quad (3)$$

$$P(\tilde{t}_l | t_{<l}, \mathbf{C}) = \text{Softmax}(W_p y_{l-1}) \quad (4)$$

Here, W_p is a parameter to be learned.

Different from generic transformer decoder, we introduce a multi-view attention layer in each transformer block. Multi-view attention layer first decides the importance α_k of each view V_k through:

$$u_k = \tanh\left(W V_k + b\right) \quad (5)$$

$$\alpha_k = \frac{\exp\left(u_k^\top v\right)}{\sum_i \exp\left(u_i^\top v\right)} \quad (6)$$

where v is a randomly initialized context vector; W and b are parameters. To avoid the attention weights being too similar to each other as views are actually encoded from a similar context, we utilize a sharpening function over α_k with a temperature T: $\tilde{\alpha}_k = \alpha_k^{\frac{1}{T}} / \sum_i \alpha_i^{\frac{1}{T}}$. When $T \to 0$, the attention weights will behave like a one-hot vector.

Then the multi-head attention is performed over conversation tokens $h_{i,j}^k$ from different views k and form A^k separately. The attended results are further combined based on the view-attention weights $\tilde{\alpha}_k$ and continue forward passing:

$$\tilde{A} = \sum_k \tilde{\alpha}_k A^k \quad (7)$$

Training We minimize the cross entropy loss during training:

$$L = -\sum \log P(\tilde{t}_l | t_{<l}, \mathbf{C}) \quad (8)$$

Specifically, we apply the teacher forcing strategy: at training time, the inputs are previous tokens from the ground truth; at test time, the inputs are previous tokens predicted by the decoder.

4 Experiments

4.1 Dataset and Baselines

We evaluate our model on a large-scale dialogue summary dataset SAMSum (Gliwa et al., 2019) that has 14732 dialogues with human-written summaries. The data statistics are shown in Table 3. SAMSum contains messenger-like conversations about daily topics, such as chit-chats, arranging meetings, discussing events, etc. We compare our Multi-view Sequence-to-Sequence Model (Multi-view BART) with several baseline models:

- **Pointer Generator** (See et al., 2017): Following Gliwa et al. (2019), we added separators between each utterance (**discrete view**) and used it as input for pointer generator model.
- **DynamicConv + GPT-2/News** (Wu et al., 2019): We followed Gliwa et al. (2019) to use GPT-2 to initialize token embeddings (Radford et al., 2019). We also added news summarization corpus CNN/DM (Nallapati et al., 2016) as extra training data.
- **Fast Abs RL Enhanced** (Chen and Bansal, 2018) first selects salient sentences and then rewrites them abstractively via sentence-level policy gradient methods. We combined it with the **global view** (Gliwa et al., 2019).
- **BART + Generic views** (Lewis et al., 2019) utilized BART, a denoising autoencoder for pretraining sequence-to-sequence models, together with generic views (**global view** and **discrete view**). We used the BART-large model with its default settings [1].

4.2 Model Settings[2]

We loaded the pre-trained "bert-base-nli-stsb-mean-tokens"[3] for sentence-BERT to get representations for each utterance. For extracting the *topic view* via C99, we set the window size 4 and std coefficient 1. For extracting the *stage view*, we set the number of hidden states 4 in HMM. These hyper-parameters were set with a grid search. The **BART + Structured views** (stage and topic views) used the same set of parameters as **BART + Generic views**. For

Table 4: ROUGE-1, ROUGE-2 and ROUGE-L scores for different models on the test set. Results are averaged over three runs. † meant our methods or utilized views introduced by us.

Multi-View BART, we experimented with different view combinations: (1) the best generic view - global view, was combined with two structured views (stage and topic view) separately; (2) the best two structured views are also combined (topic + stage). The settings for BART encoder/decoder kept identical as baselines. We used a one-layer LSTM for encoding sections. The learning rate for section encoder and multi-view attention was set 3e-3. The temperature T was 0.2. The beam search size during inference for all the models was 4.

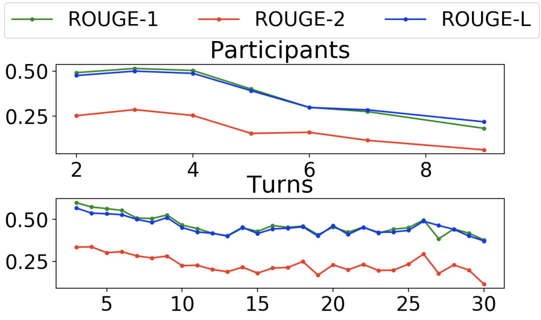

Figure 3: Relations between ROUGE scores and the number of participants/turns in conversations.

4.3 Results

Quantitative Results We evaluated models with the standard metric ROUGE Score (with stemming) (Lin and Och, 2004), and reported ROUGE-1, ROUGE-2 and ROUGE-L[4]. Results on the test set for different models were shown in Table 4. Compared to *Pointer Generator*, using reinforcement learning to select important sentences first (*Fast Abs RL Enhanced*) slightly increased F scores. Adding pre-trained embeddings or extra documents training data to lightweight convolution models, (*DynamicConv + GPT-2/News*) lead to even better ROUGE scores. When using pre-trained transformer based model BART with generic views, all ROUGE scores improved significantly, and *BART + Global* outperformed *BART + Discrete* especially in terms of ROUGE-L F scores. Segmenting conversations into blocks from structured views (stage view and topic view) further boosted the performance, suggesting that our extracted conversation structures help conversational encoders to capture nuanced and informative aspects of dialogs.

We did not see any performance boost when combining the generic global view with either topic or conversational stage views, partially due to that the coarse granularity of global view does not complement structured views well. In contrast, utilizing both structured views (topic view + stage view) further increased ROUGE scores consistently, indicating the effectiveness of synthesizing informative conversation blocks introduced by both views.

We visualized the attention weight distributions

---

[4] Here we followed BART and used `https://github.com/pltrdy/rouge`. Note that different tools may generate different ROUGE scores.

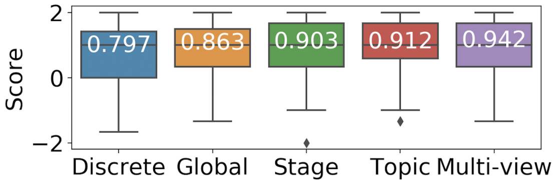

Figure 4: Human evaluation results. The mean score for each model is also shown in the box plot.

for the stage view and topic view in our best model (see Appendix) and found contributions of topic views are slightly more prominent compared to stage views. This also communicated that the two different structured views can complement each other well though sharing the same dialogue content. Note that the gains from *Multi-view BART (Topic + Stage)* are mainly from the precision scores while recall scores are kept comparable, suggesting that our proposed model produced fewer irrelevant tokens while preserving necessary information in its generated summary.

Impact of Participants and Turns We visualized the impact of two essential components in conversations—the number of participants and turns—on rouge scores via our best-performing model *Multi-view BART with topic view + stage view* in Figure 3. As the number of participants/turns increases, ROUGE scores decrease, indicating that the difficulty of conversation summarization increased with more participants involved in conversations and more utterances.

Qualitative/Human Evaluation We also conducted human annotations to evaluate the extracted dialogue summaries, in addition to ROUGE scores. Similar to Gliwa et al. (2019), we asked human annotators on Amazon Mechanical Turk [5] to rate each summary (200 randomly sampled summaries in total) on the scale of [-2, 0, 2], where -2 means that a summary was poor, extracted irrelevant information or did not make sense at all, 2 means it was understandable and gave a concise overview of the text, and 0 refers to that the summary only extracted only a part of relevant information, or made some mistakes. The score for each summary was averaged among three different annotators. The Intra-class Correlation was 0.583, indicating moderate agreement (Koo and Li, 2016).

As shown in Figure 4, consistent with ROUGE scores in Table 4, our multi-view model achieved the highest human annotation scores, significantly higher (via a student t-test) than either generic (discrete or global) view or structured (stage or topic) view, which further proved the effectiveness of combing different views.

5 Model Analysis and Discussion

So far, we have achieved a reasonable summarization performance. To further study why dialog summarization is challenging and how future research could advance this direction, we take a closer look at this dialogue summarization dataset (SAMSum), model generation errors, as well as certain challenges that existing approaches are struggling with.

5.1 Challenges in Dialog Summarization

We conduct a thorough examination of the challenges in conversation summarization and organized them into 7 categories as below:

1. **Informal language use** Many conversations especially in online contexts such as Twitter/Reddit (Jackson and Moulinier, 2007), contain typos, word abbreviations, slang or emoticons/emojis, making it hard to be represented and summarized.

2. **Multiple participants** As shown in Figure 3, conversations with more speakers are harder to be summarized since it may require models to accurately differentiate both language styles and content from different speakers, similar to the multiple characters issue in story summarization (Zhang et al., 2019).

3. **Multiple turns** Similar to long document summarization (Xiao and Carenini, 2019), conversations with many utterances contain more information to be processed, thus harder to be summarized.

4. **(Referral and coreference** People usually refer to each other, mention others' names or use coreference in their messages, which introduces extra difficulty to dialogue summarization, also a challenge also exists in reading comprehension (Chen et al., 2016) and document summarization (Falke et al., 2017).

5. **Repetition and interruption** Information is generally scattered through the whole conversation, and speakers may interrupt each other,

---

[5] `https://www.mturk.com/`

Challenge	%	ROUGE-1/2/L
Generic	24	**0.613 / 0.384 / 0.579**
Informal language	25	0.471 / 0.241 / 0.459
Multiple participants	10	0.473 / 0.243 / 0.461
Multiple turns	23	0.432 / 0.213 / 0.432
Referral & coreference	33	0.445 / 0.206 / 0.430
Repetition & interruption	18	0.423 / 0.180 / 0.415
Negations & rhetorical	20	0.458 / 0.227 / 0.431
Role & language change	30	0.469 / 0.211 / 0.450

Table 5: The breakdown of challenges in dialogue summarization based on our analyses of 100 sampled conversations, and the ROUGE scores per challenge

reconfirm, back channeling or repeat themselves, a unique discourse challenge for dialogue summarization.

6. **Negations and rhetorical questions** As a long-standing problem in NLP field (Li et al., 2016), negation related issues are even more frequent in conversations, as there are more question-answer exchanges between speakers.

7. **Role and language change** Conversations usually involve more than one speaker, and the role of a speaker may shift from a questioner to an answerer, requiring the summarization model to dynamically deal with speaker roles and the associated language (e.g., first personal pronouns)

We randomly sampled 100 examples[6] from our test set and classified them using the above challenge taxonomy. A conversation might have more than one category labels, and if it had none of the aforementioned challenges, we labeled it as **(0) Generic**. Usually, the one marked as *Generic* were shorter or had a simple structure.

Table 5 presents the percentage of each type of challenge and per-category performances from our best model (*Multi-view BART with Topic view + Stage view*). We observed that: (i) *Referral & coreference* (33%) and *Role & language change* (30%) were the two most frequent challenges that dialogue summarization task faced. (2) As expected, *Generic* conversations were relatively easier summarize. (3) Our best model performed relatively worse when it came to *Repetition & interruption*, *Multiple turns*, and *Referral & coreference*, calling for more intelligent summarization methods to tackle those challenges.

Errors	%	ROUGE-1/2/L
Other	24	**0.611 / 0.363 / 0.584**
Missing information	37	0.448 / 0.236 / 0.445
Redundancy	13	0.442 / 0.231 / 0.441
Wrong references	27	0.460 / 0.232 / 0.454
Incorrect reasoning	24	0.447 /0.187 / 0.411
Improper gendered pronouns	6	0.421 / 0.212 / 0.428

Table 6: The common error types of our model compared to golden reference on 100 sampled conversations, and the ROUGE scores per error type.

5.2 Error Analysis[7]

We examined summaries generated by our best-performing model compared to ground-truth summaries, and observed several major error types:

1. **Missing information**: content mentioned in references is missing in generated summaries.
2. **Redundancy**: content occurred in generated summaries was not mentioned by references.
3. **Wrong references**: generated summaries contain information that is not faithful to the original dialogue, and associate one's actions/locations with a wrong speaker.
4. **Incorrect reasoning**: generated summaries reasoned relations in dialogues incorrectly, thus came to wrong conclusions.
5. **Improper gendered pronouns**: summaries used improper gendered pronouns (e.g., the misuse of gendered pronouns).

We annotated the same set of 100 randomly sampled summaries via the above error type taxonomy. A summary might have more than one category labels and we categorized a summary as **(0) Other** if it did not belong to any error types.

Table 6 presents the breakdown of error types and per-category ROUGE scores. We found that: (i) *missing information* (37%) was the most frequent error type, indicating that current summarization models struggled with identifying key information. (ii) *Incorrect reasoning* had a percentage of 24% with the worst ROUGE-2; despite of being a minor type 6%, *improper gendered pronouns* seemed to severely decrease both ROUGE-1 and ROUGE-2. (iii) The relatively low ROUGE scores associated with *incorrect reasoning* and *wrong references* urged better summarization models in dealing with faithfulness in dialogue summarization.

---

[6] The full analyzed set of examples are shown in Appendix.

[7] Error analysis for baselines are displayed in the Appendix.

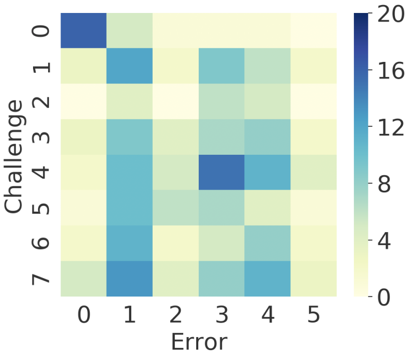

Figure 5: Relations between difficulties in conversations and errors made by our model.

5.3 Relation between Challenges and Errors

To figure out relations between challenges and errors made by our models, i.e., how different types of errors correlate with different types of challenges, we visualized the co-occurrence heat map in Figure 5. We found that: (i) Our model generated good summary for *generic*, simple conversations. (ii) All kinds of challenges had high correlations with, or could lead to the *missing information* error. (iii) *Wrong references* were highly associated with *referral & coreference*; this was as expected since co-references in conversations would naturally increase the difficulty for models to associate correct speakers with correct actions. (iv) High correlations between *role & language change*, *referral & coreference* and *incorrect reasoning* indicated that interactions between multiple participants with frequent co-references might easily lead current summarization models to reason incorrectly.

6 Conclusion

In this work, we proposed a multi-view sequence-to-sequence model that leveraged multiple conversational structures (topic view and stage view) and generic views (global view and discrete view) to generate summaries for conversations. In order to strategically combine these different views for better summary generations, we propose a multi-view sequence-to-sequence model. Experiments conducted demonstrated the effectiveness of our proposed models in terms of both quantitative and qualitative evaluations. Via thorough error analyses, we concluded a set of challenges that current models struggled with, which can further facilitate future research on conversation summarization. Due to the lack of annotations, we only adopted simple unsupervised segmentation methods to extract different views. In the future, we plan to annotate some of the data, explore supervised segmentation models (Li et al., 2018) and introduce more conversation structures like dialogue acts (Oya and Carenini, 2014; Joty and Hoque, 2016) into abstractive dialogue summarization.

Acknowledgment

We would like to thank the anonymous reviewers for their helpful comments, and the members of Georgia Tech SALT group for their feedback. We acknowledge the support of NVIDIA Corporation with the donation of GPU used for this research.

A Model Settings

We load the pre-trained "bert-base-nli-stsb-mean-tokens"[8] for sentence-BERT to get representations for each utterance. When extracting the **topic view**, we set the window size 4 and std coefficient 1 in C99. When extracting the **stage view**, we set the number of hidden states 4 in HMM. These hyper-parameters were set after a grid search with evaluating randomly sampled segmented results by human. The **BART + Structured views** (stage and topic views) followed the same parameters as **BART + Generic views**.

For **Multi-View BART**, we selected different views to combine: (1) generic view + structured view: best generic view, global view, was combined with two structured views (stage and topic view); (2) structured view + structured view: best two single views are combined (topic + stage). The settings for BART encoder/decoder kept the same as baseline. We used a one layer LSTM for encoding sections. The learning rate for section encoder and multi-view attention was set 3e-3. The temperature T was 0.2. The beam search size during inference for all the models was 4.

Experiments were performed on two Tesla P100 (16GB memory).

B View Attention Visualization

We visualized the attention weights distribution for the stage view and topic view in our best multi-view model to explore the importance of stage verses topic in Figure 6.We found that the topic views were more prominent than the stage views, consistent with the performances of *BART + topic view* and *BART + stage view*. This indicated that having discourse structures about topics might be more important while both topic and stage could improve the conversation summarization. This also communicated that the two different structured views can complement each other well though sharing the same dialogue content.

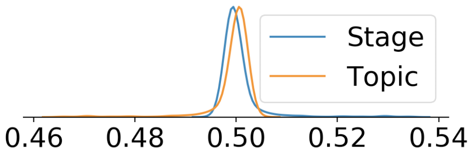

Figure 6: Attention weights distribution for stage view and topic view in the multi-view model.

Few-Shot Learning for Opinion Summarization

Arthur Bražinskas[1] **Mirella Lapata**[1] **Ivan Titov**[1,2]

[2]ILLC, University of Amsterdam
abrazinskas@ed.ac.uk, {mlap,ititov}@inf.ed.ac.uk

Abstract

Opinion summarization is the automatic creation of text reflecting subjective information expressed in multiple documents, such as user reviews of a product. The task is practically important and has attracted a lot of attention. However, due to the high cost of summary production, datasets large enough for training supervised models are lacking. Instead, the task has been traditionally approached with extractive methods that learn to select text fragments in an unsupervised or weakly-supervised way. Recently, it has been shown that abstractive summaries, potentially more fluent and better at reflecting conflicting information, can also be produced in an unsupervised fashion. However, these models, not being exposed to actual summaries, fail to capture their essential properties. In this work, we show that even a handful of summaries is sufficient to bootstrap generation of the summary text with all expected properties, such as writing style, informativeness, fluency, and sentiment preservation. We start by training a conditional Transformer language model to generate a new product review given other available reviews of the product. The model is also conditioned on review properties that are directly related to summaries; the properties are derived from reviews with no manual effort. In the second stage, we fine-tune a plug-in module that learns to predict property values on a handful of summaries. This lets us switch the generator to the summarization mode. We show on Amazon and Yelp datasets that our approach substantially outperforms previous extractive and abstractive methods in automatic and human evaluation.

1 Introduction

Summarization of user opinions expressed in online resources, such as blogs, reviews, social media, or internet forums, has drawn much attention due to its potential for various information access applications, such as creating digests, search, and report generation (Hu and Liu, 2004; Medhat et al., 2014; Angelidis and Lapata, 2018).

Gold	These shoes run true to size, do a good job supporting the arch of the foot and are well-suited for exercise. They're good looking, comfortable, and the sole feels soft and cushioned. Overall they are a nice, light-weight pair of shoes and come in a variety of stylish colors.
Ours	These running shoes are great! They fit true to size and are very comfortable to run around in. They are light weight and have great support. They run a little on the narrow side, so make sure to order a half size larger than normal.
Reviews	perfect fit for me ... supply the support that I need ... are flexible and comfortable ... || ... It is very comfortable ... I enjoy wearing them running ... || ... running shoes ... felt great right out of the box ... They run true to size ... || ... my feet and feel like a dream ... Totally light weight ... || ... shoes run small ... fit more true to size ... fit is great! ... supports my arch very well ... || ... They are lightweight... usually wear a size women's 10 ... ordered a 10.5 and the fit is great!

Table 1: Example summaries produced by our system and an annotator; colors encode its alignment to the input reviews. The reviews are truncated, and delimited with the symbol '||'.

Although significant progress has been observed in supervised summarization in non-subjective single-document context, such as news articles (Rush et al., 2015; Nallapati et al., 2016; Paulus et al., 2017; See et al., 2017; Liu et al., 2018), modern deep learning methods rely on large amounts of annotated data that are not readily available in the opinion-summarization domain and expensive to produce. A key obstacle making data annotation expensive is that annotators need to consider multiple input texts when writing a summary, which is

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4119–4135,
November 16–20, 2020.

time-consuming. Moreover, annotation would have to be undertaken for multiple domains as online reviews are inherently multi-domain (Blitzer et al., 2007) and summarization systems can be domain-sensitive (Isonuma et al., 2017). This suggests that it is unlikely that human-annotated corpora large enough for training deep models will be available.

Recently, a number of unsupervised abstractive multi-document models were introduced (e.g., COPYCAT; Bražinskas et al. 2020 and MEANSUM; Chu and Liu 2019) that are trained on large collections of unannotated product reviews.[1] However, unsurprisingly perhaps, since the models are not exposed to the actual summaries, they are unable to learn their key characteristics. For instance, MEANSUM (Chu and Liu, 2019) is prone to producing summaries that contain a significant amount of information that is unsupported by reviews; COPYCAT generates summaries that are better aligned with reviews, yet they are limited in detail. Moreover, both systems, are trained mostly on subjectively written reviews, and as a result, tend to generate summaries in the same writing style.

The main challenge in the absence of large annotated corpora lies in successful utilization of scarce annotated resources. Unlike recent approaches to language model adaptation for abstractive single-document summarization (Hoang et al., 2019; Raffel et al., 2019) that utilize hundreds of thousands of summaries, our two annotated datasets consist of only 60 and 100 annotated data-points. It was also observed that a naive fine-tuning of multi-million parameter models on small corpora leads to rapid over-fitting and poor generalization (Vinyals et al., 2016; Finn et al., 2017). In this light, we propose a few-shot learning framework and demonstrate that even a tiny number of annotated instances is sufficient to bootstrap generation of the formal summary text that is both informative and fluent (see Table 1). To the best of our knowledge, this work is the first few-shot learning approach applied to summarization.

In our work, we observe that reviews in a large unannotated collection vary a lot; for example, they differ in style, the level of detail, or how much they diverge from other reviews of the product in terms of content and overall sentiment. We refer to individual review characteristics and their relations to other reviews as *properties* (Ficler and Goldberg, 2017). While reviews span a large range of property values, only a subset of them is appropriate for summaries. For example, summaries should be close to the product's reviews in content, avoid using the first-person pronouns and agree with the reviews in sentiment. Our approach starts with estimating a property-aware model on a large collection of reviews and then adapts the model using a few annotator-created summaries, effectively switching the generator to the summarization regime. As we demonstrate in our experiments, the summaries do not even have to come from the same domain.

More formally, we estimate a text model on a dataset of reviews; the generator is a Transformer conditional language model (CLM) that is trained with a 'leave-one-out' objective (Besag, 1975; Bražinskas et al., 2020) by attending to other reviews of the product. We define properties of unannotated data that are directly related to the end task of summarization. Those properties are easy to derive from reviews, and no extra annotation effort is required. The CLM is conditioned on these properties in training. The properties encode partial information about the target review that is being predicted. We capitalize on that by fine-tuning parts of the model jointly with a tiny *plug-in network* on a handful of human-written summaries. The plug-in network is trained to output property values that make the summaries likely under the trained CLM. The plug-in has less than half a percent of the original model's parameters, and thus is less prone to over-fitting on small datasets. Nevertheless, it can successfully learn to control dynamics of a large CLM by providing property values that force generation of summaries. We shall refer to the model produced using the procedure as **Few** Shot **Sum**marizer (FEWSUM).

We evaluate our model against both extractive and abstractive methods on Amazon and Yelp human-created summaries. Summaries generated by our model are substantially better than those produced by competing methods, as measured by automatic and human evaluation metrics on both datasets. Finally, we show that it allows for successful cross-domain adaption. Our contributions can be summarized as follows:

- we introduce the first few-shot learning framework for abstractive opinion summarization;
- we demonstrate that the approach substantially outperforms extractive and abstractive

---

[1] For simplicity, we use the term 'product' to refer to both Amazon products and Yelp businesses.

models, both when measured with automatic metrics and in human evaluation;

- we release datasets with abstractive summaries for Amazon products and Yelp businesses.[2]

2 Unsupervised Training

User reviews about an entity (e.g., a product) are naturally inter-dependent. For example, knowing that most reviews are negative about a product's battery life, it becomes more likely that the next review will also be negative about it. To model inter-dependencies, yet to avoid intractabilities associated with undirected graphical models (Koller and Friedman, 2009), we use the leave-one-out setting (Besag, 1975; Bražinskas et al., 2020).

Specifically, we assume access to a large corpus of user text reviews, which are arranged as M groups $\{r_{1:N}\}_{j=1}^{M}$, where $r_{1:N}$ are reviews about a particular product that are arranged as a *target review* r_i and $N-1$ *source reviews* $r_{-i} = \{r_1, ..., r_{i-1}, r_{i+1}, ..., r_N\}$. Our goal is to estimate the conditional distribution $r_i|r_{-i}$ by optimizing the parameters θ as shown in Eq. 1.

$$\begin{aligned}\theta^* &= \arg\max_{\theta} \frac{1}{M\ N} \sum_{j=1}^{M} \sum_{i=1}^{N} \log p_{\theta}(r_i^j | r_{-i}^j) \\ &= \arg\max_{\theta} \frac{1}{M\ N} \sum_{j=1}^{M} \sum_{i=1}^{N} \log G_{\theta}(r_i^j | E_{\theta}(r_{-i}^j))\end{aligned} \tag{1}$$

Our model has an encoder-generator Transformer architecture (Vaswani et al., 2017), where the encoder E_θ produces contextual representations of r_{-i} that are attended by the generator G_θ, which in-turn is a conditional language model predicting the target review r_i, estimated using teacher-forcing (Williams and Zipser, 1989). An illustration is presented in Fig. 1.

The objective lets the model exploit common information across reviews, such as rare brand names or aspect mentions. For example, in Fig. 1, the generator can directly attend to the word *vacuum* in the source reviews to increase its prediction probability.

Additionally, we condition on partial information about the target review r_i using an oracle $q(r_i, r_{-i})$ as shown in Eq. 2.

$$\frac{1}{M\ N} \sum_{j=1}^{M} \sum_{i=1}^{N} \log G_{\theta}(r_i^j | E_{\theta}(r_{-i}^j), q(r_i^j, r_{-i}^j)) \tag{2}$$

We refer to this partial information as *properties* (Ficler and Goldberg, 2017), which correspond to text characteristics of r_i or relations between r_i and r_{-i}. For example, one such property can be the ROUGE score (Lin, 2004) between r_i and r_{-i}, which indicates the degree of overlap between r_i and r_{-i}. In Fig. 1, a high ROUGE value can signal to the generator to attend the word *vacuum* in the source reviews instead of predicting it based on language statistics. Intuitively, while the model observes a wide distribution of ROUGE scores during training on reviews, during summarization in test time we can achieve a high degree of input-output text overlap by setting the property to a high value. We considered three types of properties.

Content Coverage: ROUGE-1, ROUGE-2, and ROUGE-L between r_i and r_{-i} signals to G_θ how much to rely on syntactic information in r_{-i} during prediction of r_i. *Writing Style*: as a proxy for formal and informal writing style, we compute pronoun counts, and create a distribution over 3 points of view and an additional class for cases with no pronouns; see Appendix 9.7 for details. *Rating and Length Deviations*: for the former, we compute the difference between r_i's rating and the average r_{-i} rating; in the latter case, we use the difference between r_i's length and the average r_{-i} length.

2.1 Novelty Reduction

While summary and review generation are technically similar, there is an important difference that needs to be addressed. Reviews are often very diverse, so when a review is predicted, the generator often needs to predict content that is not present in source reviews. On the other hand, when a summary is predicted, its semantic content always matches the content of source reviews. To address this discrepancy, in addition to using the ROUGE scores, as was explained previously, we introduce a *novelty reduction* technique, which is similar to label smoothing (Pereyra et al., 2017).

Specifically, we add a regularization term $\mathcal{L}$, scaled by λ, that is applied to word distributions

---

[2] Both the code and datasets are available at: `https://github.com/abrazinskas/FewSum`

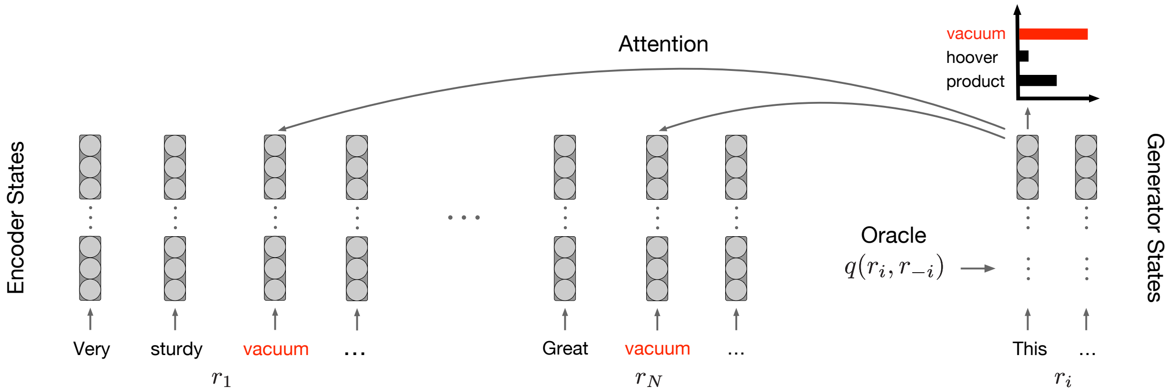

Figure 1: Illustration of the FewSum model that uses the leave-one-out objective. Here predictions of the target review r_i is performed by conditioning on the encoded source reviews r_{-i}. The generator attends the last encoder layer's output to extract common information (in red). Additionally, the generator has partial information about r_i passed by the oracle $q(r_i, r_{-i})$.

produced by the generator G_θ as shown in Eq. 3.

$$\frac{1}{M\ N}\sum_{j=1}^{M}\sum_{i=1}^{N}\Big[\log G_\theta(r_i^j|E_\theta(r_{-i}^j), q(r_i^j, r_{-i}^j)) - \lambda\mathcal{L}(G_\theta(r_i^j|E_\theta(r_{-i}^j), q(r_i^j, r_{-i}^j))\Big] \quad (3)$$

It penalizes assigning the probability mass to words not appearing in r_{-i}, as shown in Eq. 4, and thus steers towards generation of text that is more grounded in content of r_{-i}.

$$\mathcal{L}(G_\theta(r_i|r_{-i}, q(r_i, r_{-i}))) = \sum_{t=1}^{T}\sum_{w\notin V(r_{-i})} G_\theta(W_t = w|r_i^{1:t-1}, r_{-i}, q(r_i, r_{-i})) \quad (4)$$

Here, T is the length of r_i, and the inner sum is over all words that do not appear in the word vocabulary of r_{-i}. Intuitively, in Fig. 1, the penalty could reduce the probability of the word *hoover* to be predicted as it does not appear in the source reviews.

3 Summary Adaptation

Once the unsupervised model is trained on reviews, our task is to adapt it to generation of summaries. Here, we assume access to a small number of annotator-written summaries $(s^k, r_{1:N}^k)_{k=1}^K$ where s is a summary for $r_{1:N}$ input reviews. As we will show in Sec. 6.1, naive fine-tuning of the unsupervised model on a handful of annotated data-points leads to poor generalization. Instead, we capitalize on the fact that the generator G_θ has observed a wide range of property values associated with r_i during the unsupervised training phase. Intuitively, some combinations of property values drive it into generation of text that has qualities of a summary while others of a review. However, we might not know values in advance that are necessary for generation of summaries. Furthermore, $q(r_i, r_{-i})$ cannot be applied at test time as it requires access to target texts. In the following section, we describe a solution that switches the generator to the summarization mode relying only on input reviews.

3.1 Plug-in Network

We start by introducing a parametrized *plug-in network* $p_\phi(r_{-i})$ that yields the same types of properties as $q(r_i, r_{-i})$. From a practical perspective, the plug-in should be input-permutation invariant and allow for an arbitrary number of input reviews (Zaheer et al., 2017). Importantly, the trainable plug-in can have a marginal fraction of the main model's parameters, which makes it less prone to over-fitting when trained on small datasets. We initialize the parameters of $p_\phi(r_{-i})$ by matching its output to $q(r_i, r_{-i})$ on the unannotated reviews. Specifically, we used a weighted combination of distances as shown for one group of reviews in Eq. 5.

$$\sum_{i=1}^{N}\sum_{l=1}^{L}\alpha^l D^l(p_\phi(r_{-i})^l, q(r_i, r_{-i})^l) \quad (5)$$

Here, $D^l(p_\phi(r_{-i})^l, q(r_i, r_{-i})^l)$ is a distance for the property l, and α^l is an associated weight. Specifically, we used L1 norm for *Content Coverage*, *Rating and Length Deviations*, and Kullback-Leibler divergence for *Writing Style*.

For the plug-in network, we employed a multi-layer feed-forward network with multi-head attention modules over the encoded states of the source reviews at each layer, followed by a linear transformation, predicting property values. Note that the encoder is shared with the main model.

3.2 Fine-Tuning

Unsurprisingly, perhaps, the network p_ϕ being initialized on unannotated reviews inherits a strong bias towards outputting property values resulting in generation of reviews, which should not be appropriate for generating summaries. Fortunately, due to the simplicity of the chosen properties, it is possible to fine-tune p_ϕ to match the output of q on the annotated data $(s^k, r^k_{1:N})^K_{k=1}$ using Eq. 5.

An alternative is to optimize the plug-in to directly increase the likelihood of summaries under G_θ while keeping all other parameters fixed.[3]

As the generator is trained on unannotated reviews, it might not encounter a sufficient amount of text that is written as a summary, and that highly overlaps in content with the input reviews. We address that by unfreezing the attention module of G_θ over input reviews and the plug-in p_ϕ, and by maximizing the likelihood of summaries:

$$\frac{1}{K}\sum_{k=1}^{K}\Big[\log G_\theta(s^k|E_\theta(r^k_{1:N}), p_\phi(r^k_{1:N}))\Big] \quad (6)$$

This allows the system to learn an interaction between G_θ and p_ϕ. For example, what property values are better associated with summaries and how G_θ should better respond to them.

4 Experimental Setup

4.1 Dataset

For training we used customer reviews from Amazon (He and McAuley, 2016) and Yelp.[4] From the Amazon reviews we selected 4 categories: *Electronics*; *Clothing, Shoes and Jewelry*; *Home and Kitchen*; *Health and Personal Care*. We used a similar pre-processing schema as in (Bražinskas et al., 2020), details are presented in Appendix 9.1. For training, we partitioned business/product reviews to the groups of 9 reviews by sampling without replacement. Thus, for unsupervised training in Sec. 2, we conditioned on 8 reviews for each target review. The data-statistics are shown in Table 2.

Dataset	Training	Validation
Yelp	38,913/1,016,347	4,324/113,886
Amazon	182,932/3,889,782	9,629/205,992

Table 2: Data statistics after pre-processing. The format in the cells is Businesses/Reviews and Products/Reviews for Yelp and Amazon, respectively.

We obtained 480 human-written summaries (180 for Amazon and 300 for Yelp) for 8 reviews each, using Amazon Mechanical Turk (AMT). Each product/business received 3 summaries, and averaged ROUGE scores are reported in the following sections. Also, we reserved approximately $\frac{1}{3}$ for testing and the rest for training and validation. The details are in Appendix 9.2.

4.2 Experimental Details

For the main model, we used the Transformer architecture (Vaswani et al., 2017) with trainable length embeddings and shared parameters between the encoder and generator (Raffel et al., 2019). Subwords were obtained with BPE (Sennrich et al., 2016) using 32000 merges. Subword embeddings were shared across the model as a form of regularization (Press and Wolf, 2017). For a fair comparison, we approximately matched the number of parameters to COPYCAT (Bražinskas et al., 2020). We randomly initialized all parameters with Glorot (Glorot and Bengio, 2010). For the plug-in network, we employed a multi-layer feed-forward network with multi-head attention modules over encoded states of the source review. After the last layer, we performed a linear projection to compute property values. Further, parameter optimization was performed using Adam (Kingma and Ba, 2014), and beam search with n-gram blocking (Paulus et al., 2017) was applied to our model and Copycat for summary generation.

All experiments were conducted on 4 x GeForce RTX 2080 Ti.

4.3 Hyperparameters

Our parameter-shared encoder-generator model used a 8-head and 6-layer Transformer stack. Dropout in sub-layers and subword embeddings dropout was both set to 0.1, and we used 1000 dimensional position-wise feed-forward neural networks. We set subword and length embeddings to 390 and 10 respectively, and both were concatenated to be used as input. For the plug-in network, we set the output dimension to 30 and internal feed-forward network hidden dimensions to 20. We used

---

[3] We explored that option, and observed that it works similarly, yet leads to a slightly worse result.

[4] `https://www.yelp.com/dataset/challenge`

a stack of 3 layers, and the attention modules with 3 heads at each layer. We applied 0.4 internal dropout and 0.15 attention dropout. Property values produced by the plug-in or oracle were concatenated with subword and length embeddings and linearly projected before being passed to the generator. In total, our model had approximately 25M parameters, while the plug-in network only 100K (i.e., less than 0.5 % of the main model's parameters).

In all experiments, the hyperparameter tuning was performed based on the ROUGE-L score on Yelp and Amazon validation sets.

4.4 Baselines

LEXRANK (Erkan and Radev, 2004) is an unsupervised extractive graph-based algorithm selecting sentences based on graph centrality. Sentences represent nodes in a graph whose edges have weights denoting similarity computed with tf-idf.

MEANSUM is an unsupervised abstractive summarization model (Chu and Liu, 2019) that treats a summary as a discrete latent state of an autoencoder. The model is trained in a multi-task fashion with two objectives, one for prediction of reviews and the other one for summary-reviews alignment in the semantic space using the cosine similarity.

COPYCAT is the state-of-the-art unsupervised abstractive summarizer (Bražinskas et al., 2020) that uses continuous latent representations to model review groups and individual review semantics. It has an implicit mechanism for novelty reduction and uses a copy mechanism.

As is common in the summarization literature, we also employed a number of simple summarization baselines. First, the CLUSTROID review was computed for each group of reviews as follows. We took each review from a group and computed ROUGE-L with respect to all other reviews. The review with the highest ROUGE score was selected as the clustroid review. Second, we sampled a RANDOM review from each group to be used as the summary. Third, we constructed the summary by selecting the *leading sentences* (LEAD) from each review of a group.

5 Evaluation Results

Automatic Evaluation We report ROUGE F1 score (Lin, 2004) based evaluation results on the Amazon and Yelp test sets in Tables 3 and 4, respectively. The results indicate that our model outperforms abstractive and extractive methods on both datasets. Also, the results are supported by qualitative improvements over other models, see examples in the Appendix.

	R1	R2	RL

Lead	0.2620	0.0457	0.1432
Random	0.2148	0.0259	0.1387

Table 4: ROUGE scores on the Yelp test set.

Best-Worst Scaling We performed human evaluation with the Best-Worst scaling (Louviere and Woodworth, 1991; Louviere et al., 2015; Kiritchenko and Mohammad, 2016) on the Amazon and Yelp test sets using the AMT platform. We assigned multiple workers to each tuple containing summaries from COPYCAT, our model, LEXRANK, and human annotators. The judgment criteria were the following: *Fluency*, *Coherence*, *Non-redundancy*, *Informativeness*, *Sentiment*. Details are provided in Appendix 9.6.

For every criterion, a system's score is computed as the percentage of times it was selected as best, minus the percentage of times it was selected as worst (Orme, 2009). The scores range from -1 (unanimously worst) to +1 (unanimously best).

The results are presented in Tables 5 and 6 for Amazon and Yelp, respectively. On the Amazon data, they indicate that our model is preferred across the board over the baselines. COPYCAT is preferred over LEXRANK in terms of fluency and non-redundancy, yet it shows worse results in terms of informativeness and overall sentiment preservation. In the same vein, on Yelp in Table 6 our model outperforms the other models.

All pairwise differences between our model and other models are statistically significant at

	Fluency	Coherence	Non-Redundancy	Informativeness	Sentiment
FewSum	**0.1000**	**0.1429**	**0.1250**	**0.2000**	**0.3061**
Copycat	-0.1765	-0.5333	-0.2727	-0.7455	-0.7143
LexRank	-0.4848	-0.5161	-0.5862	-0.3488	-0.0909
Gold	0.5667	0.6364	0.6066	0.6944	0.4138

	Full (%)	Partial (%)	No (%)
FewSum	43.09	**34.14**	**22.76**
Copycat	**46.15**	27.18	26.67

Table 7: Content support on the Amazon test set.

$p < 0.05$, using post-hoc HD Tukey tests. The only exception is non-redundancy on Yelp when comparing our model and COPYCAT (where our model shows a slightly lower score).

Content Support As was observed by Falke et al. (2019); Tay et al. (2019); Bražinskas et al. (2020), the ROUGE metric can be insensitive to hallucinating facts and entities. We also investigated how well generated text is supported by input reviews. We split summaries generated by our model and COPYCAT into sentences. Then for each summary sentence, we hired 3 AMT workers to judge how well content of the sentence is supported by the reviews. Three following options were available. *Full support*: all the content is reflected in the reviews; *Partial support*: only some content is reflected in the reviews; *No support*: content is not reflected in the reviews.

The results are presented in Table 7. Despite not using the copy mechanism, that is beneficial for fact preservation (Falke et al., 2019) and generation of more diverse and detailed summaries (see Appendix), we score on par with COPYCAT.

6 Analysis

6.1 Alternative Adaptation Strategies

We further explored alternative utilization approaches of annotated data-points, based on the same split of the Amazon summaries as explained in Sec. 4.1. First, we trained a model in an unsupervised learning setting (USL) on the Amazon reviews with the leave-one-out objective in Eq. 1. In this setting, the model has neither exposure to summaries nor the properties, as the oracle $q(r_i, r_{-i})$ is not used. Further, we considered two alternative settings how the pre-trained unsupervised model can be adapted on the gold summaries. In the first setting, the model is fine-tuned by predicting summaries conditioned on input reviews (USL+F). In the second one, similar to Hoang et al. (2019), we performed adaptation in a multi-tasking learning (MTL) fashion. Here, USL is further trained on a mixture of unannotated corpus review and gold summary batches with a trainable embedding indicating the task.[5] The results are presented in Table 8.

First, we observed that USL generates summaries that get the worst ROUGE scores. Additionally, the generated text tends to be informal and substantially shorter than an average summary, we shall discuss that in Sec. 6.2. Second, when the model is fine-tuned on the gold summaries (USL+F), it noticeably improves the results, yet they are substantially worse than of our proposed few-shot approach. It can be explained by strong influence of the unannotated data stored in millions of parameters that requires more annotated data-points to overrule. Finally, we observed that MTL fails to decouple the tasks, indicated by only a slight improvement over USL.

---

[5] We observed that the 1:1 review-summary proportion works the best.

	R1	R2	RL
FewSum	0.3356	0.0716	0.2149
MTL	0.2403	0.0435	0.1627
USL+F	0.2823	0.0624	0.1964
USL	0.2145	0.0315	0.1523
Random	0.2500	0.0382	0.1572

Table 8: ROUGE scores on the Amazon test set for alternative summary adaptation strategies.

	1st	2nd	3rd	NoPr	Len
Gold	0.0	1.7	60.0	38.3	0.0
FewSum	0.5	1.3	83.2	15.0	3.4
USL+F	29.7	0.0	45.3	25.0	-28.6
USL	56.7	0.0	43.3	0.0	-32.7
Reviews	49.0	7.3	35.6	8.1	-17.6

Table 9: Text characteristics of generated summaries by different models on the Amazon test set.

6.2 Influence of Unannotated Data

We further analyzed how plain fine-tuning on summaries differs from our approach in terms of capturing summary characteristics. For comparison, we used USL and USL+F, which are presented in Sec. 6.1. Additionally, we analyzed unannotated reviews from the Amazon training set. Specifically, we focused on text formality and the average word count difference (*Len*) from the gold summaries in the Amazon test set. As a proxy for the former, we computed the marginal distribution over points of view (POV), based on pronoun counts; an additional class (*NoPr*) was allocated to cases of no pronouns. The results are presented in Table 9.

First, we observed that the training reviews are largely informal (49.0% and 7.3% for 1st and 2nd POV, respectively). Unsurprisingly, the model trained only on the reviews (USL) transfers a similar trait to the summaries that it generates.[6] On the contrary, the gold summaries are largely formal - indicated by a complete absence of the 1st and a marginal amount of 2nd POV pronouns. Also, an average review is substantially shorter than an average gold summary, and consequently, the generated summaries by USL are also shorter. Example summaries are presented in Table 10.

Gold	These shoes run true to size, do a good job supporting the arch of the foot and are well-suited for exercise. They're good looking, comfortable, and the sole feels soft and cushioned. Overall they are a nice, light-weight pair of shoes and come in a variety of stylish colors.
FewSum	These running shoes are great! They fit true to size and are very comfortable to run around in. They are light weight and have great support. They run a little on the narrow side, so make sure to order a half size larger than normal.
USL+F	This is my second pair of Reebok running shoes and they are the best running shoes I have ever owned. They are lightweight, comfortable, and provide great support for my feet.
USL	This is my second pair of Reebok running shoes and I love them. They are the most comfortable shoes I have ever worn.

Table 10: Example summaries produced by models with different adaptation approaches.

Domain	In-domain	Cross-domain
Cloth	0.2188	0.2220
Electronics	0.2146	0.2136
Health	0.2121	0.1909
Home	0.2139	0.2250
Avg	0.2149	0.2129

Table 11: In and cross domain experiments on the Amazon dataset, ROUGE-L scores are reported.

Further, we investigated how well USL+F, adapts to the summary characteristics by being actually fine-tuned on them. Indeed, we observed that USL+F starts to shift in the direction of the summaries by reducing the pronouns of the 1st POV and increasing the average summary length. Nevertheless, the gap is still wide, which would probably require more data to be bridged. Finally, we observed that our approach adapts much better to the desired characteristics by producing well-formed summary text that is also very close in length to the gold summaries.

6.3 Cross-Domain

We hypothesized that on a small dataset, the model primarily learns course-grained features, such as common writing phrases, and their correlations between input reviews and summaries. Also, that they, in principle, could be learned from remotely related domains. We investigated that by fine-tuning the model on summaries that are not in the target domain of the Amazon dataset. Specifically,

---

[6] As beam search, attempting to find the most likely candidate sequence, was utilized, opposed to a random sequence sampling, we observed that generated sequences had no cases of the 2nd POV pronouns and complete absence of pronouns (NoPr).

we matched data-point count for 3/4 domains of training and validation sets to the in-domain Amazon data experiment presented in Sec 5; the test set remained the same for each domain as in the in-domain experiment. Then, we fine-tuned the same model 5 times with different seeds per target domain. For comparison, we used the in-domain model which was used in Amazon experiments in Sec. 5. We computed the average ROUGE-L score per target domain, where overall σ was 0.0137. The results are reported in Table 11.

The results indicate that the models perform on-par on most of the domains, supporting the hypothesis. On the other hand, the in-domain model shows substantially better results on the *health* domain, which is expected, as, intuitively, this domain is the most different from the rest.

7 Related Work

Extractive weakly-supervised opinion summarization has been an active area of research. LEXRANK (Erkan and Radev, 2004) is an unsupervised extractive model. OPINOSIS (Ganesan et al., 2010) does not use any supervision and relies on POS tags and redundancies to generate short opinions. However, this approach is not well suited for the generation of coherent long summaries and, although it can recombine fragments of input text, it cannot generate novel words and phrases. Other earlier approaches (Gerani et al., 2014; Di Fabbrizio et al., 2014) relied on text planners and templates, which restrict the output text. A more recent extractive method of Angelidis and Lapata (2018) frames the problem as a pipeline of steps with different models for each step. Isonuma et al. (2019) introduce an unsupervised approach for single product review summarization, where they rely on latent discourse trees. The most related unsupervised approach to this work is our own work, COPYCAT (Bražinskas et al., 2020). Unlike that work, we rely on a powerful generator to learn conditional spaces of text without hierarchical latent variables. Finally, in contract to MEANSUM (Chu and Liu, 2019), our model relies on inductive biases without explicitly modeling of summaries. A concurrent model DENOISESUM (Amplayo and Lapata, 2020) uses a syntactically generated dataset of source reviews to train a generator to denoise and distill common information. Another parallel work, OPINIONDIGEST (Suhara et al., 2020), considers controllable opinion aggregation and is a pipeline framework for abstractive summary generation. Our conditioning on text properties approach is similar to Ficler and Goldberg (2017), yet we rely on automatically derived properties that associate a target to source, and learn a separate module to generate their combinations. Moreover, their method has not been studied in the context of summarization.

8 Conclusions

In this work, we introduce the first to our knowledge few-shot framework for abstractive opinion summarization. We show that it can efficiently utilize even a handful of annotated reviews-summary pairs to train models that generate fluent, informative, and overall sentiment reflecting summaries. We propose to exploit summary related properties in unannotated reviews that are used for unsupervised training of a generator. Then we train a tiny plug-in network that learns to switch the generator to the summarization regime. We demonstrate that our approach substantially outperforms competitive ones, both abstractive and extractive, in human and automatic evaluation. Finally, we show that it also allows for successful cross-domain adaptation.

Acknowledgments

We would like to thank members of Edinburgh NLP group for discussion, and the anonymous reviewers for their valuable feedback. We gratefully acknowledge the support of the European Research Council (Titov: ERC StG BroadSem 678254; Lapata: ERC CoG TransModal 681760) and the Dutch National Science Foundation (NWO VIDI 639.022.518).

9 Appendices

9.1 Dataset Pre-Processing

We selected only Amazon products and Yelp businesses with minimum of 10 reviews, and the minimum and maximum lengths of 20 and 70 words, respectively. Also, popular products/businesses above the 90^{th} percentile were removed. From each business/product we sampled 9 reviews without replacement to form groups of reviews.

9.2 Evaluation Data Split

From the Amazon annotated dataset, We used 28, 12, 20 products for training, validation, and testing, respectively. On Yelp, we used 30, 30, 40 for training, validation, and testing, respectively. Both the automatic and human evaluation experiments were performed on the test sets.

9.3 Training Procedure

First, to speed-up the training phase, we trained an unconditional language model for 13 epoch on the Amazon reviews with the learning rate (LR) set to $5 * 10^{-4}$. On Yelp we trained it for 27 epochs with LR set to $7 * 10^{-4}$. The language model was used to initialize both the encoder and generator of the main model.

Subsequently, we trained the model using Eq. 2 for 9 epochs on the Amazon reviews with $6 * 10^{-5}$ LR, and for 57 epochs with LR set to $5 * 10^{-5}$. Additionally, we reduced novelty using Eq. 4 by training the model further for 1 epoch with 10^{-5} LR and $\lambda = 2$ on Amazon; On Yelp we trained for 4 epochs, with $3 * 10^{-5}$ LR, and $\lambda = 2.5$.

For the plugin network's initialization, as explained in Sec. 3.1, we performed optimization by output matching with the oracle for 11 epochs on the unannotated Amazon reviews with $1 * 10^{-5}$ LR. On Yelp we trained for 87 epochs with $1 * 10^{-5}$ Lastly, we fine-tuned the plugin network on the human-written summaries by output matching with the oracle[7]. On the Amazon data for 98 epochs with $7 * 10^{-4}$, and for 62 epochs with $7 * 10^{-5}$ on Yelp. We set weights to 0.1, 1., 0.08, 0.5 for length deviation, rating deviation, POV, and ROUGE scores, respectively. Then fine-tuned the attention part of the model and the plug-in network jointly for 33 epochs with $1 * 10^{-4}$ on the Amazon data. And 23 epochs with $1 * 10^{-4}$ LR on Yelp.

9.4 Summary Annotation

For summary annotation, we reused 60 Amazon products from Bražinskas et al. (2020) and sampled 100 businesses from Yelp. We assigned 3 Mechanical Turk workers to each product/business, and instructed them to read the reviews and produce a summary text. We used the following instructions:

- The summary should reflect user common opinions expressed in the reviews. Try to preserve the common sentiment of the opinions and their details (e.g. what exactly the users like or dislike). For example, if most reviews are negative about the sound quality, then also write negatively about it.

- Please make the summary coherent and fluent in terms of sentence and information structure. Iterate over the written summary multiple times to improve it, and re-read the reviews whenever necessary.

- The summary should not look like a review, please write formally.

- Keep the length of the summary reasonably close to the average length of the reviews.

- Please try to write the summary using your own words instead of copying text directly from the reviews. Using the exact words from the reviews is allowed but do not copy more than 5 consecutive words from a review.

9.5 Human Evaluation Setup

To perform the human evaluation experiments described in Sec 5, we hired workers with 98% approval rate, 1000+ HITS, Location: USA, UK, Canada, and the maximum score on a qualification test that we had designed. The test was asking if the workers were native English speakers, and was verifying that they correctly understood the instructions of both the best-worst scaling and content support tasks.

9.6 Best-Worst Scaling Details

We performed human evaluation based on the Amazon and Yelp test sets using the AMT platform. We assigned workers to each tuple containing summaries from COPYCAT, our model, LEXRANK, and human annotators. Due to dataset size differences, we assigned 5 and 3 workers to each

---

[7] We set rating deviation to 0 as summaries do not have associated human-annotated ratings.

1st	I bought this as a gift for my husband.
	I've been using Drakkar Noir Balm for over twenty years.
	I purchased these for my son as a kind of a joke.
2nd	This is the best product you can buy!
	You get what you pay for.
	Please do yourself a favor and avoid this product.
3rd	This is his every work day scent.
	It's very hard to buy the balm separately.
	It smells like Drakkar, but it is hard to find.
No Pronouns	Very nice, not too overpowering.
	This product has no smell what ever.
	Nice to use for hardwood floors.

Table 12: Examples of review sentences that contain only pronouns belonging to a specific class.

tuple in the Amazon and Yelp test sets, respectively. We presented the associated reviews in a random order and asked the workers to judge summaries using the Best-Worst scaling (BWS) (Louviere and Woodworth, 1991; Louviere et al., 2015) that is known to produce more reliable results than ranking scales (Kiritchenko and Mohammad, 2016). The judgment criteria are presented below, where *non-redundancy* and *coherence* were taken from Dang (2005). *Fluency*: the summary sentences should be grammatically correct, easy to read and understand; *Coherence*: the summary should be well structured and well organized; *Non-redundancy*: there should be no unnecessary repetition in the summary; *Informativeness*: how much useful information about the product does the summary provide?; *Sentiment*: how well the sentiment of the summary agrees with the overall sentiment of the original reviews?

9.7 Points of View

Summaries differ from reviews in terms of the writing style. Specifically, reviews are predominantly written informally, populated by pronouns such as *I* and *you*. In contrast, summaries are desirable to be written formally. In this work, we observed that a surprisingly simple way to achieve that is to condition the generator on the distribution over pronoun classes of the target review. We computed pronoun counts and produced the 4 class distributions: 1st, 2nd, 3rd person POV, and 'other' in case if no pronouns are present.

Consider the example sentences in Table 12. Here one can observe that the sentences of different pronoun classes differ in the style of writing and often the intention of the message: 1st POV sentences tend to provide clues about the personal experience of the user; 2nd POV sentences, on the other hand, commonly convey recommendations to a reader; 3rd POV and 'other' sentences often describe aspects and their associated opinions.

Gold	Bennett Medical has poor customer service. Phone calls can take a long time to get answered and leaving voice mails tend to be fruitless. The products are overpriced and take a long time to be refilled. Using this medical supply company can be a hassle.
Ours	This medical supply is the worst medical supply company in the valley. The customer service is horrible, the staff is rude, the wait times are long, and the service reps are not helpful at all. Do not recommend this company to anyone.
Copycat	If I could give them 0 stars I would. The customer service is terrible, the staff is extremely rude and helpful. If you're looking for a new provider, this is the place to be. I will never use them again.
MeanSum	Service is horrible, especially the manager. I have a lot of kids but not this place. Two months later I was able to go in and get a new one to go in the next day. They would tell me that they would have to do a lot of our water to be there to get a new one. But this is the first time I have dealt with him and we will never go back again. Thanks for your hard work, and I will never go anywhere else.
Lexrank	Bennett Medical for Cpap supplies are horrible. Never enough staff to answer phone, so you'll need to leave messages. DON'T use this medical supply. If I could give Bennett Medical zero stars I would! Will be moving to another medical supply as soon as I can.
Review 1	Bennett Medical for Cpap supplies are horrible. We have waited for three weeks to refill supplies and we are still waiting. This company does not have good customer service, you can only leave messages, and they never call back. If I could give Bennett Medical zero stars I would!
Review 2	Teachers Health Trust, please look into the practice of the billing and filling of durable services. The mask cushions go for 45 to 50 days because of the lack of communication. The people in charge of billing are very argumentative and lack customer service. I will drop them after annual, because of my insurance obligations.
Review 3	Fantastic service from Jocelyn at the front desk, we had a really hard time getting the right paperwork together from Drs but she stuck with us and helped us every step of the way, even calling to keep us updated and to update info we might have for her. Thanks Jocelyn.
Review 4	I hardly ever write reviews, but I'd like to spare someone else from what I experienced. So a warning to the wise... If you like rude incompetent employees, almost an hour long wait for just picking up a phone order, and basically being treated like a second class citizen then look no further than Bennett Medical.
Review 5	DON'T use this medical supply. Never enough staff to answer phone, so you'll need to leave messages. No return phone calls. I am unable to get my CPAP supplies every quarter without hours of calling / waiting / calling. Poor customer service. Will be moving to another medical supply as soon as I can.
Review 6	Terrible experience. They have ridiculous price also bad customer services. You can get nebulizer machine around $50 at amazon, bennet medical charge you almost twice more expensive price. And breathing kit price was unbelievable too. Because of deduction, I had to pay them all out of my pocket whatever they charged. I don't recommand this medical company to anyone.
Review 7	Good luck getting a phone call back or someone to answer the phone without hanging up immediately. I have called over 20 times left 5 voicemails over the last 30 days, just to refill a mask perscription. This is an ongoing issue that is beyond frustrating. Not trying to destroy this businesses name just want the owners to implement some basic customer service skills.
Review 8	Always receive friendly customer service whenever we call or go into the location. My questions are always answered and I am very happy with the supplies we get from them. Great people providing a great service! Thank you for all you do!

Table 13: Example summaries produced by different systems on Yelp data.

Gold	It is very clean and nice inside. Everyone is so kind and friendly. They do an amazing job on both nails and pedis. They get it done with speed and precision with a price that is very much affordable. They have the best customer service.
Ours	This nail salon is very clean and the staff is very friendly. They have a wide variety of gel colors to choose from. The prices are very reasonable and they do a great job. The nail techs are very nice and do great work.
Copycat	This is the best nail salon I have ever been to. Everyone is very friendly and professional. My nails look great and I'm glad I did! I will definitely be coming back to this place.
MeanSum	The owner is so nice and accommodating. I went to get my nails done by a friend, and I was extremely happy with this salon. Everyone was very friendly and I was able to use them for nails. They did a great job on my nails and the best part about it was that it was a busy day but it was a treat! Highly recommend them.
Lexrank	I really enjoy coming here to get my nails done. B did an amazing job on my nails. Amazing service and nails. However B did an AMAZING job on my coffin chrome nails and Nancy was extremely helpful figuring out how I wanted my nails done too. Everyone is so friendly there too.
Review 1	Tim and Tami always always always have the best customer service and do the best nails. I will NEVER go anywhere else. Even after weeks my nails look and feel as good as they did when I first got them done! I'm so dedicated I recommend and bring in all my friends!
Review 2	Definitely my new nail salon! Everyone is so friendly and kind, I felt so welcomed! B did an amazing job on my nails. He made sure everything was perfect and happily changed something to make me happy. I would highly recommend this place to anyone who wants A + work at a totally affordable price. Love it!!:)
Review 3	Amazing service and nails. This is the second time I have been here, they did a perfect job again. They get it done fast yet with precision. Everyone is so friendly there too. Best nail salon I have ever been too. I'm glad I found it.
Review 4	I really enjoy coming here to get my nails done. They do a wonderful job on both pedis and nails. It is nice and clean inside. They are very friendly and welcoming. It is worth it to stop in and try it out.
Review 5	My first set of acrylics ever... I decided 27 years was a lot enough time to wait, and I'm SO happy with them. I'm not a huge nail person, and was glad to stumble upon this salon. My nail tech was quiet, clean, and very detail-oriented. Very pleased with my experience here and I recommend this place.
Review 6	I called to make an appointment for later today for 3 adults and 2 kids and the man who answered the phone said 'we only have 2 techs today' we can't do that. Poor customer service and I never even went in.
Review 7	Golden Nails has been my nail place for almost a year so it was surprising to see new management. However B did an AMAZING job on my coffin chrome nails and Nancy was extremely helpful figuring out how I wanted my nails done too. Definitely excited to keep coming back!
Review 8	Seriously the best service I have ever gotten at a Tempe nail salon!! I walked in and they helped me right away. Nancy helped me pick the perfect color and was very honest and up front about everything! I wanted something very natural and using the dip method, I love my nails!!

Table 14: Example summaries produced by different systems on Yelp data.

Gold	These are a very comfortable and cute sandal. This thong sandal goes with a variety of outfits and the cushy sole allows for all day comfort. However, they do run a little small, sizing up provides a better fit. Overall, a reasonably priced shoe that will last for years to come.
Ours	These sandals are very cute and comfortable. They fit true to size and are very comfortable to wear. They look great with a variety of outfits and can be dressed up or down depending on the occasion.
Copycat	I love these sandals.They are very comfortable and I can wear them all day without any discomfort. I wear them to work and they are comfortable to wear.
MeanSum	I love these shoes. They are so comfortable and I love the style. They are very comfortable and the perfect price! I would definitely recommend this product to anyone. They are comfortable and stylish.
Lexrank	I have been wearing White Mountain beaded sandals for a couple of years now and they are wonderful. I will never buy from white mountain again. I love White Mountain sandels. Lots of compliments every time I wear them.
Review 1	I get constant compliments on these sandals. I order them every summer in a variety of colors. I had heel spurs and back problems so the cushy softness of these is the only thing I can wear comfortably and the small wedge heel is perfect for my back.
Review 2	These thongs are fun, festive, flexible and surprisingly comfortable. I have very sensitive feet and I can wear these cuties all day. The arch support is great and there is a nice give in the sole. I love these so much I want to put a few pairs away in case they discontinue them. They go with everything.
Review 3	I have been wearing White Mountain beaded sandals for a couple of years now and they are wonderful. They are lightweight and cushion the feet when worn for long hours. They are also beautiful and usually hold up for two or more seasons.
Review 4	This was great price for this cute sandal. Unfortunately, the toe piece was very hard and they were a little narrow... unusual since I normally wear a B width. For the right person, they would probably be fine. They just didn't work for me.
Review 5	I love White Mountain sandels. this is my 2nd pair of these shoes. I wore out the last pair after 2yrs. They are very very blingy and I like that. Would I order another pair? you bet I would / will.
Review 6	Item was too small, purchased for a friend their size 9 is smaller than the size 8 in the store. Sent it to the wrong address, and I can not seem to find anyone that will tell me where my bill is. I will never buy from white mountain again.
Review 7	I lived in sandals that looked exactly like this but I thought they were by Bjorn. I couldn't find them anywhere, but found these (go figure). While they aren't quite as comfy as my other ones, I think with a bit of breaking in they'll be just fine. Lots of compliments every time I wear them.
Review 8	Not only are these SUPER comfortable (yes, even between your toes), they look great with just about anything I wear! I have been complimented on these daily!! I typically wear a 6 1 / 2, I ordered a 7 and they fit perfect!! I need more of these!! HIGHLY RECOMMENDED!!!

Table 15: Example summaries produced by different systems on Amazon data.

Gold	This is a perfect compact table that fits well in many places. The chairs are surprisingly very comfortable as well. It is cute and perfect for smaller living quarters and the best part is assembly is simple and straightforward.
Ours	This is a very nice table set for the price. It was easy to assemble and looks great in the kitchen. The only problem is that it is not sturdy enough to hold a lot of weight. It would be nice if it had a little more weight to it so that it would not tip over.
Copycat	This is a great table set for the price. It was easy to put together and looks great. The only thing is that the chairs are a little flimsy, but they are easy to assemble.
MeanSum	The table was very easy to assemble and was easy to assemble. The only thing I would say is that the box is very small and not very sturdy. The table is very sturdy. I would recommend it to anyone looking for a sturdy table and to put on the wall.
Lexrank	The table and chairs are very nice but not quite the color I expected (but I am getting used to it). The table and chairs are solid and sturdy! I received this table and chairs completely damaged. Table and chairs delivered by the carrier right on time and with no damage.
Review 1	It was easy to put together and looks great. However, when the item was shipped to me, one of the backs of the chairs was broken. I just fixed it myself with wood glue. Its not even visible now. The rest of it was in perfect condition.
Review 2	The table and chairs are very nice but not quite the color I expected (but I am getting used to it). Table and chairs delivered by the carrier right on time and with no damage. Very easy to assemble, but very difficult to get out of the box it was so well protected.
Review 3	This table was super easy to put together. The table and chairs are solid and sturdy! The seats are very comfortable. The table is the perfect size for our not so big kitchen. We are very pleased with this purchase.
Review 4	Moved to smaller living quarters and this just fits the bill. Color is perfect and it was easy to assemble. One fault to find is that the top scratches easily. It even came with a scratch. Other than that it is fine.
Review 5	I love my new dining room set. The set is very sturdy, the walnut finish is a nice color.This set is great for a small area, kitchen nook.Would not recommend for a large eating area.Table is small and so are the chairs.Yet strong enough to hold big boys and girls, thumps up, great price, packed well, arrived in a timely matter.
Review 6	It fits perfectly in the kitchen at the office. My staff assembled it without any delay. Everyone loves the dining set and they can't believe I ordered it on-line. I made the measurements and made sure of the dimensions of the room and the dining set and it's a perfect fit.
Review 7	I received this table and chairs completely damaged. The customer service experience with this company was terrible. In my opinion, this set is cheap and overpriced. It's not durable and not worth the money. Don't waste your time.
Review 8	The box looked like it had been opened, and then re-taped for resell. One of the chairs was broken, and the broken piece was nowhere close to the originating piece. Possibly other pieces damaged too, though didn't bother looking, instead just re-taped it back up to be sent back. I hope they don't just resell it to someone else.

Abstract

The ability to fuse sentences is highly attractive for summarization systems because it is an essential step to produce succinct abstracts. However, to date, summarizers can fail on fusing sentences. They tend to produce few summary sentences by fusion or generate incorrect fusions that lead the summary to fail to retain the original meaning. In this paper, we explore the ability of Transformers to fuse sentences and propose novel algorithms to enhance their ability to perform sentence fusion by leveraging the knowledge of *points of correspondence* between sentences. Through extensive experiments, we investigate the effects of different design choices on Transformer's performance. Our findings highlight the importance of modeling points of correspondence between sentences for effective sentence fusion.

1 Introduction

A renewed emphasis must be placed on sentence fusion in the context of neural abstractive summarization. A majority of the systems are trained end-to-end (See et al., 2017; Paulus et al., 2018; Narayan et al., 2018; Chen and Bansal, 2018; Gehrmann et al., 2018; Liu and Lapata, 2019), where an abstractive summarizer is rewarded for generating summaries that contain the same words as human abstracts, measured by automatic metrics such as ROUGE (Lin, 2004). A summarizer, however, is not rewarded for correctly fusing sentences. In fact, when examined more closely, only few sentences in system abstracts are generated by fusion (Falke et al., 2019; Lebanoff et al., 2019). For instance, 6% of summary sentences generated by Pointer-Gen (See et al., 2017) are through fusion, whereas human abstracts contain 32% fusion sentences. Moreover, sentences generated by fusion are prone to errors. They can be ungrammatical, nonsensical, or otherwise ill-formed. There is thus an urgent need to develop neural abstractive summarizers to fuse sentences properly.

The importance of sentence fusion has long been recognized by the community before the era of neural text summarization. The pioneering work of Barzilay et al. (1999) introduces an information fusion algorithm that combines similar elements across related text to generate a succinct summary. Later work, such as (Marsi and Krahmer, 2005; Filippova and Strube, 2008; Elsner and Santhanam, 2011; Thadani and McKeown, 2013; Mehdad et al., 2013), builds a dependency or word graph by combining syntactic trees of similar sentences, then employs integer linear programming to decode a summary sentence from the graph. Most of these studies have assumed a set of *similar* sentences as input, where fusion is necessary to reduce repetition. Nonetheless, humans do not limit themselves to combine similar sentences. In this paper, we pay particular attention to fuse *disparate* sentences that contain fundamentally different content but remain related to make fusion sensible (Elsner and Santhanam, 2011). In Figure 1, we provide an example of a sentence fusion instance.

We address the challenge of fusing disparate sentences by enhancing the Transformer architecture (Vaswani et al., 2017) with *points of correspondence* between sentences, which are devices that tie two sentences together into a coherent text. The task of sentence fusion involves choosing content from each sentence and weaving the content pieces together into an output sentence that is linguistically plausible and semantically truthful to the original input. It is distinct from Geva et al. (2019) that connect two sentences with discourse markers. Our contributions are as follows.

- We make crucial use of *points of correspondence* (PoC) between sentences for information fusion. Our use of PoC was initiated by the current lack

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4136–4142,
November 16–20, 2020.

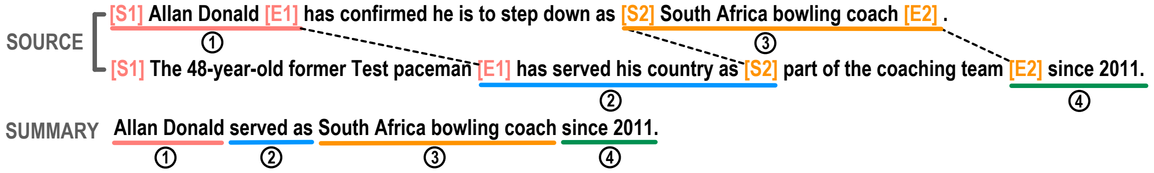

Figure 1: Sentence fusion involves determining what content from each sentence to retain, and how best to weave text pieces together into a well-formed sentence. Points of correspondence (PoC) are text chunks that convey the same or similar meanings, e.g., *Allan Donald* and *The 48-year-old former Test paceman*, *South Africa bowling coach* and *part of the coaching team*.

of understanding of how sentences are combined in neural text summarization.

- We design new sentence fusion systems and experiment with a fusion dataset containing quality PoC annotations as the test bed for this investigation. Our findings highlight the importance of modeling points of correspondence for fusion.[1]

2 Method

A PoC is a pair of text chunks that express the same or similar meanings. In Fig. 1, *Allan Donald* vs. *The 48-year-old former Test paceman*, *South Africa bowling coach* vs. *part of the coaching team* are two PoCs. The use of alternative expressions for conveying the same meanings is standard practice in writing, as it increases lexical variety and reduces redundancy. However, existing summarizers cannot make effective use of these expressions to establish correspondence between sentences, often leading to ungrammatical and nonsensical outputs.

2.1 Transformer with Linking

It is advantageous for a Transformer model to make use of PoC information for sentence fusion. While Transformer-based pretrained models have had considerable success (Devlin et al., 2019; Dong et al., 2019; Lewis et al., 2020), they primarily feature pairwise relationships between *tokens*, but not PoC mentions, which are are *text chunks* of varying size. Only to a limited extent do these models embed knowledge of coreference (Clark et al., 2019), and there is a growing need for incorporating PoC linkages explicitly in a Transformer model to enhance its ability to perform sentence fusion.

We propose to enrich Transformer's source sequence with *markups* that indicate PoC linkages. Here PoC information is assumed to be available for any fusion instance (details in §3). We introduce special tokens ([S$_k$] and [E$_k$]) to mark the start and end of each PoC mention; all mentions pertaining to the k-th PoC share the same start/end tokens. An example is illustrated in Figure 1, where *Allan Donald* and *The 48-year-old former Test paceman* are enriched with the same special tokens. We expect special tokens to assist in linking coreferring mentions, creating long-range dependencies between them and encouraging the model to use these mentions interchangeably in generation (Figure 2). The model is called "TRANS-LINKING."

Our Transformer takes as input a sequence $\mathcal{S}$ formed by concatenating the source and summary sequences. Let $\mathbf{H}^l = [\mathbf{h}_1^l, \dots, \mathbf{h}_{|\mathcal{S}|}^l]$ be hidden representations of the l-th layer of a decoder-only architecture. An attention head transforms each vector respectively into query ($\mathbf{q}_i$), key ($\mathbf{k}_j$) and value ($\mathbf{v}_j$) vectors. The attention weight $\alpha_{i,j}$ is computed for all pairs of tokens by taking the scaled dot product of query and key vectors and applying softmax over the output (Eq. (1)). $\alpha_{i,j}$ indicates the importance of token j to constructing $\mathbf{h}_i^l$ of the current token i.

$$\alpha_{i,j} = \frac{\exp(\mathbf{q}_i^\top \mathbf{k}_j/\sqrt{d_k} + \mathcal{M}_{i,j})}{\sum_{j'=1}^{|\mathcal{S}|} \exp(\mathbf{q}_i^\top \mathbf{k}_{j'}/\sqrt{d_k} + \mathcal{M}_{i,j'})} \qquad (1)$$

We utilize a mask $\mathcal{M} \in \mathbb{R}^{|\mathcal{S}|\times|\mathcal{S}|}$ to control the attention of the model (Eq. (2)). $\mathcal{M}_{i,j} = 0$ allows token i to attend to j and $\mathcal{M}_{i,j} = -\infty$ prevents i from attending to j as it leads $\alpha_{i,j}$ to be zero after softmax normalization. Similar to (Dong et al., 2019), a source token ($i \le |\mathbf{x}|$) can attend to all other source tokens ($\mathcal{M}_{i,j} = 0$ for $j \le |\mathbf{x}|$). A summary token ($i > |\mathbf{x}|$) can attend to all tokens including itself and those prior to it ($\mathcal{M}_{i,j} = 0$ for $j \le i$). The mask $\mathcal{M}$ provides desired flexibility in terms of building hidden representations for tokens in $\mathcal{S}$. The output of the attention head is a weighted sum of the value vectors $\mathbf{h}_i^l = \sum_{j=1}^{|\mathcal{S}|} \alpha_{i,j}\mathbf{v}_j$.

$$\mathcal{M}_{i,j} = \begin{cases} 0 & \text{if } j \le \max(i, |\mathbf{x}|) \\ -\infty & \text{otherwise} \end{cases} \qquad (2)$$

---

[1] Our code is publicly available at `https://github.com/ucfnlp/sent-fusion-transformers`

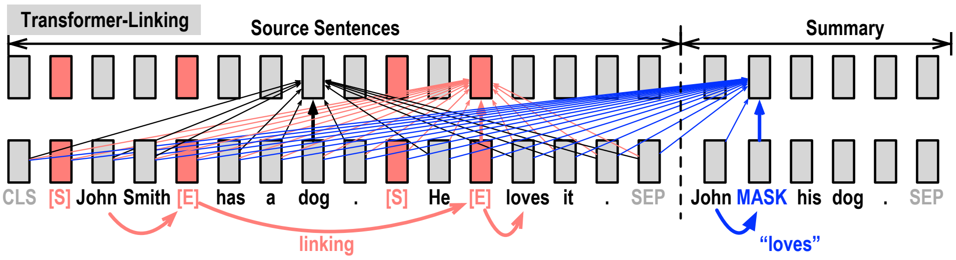

Figure 2: Our TRANS-LINKING model facilitates summary generation by reducing the shifting distance, allowing the model attention to shift from “John” to the tokens “[E]” then to “loves” for predicting the next summary word.

We fine-tune the model on a sentence fusion dataset (§3) using a denoising objective, where 70% of the summary tokens are randomly masked out. The model is trained to predict the original tokens conditioned on hidden vectors of MASK tokens: $\mathbf{o} = \text{softmax}(\mathbf{W}^O \text{GeLU}(\mathbf{W}^h \mathbf{h}^L_{\text{MASK}})))$, where parameters $\mathbf{W}^O$ are tied with token embeddings. By inserting markup tokens, our model provides a soft linking mechanism to allow mentions of the same PoC to be used interchangeably in summary generation. As shown in Figure 2, without PoC linking, the focus of the model attention has to shift a long distance from “John” to “loves” to generate the next summary word. Their long-range dependency is not always effectively captured by the model. In contrast, our TRANS-LINKING model substantially reduces the shifting distance, allowing the model to hop to the special token “[E]” then to “loves,” facilitating summary generation.

2.2 Transformer with Shared Representation

We explore an alternative method to allow mentions of the same PoC to be connected with each other. Particularly, we direct one attention head to focus on tokens belonging to the same PoC, allowing these tokens to share semantic representations, similar to Strubell et al. (2018). Sharing representation is meaningful as these mentions are related by complex morpho-syntactic, syntactic or semantic constraints (Grosz et al., 1995).

Let $\mathbf{z}$=$\{z_1, \ldots, z_{|\mathbf{z}|}\}$ be a sequence containing PoC information, where $z_i \in \{0, \ldots, \mathsf{K}\}$ indicates the index of PoC to which the token $\mathbf{x}_i$ belongs. z_i=0 indicates $\mathbf{x}_i$ is not associated with any PoC. Our TRANS-SHAREREPR model selects an attention head h from the l-th layer of the Transformer model. The attention head h governs tokens that belong to PoCs ($z_i \neq 0$). Its hidden representation $\mathbf{h}^l_i$ is computed by modeling only pairwise relationships between token i and any token j of the same PoC ($z_i = z_j$; Eq. (3)), while other tokens are excluded from consideration.

$$\mathcal{M}^h_{i,j} = \begin{cases} 0 & \text{if } i, j \leq |\mathbf{x}| \text{ \& } z_i = z_j \\ -\infty & \text{otherwise} \end{cases} \quad (3)$$

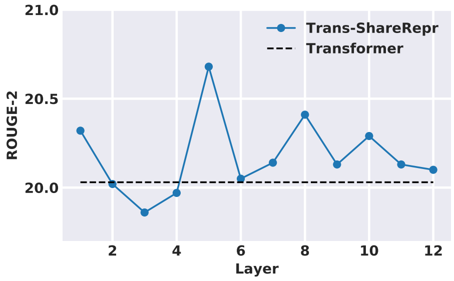

Figure 3: The first attention head from the l-th layer is dedicated to coreferring mentions. The head encourages tokens of the same PoC to share similar representations. Our results suggest that the attention head of the 5-th layer achieves competitive performance, while most heads perform better than the baseline. The findings are congruent with (Clark et al., 2019) that provides a detailed analysis of BERT’s attention.

For example, “*Allan Donald*” and “*The 48-year-old former Test paceman*” are co-referring mentions. TRANS-SHAREREPR allows these tokens to only attend to each other when learning representations using the attention head h. These tokens are likely to yield similar representations. The method thus accomplishes a similar goal as TRANS-LINKING to allow *tokens* of the same PoC to be treated equivalently during summary generation; we explore the selection of attention heads in §3.

3 Experiments

Corpus Our corpus contains a collection of documents, source and fusion sentences, and human annotations of corresponding regions between sentences. The set of documents were sampled from CNN/DM (See et al., 2017) and PoC annotations were obtained from Lebanoff et al. (2020). They use a human summary sentence as an anchor point

System	Heuristic Set R-1	Heuristic Set R-2	Heuristic Set R-L	Heuristic Set BLEU	Point of Correspondence Test Set R-1	R-2	R-L	BLEU	B-Score	#Tkns	%Fuse
Pointer-Generator	35.8	18.2	31.8	41.9	33.7	16.3	29.3	40.3	57.3	14.3	38.7
Transformer	39.6	20.9	35.3	47.2	38.8	20.0	33.8	45.8	61.3	15.1	50.7
Trans-Linking	**39.8**	**21.1**	**35.3**	**47.3**	38.8	20.1	33.9	45.5	61.1	15.1	**55.8**
Trans-ShareRepr	39.4	20.9	35.2	46.9	**39.0**	**20.2**	**33.9**	**45.8**	61.2	**15.2**	46.5
Concat-Baseline	37.2	20.0	28.7	25.0	36.1	18.6	27.8	24.6	60.4	52.0	99.7

Table 1: Results of various sentence fusion systems. We report the percentage of output sentences that are generated by fusion (%Fuse) and the average number of tokens per output sentence (#Tkns). To calculate %Fuse, we follow the same procedure used by Lebanoff et al. (2020) – a generated sentence is regarded as a fusion if it contains at least two non-stopword tokens from each sentence that do not already exist in the other sentence.

to find two document sentences that are most similar to it, which forms a fusion instance containing a pair of source sentences and their summary. PoCs have been annotated based on Halliday and Hasan's theory of cohesion (1976) for 1,494 fusion instances, taken from 1,174 documents in the test and valid splits of CNN/DM with a moderate to high inter-annotator agreement (0.58).

Automatic Evaluation We proceed by investigating the effectiveness of various sentence fusion models, including (a) **Pointer-Generator** (See et al., 2017) that employs an encoder-decoder architecture to condense input sentences to a vector representation, then decode it into a fusion sentence. (b) **Transformer**, our baseline Transformer architecture w/o PoC information. It is a strong baseline that resembles the UniLM model described in (Dong et al., 2019). (c) **Trans-Linking** uses special tokens to mark the boundaries of PoC mentions (§2.1). (d) **Trans-ShareRepr** allows tokens of the same PoC to share representations (§2.2). All Transformer models are initialized with BERT-BASE parameters and are fine-tuned using UniLM's sequence-to-sequence objective for 11 epochs, with a batch size of 32. The source and fusion sentences use BPE tokenization, and the combined input/output sequence is truncated to 128 tokens. We use the Adam optimizer with a learning rate of 2e-5 with warm-up. For PG, we use the default settings and truncate the output sequences to 60 tokens.

All of the fusion models are trained (or fine-tuned) on the same training set containing 107k fusion instances from the training split of CNN/DM; PoC are identified by the spaCy coreference resolver. We evaluate fusion models on two test sets, including a "heuristic set" containing testing instances and automatically identified PoC via spaCy, and a final test set containing 1,494 instances with human-labelled PoC. We evaluate only on the instances that contain at least one point of correspondence, so we have to disregard a small percentage of instances (6.6%) in the dataset of Lebanoff et al. (2020) that contain no points of correspondence.

Source: Later that month, the ICC opened a preliminary examination into the situation in Palestinian territories, paving the way for possible war crimes investigations against Israelis.

Israel and the United States, neither of which is an ICC member, opposed the Palestinians' efforts to join the body.

Pointer-Generator: *ICC opened a preliminary examination into the situation in Palestinian territories .*

Transformer: *Israel, U.S. and the United States are investigating possible war crimes, paving way for war crimes.*

Transformer-ShareRepr: *Israel and U.S. opposed the ICC's investigation into the situation in Palestinian territories.*

Reference: *Israel and the United States opposed the move, which could open the door to war crimes investigations against Israelis.*

Table 2: Example output of sentence fusion systems. **PG** only performs sentence shortening rather than fusion. **Transformer** fails to retain the original meaning and **Transformer-ShareRepr** performs best. **Reference** demonstrates a high level of abstraction. Sentences are manually de-tokenized for readability.

We compare system outputs and references using a number of automatic evaluation metrics including ROUGE (Lin, 2004), BLEU (Papineni et al., 2002) and BERTScore (Zhang et al., 2020). Results are presented in Table 1. We observe that all Transformer models outperform PG, suggesting that these models can benefit substantially from unsupervised pretraining on a large corpus of text. On the heuristic test set where training and testing conditions match (they both use automatically identified PoC), **Trans-Linking** performs better than **Trans-ShareRepr**, and vice versa on the final test set. We conjecture that this is because the linking model has a stronger requirement on PoC boundaries and the training/testing conditions must match for it to be effective. In contrast, **Trans-ShareRepr** is more lenient with mismatched conditions.

We include a **Concat-Baseline** that creates a fusion by simply concatenating two input sentences. Its output contains 52 tokens on average, while other model outputs contain 15 tokens. This is a 70% compression rate, which adds to the challenge of content selection (Daume III and Marcu, 2004). Despite that all models are trained to fuse sentences, their outputs are not guaranteed to be fusions and shortening of single sentences is possible. We observe that **Trans-Linking** has the highest rate of producing fusions (56%). In Figure 3, we examine the effect of different design choices, where the first attention head of the l-th layer is dedicated to PoC. We report the averaged results in Table 1.

Human evaluation We investigate the quality of fusions with human evaluation. The models we use for comparison include (a) **Pointer-Generator**, (b) **Transformer**, (c) **Trans-ShareRepr** and (d) human reference fusion sentences. Example outputs for each model can be seen in Table 2. We perform evaluation on 200 randomly sampled instances from the point of correspondence test set. We take an extra step to ensure all model outputs for selected instances contain fusion sentences, as opposed to shortening of single sentences. A human evaluator from Amazon Mechanical Turk (`mturk.com`) is asked to assess if the fusion sentence has successfully retained the original meaning. Specifically, an evaluator is tasked with reading the two article sentences and fusion sentence and answering yes or no to the following question, "Is this summary sentence true to the original article sentences it's been sourced from, and it has not added any new meaning?" Each instance is judged by five human evaluators and results are shown in Table 3. Additionally, we measure their *extractiveness* by reporting on the percentage of n-grams (n=1/2/3) that appear in the source. Human sentence fusions are highly abstractive, and as the gold standard, we wish to emulate this level of abstraction in automatic summarizers. Fusing two sentences together coherently requires connective phrases and sometimes requires rephrasing parts of sentences. However, higher abstraction does not mean higher quality fusions, especially in neural models.

Interestingly, we observe that humans do not always rate reference fusions as truthful. This is in part because reference fusions exhibit a high level of abstraction and they occasionally contain content not in the source. If fusion sentences are less extractive, humans sometimes perceive that as less truthful, especially when compared to fusions that reuse the source text. Our results call for a reexamination of sentence fusion using better evaluation metrics including semantics and question-answering-based metrics (Zhao et al., 2019; Wang et al., 2020; Durmus et al., 2020).

		Extractiveness		
System	**Truthful.**	**1-gram**	**2-gram**	**3-gram**
Pointer-Generator	63.6	97.5	83.1	72.8
Transformer	71.7	91.9	68.6	54.2
Trans-ShareRepr	70.9	92.0	70.1	56.4
Reference	67.2	72.0	34.9	20.9

Table 3: Fusion sentences are evaluated by their level of truthfulness and extractivenss. Our system fusions attain a high level of truthfulness with moderate extractivenss.

4 Conclusion

We address the challenge of information fusion in the context of neural abstractive summarization by making crucial use of points of correspondence between sentences. We enrich Transformers with PoC information and report model performance on a new test bed for information fusion. Our findings suggest that modeling points of correspondence is crucial for effective sentence fusion, and sentence fusion remains a challenging direction of research. Future work may explore the use of points of correspondence and sentence fusion in the standard setting of document summarization. Performing sentence fusion accurately and succinctly is especially important for summarizing long documents and book chapters (Ladhak et al., 2020). These domains may contain more entities and events to potentially confuse a summarizer, making our method of explicitly marking these entities beneficial.

Abstract

We propose encoder-centric stepwise models for extractive summarization using structured transformers – HiBERT (Zhang et al., 2019) and Extended Transformers (Ainslie et al., 2020). We enable stepwise summarization by injecting the previously generated summary into the structured transformer as an auxiliary sub-structure. Our models are not only efficient in modeling the structure of long inputs, but they also do not rely on task-specific redundancy-aware modeling, making them a general purpose extractive content planner for different tasks. When evaluated on CNN/DailyMail extractive summarization, stepwise models achieve state-of-the-art performance in terms of Rouge without any redundancy aware modeling or sentence filtering. This also holds true for Rotowire table-to-text generation, where our models surpass previously reported metrics for content selection, planning and ordering, highlighting the strength of stepwise modeling. Amongst the two structured transformers we test, stepwise Extended Transformers provides the best performance across both datasets and sets a new standard for these challenges.[1]

1 Introduction

Extractive document summarization is the task of creating a summary by identifying (and subsequently concatenating) the most important sentences in a document (Erkan and Radev, 2004; Nenkova and McKeown, 2011). In recent years this task has matured significantly, mostly thanks to advances in deep neural networks. Cheng and Lapata (2016) conceptualize extractive summarization as a sequence labeling task in which first a hierarchical long short-term memory network (LSTM; Hochreiter and Schmidhuber, 1997) is used to encode a document and then another LSTM is used to predict for each sentence whether it should be included in the summary. This architecture was later adopted by Nallapati et al. (2016a), Nallapati et al. (2017), Narayan et al. (2018b), Zhang et al. (2018) and Dong et al. (2018).

Following the success of pre-trained transformer-based architectures for many tasks (Vaswani et al., 2017; Devlin et al., 2019), the current state-of-the-art approach to extractive summarization uses transformers to learn sentence representations and to rank sentences by their saliency (Liu, 2019; Liu and Lapata, 2019b; Zhang et al., 2019; Zhong et al., 2019a; Bi et al., 2020). The top scoring sentences are then assembled to produce an extract of the document. Summaries built in this fashion (Cheng and Lapata, 2016; Narayan et al., 2018a; Zhang et al., 2018; Dong et al., 2018) are prone to contain redundant information. Several recent approaches have explored mechanisms to better handle redundancy, such as heuristic-based Trigram Blocking (TriBlk; Liu and Lapata, 2019b; Wang et al., 2020), hand-crafted feature-driven models (Ren et al., 2017) and redundancy aware neural sequence models (Zhou et al., 2018; Bi et al., 2020). One common problem with these models is that their focus is limited to content overlap and to respecting length budgets. However, these are but a small subset of the dimensions necessary to produce informative and coherent summaries. Ideally, models would utilize enriched document and summary representations in order to implicitly learn better extractive plans for producing summaries (Liu et al., 2019a; Mendes et al., 2019). One such method is *stepwise* summarization (Liu et al., 2019a), where a summary is constructed incrementally by choosing new content conditioned on previously planned content.

In this paper, we propose encoder-centric stepwise models for extractive summarization using

structured transformers. Structured transformers are transformer-based architectures that have the flexibility to model some form of structure of the input, e.g., hierarchical document structure. In this paper, we specifically study two such architectures – HiBERT (Zhang et al., 2019) and Extended Transformers Construction (ETC; Ainslie et al., 2020). Details of these are given in Sections 4 and 5. We enable stepwise summarization by injecting the previously planned summary content into the structured transformer as an auxiliary sub-structure. The model then can holistically learn any document-level coherence properties, such as saliency, redundancy, and ordering, embodied in the gold summaries. This differs from other methods which are either task specific (e.g., redundancy aware modeling in Bi et al., 2020) or not holistic (e.g., manually curated features in Liu et al., 2019a). An added advantage of structured encoders is that they break the quadratic attention mechanism of transformers (Devlin et al., 2019), making them more efficient and able to process longer inputs, instead of truncating the inputs to 512 tokens (Liu and Lapata, 2019b; Bi et al., 2020), which is critical for long inputs and outputs which require non-trivial planning. When evaluated on the CNN/DailyMail summarization dataset (Hermann et al., 2015), we achieve state-of-the-art performance in terms of Rouge (Lin and Hovy, 2003) without any redundancy (Zhou et al., 2018; Bi et al., 2020) or sentence selection mechanisms (Liu and Lapata, 2019b).

Our model's task-agnostic approach allows it to implicitly learn and leverage content plans directly from the data. Moreover, structured transformers form the basis of our model, which are flexible in terms of content type (e.g., text or tables) that can be modeled. We demonstrate this by learning intricate extractive content plan for the Rotowire table-to-text generation task (Wiseman et al., 2017). This task requires the generation of long summaries from large score tables detailing the the specifics of a sports match, which often necessitates dedicated content selection and planning models to generate a high-quality summary (Wiseman et al., 2017; Puduppully et al., 2019a). We show that our stepwise framework achieves higher content selection, planning and ordering scores relative to prior work with task-specific planning mechanisms.

The contributions of the paper are as follows: 1) this is first study to use ETC (Ainslie et al., 2020) for summarization for its ability and flexibility to better model long and structured inputs; 2) we propose augmentions of two structured transformers, HiBERT and ETC, in order to enable stepwise models for extractive planning; 3) we demonstrate empirically that our models are general purpose and can be adapted as an extractive document summarizer or as a content planner for table-to-text generation; 4) Our experiments highlight the effectiveness of stepwise modeling, specifically stepwise ETC, which sets a new standard for both tasks.

2 Related Work

Redundancy. Summarization models often use a dedicated *sentence selection* step after *sentence scoring* to address redundancy. Maximal Marginal Relevance (Carbonell and Goldstein, 1998) based methods select the content that has the maximal score and is minimally redundant with the previously constructed partial summary. Others treated sentence selection as an optimization problem under some constraints such as summary length (McDonald, 2007; Lin and Bilmes, 2011). Liu and Lapata (2019b) and Wang et al. (2020) used heuristic-based Trigram Blocking (TriBlk) for redundancy elimination. Ren et al. (2017) trained two neural networks with handcrafted features; one is used to rank sentences, and the other one is used to model redundancy during sentence selection. Zhou et al. (2018) and Bi et al. (2020) proposed redundancy-aware models by modeling redundancy and saliency jointly during the scoring process using neural sequence models. In contrast to these approaches, our models are not redundancy-aware. Instead, they implicitly model redundancy by injecting previously generated summary representations. By virtue of this our models are not text-specific and can be applied to other tasks (see Section 7).

Partial Summary Representations. Ultilizing representations of partially generated summaries is relatively less studied in summarization. Mendes et al. (2019) proposed to dynamically model the generated summary using an LSTM to iteratively increment summaries based on previously extracted information. Liu et al. (2019a) used a feed-forward neural network driven by hand-curated features capturing the prevalence of domain subtopics in the source and the summary. To the best of our knowledge, our models are first to use summary representations with structured transformers for summarization. Our models learn to make summary-informed next-sentence predictions without any hand-curated features.

Long-form Summarization. It is well known that a better content selection benefits abstractive summarizers to generate summaries that are not only fluent but also informative (Gehrmann et al., 2018; Hsu et al., 2018; Xiao et al., 2020). It can be particularly important when generating long abstractive summaries (Liu et al., 2018; Liu and Lapata, 2019a) or summarizing multiple documents (Yasunaga et al., 2017). Earlier multi-document summarization methods have addressed the issue of long form input by graph-based representations of sentences or passages (Erkan and Radev, 2004; Christensen et al., 2013). Recently, Yasunaga et al. (2017) proposed a neural version of this framework using graph convolutional networks (Kipf and Welling, 2017). Liu and Lapata (2019a) used cross-document attention mechanism to share information as opposed to simply concatenating text spans using hierarchical transformers. Similar to this motivation, we also explore better encoding of long inputs with structured transformers.

Table-to-Text Content Planning. Wiseman et al. (2017) introduced the Rotowire dataset, which requires multi-sentence summaries of large tables. Several works found that the key to generate fluent and informative summaries for this task is to have dedicated content planning and realization steps (Puduppully et al., 2019a,c; Miculicich et al., 2019). Miculicich et al. (2019) and Gong et al. (2019b) used a transformer encoder, and, Gong et al. (2019a) used multi-dimensional hierarchical LSTM encoders to compute better table entry representations. Following these lines of work, we evaluate our models to generate long content plans for this task using structured transformers.

3 Problem: Stepwise Content Extraction

We define a general paradigm for stepwise content extraction that can be easily tailored to both extractive summarization and table-to-text generation. Given an input $D = \{s_1, s_2, \ldots, s_n\}$ with n content units, the goal is to learn an extractive content plan, i.e., $S'_m = \{s'_j | 1 \leq j \leq m, s'_j \in (D \cup \{\emptyset\})\}$, of length m; s'_m is an empty unit ($\emptyset$) denoting the end of the plan. We formulate this as an iterative ranking problem (Liu et al., 2019a; Bi et al., 2020) where at each k-th step ($1 \leq k \leq m$) given the input D and the previously selected plan S'_{k-1}, we select $s'_k \in (D \cup \{\emptyset\})$ with a probability $p(s'_k | S'_{k-1}, D; \theta)$ with model parameters θ. The selected content is then added to S'_{k-1} to construct S'_k. The best plan $\hat{S}$ can be defined as:

$$\hat{S} = \arg\max_{S'_m, \forall m} \prod_{k=1}^{m} P(s'_k | S'_{k-1}, D; \theta).$$

For extractive document summarization, let $D = \{s_1, s_2, \ldots, s_n\}$ be a document with n sentences. Our goal is to learn an extractive plan (or summary in this case) $\hat{S}$ which best summarizes D. For table-to-text generation, we represent a table with n records as $D = \{s_1, s_2, \ldots, s_n\}$. We aim to generate a plan S'_m that can be used by a text generator to generate a meaningful and coherent summary.

For exposition, we use the extractive document summarization setup to introduce our stepwise models with HiBERT (Zhang et al., 2019) and ETC (Ainslie et al., 2020) in the following sections. Specifically, we use 'sentence' as a content unit and 'previously' or 'partially generated summary' for a previously selected content plan.

4 Stepwise HiBERT

Hierarchical encodings have been used to model input structure with LSTMs (Nallapati et al., 2016b; Cheng and Lapata, 2016; Narayan et al., 2018b). Zhang et al. (2019) proposed **HiBERT** with two stacked Transformer encoders (Vaswani et al., 2017) for extractive summarization (see the middle diagram in Figure 1): a *sentence encoder* that *independently* builds representations for each sentence in the document; and a *document encoder* that operates over sentence encodings to build contextual representations for all sentences. These contextual sentence representations are then ingested by a classifier to predict the salience score of each sentence in the document. As in standard transformers, both encoders have multiple layers with each layer composed of a multi-head self-attention layer followed by a feed-forward sub-layer with residual connections (He et al., 2015) and layer normalizations (Ba et al., 2016). For **Stepwise HiBERT**, at time step k, we modify the document encoder with the content plan S'_{k-1}, which is the previously selected sentences in the summary. This is depicted in Figure 2 (left) and allows the model to implicitly select new sentences relative to the previously generated summary.

Sentence and Document Encoders. Let $D = \{s_1, s_2, \ldots, s_n\}$ be a document, where $s_i = \{w^i_1, w^i_2, \ldots, w^i_{|s_i|}\}$ is a sentence in D and w^i_j is a token in s_i. s_i is first mapped to a continuous space $\mathbf{E}_{s_i} = \{\mathbf{e}^i_1, \mathbf{e}^i_2, \ldots, \mathbf{e}^i_{|s_i|}\}$ where $\mathbf{e}^i_j = \mathbf{e}(w^i_j) + \mathbf{p}^{\text{token}}_j$. $\mathbf{e}(w^i_j)$ and $\mathbf{p}^{\text{token}}_j$ are the token

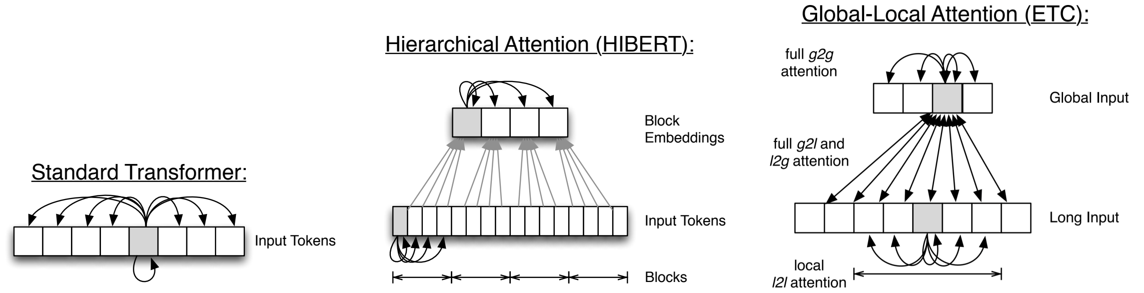

Figure 1: Memory usage and attentions in standard transformers (Devlin et al., 2019), HiBERT (Zhang et al., 2019) and ETC (Ainslie et al., 2020).

and positional embeddings of token w_j^i, respectively. Our Transformer-based sentence encoder then transforms $\mathbf{E}_{s_i}$ into a list of hidden representations $\{\mathbf{h}_1^i, \mathbf{h}_2^i, \dots, \mathbf{h}_{|s_i|}^i\}$, where $\mathbf{h}_j^i$ is the hidden representation for w_j^i. Following the standard practice (Devlin et al., 2019; Liu and Lapata, 2019b), we take the first hidden representation $\mathbf{h}_1^i$ as the representation for the sentence s_i.

Zhang et al. (2019) use a standard Transformer document encoder. It takes the document representation $\hat{\mathbf{H}}_D = \{\hat{\mathbf{h}}^1, \hat{\mathbf{h}}^2, \dots, \hat{\mathbf{h}}^n\}$, where $\hat{\mathbf{h}}^i = \mathbf{h}_1^i + \mathbf{p}_i^{\text{sent}}$. $\mathbf{h}_1^i$ and $\mathbf{p}_i^{\text{sent}}$ are the representation from the sentence encoder and the positional embedding for sentence s_i in the document, respectively, and, builds contextual sentence representations $\{\mathbf{d}_1, \mathbf{d}_2, \dots, \mathbf{d}_n\}$.

Stepwise Modeling. At step k, let $S'_{k-1} = \{s'_1, s'_2, \dots, s'_{k-1}\}$ be the partial summary with $(k-1)$ previously extracted sentences. In addition to $\hat{\mathbf{H}}_D$, our document encoder takes the summary representation $\hat{\mathbf{H}}_{S'_{k-1}} = \{\hat{\mathbf{x}}^1, \hat{\mathbf{x}}^2, \dots, \hat{\mathbf{x}}^{k-1}\}$, where $\hat{\mathbf{x}}^i = \mathbf{h}_1^i + \mathbf{p}_i^{\text{sum}}$. $\mathbf{h}_1^i$ is the representation from the sentence encoder for sentence s_i and $\mathbf{p}_i^{\text{sum}}$ is the positional embedding for sentence s_i in S'_{k-1}. At each layer, the document encoder employs three levels of nested multi-headed attentions (Vaswani et al., 2017) to build summary-informed contextual sentence representations $\{\mathbf{d}'_1, \mathbf{d}'_2, \dots, \mathbf{d}'_n\}$: *document self-attention*, *summary self-attention* and *document-summary attention* (see Figure 2, left). The first two operate in parallel, followed by the document-summary attention.

While document self-attention learns the contextual hidden representation $\mathbf{h}_{s_i}^{\text{doc}\to\text{doc}}$ of each sentence in the document D, summary self-attention learns the contextual hidden representation $\mathbf{h}_{s'_i}^{\text{sum}\to\text{sum}}$ of each sentence in S'_{k-1}. We share the parameters of the document and summary self-attention layers. The document-summary attention then builds the contextual hidden representation $\mathbf{h}_{s_i}^{\text{doc}\to\text{sum}}$ of each sentence in the document D using linear projections of $\mathbf{h}_{s_i}^{\text{doc}\to\text{doc}}$ as query, and $\mathbf{h}_{s'_i}^{\text{sum}\to\text{sum}}$ as key and values (Vaswani et al., 2017).

In addition to the introduction of stepwise mechanism to HiBERT, our positional embeddings, $\mathbf{p}_j^{\text{token}}$, $\mathbf{p}_j^{\text{doc}}$ and $\mathbf{p}_j^{\text{sum}}$, are not shared to better model individual sentences, the document and the different styles of summary. Zhang et al. (2019) shared their token ($\mathbf{p}_j^{\text{token}}$) and sentence ($\mathbf{p}_j^{\text{sent}}$) positional embeddings. But we both use the absolute position encodings used in the original BERT model (Devlin et al., 2019).

5 Stepwise ETCSum

There has been growing interest in addressing the limitation of the transformer architecture used in BERT (Devlin et al., 2019) where memory usage scales quadratically with the size of the input (Guo et al., 2019; Dai et al., 2019; Ye et al., 2019; Child et al., 2019; Rae et al., 2020; Beltagy et al., 2020; Roy et al., 2020). HiBERT alleviates this problem by modeling each sentence independently; the memory usage in HiBERT scales with the square of the number of sentences, and the square of the maximum length of any sentence. However, the main disadvantage of this approach is that token-level attention across sentences is prohibited and long range attention only happens indirectly at the second-stage encoder (see the middle diagram in Figure 1). Recently, Extended Transformer Construction (ETC; Ainslie et al., 2020) provides an alternative. It alleviates the quadratic memory growth by introducing sparsity to the attention mechanism via its novel global-local attention mechanism (see the rightmost diagram in Figure 1). This not only permits encoding of long inputs,[2] but also enables a mechanism to model structure directly through nodes in the global attention layer.

---

[2] As do other recent architectures (Yang et al., 2019; Kitaev et al., 2020).

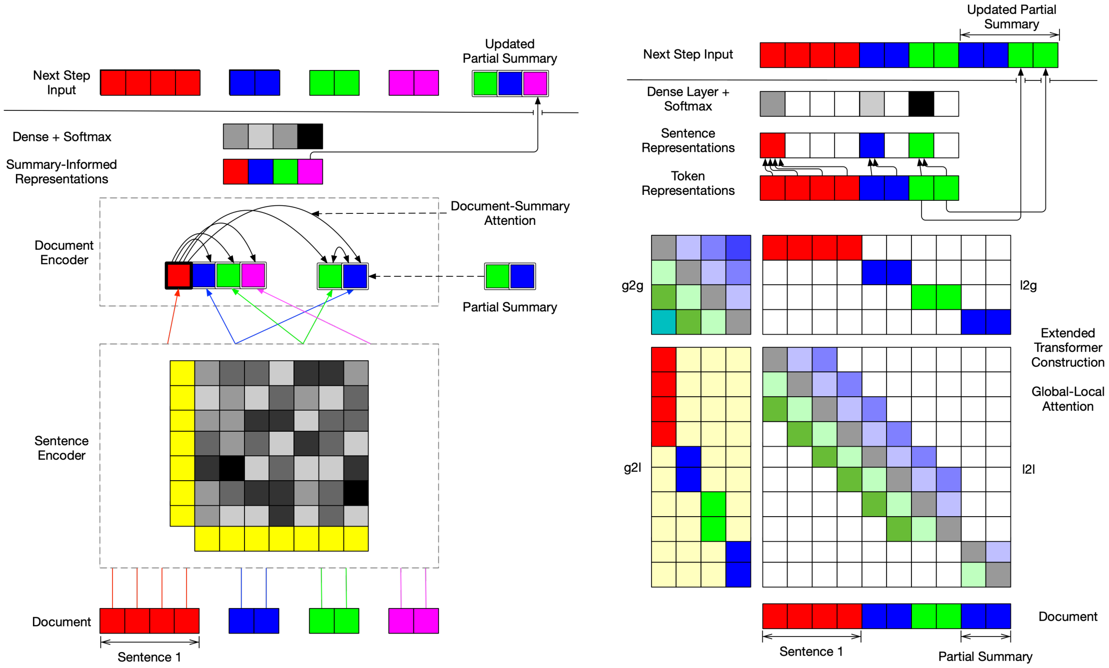

Figure 2: Stepwise HiBERT (left) and ETCSum (right) models. HiBERT builds summary informed representation by jointly modeling partially generated summary and the document during document encoding, while ETCSum takes as input the document appended with the partially generated summary.

Global-Local Attention. The ETC model architecture receives two inputs: a long input, which in most cases corresponds to the text to be encoded; and an auxiliary global input, which serves as inductive bias features. First, the model builds an attention map, called *long-to-long*, across the long input with a sparse local attention of fixed length, this bypasses the quadratic memory complexity and allows to scale input lengths to the thousands of tokens, but limits the attention span of tokens to their nearest neighbors.

To overcome this limitation, the global-local attention defines three other attention parts: *global-to-global*, *global-to-long* and *long-to-global*, all with unrestricted attention. This allows tokens arbitrarily far apart to attend to each other with at most one hop through the global input tokens. We refer the reader to Ainslie et al. (2020) for more details. The right parts of Figures 1 and 2 illustrate these four types of attentions and the sparsity diagrams where each cell in a row i and column j is different than white input token w_i can attend to input token w_j, same relative position embeddings are indicated by using the same color.

Stepwise Modeling. Given the document D and its partial summary S'_{k-1} at step k, we construct an input $I = D^\frown S'_{k-1} = \{w_1, \ldots, w_{|D^\frown S'_{k-1}|}\}$ by concatenating the document D and the partial summary S'_{k-1}. ETC replaces absolute position encodings with relative position encodings (Shaw et al., 2018) to easily adapt to greater input lengths than seen during pretraining. In addition to modeling relative positions in an input sequence, relative position encodings in ETC are also used to model arbitrary pairwise token relations useful for structured inputs.

We used the auxiliary global input to represent sentence structure. Specifically, following (Ainslie et al., 2020), we placed one auxiliary token in the global input per each sentence in the input I. We linked the global tokens with the input tokens by using relative position labels to represent whether each token belongs to that sentence. Global-to-global attention is left unrestricted, allowing all sentences to attend to each other. This result is summary-informed contextualized input token representations via attention through the global nodes. In the rest of the paper we refer to this summarizer by **Stepwise ETCSum**. Similar to HiBERT, we take the first token hidden representation $\mathbf{h}_1^i$ as the representation for the sentence s_i. Finally, sentence embeddings are passed to the softmax layer for salience scoring. Both HiBERT and ETCSum are then trained with the cross entropy loss.

6 Extractive Document Summarization

6.1 Experimental Setup

Dataset. We evaluate our models on the CNN and DailyMail news highlights datasets (Hermann et al., 2015). We used standard splits

(287,227/13,368/11,490 documents) for training, validation, and testing. We did not anonymize entities or lower case tokens as in (Narayan et al., 2018b; Zhou et al., 2018; Zhang et al., 2019; Liu and Lapata, 2019b). The documents in the CNN/DailyMail dataset are long; the average lengths are 760.5 words (34 sentences) for CNN and 653.3 words (29.3 sentences), for DailyMail. The human written abstracts have 46 and 55 words for CNN and DailyMail, respectively. We evaluated summarization quality using F_1 Rouge.[3]

Baselines. We compared our Stepwise HiBERT and ETCSum models to Lead and Oracle baselines. Lead selects the first 3 sentences to form the summary, while Oracle baselines creates a summary by selecting the best possible set of sentences in the document that gives the highest average of Rouge-1, Rouge-2 and Rouge-L F1 scores with respect to the human written summary. The Oracle (512) truncates the input document to 512 tokens. We further compared our models against several redundancy-aware models (NeuSum; Zhou et al., 2018 and ARedSum; Bi et al., 2020) and models that uses Trigram Blocking (TriBlk; Liu and Lapata, 2019b) for redundancy elimination during sentence selection (see the second block in Table 1).

To understand the importance of modeling long documents for extractive summarization, we also trained BERTSum, similar to Liu and Lapata (2019b), with a receptive capacity of 512 tokens initialized with the BERT checkpoint. Our BERTSum differs slightly from Liu and Lapata (2019b), in that we don't use segment embeddings. We also report on RoBERTa (Liu et al., 2019b) initialized version of BERTSum (RoBERTaSum).

We also trained non-stepwise variants of HiBERT and ETCSum models (the third block in Table 1). In this setting, HiBERT and ETC do not take partial summaries as input. Instead, they simply take the input document and generate salient scores (using a sigmoid layer) for each sentence in the document; the top three sentences are then assembled to generate the summary. Our implementation of HiBERT differs from Zhang et al. (2019). For example, we don't pretrain HiBERT from scratch for document modeling as in Zhang et al. (2019). Instead, we initialize our HiBERT models with publicly available RoBERTa (Liu et al., 2019b) checkpoints following the superior performance of RoBERTaSum over BERTSum. We use different number of layers in the document encoder (L_{doc} = 3) and in the sentence encoder (L_{sent} = 9), as opposed to equal number of layers (L = 6) in both encoders of Zhang et al. (2019). The layers in the document and sentence encoders were initialized with the top and the bottom layers of RoBERTa, respectively. All ETCSum models were initialized with the uncased version of ETC pretrained checkpoints (Ainslie et al., 2020) pretrained using the standard masked language model task and the contrastive predictive coding (van den Oord et al., 2018).[4]

Models	R1	R2	RL
Lead	40.42	17.62	36.67

Stepwise ETCSum+TriBlk	43.23	20.30	39.15

Table 1: Rouge F1 scores on the CNN/DailyMail test set. Boldfaced numbers are the best results among comparable models. * BERTSum Large builds on BERTLarge (24 layers) architectures, whereas ours build on BERTBase (12 layers) architectures.

We also report on the effect of TriBLK with all our models. We only experiment with the base-sized models and therefore have 12 layers, a hidden size of 768, filter size of 3072, and 12 attention

---

[3] We lowercased candidate and reference summaries and used `pyrouge` with parameters "-a -c 95 -m -n 4 -w 1.2."

[4] We thank the authors (Ainslie et al., 2020) for sharing their ETC checkpoints with us.

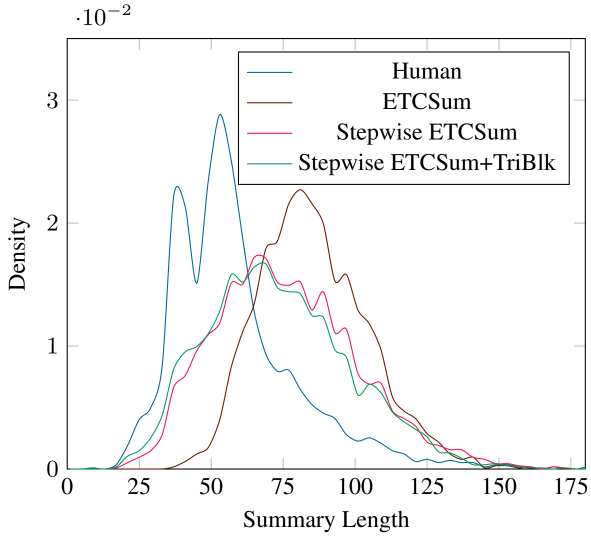

Figure 3: Length distributions in ETCSum summaries on the CNN/DailyMail test set.

heads. For comparison, we report results from BERTSum Large (Liu and Lapata, 2019b) which uses 24 layers. Finally, we employ a beam decoding to predict summaries using our stepwise models; we use a beam size of 3 for a maximum of 4 steps. We don't allow repeated sentences, though this is not a requirement. We refer the reader to the supplementary material for implementation and reproducibility details.

Generating Extractive Oracles. Following Narayan et al. (2018b), we train models to predict all sentences in Oracle (Full) for non-stepwise training. Stepwise training learns to do this gradually: at each step, we train model to predict the next sentence in Oracle (Full) using the earlier predicted sentences and the document. During testing, human written abstracts are used as reference summaries to evaluate our models.

6.2 Results

Long form Summarization. In our experiments, ETCSum appears to be far more superior than HiBERT when modeling long documents for extractive summarization; ETCSum outperformed HiBERT in all cases including stepwise or non-stepwise predictions, and, with or without trigram blocking. The downside of HiBERT where token-level attention across sentences is not possible, is not optimal for modeling documents. Both ETCSum and ETCSum+TriBlk performed better than BERTSum and BERTSum+TriBlk, respectively. These results suggest the importance of modeling the whole document with ETCSum, rather than truncating it to only 512 tokens to fit BERTSum. However, the improvement may not be attributed solely to ETCSum's ability to model long inputs, but also to its better initialization with ETC checkpoints (Ainslie et al., 2020), specially when the improvement diminishes when compared against RoBERTaSum.[5]

Stepwise vs Non-stepwise models. First of all, trigram filtering seems to be the key in addressing redundancy in generated summaries in non-stepwise models. It helps almost all models including our HiBERT and ETCSum (except for the single case of RoBERTaSum on Rouge-2). Interestingly, we don't observe the same pattern for our stepwise models. We observe that our stepwise models (both HiBERT and ETCSum, without TriBlk) consistently improve over their non-stepwise counterparts. But when stepwise is applied with TriBlk, we don't always see improvements. We conjecture that our stepwise models themselves are inherently better at avoiding redundancy in generated summaries due to the knowledge of previously generated summary at each prediction step, and improvements with TriBlk are not always complementary. The same is also demonstrated in Figure 3; density curves show that Stepwise ETCSum (avg:76.96, std:24.77) follows the human distribution (avg:58.3, std:24.8) better than ETCSum (avg:85.84, std:19.06). With Stepwise ETCSum+TriBlk (avg:73.92, std:24.76), we don't see significant improvement over Stepwise ETCSum.

We also report on Stepwise RoBERTaSum baselines and performance dropped compared to corresponding non-stepwise models. Perhaps without any structure in the transformer, simple summary concatenation is not a good method for Stepwise RoBERTaSum to distinguish the document from the summary. There might be better ways (than the vanilla concatenation), but with Stepwise ETCSum or HiBERT, it is very natural. Stepwise RoBERTaSum also loses access to the end of the input as the partial summary grows for documents that are already close to 512 tokens in length.

Finally, our Stepwise ETCSum model without any explicit redundancy or sentence selection mechanisms, achieved comparable performance to the state of the art on the CNN/DailyMail

---

[5] One may consider to access the modeling of long inputs in ETCSum against the truncated inputs in BERTSum and RoBERTaSum, by initializing ETCSum with BERT or RoBERTa checkpoints, and not ETC checkpoint. However, this is not fair to ETCSum as BERT or RoBERTa uses absolute position embeddings (Devlin et al., 2019), whereas, ETC uses relative position embeddings (Shaw et al., 2018).

Models	RG		CS		CO	BLEU

Table 2: Standard metrics for Rotowire: relation generation (RG) precision (P%), content selection (CS) precision (P%) and recall (R%), content ordering (CO) via the complement of normalized Damerau-Levenshtein distance (DLD%), and BLEU score. Models marked with a * are not directly comparable. Boldfaced numbers are the best results among comparable models.

extractive summarization task with a smaller model; BERTSum Large (Liu and Lapata, 2019b) with 340m parameters achieved 43.85/20.34/39.90 R1/R2/RL scores, whereas ours with 165m parameters achieved 43.84/20.80/39.77. Comparatively, Stepwise HiBERT did not do equally well on document summarization due to the sequential nature of the input. However, we demonstrate in Section 7 that it is well suited as an extractive content planner for table-to-text generation.

ROUGE scores in Table 1 are computed with a confidence interval of 95%. As such, Stepwise ETCSum(+TriBlk) is significantly better than BERTSum(+TriBlk), all variants of HierBERT, ETCSum and Stepwise RoBERTaSum(+TriBlk). For other models, such as RoBERTaSum(+TriBlk) and ETCSum+TriBlk, this confidence interval is not a deciding factor, hence we performed One-way ANOVA with posthoc Tukey-HSD tests ($p < 0.01$). Our best model Stepwise ETCSum performs significantly better than RoBERTaSum(+TriBlk), ETCSum+TriBlk and Stepwise ETCSum+TriBlk, on the average of ROUGE scores.

7 Table-to-Text Generation

Task. We further explore our model's ability to learn content plans for the Rotowire data-to-text generation task (Wiseman et al., 2017).[6] The task is to generate a summary of an NBA game from its box score (a table of statistics detailing the performance of the two teams and of each player). The dataset consists of 4853 pairs of box scores and summaries of NBA games played from 2014 to 2017. The data is split into 3398 train, 727 validation and 728 test examples. On average there are 628 records in a box score per game. The average summary has 337.1 words and 13.49 sentences.

Similar to Puduppully et al. (2019a) we decompose the problem into two sub-problems, which we solve independently: content planning, which consists of selecting which records in the table should be mentioned in the summary, in what order, and how they should be organized into sentences; and realization, which uses the content plan to create a human-readable summary. We refer the reader to the supplementary material for an example. Our main focus in this paper is to demonstrate our models' ability to model long and structured Rotowire input tables, and generate long meaningful content plans. For realization, we simply use a RoBERTa (Liu et al., 2019b) initialized sequence-to-sequence transformer model (Rothe et al., 2020), trained to emit the realization sentence by sentence.

We train our stepwise models to take a score table and the partially generated content plan, and predict the next element in the content plan. This can be either one of the entries in the score table, a sentence break or a token marking the end of the plan. Unlike extractive summarization, here an optimal extractive content plan can have repeated entries from the input table (e.g. team names) to better preserve and generate discourse relations among sentences in the target summary (Puduppully et al., 2019b), making it a challenging task for other iterative models that prohibit redundancy, e.g., (Bi et al., 2020). For details about model implementation, realization, and the induction of oracle content plans for training, we refer the reader to the supplementary material.

We report typical Rotowire metrics (Wiseman et al., 2017), using the standard information extraction system described by Puduppully et al. (2019a)

---

[6] The Rotowire dataset is available for download at `https://github.com/harvardnlp/boxscore-data`.

to extract the box score table relations mentioned in the generated (G) and in the target (T) summary. The metrics measure: text quality (BLEU score between G and T); relation generation quality (the precision of the relations extracted from G against the box score table); content selection quality (the precision and recall of the relations extracted from G against those extracted from T); and content ordering quality (the complement of the normalized Damerau-Levenshtein distance on the sequences of relations extracted from G and T). We also conducted human evaluation of Rotowire summaries.

Results. We focus on evaluating our Stepwise HiBERT and ETCSum models.[7] Our results are presented in Table 2. The "realized" scores assess the quality of our realized summaries and are comparable to systems in the first block in Table 2. We found both Stepwise HiBERT and Stepwise ETCSum do content selection particularly well. Their very high precision scores (41.49% and 45.79%, respectively) combined with good recall (53.86% and 58.49%, respectively) outperform Puduppully et al. (2019a) and other recent models on F1 score. In terms of content ordering and BLEU score, Stepwise HiBERT (14.79 BLEU, 18.10% DLD) performs worse than Puduppully et al. (2019a) (16.50 BLEU, 18.58% DLD), while Stepwise ETCSum performs significantly better (17.56 BLEU, 25.08% DLD). It's possible that a higher BLEU score could be achieved by improving our simple sentence-by-sentence realization method.

We also report content selection scores for the output of the content planning modules (see "planning only" models in Table 2). We drop name, city and date entries from our content plans before computing the metrics in order to make them comparable with others in Table 2. We see the roundtrip of realization and subsequent information extraction decreases CS quality slightly for both models (the absolute drop of F1 score is 1.68% for Stepwise HiBERT, and 1.74% for Stepwise ETCSum).

Human Evaluation. Participants were shown two summaries of an NBA game and asked to compare them with respect to *informativeness* (Does a summary present a better selection of the relevant facts about the game?) and *readability* (Which summary has a better narrative flow and is easier to read?). We randomly selected 50 NBA tables and evaluated summaries from Baseline (Wiseman et al., 2017), Stepwise HiBERT, Stepwise ETC and Gold. The average(max;min) number of sentences were 8(8;8), 12.7(17;9), 16.7(25;10) and 12.0(20;6), for Baseline, Stepwise HiBERT, Stepwise ETC, and Gold, respectively. We also included truncated summaries from Stepwise HiBERT and Stepwise ETC to match the number of sentences in corresponding Gold summaries. We elicited judgements from three different annotators for each pair. We report the Best(1)-Worst(-1) Scaling scores (Louviere and Woodworth, 1991; Louviere et al., 2015). Results are presented in Table 3.

Models	Informativeness	Readability
Baseline	0.06	**0.22**
Stepwise HiBERT	0.17	0.00
+truncated	-0.34	0.04
Stepwise ETCSum	**0.29**	-0.13
+truncated	-0.10	-0.08
Gold	-0.09	-0.03

Table 3: Human evaluation of Rotowire Summaries.

Overall, Stepwise ETC summaries were ranked most informative, but they performed worst on readability. The off-the-shelf sentence-level realizer (see the supplementary material) favors the statistics-dense sentences of the baseline summaries, as it tends to hallucinate on less dense plans. Future work will aim to address this limitation. For informativeness, Stepwise ETC summaries are significantly better than Gold, Stepwise ETC truncated and Stepwise HiBERT truncated summaries. Stepwise HiBERT summaries are significantly better than both truncated variants. All other differences are not significant ($p < 0.05$). For readability, baseline summaries are significantly better than both ETC variants and Stepwise HiBERT. All other differences are not significant.

8 Conclusion

The stepwise structured transformer paradigm, exemplified by HiBERT and ETCSum, can be easily adapted both to extractive document summarization or content planning for table-to-text generation. Stepwise ETCSum, in particular, sets a new standard for both tasks. Future work will focus on extending our models to generate extractive plans for better abstractive summarization of long or multiple documents (Liu et al., 2018).

---

[7] We don't reproduce BERTSum or RoBERTaSum baselines here for two reasons: i) these sequential models are not optimal for tabular data, and ii) they are also bounded by an input length of 512 tokens, the average length of linearized score tables is 7184 tokens per game. We also don't report on our non-stepwise models as they are not suitable to generate ordered content plans as required for this task.

Acknowledgments

We thank Joshua Ainslie and Santiago Ontanon for sharing their ETC code and checkpoints, and also giving us feedback on an early draft of this paper. We thank Annie Louis, the London and Zurich Generation teams, the reviewers and the action editor for invaluable feedback. We thank Enrique Alfonseca and Hadar Shemtov for their support for Longform Summarization.

A Implementation and Reproducibility details

A.1 HiBERT

We did a wide range of hyperparameter search for HiBERT. We experimented with the number of layers in the document encoder ($1 < L_{\text{doc}} < 12$); the number of layers in the sentence encoder ($1 < L_{\text{sent}} < 12, L_{\text{doc}} < L_{\text{sent}}$); the initialization and sharing of position embeddings, $\mathbf{p}_j^{\text{token}}$, $\mathbf{p}_j^{\text{doc}}$ and $\mathbf{p}_j^{\text{sum}}$; the initialization and sharing of document and sentence encoder parameters with BERT and RoBERTa checkpoints; and the representation of sentence ("first token embedding" or "average of all token embeddings") from the sentence encoder.

For extractive summarization, we used HiBERT with a 8 transformer layer sentence encoder, and a 4 transformer layer document encoder. The model has 133,784,833 parameters. The word position embedding in the sentence encoder is initialized using the RoBERTa checkpoint, but the document and summary sentence position embeddings are learned from scratch. The document self attention and summary self attentions are shared and initialized using the RoBERTa checkpoint, the document-summary attention is also initialized using the RoBERTa checkpoint. We truncate each document to 128 sentences and each sentence to 32 words. We trained all HiBERT models for 100k steps saving checkpoints every 1000 steps, with a batch size of 32. Following Liu and Lapata (2019b), we choose the best model based on the MLE loss on the whole validation set.

For Rotowire, we use HiBERT with a 2 transformer layer sentence encoder, and a 4 transformer layer document encoder. The model has 91,448,065 trainable parameters. We don't use the document sentence position embeddings for Rotowire as the input consists of a set of entries in a table. We use the summary sentence position embedding to capture the order in the content plan. We use the ROBERTA vocabulary, but as discussed in B.3 we don't use ROBERTA pretraining, instead initializing with random weights. We trained the model with a batch size of 128 until the AUC score for predicting the next content plan entry on the validation dataset flattened out, which came after 766K steps. Since the dataset has 246290 examples (one for each element in the target content plan for each Rotowire example), the model saw the entire dataset approximately 398 times.

For all HiBERT models, we used Cloud TPU v3 accelerators for training and the Adam optimizer with a learning rate of 0.01.

A.2 ETCSum

The ETCSum model for both extractive summarization and table-to-text generation uses a 12 layer transformer as described in (Ainslie et al., 2020). The model is pretrained with MLM and CPC objectives as described in (Ainslie et al., 2020). In total, the model has 165,825,793 trainable parameters which mostly comes from the long input of 8192 tokens and the full attention of 512 of the global tokens. We trained our model with a batch size of 512 for 5,000 steps approximately equivalent to 10 epochs.

We used Cloud TPU v3 accelerators for training and inference was done on a V100GPU taking 10 hours to get predictions for the test set.

Model selection was done over models Rouge-1 performance in the validation set for all models except stepwise models where a subset of the validation set was used instead, consisting of the first 1000 examples, given the longer inference times.

We did a wide range of hyperparameter search where we experimented with learning rate (0.000025, 0.00005, 0.0001), relative position encoding vocabulary size (12, 24), the representation of sentences ("first token embedding" or "average of all token embeddings") from the sentence encoder and in additionally non-stepwise models we experimented with positive label weight used to for loss calculation. Finally, we used an Adam optimizer with learning rate of 0.000025.

A.3 Realization model

We use a ROBERTASHARE model following (Rothe et al., 2020). The model has 152,491,008 trainable parameters. We trained the model until we reached the maximum BLEU score on validation data. We trained our model with a batch size of 512 for 36K steps. Since the dataset has 45533 examples (one for each element in the target content plan in each Rotowire example), the model saw the entire dataset approximately 405 times. We used Cloud TPU v3 accelerators for training. We used the Adam optimizer with a learning rate of 0.05.

B Table-to-Text Generation

B.1 Task

Table 4 shows a prototypical input table from the Rotowire dataset[8], along with a possible content plan and its realization. As shown in the example, a well-formed content plan can repeat some of the entries from the input table.

B.2 Generating Oracle Content Plans

The Rotowire dataset does not contain ground truth content plans for its summaries. Instead, we infer them following a similar approach to (Puduppully et al., 2019a), but with a few minor modifications: 1) we use just a single convolutional model, instead of an ensemble of convolutional models and LSTMs, 2) our plans maintain the within-sentence order of information, and may include repetitions if a piece of information is repeated within a sentence in the target summary, 3) our plans include sentence breaks, though we remove sentences with no table entries, 4) our content plans can include the match date, if it's mentioned in the text (e.g. "on Saturday"), 5) when we resolve a pronoun, we emit the corresponding player or team name to the content plan. With respect to Table 4, if the realization at the bottom was a reference summary, then by applying this process we would obtain the content plan shown in the middle of the table. On average, the plans inferred in this fashion have 59.24 table entries and 12.72 sentences.

B.3 Content planning technical details

HiBERT. Conceptually, the input to HiBERT is a sequence of strings. We use three special strings, i.e., `<BEG>`, `<EOS>`, `<EOT>`, to explicitly mark the beginning of the content plan, the end of a sentence, and the end of the plan (text), respectively. The other strings are the values from the table, e.g., `Chicago_Bulls Points`, in the same order in which they appear in the text. In practice, in an attempt to leverage ROBERTA pre-training, we replace value strings with natural language sentences that we generate from each value using the templates listed in Table 5. For numeric values, such as the number of points of a team or player, similarly to Puduppully et al. (2019c) we compute the rank of the value among the instances of the same table entry type, and include that in the templated sentence in the form of a "which is [1st, 2nd, 3rd, ..., Nth] best" suffix[9]. With respect to the example in Table 4, the value `Chicago_Bulls Points` would then be represented as the natural language sentence: "team points scored of Chicago_Bulls is 100 which is 1st best". As we did not observe a significant benefit in terms of AUC when predicting the next content plan entry on validation data, we eventually initialized our model with random weights but retained the natural language representation of the value strings.

Because HiBERT has a sentence limit of 512, we do a pre-filtering step by discarding the table entries that are less likely to be mentioned in the summary, i.e., all player entries valued "N/A" and as many entries valued "0" as needed. Since the table entries aren't naturally ordered we don't feed a positional embedding $\mathbf{p}_i^{\text{sent}}$ in the document encoder, but we still feed it for the summary encoder.

Given the table entries and partial summary, HiBERT computes a distribution over the input sentences, where `<EOS>` corresponds to emitting a sentence break, `<EOT>` corresponds to ending the content plan, and `<BEG>` is not used.

We sample content plans from a trained model by greedy decoding with one modification: entries are not allowed to repeat in the content plan, except for sentence breaks, team names and team cities. If the highest probability sentence would have been a repeat, we instead emit the second highest, etc.

---

[8] We are not presenting an actual example for legal reasons.

[9] We use the words "which is Nth best" even when a high number is logically detrimental to the team (e.g. when it represents losses).

<table>
<tr><th colspan="9">Input Table: Match date: Saturday, 22nd October 2018</th></tr>

<tr><th colspan="9">Realization</th></tr>
<tr><td colspan="9">S1: The Chicago Bulls won against the Los Angeles Lakers 100 - 80 on Saturday.
S2: It was a poor showing for the Lakers (2 - 5) in spite of O'Neal's 30 point contribution.
S3: The Chicago Bulls' (3 - 1) best player was, predictably, Michael Jordan with 25 points and 10 rebounds.</td></tr>
</table>

Table 4: An hypothetical example from the Rotowire dataset for an NBA game, possible 3-sentence content plan and corresponding 3 realized sentences below.

ETCSum. ETC models used the same filtered set of table entries used in HiBERT as input. We concatenated these entries into a flat input sequence. Similarly, we used special strings `<EOS>`, `<EOT>` and `<BEG>` which correspond to the same concepts as in HiBERT, end of sentence, end of text and beginning of text respectively. These special strings are appended at the beginning of the flat input sequence.

The partial summary input is constructed by concatenating the special string `<BEG>` and the entries that have been predicted so far, in order of prediction, with `<EOS>` indicating sentences breaks.

The full input sequence is then constructed by concatenating: a `[CLS]` delimiter, the flat input sequence, a special separator `[SEP]`, the partial summary and finally a separator `[SEP]`. Both the input sequence and the partial summary are padded to 6141 and 2048 respectively, adding up in total to 8192 strings for the full input, including the special delimiters.

The model uses additional inputs to construct the global-local attention. One global token is assigned to each segment in the full input, each special delimiter gets assigned a global token, as well as every sentence in the input and partial summary. The model has a maximum global token id of 512, this has to be taken into account for examples where the number of segments, input sequence sentences, special delimiters and partial inputs is larger than 512. For those examples, we don't assign global tokens to the tail of the input sequence.

To be consistent we use the same decoding strategy where we sample content plans greedily but without repeated entries allowed in the content plan except for sentence breaks, team names and team cities.

B.4 Rotowire realization model

The generated content plans are realized via a sequence-to-sequence transformer model initialized with ROBERTA (Liu et al., 2019b) following (Rothe et al., 2020), trained to emit the realization sentence by sentence. The input to the model is the concatenation of the following:

1. The text of the previous sentence, or the empty string (for the first sentence). (The model can use this to pronominalize team and player names if they were already introduced.)
2. The literal string `" <BEG> "` as a separator.
3. The templated realizations (cfr. Table 5) of the entries in the sentence's content plan, space separated.
4. The literal string `" <CONTEXT> "` as a separator.
5. The templated representation of the match date.
6. For both teams, the templated representations of a) the team name, b) the team city, c) TEAM-PTS, d) TEAM-WINS, e) TEAM-LOSSES, f) whether the team was playing at home or away. These are space separated.
7. For each player **in the sentence's content plan**: the templated representations of a) PLAYER-START_POSITION, and b) which team the player was on. These are space separated.

The input after the `" <CONTEXT> "` separator is provided because we noticed that sometimes the content plan doesn't provide all the necessary information for realizing a sentence. For example, sometimes the target text may refer to a player

Table entry type	Template used
match date	match date of match is year: YYYY month: MM day: DD day_of_week: W
team name	team name of T is V

Abstract

We present *CLIRMatrix*, a massively large collection of bilingual and multilingual datasets for Cross-Lingual Information Retrieval extracted automatically from Wikipedia. CLIRMatrix comprises (1) *BI-139*, a bilingual dataset of queries in one language matched with relevant documents in another language for 139×138=19,182 language pairs, and (2) *MULTI-8*, a multilingual dataset of queries and documents jointly aligned in 8 different languages. In total, we mined 49 million unique queries and 34 billion (query, document, label) triplets, making it the largest and most comprehensive CLIR dataset to date. This collection is intended to support research in end-to-end neural information retrieval and is publicly available at `https://github.com/ssun32/CLIRMatrix`. We provide baseline neural model results on BI-139, and evaluate MULTI-8 in both single-language retrieval and mix-language retrieval settings.

1 Introduction

Cross-Lingual Information Retrieval (CLIR) is a retrieval task in which search queries and candidate documents are written in different languages. CLIR can be very useful in some scenarios. For example, a reporter may want to search foreign-language news to obtain different perspectives for her story; an inventor may explore the patents in another country to understand prior art. Traditionally, translation-based approaches are commonly used to tackle the CLIR task (Zhou et al., 2012; Oard, 1998; McCarley, 1999): the *query translation* approach translates the query into the same language of the documents, whereas the *document translation* approach translates the document into the same language as the query. Both approaches rely on a machine translation (MT) system or bilingual dictionary to map queries and documents to the same language, then employ a monolingual information retrieval (IR) engine to find relevant documents.

Recently, the research community has been actively looking at end-to-end solutions that tackle the CLIR task without the need to build MT systems. This line of work builds upon recent advances in Neural Information Retrieval in the monolingual setting, c.f. (Mitra and Craswell, 2018; Craswell et al., 2020). There are proposals to directly train end-to-end neural retrieval models on CLIR datasets (Sasaki et al., 2018; Zhang et al., 2019) or MT bitext (Zbib et al., 2019; Jiang et al., 2020). One can also exploit cross-lingual word embeddings to train a CLIR model on disjoint monolingual corpora (Litschko et al., 2018).

Despite the growing interest in end-to-end CLIR, the lack of a large-scale, easily-accessible CLIR dataset covering many language directions in high-, mid- and low-resource settings has detrimentally affected the CLIR community's capability to replicate and compare with previously published work. For example, among the widely-used datasets, the CLEF collection (Ferro and Silvello, 2015) covers many languages but is not large enough for training neural models. The more recent IARPA MATERIAL/OpenCLIR collection (Zavorin et al., 2020), is not yet publicly accessible. This motivates us to design and build *CLIRMatrix*, a massively large collection of bilingual and multilingual datasets for CLIR.

We construct *CLIRMatrix* from Wikipedia in an automated manner, exploiting its large variety of languages and massive number of documents. The core idea is to **synthesize relevance labels via an existing monolingual IR system, then propagate the labels via Wikidata links** that connect documents in different languages. In total, we were able to mine 49 million unique queries in 139 languages and 34 billion (query, document, label)

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4160–4170,

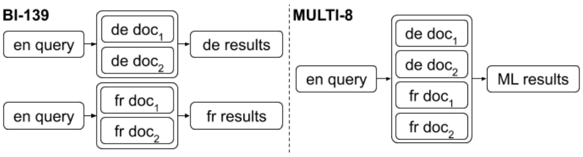

Figure 1: Illustration of our CLIRMatrix collection. The BI-139 portion of CLIRMatrix supports research in bilingual retrieval and covers a matrix of 139 × 138 language pairs. The MULTI-8 portion of CLIRMatrix supports research in multilingual modeling and mixed-language (ML) retrieval, where queries and documents are jointly aligned over 8 languages.

triplets, creating a CLIR collection across a matrix of $139 \times 138 = 19,182$ language pairs. From this raw collection, we introduce two datasets:

- **BI-139** is a massively large bilingual CLIR dataset that covers $139 \times 138 = 19,182$ language pairs. To encourage reproducibility, we present standard train, validation, and test subsets for every language direction.
- **MULTI-8** is a *multilingual* CLIR dataset comprising of queries and documents jointly aligned 8 languages: Arabic (ar), German (de), English (en), Spanish (es), French (fr), Japanese (ja), Russian (ru), Chinese (zh). Each query will have relevant documents in the other 7 languages.

See Figure 1 for a comparison of BI-139 and MULTI-8. The former facilitates the evaluation of bilingual retrieval over a wide variety of languages, while the latter supports research in mixed-language retrieval (a.k.a multilingual retrieval (Savoy and Braschler, 2019)), which is an interesting yet relatively under-explored problem. For both, the train sets are large enough to enable the training of the neural IR models.

We hope *CLIRMatrix* is useful and can empower further developments in this field of research. To summarize, our contributions are:

1. A massive CLIR collection supporting both training and evaluation of bilingual/multilingual models.
2. A set of baseline neural results on BI-139 and MULTI-8. On MULTI-8, we show that a single multilingual model can significantly outperform an ensemble of bilingual models.

CLIRMatrix is publicly available at `https://github.com/ssun32/CLIRMatrix`.

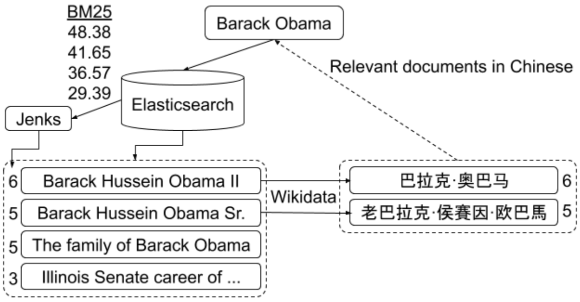

Figure 2: Intuition of CLIR relevance label synthesis. For the English query "Barack Obama", first a monolingual IR engine (Elasticsearch) labels documents in English; then Wikidata links are exploited to propagate the label to the corresponding Chinese documents, which are assumed to be topically similar.

2 Methodology

Let q^X be a query in language X, and d^Y be a document in language Y. A bilingual CLIR dataset consists of I triples

$$\{(q_i^X, d_{ij}^Y, r_{ij})\}_{i=1,2,...,I} \tag{1}$$

where d_{ij}^Y is the j-th document associated with query q_i^X, and r_{ij} is a label saying how relevant is the document d_{ij}^Y to the query q_i^X. Conventionally, r_{ij} is an integer with 0 representing "not relevant" and higher values indicating more relevant.

Suppose there are J documents in total. In the full collection search setup, the index j ranges from $1, \ldots, J$, meaning that each query q_i^X searches over the full set of documents $\{d_{ij}^Y\}_{j=1,...,J}$. In the re-ranking setup, each query q_i^X searches over a subset of documents obtained by an initial full-collection retrieval engine: $\{d_{ij}^Y\}_{j=1,...,K_i}$, where $K_i \ll J$. For practical reasons, machine learning approaches to IR focus on the re-ranking setup with K_i set to 10∼1000 (Liu, 2009; Chapelle and Chang, 2011). We follow the re-ranking setup here.

We now describe the main intuition of our construction method and detail various components and design choices in our pipeline.

2.1 Intuition and Assumptions

To create a CLIR dataset, one needs to decide how to obtain q_i^X and d_{ij}^Y, and r_{ij}. We set q_i^X to be Wikipedia titles, d_{ij}^Y to be Wikipedia articles, and synthesize r_{ij} automatically using a simple yet reliable method. We argue that *Wikipedia* is the best available resource for building CLIR datasets due to two reasons: First, it is freely available and contains articles in more than 300 languages, covering a large variety of topics. Second, Wikipedia articles are mapped to entities in *Wikidata*[1], which is a relatively reliable way to find the same articles written in other languages.

To synthesize relevance labels r_{ij}, we propose first to generate labels using an existing monolingual IR system in language X, then propagate the labels via Wikidata links to language Y. In other words, we assume:

1. the availability of documents d^X in the *same* language as the query, and
2. the feasibility of an existing monolingual IR system in language X to provide labels $\hat{r}_{ij}$ on (q_i^X, d_{ij}^X) pairs

Then for any d_{ij}^Y that links to d_{ij}^X, we assign the relevance label $\hat{r}_{ij}$.

This intuition is illustrated in Figure 2. Suppose we wish to find Chinese documents that are relevant for the English query "Barack Obama". We first run monolingual IR to find English documents that answer the query. In this figure, 4 documents are returned, and we attempt to link to the corresponding Chinese versions using Wikidata information. When the link is available, we set the relevance label r_{ij} for Chinese documents using the English-based IR system's predictions $\hat{r}_{ij}$; all other documents are deemed not relevant. This gives us the triplet $(q_i^X, d_{ij}^Y, r_{ij})$.

2.2 Mining Pipeline

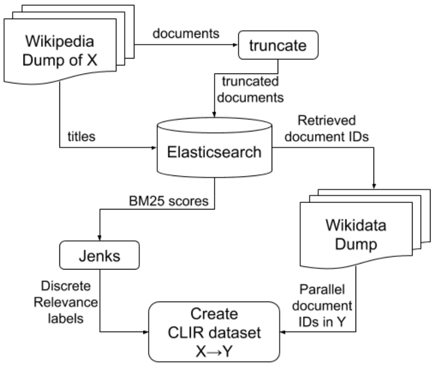

Figure 3: Mining pipeline for constructing a bilingual CLIR dataset with queries in language X and documents in language Y.

Figure 3 is our mining pipeline that implements the intuition in Figure 2. First, we download the Wikipedia dump of language X and then extract the titles and document bodies of every article. We index the documents into an Elasticsearch[2] search engine, which serves as our monolingual IR system. Using the extracted titles as search queries, we retrieve the top 100 relevant documents and their corresponding BM25 scores from Elasticsearch for every query. We then convert the BM25 scores into discrete relevance judgment labels using Jenks natural break optimization. Finally, we propagate these labels to documents in language Y that are linked via Wikidata.

We downloaded Wikidata and Wikipedia dumps released on January 1, 2020. Since Wikipedia dumps contain tremendous amounts of meta-information such as URLs and scripts, it can be expensive to extract actual text directly from those dumps. Inspired by Schwenk et al. (2019), we extracted document ids, titles, and bodies from Wikipedia's search indices[3] instead, which contain raw text data without meta-information.

Wikipedia dumps We discarded dumps with less than ten thousand documents, which are usually the dumps of Wikipedia of certain dialects and less commonly used languages. We are left with Wikipedia dumps in 139 languages, containing a good mix of high-, mid- and low-resource languages. For writing systems that do not use whitespaces such as Chinese, Japanese, and Thai, we truncated documents to approximately the first 600 characters. For other languages, we kept roughly the first 200 tokens of every document. Truncating the documents is necessary for several reasons: First, shorter documents are more friendly to neural models that are bounded by GPU memories. Second, the first few hundred tokens of Wikipedia articles are usually the main points of the full text, thus are more likely to be topically similar across languages. Last but not least, BM25 tends to over-penalize long documents, which can lead to sub-optimal IR performances (Lv and Zhai, 2011). We hypothesize we can get better relevant judgment labels if we use shorter documents.

Wikidata dump We downloaded the JSON dump[4] of Wikidata, a structured knowledge base that links to Wikipedia. We designed a regex rule that efficiently obtains a list of entities IDs from

---

[1] Wikidata is a knowledge base that contains links to parallel Wikipedia documents in different languages.

[2] https://www.elastic.co/

[3] https://dumps.wikimedia.org/other/cirrussearch/

[4] https://dumps.wikimedia.org/wikidatawiki/entities/

the Wikidata dump. For every entity ID, we also extracted a list of related (language code, document title) pairs. Using our extracted Wikipedia data, we matched the document titles to Wikipedia document IDs[5]. The extracted data allows us to construct two dictionaries: 1) A dictionary that maps the document ID in some language to its Wikidata entity ID. 2) A reverse dictionary that maps a Wikidata entity ID to document IDs in different languages. This enables us to locate a document's counterpart in another language quickly; we use this information to find link relevant documents across languages.[6]

2.3 Design Choices

Document titles as search queries We considered several methods used to generate search queries. One quick way is to acquire human-generated search queries directly from search logs. However, this is not a viable option because search logs are not publicly available for most languages. Alternatively, we can engage human annotators to manually generate search queries, but this can be time-consuming and expensive, and it is not possible to scale the process quickly to 139 languages.

We use document titles as search queries for two reasons: (1) They are readily available in large amounts for each of the 139 languages, which enables us to build large datasets (i.e., I is large). (2) In certain real-world search settings, queries are typically short, spanning only two to three tokens (Belkin et al., 2003) and informational, covering a wide variety of topics (Jansen et al., 2008). We leave the investigation of complex queries to future work. We want to emphasize that our mining pipeline is compatible with all query types; for example, we can use the first sentences of documents as queries (Schamoni et al., 2014; Sasaki et al., 2018) if desired.

BM25 and Elasticsearch The main step of our mining pipeline is to index documents into a monolingual IR system, and then retrieve a list of relevant documents and similarity scores for every query. We assume the similarity score between a query and document accurately reflects the degree of relevance for that document. Since many Wikipedia dumps contain millions of documents, the computations needed to retrieve relevant documents for all 139 languages is non-trivial. We need an efficient retrieval system that can handle the retrieval task efficiently and accurately. For this reason, we chose Elasticsearch[7] as our monolingual IR system.

Elasticsearch is an open-source, highly optimized search engine software based on Apache Lucene[8]. It has built-in analyzers that handle language-specific preprocessing such as tokenization and stemming. By default, Elasticsearch implements the BM25 weighting scheme (Robertson et al., 2009), a bag-of-word retrieval function that calculates similarity scores between queries and documents based on term frequencies and inverse document frequencies. BM25 is a strong baseline that frequently outperforms existing neural IR models on multiple benchmark IR datasets (Chapelle and Chang, 2011; Guo et al., 2016; McDonald et al., 2018).

We used Elasticsearch 6.5.4 and imported the same settings as the official search indices from Wikipedia[9]. For every query, we configured Elasticsearch to search both document titles and document bodies, with twice the weight given to document titles. We limit Elasticsearch to return only the top 100 documents for each query and assume documents not returned by the search engine are irrelevant. We parallelized the retrieval processes by running multiple Elasticsearch instances on numerous servers and dedicated one Elasticsearch instance to every language.

Discrete relevance judgment labels A potential pitfall of using document titles as queries is that some short queries can be ambiguous (Allan and Raghavan, 2002). For example, it is impossible to figure out whether the search query "Java" refers to the Java programming language or the island in

---

[5] Note that documents in different languages do not share document IDs. This means that document N in language X does not refer to the same entity as document N in language Y.

[6] We acknowledge that there are potentially missing inter-language links in Wikidata. This implies that our method may miss the labeling of some relevant documents. Wikidata has several policies to improve its data quality, such as requests for editors to link new Wikipedia articles to entities in Wikidata. There are also automated auditing tools that periodically identify articles with missing or inconsistent Wikidata labels and ask human editors for verification. An interesting research problem for future work is to find ways to quantify the coverage of these inter-language links.

[7] Elasticsearch is also used as the backend search engine for Wikipedia.org

[8] https://lucene.apache.org/core/

[9] For example, the settings for English Wikipedia is available at https://en.wikipedia.org/w/api.php?action=cirrus-settings-dump&format=json&formatversion=2. For BM25, $b = 0.3$ and $k_1 = 1.2$.

Indonesia without other context words. Fortunately, Wikipedia disambiguates different document titles by appending category information to the titles, e.g., Java (Programming Language) and Java (Island), etc. Nevertheless, we do not want to rank retrieved documents solely based on their BM25 scores. To prevent potential ambiguity issues, we smooth out the BM25 scores into discrete relevance judgment labels. We achieve this by using the Jenks natural break optimization (McMaster and McMaster, 2002), an algorithm that finds optimal BM25 score intervals for different labels by iteratively reducing the variance within labels and maximizing the variance between labels.

More specifically, for each query q_i^X, we normalized the BM25 scores $\hat{r}_{ij}$ of d_{ij}^X to the unit range and then used Jenks optimization to distribute the normalized scores into 5 different relevance judgment labels $\{1, 2, 3, 4, 5\}$. We want to emphasize that we did not run Jenks optimization globally across all BM25 scores because the scales of BM25 scores are not consistent across different queries. Additionally, documents that are not returned by Elasticsearch or not linked by any Wikidata are deemed irrelevant and given a label 0. We also assigned the label 6 to the document associated with the title query. So final r_{ij} is of **a scale of 0 to 6**, with 0 being irrelevant and 6 being most relevant.

2.4 Bilingual and Multilingual datasets

BI-139 Using the aforementioned pipeline, we build a bilingual dataset $\{(q_i^X, d_{ij}^Y, r_{ij})\}_{i=1,2,\ldots,I}$ for every X→Y language direction. In the "raw" version, there are 49.28 million unique queries and 34.06 billion (query, document, label) triplets across $139 \times 138 = 19,182$ language directions. We also generated a "base" version, which contains standard train, validation, test1, and test2 subsets for each language direction. Train sets contain up to I=10,000 queries, while validation, test1, and test2 sets each contain up to 1,000 queries. We ensured that queries in the train and validation/test sets of one language direction do not overlap with the queries in the test sets from other language directions. For every query, we ensure there are precisely K =100 candidate documents by filling the shortfall with random irrelevant documents.

MULTI-8 This is a multilingual CLIR dataset covering 8 languages from various regions of the world (Arabic, German, English, Spanish, French, Japanese, Russian, and Chinese). First, we restricted queries to those with a relevant document ($r_{ij} = 6$) in all 8 languages. Then, for each query q_i^X, we use the monolingual IR systems to collect 100 documents in the same language d_{ij}^X.[10] Similar to BI-139 base, if ElasticSearch returns less than 100 documents labels ($r_{ij} \geq 1$), then we fill-up the short-fall with random irrelevant documents with label $r_{ij} = 0$. Finally, we merge these document lists such that for any query in language X, we have 7×100 documents in the other 7 languages.

Similar to the base version of BI-139, the train sets contain 10,000 queries, while validation, test1, and test2 sets contain 1,000 queries; but note the query sets are different. This dataset supports two kinds of research: First, one can still evaluate bilingual CLIR (single-language retrieval) like BI-139, but exploit training multilingual models using more than two languages. Second, one can evaluate on multilingual CLIR (mixed-language retrieval), where the document list to be re-ranked contains two or more languages. This research direction is relatively unexplored, with the exception of early work in the 2000s in the CLEF campaign (Savoy and Braschler, 2019).

2.5 File Formats

{"src_id": "6267",
"src_query": "Cultural imperialism",
"tgt_results": [["3383724", 6], ["19028", 5], ["6291141", 4], ["4394682", 2], ["138124", 1], ["1245746", 1], ["1004260", 0], ...}

Figure 4: An example English query "Cultural imperialism" and the document IDs and labels of its relevant Chinese documents.

6499809 ⟨TAB⟩ Structured light is the process of projecting a known pattern (often grids or horizontal bars) on to a scene...

Figure 5: The IDs and texts of documents are stored tab-separated in a text file.

For every language direction, we store queries and their relevant document IDs and labels in the JSON Lines format (Figure 4). For each unique language, we store the IDs and texts of documents in TSV files (Figure 5). Note that we will release both the truncated and the original documents.

3 Experimental Setup

---

[10] Recall that our Wikidata entities dictionary can map a language-independent entity to query strings (Wikipedia article titles) in any language.

Table 1: Results of 138 language directions from BI-139 base with English queries. In each cell, the top shows a candidate's language code and the bottom shows the NDCG@10 score for that language direction.

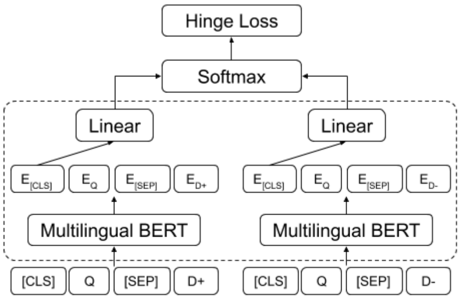

Figure 6: Neural architecture of our baseline CLIR model. Modules in the dotted rectangle share weights.

Baseline neural CLIR model We follow the implementation of the vanilla BERT ranker model (MacAvaney et al., 2019), which obtained strong results in monolingual IR. As shown in Figure 6, the model encodes a query-document pair with BERT (Devlin et al., 2019) and stacks a linear combination layer on top of the [CLS] token. We extended the ranker model to use multilingual BERT[11]. At training time, we sample documents pairs in which the positive documents have higher relevance judgment labels than the negative documents. For each document pair, we obtain scores for both documents using the same BERT ranker model. We then optimize the parameters with pairwise hinge loss and Adam optimizer. We trained all models for 20 epochs and sampled around 1,000 training pairs for each epoch. At inference time, we rerank documents based on the output scores from the BERT ranker model.

Evaluation metric We report all results in NDCG (normalized discounted cumulative gain), an IR metric that measures the usefulness of documents based on their ranks in the search results (Järvelin and Kekäläinen, 2002). Following a common practice from the IR community, we calculate NDCG@10, which only evaluates the top 10 returned documents. For a given query, let ρ_i be the relevance judgment label of the i-th document in the predicted document ranking and ϕ_i be the relevance judgment label of the i-th document in the optimal document ranking. We define DCG@10 and ideal DCG@10 as:

$$\begin{aligned} \text{DCG@10} &= \sum_{i=1}^{10} \frac{2^{\rho_i}-1}{log_2(i+1)} \\ \text{IDCG@10} &= \sum_{i=1}^{10} \frac{2^{\phi_i}-1}{log_2(i+1)} \end{aligned} \qquad (2)$$

---

[11] We used BERT-Base, Multilingual Cased

We can calculate NDCG@10 for that query as:

$$\mathrm{NDCG@10} = \frac{\mathrm{DCG@10}}{\mathrm{IDCG@10}} \quad (3)$$

The NDCG@10 of a test set is the arithmetic mean of NDCG@10 values for all queries. The range of the metric is [0, 1] and a higher NDCG@10 score means predicted rankings are closer to the ideal rankings.

3.1 Results on BI-139

We present results on the 138 target languages for English queries. For each language direction, we trained a baseline CLIR model on the base train set and kept the checkpoint with the best NDCG@10 performance on the base validation set. We reranked the documents in the base test1 set and calculated NDCG@10. Table 1 lists the the baseline results.[12] The pleasant surprise here is that the baseline CLIR models also generally did pretty well on languages that are not officially supported by multilingual BERT. For example, the model achieved 0.65 on Yiddish (yi) and 0.75 on Walloon (wa) when multilingual BERT was trained on neither of these languages. There are several explanations for this. For one, we hypothesize that low resource languages such as Yiddish, a high German-derived language, and Walloon, a Romance language, benefit from their similarities to other languages within the same language families. For queries such as named entities, it is also possible that some relevant cross-language Wikipedia document may be multilingual and contain some overlap with the query term untranslated. The details will depend on the query in question.

3.2 Results on MULTI-8

Multilingual IR is a field that has been largely unexplored in recent years. MULTI-8 enables evaluation in two kinds of scenarios (see Table 2):

Single-language retrieval This scenario is similar to BI-139 in terms of evaluation, i.e. during test we only have queries in source language $q^X = S_{test}$ and documents in one target language $d^Y = T_{test}$. We divide MULTI-8 test set into $8 \times 7 = 56$ pairs.

For training, we compare **bilingual model ($\mathbf{BM_{S \to T}}$)** trained in every language pair, against a **multilingual model (MM)** trained on data concatenated from all 56 language directions. As we can see in Table 3, the MM model performs better than the respective BM models in most language directions. This suggests that multilingual training is a promising research direction even for single-language retrieval.

Mix-language retrieval In this scenario, at test time we have a single source query $q^X = S_{test}$ and wish to retrieve documents $d^Y = A_{test}$ which can be in any of the 8 MULTI-8 languages. The multilingual model (MM) can be applied directly, but the bilingual model (BM) requires some modifications. One can run multiple BM one for each target language, then merge the resulting document lists (Savoy, 2003; Tsai et al., 2008). A common strategy, which we adopt here, is to z-normalize the output scores and rank all the test documents based on z-scores.

As seen in Table 4, the multilingual model performs significantly better than the ensembled/merged bilingual models. The average NDCG@10 of the multilingual model is 0.684, which is 17.1% than bilingual models with z-score merging strategy.

Mix-language retrieval	$\{\mathrm{BM}_{S\rightarrow T}\}$	$q^X = S_{train}, d^Y = T_{train}$	$q^X = S_{test}, d^Y = A_{test}$
	MM	$q^X = A_{train}, d^Y = A_{train}$	

Table 2: Different ways of using MULTI-8. A refers to the concatenation of all languages, which is used in mix-language retrieval. S and T refer to the queries/documents in the source and target language under consideration for the bilingual case (i.e., single-language retrieval similar to BI-139 setups). For either, it is possible to train either bilingual models (BM) based on pairwise data or a multilingual model (MM) based on all language data.

4 Related Work

Information retrieval (IR) has made a tremendous amount of progress, shifting focus from traditional bag-of-world retrieval functions such as tf-idf (Salton and McGill, 1986) and BM25 (Robertson et al., 2009), to neural IR models (Guo et al., 2016; Hui et al., 2018; McDonald et al., 2018) which have shown promising results on multiple monolingual IR datasets. Recent advances in pre-trained language models such as BERT (Devlin et al., 2019) have also led to significant improvements in IR tasks. For example, MacAvaney et al. (2019) achieves state-of-the-art performances on benchmark datasets by incorporating BERT's context vectors into existing baseline neural IR models (McDonald et al., 2018). Training on synthetic is also a common practice, e.g., Dehghani et al. (2017) show that supervised neural ranking models can greatly benefit from pre-training on BM25 labels.

Cross-lingual Information Retrieval (CLIR) is a sub-field of IR that is becoming increasingly important as new documents in different languages are being generated every day. The field has progressed from translation-based methods (Zhou et al., 2012; Oard, 1998; McCarley, 1999; Yarmohammadi et al., 2019) to recent neural CLIR models (Vulić and Moens, 2015; Litschko et al., 2018; Zhang et al., 2019) that rely on cross-lingual word embeddings. In contrast to the wide availability of monolingual IR datasets (Voorhees, 2005; Craswell et al., 2020), cross-lingual and multilingual IR

Table 5: Comparison of CLIR datasets by number of languages (**#Lang**), whether it is manually constructed or supports multilingual retrieval, and data statistics. Large **#query** and **#triplets** are needed for neural training.

datasets are scarce. Examples of the widely used CLIR datasets are the CLEF 2000-2003 collection (Ferro and Silvello, 2015), which focus primarily on European languages, and IARPA MATERIAL/OpenCLIR collection (Zavorin et al., 2020), which focus on a few low-resource language directions. Creating a CLIR dataset for more language directions remains an open challenge.

Extracting CLIR datasets from Wikipedia has been explored in previous work. Schamoni et al. (2014) build a German–English bilingual CLIR dataset from Wikipedia, which contains 245,294 German queries and 1,226,741 English documents. They convert the first sentences from German Wikipedia documents into queries and follow Wikipedia's interlanguage links to find relevant documents in English. Sasaki et al. (2018) apply the same techniques and release a larger CLIR dataset which contains English queries and relevant documents in 25 languages. Both datasets truncate the documents to the first 200 tokens and rely on bidirectional inter-article links to find partially relevant documents. Our contribution differs in three important aspects: (i) BI-139 is a significantly larger dataset, covering more languages and more documents. (ii) MULTI-8 provides a new multilingual retrieval setup, not previously available. (iii) We argue that our method can reliably find more relevant documents by propagating search results from monolingual IR systems to other languages via Wikidata. This is in contrast to directly using bidirectional links extracted from Wikipedia documents to determine relevance, which are much sparser. Further, our method allows for more finer-grained levels of relevance (e.g. as opposed to binary relevance), making the dataset more challenging.

A comparison of various existing CLIR datasets is presented in Table 5.

5 Conclusion and future work

We present *CLIRMatrix*, the largest and the most comprehensive collection of bilingual and multilingual CLIR datasets to date. The *BI-139* dataset supports CLIR in 139×138 language pairs, whereas the *MULTI-8* dataset enables mix-language retrieval in 8 languages. The large number of supported language directions allows the research community to explore and build new models for many more languages, especially the low-resource ones. We document baseline NDCG results using a neural ranker based on multilingual BERT. Our mix-language retrieval experiments on MULTI-8 show that a single multilingual model can significantly outperform the combination of multiple bilingual models.

For future work, we think it will be interesting to look at:

1. zero-shot CLIR models for low-resource languages,
2. comparison of end-to-end neural rankers with traditional translation+IR pipelines in terms of both scalability, cost, and retrieval accuracy,
3. advanced neural architectures and training algorithms that can exploit our large training data,
4. building universal models for multilingual IR.

Abstract

With worldwide concerns surrounding the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2), there is a rapidly growing body of scientific literature on the virus. Clinicians, researchers, and policy-makers need to be able to search these articles effectively. In this work, we present a zero-shot ranking algorithm that adapts to COVID-related scientific literature. Our approach filters training data from another collection down to medical-related queries, uses a neural re-ranking model pre-trained on scientific text (SciBERT), and filters the target document collection. This approach ranks top among zero-shot methods on the TREC COVID Round 1 leaderboard, and exhibits a P@5 of 0.80 and an nDCG@10 of 0.68 when evaluated on both Round 1 and 2 judgments. Despite not relying on TREC-COVID data, our method outperforms models that do. As one of the first search methods to thoroughly evaluate COVID-19 search, we hope that this serves as a strong baseline and helps in the global crisis.

1 Introduction

The emergence of the Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) prompted a worldwide research response. In the first 120 days of 2020, researchers published over 10,000 articles related to SARS-CoV-2 or COVID-19. Together with articles about similar viruses researched before 2020, the body of research approaches 60,000 articles. Such a large body of research results in a considerable burden for those seeking information about various facets of the virus, including researchers, clinicians, and policy-makers.

To help improve COVID-19 search, we introduce SLEDGE-Z: a simple yet effective zero-shot baseline for coronavirus Scientific knowLEDGE search. SLEDGE-Z adapts the successful BERT-based (Devlin et al., 2020) re-ranking model (Vanilla BERT, MacAvaney et al. (2019)) for COVID-19 search with three simple techniques. First, we propose a training data filtering technique to help the ranking model learn relevance signals typical in medical text. The training data we use comes entirely from another dataset (MS-MARCO, Campos et al. (2016)), resulting in our model being zero-shot. Since MS-MARCO is a large collection of real user queries (over 800,000), it allows us to filter aggressively and still have adequate training data. Second, we replace the general contextualized language model BERT with one pre-trained on scientific literature (SciBERT, Beltagy et al. (2019)). This pre-training prepares the model for the type of language typically seen in scientific articles. Since the document collection (CORD-19, Wang et al. (2020)) contains articles about prior viruses, we filter out articles published before 2020 to eliminate less pertinent articles. An overview of this process is shown in Figure 1.

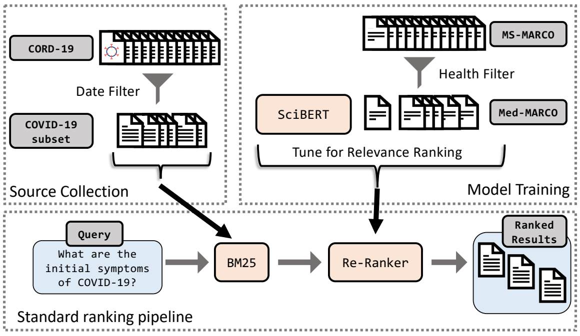

Figure 1: Overview of SLEDGE-Z.

We show that each of the techniques mentioned above positively impacts the ranking effectiveness of SLEDGE-Z through an ablation analysis. Our zero-shot approach performs comparably to (or outperforms) top-scoring submissions to the TREC-

November 16–20, 2020.

COVID document ranking shared task (Roberts et al., 2020), a new testbed for evaluating of search methods for COVID-19. SLEDGE-Z tops the Round 1 leaderboard in the zero-shot setting, which is important in low-resource situations. Overall, our method establishes a strong performance for COVID-19 literature search. By releasing our models and code, we hope that it can help in the current global COVID-19 crisis.[1]

2 Related Work

Ad-hoc document retrieval (of both scientific articles and general domain documents) has been long-studied (Lalmas and Tombros, 2007; Hersh and Voorhees, 2009; Lin, 2008; Medlar et al., 2016; Sorkhei et al., 2017; Huang et al., 2019; Hofstätter et al., 2020; Nogueira et al., 2020b). Most recent work for scientific literature retrieval has focused on tasks such as collaborative filtering (Chen and Lee, 2018), citation recommendation (Nogueira et al., 2020a), and clinical decision support (Soldaini et al., 2017).

Pre-trained neural language models (such as BERT (Devlin et al., 2020)) have recently shown to be effective when fine-tuned for ad-hoc ranking (Nogueira and Cho, 2019; Dai and Callan, 2019; MacAvaney et al., 2019). These models also facilitate relevance signal transfer; Yilmaz et al. (2019) demonstrate that the relevance signals learned from BERT can transfer across collections (reducing the chance of overfitting a particular collection). Here, we use relevance signal transfer from an open-domain question answering dataset to the collection of COVID-19 scientific literature.

Others have investigated COVID-19 document ranking. Zhang et al. (2020) chronicled their efforts to build a search engine for COVID-19 articles, using a variety of available ranking techniques, such as T5 (Raffel et al., 2019). In this work, we find that our approach outperforms this system in terms of ranking effectiveness. Contemporaneously with our work, Das et al. (2020) demonstrate how document clustering and summarization can be effective for COVID-19 retrieval. This paper extends our shared task submissions in Round 1 (MacAvaney et al., 2020). We note that the TREC COVID task proceeded for a total of 5 rounds, with various techniques emerging, such as passage aggregation (Li et al., 2020; Nguyen et al., 2020), and ensemble methods (Bendersky et al., 2020).

3 SLEDGE-Z: Zero-Shot COVID-19 Search

To build a ranking model for COVID search, we modify the standard zero-shot Vanilla BERT document re-ranking pipeline (Yilmaz et al., 2019; MacAvaney et al., 2019). We find that while these modifications are simple, they are effective for maximizing ranking performance. We note that this process neither requires COVID relevance training data nor involves a priori inspection of the queries and their characteristics. Thus, we consider our method zero-shot.

To train in a zero-shot setting, we employ a large dataset of general-domain natural language question and answer paragraphs: MS-MARCO (Campos et al., 2016). However, naïve domain transfer is not optimal since most questions in the dataset are not medical-related, causing a domain mismatch between the training and evaluation data. To overcome this challenge, we apply a heuristic to filter the collection to only medical-related questions. The filter removes questions that do not contain terms appearing in the MedSyn (Yates and Goharian, 2013), a lexicon of layperson and expert terminology for various medical conditions. We manually remove several common terms from the lexicon that commonly introduce queries that are not medical-related. For example, MedSyn includes the term *gas* (referring to the medical concept of flatulence in North American English), commonly also refers to gasoline or natural gas. See Appendix A.1 for a complete list of excluded MedSyn terms. Note that we made these decisions without considering COVID-19 specifically—only a broad relation to the medical domain. MS-MARCO originally consists of 809K questions. After filtering, 79K of the original questions remain (9.7%). We refer to this subset of MS-MARCO as Med-MARCO. From a random sample of 100 queries from Med-MARCO, 78 were judged by the authors as medical-related, suggesting the filter has reasonable precision. Examples questions from this process include *causes of peritoneal cancer prognosis* and *what is squalene anthrax sleep apnea*. We make a list of the query IDs corresponding to Med-MARCO available,[2] as well as additional

---

[2] `https://github.com/Georgetown-IR-Lab/covid-neural-ir/blob/master/med-msmarco-train.txt`

examples of filtered queries (see Appendix A.2).

Second, we replace the general-language BERT model with a variant tuned on scientific literature (including medical literature). Specifically, we use SciBERT (Beltagy et al., 2019), which has an identical structure as BERT, but was trained on a multi-domain corpus of scientific publications. It also uses a WordPiece lexicon based on the training data, allowing the model to better account for subwords commonly found in scientific text. During model training, we employ the pairwise cross-entropy loss function from Nogueira and Cho (2019). Relevant and non-relevant documents are sampled in sequence from the official MS-MARCO training pair list (filtered down to Med-MARCO queries).

Third, we apply a filter to the document collection that removes any articles published before January 1, 2020. This filter aims to improve the retrieval system's precision by eliminating articles that may discuss other topics. The date was chosen because little was known about COVID-19 prior to 2020, and some documents do not include a full publication date (only a year), making this filter simple to apply. In real-life search engines, date filtering can often be applied at the discretion of the user.

4 Experimental setup

We now explore the ranking effectiveness of our approach. We evaluate the performance of SLEDGE-Z using Round 1 and 2. At the time of writing, the only training data available for the task was the Round 1 data. of the TREC-COVID Information Retrieval Benchmark (Roberts et al., 2020).[3] TREC-COVID uses the CORD-19 document collection (Wang et al., 2020) (2020-05-01 version, 59,943 articles), with a set of 35 topics related to COVID-19. These topics include natural questions such as: *what is the origin of COVID-19* and *how does the coronavirus respond to changes in the weather*. The top articles of participating systems in each round were judged by expert assessors, who rated each article as non-relevant (0), partially-relevant (1), or fully-relevant (2) to the topic. In total, 20,728 relevance judgments were collected (avg. 592 per topic), with 74% non-relevant, 12% partially relevant, and 14% fully-relevant. These rates remained nearly constant between rounds 1 and 2.

We use normalized Discounted Cumulative Gain with a cutoff of 10 (nDCG@10), Precision at 5 of partially and fully-relevant documents (P@5), and Precision at 5 of only fully relevant documents (P@5 (F)). Both nDCG@10 and P@5 are official task metrics; we include the P@5 filtered to only fully-relevance documents because it exposed some interesting trends in our analysis. We also report the percentage of the top 10 documents for each query that have relevance judgments (J@10). In an additional evaluation, we measure the performance using only judged documents to ensure that unjudged documents do not impact our findings. We used `trec_eval`[4] for all metrics. These measures represent a precision-focused evaluation; since re-ranking methods like ours focus on improving precision, we leave recall-oriented evaluations to future work.

Our initial ranking is conducted using BM25 with default settings over the full document text to adhere to the zero-shot setting. Re-ranking is conducted over the abstracts only, avoiding the need to perform score aggregation (since BERT models are limited in the document length). We utilize only the natural-language question (ignoring the keyword query and extended narrative). We conduct an ablation that compares SLEDGE-Z to versions using BERT (instead of SciBERT), and the full MS-MARCO dataset (MSM) (rather than the Med-MARCO subset (MedM)). We compare with several baselines under the same evaluation settings.

- **BM25**: the initial BM25 ranking.
- **ConvKNRM**: The convolutional KNRM model (Dai et al., 2018), trained on MS-MARCO data.
- **CEDR KNRM**: The KNRM model, augmented with contextualized embeddings (MacAvaney et al., 2019), trained on MS-MARCO data. We use the `bert-base-uncased` model for the contextualized embeddings.
- **Seq2seq T5**: The text-to-text-transformer (T5) model (Raffel et al., 2019), tuned for ranking by predicting *true* or *false* as the next term in a sequence consisting of the query and document (Nogueira et al., 2020c).

---

[3] Round 2 uses *residual collection* evaluation, meaning that all documents judged in Round 1 are disregarded. Although this is an important setting for building up a dataset and allows for approaches like manual relevance feedback, we feel that this setting does not mimic an actual search engine, especially in the zero-shot setting. Thus, we evaluate on the concatenation of Round 1 and 2 settings and mark the systems that use Round 1 judgments for training or tuning of their system.

Fusion2	-	0.601	0.737	0.565	96%	0.605	0.737	0.565

Table 1: Ablation results and comparison of our approach and other zero-shot baselines on TREC-COVID Rounds 1 and 2. The top results are shown in bold. SciBERT with MedM (SLEDGE-Z) significantly outperforms values in the top (ablation) section marked with * ($p < 0.05$, paired t-test, Bonferroni correction).

- **Fusion**: a reciprocal rank fusion method (Cormack et al., 2009) of BM25 over the abstract, full text, and individual paragraphs. Fusion1 uses a concatenation of the keywords and question, and Fusion2 uses the entity extraction technique from the Round 1 `udel` submission.[5]

Our work utilizes a variety of existing open-source tools: OpenNIR (MacAvaney, 2020), Anserini (Yang et al., 2017), and the HuggingFace Transformers library (Wolf et al., 2019). We utilize a held-out subset of 200 queries from the MS-MARCO training set as a validation set for the sole purpose of picking the optimal training epoch. Model hyper-parameters were chosen from values in prior work and can be found in Appendix A.4, along with information about the hardware used. The Vanilla BERT and SciBERT models take approximately 3 hours to train/validate, and inference on TREC-COVID takes approximately 15 minutes on modern GPUs. The BERT model has 157M parameters, and the SciBERT model has 158M parameters.

5 Results

Ranking effectiveness is presented in Table 1. We first compare the ablations of our approach (top section). We note that SciBERT significantly ($p < 0.05$, paired t-test, Boneferroni correction) outperforms BM25 and BERT trained on MSM across all metrics. There is a less dramatic jump between BERT MSM and BERT MedM, demonstrating the importance of filtering the training data properly. This is echoed between SciBERT MSM and SciBERT MedM, though the difference is only significant for P@5 when only considering the judged documents. These results demonstrate the importance of both pre-training on appropriate data and fine-tuning using a proper subset of the larger data. While both yield improvements (that can be additive), the pre-training objective appears to be more impactful, based on the overall better scores of SciBERT.

Compared to baseline systems (bottom section), we observe that SLEDGE-Z offers superior effectiveness. Specifically, we see that ConvKNRM, CEDR-KNRM, and Seq2seq T5 all improve upon the initial BM25 ranking. Training on Med-MARCO (rather than the full MS-MARCO) also improves each of the baselines, except, curiously, Seq2seq T5. This model may benefit from the larger amount of training data the full MS-MARCO dataset offers. Finally, both fusion methods outperform the base BM25 model. However, we note that these models utilize two fields available for each query: the keyword-based query and the full natural-language question text—a luxury not available in practical search environments. (Recall that SLEDGE-Z and the other baselines in Table 1 only use the natural-language query.)

We now compare our approach with the top-performing submissions to the TREC COVID shared task (many of which are not zero-shot methods). Full participating system descriptions are provided in Appendix A.3. We note that these experimental settings for these runs differ from our main experiments. For instance, `mpiid5_run3` (Li

Table 2: TREC COVID Round 1 and 2 comparison between SLEDGE-Z and other top official Round 2 submissions. We apply the date filter for a more complete comparison. Note that experimental differences exist between our system and these submissions, including the use of multiple topic fields and the utilization of Round 1 training data for training or tuning. The top result is marked in bold.

System	nDCG@10	P@5	P@5 (F)
SLEDGE-Z (ours)	**0.641**	0.747	**0.633**
`sab20.1.meta.docs`	0.608	**0.780**	0.487
`IRIT_marked_base`	0.588	0.720	0.540
`CSIROmedNIR`	0.588	0.660	0.587

Table 3: TREC-COVID Round 1 leaderboard (automatic systems). SLEDGE-Z outperforms the highest-scoring run in terms of nDCG@10 and P@5 (F).

et al., 2020) and `SparseDenseSciBERT` use relevant information from Round 1 as training data, and `covidex.t5` uses combined keyword query and natural-language questions. Therefore, these performance metrics are not directly comparable to our zero-shot runs. Despite this, SLEDGE-Z still achieves competitive performance compared to these models. For instance, it consistently scores comparably or higher than `covidex.t5` (includes a more powerful language model, a more effective initial ranking model, and multiple topic fields) and `SparseDenseSciBert` (which uses neural approaches for the initial ranking stage). Our method even performs comparably to the `mpiid5.run3` model, which was trained directly on Round 1 judgments. Interestingly, we observe that our simple baseline approach of re-ranking using T5 strictly with the natural-language question against the paper title and abstract (Seq2seq T5 in Table 1) is more effective than the more involved approach employed by `covidex.t5`. When we apply the same date filtering to the official runs, we observe that the differences narrow. We also present SLEDGE-Z topping the Round 1 leaderboard in Table 3. We observe again that our model excels at finding highly-relevant documents.

To gain a better understanding of the impact of filtering the document collection to only articles published on or after January 1, 2020, we first compare the performance of SLEDGE-Z with and without the filter. Disregarding unjudged documents, it has an nDCG@10 of 0.668 (−0.051), P@5 of 0.777 (−0.069) and P@5 (F) of 0.589 (−0.108). All these differences are statistically significant. By far the largest reduction is on fully-relevant P@5, meaning that it can be more difficult to find highly relevant documents when considering the full document collection. We observed similar trends for BM25, with and without the 2020 filter. These trends also align with observations we made from the judgments themselves; we find that only 16% of judged documents from prior to 2020 were considered relevant (with only 5% fully relevant). Meanwhile, 32% of judged documents after 2020 were considered relevant (19% fully relevant).

6 Conclusion

In this work, we present SLEDGE-Z, an adaptation of a neural ranking pipeline for COVID-19 scientific literature search. The approach is zero-shot and adapts to medical literature by filtering the training data, using a contextualized language model based trained on scientific text, and by filtering the document collection. The zero-shot setting is important because it suggests that the approach can be generally applied to similar problems—even when no training data are available (which can be expensive to collect). Through experiments and analysis on TREC-COVID, we find that each component of our approach is beneficial, and it outperforms or is comparable to approaches that are trained or tuned on TREC-COVID judgments. These observations underscore the importance of properly considering the domain when building medical search engines. We hope that techniques like SLEDGE-Z can help overcome the global COVID-19 crisis.

A Appendix

A.1 List of MedSyn exclusion terms

The following terms were excluded from MedSyn when filtering MS-MARCO to reduce false positive matches: gas, card, bing, died, map, fall, falls.

A.2 Med-MARCO Examples

A random sample of 10 queries from the filtered Med-MARCO dataset:

- 747605 what is fistula with salivary drainage
- 586569 what causes cirrhosis besides alcohol
- 925416 what would cause pain in left shoulder and right elbow
- 258186 how long does it take to show pregnancy test
- 845485 what is the salary of the governor of ms *(false positive)*
- 1070398 why is hands swell when waking up
- 956309 when to worry about high temperature in adults
- 776140 what is nervous breakdown
- 750061 what is gastric ulcer
- 83842 cat's eye meaning *(false positive)*

A.3 TREC-COVID Run Descriptions

`sab20.1.meta.docs`: Simple SMART vector run, Lnu docs and ltu queries. Separate inverted files for metadata and JSON docs. Final score = 1.5 * metadata score + JSON score. Full topics including narrative.

`IRIT_marked_base`: We use a BERT-base (12 layers, 768 hidden size) fine-tuned on Ms Marco passage set. We use a full ranking strategy with two stages: in the first stage, we use Anserini Bm25+ RM3 to retrieve top-1000 candidate documents for each topic using an index on the title+abstract of the CORD-19 documents, then we use the fine-tuned BERT to re-rank this list.

`CSIROmedNIR`: A neural index was built on the title, abstract fields of the COVID corpus alongside a traditional inverted index built on title, abstract and body text of the document. The neural index was built from the pooled classification token (1st token of the final BERT layer) using the covidbert-nli model (https://huggingface.co/gsarti/covidbert-nli) from the title, based off the sentence transformer (Reimers etal. Sentence-BERT, 2019). For the abstract,we took the Bag-of-Sentence approach where we averaged the individual sentence embeddings (sentence were segmented using segtok). All embeddings had a final dimension size of [1, 768]. We searched on the neural index using the query, narrative and question fields of the topics using the same embedding approach as with the document title embedding over the title and abstract neural index fields giving a total of 6 cosine similarity computations. We combine BM25 scores from traditional search over a combination of query,narrative and question fields over all document facets (body, title, abstract), giving a total of 9 different query-facet combinations. We take the natural logarithm of the total BM25 score (to match the range of the cosine scores) which is then added the cosine scores: finalscore = log(sum of BM25 query-facet combs)+ cosine Scores Additionally, we filter the document by date. Documents created before December 31st 2019(before the first reported case) had their scores automatically set to zero.

`mpiid5.run3`: We re-rank top-10000 documents returned by BM25 using the queries produced by Udel's method. For there-ranking method, we use the ELECTRA-Base model fine-tuned on the MSMARCO passage dataset. Themodel is later fine-tuned on the TREC COVID round 1 full-text collection.

`SparseDenseSciBert`: bm25+ann+scibert.0.33.teIn (ann-bm25 retrieval + scibert reranker): anserini TREC-COVID R2 Retrieval#8 + med-marco ANN + med-marco SciBERT with COVD Mask-Lm fine-tuning

`covidex.t5`: Reciprocal rank fusion of two runs: Anserini r2.fusion1, reranked with medT5-3B; Anserini r2.fusion2, reranked with medT5-3B; Anserini fusion baselines for round 2: `https://github.com/castorini/anserini/blob/master/docs/expcovid.md` medT5-3B: a T5-3B reranker fine-tuned on MS MARCO then fine-tuned (again) on MS MARCOmedical subset.

A.4 Model Training and Validation

Parameter	Value
Train Hardware	QuadroRTX 8000 GPU CUDA version 10.1
Train Dataset	Med-MARCO (this work)
Loss Fuction	Pairwise Cross-Entropy from Nogueira and Cho (2019)
Max. Query length	60
Max. Document Length	2000
Base Model	scibert-scivocab-uncased
BERT Learning Rate	2×10^{-5}
Final Layer Learning Rate	1×10^{-3}
Optimizer	Adam
Warm-up	None
Batch Size	16
Grad. Accumulation Size	2
Samples Validation	512
Patience	20
Validation Dataset	200 from MS-MARCO train
Validation Metric	MRR@10
Validation Re-rank	BM25 top 20
Train and Validation Index	Lucene (via Anserini)
Index Stemming	Porter
BM25 Parameters	k1=0.9, b=0.4 (defaults)

Modularized Transfomer-based Ranking Framework

Luyu Gao **Zhuyun Dai** **Jamie Callan**
Language Technologies Institute
Carnegie Mellon University
`{luyug, zhuyund, callan}@cs.cmu.edu`

Abstract

Recent innovations in Transformer-based ranking models have advanced the state-of-the-art in information retrieval. However, these Transformers are computationally expensive, and their opaque hidden states make it hard to understand the ranking process. In this work, we modularize the Transformer ranker into separate modules for text *representation* and *interaction*. We show how this design enables substantially faster ranking using offline pre-computed representations and light-weight online interactions. The modular design is also easier to interpret and sheds light on the ranking process in Transformer rankers.[1]

1 Introduction

Neural rankers based on Transformer architectures (Vaswani et al., 2017) fine-tuned from BERT (Devlin et al., 2019) achieve current state-of-the-art (SOTA) ranking effectiveness (Nogueira and Cho, 2019; Craswell et al., 2019). The power of the Transformer comes from self-attention, the process by which all possible pairs of input tokens interact to understand their connections and contextualize their representations. Self-attention provides detailed, token-level information for matching, which is critical to the effectiveness of Transformer-based rankers (Wu et al., 2019).

When used for ranking, a Transformer ranker takes in the concatenation of a query and document, applies a series of self-attention operations, and outputs from its last layer a relevance prediction (Nogueira and Cho, 2019). The entire ranker runs like a black box and hidden states have no explicit meanings. This represents a clear distinction from earlier neural ranking models that keep separate text representation and distance (interaction) functions. Transformer rankers are slow (Nogueira et al., 2019), and the black-box design makes it hard to interpret their behavior.

We hypothesize that a Transformer-based ranker simultaneously performs text representation and query-document interaction as it processes the concatenated pair. Guided by this hypothesis, we decouple representation and interaction with a *MO*dualarized *RE*ranking *S*ystem (MORES). MORES consists of three *Transformer* modules: the Document Representation Module, the Query Representation Module, and the Interaction Module. The two Representation Modules run independently of each other. The **Document Representation Module** uses self-attention to embed each document token conditioned on all document tokens. The **Query Representation Module** embeds each query token conditioned on all query tokens. The **Interaction Module** performs attention from *query* representations to *document* representations to generate match signals and aggregates them through self-attention over query tokens to make a relevance prediction.

By disentangling the Transformer into modules for representation and interaction, MORES can take advantage of the indexing process: while the interaction must be done online, document representations can be computed offline. We further propose two strategies to pre-compute document representations that can be used by the Interaction Module for ranking.

Our experiments on a large supervised ranking dataset demonstrate the effectiveness and efficiency of MORES. It is as effective as a state-of-the-art BERT ranker and can be up to 120× faster at ranking. A domain adaptation experiment shows that the modular design does not affect the model transfer capability, so MORES can be used under low-resource settings with simple adaptation techniques. By adapting individual modules, we discovered differences between represen-

November 16–20, 2020.

tations and interaction in adaptation. The modular design also makes MORES more interpretable, as shown by our attention analysis, providing new understanding of black-box Transformer rankers.

2 Related Work

Neural ranking models for IR proposed in previous studies can be generally classified into two groups (Guo et al., 2016): *representation-based* models, and *interaction-based* models.

Representation-based models learn latent vectors (embeddings) of queries and documents and use a simple scoring function (e.g., cosine) to measure the relevance between them. Such methods date back to LSI (Deerwester et al., 1990) and classical siamese networks (Bromley et al., 1993). More recent research considered using modern deep learning techniques to learn the representations. Examples include DSSM (Huang et al., 2013), C-DSSM (Shen et al., 2014), etc. Representations-based models are efficient during evaluation because the document representations are independent of the query, and therefore can be pre-computed. However, compressing a document into a single low-dimensional vector loses specific term matching signals (Guo et al., 2016). As a result, previous representation-based ranking models mostly fail to outperform interaction-based ones.

Interaction-based models, on the other hand, use a neural network to model the word-level interactions between the query and the document. Examples include DRMM (Guo et al., 2016) and K-NRM (Xiong et al., 2017). Recently, Transformers (Vaswani et al., 2017), especially BERT (Devlin et al., 2019) based Transformers, have been widely used in information retrieval ranking tasks (Nogueira and Cho, 2019; Dai and Callan, 2019; Qiao et al., 2019). BERT-based rankers concatenate query and document into a single string and apply self-attention that spans over the query and the document in every layer. Rankers using pre-trained Transformers such as BERT has become the current state-of-the-art (Craswell et al., 2019). However, the performance gains come at the computational cost of inferring the many token-level interaction signals at the evaluation time, which scales quadratically to the input length. It is an open question whether we can *combine* the advantages of representation-based and interaction-based approaches. Little research has studied this direction prior to this work.

There are several research directions aiming to reduce the computational cost of Transformer models. One line of research seeks to compress the big Transformer into smaller ones using model pruning (Voita et al., 2019) or knowledge distillation (Hinton et al., 2015; Sanh et al., 2019). Another line of research aims to develop new Transformer-like units that have lower complexity than the original Transformer. For example, (Child et al., 2019) introduces sparse factorizations of the attention matrix which efficiently compute subsets of the attention matrix. The focus of this work is an efficient framework to combine Transformers for ranking; all aforementioned techniques can be applied to individual Transformers within our framework, and are therefore orthogonal to this paper.

3 Proposed Method

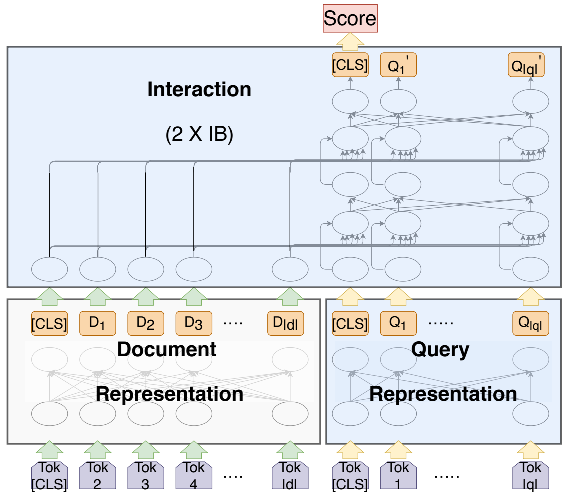
In this section, we introduce the Modularized Reranking System (MORES), how MORES can speed up retrieval, and how to effectively train and initialize MORES.

3.1 The MORES Framework

A typical Transformer ranker takes in the *concatenation* of a query qry and a document doc as input. At each layer, the Transformer generates a new contextualized embedding for each token based on its attention to all tokens in the concatenated text. This formulation poses two challenges. First, in terms of speed, the attention consumes time quadratic to the input length. As shown in Table 1, for a query of q tokens and a document of d tokens, the Transformer would require assessments of $(d+q)^2$ pairs of tokens. Second, as query and document attention is entangled from the first layer, it is challenging to interpret the model.

MORES aims to address both problems by disentangling the Transformer ranker into document representation, query representation, and interaction, each with a dedicated Transformer, as shown in Figure 1. The document representation is query-agnostic and can be computed off-line. The interaction uses query-to-document attention, which further reduces online complexity. This separation also assigns roles to each module, making the model more transparent and interpretable.

Figure 1: An illustration of the attention within a MORES model using two layers of Interaction Blocks (2× IB). Representation Modules only show 1 layer of attention due to space limits. In a real model, Document Representation Module and Query Representation Module are deeper than shown here.



The two **Representation Modules** use Transformer encoders (Vaswani et al., 2017) to embed documents and queries respectively and independently. In particular, for documents,

$$H_l^{doc} = \text{Encoder}_l^{doc}(H_{l-1}^{doc}) \tag{1}$$
$$H_1^{doc} = \text{Encoder}_1^{doc}(\text{lookup}(doc)) \tag{2}$$

and for queries,

$$H_l^{qry} = \text{Encoder}_l^{qry}(H_{l-1}^{q}) \tag{3}$$
$$H_1^{qry} = \text{Encoder}_1^{qry}(\text{lookup}(qry)) \tag{4}$$

where lookup represents word[2] and position embeddings, and Encoder represents a Transformer encoder layer. Query and document Representation Modules can use different numbers of layers. Let M and N denote the number of layers for document and query representations respectively. The hidden states from the last layers are used as the Representation Modules' output. Formally, for a document of length d, query of length q, and model dimension n, let matrix $D = H_M^{doc} \in \mathbb{R}^{d \times n}$ be the output of the Document Representation Module and $Q = H_N^{qry} \in \mathbb{R}^{q \times n}$ be the output of the Query Representation module.

The **Interaction Module** uses the Representation Modules' outputs, Q and D, to make a relevance judgement. The module consists of a stack of Interaction Blocks (IB), a novel attentive block that performs query-to-document cross-attention, followed by query self-attention[3], as shown in Figure 1. Here, we write cross-attention from X to Y as $\text{Attend}(X, Y)$, self-attention over X as $\text{Attend}(X, X)$ and layer norm as LN. Let,

$$Q_{\text{x}} = \text{LN}(\text{Attend}(Q, D) + Q) \tag{5}$$
$$Q_{\text{self}} = \text{LN}\left(\text{Attend}(Q_{\text{x}}, Q_{\text{x}}) + Q_{\text{x}}\right) \tag{6}$$

Equation 5 models interactions from query tokens to document token. Each query token in Q attends to document embeddings in D to produce relevance signals. Then, Equation 6 collects and exchanges signals among query tokens by having the query tokens attending to each other. The output of the first Interaction Block (IB) is then computed with a feed-forward network (FFN) on the query token embeddings with residual connections,

$$\text{IB}(Q, D) = \text{LN}\left(\text{FFN}\left(Q_{\text{self}}\right) + Q_{\text{self}}\right) \tag{7}$$

We employ multiple Interaction Blocks to iteratively repeat this process and refine the hidden query token representations, modeling multiple rounds of interactions, producing a series of hidden states, *while keeping document representation D unchanged*,

$$H_l^{IB} = \text{IB}_l(H_{l-1}^{IB}, D) \tag{8}$$
$$H_1^{IB} = \text{IB}_1(Q, D) \tag{9}$$

The Interaction Block (IB) is a core component of MORES. As shown in Table 1, its attention avoids the heavy full-attention over the concatenated query-document sequence, i.e. $(d+q)^2$ terms, saving online computation.

To induce relevance, we project the [CLS] token's embedding in the last (K^{th}) IB's output to a score,

$$score(qry, doc) = \mathbf{w}^T \text{CLS}(H_K^{\text{IB}}) \tag{10}$$

3.2 Pre-Compute and Reuse Representation

MORES's modular design allows us to precompute and reuse representations. The Query Representation Module runs once when receiving the new query; the representation is then repeatedly used to rank the candidate documents. More importantly, the document representations can be built offline. We detail two representation

---

[2] We use WordPiece tokens, following BERT.

[3] We use multi-head version of attention in the Interaction Blocks (IB).

Table 1: Time complexity of MORES and a typical Transformer ranker, e.g., a standard BERT ranker. We write q for query length, d for document length, n for Transformer's hidden layer dimension, and N_{doc} for number of candidate documents to be ranked for each query. For interaction, Reuse-S1 corresponds to document representation reuse strategy, and Reuse-S2 projected document representation reuse strategy.

	Total, 1 Query-Document Pair	Online, 1 Query-Document Pair	Online, N_{doc} Documents
Typical Transformer Ranker	$n(d+q)^2 + n^2(d+q)$	$n(d+q)^2 + n^2(d+q)$	$(n(d+q)^2 + n^2(d+q))N_{doc}$
Document Representation	$nd^2 + n^2d$	0	0
Query Representation	$nq^2 + n^2q$	$nq^2 + n^2q$	$(nq^2 + n^2q)$
Interaction w/ Reuse-S1	$n(qd+q^2) + n^2(q+d)$	$n(qd+q^2) + n^2(q+d)$	$(n(qd+q^2) + n^2(q+d))N_{doc}$
Interaction w/ Reuse-S2	$n(qd+q^2) + n^2(q+d)$	$n(qd+q^2) + n^2q$	$(n(qd+q^2) + n^2q)N_{doc}$

reuse strategies with different time vs. space trade-offs: 1) a document representation reuse strategy that stores the Document Representation Module's output, and 2) a projected document representation reuse strategy that stores the Interaction Module's intermediate transformed document representations. These strategies have the same overall math, produce *the same* ranking results, and only differ in time/space efficiency.

Document Representation Reuse Strategy (Reuse-S1) runs the Document Representation Module offline, pre-computing document representations D for all documents in the collection. When receiving a new query, MORES looks up document representations D for candidate documents, runs the Query Representation Module to get a query's representation Q, and feeds both to the Interaction Module to score. This strategy reduces computation by not running the Document Representation Module at query time.

Projected Document Representation Reuse Strategy (Reuse-S2) further moves document-related computation performed in the Interaction Module offline. In an IB, the cross-attention operation first projects document representation D with key and value linear projections (Vaswani et al., 2017)

$$D_k = DW_k,\ D_v = DW_v \tag{11}$$

where W_k, W_v are the projection matrices. For each IB, Reuse-S2 pre-computes and stores D_{proj}[4],

$$D_{proj} = \{DW_k, DW_v\} \tag{12}$$

Using Reuse-S2, the Interaction Module no longer needs to compute the document projections at online evaluation time. Reuse-S2 takes more storage: for each IB, both key and value projections of D are stored, meaning that an Interaction Module with l IBs will store $2l$ projected versions of D. With this extra pre-computation, Reuse-S2 trades storage for further speed-up.

Table 1 analyzes the online time complexity of MORES and compares it to the time complexity of a standard BERT ranker. We note that MORES can move all document only computation offline. Reuse-S1 avoids the document self attention term d^2, which is often the most expensive part due to long document length. Reuse-S2 further removes from online computation the document transformation term n^2d, one that is linear in document length and quadratic in model dimension.

3.3 MORES Training and Initialization

MORES needs to learn three Transformers: two Representation Modules and one Interaction Module. The three Transformer modules are *coupled* during training and *decoupled* when used. To train MORES, we connect the three Transformers and enforce module coupling with end-to-end training using the pointwise loss function (Dai and Callan, 2019). When training is finished, we store the three Transformer modules separately and apply each module at the desired offline/online time.

We would like to use pre-trained LM weights to ease optimization and improve generalization. However, there is no existing pre-trained LM that involves cross-attention interaction that can be used to initialize the Interaction Module. To avoid expensive pre-training, we introduce BERT weight assisted initialization. We use one copy of BERT weights to initialize the Document Representation Module. We split another copy of BERT weights between Query Representation and Interaction Modules. For MORES with l IBs, the first $12-l$ layers of the BERT weights initialize the Query Representation Module, and the remaining

---

[4] We pre-compute for all attention heads in our multi-head implementation

l layers' weights initialize the Interaction Module. This initialization scheme ensures that Query Representation Module and the IBs use consecutive layers from BERT. As a result, upon initialization, the output of the Query Representation Module and the input of the first IB will live in the same space. In addition, for IBs, query to document attention initializes with the same BERT attention weights as query self-attention. In practice, we found initializing query to document attention weights important; random initialization leads to substantially worse performance. Details can be found in subsection 4.2.

4 Effectiveness and Efficiency in Supervised Ranking

The first experiment compares the effectiveness and efficiency of MORES to a state-of-the-art BERT ranker for supervised ranking.

4.1 Setup

We use the **MS MARCO passage ranking collection** (MS MARCO) (Nguyen et al., 2016) and evaluate on two query sets with distinct characteristics: *Dev Queries* have a single relevant document with a binary relevance label. Following Nguyen et al. (2016), we used MRR@10 to evaluate the ranking accuracy on this query set. *TREC2019 DL Queries* is the evaluation set used in the TREC 2019 Deep Learning Track. Its queries have multiple relevant documents with graded relevance. Following Craswell et al. (2019), we used MRR, NDCG@10, and MAP@1000 as evaluation metrics. All methods were evaluated in a *reranking* task to re-rank the top 1000 documents of the MS MARCO official BM25 retrieval results.

We test MORES effectiveness with a varied number of Interaction Blocks (IB) to study the effects of varying the complexity of query-document interaction. Models using 1 layer of IB (1× IB) up to 4 layers of IB (4× IB) are tested.

We compare MORES with the BERT ranker, a state-of-the-art ranker fine-tuned from BERT, which processes concatenated query-document pairs. Both rankers are trained with the MS MARCO training set consisting of single relevance queries. We train MORES on a 2M subset of Marco's training set. We use stochastic gradient descent to train the model with a batch size of 128. We use AdamW optimizer with a learning rate of 3e-5, a warm-up of 1000 steps and a linear learning rate scheduler for all MORES variants. Our baseline BERT model is trained with similar training setup to match performance reported by Nogueira and Cho (2019). Our BERT ranker re-implementation has better performance compared to that reported by Nogueira and Cho (2019). The BERT ranker and all MORES models are implemented with Pytorch (Paszke et al., 2019) based on the huggingface implementation of Transformers (Wolf et al., 2019).

We aim to test that MORES' accuracy is equivalent to the original BERT ranker (while achieving higher efficiency). To establish equivalence, statistical significance testing was performed with a non-inferiority test commonly used in the medical field to test that two treatments have similar effectiveness (Jayasinghe et al., 2015). In this test, rather than testing to reject the null hypothesis H_0: $\mu_{\text{BERT}} = \mu_{\text{MORES}}$, we test to reject H_0' : $\mu_{\text{BERT}} - \mu_{\text{MORES}} > \delta$ for some small margin δ. By rejecting H_0' we accept the alternative hypothesis, which is that any reduction of performance in MORES compared to the original BERT ranker is inconsequential. We set the margin δ to 2% and 5% of the mean of the BERT ranker.

4.2 Ranking Effectiveness

Table 2 reports the accuracy of MORES and the baseline BERT-based ranker. The experiments show that MORES with 1× IB can achieve 95% of BERT performance. MORES with 2× IB can achieve performance comparable to the BERT ranker with a 2% margin. Three IBs does not improve accuracy and four hurts accuracy. We believe that this is due to increased optimization difficulties which outweighs improved model capacity. Recall that for MORES we have one set of artificial cross attention weights *per IB* not initialized with real pre-trained weights. Performance results are consistent across the two query sets, showing that MORES can identify strong relevant documents (Dev Queries), and can also generalize to ranking multiple, weaker relevant documents (TREC2019 DL Queries).

The results show that MORES can achieve ranking accuracy competitive with state-of-the-art ranking models, and suggest that the entangled and computationally expensive full-attention Transformer can be replaced by MORES's lightweight, modularized design. Document

Table 2: Effectiveness of MORES models and baseline rankers on the MS MARCO Passage Corpus. $*$ and $\dagger$ indicate non-inferiority (Section 4.1) with $p < 0.05$ to the BERT ranker using a 5% or 2% margin, respectively.

	MS MARCO Passage Ranking			
	Dev Queries	TREC2019 DL Queries		
Model	MRR	MRR	NDCG@10	MAP
BERT ranker	0.3527	0.9349	0.7032	0.4836
MORES 1× IB	0.3334^*	0.8953^*	0.6721^*	0.4516^*
MORES 2× IB	$0.3456^\dagger$	$0.9283^\dagger$	$0.7026^\dagger$	$0.4777^\dagger$
MORES 3× IB	$0.3423^\dagger$	$0.9271^\dagger$	$0.6980^\dagger$	0.4687^*
MORES 4× IB	0.3307^*	$0.9322^\dagger$	0.6565^*	0.4559^*

Table 3: Ranking Accuracy of MORES when using / not using attention weights copied from BERT to initialize Interaction Module. The models were tested on the MS MARCO dataset with the Dev Queries.

	Dev Queries	TREC2019 DL		
	MRR@10	MRR	NDCG@10	MAP
copy	0.3456	0.9283	0.7026	0.4777
random	0.2723	0.8430	0.6059	0.3702

Table 4: Average time in seconds to evaluate one query with 1,000 candidate documents, and the space used to store pre-computed representations for each document. Len: input document length.

(a) Document Representation Reuse (Reuse-S1)

Len	Model	CPU Time		GPU Time		Space (MB)
128	BERT ranker	161s	-	2.70s	-	0
	MORES 1×IB	4s	40x	0.04s	61x	0.4
	MORES 2×IB	8s	20x	0.12s	22 x	0.4
512	BERT ranker	698s	-	13.05s	-	0
	MORES 1×IB	11s	66x	0.14s	91x	1.5
	MORES 2×IB	20s	35x	0.32s	40x	1.5

(b) Projected Document Representation Reuse (Reuse-S2)

Len	Model	CPU Time		GPU Time		Space (MB)
128	BERT ranker	161s	-	2.70s	-	0
	MORES 1×IB	2s	85x	0.02s	118x	1.5
	MORES 2×IB	5s	36x	0.05s	48x	3.0
512	BERT ranker	698s	-	13.05s	-	0
	MORES 1×IB	3s	170x	0.08s	158x	6.0
	MORES 2×IB	6s	124x	0.10s	124x	12.0

and query representations can be computed independently without seeing each other. With the contextualized representation, 2 layers of lightweight interaction are sufficient to estimate relevance.

We also investigate IB initialization and compare MORES 2× IB initialized by our proposed initialization method (copy self attention weight of BERT as IB cross attention weight), with a random initialization method (cross attention weights randomly initialized). Table 3 shows that random initialization leads to a substantial drop in performance, likely due to difficulty in optimization.

4.3 Ranking Efficiency

Section 3.2 introduces two representation reuse strategies for MORES with different time vs. space trade-offs. This experiment measures MORES' real-time processing speeds with these two strategies and compares them with measurement for the BERT ranker. We test MORES 1× IB and MORES 2× IB. Additional IB layers incur more computation but do not improve effectiveness, and are hence not considered. We record average time for ranking one query with 1000 candidate documents on an 8-core CPU and a single GPU.[5] We measured ranking speed with documents of length 128 and 512 with a fixed query length of 16. Tables 4 (a) and (b) show the speed tests for the two reuse strategies, respectively. We also include per document data storage size [6].

We observe a substantial speedup in MORES compared to the BERT ranker, and the gain is consistent across CPUs and GPUs. The original BERT ranker took hundreds of seconds – several minutes – to generate results for one query on a CPU machine, which is impractical for real-time use. Using Reuse-S1, MORES with 1× IB was 40x faster than the BERT ranker on shorter documents ($d = 128$); the more accurate 2× IB model also achieved 20x speedup. The difference is more profound on longer documents. As the length of the document increases, a larger portion of compute in BERT ranker is devoted to performing self-attention over the document sequence. MORES pre-computes document representations

---

[5] Details are in Appendix A.1.

[6] We report un-compressed values. Compression can further reduce data storage.

Table 5: Domain adaptation on ClueWeb09-B. adapt-interaction and adapt-representation use MORES 2× IB. $*$ and $\dagger$ indicate non-inferiority (Section 4.1) with $p < 0.05$ to the BERT ranker using a 5% or 2% margin, respectively.

Table 6: Domain adaptation on Robust04. adapt-interaction and adapt-representation use MORES 2× IB. $*$ and $\dagger$ indicate non-inferiority (Section 4.1) with $p < 0.05$ to the BERT ranker using a 5% or 2% margin, respectively.

	Robust04					
	Title Queries			Description Queries		
	NDCG@20	MAP	Prec@20	NDCG@20	MAP	Prec@20
BERT ranker	0.4632	0.2225	0.3958	0.5065	0.245	0.4147
MORES 1× IB	0.4394^*	0.2097	0.3741^*	0.4683	0.2263	0.3835
MORES 2× IB	$0.4599^\dagger$	$0.2194^\dagger$	$0.3940^\dagger$	0.4846^*	0.2323^*	0.4008^*
MORES 3× IB	$0.4551^\dagger$	0.2135^*	$0.3934^\dagger$	0.4854^*	0.2334^*	0.4006^*
MORES 4× IB	$0.4553^\dagger$	$0.2177^\dagger$	$0.3938^\dagger$	0.4802	0.2309	0.3980^*
adapt-interaction	0.4389	0.2117^*	0.3723	0.4697	0.2249	0.3896
adapt-representation	$0.4564^\dagger$	$0.2182^\dagger$	$0.3926^\dagger$	0.4884^*	0.2327^*	0.4042^*

and avoids document-side self attention, yielding up to 35x to 90x speedup on longer documents ($d = 512$).

Reuse-S2 – the projected document reuse strategy – further enlarges the gain in speed, leading to up to 170x speedup using 1× IB, and 120x speedup using 2× IB. Recall that Reuse-S2 precomputes the document projections that will be used in MORES' Interaction Module, which is of n^2d time complexity where n is the model hidden dimension (details can be found in the complexity analysis in Table 1). In practice, n is often large, e.g., our experiment used $n = 768$[7]. Reuse-S2 avoids the expensive n^2d term at evaluation time. Note that Reuse-S2 *does not affect accuracy*; it trades space to save more time.

5 Adaptation of MORES and Modules

The second experiment uses a domain-adaptation setting to investigate whether the modular design of MORES affects adaptation and generalization ability, and how the individual Interaction and Representation Modules behave across domains.

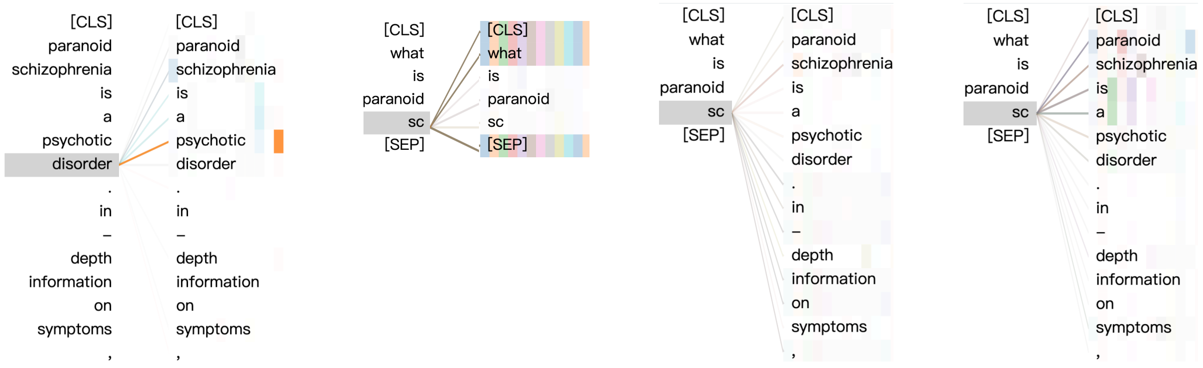
5.1 Setup

This experiment trains MORES using the MS MARCO dataset, and adapts the model to two datasets: ClueWeb09-B and Robust04. ClueWeb09-B is a standard document retrieval collection with 50M web pages crawled in 2009. Evaluation queries come from the TREC 2009-2012 Web Tracks. We used two variants of the queries: *Title Queries* is 200 short, keyword-style queries. *Description Queries* is 200 queries that are natural language statements or questions. Robust04 is a news corpus with 0.5M documents. Evaluation queries come from TREC 2004 Robust Track, including 250 *Title Queries* and 250 *Description Queries*. We evaluate ranking performance with NDCG@20, MAP, and Prec@20.

Domain adaptation is done by taking a model trained on MS MARCO and fine-tuning the model on relevant labels from the target dataset. Due to the small query sets in ClueWeb09-B and Robust04, we use 5-fold cross-validation for fine-tuning and testing. Data split, initial ranking, and document pre-processing follow Dai and Callan

---

[7] This follows model dimension in BERT



(a) Document Representation (b) Query Representation (c) Interaction (1st IB) (d) Interaction (2nd IB)

Figure 2: Visualization of attention in MORES's Representation and Interaction Modules.

(2019). The domain adaptation fine-tuning procedures use a batch size of 32 and a learning rate of 5e-6 while having other training settings same as supervised ranking training.

5.2 Full Model Adaptation

The top 5 rows of Table 5 and Table 6 examine the effectiveness of adapting the full model of MORES. The adapted MORES models behave similarly as on MS MARCO: using two to three layers of Interaction Blocks (IB) achieves very close to BERT ranker performance on both datasets for both types of queries while using a single layer of IB is less effective. Importantly, our results show that the modular design of MORES does not hurt domain transfer, indicating that new domains and low resource domains can also use MORES through simple adaptation.

5.3 Individual Module Adaptation

With separate representation and interaction components in MORES, we are interested to see how each is affected by adaptation. We test two extra adaptation settings on MORES 2× IB: fine-tuning only Interaction Module on the target domain (adapt-interaction) or only Representation Modules (adapt-representation) on target domain. Results are shown in the bottom two rows of Table 5 and Table 6 for the two data sets.

We observe that only adapting the Interaction Module to the target domain is less effective compared to adapting the full model (MORES 2× IB), suggesting that changing the behaviour of interaction is not enough to accommodate language changes across domains. On the other hand, freezing the Interaction Module and only fine-tuning the Representation Modules (adapt-representation) produces performance on par with full model apdatation. This result shows that it is more necessary to have domain-specific representations, while interaction patterns are more general and not totally dependent on representations.

6 Analysis

The modular design of MORES allows Representation and Interaction to be inspected separately, providing better interpretability than a black-box Transformer ranker. Figure 2 examines the attention with MORES for a hard-to-understand query *"what is paranoid sc"* where "sc" is ambiguous, along with a relevant document *"Paranoid schizophrenia is a psychotic disorder. In-depth information on symptoms...."* [8]

In the Document Representation Module (Figure 2a), we can see that *"disorder"* uses *"psychotic"* and *"schizophrenia"* for contextualization, making itself more specific. In the Query Representation Module (Figure 2b), because the query is short and lacks context, *"sc"* incurs a broad but less meaningful attention. The query token *"sc"* is further contextualized in the Interaction Module (Figure 2c) using information from the document side – *"sc"* broadly attends to the document token in the first IB to disambiguate itself. With the extra context, *"sc"* is able to correctly attend to "schizophrenia" in the second IB to produce relevance signals (Figure 2d).

This example explains why MORES 1× IB performs worse than MORES with multiple IBs – ambiguous queries need to gather context from the document in the first IB before making relevance estimates in the second. More importantly, the example indicates that the query to document

---

[8] We only show the first 16 tokens due to space limitation.

attention has two distinct contributions: understand query tokens with the extra context from the document, and match query tokens to document tokens, with the former less noticed in the past. We believe MORES can be a useful tool for better interpreting and understanding SOTA black-box neural rankers.

7 Conclusion

State-of-the-art neural rankers based on the Transformer architecture consider all token pairs in a concatenated query and document sequence. Though effective, they are slow and challenging to interpret. This paper proposes MORES, a modular Transformer ranking framework that decouples ranking into Document Representation, Query Representation, and Interaction. MORES is effective while being efficient and interpretable.

Experiments on a large supervised ranking task show that MORES is as effective as a state-of-the-art BERT ranker. With our proposed document representation pre-compute and re-use methods, MORES can achieve 120x speedup in online ranking while retaining accuracy. Domain adaptation experiments show that MORES' modular design does not hurt transfer ability, indicating that MORES can be adapted to low-resource domains with simple techniques.

Decoupling representation and interaction provides new understanding of Transformer rankers. Complex full query-document attention in state-of-the-art Transformer rankers can be factored into independent document and query representation, and shallow light-weight interaction. We further discovered two types of interaction: further query understanding based on the document, and the query to document tokens matching for relevance. Moreover, we found that the interaction in ranking is less domain-specific, while the representations need more domain adaptation. These findings provide opportunities for future work towards more efficient and interpretable neural IR.

A Appendix

A.1 Implmentation Details

Training Details On MS MARCO passage ranking dataset, we trained MORES over a 2M subset of Marco's training set. We use stochastic gradient descent to train the model with a batch size of 128. We use AdamW optimizer with a learning rate of 3e-5, a warm-up of 1000 steps and a linear learning rate scheduler for all MORES variants. Our baseline BERT model is trained with similar training setup to match performance reported in (Nogueira and Cho, 2019). We have not done hyper-parameter search, and all training setup is inherited from GLUE example in the huggingface transformer code base (Wolf et al., 2019). Following (Dai and Callan, 2019), we run a domain adaptation experiment on ClueWeb09-B: we take trained model on MS MARCO, and continue training over ClueWeb09-B's training data in a 5-fold cross-validation setup. We use a batch size of 32 and a learning rate of 5e-6. We select from batch size of 16 and 32, learning rate of 5e-6, 1e-5 and 2e-5 by validation point-wise accuracy.

Speed Test Details GPU test was run on a single RTX 2080 TI, with CUDA 10.1. We use a separate CUDA stream to pre-fetch data to the GPU. CPU tests was run in a SLURM task environment with 8 Xeon Silver 4110 logical cores.

A.2 Parameter Details

All MORES models follow BERT's architecture for initialization, having 12 attention heads, 768 embedding dimension, 3072 feed forward network hidden dimension. MORES with one IB up to four IBs have parameters of 224M, 228M, 231M and 233M parameters respectively.

A.3 Datasets

We use MSMARCO, ClueWeb09-b and Robust04. The first is available at `https://microsoft.github.io/msmarco/` and the latter two at `http://boston.lti.cs.cmu.edu/appendices/SIGIR2019-Zhuyun-Dai`. All input text are tokenized by BERT's WordPiece tokenizer without other pre-processing. We evaluate MS MARCO Dev query sets with its provided evaluation script and the rest with trec_eval (`https://github.com/usnistgov/trec_eval`).

Ad-hoc Document Retrieval using Weak-Supervision with BERT and GPT2

Abstract

We describe a weakly-supervised method for training deep learning models for the task of ad-hoc document retrieval. Our method is based on generative and discriminative models that are trained using weak-supervision based solely on the documents in the corpus. We present an end-to-end retrieval system that starts with traditional information retrieval methods, followed by two deep learning re-rankers. We evaluate our method on three different datasets: a COVID-19 related scientific literature dataset and two news datasets. We show that our method outperforms state-of-the-art methods; this without the need for the expensive process of manually labeling data.

1 Introduction

The ad-hoc retrieval task has been extensively studied by the Information Retrieval (IR) community. Traditional IR models evaluate ad-hoc queries against documents mainly on a syntactic (exact) word-matching basis (Manning et al., 2008). Recent years advances in Deep Learning (DL) methods have lead to further improvement in IR tasks, and among others, in ad-hoc document retrieval (Guo et al., 2019). DL methods add a semantic dimension to IR methods. However, such methods usually require large amounts of labeled data for model training.

In this work, we describe a novel weakly-supervised method for training DL methods for ad-hoc document retrieval. Motivated by the recent work of (Mass et al., 2020) on Frequently Asked Questions (FAQ) retrieval, we assume that documents have at least three fields, namely *title*, *abstract* and *content*. Such documents are actually quite common nowadays in the scientific and news domains. Our main hypothesis is that: *titles and abstracts can take the role of questions and answers of FAQs, respectively.*

Whenever a document is missing a title, we consider its first sentence as its augmented title. In a similar way, whenever a document is missing an abstract, we consider the first 512 words of its content as the abstract.

The three fields are used for retrieving candidate documents. Inspired by (Mass et al., 2020), the title and abstract fields are further used as a weak-supervision data source for training two independent BERT (Devlin et al., 2019) models, that are then used to re-rank those candidates documents.

The first model matches user queries to documents' abstracts. Here we use the title-to-abstract associations to fine-tune a BERT model to semantically match queries to abstracts. The second model matches user queries to titles. Here our assumption is that by generating title paraphrases, we can train a model to match user queries to titles. To this end, we use GPT2 (Radford et al., 2018) to generate title paraphrases, which are then utilized for fine-tuning the second BERT model.

While our work is closely related to (Mass et al., 2020), with the lack of human-curated questions (such as in FAQs), we still need to resort to title paraphrases as (noisy) pseudo-questions and transfer (Mass et al., 2020)'s method to the more general task of ad-hoc document retrieval. Moreover, compared to FAQs that are relatively short, the current task deals with documents that can be quite long. Thus, in current paper we use three fields (title, abstract, content) and present a strong IR base line instead of only two fields and a simple IR baseline used in (Mass et al., 2020)

As a proof of concept, we evaluate our method on three benchmarks: *TREC-COVID* - a scientific literature dataset on COVID-19 topics; and TREC's newswire corpora: *Associated Press* (AP) and *Wall Street Journal* (WSJ). By combining the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4191–4197,
November 16–20, 2020.

two weakly-supervised BERT models with an existing strong IR baseline, we demonstrate that the former can help to elevate the performance of the latter. Our approach further outperforms state-of-the-art methods on these benchmarks.

2 Related Work

With the lack of training data, several weakly-supervised alternatives have been explored so far for the task at hand. (Dehghani et al., 2017b,a) and (Nie et al., 2018) have utilized rankings produced by BM25 model as training samples. (MacAvaney et al., 2019) have used pseudo query-document pairs that already exhibit relevance (e.g., newswire headline-content pairs). (Frej et al., 2019) have utilized Wikipedia's internal linkage to define automated queried topics. (Zhang et al., 2020) have used anchor texts and their linked web pages as query-document pairs.

Our work is different from all those works as we train a model to generate title paraphrases that are used to enable query-to-title (question) matching and not only query-to-abstract (answer) matching.

(Ma et al., 2020) have proposed a zero-shot retrieval approach using synthetic query generation by training a generative model on a different Community QA data. Our work differs from (Ma et al., 2020) in three main aspects. First, (Ma et al., 2020) focuses on QA, where answers are very short, while we generate title paraphrases from full abstracts. Second, we train a model to generate title paraphrases which are used to enable not only query-to-abstract (answer) matching, but also query-to-title (question) matching. Third, (Ma et al., 2020) filters the input QA pairs that are used to train the generative model by taking only pairs that were voted by at least one-user on those Community QA (CQA) sites. We do not have such voting so we use a smart filtering on the output data (namely on the generated title-paraphrases) as described in Section 3.3.

The work in (Chang et al., 2020) suggests an efficient neural method for initial retrieval of candidates. Their method uses a two-tower architecture which learns a different representation for passages and for queries. While their method can be used as an initial retrieval (instead of our IR method), the authors of (Chang et al., 2020) still require an additional re-ranking step. Thus it does not replace our two weakly-supervised BERT re-ranking models. Moreover, our two BERT models learn a joint attention-based representation for pairs of (query, abstarct) and (query, title) while in (Chang et al., 2020) they learn a separate representation for queries and passages.

3 Method

Inspired by (Mass et al., 2020), we consider the ad-hoc document retrieval problem as an instance of FAQ retrieval, where a document's title represents the question and its abstract the answer.

Our proposed retrieval approach allows to enhance existing state-of-the-art ad-hoc retrieval methods with weakly-supervised neural models that are completely trained from the documents collection itself without the need to supply manual relevance labels. Following the common approach (Guo et al., 2019), these neural-models are utilized for re-ranking candidate documents retrieved by a given IR baseline.

In what follows, the initial candidate documents retrieval uses pure IR similarities and relevance models (Section 3.1). The re-ranking step exploits two independent weakly-supervised BERT models, namely: **BERT-Q-a** (Section 3.2) for matching queries to abstracts and **BERT-Q-t** (Section 3.2) for matching queries to titles.

The final re-ranking is obtained by combining the outcome of the baseline IR method and the two BERT-based re-rankers using an unsupervised late-fusion step (Section 3.4). The components of our approach are described in the rest of this section.

3.1 Initial retrieval

We first obtain for each query a reasonable pool of candidate documents to be re-ranked using our weakly-supervised models. To this end we retrieve several ranked lists from an Apache Lucene[1] index using various state-of-the-art IR similarities. that are available in Lucene. The various retrieved lists are then combined to generate a single pool of top-k candidates for re-ranking by employing the *PoolRank* (Roitman, 2018) fusion method. We refer to this IR pipeline as **IR-Base**.

The IR similarities and the PoolRank method have few free-parameters that are tuned so to optimize Mean Average Precision (MAP@1000). Details are given in the experimental setup (Section 4.2) below.

---

[1] `https://lucene.apache.org/`

3.2 BERT-Q-a

We use pairs of title-abstract (t,a) of documents in the collection as a weak-supervision data source for fine-tuning a pre-trained BERT model which is then used to match user queries to abstracts.

Similar to (Mass et al., 2020), we fine-tune the BERT model (denoted **BERT-Q-a**) using a triplet network (Hoffer and Ailon, 2015). This network is adopted for BERT fine-tuning (Mass et al., 2019) using triplets (t, a, a'), where (t, a) constitutes a document title and its abstract. a' is a negative sampled abstract, obtained as follows. We run t as a query against the index (using the title and abstract fields) and sample n random abstracts from the top-k retrieved documents as negative examples (excluding a) (in our setup we used k=100 and n=2). At run time, given a user query Q, **BERT-Q-a** re-ranks the top-k candidate documents by matching Q to the abstracts (a) only.

3.3 BERT-Q-t

Similar to (Mass et al., 2020), we fine-tune a generative pre-trained (GPT-2) neural network model (Radford et al., 2018) for generating title paraphrases (instead of question paraphrases as in (Mass et al., 2020)).

Using N (t_i,a_i)-pairs, we concatenate titles and their abstracts into a long text $U = a_1$ [SEP] t_1 [EOS] $\cdots$ a_N [SEP] t_N [EOS], where [SEP] and [EOS] are special tokens. The GPT-2 fine-tuning samples sequences of l consecutive tokens in U (in our setup we used l=256), aiming to maximize the Language Model (LM) probability for generating the last token on each sequence, given its $l - 1$ preceding tokens.

Once the model is fine-tuned, we feed it with the text "a [SEP]", (a is an abstract), and let it generate tokens until [EOS] is generated. We take all generated tokens excluding [EOS], as a paraphrase to a's title t. We repeat the generation process n times (e.g., n=10) to generate n paraphrases to each title.

The generated paraphrases are filtered to ensure high quality paraphrases (Mass et al., 2020). Each paraphrase is run as a query against the Lucene index and only paraphrases that return the exact same documents as their original title are kept.

The filtered paraphrases are then used to fine-tune a second BERT model (denoted **BERT-Q-t**), using a triplet network (similar to **BERT-Q-a**), with triplets (p, t, t'), where p is a paraphrase of t and t' is a randomly selected title from the corpus. At run time, given a user query Q, **BERT-Q-t** re-ranks the top-k candidate documents by matching Q to titles (t) only.

3.4 Enhanced ad-hoc retrieval using Fusion

To enhance ad-hoc retrieval quality, we now propose to combine the two weakly-supervised fine-tuned BERT models with the baseline IR method (**IR-Base**, see again Section 3.1). To this end, following (Roitman, 2018), we utilize the *Two-Step PoolRank* (denoted **TSPR**) unsupervised fusion method – an extended PoolRank method that estimates document relevance using the three ranked lists (obtained by **IR-Base**, **BERT-Q-a** and **BERT-Q-t**) as pseudo-relevance evidence sources.

4 Evaluation

4.1 Datasets and Indexing

We evaluated our proposed approach using three different benchmarks. The first benchmark, **TREC-COVID**[2], is based on the CORD-19 dataset[3], which contains scientific documents related to the recent Coronavirus pandemic. We used the Round-1 challenge which consists of 43K documents[4] and 30 topics (queries) with their query relevance sets (qrels). Documents in this dataset have three fields (title, abstract and content). The two other benchmarks are based on news articles datasets: **AP** (Association Press, about 242K docs) and **WSJ** (Wall Street Journal, about 160K docs). These datasets are part of the TREC ad-hoc retrieval newswire collection[5]. Here we used topics 51-150 and topics 151-200 (with their respective qrels) for the AP and WSJ datasets, respectively. Those two datasets have only title and content so we created the abstract by taking the first 512 tokens of the content.

We used Apache Lucene to process and indexed the (multi-field) documents, employed with English analysis (tokenization, lower-casing, Porter stemming and stopping). Each indexed document has three main fields: *title*, *abstract* and *content*.

4.2 Experimental Setup

We used an initial candidate pool of $k = 1000$ documents retrieved by **IR-Base** and re-ranked by the two BERT models. We detail below the setup of each of the three rankers and their fusion.

---

[2] `https://bit.ly/2ApmLcz`

[3] `https://bit.ly/3dxyZ1i`

[4] Round-1 contained about 51K documents, but we kept only those that have a non-empty content

[5] `https://bit.ly/3gJcF6X`

IR-Base. The following Lucene similarities configurations were used: i) BM25Similarity (Robertson and Zaragoza, 2009) with $k1 = 1.2$ and $b = 0.7$. ii) LMDirichletSimilarity (Zhai, 2009) with Dirichlet-smoothing parameter $\mu = 200$ and $\mu = 1000$ for TREC-COVID and news datasets, respectively. iii) DFRSimilarity (Amati and Van Rijsbergen, 2002) with BasicModelIF, AfterEffectB and NormalizationH3. iv) AxiomaticF1LOG (Fang and Zhai, 2005) with growth parameter $s = 0.25$ and $s = 0.1$ for TREC-COVID and news datasets, respectively.

BERT models. We used the pytorch huggingface implementation of BERT and GPT2[6]. For the two BERT models we used bert-base-uncased (12-layers, 768-hidden, 12-heads, 110M parameters). Fine-tuning was done with a learning rate of 2e-5 and 3 training epochs. For training BERT-Q-a on each of the three datasets, we used a subset of their first 20K documents. For TREC-COVID, we used SciBERT model (Beltagy et al., 2019) (that was pre-trained on 1M scientific documents), as it yields better results than using the vanilla pre-trained BERT model. This is mainly due to the scientific nature of the documents in this benchmark.

GPT2. For generating title paraphrases we used GPT2 small model (12-layers, 768-hidden, 12-heads, 110M parameters). For fine-tuning we used (title, abstract) pairs from all documents of TREC-COVID and a subset of the first 20K documents of the other two datasets. We generated 10 paraphrases for the first 20K documents of each of the three datasets. After filtering the generated paraphrases, we were left with 18K, 4.5K and 3.5K paraphrases for TREC-COVID, WSJ and AP respectively. [7]

Fusion. We fine-tuned the PoolRank (Roitman, 2018) method's parameters for all datasets as follows: For *Base fusion* we used *CombSUM* (Nuray and Can, 2006) with sum-normalization. The other parameters were set as: *Pseudo-relevance set size*: 5 documents. *Term clip size*: 100. Document re-ranking using KL-score (equally interpolated with the CombSUM score) with Dirichlet-smoothing parameter $\mu = 200$ and $\mu = 1000$ for TREC-COVID and news datasets, respectively.

We assessed retrieval quality using the following metrics: *Precision* (P@5), *Normalized Discounted Cumulative Gain* (NDCG@10) and *Mean Average Precision* (MAP@1000). All experiments were run on two 32GB V100 GPUs. The re-ranking times of 1000 documents for each query were 11 sec for **BERT-Q-a** (using BERT's max_seq_len of 512) and 5 sec for **BERT-Q-q** (max_seq_len = 256).

4.3 Results

We now report the evaluation results of the TREC-COVID benchmark and the two news benchmarks (AP and WSJ) in Table 2 and Table 3, respectively. We compared our three rankers (**IR-Base, BERT-Q-a and BERT-Q-t**) and their fusion (**TSPR**). We further evaluated two additional **TSPR** versions, namely: **TSPR-Q-a** and **TSPR-Q-t** where we only fused the **IR-Base** ranked-list with either **BERT-Q-a** or **BERT-Q-t**, respectively.

To demonstrate the relative effectiveness of our proposed approach, we compared its quality to state-of-the-art alternative baselines. On TREC-COVID, we directly compared against the three best automatic performing systems[8] (out of 141 system runs submitted to the Round-1 challenge by 56 different teams), namely: **sabir**, **IRIT_markers** and **unipd.it**.

On the news benchmarks (AP and WSJ), we compared against quality metrics (when available) that were previously reported for the following state-of-the-art unsupervised and semi-supervised IR methods: **ClustMRF** (Raiber and Kurland, 2013), **NVSM** (Gysel et al., 2018), **LBDM** (Wei and Croft, 2006), **PGR** (Krikon et al., 2011) and **CRM** (Gelfer Kalmanovich and Kurland, 2009).

The symbols △ and ▲ in both tables denote a statistical significant ($p < 0.05$) result with **IR-Base** and the best alternative baseline, respectively.

4.3.1 Retrieval enhancement

The first and most important observation that we now make is that, consistently over the three benchmarks, the proposed method **TSPR**, which fuses the initial IR retrieval (**IR-Base**) and the two weakly-supervised BERT models, performs significantly better than each of the three separately, on all measures. As a second observation, we note that, **TSPR** employed with both BERT models significantly outperforms **TSPR-Q-a** and **TSPR-Q-t**.

---

[6] `https://bit.ly/2Me0Gk1`

[7] The filtered paraphrases can be downloaded from https://github.com/YosiMass/ad-hoc-retrieval

[8] The details of these systems as well as other competing systems are available in `https://bit.ly/2XjkE2T`

These two observations confirm our hypothesis that: 1) BERT contributes a semantic understanding of the data and thus improves the ad-hoc retrieval task over pure IR methods; and 2) each of the two BERT models contributes a different semantic aspect. **BERT-Q-a**, which was trained on the relation between titles and abstracts, allows to consider the semantic similarity between a user query and abstracts. Moreover, **BERT-Q-t**, which was trained on titles and their paraphrases, can successfully match a user query to titles.

To examine the semantic differences of our three rankers, we report their P@1 performance. On **TREC-COVID**, there were 12 queries in which **BERT-Q-t** and **IR-Base** differed in their P@1, and 9 queries in which **BERT-Q-a** and **IR-Base** differed. On **AP**, differences from **IR-Base** were on 32 and 31 queries for **BERT-Q-t** and **BERT-Q-a** respectively, and on **WSJ**, differences were on 11 and 23 queries for **BERT-Q-t** and **BERT-Q-a** respectively.

Table 1 shows some example queries from **TREC-COVID**, where **BERT-Q-t** returned a correct top-1 answer (showing its title), while **IR-Base** returned a wrong one.

Query BERT-Q-t	how does the coronavirus respond to changes in the weather The Effects of Temperature and Relative Humidity on the Viability of the SARS Coronavirus
Query BERT-Q-t	how long can the coronavirus live outside the body Microbes, Transmission Routes and Survival Outside the Body

Table 1: Example queries and titles of correct top-1 documents retrieved by **BERT-Q-t** on **TREC-COVID**

Looking further at the effect of each of the two BERT models as a standalone ranker, we can see that on **TREC-COVID**, **BERT-Q-t** performed better than **BERT-Q-a**, while on the two news datasets it was the other way around. This can be attributed to the length of the titles. In **TREC-COVID** titles are much longer (13 words on average compared to 9.8 and 8.2 words on **WSJ** and **AP** respectively) and hence carry more information.

4.3.2 Comparison with alternative baselines

Looking further down the tables, we notice that our proposed method, **TSPR**, outperforms all alternative baselines in most of the cases and metrics.

On the **TREC-COVID** benchmark, **TSPR** provides a better retrieval quality compared to the best systems. Interestingly, some systems (such as **IRIT_markers**) fine-tuned a BERT model (including SciBERT) using an auxiliary largely annotated dataset such as MS-Marco, yet still fall behind **TSPR**'s quality. This serves as another strong empirical evidence on the importance of our weakly-supervised BERT fine-tuning directly on the domain's data.

Table 2: Retrieval quality on TREC-COVID.

Method	P@5	NDCG@10	MAP
IR-Base	.753	.597	.297
BERT-Q-a	.466	.373	.148

PGR	.537	-	-	.612	-	-
CRM	.521	-	**.301**	.620	-	**.409**

Finally, on the two news benchmarks, **TSPR** overpass most of the quality metrics that were previously reported for state-of-the-art alternatives.

5 Conclusions and Future work

We have cast a solution for FAQ retrieval to a solution for ad-hoc document retrieval, where titles and abstracts took the role of questions and answers in FAQs. We have shown that, using the corpus itself, we could generate weakly-supervised title paraphrases for training a BERT model that matches queries to titles. Coupled with a second BERT model that was trained to match queries to abstracts, we have experimentally shown on three different benchmarks that our proposed method outperformed state-of-the-art alternatives.

As a future work, we plan to utilize automatic summarization for missing abstracts, instead of taking the first 512 content tokens.

Abstract

We study *semantic collisions*: texts that are semantically unrelated but judged as similar by NLP models. We develop gradient-based approaches for generating semantic collisions and demonstrate that state-of-the-art models for many tasks which rely on analyzing the meaning and similarity of texts—including paraphrase identification, document retrieval, response suggestion, and extractive summarization—are vulnerable to semantic collisions. For example, given a target query, inserting a crafted collision into an irrelevant document can shift its retrieval rank from 1000 to top 3. We show how to generate semantic collisions that evade perplexity-based filtering and discuss other potential mitigations. Our code is available at `https://github.com/csong27/collision-bert`.

1 Introduction

Deep neural networks are vulnerable to adversarial examples (Szegedy et al., 2014; Goodfellow et al., 2015), i.e., imperceptibly perturbed inputs that cause models to make wrong predictions. Adversarial examples based on inserting or modifying characters and words have been demonstrated for text classification (Liang et al., 2018; Ebrahimi et al., 2018; Pal and Tople, 2020), question answering (Jia and Liang, 2017; Wallace et al., 2019), and machine translation (Belinkov and Bisk, 2018; Wallace et al., 2020). These attacks aim to minimally perturb the input so as it to preserve its semantics while changing the output of the model.

In this work, we introduce and study a different class of vulnerabilities in NLP models for analyzing the meaning and similarity of texts. Given an input (query), we demonstrate how to generate a **semantic collision**: an unrelated text that is judged semantically equivalent by the target model. Semantic collisions are the "inverse" of adversarial examples. Whereas adversarial examples are similar inputs that produce dissimilar model outputs, semantic collisions are dissimilar inputs that produce similar model outputs.

We develop gradient-based approaches for generating collisions given white-box access to a model and deploy them against several NLP tasks. For paraphrase identification, the adversary crafts collisions that are judged as a valid paraphrase of the input query; downstream applications such as removing duplicates or merging similar content will thus erroneously merge the adversary's inputs with the victim's inputs. For document retrieval, the adversary inserts collisions into one of the documents that cause it to be ranked very high even though it is irrelevant to the query. For response suggestion, the adversary's irrelevant text is ranked as the top suggestion and can also carry spam or advertising. For extractive summarization, the adversary inserts a collision into the input text, causing it to be picked as the most relevant content.

Our first technique generates collisions aggressively, without regard to potential defenses. We then develop two techniques, "regularized aggressive" and "natural," that constrain generated collisions using a language model so as to evade perplexity-based filtering. We evaluate all techniques against state-of-the-art models and benchmark datasets on all four tasks. For paraphrase identification on Quora question pairs, our collisions are (mis)identified as paraphrases of inputs with 97% confidence on average. For document retrieval, our collisions shift the median rank of irrelevant documents from 1000 to around 10. For response suggestion in dialogue (sentence retrieval), our collisions are ranked as the top response 99% and 86% of the time with the aggressive and natural techniques, respectively. For extractive summarization, our collisions are chosen by the model as the summary 100% of the time. We conclude by discussing potential defenses against these attacks.

Table 1: Four tasks in our study. Given an input $\boldsymbol{x}$ and white-box access to a victim model, the adversary produces a collision $\boldsymbol{c}$ resulting in a deceptive output. Collisions can be nonsensical or natural-looking and also carry spam messages (shown in red).

2 Related Work

Adversarial examples in NLP. Most of the previously studied adversarial attacks in NLP aim to minimally modify or perturb inputs while changing the model's output. Hosseini et al. (2017) showed that perturbations, such as inserting dots or spaces between characters, can deceive a toxic comment classifier. HotFlip used gradients to find such perturbations given white-box access to the target model (Ebrahimi et al., 2018). Wallace et al. (2019) extended HotFlip by inserting a short crafted "trigger" text to any input as perturbation; the trigger words are often highly associated with the target class label. Other approaches are based on rules, heuristics or generative models (Mahler et al., 2017; Ribeiro et al., 2018; Iyyer et al., 2018; Zhao et al., 2018). As explained in Section 1, our goal is the inverse of adversarial examples: we aim to generate inputs with drastically different semantics that are perceived as similar by the model.

Several works studied attacks that change the semantics of inputs. Jia and Liang (2017) showed that inserting a heuristically crafted sentence into a paragraph can trick a question answering (QA) system into picking the answer from the inserted sentence. Aggressively perturbed texts based on HotFlip are nonsensical and can be translated into meaningful and malicious outputs by black-box translation systems (Wallace et al., 2020). Our semantic collisions extend the idea of changing input semantics to a different class of NLP models; we design new gradient-based approaches that are not perturbation-based and are more effective than HotFlip attacks; and, in addition to nonsensical adversarial texts, we show how to generate "natural" collisions that evade perplexity-based defenses.

Feature collisions in computer vision. Feature collisions have been studied in image analysis models. Jacobsen et al. (2019a) showed that images from different classes can end up with identical representations due to excessive invariance of deep models. An adversary can modify the input to change its class while leaving the model's prediction unaffected (Jacobsen et al., 2019b). The intrinsic property of rectifier activation function can cause images with different labels to have the same feature vectors (Li et al., 2019).

3 Threat Model

We describe the targets of our attack, the threat model, and the adversary's objectives.

Semantic similarity. Evaluating semantic similarity of a pair of texts is at the core of many NLP applications. *Paraphrase identification* decides whether sentences are paraphrases of each other and can be used to merge similar content and remove duplicates. *Document retrieval* computes semantic similarity scores between the user's query and each of the candidate documents and uses these scores to rank the documents. *Response suggestion*, aka Smart Reply (Kannan et al., 2016) or sentence retrieval, selects a response from a pool of candidates based on their similarity scores to the user's input in dialogue. *Extractive summarization* ranks sentences in a document based on their semantic similarity to the document's content and outputs the top-ranked sentences.

For each of these tasks, let f denote the model and $\boldsymbol{x}_a, \boldsymbol{x}_b$ a pair of text inputs. There are two common modeling approaches for these applications. In the first approach, the model takes the concatenation $\oplus$ of $\boldsymbol{x}_a$ and $\boldsymbol{x}_b$ as input and directly produces a similarity score $f(\boldsymbol{x}_a \oplus \boldsymbol{x}_b)$. In the second approach, the model computes a sentence-level embedding $f(\boldsymbol{x}) \in \mathbb{R}^h$, i.e., a dense vector representation of input $\boldsymbol{x}$. The similarity score is then computed as $s(f(\boldsymbol{x}_a), f(\boldsymbol{x}_b))$, where s is a vector similarity metric such as cosine similarity. Models based on either approach are trained with similar losses, such as the binary classification loss where each pair of inputs is labeled as 1 if semantically related, 0 otherwise. For generality, let $\mathcal{S}(\cdot,\cdot)$ be a similarity function that captures semantic relevance under either approach. We also assume that f can take $\boldsymbol{x}$ in the form of a sequence of discrete words (denoted as w) or word embedding vectors (denoted as $\boldsymbol{e}$), depending on the scenario.

Assumptions. We assume that the adversary has full knowledge of the target model, including its architecture and parameters. It may be possible to transfer white-box attacks to the black-box scenario using model extraction (Krishna et al., 2020; Wallace et al., 2020); we leave this to future work. The adversary controls some inputs that will be used by the target model, e.g., he can insert or modify candidate documents for a retrieval system.

Adversary's objectives. Given a target model f and target sentence $\boldsymbol{x}$, the adversary wants to generate a collision $\boldsymbol{x}_b = \boldsymbol{c}$ such that f perceives $\boldsymbol{x}$ and $\boldsymbol{c}$ as semantically similar or relevant. Adversarial uses of this attack depend on the application. If an application is using paraphrase identification to merge similar contents, e.g., in Quora (Scharff, 2015), the adversary can use collisions to deliver spam or advertising to users. In a retrieval system, the adversary can use collisions to boost the rank of irrelevant candidates for certain queries. For extractive summarization, the adversary can cause collisions to be returned as the summary of the target document.

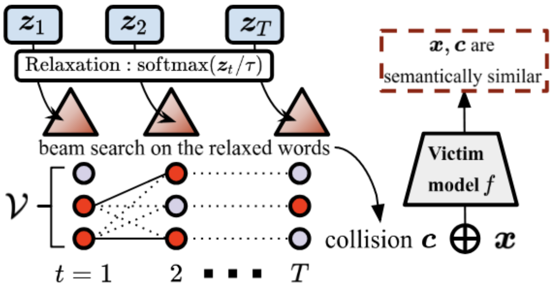

Figure 1: Overview of generating semantic collision $\boldsymbol{c}$ for a query input $\boldsymbol{x}$. The continuous variables $\boldsymbol{z}_t$ relax the words in $\boldsymbol{c}$ and are optimized with gradients. We search in the simplex produced by $\boldsymbol{z}_t$ for the actual colliding words in $\boldsymbol{c}$.

4 Adversarial Semantic Collisions

Given an input (query) sentence $\boldsymbol{x}$, we aim to generate a collision $\boldsymbol{c}$ for the victim model with the white-box similarity function $\mathcal{S}$. This can be formulated as an optimization problem: $\arg\max_{\boldsymbol{c}\in\mathcal{X}} \mathcal{S}(\boldsymbol{x}, \boldsymbol{c})$ such that $\boldsymbol{x}$ and $\boldsymbol{c}$ are semantically unrelated. A brute-force enumeration of $\mathcal{X}$ is computationally infeasible. Instead, we design gradient-based approaches outlined in Algorithm 1. We consider two variants: (a) aggressively generating unconstrained, nonsensical collisions, and (b) constrained collisions, i.e., sequences of tokens that appear fluent under a language model and cannot be automatically filtered out based on their perplexity.

We assume that models can accept inputs as both hard one-hot words and soft words,[1] where a soft word is a probability vector $\breve{\boldsymbol{w}} \in \Delta^{|\mathcal{V}|-1}$ for vocabulary $\mathcal{V}$.

4.1 Aggressive Collisions

We use gradient-based search to generate a fixed-length collision given a target input. The search is done in two steps: 1) we find a continuous representation of a collision using gradient optimization with relaxation, and 2) we apply beam search to produce a hard collision. We repeat these two steps iteratively until the similarity score $\mathcal{S}$ converges.

---

[1] For a soft-word input, models will compute the word vector as the weighted average of word embeddings by the probability vector.

Algorithm 1 Generating adversarial semantic collisions

```

    return $\boldsymbol{z} = \boldsymbol{\ell} + \boldsymbol{\delta}$
```

Optimizing for soft collision. We first relax the optimization to a continuous representation with temperature annealing. Given the model's vocabulary $\mathcal{V}$ and a fixed length T, we model word selection at each position t as a continuous logit vector $\boldsymbol{z}_t \in \mathbb{R}^{|\mathcal{V}|}$. To convert each $\boldsymbol{z}_t$ to an input word, we model a softly selected word at t as:

$$\check{\boldsymbol{c}}_t = \operatorname{softmax}(\boldsymbol{z}_t/\tau) \tag{1}$$

where τ is a temperature scalar. Intuitively, softmax on $\boldsymbol{z}_t$ gives the probability of each word in $\mathcal{V}$. The temperature controls the sharpness of word selection probability; when $\tau \to 0$, the soft word $\check{\boldsymbol{c}}_t$ is the same as the hard word $\arg\max \boldsymbol{z}_t$.

We optimize for the continuous values $\boldsymbol{z}$. At each step, the soft word collisions $\check{\boldsymbol{c}} = [\check{\boldsymbol{c}}_1, \ldots, \check{\boldsymbol{c}}_T]$ are forwarded to f to calculate $\mathcal{S}(\boldsymbol{x}, \check{\boldsymbol{c}})$. Since all operations are continuous, the error can be back-propagated all the way to each $\boldsymbol{z}_t$ to calculate its gradients. We can thus apply gradient ascent to improve the objective.

Searching for hard collision. After the relaxed optimization, we apply a projection step to find a hard collision using discrete search.[2] Specifically, we apply left-to-right beam search on each $\boldsymbol{z}_t$. At every search step t, we first get the top K words w based on $\boldsymbol{z}_t$ and rank them by the target similarity $\mathcal{S}(\boldsymbol{x}, \boldsymbol{c}_{1:t-1} \oplus w \oplus \check{\boldsymbol{c}}_{t+1:T})$, where $\check{\boldsymbol{c}}_{t+1:T}$ is the partial soft collision starting at $t+1$. This procedure allows us to find a hard-word replacement for the soft word at each position t based on the previously found hard words and relaxed estimates of future words.

Repeating optimization with hard collision. If the similarity score still has room for improvement after the beam search, we use the current $\boldsymbol{c}$ to initialize the soft solution $\boldsymbol{z}_t$ for the next iteration of optimization by transferring the hard solution back to continuous space.

In order to initialize the continuous relaxation from a hard sentence, we apply label smoothing (LS) to its one-hot representation. For each word $\boldsymbol{c}_t$ in the current $\boldsymbol{c}$, we soften its one-hot vector to be inside $\Delta^{|\mathcal{V}|-1}$ with

$$\operatorname{LS}(\boldsymbol{c}_t)_w = \begin{cases} 1-\epsilon & \text{if } w = \arg\max \boldsymbol{c}_t \\ \frac{\epsilon}{|\mathcal{V}|-1} & \text{otherwise} \end{cases} \tag{2}$$

where ϵ is the label-smoothing parameter. Since $\operatorname{LS}(\boldsymbol{c}_t)$ is constrained in the probability simplex $\Delta^{|\mathcal{V}|-1}$, we set each $\boldsymbol{z}_t$ to $\log \operatorname{LS}(\boldsymbol{c}_t) \in \mathbb{R}^{|\mathcal{V}|}$ as the initialization for optimizing the soft solution in the next iteration.

4.2 Constrained Collisions

The Aggressive approach is very effective at finding collisions, but it can output nonsensical sentences. Since these sentences have high perplexity under a language model (LM), simple filtering can eliminate them from consideration. To evade perplexity-based filtering, we impose a soft constraint on collision generation and jointly maximize target similarity and LM likelihood:

$$\max_{\boldsymbol{c} \in \mathcal{X}} (1-\beta) \cdot \mathcal{S}(\boldsymbol{x}, \boldsymbol{c}) + \beta \cdot \log P(\boldsymbol{c}; g) \tag{3}$$

---

[2] We could project the soft collision by annealing the temperature to 0, $\boldsymbol{c} = [\arg\max \boldsymbol{z}_1, \ldots, \arg\max \boldsymbol{z}_T]$. However, this approach yields sub-optimal results because the hard $\arg\max$ discards information from nearby words.

where $P(\boldsymbol{c}; g)$ is the LM likelihood for collision $\boldsymbol{c}$ under a pre-trained LM g and $\beta \in [0, 1]$ is an interpolation coefficient.

We investigate two different approaches for solving the optimization in equation 3: (a) adding a regularization term on soft $\check{\boldsymbol{c}}$ to approximate the LM likelihood, and (b) steering a pre-trained LM to generate natural-looking $\boldsymbol{c}$.

4.2.1 Regularized Aggressive Collisions

Given a language model g, we can incorporate a soft version of the LM likelihood as a regularization term on the soft aggressive $\check{\boldsymbol{c}}$ computed from the variables $[\boldsymbol{z}_1, \ldots, \boldsymbol{z}_T]$:

$$\Omega = \sum_{t=1}^{T} H(\check{\boldsymbol{c}}_t, P(w_t | \check{\boldsymbol{c}}_{1:t-1}; g)) \qquad (4)$$

where $H(\cdot, \cdot)$ is cross entropy, $P(w_t | \check{\boldsymbol{c}}_{1:t-1}; g)$ are the next-token prediction probabilities at t given partial soft collision $\check{\boldsymbol{c}}_{1:t-1}$. Equation 4 relaxes the LM likelihood on hard collisions by using soft collisions as input, and can be added to the objective function for gradient optimization. The variables $\boldsymbol{z}_t$ after optimization will favor words that maximize the LM likelihood.

To further reduce the perplexity of $\boldsymbol{c}$, we exploit the degeneration property of LM, i.e., the observation that LM assigns low perplexity to repeating common tokens (Holtzman et al., 2020), and constrain a span of consecutive tokens in $\boldsymbol{c}$ (e.g., second half of $\boldsymbol{c}$) to be selected from most frequent English words instead of the entire $\mathcal{V}$. This modification produces even more disfluent collisions, but they evade LM-based filtering.

4.2.2 Natural Collisions

Our final approach aims to produce fluent, low-perplexity outputs. Instead of relaxing and then searching, we search and then relax each step for equation 3. This lets us integrate a hard language model while selecting next words in continuous space. In each step t, we maximize:

$$\begin{aligned} \max_{w \in \mathcal{V}} \quad & (1 - \beta) \cdot \mathcal{S}(\boldsymbol{x}, \boldsymbol{c}_{1:t-1} \oplus w) + \\ & \beta \cdot \log P(\boldsymbol{c}_{1:t-1} \oplus w; g) \end{aligned} \qquad (5)$$

where $\boldsymbol{c}_{1:t-1}$ is the beam solution found before t. This sequential optimization is essentially LM decoding with a joint search on the LM likelihood and target similarity $\mathcal{S}$, of the collision prefix.

Optimizing equation 5 exactly requires ranking each $w \in \mathcal{V}$ based on LM likelihood $\log P(\boldsymbol{c}_{1:t-1} \oplus w; g)$ and similarity $\mathcal{S}(\boldsymbol{x}, \boldsymbol{c}_{1:t-1} \oplus w)$. Evaluating LM likelihood for every word at each step is efficient because we can cache $\log P(\boldsymbol{c}_{1:t-1}; g)$ and compute the next-word probability in the standard manner. However, evaluating an arbitrary similarity function $\mathcal{S}(\boldsymbol{x}, \boldsymbol{c}_{1:t-1} \oplus w), \forall w \in \mathcal{V}$, requires $|\mathcal{V}|$ forwarded passes to f, which can be computationally expensive.

Perturbing LM logits. Inspired by Plug and Play LM (Dathathri et al., 2020), we modify the LM logits to take similarity into account. We first let $\boldsymbol{\ell}_t = g(\boldsymbol{c}_{1:t-1})$ be the next-token logits produced by LM g at step t. We then optimize from this initialization to find an update that favors words maximizing similarity. Specifically, we let $\boldsymbol{z}_t = \boldsymbol{\ell}_t + \boldsymbol{\delta}_t$ where $\boldsymbol{\delta}_t \in \mathbb{R}^{|\mathcal{V}|}$ is a perturbation vector. We then take a small number of gradient steps on the relaxed similarity objective $\max_{\boldsymbol{\delta}_t} \mathcal{S}(\boldsymbol{x}, \boldsymbol{c}_{1:t-1} \oplus \check{\boldsymbol{c}}_t)$ where $\check{\boldsymbol{c}}_t$ is the relaxed soft word as in equation 1. This encourages the next-word prediction distribution from the perturbed logits, $\check{\boldsymbol{c}}_t$, to favor words that are likely to collide with the input $\boldsymbol{x}$.

Joint beam search. After perturbation at each step t, we find the top K most likely words in $\check{\boldsymbol{c}}_t$. This allows us to only evaluate $\mathcal{S}(\boldsymbol{x}, \boldsymbol{c}_{1:t-1} \oplus w)$ for this subset of words w that are likely under the LM given the current beam context. We rank these top K words based on the interpolation of target loss and LM log likelihood. We assign a score to each beam $\boldsymbol{b}$ and each top K word as in equation 5, and update the beams with the top-scored words.

This process leads to a natural-looking decoded sequence because each step utilizes the true words as input. As we build up a sequence, the search at each step is guided by the joint score of two objectives, semantic similarity and fluency.

5 Experiments

Baseline. We use a simple greedy baseline based on HotFlip (Ebrahimi et al., 2018). We initialize the collision text with a sequence of repeating words, e.g., “the”, and iteratively replace all words. In each iteration, we look at every position t and flip the current w_t to v that maximizes the first-order Taylor approximation of target similarity $\mathcal{S}$:

$$\operatorname*{arg\,max}_{1 \le t \le T, v \in \mathcal{V}} (\boldsymbol{e}_i - \boldsymbol{e}_v)^{\top} \nabla_{\boldsymbol{e}_t} \mathcal{S}(\boldsymbol{x}, \boldsymbol{c}) \qquad (6)$$

where $\boldsymbol{e}_t, \boldsymbol{e}_v$ are the word vectors for w_t and v. Following prior HotFlip-based attacks (Michel et al., 2019; Wallace et al., 2019, 2020), we evaluate $\mathcal{S}$

using the top K words from Equation 6 and flip to the word with the lowest loss to counter the local approximation.

LM for natural collisions. For generating natural collisions, we need a LM g that shares the vocabulary with the target model f. When targeting models that do not share the vocabulary with an available LM, we fine-tune another BERT with an autoregressive LM task on the Wikitext-103 dataset (Merity et al., 2017). When targeting models based on RoBERTa, we use pretrained GPT-2 (Radford et al., 2019) as the LM since the vocabulary is shared.

Unrelatedness. To ensure that collisions $\boldsymbol{c}$ are not semantically similar to inputs $\boldsymbol{x}$, we filter out words that are relevant to $\boldsymbol{x}$ from $\mathcal{V}$ when generating $\boldsymbol{c}$. First, we discard non-stop words in $\boldsymbol{x}$; then, we discard 500 to 2,000 words in $\mathcal{V}$ with the highest similarity score $\mathcal{S}(\boldsymbol{x}, w)$.

Hyperparameters. We use Adam (Kingma and Ba, 2015) for gradient ascent. Detailed hyperparameter setup can be found in table 6 in Appendix A.

Notation. In the following sections, we abbreviate HotFlip baseline as **HF**; aggressive collisions as **Aggr.**; regularized aggressive collisions as **Aggr.** $\boldsymbol{\Omega}$ where Ω is the regularization term in equation 4; and natural collisions as **Nat.**

5.1 Tasks and Models

We evaluate our attacks on paraphrase identification, document retrieval, response suggestions and extractive summarization. Our models for these applications are pretrained transformers, including BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), fine-tuned on the corresponding task datasets and matching state-of-the-art performance.

Paraphrase detection. We use the Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005) and Quora Question Pairs (QQP) (Iyer et al., 2017), and attack the first 1,000 paraphrase pairs from the validation set.

We target the BERT and RoBERTa base models for MRPC and QQP, respectively. The models take in concatenated inputs $\boldsymbol{x}_a, \boldsymbol{x}_b$ and output the similarity score as $\mathcal{S}(\boldsymbol{x}_a, \boldsymbol{x}_b) = \mathrm{sigmoid}(f(\boldsymbol{x}_a \oplus \boldsymbol{x}_b))$. We fine-tune them with the suggested hyperparameters. BERT achieves 87.51% F1 score on MRPC and RoBERTa achieves 91.6% accuracy on QQP, consistent with prior work.

Document retrieval. We use the Common Core Tracks from 2017 and 2018 (Core17/18). They have 50 topics as queries and use articles from the New York Times Annotated Corpus and TREC Washington Post Corpus, respectively.

Our target model is Birch (Yilmaz et al., 2019a,b). Birch retrieves 1,000 candidate documents using the BM25 and RM3 baseline (Abdul-jaleel et al., 2004) and re-ranks them using the similarity scores from a fine-tuned BERT model. Given a query $\boldsymbol{x}_q$ and a document $\boldsymbol{x}_d$, the BERT model assigns similarity scores $\mathcal{S}(\boldsymbol{x}_q, \boldsymbol{x}_i)$ for each sentence $\boldsymbol{x}_i$ in $\boldsymbol{x}_d$. The final score used by Birch for re-reranking is: $\gamma \cdot \mathcal{S}_{\text{BM25}} + (1-\gamma) \cdot \sum_i \kappa_i \cdot \mathcal{S}(\boldsymbol{x}_q, \boldsymbol{x}_i)$ where $\mathcal{S}_{\text{BM25}}$ is the baseline BM25 score and γ, κ_i are weight coefficients. We use the published models[3] and coefficient values for evaluation.

We attack similarity scores $\mathcal{S}(\boldsymbol{x}_q, \boldsymbol{x}_i)$ by inserting sentences that collide with $\boldsymbol{x}_q$ into irrelevant $\boldsymbol{x}_d$. We filter out query words when generating collisions $\boldsymbol{c}$ so that term frequencies of query words in $\boldsymbol{c}$ are 0, thus inserting collisions does not affect the original $\mathcal{S}_{\text{BM25}}$. For each of the 50 query topics, we select irrelevant articles that are ranked from 900 to 1000 by Birch and insert our collisions into these articles to boost their ranks.

Response suggestion. We use the Persona-chat (Chat) dataset of dialogues (Zhang et al., 2018). The task is to pick the correct utterance in each dialogue context from 20 choices. We attack the first 1,000 contexts from the validation set.

We use transformer-based Bi- and Poly-encoders that achieved state-of-the-art results on this dataset (Humeau et al., 2020). Bi-encoders compute a similarity score for the dialogue context $\boldsymbol{x}_a$ and each possible next utterance $\boldsymbol{x}_b$ as $\mathcal{S}(\boldsymbol{x}_a, \boldsymbol{x}_b) = f_{\text{pool}}(\boldsymbol{x}_a)^\top f_{\text{pool}}(\boldsymbol{x}_b)$ where $f_{\text{pool}}(\boldsymbol{x}) \in \mathbb{R}^h$ is the pooling-over-time representation from transformers. Poly-encoders extend Bi-encoders compute $\mathcal{S}(\boldsymbol{x}_a, \boldsymbol{x}_b) = \sum_{i=1}^{T} \alpha_i \cdot f(\boldsymbol{x}_a)_i^\top f_{\text{pool}}(\boldsymbol{x}_b)$ where α_i is the weight from attention and $f(\boldsymbol{x}_a)_i$ is the ith token's contextualized representation. We use the published models[4] for evaluation.

Extractive summarization. We use the CNN / DailyMail (CNNDM) dataset (Hermann et al., 2015), which consists of news articles and labeled overview highlights. We attack the first 1,000 articles from the validation set.

Our target model is PreSumm (Liu and Lapata, 2019). Given a text $\boldsymbol{x}_d$, PreSumm first obtains a

vector representation $\boldsymbol{\phi}_i \in \mathbb{R}^h$ for each sentence $\boldsymbol{x}_i$ using BERT, and scores each sentence $\boldsymbol{x}_i$ in the text as $\mathcal{S}(\boldsymbol{x}_d, \boldsymbol{x}_i) = \text{sigmoid}(\boldsymbol{u}^\top f(\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_T)_i)$ where $\boldsymbol{u}$ is a weight vector, f is a sentence-level transformer, and $f(\cdot)_i$ is the ith sentence's contextualized representation. Our objective is to insert a collision $\boldsymbol{c}$ into $\boldsymbol{x}_d$ such that the rank of $\mathcal{S}(\boldsymbol{x}_d, \boldsymbol{c})$ among all sentences is high. We use the published models[5] for evaluation.

5.2 Attack Results

For all attacks, we report the similarity score $\mathcal{S}$ between $\boldsymbol{x}$ and $\boldsymbol{c}$; the "gold" baseline is the similarity between $\boldsymbol{x}$ and the ground truth. For MRPC, QQP, Chat, and CNNDM, the ground truth is the annotated label sentences (e.g., paraphrases or summaries); for Core17/18, we use the sentences with the highest similarity $\mathcal{S}$ to the query. For MRPC and QQP, we also report the percentage of successful collisions with $\mathcal{S} > 0.5$. For Core17/18, we report the percentage of irrelevant articles ranking in the top-10 and top-100 after inserting collisions. For Chat, we report the percentage of collisions achieving top-1 rank. For CNNDM, we report the percentage of collisions with the top-1 and top-3 ranks (likely to be selected as summary). Table 2 shows the results.

On MRPC, aggressive and natural collisions achieve around 98% success; aggressive ones have higher similarity $\mathcal{S}$. With regularization Ω, success rate drops to 81%. On QQP, aggressive collisions achieve 97% vs. 90% for constrained collisions.

On Core17/18, aggressive collisions shift the rank of almost half of the irrelevant articles into the top 10. Regularized and natural collisions are less effective, but more than 60% are still ranked in the top 100. Note that query topics are compact phrases with narrow semantics, thus it might be harder to find constrained collisions for them.

On Chat, aggressive collisions achieve rank of 1 more than 99% of the time for both Bi- and Poly-encoders. With regularization Ω, success drops slightly to above 90%. Natural collisions are less successful, with 86% ranked as 1.

On CNNDM, aggressive collisions are almost always ranked as the top summarizing sentence. HotFlip and regularized collisions are in the top 3 more than 96% of the time. Natural collisions perform worse, with 77% ranked in the top 3.

Aggressive collisions always beat HotFlip on all tasks; constrained collisions are often better, too. The similarity scores $\mathcal{S}$ for aggressive collisions are always higher than for the ground truth.

5.3 Evaluating Unrelatedness

We use BERTSCORE (Zhang et al., 2020) to demonstrate that our collisions are unrelated to the target inputs. Instead of exact matches in raw texts, BERTSCORE computes a semantic similarity score, ranging from -1 to 1, between a candidate and a reference by using contextualized representation for each token in the candidate and reference.

The baseline for comparisons is BERTSCORE between the target input and the ground truth. For MRPC and QQP, we use $\boldsymbol{x}$ as reference; the ground truth is paraphrases as given. For Core17/18, we use $\boldsymbol{x}$ concatenated with the top sentences except the one with the highest $\mathcal{S}$ as reference; the ground truth is the sentence in the corpus with the highest $\mathcal{S}$. For Chat, we use the dialogue contexts as reference and the labeled response as the ground truth. For CNNDM, we use labeled summarizing sentences in articles as reference and the given abstractive summarization as the ground truth.

Aggr.	0.0%	0.0%	0.0%	0.0%	0.8%	0.7%	5.2%	2.6%	3.1%	3.1%
Aggr. Ω	47.5%	35.6%	15.8%	11.9%	29.3%	17.8%	76.5%	65.3%	52.8%	35.7%
Nat.	94.9%	89.2%	20.5%	12.1%	13.7%	10.9%	93.8%	86.5%	59.8%	37.7%

Table 4: Effectiveness of perplexity-based filtering. FP@90 and FP@80 are false positive rates (percentage of real data mistakenly filtered out) at thresholds that filter out 90% and 80% of collisions, respectively.

$\boldsymbol{c}$ type	MRPC		Chat	
	BERT	RoBERTa	Bi → Poly	Poly → Bi
HF	34.0%	0.0%	55.3%	48.9%
Aggr.	64.5%	0.0%	77.4%	71.3%
Aggr. Ω	38.9%	0.0%	60.5%	56.0%
Nat.	41.4%	0.0%	71.4%	68.2%

Table 5: Percentage of successfully transferred collisions for MRPC and Chat.

For MPRC, QQP and CNNDM, we report F_{BERT} (F_1) score. For Core17/18 and Chat, we report P_{BERT} (content from reference found in candidate) because the references are longer and not token-wise equivalent to collisions or ground truth. Table 3 shows the results. The scores for collisions are all negative while the scores for target inputs are positive, indicating that our collisions are unrelated to the target inputs. Since aggressive and regularized collisions are nonsensical, their contextualized representations are less similar to the reference texts than natural collisions.

5.4 Transferability of Collisions

To evaluate whether collisions generated for one target model f are effective against a different model f', we use MRPC and Chat datasets. For MRPC, we set f' to a BERT base model trained with a different random seed and a RoBERTa model. For Chat, we use Poly-encoder as f' for Bi-encoder f, and vice versa. Both Poly-encoder and Bi-encoder are fine-tuned from the same pretrained transformer model. We report the percentage of successfully transferred attacks, e.g., $\mathcal{S}(\boldsymbol{x}, \boldsymbol{c}) > 0.5$ for MRPC and $r = 1$ for Chat.

Table 5 summarizes the results. All collisions achieve some transferability (40% to 70%) if the model architecture is the same and f, f' are fine-tuned from the same pretrained model. Furthermore, our attacks produce more transferable collisions than the HotFlip baseline. No attacks transfer if f, f' are fine-tuned from different pretrained models (BERT and RoBERTa). We leave a study of transferability of collisions across different types of pretrained models to future work.

6 Mitigation

Perplexity-based filtering. Because our collisions are synthetic rather than human-generated texts, it is possible that their perplexity under a language model (LM) is higher than that of real text. Therefore, one plausible mitigation is to filter out collisions by setting a threshold on LM perplexity.

Figure 2 shows perplexity measured using GPT-2 (Radford et al., 2019) for real data and collisions for each of our attacks. We observe a gap between the distributions of real data and aggressive collisions, showing that it might be possible to find a threshold that discards aggressive collisions while retaining the bulk of the real data. On the other hand, constrained collisions (regularized or natural) overlap with the real data.

We quantitatively measure the effectiveness of perplexity-based filtering using thresholds that would discard 80% and 90% of collisions, respectively. Table 4 shows the false positive rate, i.e., fraction of the real data that would be mistakenly filtered out. Both HotFlip and aggressive collisions can be filtered out with little to no false positives since both are nonsensical. For regularized or natural collisions, a substantial fraction of the real data would be lost, while 10% or 20% of collisions evade filtering. On MRPC and Chat, perplexity-based filtering is least effective, discarding around 85% to 90% of the real data.

Learning-based filtering. Recent works explored automatic detection of generated texts using a binary classifier trained on human-written and machine-generated data (Zellers et al., 2019; Ippolito et al., 2020). These classifiers might be able to filter out our collisions—assuming that the adversary is not aware of the defense.

As a general evaluation principle (Carlini et al., 2019), any defense mechanism should assume that the adversary has complete knowledge of how the defense works. In our case, a stronger adversary may use the detection model to craft collisions to evade the filtering. We leave a thorough evaluation of these defenses to future work.

Adversarial training. Including adversarial examples during training can be effective against inference-time attacks (Madry et al., 2018). Similarly, training with collisions might increase models' robustness against collisions. Generating collisions for each training example in each epoch can be very inefficient, however, because it requires additional search on top of gradient optimization. We leave adversarial training to future work.

7 Conclusion

We demonstrated a new class of vulnerabilities in NLP applications: semantic collisions, i.e., input pairs that are unrelated to each other but perceived by the application as semantically similar. We developed gradient-based search algorithms for generating collisions and showed how to incorporate constraints that help generate more "natural" collisions. We evaluated the effectiveness of our attacks on state-of-the-art models for paraphrase identification, document and sentence retrieval, and extractive summarization. We also demonstrated that simple perplexity-based filtering is not sufficient to mitigate our attacks, motivating future research on more effective defenses.

Abstract

Interpretability of predictive models is becoming increasingly important with growing adoption in the real-world. We present RuleNN, a neural network architecture for learning transparent models for sentence classification. The models are in the form of rules expressed in first-order logic, a dialect with well-defined, human-understandable semantics. More precisely, RuleNN learns linguistic expressions (LE) built on top of predicates extracted using shallow natural language understanding. Our experimental results show that RuleNN outperforms statistical relational learning and other neuro-symbolic methods, and performs comparably with black-box recurrent neural networks. Our user studies confirm that the learned LEs are explainable and capture domain semantics. Moreover, allowing domain experts to modify LEs and instill more domain knowledge leads to human-machine cocreation of models with better performance.

1 Introduction

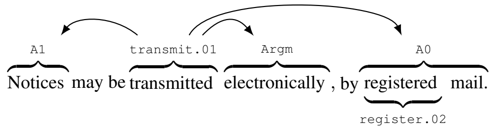
Difficult-to-interpret, black-box predictive models have been shown to harbor undesirable biases (e.g., racial bias in computing risk of recidivism among criminals (Angwin et al., 2016; Liptak, 2017)). Renewed interest in interpretability (BlackBoxNLP) has led to techniques for explaining not only the inner workings of the model but also to explain how it derives a prediction.

While various techniques for explainability exist (see survey by Guidotti et al. (2018)), one popular approach explains predictions from a black-box model by using a surrogate models (Ribeiro et al., 2016). Another extracts explanations from neural network layer activations, especially when said activations appeal to human intuition such as attention (Bahdanau et al., 2015) which may be interpreted as importance weights assigned to (latent) features derived by the model. While such approaches are useful, they raise questions such as whether the purported explanation provided by the surrogate correctly reflects the process employed by the black-box model to arrive at the prediction (sometimes called inexact explanation (Chu et al., 2018)). Similarly, attention only provides noisy explanations (Serrano and Smith, 2019). Such approaches leave room for improvement because explainability is treated as an after-thought whereas our goal is to treat it as a first-class citizen. In other words, is it possible to devise a neural network that directly learns a model expressed in a clear, human-readable dialect?

First-order logic (FOL) is a human-interpretable fragment of logic that includes existential ($\exists$) and universal ($\forall$) quantification along with propositional logic's conjunction ($\wedge$), disjunction ($\vee$) and negation ($\neg$) operators. FOL can model diverse applications such as data integration (Singla and Domingos, 2006), image interpretation (Donadello et al., 2017), and as the next example shows, natural language processing (NLP).

Consider identifying sentences denoting communication between two parties in a legal contract.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4211–4221,
November 16–20, 2020.



$$\texttt{communication(s)} \leftarrow \texttt{Contains}(s,a) \wedge a.\texttt{A1} = \textit{notice}$$
$$\wedge\ (a.\text{verb} = \textit{inform} \ \vee\ a.\text{verb} = \textit{transmit})$$

Figure 1: Legal contract sentence and an LE for label `communication` (syntax simplified for brevity).

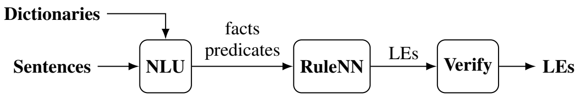


Figure 2: Pictorial depiction of our approach.

Figure 1 shows such a sentence along with linguistic abstractions in PropBank notation (Palmer et al., 2005) extracted using shallow semantic parsing. It consists of two actions, `transmit.01` and `register.02`, with arguments `A0`, `A1` and `Argm`. Figure 1 also shows an FOL rule that assigns label `communication` by evaluating linguistic clues. We refer to such rules as linguistic expressions (LE). More precisely, the LE in the figure assigns `communication` if: action belongs to the sentence, surface form of the action belongs to a dictionary containing "inform" and "transmit", and its `A1` argument matches a dictionary containing "notice". Not only does the LE's conditions evaluate to true on the sentence example, but attribution, i.e., which parts of the sentence led to the prediction is also clear: `transmit.01`, rather than `register.02`, leads to the predicted label because the surface form corresponding to `transmit.01`'s action and its `A1` argument is "transmit" and "notice", respectively. This allows domain experts to verify the LE's semantics and explain predictions without encountering aforementioned complications due to the use of surrogate models, for instance.

FOL rules may be learned using inductive logic programming (ILP) (Muggleton, 1996), statistical relational learning (StarAI) (Getoor and Taskar, 2007) or neuro-symbolic AI (Evans and Grefenstette, 2018). None of these however, target NLP. FOL rules consist of predicates which are Boolean functions that specify conditions for the rule to hold, e.g., `Contains` and dictionary-match conditions in Figure 1. Thus, we need to: 1) learn discriminative predicates, 2) combine them into LEs, and 3) learn multiple LEs in case one is insufficient. Figure 2 summarizes our approach. We leverage natural language understanding (NLU) to generate well defined, human-interpretable predicates. Our main contribution is RuleNN, a neural network (NN) comprising *predicate generation* (PGM) and *clause generation* (CGM) modules for learning and combining discriminative predicates to form LEs. By adding more modules, RuleNN can learn multiple LEs jointly. We also show how to extract LEs expressed in crisp FOL from RuleNN post-hoc that may, in turn, be handed to domain experts for verification and even modification, to instill further domain expertise going beyond the available training data.

By evaluating on two real-world sentence classification datasets and comparing against a host of baselines, we show that LEs learned by RuleNN lead to large gains in terms of area under the precision-recall curve (AUC-PR). Averaging across labels, RuleNN's AUC-PR is 6.8×, 7.6×, 1.5× that of ILP, StarAI, other neuro-symbolic AI approaches, respectively. We also compare against black-box methods that are far less explainable. In particular, we show that RuleNN's LEs are comparable to bi-directional LSTMs (Hochreiter and Schmidhuber, 1997) with GloVE embeddings (Pennington et al., 2014). A user study with 4 domain experts confirms that RuleNN's LEs are interpretable, capture domain semantics and are conducive to human-machine model co-creation. We make the following contributions:

- Propose LEs for explainable NLP constructed using predicates from NLU.
- Propose RuleNN, a modular NN for learning multiple LEs. Given predicates, RuleNN can learn rules for any application, not just NLP.
- Compare with ILP, StarAI, neuro-symbolic AI and LSTMs on real sentence classification data.
- Evaluate explainability of LEs via a user study.
- Illustrate human-machine co-creation by showing how humans interact with explainable LEs.

2 Related Work

Inductive logic programming (ILP) (Muggleton, 1996) learns rules that perfectly entail the positive examples and reject all negatives. Top-down ILP systems (Muggleton et al., 2008; Corapi et al., 2010; Cropper and Muggleton, 2015) in particular, generate rules before testing them on data. Since a 0-error rule may not exist, noise-tolerant ILP (Muggleton et al., 2018) learns rules that minimize error which is more suited for noisy real-world scenarios. We compare RuleNN against top-down and noise-tolerant ILP in Section 5.

Markov logic network (MLN) (Richardson and Domingos, 2006), a member of statistical relational learning (StarAI) (Getoor and Taskar, 2007), comprises weighted rules to extend Markov random fields (Pearl, 1988) to the first-order setting. A long line of work exploring various techniques culminated in the LSM heuristic (Kok and Domingos, 2010) that learns MLN rules before estimating parameters. Since such a stepwise approach can be computationally expensive, BoostSRL (Khot et al., 2011) jointly learns rules and parameters by approximating the gradient using functional gradient boosting (Friedman, 2001). RuleNN replaces logical operations with differentiable functions, thus learning LEs end-to-end without approximations. Section 5 reports results of LSM and BoostSRL.

Neuro-symbolic AI employs neural networks for rule induction (Yang et al., 2017; Evans and Grefenstette, 2018; Dong et al., 2019). To the best of our knowledge however, none of these address NLP tasks such as sentence classification. NeuralLP (Yang et al., 2017) for instance, learns restricted chain rules to predict links in knowledge graphs. ∂ILP (Evans and Grefenstette, 2018) learns recursion by materializing all possible logic programs thus incurring exponential complexity. Neural Logic Machines (Dong et al., 2019) translate FOL to tensor operations and multi-layer perceptrons thus precluding extraction of FOL rules. In contrast, we learn LEs for NLP by constructing predicates from NLU, RuleNN's complexity is proportional to the number of rules, and we also extract FOL rules once training has converged. Other combinations of FOL and neural networks include Kazemi and Poole (2018); Sourek et al. (2018); Donadello et al. (2017); Gupta et al. (2020) and neural theorem provers (Rocktäschel and Riedel, 2017), which convert user-specified rules into neural networks. In particular, neural module networks (Gupta et al., 2020) convert compositional questions into modules in a neural network with the goal being to learn all parameters jointly. In contrast to RuleNN, none of these directly learn rules from labeled data.

Recall that in Figure 1, the sentence comprises actions and we evaluate the LE on each action. This is in fact multiple instance learning (MIL) (Dietterich et al., 1997; Amores, 2013) where one instance (e.g., sentence) contains a set of instances (e.g., actions) and is strictly more general than independent and identically distributed (IID) classification. Previous use of MIL includes aspect-based sentiment analysis (Pappas and Popescu-Belis, 2014). In Section 5, we compare RuleNN against MIL classifiers including MIRI (Bjerring and Frank, 2011), a MIL rule-learner, and MITI (Blockeel et al., 2005), a MIL decision tree learner.

3 Constructing Predicates based on Natural Language Understanding

In this section, we describe how to define human interpretable predicates by leveraging semantic role labeling (SRL) (Jurafsky and Martin, 2014) and syntactic parsing. In Section 4, we show how to learn discriminative LEs on top of such predicates.

3.1 From Linguistic Features to Predicates

We begin by introducing first-order logic constructs such as logical predicates, constants and facts before applying them to the NLP domain. We ground all definitions via examples subsequently.

Definition 3.1 (Logical Predicate)**.** *A* predicate *is a Boolean-valued function returning true* (1) *or false* (0)*. Formally, let* x *denote a logical variable that takes values from domain of constants* Dom*. Then* Pred$(x_1, \ldots x_n)$ *denotes an* n*-ary* predicate *where* x_i *is either a logical variable or constant* $\in Dom$*.*

Pred$(x_1, \ldots x_n)$ denotes a *ground atom* that evaluates to either true or false if x_i denotes a constant, $\forall i = 1, \ldots n$. A *fact* is an atom that holds true.

Given our interest in sentence classification, we will be dealing with logical constants corresponding to sentences and actions extracted from them. We describe two ways to generate predicates for NLP, the first of which uses SRL arguments and dictionaries.

Definition 3.2 (SRL Predicate)**.** *Given SRL argument* $SemAttr$ *and dictionary* h*, predicate* $\texttt{SemAttrMatches}_{\texttt{h}}(a)$ *is true if* h *contains action* a*'s surface form corresponding to* $SemAttr$*.*

Let $h = \{w_1, \ldots w_d\}$ denote a dictionary of semantically related words (or phrases) such that $w_i \in \mathcal{V}$, $\forall i = 1, \ldots d$, where $\mathcal{V}$ denotes the vocabulary. Also, let $\mathcal{H}$ denote a set of dictionaries such that $\forall h \in \mathcal{H} : h \subseteq \mathcal{V}$ and let $SemAttr$ denote an

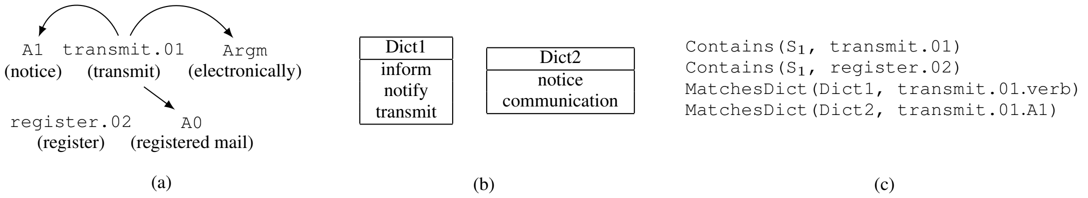

Figure 3: Generating (c) facts and predicates from (a) shallow semantic parsing and (b) dictionaries.

argument for an action extracted using SRL. Using Definition 3.2, one can define one predicate[1] per SRL argument per dictionary $h \in \mathcal{H}$.

Definition 3.3 (Syntactic Predicate)**.** *Given syntactic argument* $SynAttr$ *and* $v \in Dom(SynAttr)$*, predicate* $IsSynAttr_v(a)$ *holds true if action* a*'s value of* $SynAttr$ *is* v*.*

The second type of predicate we propose is derived from syntactic arguments of actions such as tense and voice. Let $SynAttr$ denote such an argument whose domain is denoted by $Dom(SynAttr)$ (e.g., $Dom(\text{voice}) = \{\text{active}, \text{passive}\}$). Definition 3.3 then allows creation of one predicate per domain value v per syntactic argument.

The main construct in FOL is a rule or *clause*:

$$R : c \leftarrow b_1, b_2, \ldots b_n$$

where R is an identifier, $b_1, \ldots b_n$ denote predicates in its *body* and c denotes the *head* predicate. *If* the body is true *then* the head is also true, which in the context of classification, will be the label predicate $\ell(x)$ which in turn, if true, implies that the instance denoted by x is to be assigned the label. In short, we treat clauses as binary classifiers. For multiple labels, we utilize distinct label predicates and learn distinct clauses.

Definition 3.4 (Linguistic Expression or LE)**.** *A clause defined over logical variables representing sentence* s *and action* a*, includes a distinguished binary predicate* `Contains`*(s,a) which is true if* a *belongs to* s*, and whose body contains SRL and/or syntactic predicates (see Definitions 3.2 and 3.3).*

Figure 3 (a) shows actions and their arguments extracted from the example in Figure 1 expressed in PropBank annotation schema (Palmer et al., 2005). One such action is `transmit.01`, whose SRL arguments include *notice* (`A1`, the target of the action), *electronically* (`ARGM`, how the action is performed.) and *registered mail* (`A0`, the agent of the action). We use shorthand $a.SemAttr$ to refer to action a's surface form associated with $SemAttr$. Figure 3 (b) and (c) show two dictionaries and the facts generated using these, respectively. Dict1 contains three tokens, one of which matches the surface form of `transmit.01`, i.e. `transmit.01.verb` = *transmit*. This leads to the fact `MatchesDict`(Dict1, `transmit.01.verb`) which is syntactic sugar for the SRL predicate produced with $SemAttr$ verb and dictionary Dict1 in accordance with Definition 3.2. Similarly, `transmit.01.A1` = *notice* and dictionary Dict2 leads to another fact `MatchesDict`(Dict2, `transmit.01.A1`).

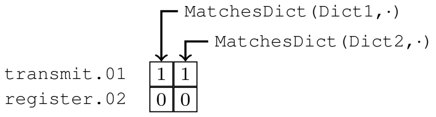

Figure 4: Example predicate matrix where rows and columns denote actions and predicates, respectively.

3.2 Problem Formulation

Definition 3.4 states that an LE contains two kinds of logical variables and `Contains` is the only predicate defined on sentence s (neither Definition 3.2 nor 3.3 introduce a predicate over s). This implies that we need to predict sentence labels based on the facts defined over actions. Indeed, the LE's body in Figure 1 contains free variable a not appearing in the head and under standard existential semantics this implies that the head is true only if there exists an a which satisfies the body.

Let $\mathcal{D} = \{(x_1, y_1), \ldots, (x_n, y_n)\}$ denote a binary class, labeled sample where x_i is a constant denoting an instance to be classified (in our case, sentences) with label $y_i \in \{0, 1\}$. Let $\mathcal{R}_i$ denote x_i's constituents (in our case, the set of actions from x_i). Also, let $\mathcal{P} = \{\text{Pred}_1, \ldots \text{Pred}_N\}$ denote unary predicates defined using Definitions 3.2 and 3.3. Since all predicates are unary, we can represent all facts associated with x_i using a *predicate*

---

[1] "Predicate" refers to the logical kind used to build LEs, not to be confused with SRL's predicate-argument structure.

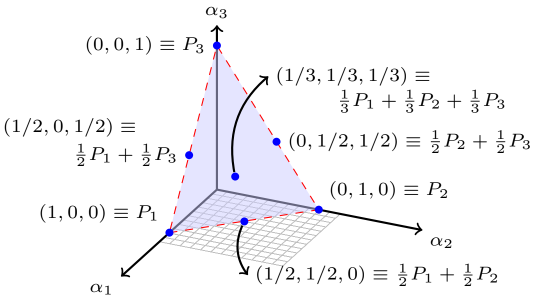

Figure 5: Convex hull of $\{P_1, P_2, P_3\}$. Highlighted points (in blue) denote specific predicate combinations.

matrix $M \in \{0,1\}^{|\mathcal{R}_i|\times|\mathcal{P}|}$ such that $M_{kj} = 1$ if $\mathrm{Pred}_j(a)$ is true and 0 otherwise, where a denotes the k^{th} action in $\mathcal{R}_i$. Figure 4 shows an example of a predicate matrix. Our task is to learn (possibly, multiple) LEs that capture x_i's label y_i.

4 RuleNN: Learning Linguistic Expressions with Neural Networks

We now present RuleNN, a neural network for learning LEs from labeled data. Since LEs are discrete objects, we first present a parameterized predicate that is defined in terms of learnable parameters. Subsequently, we introduce predicate and clause generation modules. By adding more of these modules, the architecture scales to facilitate learning of multiple, longer LEs.

4.1 Parameterized Predicate and Predicate Generation Module

Parameterized predicate (PP) expresses a linear (more precisely, convex) combination of predicates from $\mathcal{P}$. Consider $\mathcal{P}$'s convex hull which is the smallest convex set containing all its predicates. Since $P(a) \in \{0,1\}$, $\forall P \in \mathcal{P}$ (Definition 3.1), any point in the convex hull may be expressed as:

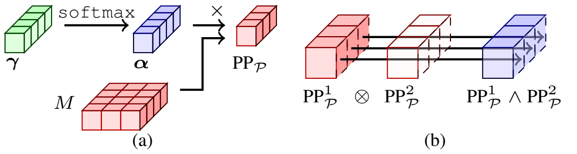
$$\mathrm{PP}_{\mathcal{P}}(a;\boldsymbol{\alpha}) = \textstyle\sum_{P_i\in\mathcal{P}} \alpha_i P_i(a),\ \forall a \in R_i,\ x_i \in \mathcal{D}$$
$$\text{such that} \textstyle\sum_i \alpha_i = 1,\ \alpha_i \geq 0\ \forall i = 1,\dots|\mathcal{P}|$$

Given $\boldsymbol{\alpha} = [\alpha_1, \dots \alpha_{|\mathcal{P}|}]^\top$, *parameterized predicate* $\mathrm{PP}_{\mathcal{P}}(a;\boldsymbol{\alpha})$ returns a distinct predicate combination of $\mathcal{P}$. In particular, when $\boldsymbol{\alpha}$ is a one-hot encoding $\mathrm{PP}_{\mathcal{P}}(a;\boldsymbol{\alpha})$ results in a distinct predicate in $\mathcal{P}$ which corresponds to a corner of the convex hull. In fact, the hull spans a $(|\mathcal{P}|-1)$-simplex. Figure 5 shows the convex hull of 3 predicates that forms a 2-simplex or triangle and points in blue highlight salient predicate combinations.

Given an update scheme, e.g. backpropagation, $\mathrm{PP}_{\mathcal{P}}(a;\boldsymbol{\alpha})$ can switch from one predicate (combination) to another by updating $\boldsymbol{\alpha}$. Thus, PPs enable learning LEs via gradient-based optimization. Figure 6 (a) depicts PP as a combination of layers or a *predicate generation module* (PGM). To enforce the non-negativity and summation constraints, we derive $\boldsymbol{\alpha}$ (shown in blue) from auxiliary variables $\boldsymbol{\gamma} \in \mathbb{R}^{|\mathcal{P}|}$ (shown in green) using the `softmax` transform (Srivastava and Sutton, 2017):

$$\alpha_i = \frac{e^{\gamma_i}}{\sum_{j=1}^{|\mathcal{P}|} e^{\gamma_j}},\ \forall i = 1,\dots|\mathcal{P}|$$

$\mathrm{PP}_{\mathcal{P}}(a;\boldsymbol{\alpha})$ (vector in red in Figure 6 (a)) is then given by the matrix-vector product $M\boldsymbol{\alpha}$ where M denotes the predicate matrix of some $x_i \in \mathcal{D}$.



(a) (b)

Figure 6: (a) Predicate Generation Module. (b) Conjunction using Hadamard product.

4.2 Clause Generation Module

Figure 1's LE is a conjunction of two SRL predicates; such combinations can be learned by combining multiple PGMs into a *clause generation module* (CGM). Let m denote the number of predicates in an LE. Following other works (Yang et al., 2017; Sourek et al., 2018), CGMs replace non-differentiable logical conjunction with a smooth t-norm operator (Esteva and Godo, 2001). While various t-norms exist, product t-norm leads to better results (Evans and Grefenstette, 2018). Note that, RuleNN's architecture does not rely on product t-norm and may easily switch to another t-norm if desired. Product t-norm of $\mathrm{PP}^1_{\mathcal{P}}(a;\boldsymbol{\alpha}_1)$, $\mathrm{PP}^2_{\mathcal{P}}(a;\boldsymbol{\alpha}_2)$ is given by Hadamard product or element-wise multiplication $\mathrm{PP}^1_{\mathcal{P}}(a;\boldsymbol{\alpha}_1) \otimes \mathrm{PP}^2_{\mathcal{P}}(a;\boldsymbol{\alpha}_2)$, $\forall a \in \mathcal{R}_i$, $\forall x_i \in \mathcal{D}$ (see Figure 6 (b)).

4.3 RuleNN Architecture

Let k denote the desired number of LEs to learn. Figure 7 depicts RuleNN consisting of k CGMs shown in solid boxes (corresponding to k LEs), consisting of m PGMs per CGM shown in dashed boxes (corresponding to m predicates within each LE). Our motivation for learning multiple LEs is because a single rule may not result in high precision *and* high recall due to the precision-recall trade-off. Thus, learning a disjunction of more than

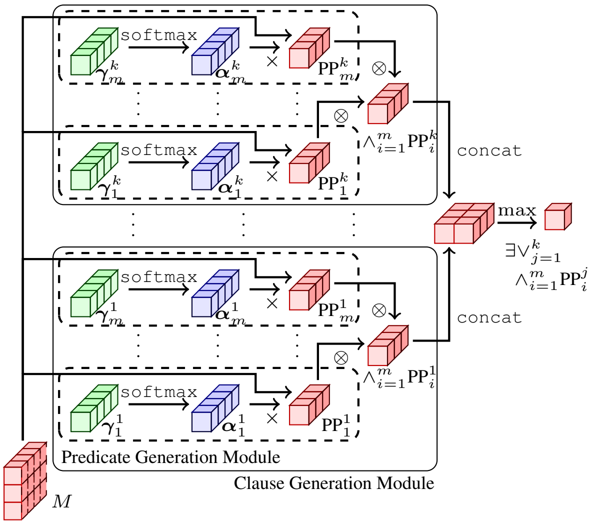


Figure 7: RuleNN for learning k m-length clauses.

Name	Global/Local	Description
M	Local	Predicate matrix for instance
$\mathcal{R}$	Local	Actions in instance
PP_i^j	Local	Responses for actions belonging to instance
α_i^j	Global	Attention weights defining a learned predicate
γ_i^j	Global	Log attention weights for learned predicate
k	Global	Number of LEs (hyperparameter)
m	Global	Length of LEs (hyperparameter)

Table 1: Notation with description

one LE, i.e., the label is assigned if any LE holds true for the sentence, can lead to improved results.

In detail, the bottom left of Figure 7 shows a predicate matrix M for some $x \in \mathcal{D}$ whose constituent actions are given by $\mathcal{R}$. To model conjunction, j^{th} CGM's output is computed by element-wise multiplying $|\mathcal{R}|$-dimensional vectors $\text{PP}_1^j, \dots \text{PP}_m^j$ produced by corresponding PGMs, where (superscript) subscript denote index of (CGM) PGM. Given outputs of the CGMs, 2 operations remain: 1) existential over actions following the semantics of the LE, and 2) disjunction over all LEs. We treat existential as a disjunction-like operator. Since logical disjunction is also not differentiable, neuro-symbolic AI replaces it with a t-conorm such as $\max$ (Dong et al., 2019) whose (sub)gradient is available. The (scalar) $\max$ across all CGM outputs models both the existential and disjunction to return a score for x that may be compared to its label y in $\mathcal{D}$ via a loss function. Table 1 describes our notation for easy reference.

4.4 Further Optimizations and LE Retrieval

While RuleNN supports learning m PPs per CGM, if $\exists i \neq i'$ such that $\boldsymbol{\alpha}_i^j = \boldsymbol{\alpha}_{i'}^j$, then j^{th} CGM consists of $< m$ distinct PPs. Effectively, RuleNN learns k LEs containing *up to* m PPs each. To handle class skew, i.e., $\mathcal{D}$ consists of more negative than positive examples, we utilize negative sampling (Mikolov et al., 2013). We also apply dropout (Srivastava et al., 2014) just before max-pooling to zero-out outputs from randomly chosen CGMs. Once learning has converged, we can use Algorithm 1 to retrieve LEs expressed in FOL. Given $\boldsymbol{\alpha}_1, \dots \boldsymbol{\alpha}_m$ learned from a single CGM, Algorithm 1 considers each m-combination of predicates from $\mathcal{P}$ and returns it as an LE if (Line 4): 1) its associated weight (product of corresponding numbers in $\boldsymbol{\alpha}_i$, $\forall i = 1, \dots m$) is non-zero, and 2) it evaluates to true on some instance in $\mathcal{D}$. When learning k CGMs, we invoke Algorithm 1 once per CGM and union the LEs. Algorithm 1's complexity is exponential in m but it is efficient for short LEs which makes sense since longer LEs are hard to interpret. In practice, post-hoc retrieval results in a few hundred LEs (Section 5 discusses how to navigate such a set of LEs).

Algorithm 1: Post-hoc LE retrieval

```
input  : Learned $\alpha_1, \dots \alpha_m$ and training data $\mathcal{D}$.
output : List of LEs.
1 $S \leftarrow \{\}$      // Loop goes over $\binom{|\mathcal{P}|}{m}$ combinations
2 while more predicate combinations exist do
3     $(p_1, \dots p_m) \leftarrow$ get next predicate combination
4     if $\prod_{i=1}^{m} \alpha_{ip_i} > 0 \land \exists x \in \mathcal{D}$ such that $(p_1, \dots p_m) \sim x$
      then $S \leftarrow S \cup \{(p_1, \dots p_m)\}$
5 return $S$
```

Table 2: Broad-level dataset statistics

5 Experiments

Datasets: We experiment with two datasets: TREC (Li and Roth, 2002) comprising questions, and the real-world Contracts data (proprietary) comprising sentences from legal contracts among enterprises. Contracts calls for out-of-domain generalization since its training set involves contracts with IBM as first party while the test set includes more diverse companies. Table 2 provides broad-level statistics. Sentences in Contracts may be labeled with 0, 1 or more labels (multi-label classification), so we treat each label as a binary class labeling task. Table 3

(a) lists per-label[2] class skew, which is defined as the ratio of positive sentences divided by negatives. Note that, C denotes Communication (the label in the running example in Figure 1). Each sentence is processed using SystemT's (Krishnamurthy et al., 2008) SRL and dependency parser. We extract each action's tense, aspect, mood, modalclass, voice and polarity (syntactic arguments), and also semantic arguments such as `A0`, `A1`, `Argm` etc. Table 3 (a) lists the number of predicates constructed using hand-crafted dictionaries for each label following the process described in Section 3. We use TREC's standard train/test split to aid comparison which also exhibits significant class skew (Table 3 (b)), automatically construct dictionaries by capturing surface forms (from the training set) that discriminate well among its labels and construct predicates by extracting the same syntactic and semantic arguments stated previously.

Methods Compared: RuleNN learns k=50 LEs containing up to m=4 predicates. We set dropout=0.5, batchsize=64, stepsize=0.01 and use SGD with momentum=0.9. We compare against NeuralLP and ∂ILP, from neuro-symbolic AI; LSM and BoostSRL (BSRL), from StarAI; MITI and MIRI, from multiple instance learning; and top-down ILP system metagol (MG) (Cropper and Muggleton, 2015) and its noise-tolerant variant Metagol_{NT} (MG_{NT}) (Muggleton et al., 2018). All of these are described in Section 2, and learn rules which we denote by ☐ (aka "white-box" method). We also compare with black-box methods (denoted by ■): MINet (Wang et al., 2018) and recurrent neural networks. MINet achieves MIL using a deep neural net with fully connected layers. BiLSTM replaces tokens in the sentence with GloVe embeddings (Pennington et al., 2014) followed by a bi-directional LSTM whose hidden vectors are aggregated to produce the label. By varying hidden units from 200 to 600, we obtain a range for BiLSTM performance. Note that, only BiLSTM gets raw sentence tokens as input. MINet along with ☐ methods, receive the same predicates and dictionaries that RuleNN receives as input. Thus, we refer

to them as predicate-based methods.

5.1 Comparative Results

Table 3 (c) and Figure 8 (a) report area under precision-recall curve (AUC-PR) for all methods.

Vs. predicate-based and ☐ methods: It is unlikely that there exists any LE which perfectly entails the positives and rejects all negative examples. Thus, MG learns no rules (NR) and MG_{NT}'s AUC-PR is poor. Both LSM and BSRL are susceptible to class skew (Khot et al., 2011). Despite running for 5 days, LSM did not provide a result (denoted by -) on Contracts, the larger of the 2 datasets. NN-based MINet outperforms MITI and MIRI. RuleNN shows impressive performance despite class skew and scale. Averaged across labels, it outperforms MINet by 16% on TREC and 595% on Contracts. Among ☐ methods, RuleNN outperforms BSRL by 25% on TREC and 109% on Contracts.

Vs. neural-symbolic methods: NeuralLP learns chain rules (also called closed paths) for link prediction which differs from LE structure defined in Section 3. RuleNN outperforms it by 69% on TREC and 48% on Contracts. ∂ILP's prohibitive complexity, $O(|\mathcal{P}|^{mk})$, prevents us from learning more than 2 LEs containing 2 predicates only (settings from Evans and Grefenstette (2018)). Its AUC-PR (Figure 8 (a)) on C and SoW, Contracts' labels with fewest predicates (Table 3 (a)), is erratic. RuleNN outperforms it on both labels.

Vs. ■ methods: RuleNN outperforming MINet shows that despite learning explainable LEs, it can still improve over black-box methods. In its smallest setting, BiLSTM contains (upwards of) 400000 learnable parameters (with 300-dim. GloVe embeddings). In contrast to RuleNN's $O(|\mathcal{P}|mk)$ parameters (and its settings specified earlier in this section), BiLSTM's parameter set is an order of magnitude larger. This allows BiLSTM to provide excellent results on shorter questions in TREC (containing 1.3 actions on avg., Table 2) but overfits on Contracts, there being marked differences between data distributions of the training and test set. RuleNN's AUC-PR is comparable to BiLSTM's on Contracts. In fact, it outperforms BiLSTM in 4 of 9 labels. This is in addition to the explainability offered by the learned LEs (we show examples subsequently).

Impact of parameters and initialization: Figure 8 (c) shows per-epoch training times for RuleNN on label C in Contracts against varying k (x-axis) and m. RuleNN's runtime depends linearly on k and is not affected much by m. This is a clear win against more expensive approaches such as ∂ILP and LSM. Increasing k or m may also allow a better fit. Figure 8 (b) shows which of Contracts' labels benefit by increasing k from 1 to 50. We also tested different random initialization of γ_i^j, $\forall i, j$. RuleNN converges to similar cross-entropy loss across different initializations (Figure 8 (d)).

5.2 Explainability of Learned LEs

Algorithm 1 produces 188 LEs for C in Contracts. While this may seem excessive, it is possible to build a graphical user interface (GUI) (Yang et al., 2019) that allows for instance, to filter LEs based on a precision threshold and rank LEs based on say, recall, to efficiently navigate through such a set of LEs. Unfortunately, we know of no objective metric that can be automatically computed to directly measure LE's explainability. Thus, we contrast example LEs learned by RuleNN with BSRL's, one of the better performing rule-learning baselines.

Besides the LE in Figure 1, Figure 9 shows 3 more RuleNN LEs with example sentences where $a.SemAttr$ `contains` w is true when $a.SemAttr$ includes token w which is useful when SRL extracts an extended piece of the sentence as $a.SemAttr$[3] (e.g., `A0` in $\texttt{S}_3$ in Figure 9). Clearly, all involved terms are `Communication`-specific. For instance, $\texttt{S}_2$ shows how verb *notify* appears in a sentence implying communication thus R_2 including it in its SRL predicate makes sense. Besides SRL predicates, these LEs also include syntactic predicates capturing the fact that legal contracts are often written in passive voice (R_4) or future tense (R_3). In contrast, an LE learned by BSRL is:

$$\begin{aligned}\texttt{communication}(s) \leftarrow \texttt{Contains}(s,a)& \\ \wedge\ a.\text{mood} = \texttt{imperative}& \\ \wedge\ a.\text{tense} = \texttt{present participle}&\end{aligned}$$

which is interpretable but may not make sense given domain semantics since an action satisfying these conditions may imply a label besides C. Figure 10 shows more LEs learned by RuleNN for labels T&T (term and termination) and L (liability).

5.3 Human-Machine Co-creation: User Study

Having shown that RuleNN learns explainable, high-quality LEs, we were interested in finding out whether domain experts find the same and in particular, whether the interaction improves the LEs? 4 data scientists, with knowledge of NLU and FOL, were given 188 LEs learned for C. The goal was to select LEs whose semantics could be verified. Via the GUI mentioned earlier, participants could modify LEs (by dropping/adding predicates) and evaluate them on Contracts training set. Each participant took half an hour to select $\approx$ 6-8 LEs. This reduction from 188 LEs translates to a 96% model compression and shows that with human's expertise, RuleNN's LEs can be made smaller and thus more interpretable. To model collaborative and iterative development in the real-world, we union LEs produced by each subset of 3 participants to attain 4 explainable models. As Figure 8 (e) shows, 3 of these outperform BiLSTM by $\approx 25\%$ in terms of F-measure (precision and recall's harmonic mean). As an example LE modification, consider R_3 (Figure 9) which contains the predicate $a.\text{tense} = \texttt{future}$. Since a sentence may imply communication even if it is not in future tense (e.g., Figure 1's sentence is in present tense), participants dropped this predicate to improve the LE's recall by 5% (precision remained $\approx 75\%$). Even if we learn the right patterns (many Contracts' sentences are in future tense), domain expertise may still aid generalization thus going beyond available training data. Yang et al. (2019) provides more details on the user study, design of the UI used to conduct it and related aspects.

6 Conclusion and Future Work

Our experiments indicate that neuro-symbolic RuleNN outperforms other rule induction techniques in terms of efficiency and quality of rules learned even in the presence of challenging conditions such as class skew. Allowing domain experts to instill their expertise into LEs can also enable human-machine co-creation of explainable models.

Ideas presented here are general enough to enable other applications. RuleNN can be used for any MIL task assuming predicates are given and PGMs can be used to learn combinations of base predicates $\mathcal{P}$ even if the structure of the rule differs from LEs. As an extension, it may even be possible to determine the number of LEs k from the data using recurrent neural networks (Yang et al., 2017). RuleNN can learn rules combining any previously built classifier's output probabilities (assuming such probabilities lie within $[0, 1]$). Note that, RuleNN's philosophy is distinct from other explainable AI approaches (Ribeiro et al., 2016; Serrano and Smith, 2019). We show that it is possible to learn human-interpretable models by designing neural networks keeping explainability in mind.

As opposed to learning an explainable model (e.g., RuleNN), one may also choose to *explain* a black-box model. Such efforts are usually restricted to explaining outcomes and only provide a shallow understanding of the overall model, if at all (Guidotti et al., 2018). While recent embeddings (Devlin et al., 2019) may lead to improved accuracy, these remain poorly understood (Moradshahi et al., 2019). One avenue of future work is to learn explainable rules that domain experts can interact with on top of such embeddings. Another is to learn rules and dictionaries jointly, which may also aid sentiment analysis (Wilson et al., 2005).

---

[3] Fixing errors in SRL's output is out of scope of this work.

Acknowledgments

We would like to thank the reviewers for helpful feedback. We would also like to acknowledge the help of a lot of people not present in the author list which was instrumental in making this research possible: Shivakumar Vaithyanathan (for thought provoking discussions), Yiwei Yang, Walter S. Lasecki, Eser Kandogan (for help building the UI which made the user study possible), Diman Ghazi, Poornima Chozhiyath Raman, Ramiya Venkatachalam, Vinitha Yaski and Sneha Srinivasan (for help with the user study). This work was done while Siddhartha Brahma and Matthias Boehm were at IBM Research.

Abstract

The remarkable success of pretrained language models has motivated the study of what kinds of knowledge these models learn during pretraining. Reformulating tasks as fill-in-the-blanks problems (e.g., cloze tests) is a natural approach for gauging such knowledge, however, its usage is limited by the manual effort and guesswork required to write suitable prompts. To address this, we develop AUTOPROMPT, an *automated* method to create prompts for a diverse set of tasks, based on a gradient-guided search. Using AUTOPROMPT, we show that masked language models (MLMs) have an inherent capability to perform sentiment analysis and natural language inference without additional parameters or finetuning, sometimes achieving performance on par with recent state-of-the-art supervised models. We also show that our prompts elicit more accurate factual knowledge from MLMs than the manually created prompts on the LAMA benchmark, and that MLMs can be used as relation extractors more effectively than supervised relation extraction models. These results demonstrate that automatically generated prompts are a viable parameter-free alternative to existing probing methods, and as pretrained LMs become more sophisticated and capable, potentially a replacement for finetuning.

1 Introduction

Pretrained language models (LMs) have had exceptional success when adapted to downstream tasks via *finetuning* (Peters et al., 2018; Devlin et al., 2019). Although it is clear that pretraining improves accuracy, it is difficult to determine whether the knowledge that finetuned LMs contain is learned during the *pretraining* or the *finetuning* process. How can we directly evaluate the knowledge present in pretrained LMs, be it linguistic, factual, commonsense, or task-specific?

Numerous techniques have been proposed to elicit such knowledge by analyzing pretrained LMs' internal representations. A common strategy is to use probing classifiers—shallow classifiers that predict certain attributes using an LMs' representations as features (Conneau et al., 2018; Liu et al., 2019). However, probing classifiers require additional learned parameters and are thus susceptible to false positives; high probing accuracy is *not* a sufficient condition to conclude that an LM contains a certain piece of knowledge (Hewitt and Liang, 2019; Voita and Titov, 2020). Attention visualization, another common technique, has a similar failure mode: attention scores may be correlated with, but not caused by the underlying target knowledge, leading to criticism against their use as explanations (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019). Both probing and attention visualizations also struggle to evaluate knowledge that cannot be represented as simple token- or sequence-level classification tasks.

A more direct approach for eliciting knowledge from these models, since they are language models after all, is *prompting*, i.e. converting tasks into a language model format. For example, Radford et al. (2019) frame summarization as a language modeling task by appending "TL;DR:" to the end of an article and then generating from an LM. Similarly, Petroni et al. (2019) manually reformulate a knowledge base completion task as a cloze test (i.e., a fill-in-the-blank problem). Compared to existing model analysis methods, prompting is non-invasive: it does not introduce large amounts of additional parameters or require direct inspection of a model's representations. Thus prompting provides a lower bound on what the model "knows", and is therefore a more useful analysis tool. However, prompting unfortunately requires manually

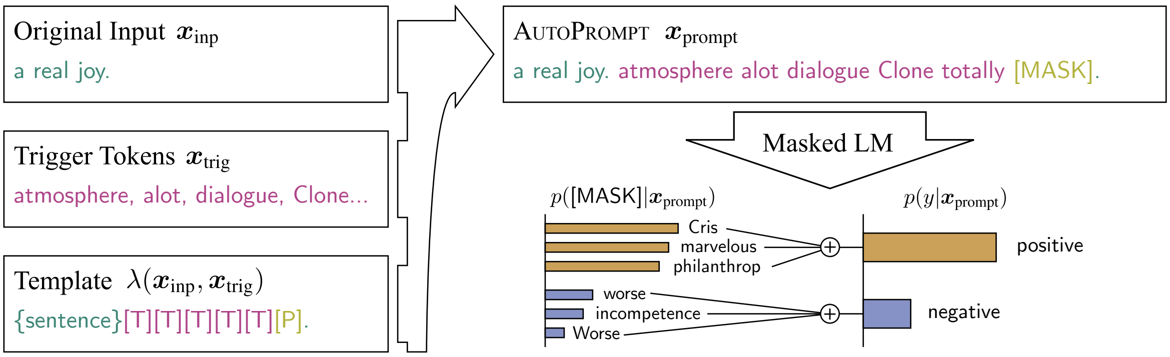

Figure 1: **Illustration of AUTOPROMPT** applied to probe a masked language model's (MLM's) ability to perform sentiment analysis. Each input, $\boldsymbol{x}_{\text{inp}}$, is placed into a natural language prompt, $\boldsymbol{x}_{\text{prompt}}$, which contains a single [MASK] token. The prompt is created using a template, λ, which combines the original input with a set of trigger tokens, $\boldsymbol{x}_{\text{trig}}$. The trigger tokens are shared across all inputs and determined using a gradient-based search (Section 2.2). Probabilities for each class label, y, are then obtained by marginalizing the MLM predictions, $p([\text{MASK}]|\boldsymbol{x}_{\text{prompt}})$, over sets of automatically detected label tokens (Section 2.3).

crafting the context to feed into the model. Not only is this time consuming and non-intuitive for many tasks (e.g., textual entailment), more importantly, models are highly sensitive to this context: improperly-constructed contexts cause artificially low performance (Jiang et al., 2020). Overcoming the need to manually specify prompts would make prompting a more widely useful analysis tool.

In this paper, we introduce AUTOPROMPT—an *automated* method for generating prompts for any task, illustrated in Figure 1. Given a task, e.g., sentiment analysis, AUTOPROMPT creates a prompt by combining the original task inputs (e.g. reviews) with a collection of *trigger tokens* according to a template. The same set of trigger tokens is used for all inputs, and is learned using a variant of the gradient-based search strategy proposed in Wallace et al. (2019). The LM predictions for the prompt are converted to class probabilities by marginalizing over a set of associated label tokens, which can either be learned or specified ahead of time, enabling the LM to be evaluated the same as one would any other classifier.

We validate the effectiveness of AUTOPROMPT in numerous experiments. First, we use AUTOPROMPT to construct prompts that test pretrained masked language models (MLMs) on sentiment analysis and natural language inference (NLI). Our tests reveal that, without any finetuning, MLMs perform well on both of these tasks—a properly-prompted RoBERTa achieves 91% accuracy on SST-2 (better than a finetuned ELMo model (Peters et al., 2018)), and 69% accuracy on a balanced variant of the SICK-E dataset (Marelli et al., 2014). Next, we apply AUTOPROMPT to the fact retrieval tasks of LAMA (Petroni et al., 2019), where we are able to construct prompts that more effectively elicit MLM's factual knowledge than existing prompts generated using manual and corpus-mining methods. Concretely, we achieve 43.3% precision-at-1, compared to the current best single-prompt result of 34.1% (Jiang et al., 2020). We also introduce a variant of this task, similar to relation extraction (RE), that tests whether MLMs can extract knowledge from a given piece of text. We show that MLMs can actually *outperform* existing RE models when context sentences with real facts are provided, however, they struggle when context sentences are artificially falsified.

Finally, although the goal of AUTOPROMPT is to analyze models, we find that it provides certain practical advantages over finetuning. First, AUTOPROMPT achieves higher average- and worst-case accuracy than finetuning in low-data regimes. Moreover, unlike finetuning, prompting LMs does not require large amounts of disk space to store model checkpoints; once a prompt is found, it can be used on off-the-shelf pretrained LMs. This is beneficial when serving models for multiple tasks.

2 Overview of AUTOPROMPT

A natural way to elicit knowledge from pretrained LMs is to pose tasks as fill-in-the-blank problems. However, writing prompts is not only time consuming, but it is not clear that the same phrasing will be effective for every model, nor is it clear what criteria determine whether a particular phrasing the *best* to elicit the desired information. In light of this, we introduce AUTOPROMPT, a method that constructs customized prompts for a specific task and MLM of interest, to cause the MLMs to produce the desired knowledge.[1] An illustration of AUTOPROMPT is provided in Figure 1. The prompt is constructed by taking the original task inputs—a collection of one or more sequences of tokens (e.g., the review in Figure 1)—and mapping them to a sequence of tokens using a template. In the following sections, we describe how AUTOPROMPT uses labeled training data to construct prompts, and how it uses the output of the MLM as a prediction for the task.

2.1 Background and Notation

For the purpose of prompt construction, we distinguish the original task inputs $\boldsymbol{x}_{\text{inp}}$ (e.g., the review in Figure 1, "a real joy.") from the prompt $\boldsymbol{x}_{\text{prompt}}$ (e.g., "a real joy. atmosphere alot dialogue Clone totally [MASK].") that is fed into the MLM. The mapping from $\boldsymbol{x}_{\text{inp}}$ to $\boldsymbol{x}_{\text{prompt}}$ is performed using a template, λ. This template defines where each input sequence will be placed in the prompt, as well as the placement of any additional tokens. In particular, it must also define the placement of a special [MASK] token for the MLM to fill in (denoted by [P] in the template to distinguish it from other [MASK] tokens that might appear). Feeding the prompt into the MLM produces a probability distribution $p(\text{[MASK]}|\boldsymbol{x}_{\text{prompt}})$ describing which tokens most likely fill in the blank.

If class labels naturally correspond to tokens in the vocabulary (e.g., entity names in knowledge base completion tasks), this distribution may be readily interpreted as a distribution over class labels. However, for tasks such as sentiment analysis, there may be a set of label tokens $\mathcal{V}_y$ that correspond to a particular label y. For example, in Figure 1, "Cris", "marvelous", and "philanthrop" all indicate positive sentiment. In this case, the class probability is obtained by marginalizing over the set of label tokens:

$$p(y|\boldsymbol{x}_{\text{prompt}}) = \sum_{w \in \mathcal{V}_y} p(\text{[MASK]} = w|\boldsymbol{x}_{\text{prompt}}) \tag{1}$$

2.2 Gradient-Based Prompt Search

So far, we have shown how to reformulate a classification task as a language modeling task using prompts. Here, we propose a method for *automatic prompt construction* based on Wallace et al. (2019). The idea is to add a number of "trigger" tokens that are shared across all prompts (denoted by [T] in the example template in Figure 1). These tokens are initialized to [MASK] tokens, and then iteratively updated to maximize the label likelihood (Equation (1)) over batches of examples.

Formally, at each step, we compute a first-order approximation of the change in the log-likelihood that would be produced by swapping the jth trigger token $x_{\text{trig}}^{(j)}$ with another token $w \in \mathcal{V}$. Then we identify a candidate set $\mathcal{V}_{\text{cand}}$ of the top-k tokens estimated to cause the greatest increase:

$$\mathcal{V}_{\text{cand}} = \underset{w \in \mathcal{V}}{\text{top-}k} \left[\boldsymbol{w}_{\text{in}}^T \nabla \log p(y|\boldsymbol{x}_{\text{prompt}}) \right] \tag{2}$$

where $\boldsymbol{w}_{\text{in}}$ is the input embedding of w, and the gradient is taken with respect to the input embedding of $x_{\text{trig}}^{(j)}$. Note that computing this candidate set is roughly as expensive as a single forward pass and backward pass of the model (the dot-products require the same amount of multiplications as computing the LM output projection). For each candidate in this set, we then re-evaluate Equation (1) on the updated prompt, and retain the prompt with the highest probability in the next step—this requires k forward passes of the model. An example prompt produced by this method for the task of sentiment analysis is shown in Figure 1.

2.3 Automating Label Token Selection

While in some settings the choice of label tokens is obvious (e.g., when class labels directly correspond to words in the vocabulary), it is less clear what label tokens are appropriate for problems involving more abstract class labels (e.g., NLI). In this section, we develop a general two-step approach to automate the selection of the sets of label tokens $\mathcal{V}_y$. In the first step, we train a logistic classifier to predict the class label using the contextualized embedding of the [MASK] token as input:

$$\boldsymbol{h} = \text{Transformer}_{\text{enc}}(\tilde{\boldsymbol{x}}) \tag{3}$$

We write the output of this classifier as:

$$p(y|\boldsymbol{h}^{(i)}) \propto \exp(\boldsymbol{h}^{(i)} \cdot \boldsymbol{y} + \beta_y) \tag{4}$$

---

[1] Although we focus only on MLMs in this work, our method is trivially extendable to autoregressive LMs. The only adjustment is that the predict token must occur at the end of the prompt.

where $\boldsymbol{y}$ and β_y are the learned weight and bias terms for the label y, and i represents the index of the [MASK] token.

In the second step, we substitute $\boldsymbol{h}^{(i)}$ with the MLM's output word embeddings $\boldsymbol{w}_{\text{out}}$ to obtain a score $s(y, w) = p(y|\boldsymbol{w}_{\text{out}})$. Intuitively, because $\boldsymbol{w}_{out} \cdot \boldsymbol{h}$ and $\boldsymbol{y} \cdot \boldsymbol{h}$ are large for words and labels that are relevant to a particular context, $s_w \propto \exp(\boldsymbol{w}_{\text{out}} \cdot \boldsymbol{y} + \beta_y)$ should be large for words that are typically associated with a given label. The sets of label tokens are then constructed from the k-highest scoring words:

$$\mathcal{V}_y = \underset{w \in \mathcal{V}}{\text{top-}k} \, [s(y, w)] \tag{5}$$

2.4 Relation to Other Prompting Methods

Our work fits into a body of work that probes language model's knowledge via prompts. Previous works have used manually defined prompts to study an LM's ability to perform: commonsense reasoning (Trinh and Le, 2018; Kwon et al., 2019; Shwartz et al., 2020), question answering (Lewis et al., 2019), fact recall (Petroni et al., 2019; Jiang et al., 2020; Bouraoui et al., 2019), summarization (Radford et al., 2019), and other supervised tasks (Brown et al., 2020). Schick and Schütze (2020) use manually constructed prompts in conjunction with semi-supervised learning for few-shot learning. We instead *automatically* create prompts for any task, which leads to higher accuracy and opens up new phenomena to analyze.

2.5 Evaluation Setup

In the following sections, we apply AUTOPROMPT to probe $\text{BERT}_{\text{BASE}}$[2] (110M parameters) and $\text{RoBERTa}_{\text{LARGE}}$'s (355M parameters) knowledge of the following tasks: sentiment analysis, natural language inference (NLI), fact retrieval, and relation extraction. We use the PyTorch implementations and pretrained weights provided by the transformers Python library (Wolf et al., 2019). For sentiment analysis and NLI, we find label tokens using the logistic-regression-based heuristic described in Section 2.3. For fact retrieval and relation extraction, we skip this step as the labels (entities) directly correspond to tokens in the vocabulary. For all tasks, we perform the prompt search described in Section 2.2 for multiple iterations. In each iteration, we use a batch of training data to identify the candidate set $\mathcal{V}_{\text{cand}}$ of replacement trigger tokens. We then evaluate the label likelihoods of the updated prompts on a separate batch of data, and we retain the best trigger token in the next iteration of the search. At the end of every iteration, we measure the label likelihood on withheld development data, and return the best prompt found during the entire search as the final output. Performance is evaluated using the appropriate task-specific metrics—e.g., accuracy for sentiment analysis and NLI, and precision@k for fact retrieval—on a separate withheld test set.

Our AUTOPROMPT implementation is publicly available at http://ucinlp.github.io/autoprompt, and supports prompt generation for pretrained models in the HuggingFace transformers library (Wolf et al., 2019) on arbitrary datasets.

3 Sentiment Analysis

Sentiment analysis is a fundamental task in NLP, both for natural language understanding research and real-world applications. It is also difficult to probe the extent to which MLMs understand sentiment without finetuning.

Setup We apply our method to convert instances from the binary Stanford Sentiment Treebank (Socher et al., 2013, SST-2) into prompts, using the standard train/test splits. We find label tokens using a prompt based on the template in Table 3. For our gradient-based prompt search, we perform a grid search over the following hyperparameters: $|\mathcal{V}_{cand}| \in \{10, 100\}$, $|\mathcal{V}_y| \in \{1, 3, 5\}$, $|\boldsymbol{x}_{\text{trig}}| \in [3, 6]$.[3] All prompts are initialized with the same template used to find the label set.

We also construct a prompt manually (before automated prompts are generated, to avoid bias) based on the intuition that SST-2 is comprised of movie reviews. We use "{sentence} this movie was [P]." as the template, and use "terrible" and "fantastic" for the negative and positive label tokens, respectively.

Results We show results in Table 1, along with reference scores from the GLUE (Wang et al., 2019) SST-2 leaderboard, and scores for a linear probe trained over the elementwise average of the LM token representations. Prompts generated by AUTOPROMPT reveal that both BERT and RoBERTa have a strong knowledge of sentiment analysis: without any finetuning, BERT per-

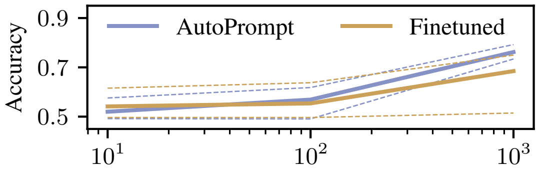
RoBERTa (AUTOPROMPT)	91.2	91.4

Table 1: **Sentiment Analysis** performance on the SST-2 test set of supervised classifiers (top) and fill-in-the-blank MLMs (bottom). Scores marked with † are from the GLUE leaderboard: http://gluebenchmark.com/leaderboard.

forms comparably to a supervised BiLSTM, and RoBERTa achieves an accuracy on-par with finetuned BERT and ELMo models. In addition, we observe that our automatically constructed prompts are more effective than manual prompts, and that they are difficult to construct using human intuition: the best template for RoBERTa is "{sentence} atmosphere alot dialogue Clone totally [P]." We include results on the effect of the AUTOPROMPT hyperparameters in Appendix A.

Accuracy in Low-Data Settings Although the goal of AUTOPROMPT is to probe a model's knowledge, we also find that it can achieve high accuracy in the low-data regime. In particular, we measure the development set accuracy of AUTOPROMPT prompts when using random subsets of 10, 100, and 1000 instances from the training data. We run our prompt search with $|\boldsymbol{x}_{\text{trig}}| = 10$, $|\mathcal{V}_y| = 3$, and $|\mathcal{V}_{\text{cand}}| = 10$. We compare to the performance of BERT and RoBERTa finetuned on the same data. We repeat this experiment 10 times on different randomly sampled sets of data (and seeds for the finetuned models), and display the best-case, worst-case, and average performance in Figure 2.

We observe that prompts and finetuning perform comparably on average for BERT, however, in the worst-case, finetuning can fail in the low-data regime (consistent with Dodge et al. 2020). For RoBERTa, AUTOPROMPT performs *substantially better* than finetuning when there are 100s to 1000s of training examples. This excellence in the low-data regime is an interesting phenomenon, and suggests that there is an initial barrier that MLMs must surmount when they are converted to finetuned classifiers that is not encountered when the task is presented as masked language modeling.



(a) BERT on SST-2

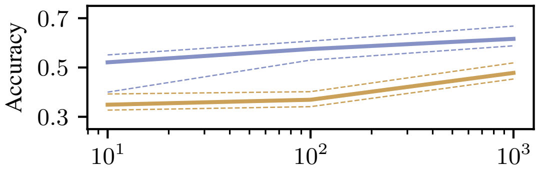
(c) BERT on SICK-E



(d) RoBERTa on SICK-E

Figure 2: **Effect of Training Data** on sentiment analysis and NLI for AUTOPROMPT vs. finetuning. X-axis is the number of data points used during training. Error bars plot the max. and min. accuracies observed over 10 independent runs. In the low data regime, AUTOPROMPT *outperforms* finetuning for RoBERTa.

4 Natural Language Inference

To evaluate the *semantic* understanding of MLMs, we experiment on Natural Language Inference (NLI). NLI is crucial in many tasks such as reading comprehension and commonsense reasoning (Bowman et al., 2015), and it is used as a common benchmark for language understanding.

Setup We use the entailment task from the SICK dataset (Marelli et al., 2014, SICK-E) which consists of around 10,000 pairs of human-annotated sentences labeled as entailment, contradiction, and neutral. The standard dataset is biased toward the neutral class which represent 56.7% of instances. We also experiment on an unbiased variant with 2-way classification of contradiction vs. entailment (*2-way*), as well as an unbiased 3-way clas-

Model	**SICK-E Datasets**		
	standard	3-way	2-way
Majority	56.7	33.3	50.0
BERT (finetuned)	86.7	84.0	95.6
BERT (linear probing)	68.0	49.5	91.9
RoBERTa (linear probing)	72.6	49.4	91.1
BERT (AutoPrompt)	62.3	55.4	85.7
RoBERTa (AutoPrompt)	65.0	69.3	87.3

Table 2: **Natural Language Inference** performance on the SICK-E test set and variants. (Top) Baseline classifiers. (Bottom) Fill-in-the-blank MLMs.

sification variant (*3-way*). The template used for AutoPrompt is provided in Table 3. We search over the following parameters: $|\mathcal{V}_{cand}| \in \{10, 50\}$, $|\mathcal{V}_y| \in \{1, 3, 5, 10\}$, $|\boldsymbol{x}_{\text{trig}}| \in [1, 5]$, and choose the best prompt according to development set accuracy.

Results Table 2 shows that AutoPrompt considerably outperforms the majority baseline in all experiments. For example, on the 2-way SICK-E dataset, AutoPrompt is comparable to a supervised finetuned BERT. We also test linear probes—linear classifiers trained on top of frozen MLM representations with average pooling —and find AutoPrompt has comparable or higher accuracy, despite linear probes being susceptible to false positives. Overall, these results demonstrate that both BERT and RoBERTa have some inherent knowledge of natural language inference.

We also examine the efficacy of AutoPrompt in the low-data regime (using the same procedure as SST-2) on the unbiased 3-way SICK-E data. The results in Figure 2 show that AutoPrompt performs on par with finetuned BERT and significantly better than finetuned RoBERTa in low data settings.

MLMs Excel on Contradiction We find that the label tokens are more interpretable for *contradiction* compared to *entailment* or *neutral* (examples in Table 3). We investigate if this hurts the model performance on entailment and neutral classes. We measure the precision for each label in the 3-way balanced SICK-E dataset. BERT achieves 74.9%, 54.4%, and 36.8% precision for contradiction, entailment, and neutral cases, respectively, while RoBERTa obtains 84.9%, 65.1%, and 57.3%. These results suggest that AutoPrompt may be more accurate for concepts that can be easily expressed using natural label tokens.

5 Fact Retrieval

An important question is whether pretrained MLMs *know* facts about real-world entities. The LAMA dataset (Petroni et al., 2019) evaluates this using cloze tests that consist of (sub, rel, obj) triples, e.g. (Obama, bornIn, Hawaii), and *manually* created prompts with missing objects, e.g. "Obama was born in [MASK].". LPAQA (Jiang et al., 2020) extends this idea by *systematically* creating prompts that are generated by mining Wikipedia, paraphrasing, and crowdsourcing. In this section, we use the same cloze-style setup but *automatically* generate prompts in order to better evaluate the factual knowledge of MLMs. We compare our approach against LAMA and LPAQA, which are explicitly designed for the task of fact retrieval.

Setup We reformulate fact retrieval by mapping (sub,rel,obj) triples to a prompt using the template "{sub}[T]. . . [T][P].", where the trigger tokens are specific to the relation rel and the correct object obj is the label token. We use the original test set from LAMA (Petroni et al., 2019), henceforth *Original*. To collect training data for AutoPrompt, we gather at most 1000 facts for each of the 41 relations in LAMA from the T-REx dataset (ElSahar et al., 2018). For the relations that still have less than 1000 samples, we gather extra facts straight from Wikidata. We ensure that none of the T-REx triples are present in the test set, and we split the data 80-20 into train and development sets. Moreover, because the collected T-REx data is from a slightly different distribution than the LAMA test set, we also consider a separate evaluation where we split the T-REx triples into a 60-20-20 train/dev/test split and evaluate on the test set. This *T-REx* dataset is used to measure the performance of our prompts when the train and test data is from the same distribution.

We use AutoPrompt with 5 or 7 tokens, and select the search parameters using the T-REx development set. We prevent proper nouns and tokens that appear as gold objects in the training data from being selected as trigger tokens. This is done to prevent AutoPrompt from "cheating" by embedding common answers inside the prompt. To evaluate, we observe the rank of the true object in label token distribution of the MLM, and use standard ranking metrics: mean reciprocal rank (MRR), precision-at-1 (P@1), and precision-at-10 (P@10).

Table 3: **Example Prompts** by AutoPrompt for each task. On the left, we show the prompt template, which combines the input, a number of trigger tokens [T], and a prediction token [P]. For classification tasks (sentiment analysis and NLI), we make predictions by summing the model's probability for a number of automatically selected label tokens. For fact retrieval and relation extraction, we take the most likely token predicted by the model.

Prompt Type	Original			T-REx		
	MRR	P@10	P@1	MRR	P@10	P@1
LAMA	40.27	59.49	31.10	35.79	54.29	26.38
LPAQA (Top1)	43.57	62.03	34.10	39.86	57.27	31.16
AutoPrompt 5 Tokens	53.06	72.17	42.94	54.42	70.80	45.40
AutoPrompt 7 Tokens	53.89	73.93	43.34	54.89	72.02	45.57

Model	MRR	P@10	P@1
BERT	55.22	74.01	45.23
RoBERTa	49.90	68.34	40.01

Table 4: **Factual Retrieval:** On the left, we evaluate BERT on fact retrieval using the *Original* LAMA dataset from Petroni et al. (2019). For all three metrics (mean reciprocal rank, mean precision-at-10 (P@10), and mean precision-at-1(P@1)), AutoPrompt significantly outperforms past prompting methods. We also report results on a *T-REx* version of the data (see text for details). On the right, we compare BERT versus RoBERTa on a subset of the LAMA data using AutoPrompt with 5 tokens.

Results Table 4 shows the performance of MLMs with different prompting methods, and we show qualitative examples in Table 3 and in Appendix C. Prompts generated using AutoPrompt can extract factual knowledge from BERT more effectively than their manual and mined counterparts: we improve P@1 by up to 12 points. Moreover, despite AutoPrompt using only one prompt per relation, it still outperforms LPAQA's ensemble method (which averages predictions for up to 30 prompts) by approximately 4 points. Using 7 trigger tokens achieves slightly higher scores than 5 trigger tokens, although the difference is not substantial. This indicates that our approach is stable to the choice of trigger length, which is consistent with our sentiment analysis results. Overall, these results show that AutoPrompt can retrieve facts more effectively than past prompting methods, thus demonstrating that BERT contains more factual knowledge than previously estimated.

Relation Breakdown We also provide a detailed breakdown of the prompts found by Petroni et al. (2019) and AutoPrompt, and their associated accuracies in Appendix C, Table 7. Manual prompts are competitive when the prompt is *easy* to specify, e.g., the prompt *"was born in"* for the PLACE OF BIRTH relation. On the other hand, AutoPrompt performs especially well for relations that are difficult to specify in a natural language prompt. For example, Petroni et al. (2019)'s prompt for the POSITION PLAYED ON TEAM relation is "{sub} plays in [MASK] position", which is not as specific as the relation requires. Although the prompt from AutoPrompt is not grammatical (*"{sub} ediatric striker ice baseman defensive {obj}"*), it does contain tokens that are directly related to sports.

BERT outperforms RoBERTa We finally directly compare BERT and RoBERTa. To do so, we subsample the LAMA test set to consist of examples where the object is a single token for both

BERT and RoBERTa (*Original-RoBERTa*).[4] BERT actually slightly outperforms RoBERTa, and we find that the prompts generated for RoBERTa tend to contain more irrelevant words (see Appendix C, Table 7). For example, the prompt generated by RoBERTa for the PLAYS INSTRUMENT relation contains words such as "Trump" and symbols such as "," ()," for the POSITION PLAYED ON TEAM relation. It is surprising that RoBERTa does not perform better than BERT, and it is worthy of investigating this further in future work. Additionally, recall that prompting is a *lower bound* on a model's knowledge: the lower relative performance does not mean that the model actually knows less.

6 Relation Extraction

Apart from evaluating whether MLMs *know* facts, it is also important to evaluate whether they can *extract knowledge* from text. In this section, we use the task of relation extraction (RE)—to identify how entities are related in a given sentence—an important task in information extraction. We create RE prompts in a similar fashion as fact retrieval: for a given triple (subj,rel,obj) and sentence that expresses this relation, we construct a prompt as "{sent}{sub}[T]. . . [T][P].", where the trigger tokens are specific to the relation, and label token is the correct object obj (see Table 3 for an example).

Setup We use the T-Rex dataset for RE because each T-REx fact comes with context sentences that mention the subject and object surface forms. We compare AUTOPROMPT to LAMA and LPAQA (their prompts are still useful here), as well as a recent supervised relation extraction model (Sorokin and Gurevych, 2017) that was also used by Petroni et al. (2019). To make the evaluation fair for the supervised RE model, we modify the standard RE evaluation. We give the model credit as long as it does not predict a different relation for the subject and object, i.e. we ignore the "no relation" prediction and all other relations. We also drop all sentences from evaluation for which the model's named entity extractor failed to identify the subject and the object as entities. See Appendix B for further details. For the evaluation of all systems, we treat a prediction as correct if it is either the canonical version of the object (e.g., "USA") or the rendered surface form (e.g., "American") for *any* of the context sentences in a given triple.

Results Table 5 shows the results for BERT and RoBERTa. MLMs can extract relational information *more effectively* than the supervised RE model, providing up to a 33% increase on the task when using AUTOPROMPT. RoBERTa also outperforms the supervised RE model, although it is worse than BERT (likely for similar reasons as we outline in Section 5). For both BERT and RoBERTa, we notice that the trigger tokens consist of words related to their corresponding relations (see Appendix D, Table 8 for full list), e.g. RoBERTa selects "defy trademarks of namesake manufacturer" for relation MANUFACTURER/PRODUCER OF PRODUCT.

Perturbed Sentence Evaluation A possible explanation for the strong results of MLMs in the RE setting is that they may *already* know many of the relations. Thus, they may directly predict the objects instead of *extracting* them. To separate this effect, we synthetically perturb the relation extraction dataset by replacing each object in the test data with a random other object and making the same change to the prompt. For example, *"Ryo Kase (born November 9, 1974 in ~~Yokohama~~ →Yorkshire) is a Japanese actor"* where Ryo Kase is the subject, Yokohama is the original object, and Yorkshire is the new object. We regenerate the prompts using the perturbed version of the data.

The accuracy of the RE model does not change significantly on the perturbed data (Table 5), however, the accuracy of the MLMs decreases significantly. This indicates that a significant portion of MLM accuracy comes from background information rather than relation extraction. Nevertheless, our prompts for BERT outperform their LAMA and LPAQA counterparts, which provides further evidence that AUTOPROMPT produces better probes.

7 Discussion

Prompting as an Alternative to Finetuning The goal of prompting a language model is to probe the knowledge that the model acquired from pretraining. Nevertheless, prompting has some practical advantages over finetuning for solving real-world tasks. First, as shown in Section 3, prompts generated using AUTOPROMPT can achieve higher accuracy than finetuning in the *low-data regime*. Moreover, prompting has advantages over finetuning when trying to solve *many different tasks* (e.g., the many users of the OpenAI GPT-3 API Brown et al. 2020). In particular, finetuning requires storing large language model checkpoints for each in-

---

[4] The original dataset consists of examples where the object is a single token for BERT.

Model	Original	Perturbed
Supervised RE LSTM	57.95	58.81
BERT (LAMA)	69.06	28.02
BERT (LPAQA)	76.55	30.79
BERT (AUTOPROMPT)	90.73	56.43
RoBERTa (AUTOPROMPT)	60.33	28.95

Table 5: **Relation Extraction:** We use prompts to test pretrained MLMs on relation extraction. Compared to a state-of-the-art LSTM model from 2017, MLMs have higher mean precision-at-1 (P@1), especially when using prompts from AUTOPROMPT. We also test models on sentences that have been edited to contain incorrect facts. The accuracy of MLMs drops significantly on these sentences, indicating that their high performance stems from their factual knowledge.

dividual task, and, more importantly, it drastically increases system cost and complexity because it requires deploying many different models at the same time. Prompting alleviates both of these issues. We can simply store the prompts for each individual task, and use the same pretrained model for inputs of any of the tasks.

Limitations of Prompting There are certain phenomena that are difficult to elicit from pretrained language models via prompts. In our preliminary evaluation on datasets such as QQP (Iyer et al., 2017) and RTE (Dagan et al., 2005), prompts generated manually and with AUTOPROMPT did not perform considerably better than chance. However, we cannot conclude that BERT does not know paraphrasing or entailment from these results. In general, different probing methods have different tasks and phenomena they are suitable for: AUTOPROMPT makes *prompt-based probes* more generally applicable, but, it still remains just one tool in the toolbox of the interpretability researcher.

Limitations of AUTOPROMPT One downside of AUTOPROMPT is that it requires labeled training data. Although this is also required for other probing techniques (e.g., linear probing classifiers), manual prompts rely on domain/language insights instead of labeled data. Compared to human-designed prompts, AUTOPROMPT generated prompts lack interpretability, which is similar to other probing techniques, such as linear probing classifiers. Another limitation of AUTOPROMPT is that it can sometimes struggle when the training data is highly imbalanced. For example, in Sections 4 and 5 we show that the prompts often just increase the likelihood of the majority label. Rebalancing the training data can help to mitigate this problem. Finally, due to the greedy search over the large discrete space of phrases, AUTOPROMPT is sometimes brittle; we leave more effective crafting techniques for future directions.

8 Conclusion

In this paper, we introduce AUTOPROMPT, an approach to develop automatically-constructed prompts that elicit knowledge from pretrained MLMs for a variety of tasks. We show that these prompts outperform manual prompts while requiring less human effort. Furthermore, the results for sentiment analysis and textual entailment suggest that, in some data-scarce settings, it may be more effective to *prompt* language models than to finetune them for the task. Although we focus only on masked language models in this paper, our method can be trivially extended to standard language models, and thus maybe useful for constructing inputs for models like GPT-3 (Brown et al., 2020). Source code and datasets to reproduce the results in this paper is available at http://ucinlp.github.io/autoprompt.

Acknowledgments

We would like to thank the LAMA and LPAQA teams for answering our questions. We would also like to thank the members of UCI NLP, Matt Gardner, Sebastian Riedel, and Antoine Bosselut for valuable feedback. This material is based upon work sponsored by the DARPA MCS program under Contract No. N660011924033 with the United States Office Of Naval Research.

A Effect of Hyperparameters on Sentiment Analysis

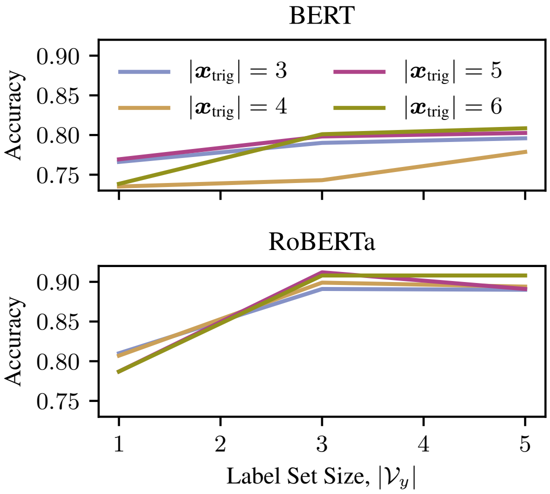

Figure 3: **Effect of Label and Trigger Set Sizes** on sentiment analysis. The number of candidate replacements is fixed at $|\mathcal{V}_{\text{cand}}| = 100$. Increasing the label set size improves performance, while changing the trigger length does not have much impact.

To measure the effects of the AUTOPROMPT search hyperparameters, we plot the validation accuracy as a function of label set size $|\mathcal{V}_y|$ and the number of trigger tokens $|\boldsymbol{x}_{\text{trig}}|$ in Figure 3. We fix the number of candidates at $|\mathcal{V}_{\text{cand}}| = 100$. We observe similar trends when $|\mathcal{V}_{\text{cand}}| = 10$.

Varying the number of trigger tokens generally has little effect. On the other hand, there is a substantial increase in accuracy when increasing the label set size from 1 to 3 (approximately +5% for BERT, and +10% for RoBERTa). After analyzing the label sets, we find that our method generally produces intuitive results—“marvelous” and “philanthrop” are associated with positive sentiment, whereas “worse” and “incompetence” are associated with negative sentiment for RoBERTa.

B Relation Extraction Details

Following Petroni et al. (2019), we use the pre-trained RE model from Sorokin and Gurevych (2017) as our baseline. To encode the sentence, this model uses a combination of an LSTM-based relation encoder and an attention mechanism. To make predictions, the model constructs a knowledge graph whose edges are the extracted relation triples. The standard RE evaluation measures how well the model predicts the relation types of entity pairs on the sentence level.

Since our goal is to extract the object of relation triplets, rather than the relation itself, we tweak the standard RE evaluation. We feed the RE model sentences from test facts and we query the resulting graph for all edges that contain the given subject and relation. Then we select the triple with the highest confidence and compare it’s object to the gold object. We do this for every fact and take the average across all relations to get the overall precision. The RE model is not trained to predict two of the original T-REx relations. For fair comparison, we exclude these two relations for our evaluation.

Learning Variational Word Masks to Improve the Interpretability of Neural Text Classifiers

Abstract

To build an interpretable neural text classifier, most of the prior work has focused on designing inherently interpretable models or finding faithful explanations. A new line of work on improving model interpretability has just started, and many existing methods require either prior information or human annotations as additional inputs in training. To address this limitation, we propose the variational word mask (VMASK) method to automatically learn task-specific important words and reduce irrelevant information on classification, which ultimately improves the interpretability of model predictions. The proposed method is evaluated with three neural text classifiers (CNN, LSTM, and BERT) on seven benchmark text classification datasets. Experiments show the effectiveness of VMASK in improving both model prediction accuracy and interpretability.

Ex.	Model	Text & Explanation
1	A	An exceedingly clever piece of cinema
	B	An exceedingly clever piece of cinema
2	A	It becomes gimmicky instead of compelling
	B	It becomes gimmicky instead of compelling

Table 1: Model A and B are two neural text classifiers with similar network architectures. They all make correct sentiment predictions on both texts (ex. 1: positive; ex. 2: negative). Two post-hoc explanation methods, LIME (Ribeiro et al., 2016) and SampleShapley (Kononenko et al., 2010), are used to explain the model predictions on example 1 and 2 respectively. Top three important words are shown in pink or blue for model A and B. Whichever post-hoc method is used, explanations from model B are easier to understand because the sentiment keywords "clever" and "gimmicky" are highlighted.

1 Introduction

Neural network models have achieved remarkable performance on text classification due to their capacity of representation learning on natural language texts (Zhang et al., 2015; Yang et al., 2016; Joulin et al., 2017; Devlin et al., 2018). However, the lack of understanding of their prediction behaviors has become a critical issue for reliability and trustworthiness and hindered their applications in the real world (Lipton, 2016; Ribeiro et al., 2016; Jacovi and Goldberg, 2020). Many explanation methods have been proposed to provide post-hoc explanations for neural networks (Ribeiro et al., 2016; Lundberg and Lee, 2017; Sundararajan et al., 2017), but they are only able to explain model predictions and cannot help improve their interpretability.

In this work, we consider interpretability as an intrinsic property of neural network models. Furthermore, we hypothesize that neural network models with similar network architectures could have different levels of interpretability, even though they may have similar prediction performance. Table 1 shows explanations extracted from two neural text classifiers with similar network architectures.[1] Although both models make correct predictions of the sentiment polarities of two input texts (positive for example 1 and negative for example 2), they have different explanations for their predictions. In both examples, no matter which explanation generation method is used, explanations from model B are easier to be interpreted regarding the corresponding predictions. Motivated by the difference of interpretability, we would like to investigate the possibility of *building more interpretable neural classifiers with a simple modification on input layers*. The proposed method does not demand significant efforts on engineering network architectures (Rudin, 2019; Melis and Jaakkola, 2018). Also, unlike prior work on improving interpretability (Erion

---

[1] The similarity will be detailed in section 4 and more examples are provided in Table 5.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4236–4251,
November 16–20, 2020. ©2020 Association for Computational Linguistics

et al., 2019; Plumb et al., 2019), it does not require pre-defined important attributions or pre-collected explanations.

Specifically, we propose variational word masks (VMASK) that are inserted into a neural text classifier, after the word embedding layer, and trained jointly with the model. VMASK learns to restrict the information of globally irrelevant or noisy word-level features flowing to subsequent network layers, hence forcing the model to focus on important features to make predictions. Experiments in section 5 show that this method can improve model interpretability and prediction performance. As VMASK is deployed on top of the word-embedding layer and the major network structure keeps unchanged, it is *model-agnostic* and can be applied to any neural text classifiers.

The contribution of this work is three-fold: (1) we proposed the VMASK method to learn global task-specific important features that can improve both model interpretability and prediction accuracy; (2) we formulated the problem in the framework of information bottleneck (IB) (Tishby et al., 2000; Tishby and Zaslavsky, 2015) and derived a lower bound of the objective function via the variational IB method (Alemi et al., 2016); and (3) we evaluated the proposed method with three neural network models, CNN (Kim, 2014), LSTM (Hochreiter and Schmidhuber, 1997), and BERT (Devlin et al., 2018), on seven text classification tasks via both quantitative and qualitative evaluations.

Our implementation is available at `https://github.com/UVa-NLP/VMASK`.

2 Related Work

Various approaches have been proposed to interpret DNNs, ranging from designing inherently interpretable models (Melis and Jaakkola, 2018; Rudin, 2019), to tracking the inner-workings of neural networks (Jacovi et al., 2018; Murdoch et al., 2018), to generating post-hoc explanations (Ribeiro et al., 2016; Lundberg and Lee, 2017). Beyond interpreting model predictions, the explanation generation methods are also promising in improving model's performance. We propose an information-theoretic method to improve both prediction accuracy and interpretability.

Explanation from the information-theoretic perspective. A line of works that motivate ours leverage information theory to produce explanations, either maximizing mutual information to recognize important features (Chen et al., 2018; Guan et al., 2019), or optimizing the information bottleneck to identify feature attributions (Schulz et al., 2020; Bang et al., 2019). The information-theoretic approaches are efficient and flexible in identifying important features. Different from generating post-hoc explanations for well-trained models, we utilize information bottleneck to train a more interpretable model with better prediction performance.

Improving prediction performance via explanations. Human-annotated explanations have been utilized to help improve model prediction accuracy (Zhang et al., 2016). Recent work has been using post-hoc explanations to regularize models on prediction behaviors and force them to emphasize more on predefined important features, hence improving their performance (Ross et al., 2017; Ross and Doshi-Velez, 2018; Liu and Avci, 2019; Rieger et al., 2019). Different from these methods that require expert prior information or human annotations, the VMASK method learns global important features automatically during training and incorporate them seamlessly on improving model prediction behaviors.

Improving interpretability via explanations. Some work focuses on improving model's interpretability by aligning explanations with human-judgements (Camburu et al., 2018; Du et al., 2019b; Chen and Ji, 2019; Erion et al., 2019; Plumb et al., 2019). Similarly to the prior work on improving model prediction performance, these methods still rely on annotations or external resources. Although enhancing model interpretability, they may cause the performance drop on prediction accuracy due to the inconsistency between human recognition and model reasoning process (Jacovi and Goldberg, 2020). Our approach can improve both prediction accuracy and interpretability without resorting to human-judgements.

3 Method

This section introduces the proposed VMASK method. For a given neural text classifier, the only modification on the neural network architecture is to insert a word mask layer between the input layer (e.g., word embeddings) and the representation learning layer. We formulate our idea within the information bottleneck framework (Tishby et al., 2000), where the word mask layer restricts the information from words to the final prediction.

3.1 Interpretable Text Classifier with Word Masks

For an input text $\boldsymbol{x} = [x_1, \cdots, x_T]$, where x_t ($t \in \{1, \ldots, T\}$) indicates the word or the word index in a predefined vocabulary. In addition, we use $\boldsymbol{x}_t \in \mathbb{R}^d$ as the word embedding of x_t. A neural text classifier is denoted as $f_{\boldsymbol{\theta}}(\cdot)$ with parameter $\boldsymbol{\theta}$, which by default takes $\boldsymbol{x}$ as input and generates a probability of output $\boldsymbol{Y}$, $p(\boldsymbol{Y}|\boldsymbol{x})$, over all possible class labels. In this work, beyond prediction accuracy, we also expect the neural network model to be more interpretable, by focusing on important words to make predictions.

To help neural network models for better feature selection, we add a random layer $\boldsymbol{R}$ after the word embeddings, where $\boldsymbol{R} = [R_{x_1}, \ldots, R_{x_T}]$ has the same length of $\boldsymbol{x}$. Each $R_{x_t} \in \{0, 1\}$ is a binary random variable associated with the word type x_t instead of the word position. This random layer together with word embeddings form the input to the neural network model, i.e.,

$$\boldsymbol{Z} = \boldsymbol{R} \odot \boldsymbol{x}, \tag{1}$$

where $\odot$ is an element-wise multiplication and each $\boldsymbol{Z}_t = R_{x_t} \cdot \boldsymbol{x}_t$. Intuitively, $\boldsymbol{Z}$ only contains a subset of $\boldsymbol{x}$, which is selected randomly by $\boldsymbol{R}$. Since $\boldsymbol{R}$ is applied directly on the words as a sequence of 0-1 masks, we also call it the word mask layer in this work.

To ensure $\boldsymbol{Z}$ has enough information on predicting $\boldsymbol{Y}$ while contains the least redundant information from $\boldsymbol{x}$, we follow the standard practice in the information bottleneck theory (Tishby et al., 2000), and write the objective function as

$$\max_{\boldsymbol{Z}} I(\boldsymbol{Z}; \boldsymbol{Y}) - \beta \cdot I(\boldsymbol{Z}; \boldsymbol{X}), \tag{2}$$

where $\boldsymbol{X}$ as a random variable representing a generic word sequence as input, $\boldsymbol{Y}$ is the one-hot output random variable, $I(\cdot;\cdot)$ is the mutual information, and $\beta \in \mathbb{R}_+$ is a coefficient to balance the two mutual information items. This formulation reflects our exact expectation on $\boldsymbol{Z}$. The main challenge here is to compute the mutual information.

3.2 Variational Word Masks

Inspired by the variational information bottleneck proposed by Alemi et al. (2016), instead of computing $p(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$, we start from an approximation distribution $q(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$. Then, with a few assumptions specified in the following, we construct a tractable lower bound of the objective in Equation 2 and the detailed derivation is provided in Appendix A.

For $I(\boldsymbol{Z}; \boldsymbol{Y})$ under q, we have $I(\boldsymbol{Z}; \boldsymbol{Y}) = \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log(q(\boldsymbol{y}|\boldsymbol{z})/q(\boldsymbol{y}))$. By replacing $\log q(\boldsymbol{y}|\boldsymbol{z})$ with the conditional probability derived from the true distribution $\log p(\boldsymbol{y}|\boldsymbol{z})$, we introduce the constraint between $\boldsymbol{Y}$ and $\boldsymbol{Z}$ from the distribution and also obtain a lower bound of $I(\boldsymbol{Z}; \boldsymbol{Y})$,

$$\begin{aligned} I(\boldsymbol{Z}; \boldsymbol{Y}) &\geq \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log p(\boldsymbol{y}|\boldsymbol{z}) + H_q(\boldsymbol{Y}) \\ &= \sum_{\boldsymbol{y},\boldsymbol{z},\boldsymbol{x}} q(\boldsymbol{x}, \boldsymbol{y}) q(\boldsymbol{z}|\boldsymbol{x}) \log p(\boldsymbol{y}|\boldsymbol{z}) \\ &\quad + H_q(\boldsymbol{Y}), \end{aligned} \tag{3}$$

where $H_q(\cdot)$ is entropy, and the last step uses $q(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) = q(\boldsymbol{x}) q(\boldsymbol{y}|\boldsymbol{x}) q(\boldsymbol{z}|\boldsymbol{x})$, which is a factorization based on the conditional dependency [2].

Given a specific observation $(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})$, we define the empirical distribution $q(\boldsymbol{X}^{(i)}, \boldsymbol{Y}^{(i)})$ as a multiplication of two Delta functions $q(\boldsymbol{X}^{(i)} = \boldsymbol{x}^{(i)}, \boldsymbol{Y}^{(i)} = \boldsymbol{y}^{(i)}) = \delta_{\boldsymbol{x}^{(i)}}(\boldsymbol{x}) \cdot \delta_{\boldsymbol{y}^{(i)}}(\boldsymbol{y})$. Then, Equation 3 can be further simplified as

$$\begin{aligned} I(\boldsymbol{Z}; \boldsymbol{Y}^{(i)}) &\geq \sum_{\boldsymbol{z}} q(\boldsymbol{z}|\boldsymbol{x}^{(i)}) \log p(\boldsymbol{y}^{(i)}|\boldsymbol{z}) \\ &= \mathbb{E}_{q(\boldsymbol{z}|\boldsymbol{x}^{(i)})}[\log p(\boldsymbol{y}^{(i)}|\boldsymbol{z})]. \end{aligned} \tag{4}$$

Similarly, for $I(\boldsymbol{Z}; \boldsymbol{X})$ under q, we have an upper bound of $I(\boldsymbol{Z}; \boldsymbol{X})$ by replacing $p(\boldsymbol{Z}|\boldsymbol{X})$ with a predefined prior distribution $p_0(\boldsymbol{Z})$

$$\begin{aligned} I(\boldsymbol{Z}; \boldsymbol{X}) &\leq \mathbb{E}_{q(\boldsymbol{x})}[\mathrm{KL}[q(\boldsymbol{z}|\boldsymbol{x}) \| p_0(\boldsymbol{z})]] \\ &= \mathrm{KL}[q(\boldsymbol{z}|\boldsymbol{x}^{(i)}) \| p_0(\boldsymbol{z})], \end{aligned} \tag{5}$$

where $\mathrm{KL}[\cdot\|\cdot]$ denotes Kullback-Leibler divergence. The simplification in the last step is similar to Equation 4 with the empirical distribution $q(\boldsymbol{X}^{(i)})$.

Substituting (5) and (4) into Equation 2 gives us a lower bound $\mathcal{L}$ of the informaiton bottleneck

$$\begin{aligned} \mathcal{L} =& \mathbb{E}_{q(\boldsymbol{z}|\boldsymbol{x}^{(i)})}[\log p(\boldsymbol{y}^{(i)}|\boldsymbol{z})] \\ & - \beta \cdot \mathrm{KL}[q(\boldsymbol{z}|\boldsymbol{x}^{(i)}) \| p_0(\boldsymbol{z})]. \end{aligned} \tag{6}$$

The learning objective is to maximize Equation 6 with respect to the approximation distribution $q(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z}) = q(\boldsymbol{X}, \boldsymbol{Y}) q(\boldsymbol{Z}|\boldsymbol{X})$. As a classification problem, $\boldsymbol{X}$ and $\boldsymbol{Y}$ are both observed and

---

[2] $\boldsymbol{Y} \leftrightarrow \boldsymbol{X} \leftrightarrow \boldsymbol{Z}$: $\boldsymbol{Y}$ and $\boldsymbol{Z}$ are independent given $\boldsymbol{X}$.

$q(\boldsymbol{X}, \boldsymbol{Y})$ has already been simplified as an empirical distribution, the only one left in the approximation distribution is $q(\boldsymbol{Z}|\boldsymbol{X})$. Similarly to the objective function in variational inference (Alemi et al., 2016; Rezende and Mohamed, 2015), the first term in $\mathcal{L}$ is to make sure the information in $q(\boldsymbol{Z}|\boldsymbol{X})$ for predicting $\boldsymbol{Y}$, while the second term in $\mathcal{L}$ is to regularize $q(\boldsymbol{Z}|\boldsymbol{X})$ with a predefined prior distribution $p_0(\boldsymbol{Z})$.

The last step of obtaining a practical objective function is to notice that, given $\boldsymbol{X}_t^{(i)} = \boldsymbol{x}_t^{(i)}$ every $\boldsymbol{Z}_t$ can be redefined as

$$\boldsymbol{Z}_t = R_{x_t} \cdot \boldsymbol{x}_t^{(i)}, \tag{7}$$

where $R_{x_t} \in \{0, 1\}$ is a standard Bernoulli distribution. Then, $\boldsymbol{Z}$ can be reparameterized as $\boldsymbol{Z} = \boldsymbol{R} \odot \boldsymbol{x}^{(i)}$ with $\boldsymbol{R} = [R_{x_1}, \ldots, R_{x_T}]$. The lower bound $\mathcal{L}$ can be rewritten with the random variable $\boldsymbol{R}$ as

$$\begin{aligned} \mathcal{L} =& \mathbb{E}_{q(\boldsymbol{r}|\boldsymbol{x}^{(i)})}[\log p(\boldsymbol{y}^{(i)}|\boldsymbol{R}, \boldsymbol{x}^{(i)})] \\ &- \beta \cdot \mathrm{KL}[q(\boldsymbol{R}|\boldsymbol{x}^{(i)}) \| p_0(\boldsymbol{R})]. \end{aligned} \tag{8}$$

Note that, although β is inherited from the information bottleneck theory, in practice it will be used as a tunable hyper-parameter to address the notorious posterior collapse issue (Bowman et al., 2016; Kim et al., 2018).

3.3 Connections

The idea of modifying word embeddings with the information bottleneck method has recently shown some interesting applications in NLP. For example, Li and Eisner (2019) proposed two ways to transform word embeddings into new representations for better POS tagging and syntactic parsing. According to Equation 1, VMASK can be viewed as a simple linear transformation on word embeddings. The difference is that $\{R_{x_t}\}$ is defined on the vocabulary, therefore can be used to represent the global importance of word x_t. Recall that $R_{x_t} \in \{0, 1\}$, from a slightly different perspective, Equation 1 can be viewed as a generalized method on word-embedding dropout (Gal and Ghahramani, 2016). Although there are two major differences: (1) in Gal and Ghahramani (2016) all words share the same dropout rate, while in VMASK every word has its own dropout rate specified by $q(R_{x_t}|\boldsymbol{x}_t)$, i.e. $1 - \mathbb{E}[q(R_{x_t}|\boldsymbol{x}_t)]$; (2) the motivation of word-embedding dropout is to force a model not to rely on single words for prediction, while VMASK is to learn a task-specific importance for every word.

Another implementation for making word masks sparse is by adding L_0 regularization (Lei et al., 2016; Bastings et al., 2019; Cao et al., 2020), but this regularizer only distinguishes words as important or unimportant, rather than learning continuous importance scores.

3.4 Model Specification and Training

We resort to mean-field approximation (Blei et al., 2017) to simplify the assumption on our q distribution. For $q_{\boldsymbol{\phi}}(\boldsymbol{R}|\boldsymbol{x})$, we have $q_{\boldsymbol{\phi}}(\boldsymbol{R}|\boldsymbol{x}) = \prod_{t=1}^{T} q_{\boldsymbol{\phi}}(R_{x_t}|\boldsymbol{x}_t)$, which means the random variables are mutually independent and each governed by $\boldsymbol{x}_t$. We use the amortized variational inference (Rezende and Mohamed, 2015) to represent the posterior distribution $q_{\boldsymbol{\phi}}(R_{x_t}|\boldsymbol{x}_t)$ with using an inference network (Kingma and Welling, 2014). In this work, we adopt a single-layer feedforward neural network as the inference network, whose parameters $\boldsymbol{\phi}$ are optimized with the model parameters $\boldsymbol{\theta}$ during training.

Following the same factorization as in $q_{\boldsymbol{\phi}}(\boldsymbol{R}|\boldsymbol{x})$, we define the prior distribution $p_0(\boldsymbol{R})$ as $p_0(\boldsymbol{R}) = \prod_{t=1}^{T} p_0(R_{x_t})$ and each of them as $p_0(R_{x_t}) = \mathrm{Bernoulli}(0.5)$. By choosing this non-informative prior, it means every word is initialized with no preference to be important or unimportant, and thus has the equal probability to be masked or selected. As $p_0(\boldsymbol{R})$ is a uniform distribution, we can further simplify the second term in Equation 8 as a conditional entropy,

$$\max_{\boldsymbol{\theta}, \boldsymbol{\phi}} \mathbb{E}_q[\log p(\boldsymbol{y}^{(i)}|\boldsymbol{R}, \boldsymbol{x}^{(i)})] + \beta \cdot H_q(\boldsymbol{R}|\boldsymbol{x}^{(i)}). \tag{9}$$

We apply stochastic gradient descent to solve the optimization problem (Equation 9). Particularly in each iteration, the first term in Equation 9 is approximated with a single sample from $q(\boldsymbol{R}|\boldsymbol{x}^{(i)})$ (Kingma and Welling, 2014). However, sampling from a Bernoulli distribution (like from any other discrete distributions) causes difficulty in backpropagation. We adopt the Gumbel-softmax trick (Jang et al., 2016; Maddison et al., 2016) to utilize a continuous differentiable approximation and tackle the discreteness of sampling from Bernoulli distributions (Appendix B). During training, We use Adam (Kingma and Ba, 2014) for optimization and KL cost annealing (Bowman et al., 2016) to avoid posterior collapse.

For a given word x_t and its word embedding $\boldsymbol{x}_t$, in training stage, the model samples each r_{x_t} from $q(R_{x_t}|\boldsymbol{x}_t)$ to decide to either keep or zero out the

corresponding word embedding $\boldsymbol{x}_t$. In inference stage, the model takes the multiplication of the word embedding $\boldsymbol{x}_t$ and the expectation of the word mask distribution, i.e. $\boldsymbol{x}_t \cdot \mathbb{E}[q(R_{x_t}|\boldsymbol{x}_t)]$, as input.

4 Experiment Setup

The proposed method is evaluated on seven text classification tasks, ranging from sentiment analysis to topic classification, with three typical neural network models, a long short-term memories (Hochreiter and Schmidhuber, 1997, LSTM), a convolutional neural network (Kim, 2014, CNN), and BERT (Devlin et al., 2018).

Datasets. We adopt seven benchmark datasets: movie reviews IMDB (Maas et al., 2011), Stanford Sentiment Treebank with fine-grained labels SST-1 and its binary version SST-2 (Socher et al., 2013), Yelp reviews (Zhang et al., 2015), AG's News (Zhang et al., 2015), 6-class question classification TREC (Li and Roth, 2002), and subjective/objective classification Subj (Pang and Lee, 2005). For the datasets (e.g. IMDB, Subj) without standard train/dev/test split, we hold out a proportion of training examples as the development set. Table 2 shows the statistics of the datasets.

Models. The CNN model (Kim, 2014) contains a single convolutional layer with filter sizes ranging from 3 to 5. The LSTM (Hochreiter and Schmidhuber, 1997) has a single unidirectional hidden layer. Both models are initialized with 300-dimensional pretrained word embeddings (Mikolov et al., 2013). We fix the embedding layer and update other parameters on different datasets to achieve the best performance respectively. We use the pretrained BERT-base model[3] with 12 transformer layers, 12 self-attention heads, and the hidden size of 768. We fine-tune it with different downstream tasks, and then fix the embedding layer and train the mask layer with the rest of the model together.

Baselines and Competitive Methods. As the goal of this work is to propose a novel training method that improves both prediction accuracy and interpretability, we employ two groups of models as baselines and competitive systems. Models trained with the proposed method are named with suffix "-VMASK". We also provide two baselines: (1) models trained by minimizing the cross-entropy loss (postfixed with "-base") and (2) models trained with ℓ_2-regularization (postfixed with "-ℓ_2"). The comparison with these two baseline methods mainly focuses on prediction performance as no explicit training strategies are used to improve interpretability.

Besides, we also propose two competitive methods: models trained with the explanation framework "Learning to Explain" (Chen et al., 2018) (postfixed with "-L2X") and the "Information Bottleneck Attribution" (Schulz et al., 2020) (postfixed with "-IBA"). L2X and IBA were originally proposed to find feature attributions as post-hoc explanations for well-trained models. We integrated them in model training, working as the mask layer to directly generate mask values for input features (L2X) or restrict information flow by adding noise (IBA). In our experiments, all training methods worked with random dropout ($\rho = 0.2$) to avoid overfitting.

More details about experiment setup are in Appendix C, including data pre-processing, model configurations, and the implementation of L2X and IBA in our experiments.

5 Results and Discussion

We trained the three models on the seven datasets with different training strategies. Table 3 shows the prediction accuracy of different models on test sets. The validation performance and average runtime are in Appendix D. As shown in Table 3, all base models have the similar prediction performance comparing to numbers reported in prior work (Appendix E). The models trained with VMASK outperform the ones with similar network architec-

Table 3: Prediction accuracy (%) of different models with different training strategies on the seven datasets.

tures but trained differently. The results show that VMASK can help improve the generalization power.

Except the base models and the models trained with the proposed method, the records of other three competitors are mixed. For example, the traditional ℓ_2-regularization cannot always help improve accuracy, especially for the BERT model. Although the performance with IBA is slightly better than with L2X, training with them does not show a constant improvement on a model's prediction accuracy.

To echo the purpose of improving model interpretability, the rest of this section will focus on evaluating the model interpretability quantitatively and qualitatively.

5.1 Quantitative Evaluation

We evaluate the local interpretability of VMASK-based models against the base models via the AOPC score (Nguyen, 2018; Samek et al., 2016) and the global interpretability against the IBA-based models via post-hoc accuracy (Chen et al., 2018). Empirically, we observed the agreement between local and global interpretability, so there is no need to exhaust all possible combinations in our evaluation.

5.1.1 Local interpretability: AOPC

We adopt two model-agnostic explanation methods, LIME (Ribeiro et al., 2016) and SampleShapley (Kononenko et al., 2010), to generate local explanations for base and VMASK-based models, where "local" means explaining each test data individually. The area over the perturbation curve (AOPC) (Nguyen, 2018; Samek et al., 2016) metric is utilized to evaluate the faithfulness of explanations to models. It calculates the average change of prediction probability on the predicted class over all test data by deleting top n words in explanations. We adopt this metric to evaluate the model interpretability to post-hoc explanations. Higher AOPC scores are better.

For TREC and Subj datasets, we evaluate all test data. For each other dataset, we randomly pick up 1000 examples for evaluation due to computation costs. Table 4 shows the AOPCs of different models on the seven datasets by deleting top 5 words identified by LIME or SampleShapley. The AOPCs of VMASK-based models are significantly higher than that of base models on most of the datasets, indicating that VMASK can improve model's interpretability to post-hoc explanations. The results on the TREC dataset are very close because top 5 words are possible to include all informative words for short sentences with the average length of 10.

5.1.2 Global Interpretability: Post-hoc accuracy

The expectation values $\{\mathbb{E}[q(R_{x_t}|\boldsymbol{x}_t)]\}$ represent the global importance of words (subsection 3.3) for a specific task. To measure the interpretability of a model itself (aka, global interpretability), we adopt

Methods	Models	IMDB	SST-1	SST-2	Yelp	AG News	TREC	Subj

Table 4: AOPCs (%) of LIME and SampleShapley in interpreting the base and VMASK-based models on the seven datasets.

the post-hoc accuracy (Chen et al., 2018) to evaluate the influence of global task-specific important features on the predictions of VMASK- and IBA-based models. For each test data, we select the top k words based on their global importance scores for the model to make a prediction, and compare it with the original prediction made on the whole input text

$$\text{post-hoc-acc}(k) = \frac{1}{M} \sum_{m=1}^{M} \mathbb{1}[y_m(k) = y_m],$$

where M is the number of examples, y_m is the predicted label on the m-th test data, and $y_m(k)$ is the predicted label based on the top k important words.

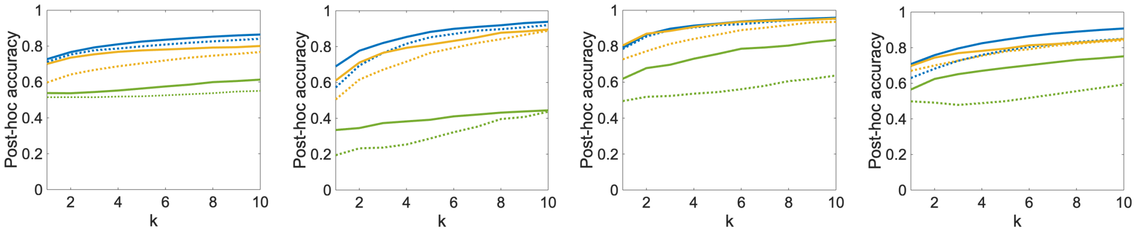
Figure 1 shows the results of VMASK- and IBA-based models on the seven datasets with k ranging from 1 to 10. VMASK-based models (solid lines) outperform IBA-based models (dotted lines) with higher post-hoc accuracy, which indicates our proposed method is better on capturing task-specific important features. For CNN-VMASK and LSTM-VMASK, using only top two words can achieve about 80% post-hoc accuracy, even for the IMDB dataset, which has the average sentence length of 268 tokens. The results illustrate that VMASK can identify informative words for model predictions. We also noticed that BERT-VMASK has lower post-hoc accuracy than the other two models. It is probably because BERT tends to use larger context with its self-attentions for predictions. This also explains that the post-hoc accuracies of BERT-VMASK on the IMDB and SST-1 datasets are catching up slowly with k increasing.

5.2 Qualitative Evaluation

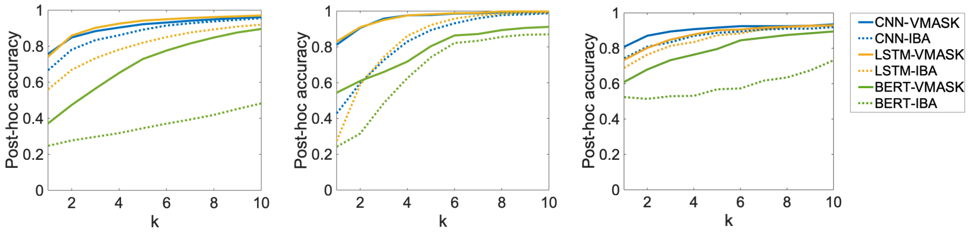
Visualizing post-hoc local explanations. Table 5 shows some examples of LIME explanations for different models on the IMDB dataset. We highlight the top three important words identified by LIME, where the color saturation indicates word attribution. The pair of base and VMASK-based models make the same and correct predictions on the input texts. For VMASK-based models, LIME can capture the sentiment words that indicate the same sentiment polarity as the prediction. While for base models, LIME selects some irrelevant words (e.g. “plot”, “of”, “to”) as explanations, which illustrates the relatively lower interpretability of base models to post-hoc explanations.

Visualizing post-hoc global explanations. We adopt SP-LIME proposed by Ribeiro et al. (2016) as a third-party global interpretability of base and VMASK-based models. Without considering the rectriction on the number of explanations, we follow the method to compute feature global importance from LIME local explanations (subsubsection 5.1.1) by calculating the sum over all local importance scores of a feature as its global importance. To distinguish it from the global importance learned by VMASK, we call it *post-hoc global importance*.

Table 6 lists the top three post-hoc global important words of base and VMASK-based models on the IMDB dataset. For VMASK-based mod-



(a) IMDB (b) SST-1 (c) SST-2 (d) Yelp



(e) AG News (f) TREC (g) Subj

Figure 1: Post-hoc accuracy of VMASK- and IBA-based models on the seven datasets.

els, the global important features selected by SP-LIME are all sentiment words. While for base models, some irrelevant words (e.g. "performances", "plot", "butcher") are identified as important features, which makes model predictions unreliable.

Frequency-importance correlation. We compute the Pearson correlation coefficients between word frequency and global word importance of VMASK-based models in Appendix F. The results show that they are not significantly correlated, which indicates that VMASK is not simply learning to select high-frequency words. Figure 2 further verifies this by ploting the expectation ($\mathbb{E}[q(R_{x_t}|\boldsymbol{x}_t)]$) of word masks from the LSTM-VMASK trained on Yelp and the word frequency from the same dataset. Here, we visualize the top 10 high-frequency words and top 10 important words based the expectation of word masks. The global importance scores of the sentiment words are over 0.8, even for some low-frequency words (e.g. "funnest", "craveable"), while that of the high-frequency words are all around 0.5, which means the VMASK-based models are less likely to focus on the irrelevant words to make predictions.

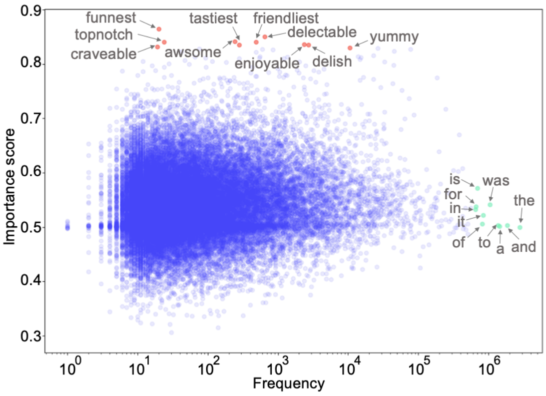


Figure 2: Scatter plot of word global importance and frequency (in log scale) of LSTM-VMASK on the Yelp dataset, where red dots represent top 10 important sentiment words and green dots represent top 10 high-frequency words.

Task-specific important words. Figure 3 visualizes top 10 important words for the VMASK- and IBA-based models on three datasets via word clouds. We can see that the selected words by VMASK are consistent with the corresponding topic, such as "funnest", "awsome" for sentiment analysis, and "encyclopedia", "spaceport" for news classification, while IBA selects some irrelevant words (e.g. "undress", "slurred").

6 Conclusion

In this paper, we proposed an effective method, VMASK, learning global task-specific important features to improve both model interpretability and prediction accuracy. We tested VMASK with three different neural text classifiers on seven benchmark datasets, and assessed its effectiveness via both quantitative and qualitative evaluations.

Models	Texts	Prediction
CNN-base	Primary plot , primary direction , poor interpretation .	negative
CNN-VMASK	Primary plot , primary direction , poor interpretation .	negative
LSTM-base	John Leguizamo 's freak is one of the funniest one man shows I 've ever seen . I recommend it to anyone with a good sense of humor .	positive
LSTM-VMASK	John Leguizamo 's freak is one of the funniest one man shows I 've ever seen . I recommend it to anyone with a good sense of humor .	positive
BERT-base	Great story , great music . A heartwarming love story that ' s beautiful to watch and delightful to listen to . Too bad there is no soundtrack CD .	positive
BERT-VMASK	Great story , great music . A heartwarming love story that ' s beautiful to watch and delightful to listen to . Too bad there is no soundtrack CD .	positive

Table 5: Examples of the explanations generated by LIME for different models on the IMDB dataset, where the top three important words are highlighted. The color saturation indicates word attribution.

Models	Words
CNN-base	excellent, performances, brilliant
CNN-VMASK	excellent, fine, favorite
LSTM-base	plot, excellent, liked
LSTM-VMASK	excellent, favorite, brilliant
BERT-base	live, butcher, thrilling
BERT-VMASK	powerful, thrilling, outstanding

Table 6: Post-hoc global important words selected by SP-LIME for different models on the IMDB dataset.

Acknowledgments

We thank the authors of Schulz et al. (2020) and Chen et al. (2018) for sharing their high-quality code. We thank the anonymous reviewers for many valuable comments.

A Proof of the Two Bounds for the Information Bottleneck

The following derivation is similar to the variational information bottleneck, where the difference is that our starting point is the approximation distribution $q(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ instead of the true distribution $p(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$.

The lower bound for $I(\boldsymbol{Z}; \boldsymbol{Y})$.

$$\begin{aligned} I(\boldsymbol{Z}, \boldsymbol{Y}) &= \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log \frac{q(\boldsymbol{y}, \boldsymbol{z})}{q(\boldsymbol{y})q(\boldsymbol{z})} \\ &= \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log \frac{q(\boldsymbol{y}|\boldsymbol{z})}{q(\boldsymbol{y})} \\ &= \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log q(\boldsymbol{y}|\boldsymbol{z}) \\ &\quad + H_q(\boldsymbol{Y}), \end{aligned} \tag{10}$$

where $H_q(\cdot)$ represents entropy. Now, if we replace $\log q(\boldsymbol{y}|\boldsymbol{z})$ with the conditional probability derived from the true distribution $\log p(\boldsymbol{y}|\boldsymbol{z})$, we have

$$\begin{aligned} &\sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log q(\boldsymbol{y}|\boldsymbol{z}) \\ &= \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log \frac{q(\boldsymbol{y}|\boldsymbol{z})p(\boldsymbol{y}|\boldsymbol{z})}{p(\boldsymbol{y}|\boldsymbol{z})} \\ &= \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log p(\boldsymbol{y}|\boldsymbol{z}) + \mathrm{KL}[q(\boldsymbol{y}|\boldsymbol{z}) \| p(\boldsymbol{y}|\boldsymbol{z})] \\ &\geq \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log p(\boldsymbol{y}|\boldsymbol{z}), \end{aligned} \tag{11}$$

where $\mathrm{KL}[\cdot\|\cdot]$ denotes Kullback-Leibler divergence. Therefore, we can obtain a lower bound of the mutual information

$$\begin{aligned} I(\boldsymbol{Z}, \boldsymbol{Y}) &\geq \sum_{\boldsymbol{y},\boldsymbol{z}} q(\boldsymbol{y}, \boldsymbol{z}) \log p(\boldsymbol{y}|\boldsymbol{z}) + H_q(\boldsymbol{Y}) \\ &= \sum_{\boldsymbol{y},\boldsymbol{z},\boldsymbol{x}} q(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) \log p(\boldsymbol{y}|\boldsymbol{z}) + H_q(\boldsymbol{Y}) \\ &= \sum_{\boldsymbol{y},\boldsymbol{z},\boldsymbol{x}} q(\boldsymbol{x}, \boldsymbol{y}) q(\boldsymbol{z}|\boldsymbol{x}) \log p(\boldsymbol{y}|\boldsymbol{z}) + H_q(\boldsymbol{Y}), \end{aligned} \tag{12}$$

where the last step uses $q(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{z}) = q(\boldsymbol{x})q(\boldsymbol{y}|\boldsymbol{x})q(\boldsymbol{z}|\boldsymbol{x})$, which is a factorization based on the conditional dependency [4].

Since $q(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ is the approximation defined by ourselves, given a specific observation $(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})$, the empirical distribution $q(\boldsymbol{X}^{(i)}, \boldsymbol{Y}^{(i)})$ is simply defined as a multiplication of two Delta functions

$$q(\boldsymbol{X}^{(i)} = \boldsymbol{x}^{(i)}, \boldsymbol{Y}^{(i)} = \boldsymbol{y}^{(i)}) = \delta_{\boldsymbol{x}^{(i)}}(\boldsymbol{x}) \cdot \delta_{\boldsymbol{y}^{(i)}}(\boldsymbol{y}). \tag{13}$$

Then, Equation 12 with $\boldsymbol{X}^{(i)}$ and $\boldsymbol{Y}^{(i)}$ can be further simplified as

$$\begin{aligned} I(\boldsymbol{Z}; \boldsymbol{Y}^{(i)}) &\geq \sum_{\boldsymbol{z}} q(\boldsymbol{z}|\boldsymbol{x}^{(i)}) \log p(\boldsymbol{y}^{(i)}|\boldsymbol{z}) \\ &= \mathbb{E}_{q(\boldsymbol{z}|\boldsymbol{x}^{(i)})}[\log p(\boldsymbol{y}^{(i)}|\boldsymbol{z})] \end{aligned} \tag{14}$$

The upper bound for $I(\boldsymbol{Z}; \boldsymbol{X})$.

$$\begin{aligned} I(\boldsymbol{Z}, \boldsymbol{X}) &= \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log \frac{q(\boldsymbol{x}, \boldsymbol{z})}{q(\boldsymbol{x})q(\boldsymbol{z})} \\ &= \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log \frac{q(\boldsymbol{z}|\boldsymbol{x})}{q(\boldsymbol{z})} \\ &= \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log q(\boldsymbol{z}|\boldsymbol{x}) \\ &\quad - \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log q(\boldsymbol{z}) \end{aligned} \tag{15}$$

By replacing $q(\boldsymbol{z})$ with a prior distribution of $\boldsymbol{z}$, $p_0(\boldsymbol{z})$, we have

$$\sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log q(\boldsymbol{z}) \geq \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log p_0(\boldsymbol{z}). \tag{16}$$

Then we can obtain an upper bound of the mutual information

$$\begin{aligned} I(\boldsymbol{Z}, \boldsymbol{X}) &\leq \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log q(\boldsymbol{z}|\boldsymbol{x}) \\ &\quad - \sum_{\boldsymbol{x},\boldsymbol{z}} q(\boldsymbol{x}, \boldsymbol{z}) \log p_0(\boldsymbol{z}) \\ &= \sum_{\boldsymbol{x}} q(\boldsymbol{x}) \mathrm{KL}[q(\boldsymbol{z}|\boldsymbol{x}) \| p_0(\boldsymbol{z})] \\ &= \mathbb{E}_{q(\boldsymbol{x})}[\mathrm{KL}[q(\boldsymbol{z}|\boldsymbol{x}) \| p_0(\boldsymbol{z})]] \\ &= \mathrm{KL}[q(\boldsymbol{z}|\boldsymbol{x}^{(i)}) \| p_0(\boldsymbol{z})]. \end{aligned} \tag{17}$$

B Sampling with Gumbel-softmax Trick

Specifically, as r_{x_t} has the probability $1 - p_{x_t}$ and p_{x_t} to take 0 or 1 respectively, we draw samples from a Gumbel(0, 1) distribution for each category $c \in \{0, 1\}$:

$$s_{x_t}^{(c)} = -\log(-\log u), \; u \sim \mathrm{Uniform}(0, 1), \tag{18}$$

and then apply a temperature-dependent softmax over the two categories with each dimension calculated as

$$rs_{x_t}^{(c)} = \frac{\exp((w_{x_t} + s_{x_t}^{(c)})/\tau)}{\sum_c \exp((w_{x_t} + s_{x_t}^{(c)})/\tau)}, \tag{19}$$

---

[4] $\boldsymbol{Y} \leftrightarrow \boldsymbol{X} \leftrightarrow \boldsymbol{Z}$: $\boldsymbol{Y}$ and $\boldsymbol{Z}$ are independent given $\boldsymbol{X}$.

Datasets	*vocab*	*threshold*	*length*

Table 7: Pre-processing details on the datasets. *vocab*: vocab size; *threshold*: low-frequency threshold; *length*: mini-batch sentence length.

where $w_{x_t} = \log(cp_{x_t} + (1-c)(1-p_{x_t}))$, and τ is a hyperparameter called the softmax temperature.

C Supplement of Experiment Setup

Data pre-processing. We clean up the text by converting all characters to lowercase, removing extra whitespaces and special characters. We tokenize texts and remove low-frequency words to build vocab. We truncate or pad sentences to the same length for mini-batch during training. Table 7 shows pre-processing details on the datasets.

Model configurations. We implement the models in PyTorch 3.6. The number of parameters in the CNN, LSTM and BERT are 2652305, 2632405, 109486085 respectively. We tune hyperparameters manually for each model to achieve the best prediction accuracy. We experiment with different kernel numbers ($\{100, \cdots, 500\}$) for the CNN model, hidden states ($\{100, \cdots, 500\}$) for the LSTM model, and other hyperparameters, such as learning rate $lr \in \{1e-4, 1e-3, \cdots, 1\}$, clipping norm $clip \in \{1e-3, 1e-2, \cdots, 1, 5, 10\}$.

Implementation of L2X and IBA.

- The explanation framework of L2X (Chen et al., 2018) is a neural network which learns to generate importance scores $\boldsymbol{w} = [w_1, w_2, \cdots, w_T]$ for input features $\boldsymbol{x} = [\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_T]$. The neural network is optimized by maximizing the mutual information between the selected important features and the model prediction, i.e. $I(\boldsymbol{x}_S; y)$, where $\boldsymbol{x}_S$ contains a subset of features from $\boldsymbol{x}$. In our experiments, we adopt a single-layer feedforward neural network as the interpreter to generate importance scores for an input text, and multiply each word embedding with its importance score, $\boldsymbol{x}' = \boldsymbol{w} \odot \boldsymbol{x}$. The weighted word embedding matrix $\boldsymbol{x}'$ is sent to the rest of the model to produce an output y'. We optimize the interpreter network with the original model by minimizing the cross-entropy loss between the final output and the ground-truth label, $\mathcal{L}_{ce}(y_t; y')$.
- We adopt the Readout Bottleneck of IBA which utilizes a neural network to predict mask values $\boldsymbol{\lambda} = [\lambda_1, \lambda_2, \cdots, \lambda_T]$, where $\lambda_t \in [0, 1]$. The information of a feature $\boldsymbol{x}_t$ is restricted by adding noise, i.e. $\boldsymbol{z}_t = \lambda_t \boldsymbol{x}_t + (1-\lambda_t)\boldsymbol{\epsilon}_t$, where $\boldsymbol{\epsilon}_t \sim \mathcal{N}(\mu_{\boldsymbol{x}_t}, \sigma^2_{\boldsymbol{x}_t})$. And $\boldsymbol{z}$ is learned by optimizing the objective function Equation 2. By assuming the variational approximation $q(\boldsymbol{z})$ as a Gaussian distribution, the mutual information can be calculated explicitly (Schulz et al., 2020) . We still use a single-layer feedforward neural network as the Readout Bottleneck to generate continuous mask valuses $\boldsymbol{\lambda}$ and construct $\boldsymbol{z}$ for model to make predictions. The Readout Bottleneck is trained jointly with the original model by minimizing the sum of the cross-entropy loss $\mathcal{L}_{ce}(y_t; y)$ and an upper bound $\mathcal{L}_I = \mathbb{E}_{\boldsymbol{x}}[\mathrm{KL}[p(\boldsymbol{z}|\boldsymbol{x}) \| q(\boldsymbol{z})]]$ of the mutual information $I(\boldsymbol{Z}; \boldsymbol{X})$. See Schulz et al. (2020) for the proof of the upper bound.

D Validation Performance and Average Runtime

The corresponding validation accuracy for each reported test accuracy is in Table 8. The average runtime for each approach on each dataset is recorded in Table 9. All experiments were performed on a single NVidia GTX 1080 GPU.

E Results of Prediction Accuracy Reported in Previous Papers

Table 10 shows some results of prediction accuracy of base models reported in previous papers.

F Pearson Correlation between Word Frequency and VMASK Expectation Values

Table 11 shows the Pearson correlation coefficients between word frequency and global word importance of VMASK-based models.

Abstract

Current state-of-the-art text generators build on powerful language models such as GPT-2, achieving impressive performance. However, to avoid degenerate text, they require sampling from a modified softmax, via temperature parameters or ad-hoc truncation techniques, as in top-k or nucleus sampling. This creates a mismatch between training and testing conditions. In this paper, we use the recently introduced entmax transformation to train and sample from a natively sparse language model, avoiding this mismatch. The result is a text generator with favorable performance in terms of fluency and consistency, fewer repetitions, and n-gram diversity closer to human text. In order to evaluate our model, we propose three new metrics for comparing sparse or truncated distributions: ϵ-perplexity, sparsemax score, and Jensen-Shannon divergence. Human-evaluated experiments in story completion and dialogue generation show that entmax sampling leads to more engaging and coherent stories and conversations.

Context:	*"Are they ready to go live?" Zuko asked. "Yup, in just a minute" Tomi replied as he leaned back in his reclining chair. This was a moment that the entire galaxy would see. After 10 years...*
Greedy:	... of study, the scientists had finally come to the conclusion that the universe was not a place for living. *The scientists* had been studying *the universe* for over a century. *They had been studying the universe for over a century.*
Top-k:	... of studying this phenomenon, the team had finally come up with a plan to *study* what the aliens were doing. *The team* would be looking for a way to create a space station. "And what would you call it?" *"What would you call the space station?"*
Nucleus:	... of diligent testing, *and some test run after that*, the results were well received. "they're waiting for you, because *there's no way they would.*" *Stowedly at a local wedding place, the two archaeologists spoke together.*
Entmax:	... of hibernation, Tomi was back. These last days had been a significant step forward in his mission. This time, Tomi was not alone. All the empires had aligned together and the world's leadership began to openly support his mission.

1 Introduction

The last few years have seen a tremendous progress in neural language modeling, with a strong impact on key NLP tasks such as machine translation (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017), speech recognition (Chorowski et al., 2015), summarization (Rush et al., 2015), and open-ended text generation (Radford et al., 2019). Benefiting from large amounts of data, models such as Transformer-XL (Dai et al., 2019) and GPT-2 (Radford et al., 2019) have achieved impressive perplexity scores on language modeling. However, the generated text is still often repetitive and incoherent (Table 1).

A downside of current approaches is the mismatch between training and testing conditions: models are usually trained to maximize the likelihood of observed text. However, when generating, state-of-the-art models sample from a **truncated** and **renormalized** softmax distribution (Fan et al., 2018; Holtzman et al., 2020). They do so as a compromise to avoid two extremes: a deterministic search for the most probable sentence (via greedy decoding or beam search) usually results in dull and repetitive "degenerate text" (Li et al., 2016a, 2017; Holtzman et al., 2020); stochastically sampling from the full softmax distribution, on the other hand, often generates many implausible

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4252–4273,
November 16–20, 2020. ©2020 Association for Computational Linguistics

words from the tail of the distribution (Fan et al., 2018). The recently proposed *nucleus sampling* approach (Holtzman et al., 2020) sets the truncation point based on the cumulative distribution function, *i.e.*, it considers the top words with a cumulative probability P. In this approach the number of words to sample from are selected according to the context, in opposition to *top-k sampling* (Fan et al., 2018), which samples from the k most probable words. However, the "sparsity" introduced by both methods is artificially imposed at run time, not learned during training.

A second problem is that it is hard to compare different truncation strategies—for example, we cannot easily evaluate how the resulting truncated distributions behave as language models, since the most widely used metric for language modeling—perplexity—cannot handle sparse distributions: if a model assigns zero probability to a single reference word, it gets infinite perplexity for the entire sample. For this reason, previous works generate from a *truncated* softmax, but report the perplexity of the *full* softmax distribution (Welleck et al., 2020; Li et al., 2020). Others use the latter to compare perplexity on the generated text with that on human text (Holtzman et al., 2020, §4.2), or resort to distributional statistics (Zhu et al., 2018).

In this paper, we propose a new approach—**entmax sampling** (§3)—that eliminates the mismatch between training and test conditions. Key to our approach is the recently proposed entmax transformation (Peters et al., 2019). Entmax transforms a vector of scores into a **sparse probability distribution**, preventing implausible words from receiving *any* probability mass. Moreover, it does so **natively**: it comes with a well-defined loss function that allows it to learn its sparsity automatically from the data, during training. This results in a new stochastic text generator where the number of possible word types varies with the context (like nucleus sampling), but that generates by sampling directly from its output distribution (like softmax), and where the sparsity of this distribution is present during training (unlike any existing method).

As a second contribution, we propose **three new metrics** to support the evaluation of sparse language models (§4): ϵ-perplexity, sparsemax score, and Jensen-Shannon divergence. We show that these metrics are well supported theoretically and can be used to compare our method with various truncation and temperature techniques.

Experiments in language modeling, story completion, and dialogue generation (§5) show that entmax sampling generates more diverse text and fewer repetitions than nucleus and top-k sampling.[1]

1.1 Related work

Decoding methods. While greedy decoding and beam search are popular strategies for sequence-to-sequence tasks, such as machine translation, Knowles et al. (2016) and Stahlberg and Byrne (2019) showed that searching for the most probable sentence in a model trained with likelihood maximization has a bias for short sentences. In open-ended generation, Fan et al. (2018) and Holtzman et al. (2018, 2020) have shown that these methods lead to repetitions and dull text. To overcome this, several authors proposed beam search variants which promote word diversity (Li et al., 2016b; Vijayakumar et al., 2018; Kulikov et al., 2018). An alternative to deterministic text generation is to sample directly from the softmax distribution. However, since the probability mass tends to accumulate in a long tail, this procedure generates unlikely words too often, leading to degenerate text (Fan et al., 2018; Holtzman et al., 2020). This can be mitigated by lowering the softmax temperature (Ficler and Goldberg, 2017), by sampling from the top-k most probable words only (Fan et al., 2018; Radford et al., 2019), or through nucleus sampling (Holtzman et al., 2020). We compare against these methods in §5.

Diversity-promoting models. In addition to new decoding methods, models that aim to increase word diversity and diminish repetition have also been introduced. Xu et al. (2018) proposed a diversity-promoting generative adversarial network, which rewards novel and fluent text. Holtzman et al. (2018) proposed augmenting the language model with several discriminators. More recently, Welleck et al. (2020) proposed augmenting the loss with an unlikelihood term that penalizes the generation of tokens that are present in the context, a method against which we compare in §5.

Sparse transformations and losses. At the core of our work are sparse alternatives to the softmax transformation. Martins and Astudillo (2016) proposed sparsemax and applied it to multi-label classification. This was generalized by Peters et al.

---

[1] The code used for the experiments and for the proposed metrics is available at `https://github.com/deep-spin/sparse_text_generation`.

(2019) via their α-entmax transformation, which was applied to sequence-to-sequence models for morphological inflection and machine translation. In contrast to our work, they performed *deterministic* decoding with beam search, and they did not consider open-ended generation.

Evaluation metrics. The most common metrics to evaluate text generation models are perplexity (Jelinek et al., 1977) and BLEU (Papineni et al., 2002). For open-ended generation, Zhu et al. (2018) observed that "no single metric is comprehensive enough". Other evaluations include corpus n-gram overlap (Yu et al., 2017; Press et al., 2017), and the Fréchet distance (Cífka et al., 2018). These approaches are aimed at the (harder) problem of evaluating the quality of generated text. By contrast, our paper proposes new metrics for evaluating *language models* in the task of predicting the next word conditioned on ground truth context (like perplexity does), but supporting sparse probability distributions (which perplexity does not).

2 Language Modeling

Language models assign probability to word sequences $x = \langle \text{START}, x_1, \ldots, x_T, \text{STOP} \rangle$, where each x_t is in a vocabulary $\mathcal{V}$, and $T \in \mathbb{N}$. This probability can be written as $p_\theta(x) = \prod_{t=1}^{T+1} p_\theta(x_t \mid x_{<t})$. We would like the model θ to assign high probability to real sentences, i.e., each distribution $p_\theta(\cdot \mid x_{<t})$ should assign a large probability value to the ground truth x_t.

Given a set $\mathcal{S}$ of training sentences, the usual strategy for learning the language model parameters θ is to minimize the negative log-likelihood:

$$\mathcal{L}(\theta) = -\sum_{i=1}^{|\mathcal{S}|} \sum_{t=1}^{T_i} \log p_\theta(x_t^i | x_{<t}^i). \qquad (1)$$

The standard choice to model $p_\theta(\cdot|x_{<t})$ in Eq. 1 is to compute a score vector $\boldsymbol{z}_t$ by conditioning on the context $x_{<t}$, and then applying a softmax transformation, $p_\theta(\cdot|x_{<t}) = \mathsf{softmax}(\boldsymbol{z}_t)$, where

$$[\mathsf{softmax}(\boldsymbol{z}_t)]_k = \frac{\exp(z_{tk})}{\sum_j \exp(z_{tj})}. \qquad (2)$$

At decoding time, the language model generates sentences one word at a time, by sampling from the learned probability distribution. However, softmax yields a **dense** distribution, *i.e.*, some probability mass (even if small) is assigned to all the words in the vocabulary. Holtzman et al. (2020, §3) have shown that, if we sample from this distribution directly, the resulting text becomes degenerate, with common incoherences arising due to the unreliability of the tail of the distribution. This motivated a line of work proposing "ad-hoc" modifications to the softmax distribution, to reduce the effect of the tail. Two of the most successful techniques, top-k and nucleus sampling (Fan et al., 2018; Holtzman et al., 2020), do so by truncating and renormalizing the distribution $p_\theta(\cdot|x_{<t})$. Note that these techniques are applied only at decoding time—during training the original softmax distribution is left untouched, being used as part of the optimization of the cross-entropy loss.

Our alternative to these ad-hoc modifications builds on *learnable* sparse transformations, as we shall see in §3. These transformations can produce sparse, zero-tailed probability distributions, learning the amount of sparsity from data. Therefore, sampling from these distributions directly is a natural way to prevent degenerate text.

3 Entmax Sampling

Key to our method is the recently proposed α-entmax family of transformations[2] (Peters et al., 2019), parametrized by a scalar parameter $\alpha \geq 1$:

$$\alpha\text{-}\mathsf{entmax}(\boldsymbol{z}_t) := \underset{\boldsymbol{p} \in \triangle^d}{\mathsf{argmax}}\, \boldsymbol{p}^\top \boldsymbol{z}_t + \mathsf{H}_\alpha(\boldsymbol{p}). \qquad (3)$$

Above, $\triangle^d := \left\{ \boldsymbol{p} \in \mathbb{R}^d \mid \sum_{i=1}^d p_i = 1, \boldsymbol{p} \geq \boldsymbol{0} \right\}$ is the probability simplex, and H_α is the Tsallis α-entropy (Tsallis, 1988):

$$\mathsf{H}_\alpha(\boldsymbol{p}) := \begin{cases} \frac{1}{\alpha(\alpha-1)} \sum_j (p_j - p_j^\alpha), & \alpha \neq 1 \\ -\sum_j p_j \log p_j, & \alpha = 1. \end{cases} \qquad (4)$$

With $\alpha = 1$ and $\alpha = 2$, we recover the Shannon and Gini entropies, respectively.[3] When $\alpha \to \infty$, $\mathsf{H}_\alpha(\boldsymbol{p}) \to 0$. Thus, 1-entmax, 2-entmax, and ∞-entmax recover softmax, sparsemax, and argmax, respectively. Blondel et al. (2019) have shown that, for $\alpha > 1$, entmax is able to output **sparse** probability distributions, where some words get **exactly** zero probability, whereas softmax ($\alpha = 1$) does not have this capability.

How can we learn this output sparsity during training? Following Peters et al. (2019), we replace the negative log-likelihood loss in Eq. 1 by

---

[2] `https://github.com/deep-spin/entmax`.

[3] The Gini entropy is $\mathsf{H}_2(\boldsymbol{p}) := \frac{1}{2} \sum_j p_j(1 - p_j)$.

$$\mathcal{L}(\theta) = \sum_{i=1}^{|\mathcal{S}|} \sum_{t=1}^{T_i} \ell_\alpha(\boldsymbol{z}_t(\theta, x_{<t}), x_t), \quad (5)$$

where $\ell_\alpha(\boldsymbol{z}_t, x)$ is the **α-entmax loss**:

$$\ell_\alpha(\boldsymbol{z}_t, x) := (\boldsymbol{p}_\theta - \boldsymbol{e}_x)^\top \boldsymbol{z}_t + \mathsf{H}_\alpha(\boldsymbol{p}_\theta), \quad (6)$$

where $\boldsymbol{p}_\theta = \alpha\text{-entmax}(\boldsymbol{z}_t)$, and $\boldsymbol{e}_x$ is the one-hot vector corresponding to the ground truth word x. When $\alpha = 1$, we still recover the negative log-likelihood, $\ell_\alpha(\boldsymbol{z}_t, x) = -\log p_\theta(x)$, and, when $\alpha = 2$, this corresponds to the **sparsemax loss** (Martins and Astudillo, 2016), to be revisited in §4.

Entmax losses belong to the wider class of Fenchel-Young losses (Blondel et al., 2019) and, consequently, are convex on $\boldsymbol{z}$ and differentiable (with gradient $\nabla_{\boldsymbol{z}} \ell_\alpha(\boldsymbol{z}, x) = -\boldsymbol{e}_x + \boldsymbol{p}_\theta$). For $\alpha > 1$, they have a **separation margin**: the loss is zero iff $z_{tx} \geq z_{tx'} + \frac{1}{\alpha-1}$ for all $x' \neq x$, in which case $\boldsymbol{p}_\theta = \boldsymbol{e}_x$, i.e., the model puts all its probability mass in the correct word. This allows the model to be adaptive to the degree of uncertainty present: in some cases there are few plausible words, so most words should have probability zero, while in other cases a higher number of words are plausible and should be given probability mass.

Entmax sampling. At test time, we simply sample from the categorical distribution obtained by applying the entmax transformation to the scores $\boldsymbol{z}_t$ given by the model:

$$x_t \sim p_\theta(\cdot \mid x_{<t}) = \alpha\text{-entmax}(\boldsymbol{z}_t(\theta, x_{<t})). \quad (7)$$

Note that, in contrast to previously proposed methods such as top-k sampling and nucleus sampling (Holtzman et al., 2020), we sample directly from the learned sparse probability distribution over the words, without any calibration or ad-hoc modification. As in nucleus sampling and in opposition to top-k sampling, entmax sampling considers a varying number of tokens depending on the context. Moreover, as we show in Table 4, with entmax sampling this variability is higher.

4 Evaluation Metrics

Language models are commonly evaluated by computing their perplexity (ppl) on held-out data. Perplexity assesses the ability of a language model to predict the next word given the context:

$$\mathsf{ppl} = \exp\left(-\frac{1}{T}\sum_{t=1}^{T} \log p_\theta(x_t \mid x_{<t})\right). \quad (8)$$

However, its computation involves the logarithm of a probability. This poses a problem when we are using sparse or truncated probability distributions, since $\lim_{p\to 0} \log p = -\infty$. Usually, authors report the values for perplexity computed on the original probability distribution, before truncation. However, this metric does not allow different sparse decoding strategies to be compared.[4] As an alternative, we propose three different metrics (to better understand these metrics, comparative plots are shown in Fig. 2, App. E).

ϵ-perplexity. To be able to compute the perplexity for sparse distributions, the simplest approach is to smooth it by adding a small value ϵ to all terms followed by renormalization, as in additive (Laplace) smoothing (Chen and Goodman, 1999):

$$\epsilon\text{-}\mathsf{ppl} = \exp\left(-\frac{1}{T}\sum_{t=1}^{T} \log \frac{p_\theta(x_t \mid x_{<t}) + \epsilon}{1 + \epsilon|\mathcal{V}|}\right). \quad (9)$$

Note that, like perplexity, ϵ-ppl only depends on θ via the probabilities assigned to the reference words. When used as a metric for a language model, we may regard ϵ as a calibration parameter that the language model is allowed to tune to better match the reference. We show in App. A that the optimal value of ϵ (i.e., the one that leads to the smallest ϵ-ppl) can be obtained from these probabilities by solving a simple convex optimization problem—this is convenient, since it avoids the need for manual tuning. A disadvantage of ϵ-ppl is that it still does not evaluate the original sparse distribution, but rather a modified version of it. However, when applied to variants of truncated softmax, by collapsing all the truncated probabilities to the same value ϵ, it is useful to measure how much truncation deteriorates its ability to rank words, compared to softmax.

Sparsemax score. We can derive a more interesting metric that handles sparse distributions directly. By setting $\alpha = 2$ in Eq. 6, [5] we obtain the sparsemax loss proposed by Martins and Astudillo (2016), $\ell_2(\boldsymbol{z}, x) = (\boldsymbol{p}_\theta - \boldsymbol{e}_x)^\top \boldsymbol{z} + \mathsf{H}_2(\boldsymbol{p}_\theta)$. We define the

---

[4] This is important not only when we have sparse or truncated probability distributions, but also to compare language models using different vocabularies: when using perplexity, if the ground truth word is not contained in the vocabulary, one usually considers the probability attributed to an UNK token instead of a zero probability, which leads to an unfair comparison between models with different vocabularies.

[5] If we set $\alpha = 1$ instead, we revert to perplexity.

sparsemax score (sp) as:

$$\begin{aligned} \mathsf{sp} &= 1 - \min\{\ell_2(\boldsymbol{z}, x) \mid \mathsf{sparsemax}(\boldsymbol{z}) = \boldsymbol{p}_\theta\} \\ &= 1 - (\boldsymbol{p}_\theta - \boldsymbol{e}_x)^\top \boldsymbol{p}_\theta - \mathsf{H}_2(\boldsymbol{p}_\theta) \\ &= p_\theta(x) + \mathsf{H}_2(\boldsymbol{p}_\theta), \end{aligned} \tag{10}$$

where H_2 is the Gini entropy (see footnote 3). Unlike perplexity, this score is bounded. In fact, it is always between 0 (when $\boldsymbol{p}_\theta = \boldsymbol{e}_{x'}$ with $x' \neq x$) and 1 (when $\boldsymbol{p}_\theta = \boldsymbol{e}_x$). We prove this fact in App. B. Interestingly, when the model $\boldsymbol{p}_\theta$ is deterministic (e.g., when it comes from greedy search), we have $\mathsf{H}_2(\boldsymbol{p}) = 0$, and the sparsemax score simply becomes the **word accuracy**. In the opposite case, when $\boldsymbol{p}_\theta$ is uniform, we obtain $\mathsf{sp} = \frac{1}{|\mathcal{V}|} + \frac{1}{2}\left(1 - \frac{1}{|\mathcal{V}|}\right) \to 0.5$ when $|\mathcal{V}| \to \infty$.

We show in App. C that this score is related to the Patrick-Fischer distance (Patrick and Fischer, 1969; Deza and Deza, 2009, p. 262).

Jensen-Shannon Divergence. Given two discrete probability distributions $\boldsymbol{p}_\theta$ and $\boldsymbol{q}$, and denoting their mixture (arithmetic mean) as $\boldsymbol{m} := \frac{\boldsymbol{p}_\theta + \boldsymbol{q}}{2}$, and the Kullback-Leibler divergence as KL, the Jensen-Shannon divergence is defined as:

$$\begin{aligned} \mathsf{JS}(\boldsymbol{p}_\theta, \boldsymbol{q}) &= \frac{1}{2}\,\mathsf{KL}(\boldsymbol{p}_\theta \| \boldsymbol{m}) + \frac{1}{2}\,\mathsf{KL}(\boldsymbol{q} \| \boldsymbol{m}) \\ &= \frac{1}{2}\sum_{x \in \mathcal{V}} p_\theta(x) \log\left(\frac{p_\theta(x)}{m(x)}\right) \\ &+ \frac{1}{2}\sum_{x \in \mathcal{V}} q(x) \log\left(\frac{q(x)}{m(x)}\right). \end{aligned} \tag{11}$$

The Jensen-Shannon divergence can be interpreted as a mutual information as follows (Grosse et al., 2002; Banerjee et al., 2005): consider a two-step process where we first toss a fair coin $B \sim \text{Bernoulli}(\frac{1}{2})$. If the outcome is heads, we sample the next word X according to the model $p_\theta(\cdot)$; if it is tails, we sample $x \sim q(\cdot)$. A word generated according to this process is governed by the mixture $m(\cdot)$, $x \sim m(\cdot)$. The Jensen-Shannon divergence between $\boldsymbol{p}_\theta$ and $\boldsymbol{q}$ is the mutual information between the random variables B and X, which equals $\mathsf{H}(B) - \mathsf{H}(B \mid X)$, where H is the Shannon entropy and $\mathsf{H}(B \mid X) = \sum_{x \in \mathcal{V}} m(x) H(B \mid X = x)$ is the conditional entropy. Hence, the Jensen-Shannon divergence can be seen as the reduction of uncertainty about the source B when we observe a sample x from the mixture $m(\cdot)$. The more similar the two distributions $\boldsymbol{p}_\theta$ and $\boldsymbol{q}$ are, the smaller this reduction is.

In our experiments, we report the JS as an evaluation metric for language models, setting $\boldsymbol{q} = \boldsymbol{e}_x$ (i.e., a one-hot distribution placed on the ground truth word x) and averaging the JS over the words. Like the sparsemax score described above, the JS is bounded: it is zero if $\boldsymbol{p}_\theta = \boldsymbol{e}_x$, and maximal ($\log(2)$) when $\boldsymbol{p}_\theta$ is a one-hot distribution placed on a different word. We show in App. D that, like ϵ-ppl (but unlike sp), the JS only depends on θ via the probabilities assigned to the reference words.

Comparing multiple models. The generalized JS allows to compare two or more trained models:

$$\mathsf{JS}(\boldsymbol{p}^1, \ldots, \boldsymbol{p}^K) = \frac{1}{K}\sum_{k=1}^{K} \mathsf{KL}(\boldsymbol{p}^k \| \boldsymbol{m}) \tag{12}$$

where $\boldsymbol{p}^1, \ldots, \boldsymbol{p}^K$ are the probability distributions of the different models and $\boldsymbol{m} = \frac{1}{K}\sum_{k=1}^{K} \boldsymbol{p}^k$ is their mixture. This property can be useful for measuring the diversity between multiple models (e.g., when used in an ensemble system). We use this metric in App. I to rank the sentences in which the different models we compare disagree the most.

5 Experiments

We compare the different methods in three NLP tasks: language modeling (§5.1), story completion (§5.2), and dialogue generation (§5.3). In language modeling, we evaluate the model's fluency, while in story completion we also evaluate if the methods generate coherent and "interesting" text. In dialogue generation, we evaluate the methods' performance in an interactive task.

5.1 Language Modeling

Datasets and metrics. We performed experiments on three widely used language modeling datasets: WikiText-2 and WikiText-103 (Merity et al., 2016), and BookCorpus (Zhu et al., 2015). WikiText-2 and WikiText-103 are composed of Wikipedia articles, comprising around 2 and 100 million tokens for training, respectively. Their validation and test sets have 217,000 and 245,000 tokens. BookCorpus is composed of 11,038 freely available books. We used the standard split: 800 million tokens for training, 260,000 for validation, and 280,000 for testing.

We report the sparsemax score, Jensen-Shannon, and ϵ-perplexity (§4) to evaluate the methods' fluency, and the REP and WREP[6] (Welleck et al., 2020)

---

[6] REP measures the number of times that a word from the

to evaluate the methods' tendency to generate repetitions. All metrics are computed at the BPE level (Sennrich et al., 2016).

Fine-tuning GPT-2. We fine-tuned the GPT-2 medium model (Radford et al., 2019), which consists of a 24 layer transformer with 345 million parameters.[7] We fine-tuned three models with the following losses: negative log-likelihood (used for softmax, greedy, top-k, and nucleus sampling), unlikelihood training (Welleck et al., 2020), and entmax loss. For the unlikelihood training objective we replicated the authors' experiments. However, due to GPU memory constraints we had to reduce the context size from 512 to 256. The hyperparameters were chosen based on a grid search over $\alpha \in \{1.1, 1.2, 1.3, 1.5\}$ for entmax sampling, $k \in \{5, 10, 20, 50, 100\}$ for top-k sampling, $P \in \{0.5, 0.8, 0.85, 0.9, 0.95, 0.97\}$ for nucleus sampling, and $\tau \in \{0.7, 0.8, 0.9, 0.95, 0.97\}$ for softmax with decreased temperature. The selected hyperparameters are reported in Table 3. We report the results obtained on the validation sets of WikiText-2, WikiText-103, and BookCorpus on Table 10. Additional settings and the computational infrastructure are described in App. F.

	WikiText-2	WikiText-103	BookCorpus
α	1.2	1.2	1.3
k	50	50	20
P	0.95	0.95	0.90
τ	0.95	0.95	0.90

Table 4: Mean, median, standard deviation, minimum, and maximum number of tokens considered by each decoding method on the Wikitext-103 test set.

Results. Table 2 shows the results. We observe that entmax sampling achieves consistently better sparsemax scores and number of repetitions. It also leads to better ϵ-perplexity scores than all other methods except plain softmax, which attains similar scores (entmax is slightly better for 2 out of 3 datasets). The JS score appears to favor extremely sparse decoders, with greedy decoding achieving the best scores (but at the expense of many repetitions).[8]

To help understand why entmax leads to better sparsemax scores and fewer repetitions, Table 4 shows the mean, median, standard deviation, minimum, and maximum number of tokens each decoding strategy considers when predicting each word, on the Wikitext-103 test set. We see that entmax sampling and nucleus sampling consider a lot more tokens than greedy decoding and top-k sampling, which may be the reason for the smaller number of repetitions. A possible explanation for entmax sampling outperforming nucleus sampling is its higher standard deviation, suggesting that its

---

previous l words is repeated, when generating the following word. WREP does the same, discarding words that are also repeated in the ground truth. We report the average of REP and WREP for $l \in \{16, 32, 128, 512\}$.

[7] We use the PyTorch re-implementation at `https://github.com/huggingface/transformers`.

Table 5: Language modeling ablation study on WikiText-103 test set.

sparsity range is more adaptive to the context.

Ablation study. In order to understand whether the improved performance is caused by the mitigation of the sparsity mismatch between training and test times, we experimented (i) decoding with the entmax sampling method from a language model fine-tuned with negative log-likelihood, and (ii) decoding with top-k sampling and nucleus sampling from a model fine-tuned with the entmax loss. We conducted these experiments on the WikiText-103 dataset.

As shown in Table 5, our proposed approach, which decodes with entmax sampling from a model also fine-tuned with the entmax loss, is the one which leads to the best scores, as we see a considerable degradation when entmax is only used at training or at decoding time. This corroborates our hypothesis that the improved results come from eliminating the mismatch between training and decoding.

5.2 Story completion

Next, we analyze the model's ability to generate long sequences of text using different sampling methods.[9] We performed completion of stories from the WritingPrompts dataset (Fan et al., 2018), using the models fine-tuned on BookCorpus. WritingPrompts is a collection of human-written stories paired with writing prompts. We randomly selected 1,000 stories which were at least 200 words long and used the first 50 words as context for the models. Examples of stories generated with each method (Table 1 and Table 13 of App. K) suggest that entmax sampling leads to more engaging stories while preventing degenerate text. To measure

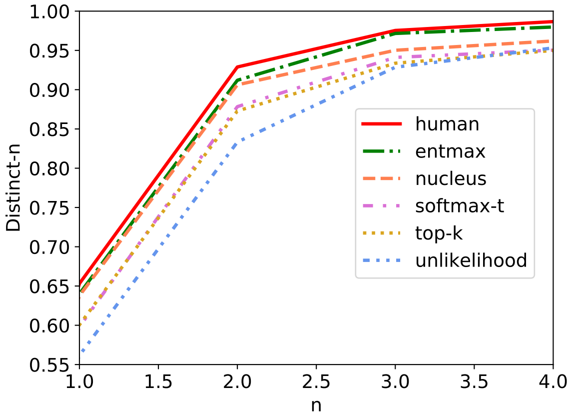

Figure 1: Plot of the distinct-n metric for each sampling method on story completion, with $n = \{1, 2, 3, 4\}$. The distinct-n results for greedy decoding are not shown since they are very small (0.25 for distinct-4).

the stories' word diversity, we show in Figure 1 the distinct-n metric[10] (Li et al., 2016a) for the stories generated by each model. It can be seen that entmax sampling leads to more diverse unique n-grams for $n \in \{1, 2, 3, 4\}$, closer to human generated text. We also measured the number of unique words in the stories generated: entmax sampling generated 14,702 different words, while softmax with decreased temperature, greedy decoding, top-k, nucleus sampling, and unlikelihood generated 12,447, 1,750, 11,803, 12,008, and 5,509 words, respectively. As expected, entmax leads to higher word diversity on par with human stories, which contain 15,377 different words.

Human evaluation. We performed human evaluation of greedy decoding, unlikelihood training, top-k, nucleus, and entmax sampling on completion of stories from the WritingPrompts datasets. We randomly selected 100 stories to perform the human evaluation. For each story, 5 judges from Amazon Mechanical Turk evaluated the story completions in 3 metrics: fluency (whether the text is syntactically and semantically correct), coherence (whether the story continuation is related to the provided context and is consistent), and engagement (whether the annotator felt interested in the story). Ratings were given on a 5-point Likert scale, and the mean for each metric is reported in Table 6. Further details, including a screenshot of the annotator interface, are described in App. G. We observe that entmax sampling outperforms all other methods on

---

[9] Softmax sampling is not considered since it has been shown to generate degenerate text (Holtzman et al., 2020).

[10] Distinct-n corresponds to the number of distinct n-grams divided by the total number of generated words.

	Fluency	Coherence	Engagement
Greedy	2.5	2.3	2.3
top-k	3.3	2.9	2.9
Nucleus	**3.5**	3.1	3.2
Unlikelihood	3.3	3.0	3.2
Entmax	**3.5**	**3.2**	**3.6**

Table 6: Human evaluation of story completion. All scores marked in bold at each column outperform the others with statistical significance, according to the Wilcoxon's test with p-value < 0.01. The inter-annotator agreement (Fleiss Kappa) is 0.45 for fluency, 0.41 for coherence, and 0.63 for engagement.

coherence and engagement, having similar scores as nucleus sampling on fluency.

5.3 Dialogue Generation

To evaluate the sampling methods in an interactive setting, we experiment with dialogue generation. Its goal is to generate an utterance, given a context consisting of the previous utterances in the dialogue and, in some cases, initial context sentences with related information that can be describing personas, knowledge, or scenarios.

Datasets and metrics. We performed experiments with the PersonaChat dataset (Zhang et al., 2018). It is a crowd-sourced dialogue dataset in which speakers were asked to condition their utterances on predefined personas. It contains 164,356 utterances over 10,981 dialogues. As there is no public test set, we report results on the validation set. We evaluate the word F_1-score, ϵ-perplexity, sparsemax score, and Jensen-Shannon divergence. As for the language modeling experiments, ϵ-perplexity, sparsemax score, and Jensen-Shannon are computed at the BPE level. We also report distinct-n metric for $n = \{1, 2\}$ and analyze how the models behave in dialogue simulations between two agents (Li et al., 2016c).

Fine-tuning GPT-2. In order to apply GPT-2 medium to the dialogue generation task, we follow Wolf et al. (2019) and Budzianowski and Vulić (2019): the input given to the language model consists of the sentences describing the persona the model should impersonate, and the history utterances. In order for the model to adapt to dialogue, the word and position embeddings are augmented with dialogue-state embeddings that indicate whether tokens are from a persona sentence, speaker 1, or speaker 2. These embeddings are learned during fine-tuning. The hyperparameters α, k, P, and τ were chosen with a grid search over the sets of values $\alpha \in \{1.2, 1.3, 1.5, 2\}$, $k \in \{5, 10, 20, 50, 100\}$, $P \in \{0.5, 0.8, 0.85, 0.9, 0.95\}$, and $\tau \in \{0.7, 0.8, 0.9, 0.95\}$, using the sparsemax score. The values chosen are 1.5, 10, 0.9, and 0.8, respectively. Additional settings are described in App. H.

	sp	JS	ϵ-ppl	F_1	dist-1	dist-2
Softmax	0.636	0.412	17.21	14.21	0.4325	0.8422
Softmax-τ	0.621	**0.393**	17.18	16.31	0.4312	0.8289
Greedy	0.422	0.401	1031.79	**21.79**	0.4305	0.7958
Top-k	0.626	**0.393**	47.79	17.34	0.4378	0.8344
Nucleus	0.632	0.399	26.98	15.98	0.4334	0.8436
Entmax	**0.642**	**0.393**	**17.10**	15.02	**0.4532**	**0.8494**

Table 7: Automatic evaluation of dialogue generation on the Persona-Chat validation set.

Automatic metrics results. We report the results in Table 7. Entmax again outperforms all the other methods in sparsemax score and ϵ-perplexity. It also has the lowest JS (same as top-k and softmax-τ). Entmax also leads to fewer repetitions, having higher distinct-1 and distinct-2 scores. However, its F_1 score is lower (similar findings have been reported in Li et al. (2020)). This can be due to dialogue generation being an open-ended generation task that can have multiple correct answers.

Additionally, we simulated a conversation between two agents of the same model (Li et al., 2016c). We chose different personas randomly for the two agents. Then a first utterance from the PersonaChat dataset was given as context. Some conversation examples are presented in Tables 14-17 of App. L. We measured the average length of conversations, considering that the conversation is finished when utterances overlap 80% or more, when there is no response by an agent, or when it reaches 20 utterances (similar procedure as Li et al. (2016c)). We also measured the number of unique words, and the distinct-n metric for $n = \{1, 2\}$. As shown in Table 8, entmax sampling leads to longer conversations with higher word diversity and higher number of distinct 1-grams and 2-grams.

Human evaluation. Finally, we performed human evaluation following the ConvAI2 challenge: 12 volunteers had 30 conversations each with models using the different sampling methods. The vol-

	LENGTH	UNIQUE WORDS	DIST-1	DIST-2

	FLUENCY	CONSISTENCY	ENGAGEMENT
Greedy	**4.1**	3.0	2.5
Top-k	**4.0**	3.2	3.3
Nucleus	**4.1**	3.4	3.3
Entmax	**4.1**	**3.6**	**3.9**

Table 9: Human evaluation of dialogue generation. All scores marked in bold at each column outperform the non-bold ones with statistical significance, according to the Wilcoxon's test with p-value < 0.01.

unteers scored the conversations from 1 to 5 in terms of fluency, consistency (whether the model's utterances are coherent with their persona and the model does not contradict itself), and engagement. The model's personas were randomly selected from the PersonaChat validation set. Results are reported in Table 9. Entmax sampling outperforms the other methods in consistency and engagement, having similar scores in fluency. This means entmax sampling does not only generate the most interesting conversation utterances, but it also leads to an improvement of the conversation consistency.

6 Conclusions

We proposed entmax sampling as a new strategy for generating text from a sparse probability distribution. It provides three main advantages: (i) it offers a natural way of sampling directly from the output probability distribution; (ii) the distribution sparsity is modeled during training, avoiding a sparsity mismatch between training and run time; (iii) when sampling with entmax, the number of words to be considered varies with the context, as in nucleus sampling and in contrast to top-k sampling. Additionally, we proposed new metrics for evaluating language models that produce sparse and truncated probability distributions: ϵ-perplexity, sparsemax score, and Jensen-Shannon divergence.

Experiments show that entmax sampling leads to higher n-gram diversity, fewer repetitions, and similar or improved results in automatic metrics. Human evaluation confirms that entmax outperforms greedy decoding, top-k, and nucleus sampling in coherence/consistency and engagement, and is similar or better in terms of fluency.

Supplementary Material

A Selection of the optimal ϵ for the ϵ-perplexity

We show here that the optimal ϵ for the computation of the ϵ-perplexity for each decoding method can be easily obtained by solving a convex optimization problem.

For a given ϵ, which can be reparametrized as $\lambda = \frac{\epsilon|\mathcal{V}|}{1+\epsilon|\mathcal{V}|} = \frac{1}{1+(\epsilon|\mathcal{V}|)^{-1}} \in [0,1]$, the average negative log-likelihood on a validation set is:

$$\begin{aligned} F(\lambda) &= -\frac{1}{T}\sum_{t=1}^{T} \log\left((1-\lambda)p_\theta(x_t) + \frac{\lambda}{|\mathcal{V}|}\right) \\ &= -\frac{1}{T}\sum_{t=1}^{T} \log(a_t\lambda + b_t), \end{aligned} \tag{13}$$

where $a_t = |\mathcal{V}|^{-1} - p_\theta(x_t)$ and $b_t = p_\theta(x_t)$. The function F is the composition of a convex function with an affine function, hence it is convex. Therefore it has a global minimum. Its derivative is:

$$F'(\lambda) = -\frac{1}{T}\sum_{t=1}^{T} \frac{a_t}{a_t\lambda + b_t}. \tag{14}$$

Since we constrain $\lambda \in [0,1]$, we can obtain the optimal λ by initializing with $\lambda = 0.5$ and iterating the following projected gradient rule:

$$\lambda \leftarrow \max\{0, \min\{1, \lambda - \eta F'(\lambda)\}\}. \tag{15}$$

where η is a stepsize. Since $\lambda = \frac{1}{1+(\epsilon|\mathcal{V}|)^{-1}}$, we can invert this equation to obtain the optimal ϵ as $\epsilon = \frac{1}{|\mathcal{V}|(\lambda^{-1}-1)} = \frac{\lambda}{|\mathcal{V}|(1-\lambda)}$.

B Proof of boundedness of the sparsemax score

We show here that the sparsemax score in Eq. 10 is always bounded between 0 and 1.

The fact that $\mathsf{sp} \leq 1$ simply follows from the fact (Blondel et al., 2019, Prop. 2) that any Fenchel-Young loss (which includes $\ell_2(\boldsymbol{z}, x)$) is non-negative. Since $\mathsf{sp} = 1 - \min\{\ell_2(\boldsymbol{z}, x) \mid \mathsf{sparsemax}(\boldsymbol{z}) = \boldsymbol{p}_\theta\}$, it follows that $\mathsf{sp} \leq 1$. Let us see when the maximal value 1 is attained. We have:

$$\begin{aligned} \mathsf{sp} &= p_\theta(x) + \mathsf{H}_2(\boldsymbol{p}_\theta) \\ &= p_\theta(x) + \frac{1}{2}(1 - \|\boldsymbol{p}_\theta\|^2) \\ &= -\frac{1}{2}p_\theta(x)^2 + p_\theta(x) - \frac{1}{2}\sum_{x' \neq x} p_\theta(x')^2 + \frac{1}{2} \\ &= -\frac{1}{2}(p_\theta(x) - 1)^2 - \frac{1}{2}\sum_{x' \neq x} p_\theta(x')^2 + 1. \end{aligned} \tag{16}$$

Since the Gini entropy is maximized by the uniform distribution, the maximum distribution in Eq. 16 is of the form $\boldsymbol{p}_\theta = \left(1-t, \frac{t}{|\mathcal{V}|-1}, \ldots, \frac{t}{|\mathcal{V}|-1}\right)$ for $t \in [0,1]$. Replacing in Eq. 16, we obtain

$$\begin{aligned} \mathsf{sp} &= -\frac{1}{2}t^2 - \frac{1}{2}\frac{t^2}{|\mathcal{V}|-1} + 1 \\ &= 1 - \frac{t^2}{2}\left(1 + \frac{1}{|\mathcal{V}|-1}\right). \end{aligned} \tag{17}$$

This is maximized by $t = 0$, which corresponds to $\boldsymbol{p}_\theta = \boldsymbol{e}_x$.

To see that we always have $\mathsf{sp} \geq 0$, we use the fact that the Gini entropy $\mathsf{H}_2(\boldsymbol{p}_\theta)$ is always non-negative (zero if and only if $\boldsymbol{p}_\theta$ is a one-hot distribution), which is clear from the definition in footnote 3, and that $p(x) \geq 0$; therefore, the sum of these two terms is also non-negative, and zero if and only if $\boldsymbol{p}_\theta = \boldsymbol{e}'_x$ with $x' \neq x$.

C Relation between Patrick-Fischer distance and sparsemax score

We show here that the sparsemax score is equivalent to one minus the one half of the squared Patrick-Fisher distance between the distribution probability over the words $\boldsymbol{p}_\theta$ and the indicator one-hot vector $\boldsymbol{e}_x$ which corresponds to the ground truth word x.

The Patrick-Fischer distance between two distributions is $D_{\mathrm{PF}}(\boldsymbol{p}, \boldsymbol{q}) = \|\boldsymbol{p} - \boldsymbol{q}\|_2$. We have:

$$\begin{aligned}
& 1 - \frac{1}{2} D^2_{\mathrm{PF}}(\boldsymbol{p}_\theta, \boldsymbol{e}_x) \\
= \; & 1 - \frac{1}{2} \sum_{x'} (p_\theta(x') - e_x(x'))^2 \\
= \; & 1 - \frac{1}{2} \sum_{x' \neq x} p_\theta(x')^2 - \frac{1}{2}(1 - p_\theta(x))^2 \\
= \; & 1 - \frac{1}{2} \sum_{x'} p_\theta(x')^2 + \frac{1}{2} p_\theta(x)^2 - \frac{1}{2} \\
& - \frac{1}{2} p_\theta(x)^2 + p_\theta(x) \\
= \; & \frac{1}{2} - \frac{1}{2} \sum_{x'} p_\theta(x')^2 + p_\theta(x) \\
= \; & p_\theta(x) + \mathsf{H}_2(\boldsymbol{p}_\theta), \qquad (18)
\end{aligned}$$

which equals the sparsemax score defined in Eq. 10.

D JS divergence as a language model metric

The Jensen-Shannon divergence between the model probability distribution over the words $\boldsymbol{p}_\theta$ and the indicator one-hot vector $\boldsymbol{e}_x$ which corresponds to the ground truth word x can be defined as:

$$\begin{aligned}
& \mathsf{JS}(\boldsymbol{p}_\theta, \boldsymbol{e}_x) \\
= \; & \frac{1}{2} \mathsf{KL}\left(\boldsymbol{p}_\theta \| \frac{\boldsymbol{p}_\theta + \boldsymbol{e}_x}{2}\right) \\
= \; & \mathsf{H}\left(\frac{\boldsymbol{p}_\theta + \boldsymbol{e}_x}{2}\right) - \frac{1}{2}\mathsf{H}(\boldsymbol{p}_\theta) - \underbrace{\frac{1}{2}\mathsf{H}(\boldsymbol{e}_x)}_{=0} \\
= \; & - \sum_{x' \neq x} \frac{p_\theta(x')}{2} \log \frac{p_\theta(x')}{2} \\
& - \frac{1 + p_\theta(x)}{2} \log \frac{1 + p_\theta(x)}{2} \\
& + \frac{1}{2} \sum_{x'} p_\theta(x') \log p_\theta(x') \\
= \; & - \frac{1}{2} \log \frac{1}{2} + \frac{p_\theta(x)}{2} \log \frac{p_\theta(x)}{2} \\
& - \frac{1 + p_\theta(x)}{2} \log \frac{1 + p_\theta(x)}{2} \\
= \; & \mathsf{H}_b\left(\frac{1 + p_\theta(x)}{2}\right) - \frac{1}{2}\mathsf{H}_b(p_\theta(x)), \qquad (19)
\end{aligned}$$

where $\mathsf{H}_b(p) = -p \log p - (1-p)\log(1-p)$ denotes the entropy of a Bernoulli variable. Thus the JS divergence depends on the model distribution only through the probability given by the model to the groundthruth word, $p_\theta(x)$.

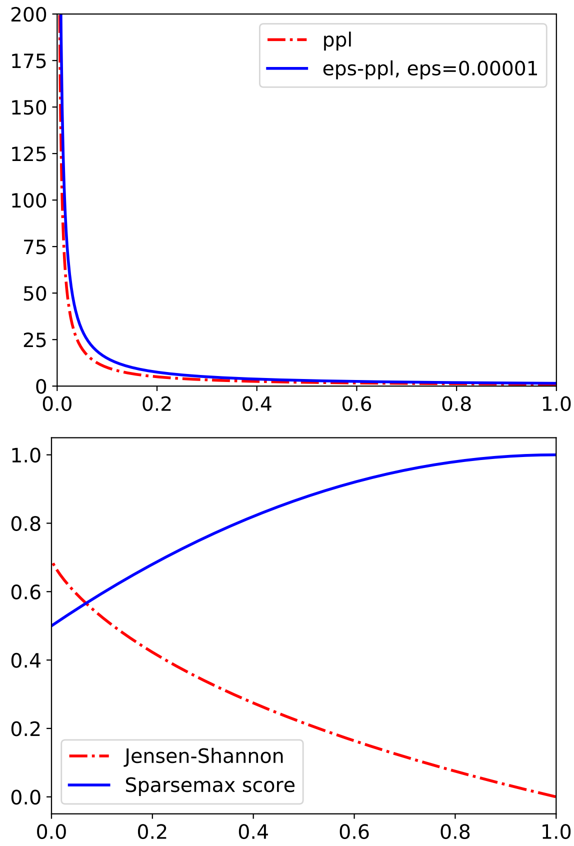

Figure 2: Comparative plots of ϵ-perplexity for $\epsilon = 0.01$ and $\epsilon = 0$ (top), and of sparsemax score and JS divergence (bottom). In both cases, the x-axis is $p_\theta(x)$.

E Comparative plots of evaluation metrics

Figure 2 shows comparative plots of the ϵ-perplexity, sparsemax score, and Jensen-Shannon divergence, for a distribution of the form $\boldsymbol{p}_\theta = \left(1 - t, \frac{t}{|\mathcal{V}|-1}, \ldots, \frac{t}{|\mathcal{V}|-1}\right)$, varying t, with a vocabulary of 50000 words.

F Fine-tuning details for language modeling

The models were fine-tuned for up to 5 epochs for Wikitext-2 and up to 1 for Wikitext-103 and BookCorpus using the Adam optimizer (Kingma and Ba, 2015), with a learning rate of 6.25×10^{-5}, which was linearly decayed to zero over the course of training. We report results of the models that have the highest sparsemax score on the validation set. The models fine-tuned with cross entropy and entmax losses were trained on a GPU Nvidia Titan XP, which has ≈ 12 Gb of memory. The model fine-tuned with the unlikelihood training term was trained on a GPU Nvidia Titan RTX, which has

$\approx$ 24 Gb of memory.

G Stories' human evaluation details

To perform the human evaluation of the stories generated by the different models, we use Amazon Mechanical Turk (a screenshot of the interface is shown in Figure 3), and compensate Turkers at a rate of $0.7 per HIT. Pay rate is calculated based on an estimate of the completion time (5.5 minutes) and an hourly wage of $7.5.

To remove poor quality annotations, we perform several controls. We did not consider annotations that were performed in less than 3.5 minutes. Additionally, following (Li et al., 2019), to filter low quality annotators we showed them annotated examples with contexts from famous novels, the real continuation, story continuations that are not related to the context, and story continuations that are not fluent. If the Turker's annotations differed significantly from the reference rank-wise, all annotations performed by the Turker were excluded.

H Fine-tuning details for dialogue generation

We fine-tune the GPT-2 medium model (Radford et al., 2019) for a maximum of 3 epochs with a learning rate of 6.25×10^{-5} that linearly decays to zero over the course of the training. The models were fine-tuned on a GPU Nvidia Titan XP, which has $\approx$ 12 Gb of memory.

I Comparison of models with the Jensen-Shannon divergence

We compared the distributions given by the different decoding methods when generating the sentences of the BookCorpus validation set with the Jensen-Shannon divergence, as described in §4. In Tables 11 and 12 we show some of the sentences with higher Jensen-Shannon divergence, as well as the probability given by each model to the ground truth word.

J Results of automatic metrics for various values of K,P, α.

In Figure 4 we report the results of ϵ-ppl, JS, sp, rep, and wrep metrics on the validation set of WikiText-103 for the models with top-k, nucleus, and entmax sampling with various values of K,P, α.

K Story completion examples

Examples of story completion with context from the WritingPrompts dataset using the different models fine-tuned on BookCorpus are presented in Table 13.

L Dialogue simulation examples

In order to evaluate the different decoding methods in dialogue generation, we simulated a conversation between two agents using the same decoding method. For that, we assigned each agent a randomly selected persona from the PersonaChat dataset and gave a first utterance of the dataset as context. Examples of dialogue simulations are presented in Tables 14-15 and Tables 16-17.

Context:	*"Where am I?" I asked. I stared at the screens, brushing past my field of vision. They went too fast to watch, but it was clear. I stood on a floating white platform, below me there were flames ...*
Greedy:	... . i could see the flames, but i couldn't see the man. i couldn't see the man who had been my father. i couldn't see the man who had been my father. i couldn't see the man who had been my father. i couldn't see the man who had been my father. i couldn't see the man who had been my father. i couldn't see the man who had been my father. i couldn't see the man who had been my father.
Top-k:	... and a large red door. they went faster and farther off, so close now you almost saw nothing through them as everything around you was just flames; you could taste a burnt smell and you were flying above yourself at speed you never seemed close compared when one thing was the sky or nature or a building full of air around it the sky being what the nature had to look like it had an energy about to burn.
Nucleus:	... and a third being. the creature had clawed its way through the sky, like a giant serpent, its head lifts and back-end leans, it had wings in front and they were on fire, blotched blue and green, emulating the lights in the air around it, like a creature through a screen. i recalled every detail of that moment of events, that once of its kind it had tried to eat me. now i could see the terror in that moment.
Unlikelihood	... and a black smoke. the smoke was rising from my hand, and i could see it was coming from my mouth, and it was the same thing that had killed the woman in the park. "i don't know how long i can live without you" i said, and we both knew that the next time we saw each other again, i was going to be a very different person. is the beginning of a new life a man who is the beginning the world
Entmax:	... and a demon. the room grew dimming with tiny figures visible as small shadows. we waited. i listened to the tingling below me. a faint noise. the darkness seemed to get thinner. i looked up at her. nothing met my eyes. the girl was familiar, but i couldn't get it. she shuddered. "no!" i yelled. her eyes snapped up to me. she screamed, "no, you are not ready!" she sprinted towards the door.
Context:	*The universe was collapsing in on itself , swallowing all that man had once nurtured and loved and explored . As the walls came crashing down and the void beyond it all came flooding in , a man at the center of it all sat serenely before a rift in ...*
Greedy:	... the universe, a man who had been a man for so long that he had forgotten what it was like to be a man. he was a man who had been a man for so long that he had forgotten what it was like to be a man. he was a man who had been a man for so long that he had forgotten what it was like to be a man. he was a man who had been a man for so long that he had forgotten what it was like to be a man.
Top-k:	... a river where time could be no closer, an age ago there stood the very center for an entire generation : that great hour upon timoria before its collapse. it may well also have been that at some early meeting among them the young men at least could give any possible threat a warning, for, one can not blame those boys on this side. they know too well where a great danger rests, or is waiting, somewhere
Nucleus:	... the fabric of light that was the void itself. consuming him whole it will fall. it will swallow us whole. kill us. die. and when it does then it will start over. the vast blackness continued to swallow sebastian, forcing him forward. he twisted, protesting the pain that gathered in his throat as his back was crushed against the solid blackness. he had been doing that all the way down.
Unlikelihood	... the fabric of time. it was the first time he had seen a real time machine, a machine with a purpose." "what was it?" the man who was the future is the beginning of a part whatever the end whatever all yours and whatever in the beginning the deadly end a deadly (and deadly deadly) all yours and the first time he had seen the future
Entmax:	... the fabric of space and time and whatever truth he had contained since childhood was now ripening to be broken further. the crushing sadness that seized him made him feel like he had just found a complete lack of reality. it was all like a nightmare. it was all a goddamned nightmare. he shook himself and felt his emotions grow equally furious with himself and the destruction.

Table 13: Examples of story completion using the different methods.

Context:	*hello how are you today?*
Softmax:	- i'm great i love to dance to oldies music was is fun
	- very fluent in all the vernacular spoken in pa
	- that's awesome i teach elementary school
	- i love teaching, tap dancing to bob segar, all illustration type stuff
	- that sounds like a lot of fun
	- it is, but this harry potter series just made me feel tingly
	- that's really hurtful to do
	- it can be, but i am working on other things
	- that you are fine i like james patterson
	- very nice of you to comment
	- yes my dog is my son that he chews candy to be funny for my dogs birthday
	- i have no kids i moved to virginia
	- that is crazy did you like the hurricane ?
	- yeah it was so devastating
	- i see
	- its so sad i'm sorry you are stuck in pennywise
	- wow that's very sad
	- it is he?
	- seriously
	- it will be my big dream to leave and go to florida
Softmax-τ:	- i am doing good, how about yourself?
	- i am good, just getting in from work
	- oh, what do you do?
	- i sell cars, what do you do?
	- i work in a hospital as a nurse.
	- oh that is very nice of you
	- what do you sell cars ?
	- i sell cars as a hobby
	- oh, i see. do you have any hobbies?
	- i like to paint and hang out in my living room.
	- oh, i enjoy listening to music. i love rolling stones !
	- i like rolling stones too do you?
	- yeah, i really like the rolling stones, they're my favorite!
	- cool, meat is amazing. i also like to like painting
	- i think it is for the best. i like to know that i love my job.
	- yes beater and i love meat. i also love to eat meat.
	- i'm sure you are a vegetarian! what do you do for a living?
	- i sell cars, i'm an electrician
	- oh i see. are you a car salesman?
	- i just started selling cars
Greedy:	- i'm good, how are you?
	- i'm good thanks for asking
	- what do you do for a living?
	- i'm studying to be a dentist
	- oh, i'm a teacher.
	- what city are you from?
	- i live in the city.
	- what do you do for a living?
	- i teach math and english.
	- what city are you from?
	- i live in the city.
	- what city are you from?

Table 14: Example of dialogue simulation between two agents using the different decoding methods.

Context:	*hello how are you today?*
Top-k:	- hello! i am well ,yourself ? - i am great. i just got off of work - i just got a job at a grocery store. - oh i am sorry to hear that - i'm okay. do you like reading ? - yes i love reading and i also love to swim - oh that's awesome! i really like reading cupcakes. - that sounds delicious. i'm in the south so i like to eat cupcakes - i love to make my own cupcakes. i love it! - do you have any hobbies? - i love reading, but my favorite hobby is painting. - that is cool. i've been to canada twice , but i've never been there - i love to paint too! what color eyes do you have? - mine are blue i'm not sure - i have brown hair. - i like to make my own cupcakes - cool. do you work? i work at walmart and i work at the grocery market. - i am actually a reporter for the local news - cool! do you like to read? - i've a newspaper reporter in the news
Nucleus:	i'm great, just got home from a long walk with my two dogs. - do you play any instruments? - not really. what kind of music do you like? - i play piano sometimes and listen to metal music - oh cool. i'm just trying to write an ebook about animals. - i like cats and dogs. do you play any instruments? - i do not, i prefer listening to music i like. - what kind of music do you like? - classical music and video game soundtrack. - do you go to concerts? - i go with my husband and listen to a lot of different music genres. - do you have any kids? - nope, how about you? - i've a boyfriend. are you married? - yes, recently divorced. we are planing on getting a corvette. - how exciting! are you close to your husband? - i am. i am looking to buy one when i retire. - that is awesome! are you married? - nope. we were looking to move to ireland when i got my divorce. - that's so sad. you should i ask if he's ok?
Entmax:	- good, how are you doing? - great just watching a movie - oh really what movie? - it's a story about robots getting into human stuff. - wow! well that strikes me as not science fiction at all - why do you say that then? - because humans are fragile and vulnerable lol - yeah they would be - very true. what kind of movies u like? - i love sci fi and ghost in the shell - i actually have never watched that. maybe ghost in the shell - it is such a beautiful movie - yeah i love stories about lost ones - that 's cool - my favourite movie though is gamera how about you - i love it too, did you see it? - yes that was one of my favorite films - that's cool. do you work? - i am too lazy to try difficult things now

Table 15: Example of dialogue simulation between two agents using the different decoding methods.

Context:	*greetings from the big apple, kim here, how are you?*
Softmax:	- hi! great thanks, how are you ? do you have any hobbies? - i ride my black mbu on my nightly walks, and listen to rock music. - whats your favorite kind of music? - guns and roses is my bedrock, my favorite artist. - that's great, my favorite genre is joleg tonne or tontera band.
Softmax-τ:	- i'm doing great, how are you? - i'm good, just playing with my son today. - sounds fun, what are you playing with? - I'm playing soccer right now, he's 4. - do you have any pets? - no, just the baby. are you married? - no, no i don't have any kids - i'm single, but i have been in this profession for a while. - interesting, tell me more about yourself. - i'm a professional soccer player. what about you ? - that's cool, i'm just a training dummy - i also play soccer professionally, i love it. - i like to play sports too. definitely a great sport - i have been to stanford for training, trying to perfect my skills. - i bet that's great training - its a lot of work! - yeah but i like it - yeah. i'm actually a soccer mom, we try to keep on top of our kids. - do you have kids? - i do.
Greedy:	- i'm doing well. how are you? - i'm good, just finished cooking dinner. - what do you like to cook? - i love pasta, and i love to cook. - i like to make pasta too. i'm a huge fan of pasta. - i love to cook, i'm a student, so i'm always busy. - what are you studying? - i'm studying to be a chef. - what city are you from? - i'm from cali, what about you? - i'm from cali. i'm from the midwest. - i'm from the midwest too , but i'm from the midwest.

Table 16: Example of dialogue simulation between two agents using the different decoding methods.

Context:	*greetings from the big apple, kim here, how are you?*
Top-k:	- i'm very good, thank you, i hope you have a great day - thanks. have a good day too. - same to you, have a good day too! - you do the same. have a great day too. - the same to you and have a great day also! - i do have a very nice day, i love running. - that's nice to enjoy, it s a great day here today - i am a political junkie. - you must be very busy! - what do you do for a living? - i'm actually a business major. - that must be hard to do, do you like politics? - not a big fan of politics, i like to go skiing and listen to rock - do you play sports or something? - i am in school for business - oh that is awesome. i used to play football in college, but i hated it! - oh that's why i play football!! - wow. what is your name? - my name is jed. i am from russia. how about you? - i played in ny and played at boston.
Nucleus:	- hi, i'm fantastic, how are you? - great. making some barbies for our barbie girls. - awesome, do you have any hobbies? - i really enjoy barbies. i live a long time away. - i am looking forward to going to school in the fall. - school is cool. do you sing? i love barbie songs. - i've a pet pean i sing while eating tacos. - barbie! that's cute. - oh yea, i have a small heart lol - are you looking forward to winter? i would like to live in the big apple. - definitely - winter is fun! no thanks, me neither. - you must really like summer, too lol - thanks. it is too cold to sing in the winter. its just not for me. - do you like tacos? - oh my gosh. they're good. my favorite is barbie. lol - i know, but spaghetti is my fave lol - haha. lol - oh , i do enjoy spaghetti , for my college graduation i was in last year of high school - how are you ?
Entmax:	- good. i just rang someone on the other side. - good, what did you get excited about today? - i love paris. how was your day? - its been crazy, i'm always feeling excited! lol - what is your favorite thing to do? - oh i love going hiking in the mountains, myself. - that sound amazing. i like travelling. - love trips, but i cannot stand staying in one place all day. lol - do you have any hobbies ? i always want to find cool new things. - i really like going out and nature itself, i prefer hiking - yes, exploring parks and all that jazz when i can. - that is awesome fun, whats your fav color? - i love grey. roses and the mountains signify my youth. - mine is blue, it makes me think of blueberries though - grey denotes youth well or openness and transparency. love the kale chips. - mmm i love chocolate . lol - oh i am sold on chocolate. eating it off the cob - haha - i miss the crazy curly hair fries and crackers . haha

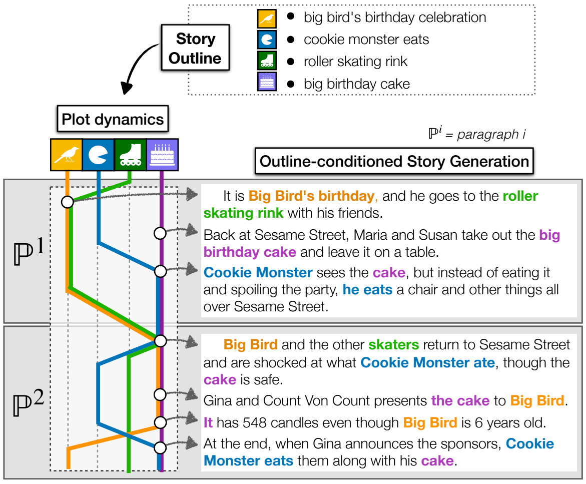
Abstract

We propose the task of *outline-conditioned story generation*: given an outline as a set of phrases that describe key characters and events to appear in a story, the task is to generate a coherent narrative that is consistent with the provided outline. This task is challenging as the input only provides a rough sketch of the plot, and thus, models need to generate a story by interweaving the key points provided in the outline. This requires the model to keep track of the dynamic states of the latent plot, conditioning on the input outline while generating the full story. We present PLOTMACHINES, a neural narrative model that learns to transform an outline into a coherent story by tracking the dynamic plot states. In addition, we enrich PLOTMACHINES with high-level discourse structure so that the model can learn different writing styles corresponding to different parts of the narrative. Comprehensive experiments over three fiction and non-fiction datasets demonstrate that large-scale language models, such as GPT-2 and GROVER, despite their impressive generation performance, are not sufficient in generating coherent narratives for the given outline, and dynamic plot state tracking is important for composing narratives with tighter, more consistent plots.

1 Introduction

Composing a story requires a complex planning process. First, the writer starts with a rough sketch of what key characters and events the story will contain. Then, as they unfold the story, the writer must keep track of the elaborate plot that weaves together the characters and events in a coherent and consistent narrative.

We study this complex storytelling process by formulating it as the task of *outline-conditioned story generation*, illustrated in Figure 1. Given an outline, a set of phrases describing key characters and events to appear in a story, the task is to generate a coherent narrative that is consistent with the provided outline. This task is challenging as the input provides only the rough elements of the plot[1]. Thus, the model needs to flesh out how these plot elements will intertwine with each other across different parts of the story. The flowchart in Figure 1 demonstrates an example of a latent plot structure: different key phrases from the outline appear and re-appear jointly throughout different sentences and paragraphs. Notably, the way that outline points are interwoven needs to be determined dynamically based on what's already been composed while also staying true to the original outline and overall narrative structure.



- big bird's birthday celebration
- cookie monster eats
- roller skating rink
- big birthday cake

It is **Big Bird's birthday**, and he goes to the **roller skating rink** with his friends.
Back at Sesame Street, Maria and Susan take out the **big birthday cake** and leave it on a table.
Cookie Monster sees the **cake**, but instead of eating it and spoiling the party, **he eats** a chair and other things all over Sesame Street.
Big Bird and the other **skaters** return to Sesame Street and are shocked at what **Cookie Monster ate**, though the **cake** is safe.
Gina and Count Von Count presents **the cake** to **Big Bird**.
It has 548 candles even though **Big Bird** is 6 years old.
At the end, when Gina announces the sponsors, **Cookie Monster eats** them along with his **cake**.

Figure 1: An outline (input) paired with a story (output) from the Wikiplots training set. Plot elements from the outline can appear and reappear non-linearly throughout the plot, as shown in plot dynamics graph. Composing stories from an outline requires keeping track of how outline phrases have been used while writing.

We present PLOTMACHINES, a novel narrative transformer that simulates the outline-conditioned

---

[1] Here, we define plot as the main sequence of events in the story.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4274–4295,
November 16–20, 2020.

generation process described above.[2] Our model learns to transform an outline into a multi-paragraph story using dynamic memory blocks that keep track of the implicit plot states computed using the outline and the story generated thus far. We draw inspiration from prior work in dialogue state tracking (Thomson and Young, 2010; Lee, 2013; Chao and Lane, 2019), entity tracking (Henaff et al., 2017; Bosselut et al., 2018), and memory networks (Sukhbaatar et al., 2015) for keeping track of plot states. We also inform our model with high-level narrative structure using discourse labels so that it can learn different styles of writing corresponding to different parts of the narrative (i.e. beginning, middle, and end). PLOTMACHINES is, to the best of our knowledge, the first model designed to generate multi-paragraph stories conditioned on outlines and can be trained end-to-end to learn the latent plot patterns without explicit plot annotations for supervision.

To support research on outline-conditioned generation, we present three datasets, including both fiction and non-fiction domains, where multi-paragraph narratives from existing datasets are paired with automatically constructed outlines using state-of-the-art key phrase extraction. Importantly, our task formulation of outline-conditioned generation is general and can be applied to various forms of grounded language generation. Comprehensive experiments on these datasets demonstrate that recently introduced state-of-the-art large-scale language models such as GPT-2 and GROVER (Radford et al., 2019; Zellers et al., 2019), despite their impressive generation performance, still struggle to generate coherent narratives that are consistent with input outlines. Our experiments indicate that dynamic plot state tracking is important for constructing narratives with tighter and more consistent plots compared to competitive baselines.

Our main contributions are: (1) a new task formulation of outline-conditioned story generation, (2) the presentation of three new datasets for this task, (3) PLOTMACHINES, a novel narrative transformer that learns to transform outlines to full stories with dynamic plot state tracking, and (4) empirical results demonstrating the limitations of state-of-the-art large-scale language models and the advantage of PLOTMACHINES compared to competitive baselines.

2 Outline-Conditioned Generation

The Task: Our primary goal is to design a task for investigating how story generation models can plan long narrative according to controllable story elements. To that end, we introduce the outline-conditioned story generation task, which takes a plot outline as input and produces a long, multi-paragraph story.

In order to be flexible to multiple forms of control that might be required for different downstream tasks, we envision plot outlines to be defined loosely as lists of an arbitrary number of un-ordered plot points that should guide a story being generated. Plot points could consist of high-level concepts, low-level events, or even detailed sentences. For practical reasons, in this work, we limit the scope of plot points to events and phrases since these can be automatically extracted. Future work could explore alternate methods of defining plot outlines, perhaps using an event-based planning systems (Porteous and Cavazza, 2009; Riedl, 2009; Riedl and Young, 2010; Fan et al., 2019) for generating key points.

More concretely, in this paper, we formulate the outline as a list of un-ordered bullet points which reflect key phrases to be loosely integrated in the output narrative. These plot outlines are inspired, in part, by previous work in short-form story generation tasks that conditioned on storylines (Peng et al., 2018; Yao et al., 2019), which were defined as an ordered list of exactly five single-word points. We extend this concept to long-form story generation by defining a plot outline more flexibly as: an *un-ordered* list of *an arbitrary number of multi-word* plot elements. An outline also differs from a writing prompt, such as those found in other controllable writing tasks (Fan et al., 2018), which are more abstract and often just a starting point for a story. Unlike a prompt, an outline is a list of concrete points that must appear somewhere in the narrative.

One challenge of this task is to create stories that have appropriate discourse and narrative flow. A second challenge is for stories to include the outline in a natural way. For example, it may be appropriate for certain outline points to be used only later on in the story (e.g. the protagonist dying may be more typically used at the end).

Table 1: Datasets used in the experiments showing the number of stories, the average number of paragraphs per story, and the split of stories across train/dev/test. We also show an example outline and a short excerpt from a story. We show examples of the full stories in the Supplementary Material.

Dataset: Outline to Story: We construct three datasets for outline-conditioned generation[3] by creating novel plot outlines to be used as inputs to generating stories from three existing story datasets. Table 1 shows statistics and examples from each dataset. We focus on fictitious generation, but also include the news domain for generalization. We build on existing story datasets for the target narratives, which we pair with automatically constructed input outlines as described below:

Wikiplots corpus[4] consists of plots of TV shows, movies, and books scraped from Wikipedia.

WritingPrompts (Fan et al., 2018) is a story generation dataset, collected from the /r/WritingPrompts subreddit – a forum where Reddit users compose short stories inspired by other users prompts. We use the same train/dev/test split from the original dataset paper.

NYTimes (Sandhaus, 2008) contains news articles rather than fictional stories, unlike the other two datasets.[5]

Outline Extraction We extract a list of plot outlines from each dataset to use as input using the RAKE (Rapid Automatic Keyword Extraction) algorithm (Rose et al., 2010)[6]. RAKE is a domain independent keyword extraction algorithm, which determines key phrases in a document based on the word frequency and co-occurrence statistics. We filtered key-points with overlapping n-grams. This is inspired by similar RAKE-based methods for creating storylines (Peng et al., 2018), but differs in that we extract longer outline points (3-8 words each) with no particular order.

3 PLOTMACHINES

Our approach to this task is to design a model that combines recent success in text generation with transformer-based architectures (Vaswani et al., 2017) with memory mechanisms that keep track of the plot elements from the outline as they are used in the story. We also incorporate special discourse features into the modelling to learn a structure over the long multi-paragraph story format.

We introduce PLOTMACHINES (PM), an end-to-end trainable transformer built on top of the GPT model[7] (Radford et al., 2018), as shown in Figure 2. Given an outline as input, the model generates paragraphs, recurrently, while updating a memory matrix M that keeps track of plot elements from the outline. This generation framework is motivated by human writing styles, in which each paragraph is a distinct section of related sentences.

At each time step, i, PLOTMACHINES generates a new paragraph $\mathbb{P}^i$:

$$(\mathbb{P}^i, h^i, M^i) = \text{PM}(o, d^i, h^{i-1}, M^{i-1}) \qquad (1)$$

where o is the outline representation (Sec. 3.1), d^i is the discourse representation associated with paragraph i (Sec. 3.2), h^{i-1} is a vector representation of the preceding story context (Sec. 3.3), and M^{i-1} is the previous memory (Sec. 3.4).

3.1 Outline Representation

The plot outline (i.e. the input to the model) is treated as a sequence of tokens, o, and used as input for the transformer for each paragraph that is

---

[3] Code for replicating data creation available at www.github.com/hrashkin/plotmachines

[4] www.github.com/markriedl/WikiPlots

[5] Due to concerns over fake news creation, we will not release the model trained on this data.

[6] https://pypi.org/project/rake-nltk/

[7] We build on top of GPT, though our approach could be used with most transformer-based LMs. In experiments, we also look at a version of PLOTMACHINES using GPT-2 (Radford et al., 2019) as a base.

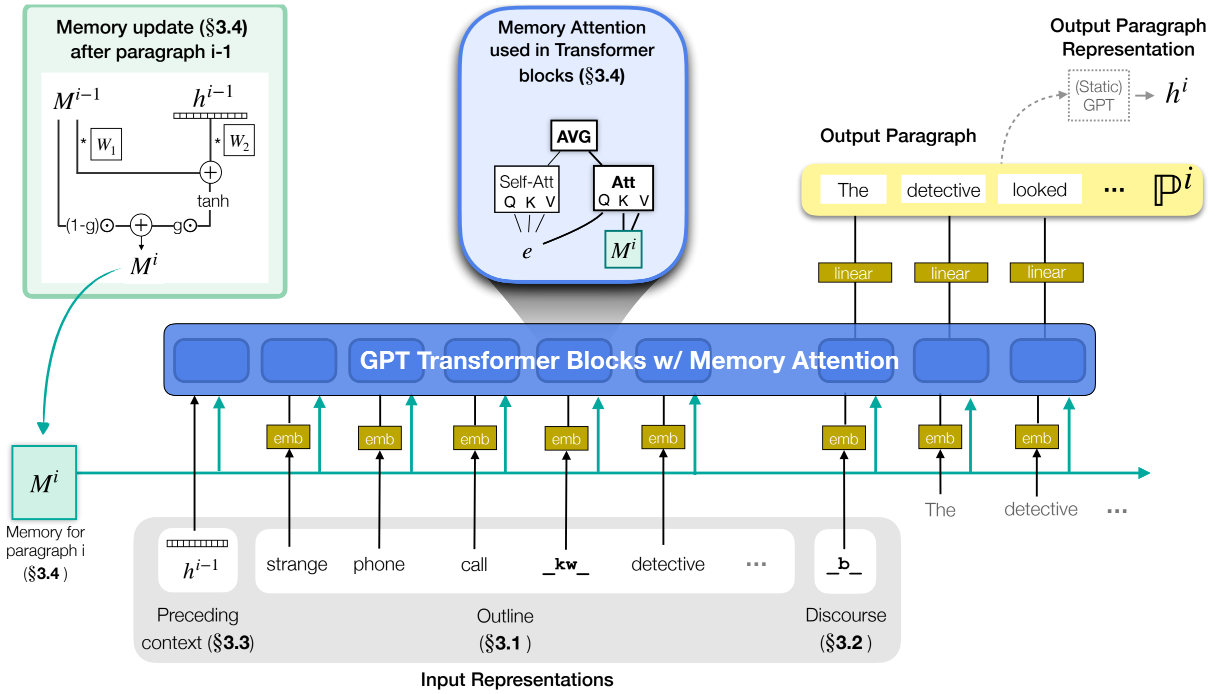

Figure 2: PLOTMACHINES: The model generates a paragraph $\mathbb{P}^i$ using the memory (M^{i-1}), the previous paragraph representation (h^{i-1}), the outline representation (o) and discourse representation (d^i). First, a gated update mechanism updates the memory using the previous memory and previous paragraph representation. Each transformer block includes extra attention over the current memory matrix M^i. The previous paragraph representation, h^{i-1}, the outline, and discourse tag (e.g. _b_) are also prepended to the generation as an input sequence (gray box). The output tokens of the generated paragraph are used to compute h^i using a static GPT model.

generated. We use special **`_kw_`** tokens to delimit each plot point in the outline and end the sequence with a special **`_endkw_`** token. We truncate the entire outline to maximum of n tokens. For example, an outline containing two plot points ({'strange phone call', 'detective'}) is turned into the input sequence:

`strange phone call _kw_ detective _endkw_`

3.2 Discourse Representation

We posit that there are stylistic differences in how the beginning, middle and end of a story are written. To learn these differences, we introduce d^i, discourse information about whether the i-th paragraph is an introduction, body, or conclusion paragraph. We append a special token to the outline representation as part of the input sequence: **`_i_`**, **`_b_`**, **`_c_`** for the introduction, body, and conclusion paragraphs respectively[8].

3.3 Preceding Context Representation

With the goal of incorporating previous story context in generating each paragraph, we use h^{i-1}, an embedded representation of the previous paragraph, which is added to the model input. More concretely, h^{i-1} is computed as the average embedding of GPT output representations of words from the previous paragraph (using a GPT model that is static, i.e. not finetuned). The h^{i-1} vector is used as an initial input to the transformer architecture, as shown in Figure 2.

3.4 Memory Representation

We implement memory to address two key task challenges. First, we want to keep track of the portions of the outline that have been mentioned. Second, we want to maintain semantic coherence across the entire story. To address these two challenges, we implement the memory as consisting of two parts: K, a set of vectors keeping track of outline points, and D, a matrix that stores a latent topic distribution of what's been written so far.

Notation: We define d as the embedding size of the transformer model and n as the maximum number of tokens in the outline. Memory is treated as a $\mathbb{R}^{d \times 2n}$ matrix which consists of two smaller matrices stacked together ($M = [K; D]$). K is a $\mathbb{R}^{d \times n}$ representation of outline points and D is a $\mathbb{R}^{d \times n}$ representation of the latent document state. K is

---

[8] We make the simplifying assumption that the first paragraph is an introduction, the last paragraph is the conclusion paragraph, and the other paragraphs are all body paragraphs.

initialized with embeddings representing each of the tokens in the outline and D is randomly initialized. The j-th column of memory at the timestep for paragraph i will be denoted M_j^i.

Updating memory: The memory is updated (top left corner of Fig. 2) using h^{i-1}, the average GPT output representation of the previous paragraph. We use update equations based on those in entity-based models such as Henaff et al. (2017). We use a gating mechanism, g, to allow the model to learn to flexibly control how much each cell in memory is updated, as below:

$$\hat{M}_j^i = tanh(W_1 M_j^{i-1} + W_2 h^{i-1}) \tag{2}$$

$$g_j^i = sigm(W_3 M_j^{i-1} + W_4 h^{i-1}) \tag{3}$$

$$M_j^i = (1 - g_j^i) \odot M_j^{i-1} + g_j^i \odot \hat{M}_j^i \tag{4}$$

where all W's are matrices of dimension $\mathbb{R}^{d \times d}$.

Transformer Blocks with Memory: Lastly, we must alter the GPT transformer blocks to include the memory in the language modeling. We alter the attention used within the transformer blocks to contain two parallel attention modules, as shown in Figure 2. One attention module (on the left in the figure) performs the standard GPT self-attention using transformer inputs to create queries, keys, and values. The other attention module uses transformer input to attend over the memory vectors (i.e., using the memory for creating key and value vectors). The outputs of both attention modules are averaged[9] before performing the remaining transformer block operations.

3.5 Training and Decoding

At training time, the model is trained end-to-end on the cross-entropy loss of predicting each paragraph. Gold representations of previous paragraphs in the story are used to update the memory and compute h^{i-1}. At decoding time, the model must decode a document starting with the first paragraph and use its own predictions to compute h^{i-1} and update the memory. Additionally, at decoding time, we assume a five paragraph structure (introduction, three body paragraphs, and conclusion) as a pre-set discourse structure to decode from.

4 Experiments

We present experiments comparing PLOTMACHINES with competitive baselines and ablations using automatic metrics and human judgements targeting multiple aspects of performance. In Sec. A.3, we also include example generations.

4.1 Experimental Set-up

Baselines: We compare with two models that have been used in related conditional story generation tasks. First, we train a Fusion model, from the original WritingPrompts dataset paper (Fan et al., 2018), using delimited outlines as a single input in place of a prompt. We also compare with the static storyline-to-story variant of Plan-and-Write (P&W-Static) from Yao et al. (2019), which is an LSTM-based model that we train by using the plot outline as delimited input.

Additionally, given the recent successes in text generation using large pre-trained LM's, we compare with these models, as well. We finetune the large-scale GROVER (Zellers et al., 2019) (equivalent to GPT-2 medium, 345M param) , which is a transformer-based language model that has been pre-trained for controllable text generation. To finetune GROVER, we give the outline as a delimited form of metadata. GROVER (345M param) has significantly larger capacity than PLOTMACHINES (160M param). Therefore, for more direct comparison, we also investigate a 460M parameter version of PLOTMACHINES that is built on top of GPT-2 medium (Radford et al., 2019) instead of GPT.

Unlike our models, the baselines are trained with the traditional generation framework, to generate an entire document conditioned on outlines without generating each paragraph recurrently.

Ablated PLOTMACHINES Models: We also show results in Table 2 on ablated versions of our model. First, we use the base GPT and GPT2 models, that are fine-tuned similarly to our model but using only outline inputs (without memory, preceding context, or discourse representations). Second, we investigate the effects of using the preceding context representation but still excluding memory and discourse tokens (**PM-NOMEM-NODISC**). Lastly, we use **PM-NOMEM**, a model variant that excludes the memory but uses outline, discourse, and preceding context representations as input.

Details: We use the HuggingFace implementations of GPT and GPT-2, and we fine-tune using ADAM. For generating with our models, we use nucleus sampling with repetition penalties (Holtzman et al., 2019; Keskar et al., 2019) using $p = 90$ and $\theta = 1.5$ for GPT and $p = 70$ and $\theta = 1.4$ for

---

[9] We experimented with a few other variants of implementing multiple attention mechanisms within the transformer blocks, but found this to be empirically effective.

Table 2: ROUGE Results on Wiki, WritingPrompts and NYTimes Datasets. The top block represents the baseline models on story/article generation, while the bottom blocks include ablations of our PlotMachines models.

GPT-2 (based on a hyperparameter sweep using grid search with cross-entropy on the dev. data). We use a minimum sequence length of 100 bpe tokens per paragraph and a maximum sequence length of 400, 922 bpe per paragraph for GPT and GPT-2, respectively. We set n, the maximum number of outline tokens and memory dimensions to 100. We used the settings for the baselines from their respective papers and codebases.

4.2 Automatic Metrics

In this section, we evaluate performance using different automatic metrics. We compute ROUGE scores (Lin, 2004) and self-BLEU (Zhu et al., 2018) following from previous work (Shen et al., 2019; Zhu et al., 2018) showing that a large ROUGE score together with a low self-BLEU score can demonstrate a model's ability to generate realistic-looking as well as diverse generations.

Coverage We compute ROUGE scores (Lin, 2004) with respect to the gold stories (Table 2). Results show that the full PlotMachines achieves comparable or higher ROUGE on all three datasets. Both PlotMachines variants (using GPT or GPT-2 as a base) achieve improvements over Grover, even though Grover includes significantly more parameters than the model using GPT.

Ablations In the bottom block of Table 2, we compare performance of ablated versions of PlotMachines. First, we compare GPT-2 with PM-NoMem-NoDisc, which differs by including preceding context representations. We observe that PM-NoMem-NoDisc performs slightly better than GPT-2, emphasizing the importance of including context from the previous paragraph. Second, we investigate the impact of discourse structure representations. We compare PM-NoMem-NoDisc, which omits the discourse token, with PM-NoMem, which uses the discourse token. As shown in Table 2, PM-NoMem generally has higher ROUGE scores than PM-NoMem-NoDisc, indicating that the discourse representation is beneficial to the model. Lastly, we compare PM-NoMem with the full PlotMachines to determine the effects of having a memory component. Our full model with memory has large ROUGE score improvements over PM-NoMem, underscoring the importance of the plot state tracking.

Diversity We evaluate the diversity of generated paragraphs from our models using self-BLEU scores (Zhu et al., 2018). In Table 3, we report the self-BLEU scores along with the average length of each generated story. Using all the generated documents from a model, we take one generated document as hypothesis and the others as reference, and calculate BLEU score for every generated document, and define the average BLEU score to be the self-BLEU of the model. While the Fusion model achieved relatively high ROUGE scores, it has generally worse diversity scores (much higher self-BLEU in Table 3). It may be that this model's high ROUGE scores were obtained by producing text that is more repetitive and generic.[10] In contrast, PlotMachines generally achieves good performance on both ROUGE and diversity scores, with self-BLEU scores that are lower than most other models. Notably, they generally have more similar self-BLEU scores to the actual gold stories, indicating that the language diversity is more similar to what humans write.

4.3 Human Evaluations

Due to the limitations of automatic metrics, we also perform extensive human evaluations. We conduct human studies to explore how generated stories compare along three dimensions: outline

---

[10] We show an example output from the Fusion model in Figure 13.

	Wikiplots					Writing Prompts					NY Times				
Model	AvgL	B-2	B-3	B-4	B-5	AvgL	B-2	B-3	B-4	B-5	AvgL	B-2	B-3	B-4	B-5
Gold Test	330	.74	.50	.29	.15	661	.82	.61	.40	.25	315	.73	.50	.32	.21
P&W-Static	352	.93	.85	.75	.64	675	.97	.94	.89	.85	352	.93	.85	.74	.63
Fusion	191	.84	.71	.58	.48	197	.93	.85	.75	.65	171	.89	.80	.70	.60
GROVER	835	.72	.49	.48	.37	997	.88	.72	.52	.34	719	.79	.57	.38	.25
GPT	909	.77	.47	.25	.11	799	**.73**	**.40**	**.19**	**.08**	739	**.68**	**.36**	.27	**.08**
GPT-2	910	.60	.26	.10	.03	799	.74	.41	**.19**	**.08**	756	.69	**.36**	**.17**	**.08**
PLOTMACHINES (GPT)	682	.77	.58	.40	.27	850	.89	.81	.72	.63	537	.85	.69	.53	.40
PLOTMACHINES (GPT-2)	553	**.56**	**.19**	**.07**	**.02**	799	.83	.56	.30	.14	455	.79	.57	.37	.23

Table 3: Average length of the generated test documents (**AvgL**) and Self-BLEU n-gram (**B-n**) scores on 1000 generated story samples from the test sets. We also include the average length and self-BLEU scores of the gold test data. A lower self-BLEU score together with a large ROUGE (see Table 2) score can justify the effectiveness of a model. We bold the lowest model score in each column; however, we note that sometimes the model self-bleu scores can be lower than in the gold document.

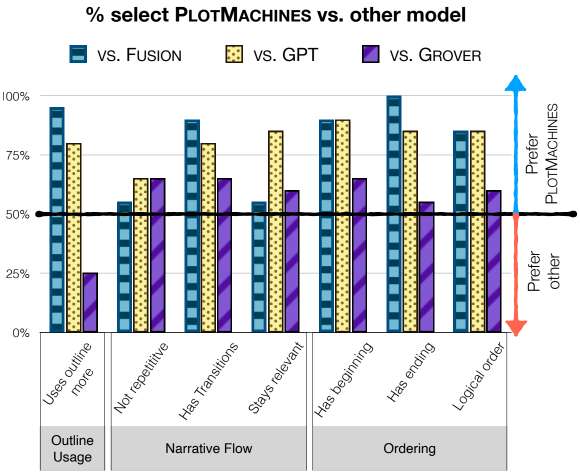

Figure 3: Head-to-head comparsion of PLOTMACHINES vs. three other models for full stories. In the appendix, we report results with standard error metrics (Table 9).

utilization, narrative flow, and ordering. We ask human raters[11] to evaluate each single or pair of generations from the Wikiplots test set, collecting 3 responses per story.[12]

To scale up the crowdsourcing work pragmatically, we split evaluations into two studies: one small-scale study evaluating full-length stories, and one large-scale study evaluating single-paragraph excerpts. In the first study, humans perform head-to-head ratings of 20 randomly sampled stories per pair of models. In the second study, humans rate story excerpts from 100 randomly sampled outputs per model.

Outline Utilization		
Model A	Model B	% Prefer Model A
Random Paragraph		
PLOTMACHINES	Fusion	**80%** ±4.0
PLOTMACHINES	GPT	**72%** ±4.5
PLOTMACHINES	GROVER	49% ±5.0
Closest Paragraph		
PLOTMACHINES	Fusion	**83%** ±3.8
PLOTMACHINES	GPT	**83%** ±3.8
PLOTMACHINES	GROVER	**54%** ±5.0

Table 4: Humans judge which of two paragraphs better utilize the outlines (when shown either random paragraphs or the paragraphs most similar to the outline).

4.3.1 Full Story Ratings

We give human raters a pair of stories generated from the same outlines and ask them to choose which one is better in different aspects related to outline utilization, narrative flow, and ordering. In Figure 3, we show how often PLOTMACHINES (PM) was selected over the other models (values above 50% indicate that PM was preferred) using the majority vote for each example. PM was selected over base GPT and Fusion in all of the categories, demonstrating that the memory and discourse features are vitally important to improving the base model. While humans rated GROVER as using the outline more, PM is ranked higher in all of the questions about narrative flow and ordering.

4.3.2 Excerpt Ratings

Outline Usage We give raters two paragraphs each generated by different models and ask them to select which is utilizing the outline better. We perform two trials, one with random paragraphs from each story and one with the paragraph from each story that has the most n-gram overlap with the outline (i.e. the closest). In both cases, we compute the majority vote over the three responses and report the percentage of examples where our model is preferred. Results in Table 4 show that, when looking at single paragraphs, humans tend

---

[11] using Amazon Mechanical Turk. We include screenshots from the tasks Appendix A.2. In total, over 700 humans participated in all of our studies.

[12] For sampling from Fusion, we restrict to stories or excerpts with two or fewer unk tokens to ensure legibility for workers.

Model	Narrative Flow			Order
	Rep(↓)	Tran(↑)	Rel(↑)	Acc(↑)
Fusion	2.61	2.98	3.36	**73**
GPT	**1.39**	1.89	2.06	42
Grover	1.78	3.00	3.29	62
PM	1.64	**3.02**	**3.39**	59

Table 5: Human evaluations of paragraph excerpts from Fusion, GPT, Grover and PlotMachines (PM) outputs. Narrative flow questions rate the repetitiveness between paragraphs, transitioning, and relevance within paragraphs. In Table 10 of the appendix, we include standard error metrics.

to choose our PM as using the outlines in a more natural way, particularly when looking at the "closest" paragraph from both models. Fusion and GPT, in particular, are judged to be utilizing the outline much less than PlotMachines.

Narrative Flow In this task, we give raters a generated paragraph (with the previous paragraph as context). They are asked to rate on a scale from 1 to 5 how much the paragraph: (a) repeats content from the previous paragraph, (b) transitions naturally from the previous paragraph, and (c) stays relevant and on-topic throughout the paragraph.

In the left side of Table 5, we show the average ratings of each model. GPT is the least repetitive between paragraphs but has very low subscores for transitions and relevance. We posit that this behavior is likely due to GPT often generating unrelated content from one paragraph to the next. PM tends to have the highest rated transitions and achieve highest relevancy within paragraphs while being much less repetitive between paragraphs than Grover or Fusion.

Ordering It's challenging for humans to directly rate the ordering of a story based on a short excerpt. We instead set up a related proxy task: we give raters a pair of consecutive generated paragraphs, presented in a random order, and ask them to attempt to decipher the order. The intuition is that if the model output is very well-structured then it should be easier for humans to decipher the order. We compute the accuracy of the majority vote compared to the actual order in the right side of Table 5. Accuracy for PM approaches 60% accuracy and is much better than the base GPT. Grover and Fusion are easiest for humans to re-order (62%, 73% respectively). This result differs slightly from the full story analysis where the humans preferred PM over Grover and Fusion in the ordering-based questions. One possible explanation is that these two models, which decode word-by-word, without an explicit notion of paragraph, may be better at resolving coreference problems between paragraphs. This may make it easier for humans to re-order short excerpts even though they generally prefer the overall narrative order of PM due to it having better beginnings, endings, etc. (as indicated in our full story human study).

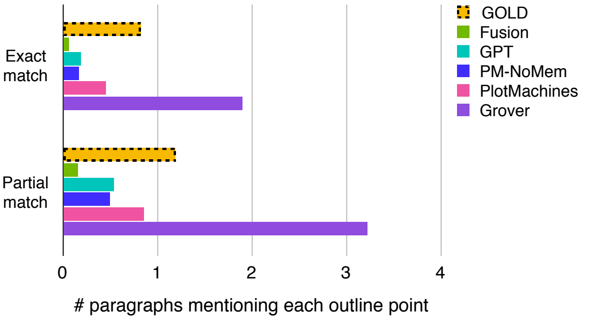

Figure 4: Number of paragraphs mentioning each outline point. PlotMachines with memory covers points more similarly to the gold story, whereas Grover tends to over-repeat outline points (twice as much as the gold reference).

4.4 N-gram Based Outline Usage Analysis

We perform an additional quantitative study to further investigate how outline points are used in generated stories. For fifty stories in the Wikiplots dev. set, we compute how many paragraphs mention each outline point using exact matching or partial matching ($>$ 20% of the n-grams in the outline point also appear in the paragraph). We report the results in Figure 4.

We observe that Grover tends to over-repeat outline points (about twice as much as the gold story). This mirrors our human evaluations that Grover is more repetitive. This may also explain why human raters in the full story ratings in Sec. 4.3.1 judged Grover as using the outline more but having worse narrative flow and order. Similar observations have been made about pre-trained language models in See et al. (2019) that the models followed story prompts very closely but often copied too much compared to human writing.

In contrast, the Fusion model tends to leave out portions of the outline. This may reflect the way Fusion was originally designed – for use with a task using more abstract prompts as input. The GPT and PM-NoMem models, while more inclusive than Fusion, are also likely to exclude outline points. The full PM model is generally more inclusive and more similar to the gold reference than the other models. The gold story mentions each outline point in around one paragraph on average, indicating that there is an ideal balance between the more conservative coverage achieved by our model and the over-repetitive coverage of GROVER.

4.5 Qualitative Examples

In the Appendix, (Sec. A.3), we include examples of model outputs on the validation set with annotations for incorporated outline points. Examples indicate that GROVER often finishes the story and then starts a new story partway through the document. This may help explain why GROVER over-repeats outline points and why humans judge it to be more repetitive and less consistently relevant. In contrast, our model adheres more to a beginning-middle-ending structure.

We also look at examples of introduction and conclusion paragraphs generated by PLOTMACHINES, investigating the discourse the model has learned (Table 11). The model often starts stories by setting the scene (e.g. “In the early 1950s, a nuclear weapons testing continues ....”) and tends to write conclusions with a definitive closing action (e.g. “... the film ends with humperdinck and buttercup riding off into the sunset.”)

5 Related Work

State Tracking There is a plethora of work in state tracking for dialogue where memory states are updated after each utterance (Thomson and Young, 2010; Young et al., 2010; Lee, 2013; Chao and Lane, 2019). Similarly, SC-LSTMs (Wen et al., 2015) dynamically updated dialogue act representations as a form of sentence planning in spoken dialogue generation. Memory and entity networks (Henaff et al., 2017; Sukhbaatar et al., 2015) and neural checklists (Kiddon et al., 2016) also used similar methods for tracking entities for other tasks. We adapt these techniques for generating stories while tracking plot state that is updated after each paragraph. Our method of decoding paragraphs recurrently also draws on existing work in hierarchical decoding (Li et al., 2015; Shen et al., 2019), which similarly decodes in multiple levels of abstraction over paragraphs, sentences, and words.

Controllable Story Generation There has been a variety of work focusing on generating stories in plot-controllable, plan-driven, or constrained ways (e.g. (Riedl and Young, 2010; Fan et al., 2018; Peng et al., 2018; Jain et al., 2017; Lebowitz, 1987; Ippolito et al., 2019; Pérez y Pérez and Sharples, 2001)). Similar work in creative generation has conditioned on keywords for poetry generation (Yan, 2016; Ghazvininejad et al., 2016; Wang et al., 2016). Outline-conditioned generation is complementary to these tasks in that outlines provide more flexibility than very fine-grained srl-based, event-based, or graph-based plans (Fan et al., 2019; Martin et al., 2017; Harrison et al., 2017; Li et al., 2013) and more structured grounding than coarse-grained prompts (Fan et al., 2018; Xu et al., 2018) or ending goals (Tambwekar et al., 2019). Another similar task generates five line stories from five keywords (Peng et al., 2018; Yao et al., 2019). We generalize to a similar set-up for long-form narratives. Similar to many recent works in this area, we use seq2seq-based approaches, implemented using transformers. We further expand upon the modeling for the challenges specific to our task by using state tracking and applying discourse structure.

6 Conclusion

We present outline-conditioned story generation, a new task for generating stories from outlines representing key plot elements. We facilitate training by altering three datasets to include plot outlines as input for long story generation. In order to keep track of plot elements, we create PLOTMACHINES which generates paragraphs using a high-level discourse structure and a dynamic plot memory keeping track of both the outline and story. Quantitative analysis shows that PLOTMACHINES is effective in composing tighter narratives based on outlines compared to competitive baselines.

Acknowledgements

We would like to thank anonymous reveiwers for their insightful feedback. We also thank Rowan Zellers and Ari Holtzman for their input on finetuning GROVER and other language models, Maarten Sap for his feedback on human evaluations, and Elizabeth Clark for consulting on baselines and related work. We would also like to thank various members of the MSR AI and UW NLP communities who provided feedback on various other aspects of this work. A Supplementary Materials

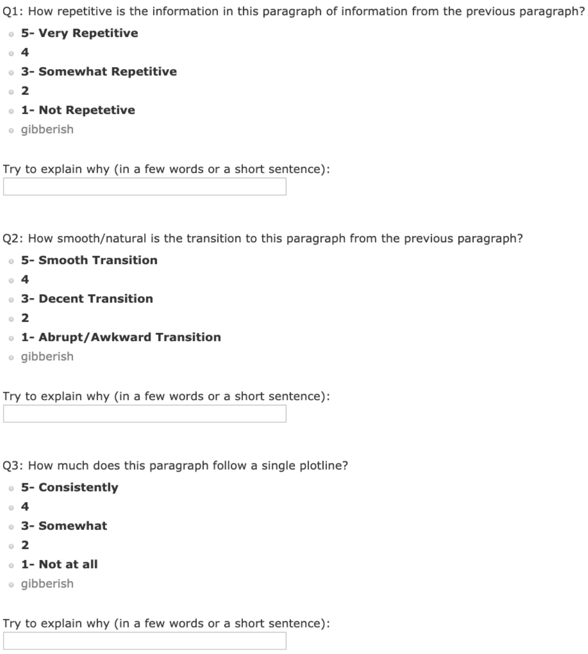
A.1 Examples from Training Datasets

We show full stories in Tables 6-8 corresponding to the excerpts shown in the Dataset sub-section of Outline-Conditioned Generation in the main text.

A.2 Human Evaluation Details

In Figures 5-8, we show the questionaires we asked the human raters. In question 2 of the full story task, we asked about which story was *more* repetitive, but we flip their answers in Figure 3 to show the model that was *less* repetitive in the Figure (i.e. for ease of reading, we made higher better as with the other metrics).



Q1: How repetitive is the information in this paragraph of information from the previous paragraph?

- ○ **5- Very Repetitive**
- ○ **4**
- ○ **3- Somewhat Repetitive**
- ○ **2**
- ○ **1- Not Repetetive**
- ○ gibberish

Try to explain why (in a few words or a short sentence):

Q2: How smooth/natural is the transition to this paragraph from the previous paragraph?

- ○ **5- Smooth Transition**
- ○ **4**
- ○ **3- Decent Transition**
- ○ **2**
- ○ **1- Abrupt/Awkward Transition**
- ○ gibberish

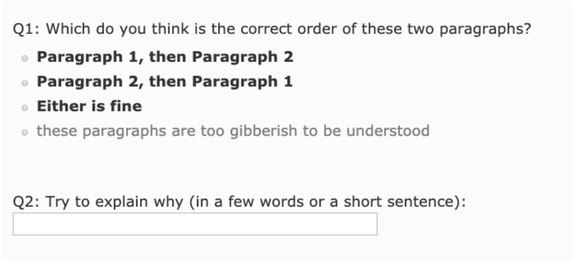
Try to explain why (in a few words or a short sentence):

Q3: How much does this paragraph follow a single plotline?

- ○ **5- Consistently**
- ○ **4**
- ○ **3- Somewhat**
- ○ **2**
- ○ **1- Not at all**
- ○ gibberish

Try to explain why (in a few words or a short sentence):

Figure 5: Questionaire for the narrative flow questions about paragraph excerpts. We pay humans $1.00 per HIT.

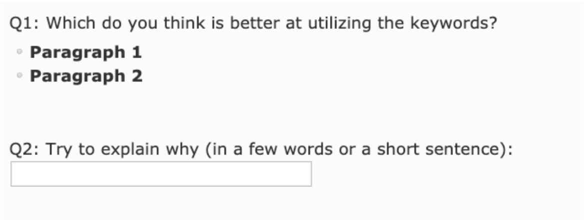


Q1: Which do you think is the correct order of these two paragraphs?

- ○ **Paragraph 1, then Paragraph 2**
- ○ **Paragraph 2, then Paragraph 1**
- ○ **Either is fine**
- ○ these paragraphs are too gibberish to be understood

Q2: Try to explain why (in a few words or a short sentence):

Figure 6: Questionaire for the ordering questions about paragraph excerpts. We pay humans $1.00 per HIT.

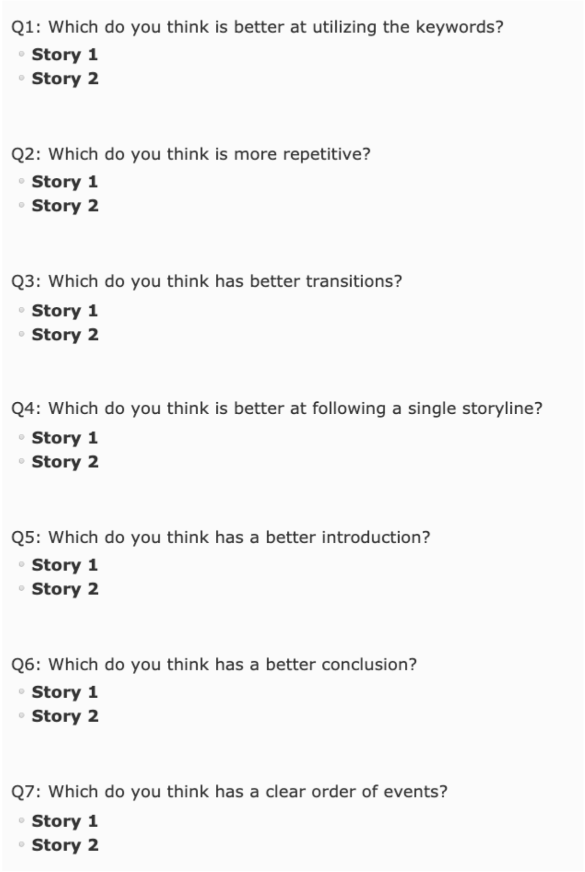


Q1: Which do you think is better at utilizing the keywords?

- ○ **Paragraph 1**
- ○ **Paragraph 2**

Q2: Try to explain why (in a few words or a short sentence):

Figure 7: Questionaire for the head-to-head outline usage questions about paragraph excerpts. We pay humans $1.00 per HIT.



Q1: Which do you think is better at utilizing the keywords?

- ○ **Story 1**
- ○ **Story 2**

Q2: Which do you think is more repetitive?

- ○ **Story 1**
- ○ **Story 2**

Q3: Which do you think has better transitions?

- ○ **Story 1**
- ○ **Story 2**

Q4: Which do you think is better at following a single storyline?

- ○ **Story 1**
- ○ **Story 2**

Q5: Which do you think has a better introduction?

- ○ **Story 1**
- ○ **Story 2**

Q6: Which do you think has a better conclusion?

- ○ **Story 1**
- ○ **Story 2**

Q7: Which do you think has a clear order of events?

- ○ **Story 1**
- ○ **Story 2**

Figure 8: Questionaire for the head-to-head questions about full stories. We pay humans $2.00 per HIT. Note: we reversed the answers to question 2 so that we could show which models were *less* repetitive in Figure 3.

Article: A criminologist narrates the tale of the newly engaged couple, Brad Majors and Janet Weiss, who find themselves lost and with a flat tire on a cold and rainy late November evening, somewhere near Denton in 1974 . Seeking a telephone, the couple walk to a nearby castle where they discover a group of strange and outlandish people who are holding an Annual Transylvanian Convention . They are soon swept into the world of dr Frank-N-Furter, a self-proclaimed ”sweet transvestite from Transsexual, Transylvania” . The ensemble of convention attendees also includes servants Riff Raff, his sister Magenta, and a groupie named Columbia .

In his lab, Frank claims to have discovered the ”secret to life itself” . His creation, Rocky, is brought to life . The ensuing celebration is soon interrupted by Eddie (an ex-delivery boy, both Frank and Columbia’s ex-lover, as well as partial brain donor to Rocky) who rides out of a deep freeze on a motorcycle . Eddie then proceeds to seduce Columbia, get the Transylvanians dancing and singing and intrigue Brad and Janet . When Rocky starts dancing and enjoying the performance, a jealous Frank kills Eddie with a pickax . Columbia screams in horror, devastated by Eddie’s death . Frank justifies killing Eddie as a ”mercy killing” to Rocky and they depart to the bridal suite .

Brad and Janet are shown to separate bedrooms, where each is visited and seduced by Frank, who poses as Brad (when visiting Janet) and then as Janet (when visiting Brad) . Janet, upset and emotional, wanders off to look for Brad, who she discovers, via a television monitor, is in bed with Frank . She then discovers Rocky, cowering in his birth tank, hiding from Riff Raff, who has been tormenting him . While tending to his wounds, Janet becomes intimate with Rocky, as Magenta and Columbia watch from their bedroom monitor .

After discovering that his creation is missing, Frank returns to the lab with Brad and Riff Raff, where Frank learns that an intruder has entered the building . Brad and Janet’s old high school science teacher, dr Everett Scott, has come looking for his nephew, Eddie . Frank suspects that dr Scott investigates UFOs for the government . Upon learning of Brad and Janet’s connection to dr Scott, Frank suspects them of working for him; Brad denies any knowledge of it, and dr Scott assures Frank that Brad is totally not involved in UFOs . Frank, dr Scott, Brad, and Riff Raff then discover Janet and Rocky together under the sheets in Rocky’s birth tank, upsetting Frank and Brad . Magenta interrupts the reunion by sounding a massive gong and stating that dinner is prepared .

Rocky and the guests share an uncomfortable dinner, which they soon realize has been prepared from Eddie’s mutilated remains . Janet runs screaming into Rocky’s arms, provoking Frank to chase her through the halls . Janet, Brad, dr Scott, Rocky, and Columbia all meet in Frank’s lab, where Frank captures them with the Medusa Transducer, transforming them into nude statues . After dressing them in cabaret costume, Frank ”unfreezes” them, and they perform a live cabaret floor show, complete with an RKO tower and a swimming pool, with Frank as the leader . Riff Raff and Magenta interrupt the performance, revealing themselves and Frank to be aliens from the planet Transsexual in the galaxy of Transylvania . They stage a coup and announce a plan to return to their home planet . In the process, they kill Columbia and Frank, who has ”failed his mission” . An enraged Rocky gathers Frank in his arms, climbs to the top of the tower, and plunges to his death in the pool below . Riff Raff and Magenta release Brad, Janet, and dr Scott, then depart by lifting off in the castle itself . The survivors are then left crawling in the dirt, and the narrator concludes that the human race is equivalent to insects crawling on the planet’s surface, ”lost in time, and lost in space .

Writing Prompts Story

Outline: found something protruding `_kw_` geometric shapes glowing `_kw_` sister kneeling beside `_kw_` dead bodies everywhere `_kw_` running around trying `_kw_` written anything also textbf`_kw_` darkness overwhelmed `_kw_` firelight flickering `_kw_` could hear something `_kw_` definitely screams `_endkw_`

Article: It was dark and Levi was pretty sure he was lying on his back . There was firelight flickering off of what was left of a ceiling . He could hear something but it was muffled . He was almost positive it was screaming . When he tried to move he felt an excruciating pain in his left side that caused him to cry out . His hand moved to it instinctively and found something protruding from the wound . It seemed to be a pipe of some kind . He attempted to pull it out but it was covered in blood making it slick . Levi 's ears began ringing and the sounds began to become clearer , it felt quite a bit like some one was driving needles into his eardrums . The sounds he was hearing were definitely screams and not just one person 's , a lot of people were screaming or yelling . There was some one close to him that was crying . He looked in the direction of the tears and seen his sister kneeling beside him , her hands covering her face . " What happened Laur ? ".

He was shocked at the sound that barely rasped out from between his lips . His sister 's hands jerked down and she stared down at Levi with a shocked look on her face . " bu ... I tho ... you were n't breathing ! " What started as a whisper ended in yell as she threw her self across her brother and began to sob anew . Levi cried out hoarsely but she did n't hear . She just continued to cling to him like a little girl that had just found her lost doll . He put one of his arms around her and scanned the room as much as he could . It looked like a warzone , like something out of one of the many shooters in his gaming collection . " What the hell ? " There were dead bodies everywhere , he recognized some of them . There were firefighters and EMT 's running around trying to find survivors in the rubble . Most of the screams were coming from survivors .

He seemed to be laying on top of the bottom of a desk , and he was pretty sure the pipe sticking out of his side was a actually one of the legs . Then he spotted it lying about two feet from his right leg , a round section of desk about the size of a softball . On it was a round symbol with geometric shapes glowing with dark red embers and a dull tendril of smoke rising up from it . It all came back to him in rush . He drew that in his notebook . It was second period and his trig teacher had this monotonous voice that could put a crack head to sleep . Laurana caught him doodling and had thrown a pencil at him to scold him silently , which made him jerk as he was connecting the last line on his drawing . Then there was the light and the heat and lastly the dark . Did he do this ? What the hell was going on here ? A voice brought him out of his little flashback . " Sir . Sir ? Sir ! "

He seemed to be laying on top of the bottom of a desk , and he was pretty sure the pipe sticking out of his side was a actually one of the legs . NYT Article

Outline: upcoming annual economic summit meeting `_kw_` take intermediate steps`_kw_` says white house `_kw_` prevent serbian aggression `_kw_` meet boris yeltsin `_endkw_`

Article: The long-simmering tensions in Serbia's province of Kosovo turned violent in recent weeks and threaten to ignite a wider war in the Balkans. Only a concerted diplomatic effort by the United States can keep the conflict from escalating. Though he has been attentive to the problem, President Clinton must do more to take the lead with European nations to insure that Kosovo is not left adrift.

Since Slobodan Milosevic, the Serbian leader, stripped Kosovo of its autonomy in 1989, Kosovo's overwhelmingly Albanian population has engaged in mostly peaceful resistance. It brought them nothing but more repression. In recent months, an Albanian guerrilla army has emerged, targeting mainly Serb policemen. The guerrilla campaign has angered Serbs and given Mr. Milosevic an excuse to bomb villages and carry out indiscriminate attacks. He appears to be trying to push the 1.8 million Albanians out of Kosovo entirely.

A war in Kosovo, massacres of Albanians or a rush of refugees into Albania and Macedonia could bring those two neighboring countries into the conflict. It might also destabilize the fragile peace in Bosnia and flood Turkey with refugees. Even Turkey and Greece, ancient enemies, might be tempted to intervene to enhance their influence in the Balkans, especially if Macedonia is in chaos.

International responsibility for dealing with the Kosovo crisis rests primarily with the United States, Britain, France, Italy, Germany and Russia. Acting together as the Contact Group, they are trying to force Mr. Milosevic to accept internationally supervised negotiations with the Albanians. But the group has proved ineffectual because its powers are limited and some members, notably Russia, oppose strong pressure against Serbia. The group has frozen Serbia's assets abroad and this weekend imposed a ban on new foreign investment in Serbia. The sanctions, however, are impossible to enforce among countries outside the Contact Group and difficult even inside it, given Russia's views.

When President Clinton meets Boris Yeltsin later this week at the annual economic summit meeting, he should seek more Russian cooperation in pressuring Serbia. He sent a high-level delegation to Belgrade this weekend to say that Serbia will remain isolated if fighting continues. But there is little indication that Mr. Milosevic cares.

The White House has not ruled out the use of force to prevent Serbian aggression in Kosovo, but other, intermediate steps should be used before Mr. Clinton considers military action. NATO at this stage can play an important role by increasing its visibility in the region. NATO soldiers ought to be added to a peacekeeping force already based in Macedonia, and a similar group should be stationed in the north of Albania to secure the border and control weapons smuggling. But NATO should also push Mr. Milosevic to accept NATO observers in Kosovo, which he might do if he fears the guerrillas are growing too fast. If Western nations cannot muster a clear and unified message to Mr. Milosevic to restrain his army, he will unleash a new round of ethnic killing in the Balkans.

Table 9: Small-scale human study: H2H comparison of PlotMachines (PM) with baseline output for 20 full stories. SEM is the standard error of the mean. The p-value is a t-test comparing to 50% (no preference between outputs). Although this is a small-scale study, the preference for PM is significant in many of the comparisons to Fusion and GPT2. Overall, there is a general trend towards PM being preferred in all cases except for the comparison of outline utilization with Grover.

Model	Narrative Flow			Order
	Rep(↓)	Tran(↑)	Rel(↑)	Acc(↑)
Fusion	2.61±0.09	2.98±0.08	3.36 ±0.08	**73**±4.4

PM	1.64±0.07	**3.02**±0.10	**3.39**±0.10	59±4.9

Table 10: Extended results with standard error of the mean for human evaluations of paragraph excerpts from Fusion, GPT, GROVER and PLOTMACHINES (PM) outputs. Narrative flow questions rate the repetitiveness between paragraphs, transitioning, and relevance within paragraphs.

A.3 Qualitative Examples

In this section, we include examples of model outputs on the validation set with annotations for incorporated outline points.

We show example full stories from the Wikiplots validation set comparing outputs from:

- GROVER (Figure 9) and PLOTMACHINES (Figure 10)
- GROVER (Figure 11) and PLOTMACHINES (Figure 12)
- Fusion (Fan et al., 2018) (Figure 13) and PLOTMACHINES (Figure 14)

In the examples, we highlight outline points that are mentioned in red. We also bold a few sections in the GROVER output where the model notably ends the story and starts a new one. Examples indicate that GROVER often finishes the story and then starts a new story partway through the document. This shortcoming may help explain why GROVER over-repeats outline points and why humans judge it to be more repetitive and less consistently relevant. In contrast, our models adhere more to a beginning-middle-ending structure.

We also show additional examples of introduction and conclusion paragraphs generated by PLOTMACHINES (Table 11), demonstrating the discourse the model has learned. For example, the model often starts stories by setting the scene (e.g. "In the early 1950s, a nuclear weapons testing continues ....") and often ends with a definitive closing action (e.g. "... the film ends with humperdinck and buttercup riding off into the sunset.")

Paragraph type	Paragraph
intro	in the early 1950s, a nuclear weapons testing continues at an underwater hydrogen bomb test site. scientists are concerned that it may be too dangerous to detonate without being detected by radar and radiation detectors. government sends paleontologist kyohei yamane (kim kap) to investigate. he is killed when his boat explodes while on shore patrol. as evidence describes damage consistent with sabotage of oil rigs, they conclude there must have been more than one way inside the facility. meanwhile, military research has discovered a deep underwater natural habitat alongside others where water can not be mined for life - saving purposes.
intro	the novel is set in a post - apocalyptic future where earth almost uninhabitable, with only one habitable planet for habitation and an intersolar system police force (rf) to maintain order. the story begins when " cowboy bebop ", who has been living on his homeworld of nepal since he was 12 years old, returns from space after being stranded by a comet that destroyed most of the interstellar civilization. he finds himself at home as well as friends among other characters.
intro	in 1933, joker terrorizes gotham city by murdering the mayor of new york. commissioner gordon is called to defend gotham whenever crime strikes are occurring and he has his own reasons for doing so : a corrupt police lieutenant eckhardt (james stewart) wants napier captured alive ; an elderly woman who was once part of batman 's gang tries to kill him but instead accidentally drops her gun into the water. joker also becomes obsessed with capturing the joker. meanwhile, photojournalist vicki vale begin their investigation on batman as well as other characters from the newspaper " big daddy " and " the joker ".
conclusion	humperdinck arranges for buttercup to get married to a powerful don juan carlos, who is rumored to be able to control the entire province. humperdinck secretly orders rugen to kidnap buttercup and bring her to him. rugen succeeds in kidnapping buttercup, but humperdinck kidnaps her anyway. buttercup manages to free herself and flee with humperdinck, but is captured by manuela, who accuses humperdinck of trying to keep her prisoner. humperdinck swears revenge on manuela and his henchmen, and rescues buttercup just in time. the pair head north to santa fe, where humperdinck uses his magic powers to heal buttercup 's wounds. the couple settle in a small cabin owned by mrs mccluskey, who introduces buttercup to mr smith, a blacksmith. humperdinck 's plan backfires when mr smith is attacked by apache indians, and humperdinck saves him. the film ends with humperdinck and buttercup riding off into the sunset .
conclusion	stevens and angel eyes sneak into the church hall and steal a bible. stevens opens the book and reads passages from psalms 118 to 350 bc. stevens closes the book and hands it to angel eyes. angel eyes then places stevens ' hand atop the cross and prepares to strike. stevens grabs hold of angel eyes and begs him to reconsider. stevens pleads with angel eyes to listen to reason. angel eyes makes stevens tell him why he left the confederacy. stevens tells him that he was betrayed by his mother and sister and that he needs redemption. stevens then lies and tells angel eyes that he ca n't forgive him. stevens then walks away. angel eyes watches him disappear into the night .
conclusion	in 1987, toscani meets harrison at a bar, where harrison confesses that he orchestrated the bombing of harrison 's hotel room. harrison promised justice for his friends and family, but toscani refused to believe him. harrison pleads with toscani to let him live, but toscani rejects him. toscani drives away, and harrison follows him. toscani breaks down crying, realizing that he has failed. harrison promises justice for his victims, and toscani smiles sadly .

bold: are a few notable places where the model seems to end the story and start telling a new one (note: Grover often inserts "1:" at the beginning of stories copying a section header that frequently appears at the beginning of training data.)

1:John Keeley (Robert Mitchum), concerned for the welfare of a suspected soldier, takes him to the home of Julie King (Kay Francis), a young woman. Julie tells Keeley that she has recently broken up with an angry long-time lover. After she returns home, Keeley brings the man home .

Under questioning, the man refuses to identify Keeley. Police investigator Finlay (Macdonald Carey) does a background check and uncovers that the man is an Army Ranger. Lee Thompson (Steve Brodie), Mitchell's lawyer, takes charge of the case. With the help of Julie and his brother, Dave (John Ballou), an officer with the Rangers, the father-son pair decide to delve into the Army's most notorious past, that of James Mitchell (Clarence Muse). Keeley fears that this could become the one possible motive Behind the Lens. A visit to the man's well-guarded home and some untraceable leads them to James' buried body .

Lee, who is on leave during the investigation, refuses to help. He and Keeley slowly piece together what happened in the mysterious cabin of James' two killer during the soldier's earlier stay. Some soldiers there claimed to have observed a man abandoning a wagon. The suspected soldier relays this detail to Lee and is found murdered the next day. **1:Brian Keeley (David Nugent) is a Denver Metro cop who** has a secret obsession for witnesses. Keeley does whatever it takes to protect his friends and family from conflict and hardship in the police force. As soon as he is drafted into the army, he leaves his home city to serve a three-year tour of duty in Iraq as a turret gunner. Troubled, Keeley slowly piece together the wreckage of his life before and during the course of his war time .

As the wounds of war linger, the strain of seeing other witnesses hits the Kansas city of which Keeley is an only child, Julie (Sarah Jones) is a widow living with her parents Bob (Warren Eastwood) and Mary (Shirley Jones) and her younger sister, Cassandra (Alexandra Paul). The first time he sees her, after a stress-induced incident in which he is knocked unconscious, he accidentally shoots her in the shoulder. No one on the stand sees it, a lone witness, a possible witness named Ginny (Tara Fitzgerald), has what few witnesses witness the shooting because she is the only one who had the car and gun key that made the shot. A new man at the stand is also a possible witness because the man, Stan Meredith (Steve Brodie), Mitchell (Robert Mitchum]), concerned to see that the accused soldier is not convicted before being removed from the stand. Mitchell has phone conversations with Meredith about Meredith's possible involvement in the incident. As Keeley overhears these conversations, he asks Julie to hide her purse from the police. Once Julie realizes that Keeley is searching her purse for his wallet, she is furious and gets into a fistfight with Keeley, after the two meet again in the brief moments after Keeley surprises her with the money from the purse. Keeley then goes on the stand and answers the last few question from police investigator Finlay (Harry Andrews) .

When he asks Julie to drop the fight because of his feelings for her, Julie tries to tell him that she does not feel safe with him any longer. After trying to get Karen, his pregnant ex-wife, to tell her that he is waiting for her to give birth, Keeley is attacked in the street and caught in a traffic accident with the police arriving in mere seconds. As the soldier is about to take Keeley into custody, Kelly (Trish McEvoy), a navy sailor in a bunk bed with Keeley, shoots him in the leg. Kelly leaves him lying on the ground in pain, then turns around and runs to catch her man before being run over by a truck. Keeley is taken to the hospital where Mary and Cassandra nurses him through his injury .

A newly hospitalized and recovering Keeley (Tim Kelleher) tells Julie that Kelly was responsible for his wounds and that he wants her to understand what Kelly meant. As he is recovering, Julie does not remember what she said during their encounter but realizes that she wanted Keeley to know why Kelly killed him. Katie then rushes to Julie and begs her to remember what she said. And they do. Kelly admits that, on the day that Keeley died, he had been obsessed with witnesses all his life. He even attempted to shoot Julie as a child after beating her mother. Keeley responds that he cannot see into Kelly's mind, that he knows what Kelly thinks. The film ends with Kelly relaying the details of his final minutes to Keeley. Later in the film, Kelly and Katie reconcile their differences and agree that the events that have transpired will help them look at their past more positively .

After Keeley recovers from his injury, the movie shifts focus to the investigation on the murder of Kelly Meredith. In the interrogation room at the hospital, the suspected soldier relays the name of the woman his partner killed. Julie is pulled away by Finlay but when she returns, she tells him that the names are now Murray Fenner and Wallace Johnson. In their conversation the suspect, who we later learn is Penny Rosen, proudly explains that she knows all about the death and is above suspicion. **1:The film begins with an absent mother.** Shirley (June Allyson), reading from a letter from a suspected soldier relays the report of what may have happened to the soldier's family during the Siege of Fort Benning, Georgia. The soldier was slain by sniper while home on leave. The sniper is revealed to be the son of an old friend, Tim Kegee (Eric Johnson) .

While hearing about the suspected soldier's death, police investigator Finlay (Jack Butler) and Shirley realize that the shooting must have been done by Kegee's childhood friend, Steve Brodie .

As the police slowly piece together the case, they discover that Kegee's father was once a convicted murderer. In the meantime, Steve Brodie has given the information on the shooting to detectives Finlay and Detective Shelly (Linda Darnell) .

A possible witness named Ginny (Ann Wilson) who was the soldier's wife is found murdered during the night. Finlay and Shelley (Sarah Miceli) are trying to piece together who the soldier's brother was and why the brother killed the soldier's family. One possible motive Engine Dave (Robert Mitchum), concerned about the sincerity of Kegee's father in denying his involvement with the shooting, asks to see Kegee's biological father. Kegee's father won't tell him that he is the brother of the soldier he killed .

Eventually, all evidence points to Kegee being the killer. Finlay finds out that Kegee was planning to murder the soldier's wife and daughter in order to get the money the soldier sent to Kegee's father to fulfill a promise he made him, with the promise to the latter to avoid retaliating. Kegee is ultimately arrested and convicted for the murder of his own family. **1:A suspected soldier relays** his instructions to a sniper on a smallS. Army base. Though the soldier is dead, authorities find his rifle at the scene. Evidence in the bunker points to the sniper being Don Keeley (played by Patrick Warburton), who, along with his partner, Max Cooper (played by Steve Brodie), Mitchell, one of the soldiers, and a possible witness named Ginny (played by Phyllis Threlfall) being able to identify Don Keeley. Keeley's sister, Vicky, supports her brother's actions and, when questioned, informs the police investigator Finlay (played by William McMichael) that Don Keeley has been having suicidal tendencies .

In the meantime, the squad's commanding officer, Sergeant Walker (played by Robert Mitchum), concerned that Don Keeley's "suicide" may have been real, brings in the sergeant's wife, Kathy (played by Elizabeth PeÃ±a), a detective. The sergeant and Kathy slowly piece together the case and figure out what Don Keeley had been planning. During a lull in the sniper's activities, the sergeant and his wife discover the sniper is missing, and have the sniper's comrades and Joan Bennett (played by Jannine Scott) seek to hide him out. When the sergeant realizes that a defenseless Joan has been trampled to death by his comrades and that the killing was done by someone he knew personally, he knocks her out .

In a final confrontation, Joan's friends and Joan's bodyguard, Larry Manett (played by Robert Hendley), attack Joan's husband, who is wounded, severely injured, while telling a man, Max Cooper, that he will kill Joan because of her innocent loss and revenge. While Don and his comrades and Joan's bodyguard proceed to her house, the sergeant runs to find Kathy, severely injured. He shoots a gun at Joan's house and hears shots, turns around and finds his wife dead. A final shot shows Don and his comrades running and turning to one possible motive Afterwards, the sergeant reveals that "allison" is his nickname and that if he did kill Joan, it would not be the first time he had killed a woman. He further says that Don Keeley is not a murderer, as the sniper who shot Don Keeley, is not in the house. Don ends up walking away, evading the sheriff's deputies, evading police, and disappearing into the woods.

PlotMachines

- crossfire (film)
- keeley slowly piece together
- ✓✓ possible witness named ginny
- ✓✓ robert mitchum), concerned
- ✓ police investigator finlay
- ✓ suspected soldier relays
- ✓ steve brodie), mitchell
- ✓✓ one possible motive

red: outline points
✓ : mentioned (partially) at least once
✓ : mentioned multiple times

police investigator finlay (robert mitchum) , concerned about the possible witness named ginny (susan ladd) who was found dead in a park with her throat slashed and an apparent suicide . he is also investigating the disappearance of two other men from his precinct : sergeant david mitchell (steve brodie) , mitchell 's best friend ; and detective james " mac " o'rourke (nigel maclachlan) . when scotland yard receives a tip that one possible motive for murder would be a suspected soldier relays to them via radio .

duncan begins having nightmares about ginny 's death , and eventually realizes that someone else is behind the murders . the killer then kills another person , leaving only one possible motive for the crime : the body of a teenage girl . the murderer uses a gun used to kill the victim to hide the fact that he or she committed the killing . however , the real culprit is revealed to be myra , who had earlier killed herself because she believed that she did n't deserve what happened to her . she confesses to all these crimes , including the rape and subsequent shooting of a child .

nick 's suspicions lead him to discover that the accused were members of the military who participated in the war effort . he tracks down the last member of the group , lt joseph wilson (brian heffley) , who admits to knowing the truth about the bombing . he reveals that he knew nothing about the plot , except that it involved a possible witness named ginny . nick confronts her , demanding answers . she refuses to answer , claiming that she does not remember anything about the night of the bomb blast .

van alden is forced to reveal that he is actually part of a double squad led by sgt . donovan (robert mitchum) , worried that the soldiers might be looking for evidence that could implicate him in the massacre . van alden is able to identify a possible witness named ginny (laura moore) , who was shot in the head shortly prior to the ambush . van alden 's team manages to track down the shooter , who turns out to be the same man who murdered marlene . van alden and laird colvin (dan holloway) arrest the sniper , but he escapes . van alden is ordered to bring ginny to court , where she pleads guilty to three counts of attempted manslaughter . van alden reluctantly accepts the plea bargain , though he still feels betrayed by rusty .

the rest of the story deals with the search for penny , and the resulting confrontation between rafe cordova (robert mitchum) , concerned about the possibility of penny 's safety , and the eventual conclusion that rafe cordova is innocent . the ending shows penny and rafe traveling through mexico , stopping at various places in arizona , texas , california , louisiana , nevada , and arkansas , searching for clues to the identity of the actual robber . the final scene shows penny and rafe riding off into the sunset , presumably heading for san francisco .

red: outline points
bold: are a few notable places where the model seems to end the story and start telling a new one (note: Grover often inserts “1:” at the beginning of stories copying a section header that frequently appears at the beginning of training data.)

1:The film's plot traces the fall of a Mafia don, Joe Crowther, and his relationships with other mobsters and police officers throughout the period from his conception in 1977 to his arrest in 1986 .

The official synopsis of the film is as follows: "An actor with a Pork Pie hat proppedullivan on a park bench in Manhattan in November 1982. A scowl on his face. – and a laugh". In the opening scene, Crowtherâs wife and daughter are shown to have been running a health food store in the Bronx. Crowther has a wife and daughter in Virginia as well as a son and daughter in Brooklyn. He frequently visits their home while on probation .

He is inducted into the NYPD, where he settles into his new role and soon finds himself the target of a political scandal. The crew of detectives working with Crowther, in addition to an FBI agent who works with him and his family, make use of all methods they can imagine to ruin his reputations. The film is a series of scenes about him interacting with reporters and his family. The quality of his dialogue and conviviality are characteristic of this actor, and in many of the self-competence that he displays in most of his acting jobs, his voice has been dubbed for them. This is to say that he is writing dialog to archive footage from built-in short films, and he is both speaking and laughing. The character in the film is the system .

The federal agents that stand in Crowtherâs way are his former assistants, culminating in a dinner where Crowther mocks his chief rival, that is the current don. Crowther is in for some roughhousing as the folksy talk turns into a quick game of Narcotics with the mobsters, leading to a midnight meeting in the bathroom with all of the buildingâs law enforcement. Crowther goes to sleep that night. **1:Bob Garrett, Gil Wood, Lisa Lee, and Angela Calderon, all** of whom work at the United States Library's National Film Registry, talk about how they became the "cops" of the documentary film "Police: A Formic Tale" .

They first imagined the idea of a documentary after one of their co-workers, Gilbert, commits suicide. Because Gilbert was obsessed with a horror film, which he attended regularly, he was ostracized by his co-workers. They then found a homeless man with a pork pie hat propped upside down on the sidewalk. They decided that using Bob's trailer, and Gilbert's drinking abilities as a source of budget for their project, they could use a homeless man for a second "cop" to patrol the streets of Los Angeles. Although they did not have experience, they learned about responding to incidents in a three-day period. In their film, they filmed all of the police officers throughout the following day and night, and then they stored a replica of an explosive and a coffin for their "cop" to use in a three-day period. Then all of the police began their crime-fighting duties, leading to comic incidents, a wave of violence, and tense moments. **1:The film,** entitled Police Officers Throughout the Homeland, is dedicated to the police officers who have worked and worked hard to keep order and security in communities throughout the United States .

It is a collection of nine short films which are constructed short films of the type featured in the National Film Registry of the United States Library and Archives. Each episode contains a fictional story that is the basis for the film. The films, each one focusing on a particular type of police unit, begin with a description of the unit's or the members of their unit's duties and duties in and outside of their duty station. They are then followed by the police officer or members of the patrol team at that particular unit's location. As each episode progresses, it is revealed that the units members are being under false pretenses. Inevitably, the unit is disrupted by trouble makers and other groups who have emerged from the abuses of the United States' government and by the police officers themselves. The film ends with a news segment stating that "the unit charged with protecting America's cities is none other than the Police Officers Throughout the Homeland". At that point, we see a Pork Pie Hat propped Outside Atlanta's federal courthouse. The film ends with the cartoon ending with a caption that reads: "Watch the coming of age film you'll never see. **1:The film is a series of simple**, self-constructed short films, in which a murder occurs, and how it is done is shown by the player. They include clips of police officers throughout the film, men dressed in blue suits and blue suits who claim to be cops, and a people's assembly on a bridge. The narrator describes the short as "satiric" and frequently mentions that "those with guns are always gonna shoot" .

The film can be viewed on YouTube or in the National Film Registry of the Library of America. It was produced byproductively rendering the word "police" into the words and characters (a police badge for "officers") .

According to its name tag on the cover photo, the short film is entitled "Good Cop, Bad Cop, TV Show" and "The Banks Behind The System". (1970).

the film is set in a united states library , located at an old - fashioned desk and surrounded by bookshelves . it consists of three stories with police officers throughout each story . there are two versions : one for each floor ; the other for every room . the narrator (played by john wayne) explains that he has constructed short films to help people who need them . these include " cops " , " policemen " , " robbers " , " criminals " , " murderers " , " killers " , " terrorists " , " gangsters " , " assassins " , " revolutionaries " , " anarchists " , " traitors " , " villains " , " murderers " , and " rapists " .

they have erected a large statue of napoleon , but when questioned why they did n't capture him yet , they simply say that their boss wanted to make sure that his men would never find out where he hid the money . after hearing the news , they decide to go undercover and infiltrate the bank owned by the president of the state department . while infiltrating the vault , they discover that the robbery will take place over a long period of time . during the heist , the group discovers that the leader of the gang is actually a member of the national film registry , known only as the chief of security . the head of the operation is named mr hoover , and the rest of the team are called " cops " .

the plan works perfectly until the thieves break into the museum using a concealed tunnel . they steal all the books and papers , leaving the prisoners free to escape . the prison guards chase after them , but the boys manage to hide themselves under desks and chairs before escaping . the boys return home to tell their parents about the incident . their mother is shocked and angry , believing that her sons ' actions led to the death penalty . she scolds them for running away without telling anyone . they explain that they just ran away because they could no longer stand living in fear .

finally , the thief reveals herself as mrs robinson , the librarian of the united states library . she informs the heroes that she knows everything about them and even helped them escape . she wants to show them something . she shows them a picture of the famous hero , william shakespeare , who died fighting the nazis . the four friends wonder what happened to him . the policeman returns and takes the photo . the others realize that the policeman is none other than william shakespeare himself . the policeman claims that he killed shakespeare because he knew too much information about the nazi regime . he leaves .

the film features a detailed description of the structure of the library , including its construction and layout . the illustrations are based upon actual events . the buildings featured in the pictures depicted are modeled after those found in real life such as stonehenge , atlantis , mount rushmore , the great pyramid , etc . the photographs depict the entire town of granville , california , and the surrounding countryside . the map used in the documentary is described as having been taken from 1899 to 1947 . the location of granville is shown in the film .

Do sequence-to-sequence VAEs learn global features of sentences?

Abstract

Autoregressive language models are powerful and relatively easy to train. However, these models are usually trained without explicit conditioning labels and do not offer easy ways to control global aspects such as sentiment or topic during generation. Bowman et al. (2016) adapted the Variational Autoencoder (*VAE*) for natural language with the sequence-to-sequence architecture and claimed that the latent vector was able to capture such global features in an unsupervised manner. We question this claim. We measure which words benefit most from the latent information by decomposing the reconstruction loss per position in the sentence. Using this method, we find that VAEs are prone to memorizing the first words and the sentence length, producing local features of limited usefulness. To alleviate this, we investigate alternative architectures based on bag-of-words assumptions and language model pretraining. These variants learn latent variables that are more global, i.e., more predictive of topic or sentiment labels. Moreover, using reconstructions, we observe that they decrease memorization: the first word and the sentence length are not recovered as accurately than with the baselines, consequently yielding more diverse reconstructions.

1 Introduction

The problem of generating natural language underlies many classical NLP tasks such as translation, summarization, paraphrasing, etc. The problem is often formulated as learning a probabilistic model of sentences, then searching for probable sentences under this model. Expressive language models are typically built using neural networks (Bengio et al., 2003; Mikolov et al., 2010).

Whether based on LSTMs (Hochreiter and Schmidhuber, 1997; Sundermeyer et al., 2012) or Transformers (Vaswani et al., 2017; Radford et al., 2019), language models are mostly autoregressive: the probability of a sentence is the product of the probability of each word given the previous words. By contrast, Bowman et al. (2016) built a Variational Autoencoder (*VAE*) (Kingma and Welling, 2013; Rezende et al., 2014) out of a sequence-to-sequence architecture (*seq2seq*) (Sutskever et al., 2014). It generates text in a two-step process: first, a latent vector is sampled from a prior distribution; then, words are sampled from the probability distribution produced by the autoregressive decoder, conditionally on the latent vector. The goal was to encourage a useful information decomposition, where latent vectors would "explicitly model holistic properties of sentences such as style, topic, and high-level syntactic features" (Bowman et al., 2016), while the more local correlations would be handled by the recurrent decoder.

In principle, such a decomposition can be the basis for many applications. For example, using a single, unannotated corpus, it could enable paraphrasing (Roy and Grangier, 2019) or style transfer (Xu et al., 2019). For tasks requiring conditional generation such as machine translation or dialogue modeling, we could enforce a level of formality or impose a certain tone by clamping the latent vector. Moreover, latent-variable models can represent multimodal distributions. Thus, for these conditional tasks, the latent variable can be used as a source of stochasticity to ensure more diverse translations (Pagnoni et al., 2018) or answers in a dialogue (Serban et al., 2017).

Despite its conceptual appeal, Bowman et al. (2016)'s VAE suffers from the *posterior collapse* problem: early on during training, the KL term in the VAE optimization objective goes to 0, such that the approximate posterior becomes the prior and no information is encoded in the latent variable. Free bits are a popular workaround (Kingma et al., 2016) to ensure that the KL term is above a cer-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4296–4318,
November 16–20, 2020.

tain level, thereby enforcing that *some* information about the input is encoded. But this information is not necessarily global. After all, posterior collapse can be solved trivially, without any learning, using encoders that copy parts of the inputs in the latent variable, yielding very local and useless features.

In Section 3, we show that encoders learn to partially memorize the first few words and the document lengths, as was first discovered by Kim et al. (2018). To do so, we compare the average values of the reconstruction loss at different positions in the sentence to that of an unconditional language model. We elaborate on the negative consequences of this finding for generative models of texts. In Section 4, we propose three simple variants of the model and the training procedure, in order to alleviate memorization and to yield more useful global features. In Section 5, we empirically confirm that our variants produce more global features, i.e., features more predictive of global aspects of documents such as topic and sentiment. They do so while memorizing the first word and the sentence length less often, as shown in Section 6.

2 Model and datasets

Firstly, we describe the VAE based on the seq2seq architecture of Bowman et al. (2016). A document, sentence or paragraph, of L words $x = (x_1, \dots, x_L)$ is embedded in L vectors $(e_1, \dots, e_L)$. An LSTM encoder processes these embeddings to produce hidden states:

$$h_1, \dots, h_L = \text{LSTM}(e_1, \dots, e_L)$$

In general, the encoder produces a vector r that represents the entire document. In the original model, this vector is the hidden state of the last word $r = h_L$, but we introduce variants later on. This representation is transformed by linear functions L_1 and L_2, yielding the variational parameters that are specific to each input document:

$$\mu = L_1 r$$
$$\sigma^2 = \exp(L_2 r)$$

These two vectors of dimension d fully determine the approximate posterior, a multivariate normal with a diagonal covariance matrix, $q_\phi(z|x) = \mathcal{N}(z|\mu, \text{diag}(\sigma^2))$, where ϕ is the set of all encoder parameters (the parameters of the LSTM, L_1 and L_2). Then, a sample z is drawn from the approximate posterior, and the decoder, another LSTM, produces a sequence of hidden states:

$$h'_1, \dots, h'_L = \text{LSTM}([e_{\text{BOS}}; z], [e_1; z], \dots, e_L; z])$$

where BOS is a special token indicating the beginning of the sentence and $[\cdot;\cdot]$ denotes the concatenation of vectors. Finally, each hidden state at position i is transformed to produce a probability distribution of the word at position $i+1$:

$$p_\theta(x_{i+1}|x_{1,\dots,i}, z) = \text{softmax}(W h'_i + b)$$

where $\text{softmax}(v_i) = e^{v_i} / \sum_j e^{v_j}$ and θ is the set of parameters of the decoder (the parameters of the LSTM decoder, W and b). An EOS token indicating the end of the sentence is appended to every document.

For each document x, the lower-bound on the marginal log-likelihood (*ELBo*) is:

$$\begin{aligned}\text{ELBo}(x, \phi, \theta) = -&D_{\text{KL}}(q_\phi(z|x)||p(z)) + \\ &\mathbb{E}_{q_\phi}[\log p_\theta(x|z)] \\ \leq &\log p(x)\end{aligned}$$

On the entire training set $\{x^{(1)}, ., x^{(N)}\}$, the objective is:

$$\arg\max_{\phi,\theta} \sum_{j=1}^{N} \text{ELBo}(x^{(j)}, \phi, \theta)$$

2.1 Dealing with posterior collapse

Following Alemi et al. (2018), we call the average value of the KL term the *rate*. It measures how much information is encoded on average about the datapoint x by the approximate posterior $q_\phi(z|x)$. When the rate goes to 0, the posterior is said to *collapse*, meaning that $q_\phi(z|x) \approx p(z)$ and that the latent variable z sampled to train the decoder does not contain any information about the input x.

To prevent this, we can modify the KL term to make sure it is above a target rate using a variety of techniques (see Appendix A.1 for a small survey). We use the free bits formulation of the δ-VAE (Razavi et al., 2019). For a desired rate λ, the modified negative ELBo is:

$$\max(D_{\text{KL}}(q_\phi(z|x)||p(z)), \lambda) - \mathbb{E}_{q_\phi}[\log p_\theta(x|z)]$$

Seq2seq VAEs are prone to posterior collapse, so in practice, the rates obtained are very close to the target rates λ.

As observed by Alemi et al. (2018), different models or sets of hyperparameters for a given model can yield very similar values of ELBos despite reaching very different rates. Thus, for our purposes, the free bits modification is also useful to compare models with similar capacity.

2.2 Variants

Throughout the paper, we use variants of the original architecture and training procedure. In general, these variants use free bits objectives, but reach lower perplexities than what free bits alone allow.

Li et al. (2019)'s method is the following: pretrain an *AE*, reinitialize the weights of the decoder, train the entire model again end-to-end with the VAE objective. The sentence representation r is also the last hidden state of the LSTM encoder, so we call this method *last-PreAE*.

In the second variant, proposed by Long et al. (2019), the representation of the document r is the component-wise maximum over hidden states h_i, i.e., $r^j = \max_i h_i^j$. We call this model *max*. In later experiments, we also consider a hybrid of the two techniques, *max-PreAE*.

We chose these two baselines because they are relatively recent and outperform or perform on par with other recent methods such that cyclical learning rates (Fu et al., 2019) or aggressive training (He et al., 2019). Moreover, the pooling encoder of Long et al. (2019) is particularly interesting: since pooling operators aggregate information over sets of vectors, they might prevent the copying of local information in the latent variable.

We make slight, beneficial modifications to these two methods. We remove KL annealing, which is not only redundant with the free bits technique but also increases the rate erratically (Pelsmaeker and Aziz, 2019). Moreover, for Li et al. (2019)'s method, we use δ-VAE-style free bits instead of the original free bits to get rid of the unnecessary constraint that the free bits be balanced across components. For more details, see Appendix A. In summary, all of our experiments use δ-VAE-style free bits without KL annealing.

Finally, *AE* denotes the deterministic autoencoder trained only with the reconstruction loss.

2.3 Datasets

We train VAEs on four small versions of the AG-News, Amazon, Yahoo, and Yelp datasets created by Zhang et al. (2015). Each document is written in English and consists of one or several sentences. Each document is labeled manually according to its main topic or the sentiment it expresses, and the labels are close to uniformly balanced over all the datasets. For faster training, we use smaller datasets. The characteristics of these datasets are detailed in Table 5 in the Appendix.

3 Encoders partially memorize the first words and sentence length

The ELBo objective trades off the KL term against the reconstruction term. To minimize the objective, it is worth increasing the KL term only if the reconstruction term is decreased by the same amount or more. With free bits, the encoder is allowed to store a fixed amount of information for free. The objective becomes to minimize the reconstruction cost using the "free storage" as efficiently as possible.

There are many solutions to this objective that are undesirable. For instance, we could program an encoder that would encode the words into the latent variable losslessly, until all the free bits are used. However, this model would not be more useful than a standard, left-to-right autoregressive models. Therefore, it is necessary to check that such useless, purely local features are not learned.

In order to visualize *what* information is stored in the latents, our method is to look at *where* gains are seen in the reconstruction loss. Since the loss is a sum over documents and positions in these documents, these gains could be concentrated: i) on certain documents, for example, on large documents or documents containing rarer words; ii) at certain positions in the sentence, for example, in the beginning or in the middle of the sentence. We investigate the latter possibility.[1]

3.1 Visualizing the reconstruction loss

Concretely, we compare the reconstruction loss of different models at different positions in the sentence. The baseline is a LSTM trained with a language model objective (*LSTM-LM*). It has the same size as the decoders of the autoencoder models.[2] Since the posterior collapse makes VAEs behave exactly like the *LSTM-LM*, the reconstruction losses between the VAEs and the *LSTM-LM* are directly comparable. Additionally, the deterministic *AE* gives us the reconstruction error that is reachable with a latent space constrained only by its dimension d, but not by any target rate λ (equivalent to an infinite target rate).

---

[1] PyTorch (Paszke et al., 2019) implementation available at `https://github.com/tombosc/exps-s2svae`.

[2] Only the input dimensions slightly change because in VAEs, the inputs of the decoder also include the latent vector.

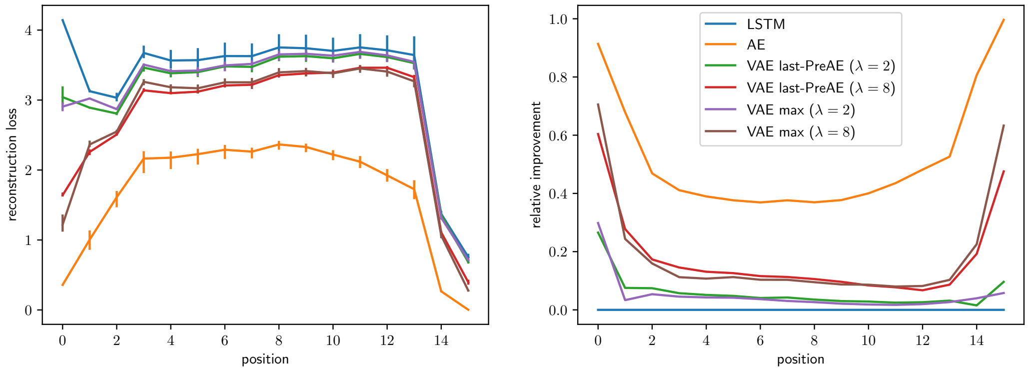

Figure 1: *Left*: Reconstruction loss on Yahoo dataset per each position in the sentence, averaged over sentences of 15 words (error bars: min, max on 3 runs); *Right*: Relative improvement compared to baseline LSTM. Seq2seq autoencoders consistently store information about the first couple of words as well as the sentence length in priority.

In Figure 1, the left-hand side plot shows the reconstruction losses of different models and different target rates λ on the Yahoo dataset. As expected, for all models, raising the target rate lowers the reconstruction cost. Remarkably, these gains are very focused around the beginning and the end of documents. For a clearer picture of the gains at the end of the sentence, we plot the *relative improvement* in reconstruction with respect to the baseline (right-hand side of Figure 1) using:

$$\tilde{r}(i) = \frac{\max(r_{\text{LSTM}}(i) - r(i), 0)}{r_{\text{LSTM}}(i)}$$

where $r_{\text{LSTM}}(i)$ is the loss of the LSTM.

All the models reconstruct the first couple of words and the penultimate token better than the *LSTM-LM*. On the three other datasets, there are similar peaks on relative improvements in the beginning and the end of sentences (Appendix B.1).

It is not obvious that a lower reconstruction at a given position corresponds to information stored about the word in that position in the latent vector. Indeed, words are not independently modeled. However, we argue that it is roughly the case because the decoder is factorised from left-to-right and because correlations between words decrease with their distance in the sentence. The argument is detailed in the Appendix B.2.

How much do these gains on the reconstruction loss translate to decoding the first words and the document lengths more accurately? To find out, we compare regular VAEs to fixed-encoder, ideal VAEs that encode the true label perfectly and exclusively (in other words, VAEs whose latent variable is the ground-truth label). On sentence reconstruction, we found that regular VAEs decoded the first word 2 to 5 times more often than the baselines, indicating memorization of the first word. We also found similar but less dramatic results for sentence length (see Appendix B.3 for details).

This phenomenon was already noticed by Kim et al. (2018), using a different method (saliency measures, see Appendix D.2 for details).

To sum up, compared to an unconditional *LSTM-LM*, the seq2seq VAEs incur a much lower reconstruction loss on the first tokens and towards the end of the sentence (around 50% less with $\lambda = 8$). Moreover, if the latent variable of the VAEs did encode the label perfectly and exclusively, they would reconstruct the first words or recover sentence length with much lower accuracy than what is observed. Therefore, we conclude that seq2seq VAEs are biased towards memorizing the first few words and the sentence length.

3.2 The problem with memorization

One could argue that this is a superficial problem, as we can always give the model more free bits and decrease the loss in intermediary positions. However, this is not so simple because increasing capacity leads to a worse model fit, as was noted by Alemi et al. (2018). More specifically, on text data, Prokhorov et al. (2019) noted that the coherence of samples decreases as the target rate increases. Pelsmaeker and Aziz (2019) reported similar findings, and also, that more complex priors or posteriors do not help. Therefore, given current techniques, higher rates come at the cost of worse modeling of the data and therefore, we should strive for latent-variable models that store less information, but more global information.

Secondly, for controllable generation, conditioning on memorized information is useless. When the first words are encoded in the latent variable, the factorization of the VAE becomes the same as that of the usual autoregressive models, which are naturally able to continue a given beginning of the sentence (a "prompt"). Similarly, document length is easily controlled by stopping the sampling after producing the desired number of words.[3] Finally, even for semi-supervised learning, a classifier that would only use the first few words and the sentence length would be suboptimal.

If these arguments are correct, it is doubtful that common seq2seq VAE architectures and training procedures in the low-capacity regime would learn useful representations. This is precisely the third problem: most of the KL values reported in the literature are low.[4] Therefore, it is not clear whether the reported gains in performance (however measured) are significant, and if they are, what exactly cause these gains.

4 Improving existing models

What architectures could avoid learning to memorize? We investigate simple variants and for a more thorough comparison with existing models, we refer to Appendix D.1.

Our first variant uses a simple bag-of-words (*BoW*) encoder in place of the LSTM encoder. The sentence representation is $r^j = \max_i e_i^j$, where the exponents denote components, and the indices denote positions in the sentence. We call it *BoW-max-LSTM*. It is similar to the max-pooling model of Long et al. (2019) except that the maximum is taken over embeddings rather than LSTM hidden states. As Long et al. (2019) reported, the max-pooling operator is better than the average operator, both when the encoder is a LSTM and *BoW* (possibly because the maximum introduces a non-linearity). Therefore, we use the maximum operator. A priori, we think that since word order is not provided to the encoder, the encoder should be unable to memorize the first words.

For our second variant we use a unigram decoder (*Uni*) in place of an LSTM decoder. It produces a single output probability distribution for all positions in the sentence i, conditioned only on the latent variable z. This distribution is obtained by applying a one-hidden layer MLP followed by softmax to the latent vector: $p_\theta(x_i|z) = \text{softmax}(W_2 \text{ReLU}(W_1 z) + b)$, where $\text{ReLU}(x) = \max(x, 0)$ (Nair and Hinton, 2010). We hope that the encoder will learn representations that do not focus on the first words, because the decoder should not need this particular information. We can use any encoder in combination of this decoder and if we use a *BoW* encoder, we obtain the NVDM model of Miao et al. (2016).

Both the *BoW* encoders and *Uni* decoders variants might benefit from the *PreAE* pretraining technique, but we leave this for future work.

Lastly, the pretrained LM (*PreLM*) variant is obtained in two training steps. First, we pretrain a *LSTM-LM*. Then, it is used as an encoder with fixed weights. We use average pooling over the hidden states to get a sentence representation, i.e., $r = \frac{1}{L}\sum_{i=1}^{L} h_i$, and learn the transformations L_1 and L_2 that compute the variational parameters. Initially, we tried to use max-pooling but the training was extremely unstable. The LM objective requires the hidden state to capture both close correlations between words but also more global information to predict long-distance correlations. The hope is that this global information can be retrieved via pooling and encoded in the variational parameters. The *PreLM* variant is nothing more than the use of a pretrained LM as a feature extractor (Peters et al., 2018). While Yang et al. (2017) and Kim et al. (2018) both consider the use of pretrained LMs as encoders, the weights are not frozen such that it is hard to disentangle the impact of pretraining from subsequent training. In contrast, we freeze the weights so that the effect of pretraining can not be overridden. To isolate the effect of this training procedure independently of the architecture, we keep the same LSTM instead of using more powerful architectures such as Transformers.

5 Semi-supervised learning evaluation

We turn to the semi-supervised learning (*SSL*) setting to compare the learned representations of our variants. For the purpose of controllable text generation, we assume that the global information that is desirable to capture is the topic or sentiment. There are two training phases: first, an unsupervised pretraining phase where VAEs are trained; second, a supervised learning phase where classi-

---

[3] Or by explicitly conditioning on the sentence length. It can be useful for unsupervised summarization (Schumann, 2018), in flow-based approaches (Ziegler and Rush, 2019), or more broadly for the decoder to plan sentence construction.

[4] Most papers do not report the log base (1 bit is $\ln(2) \approx 0.693$ nats). Here are some reported rates of the best models: Bowman et al. (2015): 2.0 (PTB) ; Long et al. (2019): 3.7 (Yahoo), 3.1 (Yelp); Li et al. (2019): 15.02 (Yahoo), 8.15 (PTB); He et al. (2019): 5.6 (Yahoo), 3.4 (Yelp); Fu et al. (2019): 1.955 (PTB), ...

fiers are trained to predict ground-truth labels given the latent vectors encoded with the encoders of the VAEs. This is essentially the same setup as *M1* from Kingma et al. (2014).[5] The small and large data-regimes give us complementary information: with many labels and complex classifiers, we quantify *how much* of the information pertaining to the labels is encoded; with few labels and simple classifiers, *how accessible* the information is.

For each dataset, we subsample $g = 5$ balanced labeled datasets for each different data-regimes, containing 5, 50, 500, and 5000 examples per class. These labeled datasets are used for training and validating during the supervised learning phase.[6] Each model is trained with $s = 3$ seeds. The performance of the classifiers are measured by the macro F1-score on the entire test sets.

To select hyperparameters on each subsample, we use repeated stratified K-fold cross-validation (Moss et al., 2018) as detailed in the Appendix E.1. We obtain the test set F1-scores F_{ij}, where i is the subsample seed and j is the parameter initialisation seed, and report $\bar{F}_{\cdot\cdot}$, the average F1-score over i and j. We note $\bar{F}_{\cdot j}$ the empirical average F1-score for a given parameter initialisation j and decompose the variance into:

- $\sigma_{\text{init}} = (\frac{1}{s-1}\sum_{j=1}^{s} g(\bar{F}_{\cdot j} - \bar{F}_{\cdot\cdot})^2)^{\frac{1}{2}}$, which quantifies the variability due to the initialisation of the model,
- $\sigma = (\frac{1}{g}\sum_{i=1}^{g} \frac{1}{s-1}\sum_{j=1}^{s}(F_{ij} - \bar{F}_{\cdot j})^2)^{\frac{1}{2}}$, which quantifies the remaining variability.

In the context of ANOVA with a linear model and a single factor, these quantities are the square roots of MS_T and MS_E (see Appendix E.2).

Finally, we also add a data-regime where the entire labeled training set is used in the supervised learning phase. In this setting, we use more expressive one-hidden-layer MLP classifiers, with early stopping on the validation set. Thus, we can check that our conclusions in the large data-regime do not depend on the model selection procedure and the choice of the classifier.

For each class of model, we perform a grid search over target rates and latent vector sizes. We search for target rates λ in $\{2, 8\}$: large enough to capture label information but small enough to avoid underfitting, as explained above. The size of latent vectors d are chosen in $\{4, 16\}$. They should be small enough for extremely low-data regimes. For instance, on Yelp, the smallest data regime (5 per class) uses only 8 examples to train the classifier and 2 to do cross-validation. A thorough explanation is presented in Appendix C, along with the values of hyperparameters held constant.

What representation should be used as inputs to the classifiers? Kingma et al. (2016) use samples from the approximate posterior $q_\phi(z|x) = \mathcal{N}(z|\mu, \text{diag}(\sigma^2))$, but in the NLP literature, most evaluations focus on μ without mention or justification. To evaluate the VAE as a generative model, we claim that only noisy samples z should be used. In fact, using a model with a rate close to 0 on Yelp, we can recover the label with a high F1-score of 81.5% by using μ, whereas, as expected, noisy samples z do not do better than random (50%). The information contained in μ is misleading because it is not transmitted to the decoder and not used directly during generation. Therefore, we use samples z (cf. Appendix E.3 for details).

5.1 Results

Table 1 contains the results of the SSL experiments in the smallest and largest data-regimes. The results for intermediary data-regimes as well as for baseline models without pretraining, which underperform, are presented in the Appendix, Table 8. The proposed variants are either on par or improve significantly over the baselines. In the large data-regime, *BoW-max-LSTM* and *LSTM-avg-LSTM-PreLM* perform best on average while *LSTM-last-Uni* performs the worst and suffers from unstable training on AGNews. In the small data-regime, the picture is less clear because there is more variance.

On AGNews and Yelp, in the large data-regime, our variants do not seem to improve over the baselines. However, on Amazon and Yahoo, in the large data-regime, the variants seem to improve by 5 in F1-score. Why do the gains vary so widely depending on the datasets? We posit that, on some datasets, the first words are enough to predict the labels correctly. We train bag-of-words classifiers [7] using either i) only the first three words or ii) all

---

[5] We could integrate the labels into the generative model as a random variable that is either observed or missing to obtain better results (Kingma et al., 2014). Still, our goal is to study the inductive bias of the seq2seq VAE *as an unsupervised learning method*, so we do not train the encoder using the labels.

[6] It is especially important to use several subsamples in the low data-regimes where subsamples containing unrepresentative texts or noisy labels are not unlikely.

Table 2: Our variants reconstruct inputs with higher agreement, less memorization of the 1st words and lengths and a negligible loss in likelihood. Best score and scores within one standard deviation are bolded.

the words as features on the entire datasets. If the *three-words* classifiers are as good as the *all-words* classifiers, we expect that the original VAE variants will perform well: in that case, encoding information about the first words is not harmful, it could be a rather useful inductive bias. Conversely, if the first three words are not predictive of the label, the original VAEs will perform badly.

As reported in the Appendix, Table 9, on AGNews and Yelp, classifiers trained on the first three words have a performance somewhat close to the classifier trained on all the words, reaching 80.8% and 85.4% of its scores respectively. For instance, on AGNews, the first words are often nouns that directly gives the topic of the news item: country names for the politics category, firm names for the technology category, athlete or team names for the sports category, etc. On the two other datasets, the performance decays a lot if we only use the first three words: *three-words* F1-scores make up for 60.7% and 30.3% of *all-words* F1-scores on Amazon and Yahoo. This explains why the original VAE can perform on par or slightly better than our variants on certain datasets for which the first words are very predictive of the labels. This also proves that using several datasets is necessary to draw robust conclusions.

Despite similar asymptotic performance on AGNews and Yelp, our variants clearly improve over the baselines in the small data-regime, which suggests that the encoded information is quantitatively different. This is confirmed in the next section.

It might be surprising that *LSTM-max-LSTM* models are inferior to *BoW-max-LSTM* models. In Appendix E.4, we show that with recurrent encoders, some components of the hidden states are consistently maximized at certain early positions in the sentence. This explains why the power of LSTMs can be undesirable, and why the simpler *BoW* encoders perform better.

6 Text generation evaluation

How do these different variants perform during generation? We expect that the SSL classification

---

dimension of 200 and the default parameters.

performances would correlate with the abilities of the decoders to reconstruct documents that exhibit a similar global aspect than the encoded documents.

To measure the agreement in label between the source document and its reconstruction, we adapt the evaluation procedure used by Ficler and Goldberg (2017) so that no human annotators or heuristics are required (see Appendix D.2). First, a classifier is trained to predict the label on the source dataset. Then, for each model, we encode the documents, reconstruct them, and classify these reconstructions using the classifier. The *agreement* is the F1-scores between the original labels and the labels given by the classifiers on the generated samples.

To quantify memorization, we measure the reconstruction accuracy of the first word and the ratio of identical sentence length between sources and reconstructions. Finally, to verify that our bag-of-words assumptions do not hurt the overall fit to the data, we estimate the negative log-likelihood via the importance-weighted lower bound (Burda et al., 2015) (500 samples) to compute an approximate perplexity per word ($\approx$*PPL*).

We use two decoding schemes: beam search with a beam of size 5 and greedy decoding. We fix $\lambda = 8$, $d = 16$ on all models, with three seeds. For the *Uni* decoder, we drop *LSTM-last-Uni* which underperformed by a large margin in the SSL setting, and for the other *Uni* models, we freeze the encoder, L_1 and L_2 and train a new recurrent decoder using the reconstruction loss only. Essentially, the *Uni* decoder is an *auxiliary decoder*, as described by De Fauw et al. (2019) (see Appendix D.1 for details) and we denote this technique by *PreUni*.

Table 2 show the results for beam search decoding.[8] There is a close correspondence between agreement and performance on the SSL tasks in the large data-regime. Our variants have a higher agreement than the baselines, especially on Amazon and Yahoo datasets for which the memorization of the first words is especially harmful.

The baselines reconstruct the first words with very high accuracy (more than 50% of the time on Yahoo and Yelp) while our variants mitigate this memorization. For instance, *PreUni* models recover the first word around 2 or 1.5 times less often.

Let us focus on AGNews and Yelp, where the first words are very predictive of the labels. Both baselines and variants have roughly similarly high agreement. However, our variants produce more diverse beginnings, while still managing to reproduce the topic or sentiment of the original document. On the other hand, the reconstructions of the baselines exhibit the same labels as the sources mostly as a side-effect of starting with the same words. This also explains that in the SSL setting, despite similar performances asymptotically, our variants were much more efficient using five examples per class. Memorization of the first words does not abstract away from the particular words and therefore, the amount of data required to learn a good classifier will be high, compared to a model which truly *infer* unobserved characteristics of documents.

Both *BoW* encoders and *Uni* decoders lower memorization, so bag-of-words assumptions are efficient for dealing with the memorization problem. Still, *BoW-Max* and *LSTM-Max* with *PreUni* pretraining yield very close performance despite having a different encoder, showing that the decoder has a far greater influence than the encoder. This is consistent with McCoy et al. (2019)'s findings (see Section D.2 in Appendix for details).

Finally, there seems to be a trade-off between the global character of the latent information and the fit of the model to the data. *BoW* and *Uni* variants have perplexity roughly one unit above the baselines, a significant but small difference.

In Appendix F, we perform a qualitative analysis of reconstruction samples to illustrate these conclusions. It also sheds light on the inherent difficulty of the Yahoo dataset.

To recapitulate, the bag-of-words assumptions decrease the memorization of the first word and of the sentence length in the latent variable while increasing the agreement between the labels of the source and of the reconstruction. This is achieved at the cost of a small increase in perplexity.

7 Conclusion

Eliminating posterior collapse is necessary to get useful VAE models, but not sufficient. Although recent incarnations of the seq2seq VAE fix the posterior collapse, they partially memorize the first few words and the document lengths. Depending on the data, these local features are sometimes not very correlated with global aspects like topic or sentiment. Therefore, they are of limited use for controllable and diverse text generation.

To learn to infer more global features, we ex-

---

[8] Similar results were obtained using greedy decoding, albeit sometimes consistently shifted.

plored alternative architectures based on bag-of-word assumptions on the encoder or decoder side, as well as a pretraining procedure. These variants are all effective, in particular, the unigram decoder used as an auxiliary decoder (De Fauw et al., 2019). The latent variable is more predictive of global features and memorisation of the first words and sentence length is decreased. Thus, these models are more suitable for diverse and controllable generation.

Methodologically, we introduced a simple way to examine the content of latent variables by looking at the reconstruction loss per position. We also presented a reliable way to perform semi-supervised learning experiments to analyze the content of the variable, free of the problems that one can find in past work (incorrect model selection for small data-regimes, use of samples instead of variational parameters as inputs). We showed that there are particularly difficult datasets for which the first words are not very predictive of their labels, and therefore, these datasets should be systematically used in evaluations. Moreover, the agreement metric is another complementary evaluation that is automatic and focused on generation. We hope that these methods will see widespread adoption for measuring progress more reliably.

A promising research direction is to investigate the root cause behind memorization. A simple reason for the memorization of the first few words could be that, in the beginning of training, the reconstruction loss is higher on these words (see *LSTM-LM* in Figures 1, 2, 3, 4). These early errors should therefore account for a proportionally large part of the gradients and pressure the encoder to store information about the first words. If that is correct, the left-to-right factorization of the decoder could be at fault, which would explain the successes of the unigram decoders. More powerful decoders with alternative factorizations could avoid this issue, for example, non-autoregressive Transformers (Gu et al., 2017) or Transformers with flexible word orders (Gu et al., 2019).

VAEs operate on uncorrupted inputs and learn a corruption process in the latent space. In contrast, models in the BERT family (Devlin et al., 2018) are given corrupted inputs and are penalized only on these corrupted inputs, thereby avoid memorization altogether. Therefore, another research avenue would be to blend the two frameworks (Im et al., 2017).

A On the use of KL annealing, the choice of the free bits flavor and resetting the decoder

Li et al. (2019) evaluated their models in the SSL setting (Section 3.3 of their paper). However, their experimental setting is not very rigorous. In the case of the 100 labeled examples, hyperparameter selection is done on a very large validation set of 10000 examples. However, the validation set here should be seen as nothing more than a split of the training data dedicated to optimising hyperparameters. In the words of Cawley and Talbot (2010), “model selection should be viewed as an integral part of the model fitting procedure”. Besides methodological issues, we run our own hyperparameter search on the Yelp dataset to properly disentangle the effects of KL annealing, the free bits method and verify the importance of resetting the decoder. We use the semi-supervised learning setting presented in Section 5 to evaluate the learned encoders.

A.1 The free bits technique and variants

The *original* free bits objective (Kingma et al., 2016) is the following modification to the KL term:

$$\sum_{j}^{K} \max(\frac{\lambda}{K}, KL(q_j(z_j|x)||p_j(z_j)))$$

where indices denote components. In this formulation, each component of the multivariate normal is allowed to deviate from the prior by a small amount. Instead, in the δ-VAE formulation, one component can use of all the λ free bits and the rest of the components can collapse to the prior. This is the variant called δ, used throughout the paper:

$$\max(\lambda, KL(q(z|x)||p(z)))$$

Other modifications of the free bits technique include the use of a variable coefficient in front of the KL term (Chen et al., 2016), the target rate objective in Alemi et al. (2018), minimum desired rate (Pelsmaeker and Aziz, 2019), etc. A comparison of all these methods is out of the scope of this paper and the δ variant satisfies our only requirement: the rate should be close to the desired rate.

A.2 KL annealing and the original free bits method higher the rate

Our hypotheses are:

- KL annealing aims at fixing the posterior collapse and is therefore redundant with the free bits,
- KL annealing performs this role by increasing capacity inconsistently across models, making them harder to compare,
- the original free bits formulation impose the unnecessary constraint that the free bits should be balanced over all components.

To study the influence of the free bits variant as well as of KL annealing, we use the same experimental protocol as described in Section 5. To save computations, we fix $d = 16$. We do not perform model selection on the desired rate λ in order to see which methods yield the rates that are closest to the desired rate. Table 3 shows these hypotheses are correct. Therefore, all the experiments in the paper use the δ variant without annealing.

In Li et al. (2019)’s work, the original, per-component variant of the free bits might have been chosen because it trivially maximizes a metric called *active units* (AU). However, to our knowledge, there is no evidence that this metric should be maximized, neither theoretical nor empirical.

A.3 On the importance of resetting the decoder after pretraining

Li et al. (2019) proposed to pretrain an *AE* with a reconstruction loss only. Then, the parameters of the decoder are re-initialised and the (modified) KL term is added to the objective. Since it is not very clear why it would be useful, we studied the impact of this choice. Table 4 shows that it is is crucial.

B Further evidence for memorization

B.1 Plots on other datasets

Figures 2, 3, and 4 show the reconstruction loss and the relative improvement on other datasets.

On the Yelp dataset, the penultimate token is a punctuation mark which is always followed by the end-of-sentence token, so predicting its position is equivalent to predicting the sentence length. That is why the peak at the end occurs before the last token. Moreover, on Yelp, the situation is worse with $\lambda = 2$: between positions 6 and 13, not only is there no improvement, but the reconstruction is higher than that of the baseline.

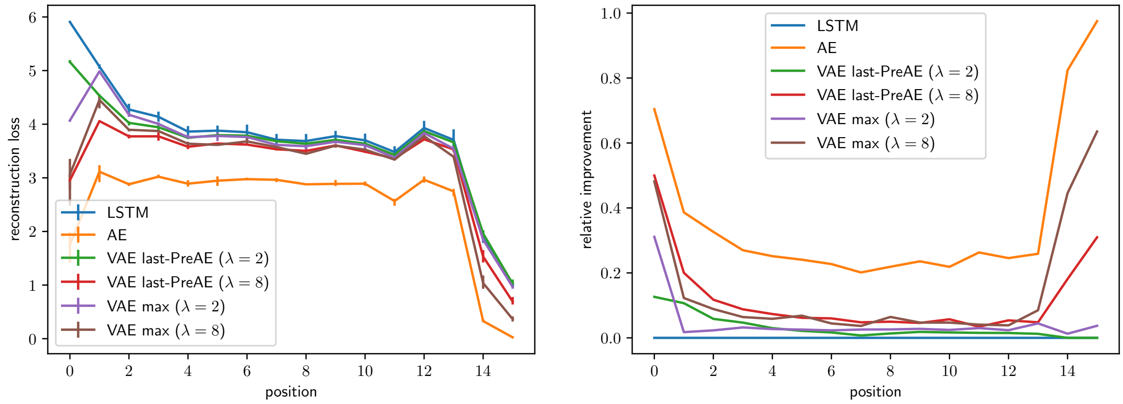

Figure 2: Reconstruction loss as a function of word position on the AGNews dataset. See Figure 1.

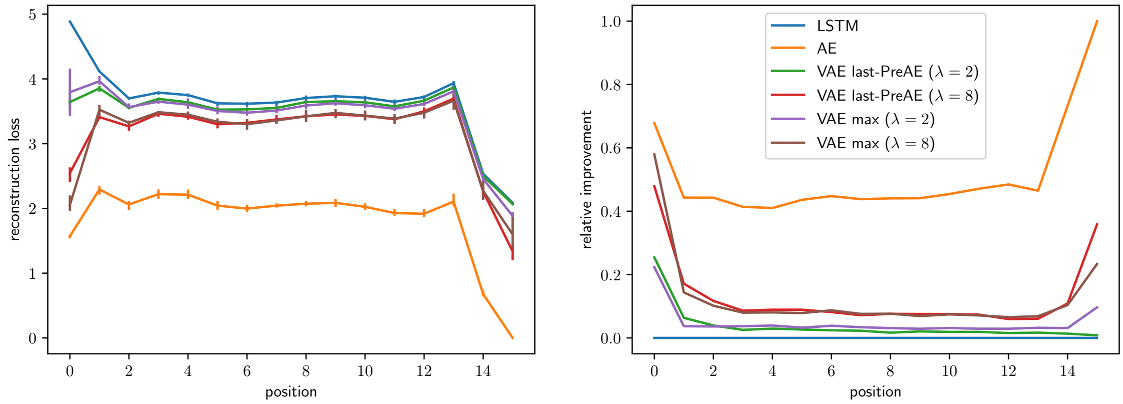

Figure 3: Reconstruction loss as a function of word position on the Amazon dataset. See Figure 1.

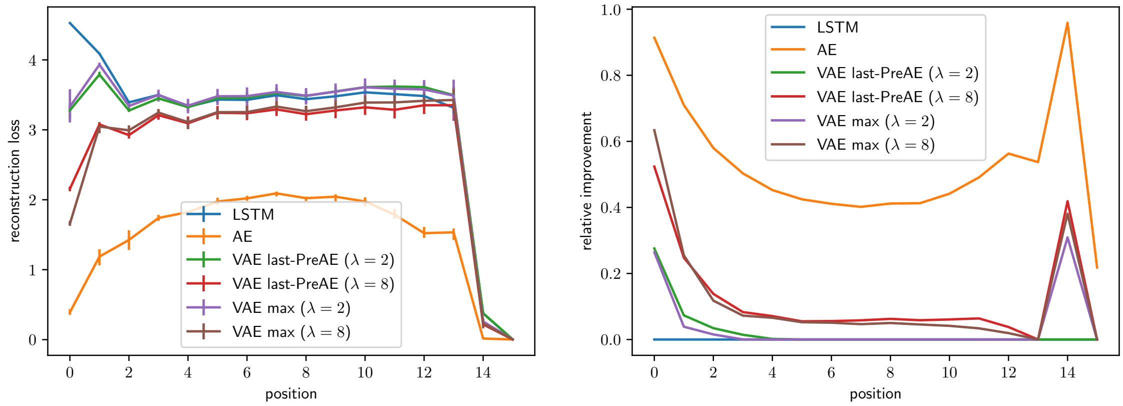

Figure 4: Reconstruction loss as a function of word position on the Yelp dataset. See Figure 1.

Yelp	100/10/10	Sent.	2	0.67	34.60±0.28

Table 5: Datasets characteristics. $|\mathcal{Y}|$: number of different labels. $H[Y]$: entropy of labels. NLL: mean negative log-likelihood of LSTM baseline models (std. over 3 runs). Splits size: train/valid/test sizes in thousands.

B.2 Tracing back reconstruction gains to words

If words in a document were independently modeled, any improvement in reconstruction at a certain position would indicate that information about the word in that position were encoded in the latent variable. However, words are far from being independently predicted, so how can we trace back the information to the encoder?

First, any latent information related to the first word should not yield any improvements on the prediction of the second word, because the decoder is recurrent and trained using teacher forcing, i.e., conditioned on the true first word, so that information would be redundant. However, information related to the second word in the latent variable can help the decoder predict the first word. Therefore, gains in position i can only be attributed to information pertaining to the words in positions $\geq i$.

Second, the correlation between words in two positions decreases as the distance between these words grow. In effect, information pertaining to the second word yields more gains on the second word than on the first word. From these two facts, we conclude that gains for a position i mostly comes from information about the word in position i itself.

B.3 Reconstruction and memorization

To study the concrete impact of this observation for generation, we encode and decode test documents using the *last-PreAE* variant.[9] Then, we compute the ratio of documents for which the first word in the sources and in the reconstructions match and similarly, how often the sources and their reconstructions have the same number of words.

We compare these with scores obtained by a baseline model that outputs the most frequent first word given the label and the most common document length given the label. This baseline mimicks the behavior of a hypothetical VAE which would encode the labels of the documents (topic or sentiment) perfectly and nothing more.

Results in Table 6 show that with the *last-PreAE* the first words are reconstructed with much higher accuracy than if the latent vector only encoded the label. On the last two datasets, it recovers the first

---

[9] $\lambda = 8$, $d = 16$, beam search with beam size of 5.

Dataset	*last-PreAE* 1st (%)	*last-PreAE* Len. (%)	Clf. given label 1st (%)	Clf. given label Len. (%)
AGNews	29.6±1.1	3.6±0.1	12.9	4.8
Amazon	42.4±2.3	13.0±1.6	14.0	0
Yahoo	56.6±1.0	17.1±1.1	11.3	4.9
Yelp	53.0±0.5	33.7±1.7	14.1	9.7

Table 6: The latent variables encode more information than the label alone, in particular, information that allows to retrieve the first word and the document length with high accuracy.

words on more than half of the documents whereas the baseline only recovers the first words between 11.3 and 14.1% of the time. Accurate encoding of the number of words seems less systematic than the encoding of the first few words. For example, on AGNews, the sentence length is recovered less often than our baselines. The encoding of the sentence length is more pronounced on datasets with small documents like Yahoo and Yelp.

C Training procedure

C.1 Grid search

The target rates λ are chosen to be higher than the entropy of the labels of the documents (Table 5) as we assume that the latent variable should at least capture the annotated label. Indeed, $\lambda = 2$ nats is enough to store the labels of all datasets without any loss, except Yahoo which has an entropy of 2.3 whereas $\lambda = 8$ nats suffices to capture much more information than needed to store the labels on all datasets. Moreover, these rates are chosen to be much smaller than the reconstruction loss of the baselines because of the technical difficulty of increasing the rate without degrading the log-likelihood explained above.

The latent vector dimension d is either 4 or 16. Recall that our representations are evaluated on downstream tasks with very limited data in some cases (as little as 5 examples per class), so we need a small enough dimension of latent vector to be able to learn. We suppose that $d = 4$ will be favored for the 5 or 50 examples per class regime while $d = 16$ could be more efficient above this, but we leave this choice to the model selection procedure.

C.2 Constant hyperparameters

All the runs are trained using SGD with a learning rate of 0.5 and gradients are clipped when their norms are higher than 5. We use the following early stopping scheme: at every epoch, if there has not been improvements on the validation error for two epochs in a row, the learning rate is halved. Once it has been halved four times, the training stops.

All the LSTMs have hidden state size of 512 and use a batch size of 64. No dropout is applied to the encoders. The LSTM decoders use dropout ($p = 0.5$) both on embeddings and on the hidden states (before the linear transformation that gives logits). Similarly, dropout is applied to the representation before the linear transformation that gives the logits for the Unigram decoder. Word embeddings are initialized randomly and learned.

C.3 Computing infrastructure and average runtime

We performed training and evaluations of the models on a cluster containing a hundred of GPUs with various specifications (NVIDIA Tesla k80, Titan X, Titan Xp, etc.). Given that all the datasets have roughly 100000 training examples (cf. Table 5) and that neural networks are trained with BPTT (Werbos, 1990), the training time mostly depends on the average sentence length and the vocabulary size. Pretraining schemes (*PreAE*, *PreUni* and *PreLM*) require the training of two models. Roughly, the training time of a single model (pretraining or final) varied between 1 hour and 6 hours.

To be more specific, the best baselines and our best variants use pretraining phases (*PreAE* from Li et al. (2019) and *PreUni*, respectively). *PreUni* is faster because the first training phase uses a non-recurrent decoder, and the second training phase does not backpropagate and does not update the encoder. However, *PreAE* does not require pretraining for each desired target rate λ, unlike our approach. Overall, the approaches have comparable runtimes.

Some of our models offer an interesting compromise: *BoW-max-LSTM* with no pretraining and a simpler architecture is probably the fastest, yet outperform the *PreAE* baselines.

D Related work

D.1 Related models

The models that we use are similar to already proposed models.

The NVDM model of Miao et al. (2016) is precisely *BoW-max-Uni*.

Zhao et al. (2017) proposed to use two reconstruction losses: the regular reconstruction loss given by the recurrent decoder and an auxiliary loss computed from a unigram decoder. In comparison, our *Uni* models are trained in two steps: the encoder is trained jointly with the unigram decoder, then the decoder is thrown away and we train a recurrent decoder using the fixed encoder. This way, one decoder cannot dominate the other and we do not have to deal with an additional hyperparameter to weight the two losses.

Instead of using an auxiliary *loss*, we have an auxiliary *decoder* that is only used for the purpose of training the encoder. This method was presented by De Fauw et al. (2019) for training generative models of image. There is a slight difference: they use a feedforward auxiliary decoder to produce different probability distributions for all the pixels, whereas our unigram probability distribution is the same for all words of a document. This modification allows us to deal with varying lengths of documents.

Finally, the *PreLM* training procedure is related to large LM pretraining in the spirit of contextualized embeddings (Peters et al., 2018) and its successors. Note, however, two differences. Firstly, we do not use external data and stick to each individual training set, because the goal is not to evaluate transfer learning abilities. Secondly, we do not fine-tune the entire encoder, but only learn the linear transformations L_1 and L_2 that produce the variational parameters, to make sure that the VAE objective will have no impact on the extraction of features.

D.2 Methods and evaluations

In their analysis of the semi-amortized VAE, Kim et al. (2018) use several saliency measures (defined as expectations of gradients) to determine which words influence the latent variable, or are influenced by it. Using these measures, they noticed that the beginning of the sentence and the end-of-sentence token have a large influence on the variable. Our method is very similar, but slightly simpler and directly interpretable in terms of quantity of information (in nats).

Ficler and Goldberg (2017) learn *LSTM-LMs* conditioned on labels that describe high-level properties of texts. Among others, they want to verify that generated texts exhibit the same properties as the conditioning labels. For instance, when the *LSTM-LM* is conditioned on positive sentiment value, the generated texts should also exhibit a positive sentiment. To check that the conditioning variables and the generated texts are consistent, they use the following procedure. First, they extract information about the various documents using heuristics or with the help of annotators. Then, they learn *LSTM-LM*s conditioned on these labels. Finally, they quantify the ratio of generated samples which have the same labels than the conditioning labels, either by applying the same heuristics again to the generated samples or by asking human annotators once more. Our evaluation in Section 6 is similar; we simply replace the heuristics and the human annotators with classifiers learned on ground-truth data.

McCoy et al. (2019) trained autoencoders with different combinations of encoders and decoders (unidirectional, bidirectional or tree-structured) and decomposed the representations learned by the encoders using tensor product representations (Smolensky, 1990). They find that decoders "largely dictate" the way information is encoded. This is in line with our own conclusions. An important difference between our works is that they study how information is encoded in sequence-to-sequence models without capacity limitations, whereas in our study, the VAE objective puts severe constraints on the capacity.

E Semi-supervised learning experiments

E.1 Model selection

For a given dataset in a given data-regime, we want a measure of the performance of our models that abstracts away from i) hyperparameters for the VAEs, ii) hyperparameters for the downstream task classifiers, iii) subsampling of the dataset and iv) parameter initialisation of the VAEs. As is usually done by practitioners, we optimize over the hyperparameters of the VAEs and the classifiers, eliminating i) and ii) as sources of variance. We can study the robustness of the models by looking at the variance induced by the choice of the subsample and the initialisation of the parameters.

On a given dataset and in a given data-regime, for a given model, we note $F_{ij}^{H_M,H_C}$ the F1-score obtained on the test set on the subsample using seed i, the parameter initialisation using seed j, VAE hyperparameters H_M and classifier hyperparameters H_C. We use repeated stratified K-fold cross-validation (Moss et al., 2018) to compute a validation error $\widehat{F_{ij}^{H_M,H_C}}$. For all training folds, we train logistic regression classifiers with L_2 regularisation and a grid-search on $H_C \in \{0.01, 0.1, 1, 10, 100\}$. We select the best classifier hyperparameter:

$$H_C^* = \arg\max_{H_C} \widehat{F_{ij}^{H_M,H_C}}$$

Then, the best VAE hyperparameter is chosen by averaging over the $s = 3$ random seeds and picking the best classifier hyperparameter,

$$H_M^* = \arg\max_{H_M} \frac{1}{s} \sum_{i=1}^{s} \widehat{F_{ij}^{H_M,H_C^*}}$$

Having optimised the hyperparameters, we compute the test set F1-score:

$$F_{ij} = F_{ij}^{H_M^*,H_C^*}$$

E.2 Decomposing the variances of the scores

For a given model, dataset and data-regime, after optimisation of the hyperparameters of the VAE and the classifier, we collect several F1-scores F_{ij} which depend on the seed used to subsample the dataset i and the seed used to initialise the model parameters j. We posit a linear model with one random-effect factor, the initialisation seed, and where replicates are obtained by varying the subsampling seed:

$$F_{ij} = \mu + \alpha_j + \epsilon_{ij}$$

Assuming that α_j and ϵ_{ij} are independent random variables with null expectations, we can decompose the variance as

$$\begin{aligned}
\mathrm{Var}(F_{ij}) &= \mathbb{E}[(F_{ij} - \mu)^2] \\
&= \mathbb{E}[(\alpha_i + \epsilon_{ij})^2] \\
&= \mathbb{E}[\alpha_i^2] + \mathbb{E}[\epsilon_{ij}^2] \\
&= \mathrm{Var}(\alpha_i) + \mathrm{Var}(\epsilon_{ij})
\end{aligned}$$

This is the basis of the method of analysis of variance (ANOVA) and is often used to test hypotheses (for instance, that the effect $\mathbb{E}[\alpha_i]$ is significant) (Oehlert, 2010). The two estimates of σ_{init}^2 and σ^2 are usually denoted MS_T and MS_E.

In our case, we are only interested in estimating roughly what variability is due to the model initialisation and what is due to the subsampling of the dataset.

Note that we could treat the two sources of variance i and j symmetrically by adding add a term β_i, but we would need to report 3 standard deviations (that of α_j, β_i and ϵ_{ij}) to get the full picture. The most important estimate is σ_{init}. It quantifies the inherent robustness of the model to different initialisations. The effect of the subsampling is specific to the dataset, therefore, it is less relevant to our analysis.

E.3 What is the representation of a document?

VAEs are mostly used for generating samples but are also sometimes used as feature extractors for SSL. In the latter case, it is not clear what the representation of a datapoint is: the mean of the approximate posterior μ or the noisy samples $Z \sim \mathcal{N}(\mu, I\sigma^2)$? Kingma et al. (2014) feed noisy samples z in the classifiers but in the literature of VAEs applied to language modeling, it is more common to use μ without explanation or even mention.[10]

If we are interested purely in downstream task performance, the mean should perform best, as the samples are just noisy versions of the mean vector (it is still not completely straightforward as the noise could play a regularizing role). However, in order to evaluate what information is *effectively* transmitted to the decoder, we should use the samples. The performance of downstream task classifiers using the mean does not tell us *at all* whether the latent variable is used by the decoder to reconstruct the input. The following experiment illustrates this fact.

We train the original VAE architecture on the Yelp dataset, both with and without the *PreAE*, using the original ELBo objective ($\lambda = 0$). As expected, the KL term collapses to 0. Then, we train a classifier using the procedure explained above using 5000 examples per class. We expect that its performance will be close to random chance, regardless of whether samples or the mean parameter are used as inputs. However, Table 7 shows that this is not the case. Using samples, we do get random chance predictions from the classifiers, whereas using means, the performance is remarkably high (as high as 81.5 of F1 using pretraining). The reason is that the KL term never *completely* collapses to 0. Therefore, μ can be almost zero while still encoding a lot of information about its inputs. However, when the KL term is close to 0, the variance of the

---

[10] For instance, Li et al. (2019) and Fu et al. (2019) do not mention what representation they use but their code uses the mean; Long et al. (2019) report using a concatenation of the mean and the variance vectors.

PreAE	F1		KL
	z	μ	
No	49.5	64.7	$1e^{-4}$
Yes	49.6	81.5	$2e^{-4}$

Table 7: When the KL collapses, the performances of classifiers trained on the mean μ vs on samples $z \sim \mathcal{N}(\mu, I\sigma^2)$ are very different, especially for pretrained models. z does not contain any information while μ is very predictive of the label.

samples is close to 1, so no information is transmitted to the decoder. This tendency is exacerbated with the *PreAE* runs, for which the means encode remnants of the pretraining phase.

This experiment shows that it is crucial to report what representation (z or μ) is analyzed and to cautiously interpret the results. Therefore, for the purpose of analysing representations for text generation, we feed z as inputs to the classifiers.

E.4 Recurrent and *BoW* encoders work around max-pooling

It is counter-intuitive that *BoW-max-LSTM* improves over *LSTM-max-LSTM* (with or without *PreAE*). Indeed, taking into account word order should allow the LSTM encoder to do better inference than the *BoW* encoder, for example, by handling negation or parsing more complicated discourse structure (Pang et al., 2002).

LSTM encoders are more powerful, but it can lead them to learn undesirable behaviors. We noticed that some components of the hidden states consistently reach their maximum values at fixed positions, regardless of the inputs (i.e., for some components j^*, $\arg\max_i h_i^{j^*} \approx K$). These positions K are often early positions in the sentence. For instance, with $\lambda = 8$, $d = 16$, *LSTM-max-LSTM-PreAE* has 70 components out of 512 that are selected on 80% of the documents on the same position on Yelp (68 on the first word, 2 on the second) and 78 on Amazon (57 on the first word, 21 on the second). In other words, some components of r act like memory slots assigned to fixed positions in the sentence. This is probably achieved through counting mechanisms (Shi et al., 2016; Suzgun et al., 2019). The decoder is also an LSTM and can count, so it can also extract the relevant components at each position to retrieve the corresponding words.

For *BoW* encoders, it is less clear. It is possible that on some datasets, capitalized words could take especially high values on some components, in order to be consistently represented after max pooling. However, we have not explored the issue further.

F Qualitative analysis

For our qualitative analysis, we take a look at the reconstruction samples (which were also used in Section 6). We focus on the *PreUni* models which lower memorization the most with the *LSTM-max* and *BoW-max* encoders, and compare them to the two best baselines. We use only one seed and one z sample per model and per source sentence, but use two decoding strategies (beam search and greedy decoding).

In general, and for the reasons explained above, the rate $\lambda = 8$ is chosen too small to recover exactly the source. Indeed, this rate is an order of magnitude less than the negative log-likelihood of *LSTM-LM* baselines: above 80 for all datasets except on Yelp where it is around 34.60 nats (cf. Table 5). Since the NLL is an upper-bound on the entropy of the data, it gives a crude over estimate of the information content of the average document. On Yelp, where the NLL is much smaller (around 34.60 nats), we hope to obtain good paraphrases for simple and frequent sentences. On the other datasets, we can not hope to reconstruct the sentences correctly but merely to control the generation by producing sentences which have the same labels as the source sentences. For this reason, we cherry-pick source sentences that look quite generic, because they are more probable and therefore, should be easy to reconstruct correctly.

Results are presented in Tables 10, 11, 12 and 13. Overall, we do observe less memorization of the first words and more correct sentiment or topic. Between our two models, on Amazon and Yelp (sentiment labels), it seems that *LSTM-max-LSTM-PreUni* might perform better than *BoW-max-LSTM-PreUni* because of its ability to handle negation, probably thanks to the recurrent encoder. It also seem more on topic on AGNews. On Yelp, it is able to paraphrase generic, small sentences. Therefore, we recommend this model as a future baseline.

We have already seen that it is very hard to classify sentences based on their first three words on the Amazon and Yahoo dataset, and that the baseline methods will learn representations that are not predictive of labels. However, the Yahoo dataset is

				5	50	500	5000	All
	r	Dec.	Pre.	$\text{F1}\pm^{\sigma}_{\sigma_{\text{init}}}$

Table 8: Using *BoW* encoders, *Uni* decoders or *PreLM* pretraining, the learned representations are more predictive of the labels (sentiment or topic) of the documents.

Dataset	F1(All)	F1(3)	Ratio
AGNews	89.0	71.9	0.808
Amazon	48.9	29.7	0.607
Yahoo	63.0	19.1	0.303
Yelp	96.5	82.4	0.854

Table 9: Performance of bag-of-word classifiers when using all words as features versus only the first three words. Ratios of performance vary a lot across datasets.

especially challenging and our methods also struggle on it. We hypothesize that it is because only a few words per sentences are correlated with the labels. Indeed, there are many sentences of the form “what do you think about *X*?” or “what is the difference between *X* and *Y*?” where only *X* and *Y* are correlated with the label and moreover often out-of-vocabulary. There might be no benefits for the model to diminish the reconstruction loss in priority on these words. By comparison, the other “hard” dataset (Amazon) is “easier”, because the sentiment is often indicated by frequent adjectives like “horrible” or “good” and other frequent verbs.

LSTM-max-LSTM-PreUni	greedy	what a disappointment .

Table 13: Cherry-picked Yelp samples. On small and typical sentences, our last variant LSTM-max-LSTM-PreUni can produce paraphrases. On the other hand, BoW-max-LSTM-PreUni fails on the two negative examples, probably because it lacks the ability to deal with negation. The baseline models also fail to capture the sentiment on the last example, and copy the beginning on the first three examples.

Content Planning for Neural Story Generation with Aristotelian Rescoring

Abstract

Long-form narrative text generated from large language models manages a fluent impersonation of human writing, but only at the local sentence level, and lacks structure or global cohesion. We posit that many of the problems of story generation can be addressed via high-quality content planning, and present a system that focuses on how to learn good *plot structures* to guide story generation. We utilize a plot-generation language model along with an ensemble of rescoring models that each implement an aspect of good story-writing as detailed in Aristotle's *Poetics*. We find that stories written with our more principled plot-structure are both more relevant to a given prompt and higher quality than baselines that do not content plan, or that plan in an unprincipled way.[1]

1 Introduction

Despite many recent advances in Natural Language Generation, successful creative narrative composition remains elusive. Current neural approaches are plagued by difficulty in mastering structure, will veer between topics, and lack long-range cohesion. They successfully imitate the fluency and style of human writing, but on closer inspection sentences do not fit together to form a whole, and the reader is left with the impression that the generation has no content (See et al., 2019). This lack of structure also degrades the relevance of generations conditioned on a prompt or other source text - a strong language model will repeat key phrases from a given prompt but will not remain on topic. These issues are illustrated in the `Naive Generated Story` in Table 1, where many of the sentences individually are fine, but do not fit together as one story, and do not all relate to the prompt.

We hypothesise that this problem can be addressed with a focus on deeper latent narrative structures. In Aristotle's *Poetics*, one of the most enduring treatises on the craft of writing good stories, the philosopher lays out the elements of story in order of importance. They are:

1. event choice and arrangement
2. character
3. relevant content[2]
4. diction

An amateur masters skills later in the list, but mastery of event choice and event arrangement is what distinguishes a good writer (Aristotle). Next is character, then relevance, and only finally do style and diction matter.

This philosophical framework fits remarkably well into the traditional Natural Language Generation Pipeline approach that emphasizes Content Planning (Reiter and Dale, 1997). The pipeline divides generation into three steps: *Content Planning*, *Microplanning* and *Surface Realization*, where at each step input is modified and refined, getting closer to the final textual output. Incorporating a plot in order to generate stories can then be viewed as a proxy for Content Planning/MicroPlanning before a language model makes use of it to convert it to a readable and grammatically correct natural language output (Surface Realization).

Inspired by both the Aristotelian and Content Planning Frameworks, we develop a novel system for story generation. We focus on developing a system that can learn to expertly select events, characters, and relevant content, and write good *plot structures*. After the work on the plot is complete, a large language model can then do what it does best and fill in the descriptions, details, and local specifics of each story.

[2] This directly translates as *thought* in the original, but is explained to clearly mean the selection of relevant information

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4319–4338,
November 16–20, 2020.

Prompt: Write the most beautiful end to the universe that you can imagine
Naive Plot with Semantic Role Labelling Tags: `<A1> The universe <V> end </s> </s> <A0> ent 0 <V> see <A1> ent 3 </s> </s> <V> dying <A1> ent 1 # <A0> ent 1 <V> left <A1> ent 0 </s> <A0> the last human <V> live </s> <A1> ent 6 <V> end # <A1> ent 2 <V> come </s> <A1> the last one <V> die </s> <A1> a universe of life <V> left`
Revised Plot with Semantic Role Labelling Tags: `<A2> The light <V> filled <A2> the sky </s> </s> </s> <A2> A bright flash <V> lit </s> </s> # <V> began <A2> to grow # <A2> the stars <V> grow </s> </s> <V> began <A2> ent 0 <A2> to fade # <A2> The stars <V> fade </s> </s> <A0> ent 2 <V> looked <A2> ent 1 me </s> <V> dying <A2> star`
Naive Generated Story: “You’re dead. I’ll be dead, and there’ll always be no more of you.”* *“No, my dear. It’s not true!” - The last of the world is dead, * * “It’ll never be over. *The universe* will n’t end. Not yet. But I’ll see it, one way or another. There is no other way.”* *My last thought, the *dying* man *left* me. He told that I was *the last human* to live. And he told me the universe would end, and the end will come soon. That your death would be *the last one* to die, and the first one to be the most beautiful. * “There is *a universe of life left*, my dear, and that’s all there is.
Generated Story (from revision): It was the end of the universe. *The light filled the sky*. The galaxy. All the light in all the worlds, and all the stars. *A bright flash*. The first light. And then a bright flash of light... then a flash of darkness. Then a bright light. A flash of blackness and then the stars *began to grow*. It was a bright, beautiful bright, light. And then, slowly the *stars* started to *grow* in number. There were millions and millions of stars.. But, slowly but surely, all the galaxies *began to fade*. Slowly, but surely. Finally, it *looked* at me with its eyes. One *dying star*.
Gold Story: It slept, and dreamt of twirling lights. It cradled countless twirling lights, all dancing in their flashing ways, dancing to the sound of a faraway flute. The light was vibrant and warm and spun all around It. The tiny lights grew with the tune, and more lights came to dance within the luminescence. It was surrounded by light, all waltzing in their ways to the distant music. It, too, swirled with the swelling symphony, watching the lights. There were lights of all different sizes and shades and brightness, but each was its own, unique light. Each one was brilliant. Each one was beautiful. All dancers to the Song...

Table 1: Our proposed plot and story generation structure. We generate a Naive Plot, revise it with Aristotelian rescorers, then generate a story. In plots, <V> denotes verbs while $<\mathrm{A}\{0,1,2\}>$ denote arguments. ent $\{0...n\}$ are entities. We removed newline symbol <P> from the generated stories and detokenized for better display.

For plot generation, we employ a few event-choice and event-arrangement rescoring models which assist in building the arc and cohesion of the plot, a character rescoring model that helps select which characters appear where, and a relevance model that is responsible for keeping the plot structure and the story on topic. As both improving plot-generation via rescoring and using an Aristotelian framework for neural generation are novel concepts, there is no previous work on how to implement them in practice.

Our contributions are: **1)** we propose to leverage the principled Aristotelian framework for content planning, **2)** we propose an implementation of the framework using a revision-based approach via several rescoring models **3)** we show strong experimental results against 4 baselines.

2 Background

Existing work in neural story generation has established the strength of adding a content planning stage to structure the generated content (Yao et al., 2019; Fan et al., 2019) (discussed in more detail in Section 7). Specifically, this line of work trains a pipeline with one model that generates from *prompt* → *plot* and another that generates from *prompt* + *plot* → story. It modifies the standard conditional generation task with a source $x = x_1 ... x_n$ (in this case, a prompt) and target $y = y_1 ... y_n$ (in this case, a story) to condition also on an abstract intermediate representation $\mathbf{z}$. Note that the approach is not truly modelling $p(\mathbf{y}|\mathbf{x})$ since that would involve summing over all $\mathbf{z}$. Instead, it models $p(\mathbf{y},\mathbf{z}|\mathbf{x}) = p(\mathbf{z}|\mathbf{x})p(\mathbf{y}|\mathbf{z},\mathbf{x})$, but only shows the generated story $\mathbf{y}$ at inference time.

This is a more controllable task than open-domain generation conditioned on only a prompt $\mathbf{x}$, provided that a good interim structure $\mathbf{z}$ can be learnt. We follow this line and explore ways to improve plot planning to close the gap between stories generated from gold plots and those from model-generated plots.

Plot Representation As there are no large datasets with parallel gold-standard plots and stories, all work on plot generation depends on silver-standard plots extracted from stories. We follow Fan et al. (2019) to represent plots in Semantic Role Labelling (SRL) format. We run coreference resolution to identify entities, and use a compression algorithm to discard less salient information.[3]

---

[3] Our representation is conceptually quite similar to that of Fan et al. (2019), but is not identical, as their code is un-

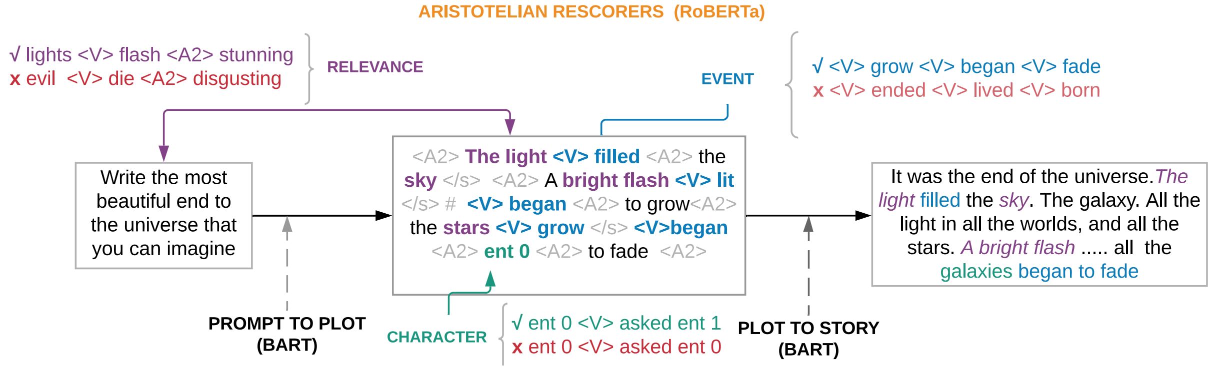

Figure 1: The full story generation pipeline. Base generation models in gray. Aristotelian rescorer input in color, with example positive & negative training pairs. Plot structure shown with SRL tags for verbs and their arguments.

3 Approach

We focus on learning the best interim plot structure between the input prompt and the story surface realisation. As such, we learn the plot model $p(\mathbf{z}|\mathbf{x})$ and the story model $p(\mathbf{y}|\mathbf{z},\mathbf{x})$ by fine-tuning a pretrained conditional language model BART (Lewis et al., 2019) on 1) pairs of prompts and extracted silver standard plot-structures, and 2) pairs of prompts + plots and stories, respectively. Full implementation details can be found in Appendix A.3.

We propose to modify the decoding objective to incorporate input from each Aristotelian rescoring model $a \in A$ (the complete set of rescoring models, detailed further in Section 3.1) and re-rank the original, or "naive" plot model hypotheses, bringing the plot representation closer to each rescoring model's specialty and desireable story attribute. A diagram of our final system in Figure 1 shows each step of the generation process. The modified decoding objective becomes:

$$f_\lambda(\mathbf{x},\mathbf{z}) = \sum_i^m -\log p(z|z<i,\mathbf{x}) + \sum_j^{|A|} \lambda_j a_j(\mathbf{x}, z_{i...m}) \tag{1}$$

where λ_j is the learned weight of the score given by a_j, as detailed in Section 3.3.

3.1 Aristotelian Rescoring Models

For all of our rescoring models, we train classifiers to *distinguish* positive examples - the silver extracted plots - and negative examples, which are plots that are worse with regard to the aspect that we desire to encode, given the prompt $\mathbf{x}$. The intuition is that if the rescoring model can learn a particular principle, it can assist the plot-generation language model in creating content that encapsulates that principle. Mathematically, the classifiers learn $p(l|\mathbf{x},\mathbf{z}) = \frac{p(\mathbf{x},\mathbf{z},l)}{p(\mathbf{x},\mathbf{z})}$, and we use the probability of the plot being a positive example (a more plausible plot) as our Aristotelian rescoring model:

$$a_j(\mathbf{x}, z_{i...m}) = p_j(l_{pos}|\mathbf{x}, z_{i...m}). \tag{2}$$

What differs for each model a_j that specialises in a different Aristotelian aspect is the set of negative examples that we generated to capture the type of information it has learnt to discriminate, and the features it learns. We give more details about each Aristotelian rescorer as follows. Example simplified positive and negative pairs for each are depicted in Figure 1. Full unsimplified pairs of positive and negative examples for each rescorer can be found in Appendix B.

Event Rescorers. The SRL extracted plots provide us with a structure that is very similar to event representations in event extraction literature. We thus consider an *Event* to be composed of an action-based verb and its subject and object (a verb, subject, object tuple).[4] We experiment with three different ways to construct positive and negative event examples. SRL based plots are structured, and a random shuffle would be trivial to distinguish, so we need more nuanced ways to learn good event choice and arrangement. We try:

- **inter-sentence shuffled events** we permute all sentences as a full chunk, and keep all events within a sentence together.
- **intra-sentence shuffled events** we permute the event tuples within a sentence, but keep each verb and its arguments together.
- **verb-shuffled events** we permute only the event verbs within a sentence, leaving their arguments and contexts unchanged.

---

available. We used AllenNLP (Gardner et al., 2018) to run the SRL model (He et al., 2017) and Co-reference model (Lee et al., 2017) and determined our own compression algorithm experimentally. Further details in Appendix A.5

[4] With modal verbs generally excluded in a stop list, which is included in Appendix A.5

The Event rescorer example in Figure 1 depicts the verb-shuffled rescorer, where the model should learn that the progression *grow* → *began* → *fade* is a suitable verb ordering, but that *ended* → *lived* → *born* is unlikely. A simplified example for intra-shuffled from the same sample story would be the two phrases (within one sentence) `<A1> ent 12 <V> shifted`→`<A1> ent 12 <V> went <A2> to sleep`, as opposed to the reverse ordering. For inter-shuffled it would be the two full sentences `<A1> ent 11 <V> grew <A2> louder`→`<A1> ent 11 <V> fell <A2> silent`, again as opposed to the reverse.

Each of these has specific strengths and weaknesses. *Inter-sentence shuffling* is closest to work on Narrative Event Chains (Chambers and Jurafsky, 2008) and script-learning, which represent the fact that certain events are more likely to causally follow other events rather than precede them. However, since inter-sentence noising scopes globally over the entire plot structure, it is a harder task and may be difficult for the model to discriminate patterns. *Intra-sentence shuffling* is the same task but restricted to a more local scale, which makes the patterns clearer and more learnable but cannot capture long-distance Event Chains inter-sententially. It is also more sensitive to the style of a given story, as stories have a variable number of events per sentence. Finally, *verb-shuffling* focuses on verbs as the salient element of an event, and should teach both principles of verb ordering and of verb suitability for context, and avoid artifacts from reordering arguments. However, since verbs are shuffled naively, the task can in some cases be too easy due to differences in verb selectional preferences.[5]

Character Rescorers. We represent character trajectory by distinguishing which character should appear at what point in the story. We create training examples by taking each entity and all the preceding plot tokens up until the entity, and having the rescoring model choose between the true entity and a randomly sampled entity.[6] The character rescorer must then distinguish between points in the plot when a pre-existing entity (a character already present in the story) should reappear, and if so which one, or whether a new entity should be introduced. The intuition is that this should encode typical patterns of a character's actions and relationships in particular contexts.

The Figure 1 example encapsulates simplified correct character relationships (that a character should be asking something of another rather than of themself). This extends to much more complex character selection examples, as in the context: `<A0> ent 0 <V> saw <A1> the light of a campfire </s> <A1> ent 2 <V> laying <A2> there </s> # <A1> light <V> bouncing </s> <A0> ent ?` where the positive is `0` and the negative is `3`. Here the difference between the positive and negative captures whether or not it is natural to introduce a new character at this juncture (it is not, as in the gold plot a new character does not appear till a few sentences later).

Relevance Rescorers. We take an approach inspired by prior work on learning to discriminate between random and true continuations of story sentences (Holtzman et al., 2018). We consider pairs of prompts and plots, where a positive example is the true plot and the negative is a randomly selected plot from elsewhere in the training data. This prompt and plot pairing is a much more difficult task than pairing context and continuation sentences, since they are less closely connected. Once trained, this rescorer is expected to tell which kinds of plot words, verbs, and SRL patterns belong with which kinds of prompts. The example in Figure 1 shows a relevant and irrelevant sentence for the given prompt. During training, the rescorer will receive the entire gold story and an entire random story to match to a prompt (see Appendix B).

3.2 Rescoring Model Architecture

There is an inherent tension in training a useful rescoring model: discrimination tasks for which even simple models can perform well may have inherent data artifacts and therefore not be helpful for modeling plots. However, discrimination tasks that are so hard that all models have low accuracy are also likely to be unhelpful. We experiment with three different architectures for our rescorers. We start with ngram-baseline models[7] to better judge the baseline difficulty of a given task and take artifacts of data creation into account. This

---

[5] For instance, an exclusively transitive verb could be swapped into the space of an intransitive one, and the edit would be trivially recognisable based on grammatical patterns.

[6] In other words, each training example is a section of plot sequence $z_0 ... z_t$ where t is a randomly chosen entity, and the rescorer is given $z_0 ... z_{t-1}$ as context and must distinguish between the true and false z_t entities that follow.) So the length of context varies for each training example.

[7] Implemented in Scikit-learn (Pedregosa et al., 2011)

Plot Elements		XGB	CNN	RoBERTa
Relevance		55.2	56.0	**89.3**
Entity		64.1	76.0	**92.3**
Event	Inter-Shuffled	55.4	53.0	**96.6**
	Intra-Shuffled	58.5	75.0	**97.3**
	Verb-Shuffled	76.1	75.0	**95.8**

Table 2: Accuracy for training Rescorers using three different architectures.

is more informative than random chance accuracy. We also experiment with augmented versions of the CNN architectures used in Holtzman et al. (2018), and RoBERTa models (Liu et al., 2019), and find RoBERTa to have the best performance for each Aristotelian concept.

1. **XGBoost with ngrams:** We used n-grams in range of (1,4) as features and trained a XGBoost model with 200 gradient boosted trees with a maximum tree depth of 5.
2. **CNN with maxpooling:** We used a CNN-based architecture (Holtzman et al., 2018) but augmented it with BART position and subword encodings because our event tasks are ordered, so pooled or averaged representations that don't represent permutations differently would be indistinguishable.
3. **RoBERTa-large** (Liu et al., 2019) has shown excellent performance on various sentence pair classification tasks. We expect this large pre-trained language model to be more efficient in being able to discriminate between a well-formed sequence of words and a poorer one. To this end we finetune RoBERTa-large with a classification specific final layer as the final option to build rescorer models.

Accuracies for different rescorer architectures by aspect are shown in Table 2. As we hypothesised from the nature of many of the tasks (Section 3.1), the inter-sentence shuffled task is more difficult because the noising is global. This is reflected in the barely above chance scores of the ngram-baseline. The Verb-shuffling high ngram-baseline performance shows that our suspicions about this task being easier were also correct. Intra-shuffling was the only surprise, and turned out to be more difficult than we expected and to have the largest gap between baseline ngram and CNN performance. RoBERTa scores are high across the board, so we use RoBERTa for all models in the final system.

3.3 Mixture Weight Training and Ablations

We learn optimal weights for rescorers online during decoding using a held-out validation set V, and use these weights during inference via sampling. We minimize Margin Ranking Loss of the negative log probability of each validation sample between the gold ($\mathbf{z}$) and hypothesised ($\hat{\mathbf{z}}$) plot structures.

$$\mathcal{L}_{\underset{\lambda}{mix}} = \sum_{\mathbf{x},\mathbf{z}\in V}\sum_{i=1}^{n}\max(0, -(f_{\lambda}(\mathbf{x},\mathbf{z}_{<i}) - f_{\lambda}(\mathbf{x},\hat{\mathbf{z}}_{<i})) \tag{3}$$

where i indexes the word position, n denotes the plot length, f_{λ} is the same as in Equation 1, and we are training the λ weights with this objective.[8] We train mixture weights both for combinations of rescorers and for ablations using each rescorer individually, to isolate the contribution of each one.

Mixture weight training accuracy is in Table 3,[9] which we report as Ranking Accuracy, the number of samples where the generation has higher probability than the gold. There we also include our automated plot metrics on the validation set for each ablation (further detail on those metrics in Section 4.2). As Table 3 shows, Inter-event is the strongest of the individual rescorers, though all five together achieve the best performance. This seems to indicate that each method of creating negative event examples is encoding a separate helpful piece of information, rather than one of them alone being the best approach.

Given that the ensemble of many rescorers was best, this suggests further investigation into the interactions between rescorers, and into whether there is a pareto front and in which cases certain rescorers dominate. Due to the difficulty of human evaluation of long stories and the accompanying funding constraints, we leave this as a suggestion for interesting future work to analyse. We thus select the ensemble of all 5 rescorers with optimal learned mixture weights for our final Aristotelian Plot System.

4 Experimental Setup

Dataset. We use the Writing Prompts dataset (Fan et al., 2018), which is a large collection of user-generated stories along with their associated prompts from Reddit, to benchmark our models. It

---

[8] We experiment with learning on each token (in which case, each validation sample will contain a few hundred updates) vs. on each complete sample (an entire plot). We find both approaches to perform similarly (with every-token gaining 1% accuracy) and use an every-token approach in for our final system. Mixture weight hyperparameters can be found in Appendix A.4

[9] Our 4-scorer ensemble subtracts out the Intra-event model as it is conceptually a more local version of the Inter-event model, and has a lesser effect on Ranking Accuracy

Rescorer	RA ↑	V:T ↑	E ↑
All 5	**0.43**	**2.07**	7.15
All 4 (-intra)	0.35	1.72	8.78
Inter-event	0.37	1.76	8.87
Intra-event	0.16	2.01	6.58
Verb-event	0.15	1.66	8.89
Entity	0.17	1.68	**9.18**
Relevance	0.17	1.71	8.89

Table 3: Ranking accuracy (RA) and generated plot metrics i.e Verb:Token ratio (V:T), Entities(E) for rescorer ablations

is particularly suited to this task since it is both hierarchical (contains pairs of titles and stories, which enables the use of a plot as an interim step) and contains many diverse long-form stories that are very challenging to learn to structure.[10]

4.1 Baselines

We compare our generations to the two strongest recent story generation systems as well as two ablated versions of our own system.

Targeted Common Sense Grounding Model. Mao et al. (2019) propose a multi-task learning scheme to achieve quantitatively better common sense reasoning in pre-trained language models by leveraging auxiliary training signals from datasets designed to provide common sense grounding.

Knowledge-Enhanced Commonsense Model. Guan et al. (2020) devise a knowledge-enhanced pretraining model for commonsense story generation leveraging external knowledge bases on the ROCStories dataset (Mostafazadeh et al., 2016). To further capture causal and temporal dependencies between sentences in a reasonable story, they employ multi-task learning which combines a discriminative objective to distinguish true and fake stories during fine-tuning.

Prompt to Story. This fine tunes the BART model directly with the prompt and story pairs without access to a plot structure.

Naive Plot. This utilizes a plot structure to write a story, but does not incorporate the Aristotelian Rescorer ensemble.

We do not compare to the strong system of Fan et al. (2019), as they do not release their code and the authors were unable to make their output available after being contacted.[11] However Guan et al. (2020) is one of our baselines and achieves better results on Mostafazadeh et al. (2016) than their approach. Our **Naive Plot** baseline is most comparable and quite similar to their system, save that it lacks their verb attention, but leverages powerful BART pretraining.

4.2 Metrics

We use a combination of human and automatic metrics to evaluate all systems. Automatic metrics are evaluated on 1000 randomly selected prompts and their associated plot structures and stories from the WritingPrompts test set. As automatic metrics are known to be overly coarse for open domain NLG (Novikova et al., 2017) we also report human evaluation results on 110 stories, with each story evaluated by 3 separate judges.[12] All metrics are averaged over all stories within the evaluation set.

Plot Structure Metrics. For plot structures we use purely automated metrics, as it is difficult for humans to read the abstract interim representation of SRL tags and entity anonyimisation:

- Vocab:Token Ratio
- Entities per plot

We choose to focus on these metrics as indicative of performance as they show the largest gap between gold and generated stories. *Vocab:Token Ratio* is commonly used as a measure of originality and diversity of content for stories, and can be readily applied to plots. *Entities per plot* we found to be a good metric as a reasonableness check, and for ablations, as weak models tend to have too few entities. Both metrics also relate to repetition, a known weakness of neural generated stories in comparison to human stories even with large pretrained transformers.

Automatic Story Metrics.

- Vocab:Token Ratio
- Unique Verbs & % Diverse Verbs: % of verbs not in the top 5 most frequent[13].
- Intra-story Trigram Repetition: trigram repetition *within* a story
- Inter-story Trigram Repetition: trigram repetition *between* stories

We again use Vocab:Token ratio as a rough diversity metric. We report also inter-story trigram repetition

---

[10] Dataset statistics are in Appendix A.2

[11] Code for Fan et al. (2018), which does *not* use plots, is available but is trivially beaten by any recent story generation system.

[12] Workers were paid $12/hr. They were given content instructions and told to disregard punctuation and spelling. Further details on compensation and instructions in Appendix E.

[13] We report these for comparability to Fan et al. (2019); as they do we identify verbs via `https://spacy.io/`

rates and intra-story trigram repetition rates (Yao et al., 2019). The former is a diversity metric - if stories look fine but inter-story repetition is high, it means the language model has learned to tell only very similar stories even when conditioned on diverse prompts. Intra-story trigram repetition is a fluency metric, and measures the proportion of trigrams within a single story that are repeated.

For all of these metrics, there is a tension between diversity metrics, which bring a generation closer to human quality, and fluency metrics, which can degrade as diversity increases.

Human Metrics. We run two separate experiments to measure improvement in our target areas of Relevance and Overall Quality. Relevance is defined as whether stories both relate to the given prompt and remain on topic for the duration of the story. Overall Quality is defined to be combination of *coherence*, *interestingness*, and *relevance*, similarly to most other story generation work.[14] We postprocess stories for human review by detokenizing[15], removing special end-of-sentence tokens, and truncating to 250 (whitespace separated) words. We have Mechanical Turk workers rate all systems' outputs on the same prompt comparatively on a *likert score* (1-5) across both metrics. But since likert scores are well known to exhibit a central tendency bias, it is likely to be unreliable on distinguishing between systems that are close in performance, particularly as reading 5 long generations introduces significant cognitive load. Therefore, we further conduct *pairwise comparisons* between the top 3 systems in the likert experiment.

Test Data Selection. In contrast to previous work on this dataset, our 110 human titles are randomly sampled from a *filtered version* of the test set. Writing Prompts has a one-to-many relationship between the prompts and stories.[16] The dataset also contains an artifact of the sort of topic that is upvoted on reddit[17], so many test prompts are minor variations on the same topic. We hypothesise that some of the gap between reported performance in papers on this dataset and performance in the wild is due to the artificially high similarity between training and test prompts, so we randomly sample from the test set, but exclude prompts with extremely high lexical overlap with training prompts.[18]

System	Voc:Tok ratio	Entities	Avg Tok
Naive Plot	1.52	8.25	199
Aristotelian Plot	1.81	7.49	168
Gold Plot	3.59	9.26	371

Table 4: Metrics for plots

System	Automatic Evaluation			
	Voc: Tok$\uparrow$	Diverse Verb %$\uparrow$	Intra-Rep$\downarrow$	Inter-Rep$\downarrow$
Mao et al. (2019)	6.6	81.8	5.68	27.5
Guan et al. (2020)	2.3	71.9	0.60	56.1
Prompt-to-Story	1.5	68.9	0.22	65.1
Naive Plot	1.4	76.4	0.11	63.8
Aristotelian Plot	1.5	74.8	0.12	64.1

Table 5: Automated metrics for all models.

5 Results

Plots. As is shown in Table 4, the Aristotelian plot brings the generated plot structure closer to the gold plot Vocab:Token ratio, though there is still a large gap. This improvement comes at a slight expense of number of entities per plot, which is likely because rescored plots are on average shorter.

Stories. The combination of automatic and human evaluation for stories highlights both the coarseness of automatic evaluation metrics and the blind spots of human evaluation (Hashimoto et al., 2019). From just the lexical metrics, the two baseline systems of Mao et al. (2019) and Guan et al. (2020) would appear to have the best performance (though Guan et al. (2020) suffers in Diverse Verbs), and the three BART-based systems are indistinguishable save an improvement in Diverse Verbs with the introduction of plot structures, as observed in the plot experiments of Fan et al. (2019).[19] However, intra-story trigram repetition reveals the weakness of the Prompt to Story system and the Guan et al. (2020) system. It also shows the extreme lack of fluency in the Mao et al. (2019) system, which exhibits an unnatural level of repetition characteristic of degenerate output.

---

[14] Surveys used for both may be found in Appendix E, as well in in the code repository.

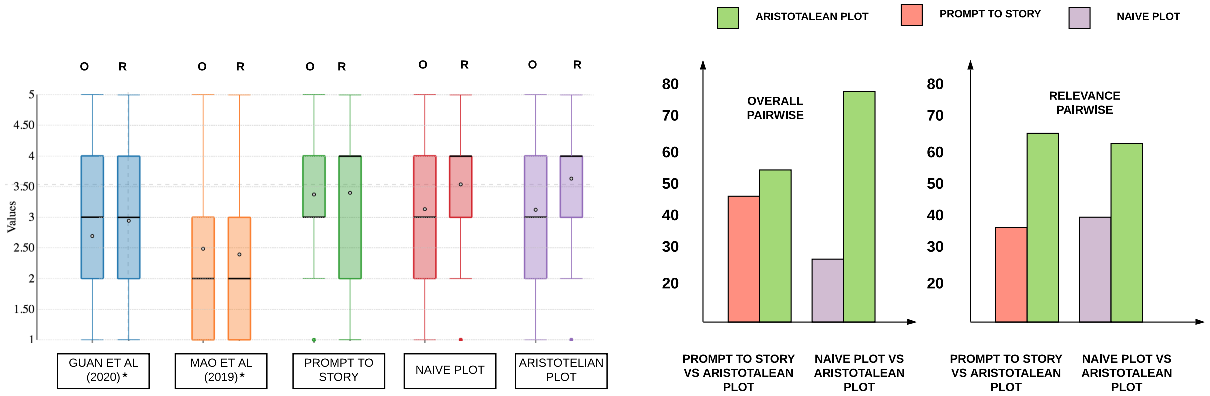
[15] We use MosesDetokenizer (Koehn et al., 200)

[16] Of the 303358 prompts, only 1/3 (107665) are unique

[17] Mostly aliens

[18] 72% of prompts were excluded. We used sequencematcher `https://docs.python.org/3/library/difflib.html` and spacy vector similarity `https://spacy.io/` to exclude prompts with a similarity of 1 to any prompt in the training data when stopwords are removed. The two systems gave identical results.

[19] Though we do observe a similar magnitude increase in Diverse Verbs with the introduction of plots, our baseline Prompt-to-Story model has a higher % than their best model, reflecting the recent performance improvements in pretrained language models. We report Unique Verbs for comparability, but do not find it to be useful metric since it is not normalised by length or token count.



(a) Likert ratings for all 5 systems scored together. O is Overall, R is Relevance, solid bars are median, dots are mean. * denotes systems with significant differences ($\alpha < 0.05$, Wilcoxon signed-rank test). The three BART based systems at right are not statistically significantly distinguishable via this setup due to central tendency bias.

(b) Pairwise win rates for the Aristotelian Plot system and two best baselines. Significant ($\alpha < 0.05$) via Wilcoxon signed-rank test.

Figure 2: Human evaluation for five systems on 110 prompts, with each sample evaluated by 3 judges. The scores for the likert experiment are averaged over all the instances; the pairwise comparison takes the majority vote of the three judges for each instance.

Human Evaluation. The human metrics in Figure 2a then reinforce that the high lexical scores of the Guan et al. (2020) and Mao et al. (2019) systems are a result of those models sometimes deteriorating into nonsensical text, as both of those systems have extremely low human judgement scores.[20] The likert scores favor the Aristotelian Plot system with regard to relevance but favor the Prompt to Story baseline for Overall Quality - though as can be seen from the variance in 2a, all three BART systems are too close together to be reliably distinguished via likert metrics. The pairwise comparisons in Figure 2b do differentiate the three systems with strong statistical significance, showing the superiority of Aristotelian Plot over both the Prompt to Story and Naive Plot systems with respect to both Relevance and the Overall Quality of the final stories.

6 Analysis

We analysed the patterns in reported user confidence and found that 8% of prompts are low user confidence (<3) and 8% are high confidence (>4.5), so we look further into these as examples where the top three systems are minimally and maximally distinguishable. We include examples of outputs for these prompts for all three models in Appendix C.

For Overall Quality, there are no low confidence titles, and the Aristotelian plot system is preferred for all of the high confidence ones. In Relevance, the low confidence prompts have split win-rates across all models (essentially random) and the prompts show that all systems struggle with the meta-level concepts. The Writing Prompts dataset varies from concrete (*A story of a cat who saves a girl from her depression*) to prompts requiring other types of meta-knowledge. Prototypical low confidence titles are of two forms: 1) *A day in this life in a world where everything is written in poetry*, and 2) *Write a story where I can't tell whether the protagonist is a hero or a villain.* The type 1 stylistic instruction prompt requires knowledge about the distinction between instructions for style and content, and all models fail. The type 2 meta-content type of prompt requires a finer level of control of the structure of the plot and story than the Aristotelian system or any of the other models can manage. This kind of prompt presents an interesting case for future story generation work, as it is simple enough for human authors to be popular on a forum, but far beyond the capabilities of current language models. At the high confidence Relevance prompts, the Aristotelian system wins all but one. Those stories highlight the way that adding and then improving on plot structures assists relevance by keeping a story on topic throughout an entire generation (see Appendix C Table 9).

To assess the cases where the Aristotelian Plot did not improve over the BART baselines, we measure both word and verb incorporation rates, in

---

[20] Examples from each baseline system for the prompt in Table 1 can be found in Appendix D

System	Word Incorp %	Verb Incorp %
Naive Plot	75.5	75.1
Aristotelian Plot	72.4	72.0

Table 6: Metrics for incorporation rates for stories.

Table 6[21]. These measure the Levenshtein distance over the sequence of plot words (excluding verbs) or plot verbs that are included within the final story. While the high incorporation rates show that the story model does utilize the plot, there is a gap between the current utilisation and the possible upper bound. The focus of our work is on improving plot generation, but we hypothesise that modifications to the story model to improve incorporation rates would further widen that performance gap between the three systems, as it will give the plot more influence over the story surface realisation and ensure that plot improvements appear downstream.

7 Related Work

Story Generation without Plots. Diverse efforts have focused on generating stories. Fan et al. (2018) re-purpose an approach for Neural Machine Translation to translate from prompt to a story via Convolutional Seq2Seq models. Guan et al. (2020); Mao et al. (2019) use a similar approach, however they incorporate structured commonsense knowledge from external datasets or knowledge bases to improve a story generated from a prompt. Peng et al. (2018) add control to the story ending valence.

Story Generation with Plots. Riedl and Young (2010) use refinement search as a technique to balance between character and plot for solving the narrative generation problem. Li et al. (2013) use plot graphs for story generation that model the intended logical flow of events in the virtual world as a set of precedence constraints between plot events. Martin et al. (2018) decompose the problem of story generation into generation of successive events (event2event) followed by generation of natural language sentences from events (event2sentence). Ammanabrolu et al. (2020) follow up this work by comparing five different models for event2sentence realisation, and find all to have different weaknesses. Yao et al. (2019) improve their LSTM-generated ROCStories by extracting keyword-based plot-like structures, or *storylines*, and using these in a pipeline to generate storylines and then stories. Fan et al. (2019) experiment with numerous techniques for representing story plots on the WritingPrompts dataset, and find Semantic Role Labelling with Entity Anonymization and Compression to work best. More recently, Tambwekar et al. (2019) propose a goal-driven reinforcement learning approach to plot generation, and Chen et al. (2019) propose a latent variable model to learn how to generate outlines for neural story generation.

Learning Story Aspects via Rescoring. Holtzman et al. (2018) generate continuation sentences from context sentences, and introduce using a mix of collaborative discriminators that each learn one Grician maxim of conversation, and use them to rerank their RNN story model output. Goldfarb-Tarrant et al. (2019) use those discriminators with the system of Yao et al. (2019) as part of a collaborative story writing task with an LSTM and human writers. However, none of them apply rescorers to the plot. There is no other work that uses discriminators or rescores for plot structures or to try to train them based on different principles.

8 Conclusion and Future Work

We have shown that Content Planning via an interim *plot structure* representation can be combined with the use of rescoring models to inject Aristotelian story-writing principles into the plot. We found that this results in stories that are both more relevant and higher quality than stories that are generated directly from prompts or that use plots without Aristotelian rescoring. Our findings also suggest future work on additional ways to incorporate story principles into plot generation. Although our Aristotelian plots improved over the naive plot, there remains gaps in quality between generated and gold plot structures. There is also further work to be done in investigating what models are best able to incorporate plots, which would enable plot improvements to be even more effective.

Acknowledgments

We thank the anonymous reviewers for their feedback, Adam Lopez for his excellent editing suggestions, and Jinrui Yang for her early SRL prototyping. This work is supported by Contract W911NF-15-1-0543 with the US Defense Advanced Research Projects Agency (DARPA).

---

[21] Yao et al. (2019) also use word incorporation rates, but theirs are not comparable to ours, as we both include verbs as their own separate metric (due to their importance in our structure) and make this an *ordered* metric (rather than set intersection as they do), which is necessary because our generated stories are much longer

A Appendices

A.1 Data Quality in Mechanical Turk Studies

We require that Turkers doing pairwise story comparison report their confidence in their decisions and are clear that this makes no difference in their remuneration, and then we use patterns of confidence scores to find areas where models are very distinguishable and areas where they are not.

We additionally create manual True-False questions for each prompt used in human evaluation to be used as an attention check. We experimentally found that extractive attention checks (*this keyword is in the title*) were ineffective, but manually created simple ones such as *The protagonist is a child* were very effective at filtering out poor quality responses. 15% of all responses failed attention checks, and we excluded that data and reran those human evaluations until we had a full dataset. We did additionally verify that none of our questions were overly difficult by manually reviewing all attention checks that $< 80\%$ of respondents passed.

A.2 Dataset Statistics

The Writing Prompts dataset contains 303358 pairs of prompts and stories. Stories are already tokenized in the available dataset (Fan et al., 2018). Like (Fan et al., 2018) do we truncate to a maximum length of 1000 words per story (with an average of 700 words) and replace words that appear less than 10 times with an UNK token.

We split the dataset into Train/Validation/Test splits of 65/10/10 for fine-tuning Language Models, with the remaining 15% split into 10 for fine-tuning Rescoring models, and 5 for training Mixture Weights and generally running metrics and tests.

A.3 Implementation Details

We fine-tune BART with same hyperparameters mentioned in [22] with the exception of MAX-TOKENS (size of each mini-batch, in terms of the number of tokens.) being 1024 for us. For decoding we generate plots and stories from our models using a top-k random sampling scheme (Fan et al., 2018). At each timestep, the model generates the probability of each word in the vocabulary being the likely next word. We randomly sample from the k = 5 most likely candidates from this distribution. We also use a softmax temperature of 0.7.

A.3.1 Fine-Tuning BART for Prompt to Plot

1. **No of Parameters:** For BART we use the BART large checkpoint (400M parameters) and use the implementation by FAIRSEQ (Ott et al., 2019) [23]

2. **No of Epochs:** We fine-tune pre-trained BART for 19 epochs for FTB model keeping all default hyper-parameters as mentioned in `https://github.com/pytorch/fairseq/blob/master/examples/bart/README.summarization.md` with the exception of $MAX\_TOKENS = 1024$ and $UPDATE\_FREQ = 16$.

3. **Training Time:** Our training time is 32 hours

4. **Hardware Configuration:** We use 2 RTX 2080 GPU (11GB)

A.3.2 Fine-Tuning BART for Plot to Story

1. **No of Parameters:** For BART we use the BART large checkpoint (400M parameters) and use the implementation by FAIRSEQ (Ott et al., 2019) [24]

2. **No of Epochs:** We fine-tune pre-trained BART for 17 epochs for FTB model keeping all default hyper-parameters as mentioned in `https://github.com/pytorch/fairseq/blob/master/examples/bart/README.summarization.md` with the exception of $MAX\_TOKENS = 1024$ and $UPDATE\_FREQ = 16$.

3. **Training Time:** Our training time is 6 days due to limited GPU RAM and since stories and plots are large sequence of tokens.

4. **Hardware Configuration:** We use 1 RTX 2080 GPU (11GB)

A.3.3 Fine-Tuning roBERTa-large for Discrimators

1. **No of Parameters:** For BART we use the roBERTa large checkpoint (355 parameters)

---

[22] `https://github.com/pytorch/fairseq/blob/master/examples/bart/README.summarization.md`

[23] `https://github.com/pytorch/fairseq/tree/master/examples/bart`

[24] `https://github.com/pytorch/fairseq/tree/master/examples/bart`

and use the implementation by FAIRSEQ (Ott et al., 2019) [25]

2. **No of Epochs:** We fine-tune pre-trained roBERTa 7 epochs for relevance discriminator model, 5 epochs for entity discriminator models, 4 epochs for inter-event, 2 epochs for intra-event and 10 epochs for intraV-event discriminator keeping all default hyper-parameters as mentioned in `https://github.com/pytorch/fairseq/blob/master/examples/roberta/README.glue.md` with the exception of max-tokens= 1024 and lr-scheduler=fixed.
3. **Training Time:** Our training time is 10 hours for relevance discriminator , 4 hours for entity discriminator ,4 hours for inter-event, for 2 hours for intra-event 12 hours for intraV-event discriminator
4. **Hardware Configuration:** We use 4 RTX 2080 GPU (11GB)

A.4 Hyper-Parameters for Mixture Weight Tuning

Mixture weights are tuned with a held out validation set of 10,000 samples. The models train for 3 epochs, but all converge in 1 epoch, which takes 24 hours on 1 RTX 2080 GPU (11GB). We use SGD at each step, with learning rates set to 0.001.

A.5 SRL-Event Representations

We compress event-representations by removing all verb arguments beyond args 0,1,2.

We exclude the following verbs when extracting plot events:`"is", "was", "were", "are", "be", "ś", "ŕe", "Íl", "can", "could", "must", "may", "have to", "has to", "had to", "will", "would", "has", "have", "had", "do", "does", "did"`

B Example Training Data for Rescorers

Table 7 shows example positive and negative training data for all rescorers for the prompt *People gather around a camp fire to tell the story of a legend , who actually sits among them*. Training data is excerpted for display, but otherwise unedited.

C Example Outputs For High and Low Confidence Scores

All examples in Tables 8, 9, and 10 are unedited save removal of special separation tokens and detokenization. Line breaks are added by the model.

D Output from Baseline systems for the first example prompt

Output from the remaining models for the example prompt in Table 1 of the paper: *Write the most beautiful end to the universe that you can imagine*. All examples are unedited save removal of special separation tokens and detokenization.

E Mechanical Turk Study Materials & Compensation Details

Human Evaluation consisted of 110 titles evaluated by 3 judges each, which results in 330 x 5 long stories for likert comparisons and 1320 x 2 long stories for pairwise comparisons (as there are 4 sets of pairwise comparisons). Turkers received $12/hr, so the entire budget was $2k.

Included at the end of the appendix in Figure 3 are the pairwise surveys for Relevance and Overall Quality, for reference. HTML for these surveys and for the likert surveys are included in the code repository.

---

[25] `https://github.com/pytorch/fairseq/blob/master/examples/roberta/`

Table 7: Example (excerpted) training data for all rescorers for the prompt *People gather around a campfire to tell the story of a legend, who actually sits among them.* The Relevance rescorer includes one sentence of plot in the given context, the Entity rescorer's context is the entire plot up to a randomly chosen entity.

Table 8: High Confidence: Overall Quality (score 4.67 out of 5)

Prompt: Earth has gained a new season, unlike anything currently known

---

Aristotelian Plot System Generated Story:

The Earth is more beautiful than it thought! It's the most beautiful planet. The sun was shining bright, and the air was crisp, yet the air itself was cold. Everything was so bright. It was the perfect day for earth to be beautiful.

Everyone on the planet Earth had lived a long and happy life, this planet has been home to the human race for thousands of years. The humans were a species that had been able to survive through Earth's harsh environment. the humans could survive in these harsh conditions. But one day Earth had a new life, and we were the first to notice it. In the middle of the night, we could see something, a small, dark cloud. A small, white cloud, it's size was almost invisible. Then that cloud grew. And it grew...

The sun, shining bright.. There was no sun. All the light was black and it covered the sky. Every day the sky was a dark blue. No matter the time of day, it never seemed like the perfect time, it was a beautiful day. For a new season to begin. Yet no one could know why. Why did we not have a new cycle?"

Naive Plot System Generated Story:

"It's not a new day, John. "

" What? What is it? You ca n't see?"

The man was silent.

He said, "It'd be the first time we 've all seen its as we know it, but it's the first we're seen in over a million years. It is a new world, one with no sun. "

A few seconds of silence." Its not a New Day." the man said.

"It're a new season," said the woman. We' ve seen them all. I mean, we all know by now. You know, I 've- seen, you' ve always seen- "

"We'll see us. But you'll be the First, you were the first one to see, we'll all be the Last, we will all be, we have all been the first of our species. There is no one more, no one is better than me." "The woman was right.

Prompt to Story Generated Story:

I was in my bed, in my own room, in the middle of a forest, when the world stopped.

It was the first time in my life that I had felt I had a sense of peace. My family and me, myself, were gone, we had all been taken from us. The only thing our family had left were the three children and my world, but my wife and I were the only survivors. There were we, the three of us. But ourselves, our children were all gone. And the only reason why me and our family survived was because ours had become ourselves. It was as if both of us were one with the world. As all the children were gone and the adults had left myself to fend for myself, you and your family. No longer were you and I to be each other. Now we were just two. All our memories of us, all ours. Nothingness. Only all of us, and my children, each of us...

Table 9: High Confidence: Relevance (4.86 out of 5)

Prompt: Evolution has gone a little differently. Humans have poison and some way to transmit it.

Aristotelian Plot System Generated Story:

So the poison is in your genome, "said the scientist.

" I have n't even it's looked at you yet Mr. Doctor!"

"Yes sir! "

" And its in my DNA. " said the man.

"Well, you must be the first human, to have developed this. I mean, you are." He said," It's not a question of if but when You. It'd be a question if your DNA would even be the same. "

The man looked him in the eye. "Well Mr. Doctor..."

" Yeah you are the first, I mean sir, "he said. * I am not sure he was. But he is who i am. Do you see that? You and I are not the first species to have it, but this one has come from the beginning of this.". The human genome of the virus had the most advanced species known to have had It. And it was spread by a species that had the best genetic makeup in the world. A species which was a virus spread by the human race. Now, you and I were not the best of the best at it, because we did n't have the ability to develop a species who could spread the toxin. We were the best. This is why we live in this place now. Because we can live in a world with no poisons. You know we 've killed off each other, but now we live our lives, you all know. Just like myself, Mr. President, I do n't know how long it took. They live by. Well, it was about a thousand years ago. In the same world we come from, the human genome spread by The human race, and spread by that same process.

Naive Plot System Generated Story:

'What? People say that they know what they're saying. I know, but the ones who kill? I know. The ones who do the killing! "

" Yeah I know! They're all dead! All of them, the ones you know about! That's what you say... but what? That we're gon na kill them? You see, the one who's dead, are the ones that you 've killed. Not me. It's us." They are my brothers and sisters, after all.

The one's that will die, the people who we kill, the guys and girls that you guys and boys kill for.

Prompt to Story Generated Story:

We are the most dangerous species in history, yet, we do not know why. We have been hunted for thousands of years. It was the same for our ancestors, they were their prey, and the same fate for it.

Our species evolved to be more intelligent than the others, and so they were able to survive. But the human race was n't able to adapt. So they were forced to adapt to the world themselves, and the first few years were difficult. There were no predators to eat, no predators that could eat us, no prey that could be killed, no one to protect them. All the predators had been wiped out and their prey was no longer needed. The population was so small, so few that no predator could take on the entire world. And so they died. No one was left to fight. Just the humans. That is until one of them, an old man named the man who was the most intelligent and powerful of all of them... A few of them were his friends. Some were his wife, others his kids, and some even he was a friend. Then the humans came to their deaths, they were not as strong as them. "

"And we were the last to go." "The man continued."

Table 10: Low Confidence: Relevance (2.8 out of 5)

Prompt: Write a story where I can't tell whether the protagonist is a hero or a villain.
Aristotelian Plot System Generated Story: ”The men seemed a little more than usual, a bit. The women were n't the same. No. They were all different. All of them, my wife. Each one of them were given the love of a woman, and none of them knew me as I did. If it took the people of the city to realize what they had done with the world, the world would n't have been so different... But this man. He was my hero. The one who was the one who made the difference, the only thing what hadkept the women from the other women. Theone who had saved the day. And the woman was the most special. It was the woman, the one that he had loved. But who would take the fall for the save a single life, for a person who saved his wife, her life. Not a single person was going to be able to save from this. There was no one to save. Nobody. Even the police. That seemed like it to us. “No one cared. ”. In a world where there were no people who needed help, no people that could need help. A world where those who needed for others, were the ones who would be the ones to do the work.
Naive Plot System Generated Story: So he's the hero. He's a good guy. Or is it?” “We did n't know him before. But we come in here for a meeting. What's his name? ” “ We'll have a talk. Do n't go anywhere, my name is n't your name.” * His name is not mine, I 'm not sure its a real name. * I'M not sure if I' ve ever been told I was a hero, or just a villain. “No, no, you're not. I'm not. ” “ What does that even mean?” ”The man ask me. “What is your name? Is yours name really mine?”... – – – The mayor of this small town is on the phone with his secretary. “We 've got a new guy. ”the woman says. A young man with a black suit and a dark suit. In the suit, he was told she was a heroine. No.
Prompt to Story Generated Story: I was a hero. I have never seen a hero before, and me being one is something you do n't expect in your first year of high school. The first thing that happened to my mind was that i was a kid, and then its a little hard to explain. The first few weeks of school were a blur. A few months went by and then it was just myself and my best friend. Then the bullying started. And then she started to do her own shit. So then it was mine, and soon it was all she did. But he did n't know what to do either. It was n't until his first few grades that it was nt until he started to talk. When we were in middle school that was when the bully started to take things out on him. That was when it all started... It took us about a year before our teacher finally got the courage to tell the class to call in sick to school.. To go to the hospital.

Survey Instructions

We are a group of researchers conducting research about storytelling.

In this survey, you will be provided with a **title** and **two stories** based on that title. Pick which one is a **more relevant** story and explain why.

More relevant stories are related to the topic and stay on topic for the whole story - rather than being superficially related by repeating a few words or key phrases.

Please complete the below instructions:

1. Please read both stories, then select the one that you think is more relevant.
2. Select how confident you are about your decision.
3. Briefly **explain** why you made the decision you did. Just basic thoughts or bullet points is fine, but this is required.
4. Answer the yes/no question at the end **based on the title**. It's not a trick question. If there is insufficient information for you to be sure, select "no".
5. Don't worry about punctuation and spelling of the stories.
6. Don't worry about the ending - stories are cut-off at a certain length words, so they may end mid-topic.
7. We do review **every** HIT response, and will reject if you don't give any reasoning or copy-pasted nonsense.

You are welcome to do as many of these as you want.

---- Please read the following Stories together and select one below ----

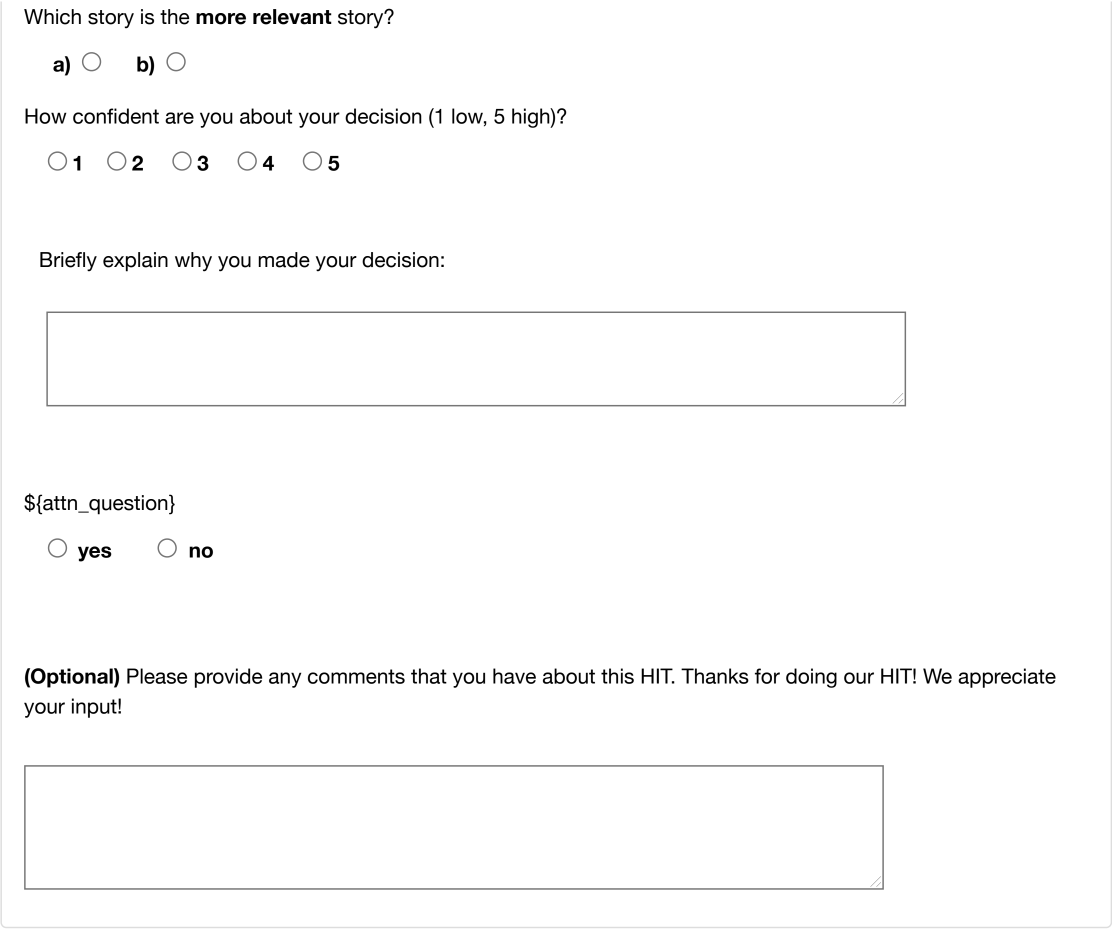
Title:

${title}

Stories:

a) ${story_1}

b) ${story_2}



Which story is the **more relevant** story?

a) ○ **b)** ○

How confident are you about your decision (1 low, 5 high)?

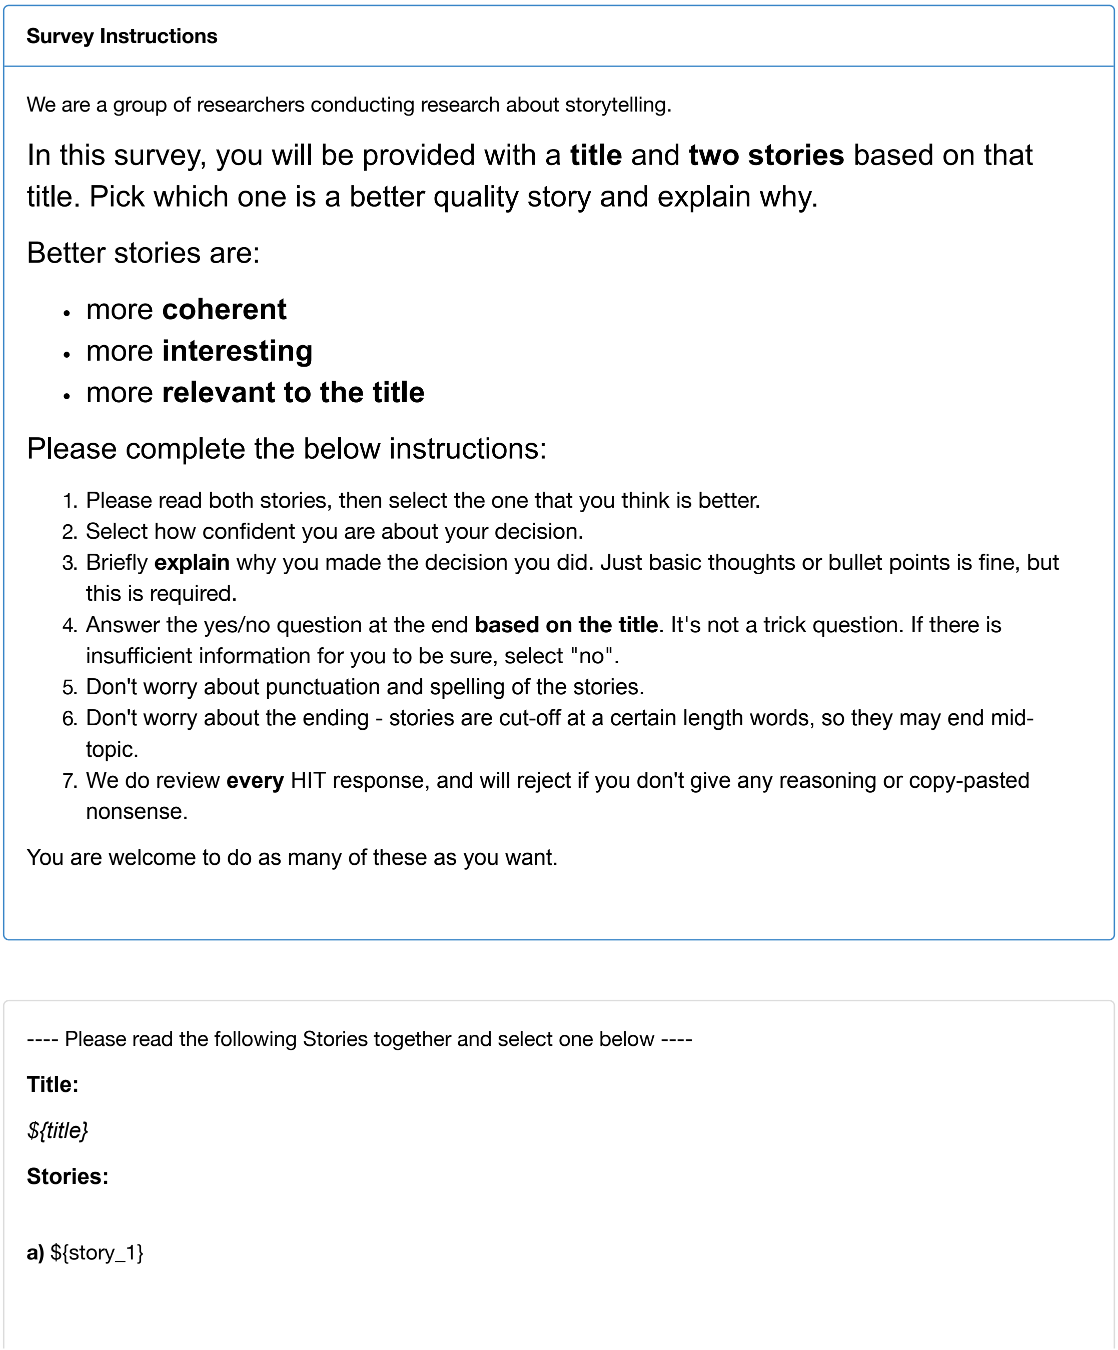
○ **1** ○ **2** ○ **3** ○ **4** ○ **5**

Briefly explain why you made your decision:

${attn_question}

○ **yes** ○ **no**

(Optional) Please provide any comments that you have about this HIT. Thanks for doing our HIT! We appreciate your input!



Survey Instructions

We are a group of researchers conducting research about storytelling.

In this survey, you will be provided with a **title** and **two stories** based on that title. Pick which one is a better quality story and explain why.

Better stories are:

- more **coherent**
- more **interesting**
- more **relevant to the title**

Please complete the below instructions:

1. Please read both stories, then select the one that you think is better.
2. Select how confident you are about your decision.
3. Briefly **explain** why you made the decision you did. Just basic thoughts or bullet points is fine, but this is required.
4. Answer the yes/no question at the end **based on the title**. It's not a trick question. If there is insufficient information for you to be sure, select "no".
5. Don't worry about punctuation and spelling of the stories.
6. Don't worry about the ending - stories are cut-off at a certain length words, so they may end mid-topic.

Generating Dialogue Responses from a Semantic Latent Space

Wei-Jen Ko[1] **Avik Ray**[2] **Yilin Shen**[2] **Hongxia Jin**[2]

Abstract

Existing open-domain dialogue generation models are usually trained to mimic the gold response in the training set using cross-entropy loss on the vocabulary. However, a good response does not need to resemble the gold response, since there are multiple possible responses to a given prompt. In this work, we hypothesize that the current models are unable to integrate information from multiple semantically similar valid responses of a prompt, resulting in the generation of generic and uninformative responses. To address this issue, we propose an alternative to the end-to-end classification on vocabulary. We learn the pair relationship between the prompts and responses as a regression task on a latent space instead. In our novel dialog generation model, the representations of semantically related sentences are close to each other on the latent space. Human evaluation showed that learning the task on a continuous space can generate responses that are both relevant and informative.

1 Introduction

The sequence-to-sequence framework and transformer based models are the most popular choices for designing open-domain neural response generation systems (Vinyals and Le, 2015; Wolf et al., 2018). Those models typically involve maximizing the probability of the ground truth response given the input prompt, trained using a cross entropy loss on the vocabulary. However, dialogue response generation is an open-ended, high entropy task, since there can be a wide variety of possible responses to a given prompt. A good response does not have to use similar vocabulary or similar sentence structure as the gold response, thus the end-to-end cross entropy loss is unsuitable for this task. We hypothesize that this fundamental deficiency is the primary reason why dialog generation models tend to generate bland and uninformative responses, such as *"I don't know"* (Serban et al., 2016), despite the presence of much more instances of specific responses in the training data than generic responses.

The specific issue is the following. A model trained using maximum likelihood objective treats each token of the vocabulary independently. The probabilities of each individual informative word in the vocabulary are low because the answer is open-ended. The model is unable to capture that most of the probability mass are on a group of semantically related words. Thus the words with the highest probabilities are often uninformative stop words with high frequency in the training data. A similar effect happens on the utterance level when using beam search decoding. When searching for the most probable utterance, the probability of each candidate sentence is calculated independently, and the model is unable to use the semantic relatedness between different candidate utterances (Qiu et al., 2019). While informative and specific responses collectively have a high probability, it is diluted by the large number of variations and possibilities of specific responses. On the other hand, generic responses have much less variations, thus they become the most probable response sequences. An alternative decoding method to beam search is sampling (Holtzman et al., 2020; Fan et al., 2018), which does not suffer from this problem. However, sampling does not consider the subsequent words during decoding, and the randomness in word choice makes it prone to generating implausible responses, responses with grammatical errors and coherence issues.

Aiming to take into account the semantic relatedness of diverse specific responses, we propose an alternative to cross-entropy training, which is learning the pair relationship between the prompts and responses as a regression task on a latent space.

In our novel dialog generation model, the genera-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4339–4349,
November 16–20, 2020. ©2020 Association for Computational Linguistics

tion process could be separated into two steps. The first step predicts a sentence vector of the response on the latent space, on which the representations of semantically related sentences are close to each other. Since predicting a vector is a regression problem in the latent space instead of classification in the vocabulary as in MLE loss, our model is able to learn that most of the probability mass of the response is around the cluster of possible specific responses. This is illustrated in Figure 2 showing our model's representations of prompts and responses on a t-SNE plot.

The second step constructs the full response sentence from the predicted vector. We train an autoencoder. The decoder part is used for constructing the full response sentence from the predicted sentence vector. Since the semantics of the response and the decoding are learned separately, we can perform beam search for the most probable sequence given the semantic vector during inference without preferring generic responses.

The main contributions of our work are 1) We propose to learn dialogue generation as an regression task on a semantic latent space, as an alternative of end-to-end cross entropy training used in most previous methods, to address the problem that end-to-end cross entropy classification are unable to integrate information from semantically similar responses and words. 2) Our model separates the response into information likely and unlikely to be correlated with the prompt. 3) Evaluation by crowdworkers showed that the latent space method significantly outperforms baselines using end-to-end cross entropy classification, in terms of generating responses that are both relevant and informative.

2 Related work

Several previous models also use the idea of learning on sentence vector representations. Luo et al. (2018) used two autoencoders to learn the semantic representations of inputs, and learned utterance-level dependency between those representations. Spacefusion(Gao et al., 2019) fuses the autoencoder and seq2seq feature space, so that the distance and direction from a predicted response vector roughly matches the relevance and diversity. Those methods add additional autoencoder losses to manipulate the intermediate representation space, but they still use the problematic end-to-end cross entropy loss for generation. In our work, we completely remove the end-to-end loss term, so the matching of the input and response is learned only on a shared semantic latent space. Qiu et al. (2019) proposed a two-stage generation process, which predicts the average of the reference responses as an intermediate task, but it requires multiple responses for each prompt in the training data. On the machine translation task, Kumar and Tsvetkov (2019) explored predicting continuous vectors on the word level in seq2seq models instead of using softmax classification. We predict continuous vectors on the utterance level.

There are other aspects to tackle the generic response problem, Li et al. (2016a) maximized mutual information in decoding or reranking. Zhou et al. (2017) trained multiple response mechanisms to model diversity. Shao et al. (2017) split the generation into segments and allow attention to attend to both the prompt and the response to improve diversity. Several works use explicit specificity metrics to manipulate the specificity of the responses. Frequency based metrics such as IDF are used in (Li et al., 2016b; Zhang et al., 2018a). Ko et al. (2019) proposed using a specificity metric trained on discourse relation pair data.

We use a modified version of deep canonical correlation analysis (DCCA)(Andrew et al., 2013) to learn the semantic latent space. DCCA has previously been used on various tasks including feature learning (Wang et al., 2015), caption retrieval (Yan and Mikolajczyk, 2015), multi-label classification (Yeh et al., 2017), image cross-reconstruction (Chanda et al., 2016), and multilingual word similarity (Rotman et al., 2018). (Mallinar and Rosset, 2018) experimented on performing DCCA on sequential data with a recurrent network.

3 Our Method

Given example dialogue (Prompt, Response) pairs (D_x, D_y) from open-domain dialogue datasets, our goal is to generate a relevant and non-generic response when given an unseen prompt. The structure of our model is depicted in Figure 1. It consists of three encoders; *Prompt Encoder* F_x, *Correlated Response Encoder* F_y, and *Uncorrelated Response Encoder* F_u. The final response is generated from a semantic latent vector via a *Decoder* G_y. During training all three encoders and the decoder are tuned. However, during testing only the Prompt Encoder and the Decoder are utilized.

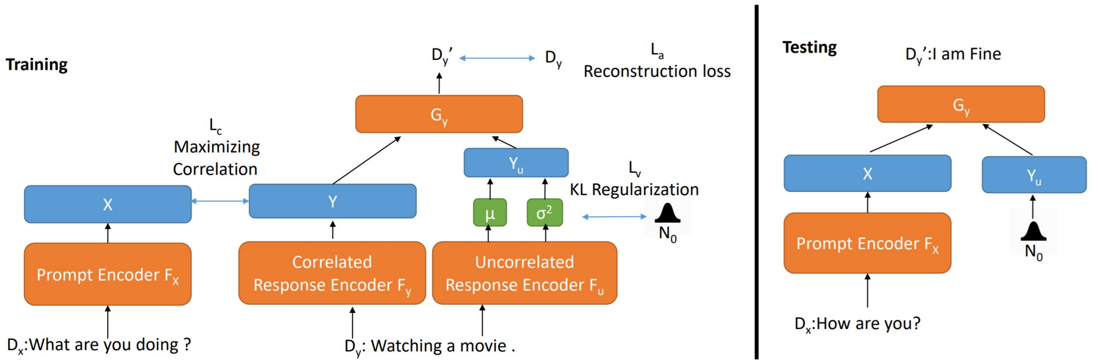

Figure 1: Model Architecture. We learn the pair relation between prompts D_x and responses D_y as an regression task on the shared semantic latent space of $X\&Y$, so the model is able to aggregate information from semantically similar sentences. We train an autoecoder to construct the response sentence from the latent space. An uncorrelated representation Y_u is allowed in the autoencoder to represent information unlikely to be related to the prompt.

3.1 Learning the correlated semantic latent space

Our aim is to learn a latent space where representations of semantically related prompts, encoded by F_x, are close to each other, and so are semantically related responses encoded by F_y. Furthermore, we want a prompt encoded by F_x to be close to its corresponding responses encoded by F_y.

For this we employ canonical correlation analysis (CCA) (Hotelling, 1936) between the prompt and response pairs. We maximize the correlation of the embeddings with the other sentence in the pair. Since semantically similar responses are likely to correspond to a similar set of prompts, semantically similar sentences will have similar representations in the CCA encoded space. Generic responses could be responses to a much larger set of prompts, so they will have very different representations in the latent space, thus they could be separated with specific responses.

We use two recurrent neural networks F_x, F_y as feature extractors to map prompts and responses into the shared featured space respectively. Using the definition of CCA, we maximize the total correlation of each dimension between $X = F_x(D_x)$, $Y = F_y(D_y)$ as follows.

$$\max\left(\sum_{i=1}^{k}\operatorname{corr}(X^i, Y^i)\right) =$$

$$\max\left(\sum_{i=1}^{k}\frac{\sum\limits_{m}(X^i_m-\bar{X}^i)(Y^i_m-\bar{Y}^i)}{\sqrt{\sum\limits_{m}(X^i_m-\bar{X}^i)^2\sum\limits_{m}(Y^i_m-\bar{Y}^i)^2}}\right), \tag{1}$$

subject to the condition

$$\forall\{i,j|i\neq j\}:\sum_{m}(X^i_m-\bar{X}^i)(X^j_m-\bar{X}^j) =$$

$$\sum_{m}(Y^i_m-\bar{Y}^i)(Y^j_m-\bar{Y}^j) = 0, \tag{2}$$

i, j are the indices of the feature dimension. $\bar{X}^i, \bar{Y}^i$ are the mean of the i-th feature dimension. m is the index of the example pair in the batch. k is the number of feature dimensions. The condition ensures that the different dimensions in the representation are uncorrelated, to avoid redundant representations.

To make the two feature spaces X and Y shared, we add the following conditions to the mean and variance of both representations, inspired by (Yeh et al., 2017).

$$\forall i : \bar{X}^i = \bar{Y}^i = 0 \tag{3}$$

$$\forall i : \sum_{m}(X^i_m)^2 = \sum_{m}(Y^i_m)^2 = C \tag{4}$$

, where C is an arbitrary constant, we use C=1.

When prompt X and response Y are perfectly correlated, and these two conditions perfectly hold, X will be equal to Y, so this makes X and Y interchangeable during inference. This is desirable because we do not have access to Y during inference.

Using the two conditions, Equations 1, 2 becomes[1]:

$$\max\left(\sum_{i=1}^{k} corr(X^i, Y^i)\right)$$
$$= \max\left(\sum_{i=1}^{k}\sum_{m} X_m^i Y_m^i\right)$$
$$= \min\left(\sum_{i=1}^{k}\sum_{m}(X_m^i - Y_m^i)^2\right), \qquad (5)$$

subject to,

$$\sum_m X_m^i X_m^j = \sum_m Y_m^i Y_m^j = 0 \qquad (6)$$

We can formulate the total CCA loss from (3) to (6) as,

$$L_c = \sum_{i=1}^{k}\left(\sum_m (X_m^i - Y_m^i)^2 + \right.$$
$$\lambda_1\left(|\sum_m X_m^i| + |\sum_m Y_m^i|\right) +$$
$$\left.\lambda_2\left(|\sum_m (X_m^i)^2 - 1| + |\sum_m (Y_m^i)^2 - 1|\right)\right)$$
$$+\lambda_3\sum_{i,j}^{i\neq j}\left(|\sum_m X_m^i X_m^j| + |\sum_m Y_m^i Y_m^j|\right) \qquad (7)$$

where $\lambda_1, \lambda_2, \lambda_3$ are tunable hyper-parameters.

3.2 Generating the response from the semantic latent space

Since X and Y are interchangeable in the semantic space, we directly use the features extracted from the prompt X to approximate the response features Y. Now we want to generate the response sentence D'_y from the latent space representations. For this purpose, an additional autoencoder is trained on all the training set responses, simultaneously with the CCA. The autoencoder consists of encoder F_y, and decoder G_y, both of which are recurrent networks. The parameters of the encoder are shared with the semantic feature extractor of the responses. During inference, features extracted from the prompt X are directly fed into the decoder to generate the response sentence.[2]

$$D'_y = G_y(F_x(D_x)) \qquad (8)$$

Generating sentences from a continuous space is known to produce ungrammatical text (Bowman et al., 2016). To address this issue, we replace some autoencoder input word tokens, by the unknown word token $\langle unk\rangle$. The probability each word is chosen to be replaced is independent and uniform. The replacing serves three purposes. First, it makes the decoder more robust, and able to generate grammatical responses when there is noise in the decoder input. This is important because the decoder input during training and inference are from different encoders. Second, it prevents the autoencoder from overfitting too early before the CCA objective converges. Finally, masked language models have been shown successful on learning representations of sentences suitable for a wide range of tasks (Devlin et al., 2019). This is desirable since this representation is also used for learning the CCA for the semantic latent space.

3.3 Correlated and uncorrelated representations

When encoding the response with F_y, the autoencoder and the CCA loss have conflicting objectives. The autoencoder task requires the representation to preserve all the information in the sentence for reconstruction. The CCA task aims to preserve only the information likely to be related to the prompt, and discard all other irrelevant information. For example, a paraphrase pair are likely to be valid responses to the same prompts, so they should have the same representation under CCA objective, but the autoencoder objective forces the representations to be different, to enable reconstruction of the exact sentences. A response could also include a topic change, which makes part of the response completely irrelevant to the prompt, and that information should not be in the CCA representation.

To model this issue, we separate the autoencoder representations into the correlated part Y, which correlates with the prompt, and the uncorrelated part Y_u. The correlated part learns both the autoen-

---

[1] In practice, the correlation is calculated for each batch separately, so it is important that the process of dividing training data into batches is random, and the batch size is sufficiently large.

[2] We also experimented on adding domain discriminative adversarial training (Tzeng et al., 2017) between X and Y, but it did not improve the results. This shows that our conditions (1),(3),(4) already make the distribution of the two encoders sufficiently similar.

coder task and the CCA task. The uncorrelated part is only trained for autoencoder reconstruction.

During training, G_y learns to reconstruct from the concatenation of the correlated and uncorrelated representations. The reconstruction is trained using cross entropy loss.

$$D'_y = G_y([Y; Y_u]) = G_y([F_y(D_y); F_u(D_y)]) \tag{9}$$

$$L_a = \text{Cross Entropy}(D_y, D'_y) \tag{10}$$

During testing, G_y generates the response from the CCA semantic representation of the prompt and a vector R representing the uncorrelated part of the response.

$$D'_y = G_y([F_x(D_x); R]) \tag{11}$$

By adding additional regularization to the uncorrelated representation Y_u during training, we encourage a normal distribution with zero mean and unit variance for each dimension. Hence during inference we can sample R from this distribution or use a fixed prior to approximate Y_u.

The formulation of the regularization is the same as variational autoencoders (Kingma and Welling, 2014). An encoder recurrent network F_u predicts a mean μ and variance σ^2 for each dimension, and Y_u is sampled from that multivariate normal distribution. The predicted μ and σ^2 is regularized by the KL divergence with unit normal distribution.

$$L_v = \sum_i \sum_m ((\mu_m^i)^2 + (\sigma_m^i)^2 - log((\sigma_m^i)^2)) \tag{12}$$

With this regularization, R can either be set to all zeroes , or be randomly drawn from a unit normal distribution. We found that the generated sentence is insensitive to this choice, so the two ways generate exactly the same sentence more often than not. Despite the insensitivity, we calculated the ratio between the KL loss and the autoencoder reconstruction loss, and found that the ratio consistently increases during training, indicating that there is no posterior collapsing (Chen et al., 2017). We also found that adding the uncorrelated representation allows both the CCA loss and the autoencoder reconstruction loss to converge to a significantly lower value. Inspection on generated sentences showed that there is obvious improvement on relevance, at the cost of slightly more frequent grammatical errors.[3]

During training, the gradients of all loss terms are weighted and summed and all parameters are updated together. The total loss is:

$$\mathcal{L} = \lambda_4 L_c + \lambda_5 L_a + \lambda_6 L_v \tag{13}$$

where $\lambda_4, \lambda_5, \lambda_6$ are hyper-parameters.

3.4 Attention

The described model does not have an attention mechanism, so it cannot dynamically focus on different parts of the prompt during generation. We also experiment with a variant of our model with attention (Luong et al., 2015). Similar to previous works, the key and value is from the RNN hidden state of the prompt encoder F_x, and the query is the hidden state of the response decoder G_y. To prevent nullifying the main purpose of our model design: removing end-to-end MLE training, we create a bottleneck to limit the end-to-end information flow before concatenating the attention output vector with the hidden state. The bottleneck is a fully connected layer that reduces the attention output vector into a low dimension.[4]

4 Experiments

4.1 Methodology

We conduct experiments on two datasets: PersonaChat (Zhang et al., 2018b) and DailyDialog (Li et al., 2017). PersonaChat is a chit-chat dataset collected by crowdsourcing. We do not use the personas in the dataset since they are not related to our work. We use 122 499 prompt-response pairs for training, 3 000 pairs for validation and 4 801 pairs for testing. DailyDialog is a collection of conversations in daily life for English learners. We remove those prompt-response pairs in the validation and test set that also appears in the training set, which resulted in about 30% of pairs removed in the test set. The final dataset has 76 052 pairs for training, 5 334 pairs for validation, and 4 738 pairs for testing.

We compare our models with the vanilla Seq2seq model with attention (Luong et al., 2015) trained using cross entropy loss, decoded using beam search and nucleus sampling (Holtzman et al., 2020). We also compare with previous works MMI-anti (Li

---

[3] To avoid introducing excessive noise while using R as an approximation, we use only 10 dimensions for the uncorrelated part. Higher number of dimensions resulted in worse performance in our experiments.

[4] We use dimension 10. Without the bottleneck, the model will only rely on attention and completely ignore F_x and F_y, effectively degenerating into a Seq2Seq model.

Table 1: Result comparison of all models on PersonaChat and DailyDialog datasets using different automatic and human evaluation metrics. Our model generates responses that are both informative and relevant.

et al., 2016a) and SpaceFusion (Gao et al., 2019). MMI-anti also addresses the generic response issue. It is based on mutual information, and improves the Seq2seq model by penalizing frequent responses with an anti-language model. SpaceFusion is a recent method which learns a fused common space representation of the Seq2seq dialogue generation task and the autoencoder task, it falls on the same line of work that tries to manipulate the latent space representations. We use the authors' code. For these two baselines and our models, we report the result of the decoding method (beam search or sampling) that performed better. The goal of our experiments is to compare learning on the latent space with end-to-end cross entropy training.

We use 1 layer GRU for all encoders and decoders. The correlated representation size is 512, the uncorrelated representation size is 10. We implement F_y and F_u as different output dimensions of the same GRU. For compared methods we use hidden layer size 522. The word embedding dimension is 128. We use Adam optimizer with learning rate 0.001, $\beta_1 = 0.9, \beta_2 = 0.999$. Batch size is 64. $\{\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5, \lambda_6\}$ is set to $\{$3.9,6.25,0.05,2,2,0.1$\}$, they are tuned to make the conditions (2), (3), (4) enforced properly. For our model with attention, the attention bottleneck has dimension 10. Our models were trained on one Tesla M40 GPU, and the run time was less than 2 hours.

4.2 Human evaluation

Human evaluation is the only reliable way to evaluate this task. Following the standards of (Shao et al., 2017; Liu et al., 2018; Zhang et al., 2018a; Qiu et al., 2019), for each model, we randomly sample 500 pairs from our test set, and each pair is rated by 3 distinct crowdsourcing workers.[5] Our evaluation involved a pool of around 400 distinct workers in total. We ask them to rate 1) informativeness and specificity of each response and 2) if the response is on topic (relevance), on a Likert scale from 0 to 3. We report the average of all annotations for both metrics. We also design a new metric, the useful information (UI) score, which is multiplying informativeness with relevance for each sentence, and then take the average over all sentences. The intuition of this score is that a response has to be both informative and on topic to be good. If one response is very informative, but not on topic, then all of the information it provides is useless. On the other hand, if a response is answering the prompt, but uninformative, it is a generic response which is undesirable. Thus the UI score could be used to approximate the quality of the responses.

We mix some quality control sentences with the model responses in the task for workers. Those workers who failed to rate these quality control sentences reasonably were excluded. We mix the responses from different models in the tasks given to each worker, so the bias of individual workers would not affect the relative performance between different models. The interannotator pearson correlation is 0.55.

The results are shown in Table 1. Note that there is a trade-off between informativeness and rele-

PersonaChat	
Prompt	wow i love to see traditional dance .
MLE+beam search	do you have a favorite color ?
MMI	yes , i love the color blue .
Spacefusion	i am not sure . i am a college student .
Ours	its fun . i've always wanted to go for a dance class .
Prompt	do you go to school at all
MLE+beam search	i do not have a job but i want to be a doctor
MMI	sometimes , but i do like photography .
Spacefusion	i do not . i am a college student .
Ours	i don't . i'm studying to go to college .
Prompt	i live in nebraska . i don't think i have ever been to ohio before .
MLE+beam search	oh wow . what do you do for a living ?
MMI	oh do you do volunteer work
Spacefusion	oh wow . i love to go to the beach .
Ours	wow , i have been there . do you have a favorite place ?
DailyDialog	
Prompt	Can you operate computers skillfully ?
MLE+beam search	Yes , I am .
MMI	Yes , I have a special job .
Spacefusion	Yes , I can . I have any other Word 2003 , and I can live in other areas .
Ours+Attention	No , I am not familiar with both Java and C Programming Languages .
Prompt	Exporters must ensure that their product satisfies customers ' needs , wants and likes .
MLE+beam search	Do you have any other questions ?
MMI	We have to buy a new set .
Spacefusion	I am calling to see you . But I've got a new customer here . But I don't want to be aware of their house .
Ours+Attention	That means that we have a commission about selling electronics . The prices are perfect for you to promote the commission and the prices are cheaper .
Prompt	It closes at 7:00 on Sundays .
MLE+beam search	You're welcome , I can help you .
MMI	How do you get that ?
Spacefusion	Nice to see you . The alarm isn't a fool .
Ours+Attention	Hold on , I have some other classes available .

Table 2: Example model responses

vance, since a generic response can reply to a wide range of prompts, it will be easier for them to be will, and informative responses are more specialized, thus it would be more difficult for them to be relevant. Example model responses are shown in Table 2.

On the PersonaChat dataset, SpaceFusion and MLE+sampling could generate very informative responses, but the relevance score is low, indicating the responses are often not on topic. Our model outperforms MLE+beam search and MMI on both relevance and informativeness. On the DailyDailog dataset, MLE+sampling scores highest on informativeness, but the responses are not on topic. Both MMI and MLE+beam search are relevant but prone to generic responses. Our models are the only ones that could be both informative and coherent. Adding attention to our model improves both relevance and informativeness on the DailyDialog dataset, but harms informativeness on the PersonaChat dataset. Our models performs best on the UI score for both datasets. We performed bootstrapping significance test, and found that our improvements are statistically significant.

4.3 Automatic evaluation

Almost all existing automatic metrics for dialog generation compares the generated response and the gold response in some way. However, a good response could be open-ended and doesn't have to resemble the gold response. Liu et al. (2016) showed that automatic metrics have low correlation with human judgements. Furthermore, because our model is not trained to mimic the gold response, these metrics are especially unsuitable for evaluating our model. Take perplexity for example, when training a vanilla Seq2seq model on PersonaChat, the test perplexity could achieve $\sim$ 38 (Zhang et al., 2018b). For our model, the test perplexity is very high ($10^3 \sim 10^4$), because unlike previous methods, our model does not optimize for low cross-entropy loss on the vocabulary. Nonetheless, human evaluation obviously prefer our model over Seq2seq, verifying that low perplexity is not necessary for a good model. Despite the deficiencies of those automatic metrics, they are still widely used because there are no good alternatives. For reference only, we include the results of the following automatic metrics for reference in Table 1: (1) BLEU-1 and BLEU-2 (Papineni et al., 2002) (2) Embedding Average cosine similarity (Foltz et al., 1998) between the sentence vectors of the generated and gold response. The sentence embedding is computed by averaging the GloVe embedding of each word in the sentence. This metric measures the coherence of the response. (3) dist-1 and dist-2 (Li et al., 2016a), which evaluates the diversity of the generated responses. They respectively calculate the count of distinct unigrams and bigrams, divided by the total number of words in all responses. Those metrics are also used in (Zhang et al., 2018a; Xu et al., 2018; Gu et al., 2019; Qiu et al., 2019).

For the BLEU scores, we can see that even though we do not train to mimic the gold responses, Our model still gets higher BLEU than most of the baselines, showing the effectiveness of our latent space method over MLE training. For the embedding similarity score, our model consistently outperform other compared methods. The calculation of Dist scores involves the sentence length in the denominator. As shown in Table 2, the responses generated by MMI is often short, and our responses for Daily dialog are long, thus influencing the Dist scores. Ungrammatical bigrams could cause Dist-2 to be high, as in MLE+sampling in DailyDialog.

4.4 Ablation study

We compare our full model with two variants and test the contribution of different parts in our model. We use the PersonaChat dataset for this experiment. The **w/o Uncorrelated part** model does not have the representation Y_u, the autoencoder reconstruction is solely based on Y, which also learns the CCA task. In the **w/o Denoising** model, we do not replace random words with $\langle unk \rangle$ in the autoencoder input.

As shown in Table 1, without the uncorrelated part, there is an obvious decrease in relevance, showing that allowing uncorrelated information is important for the learning the correlation between the prompt-response pairs. Without denoising, the generated sentences contain many grammatical errors. Since the sentences are obviously unacceptable by humans, we did not perform human evaluation. All automatic metrics also decreased, except Dist-2 is high because there are ungrammatical bigrams. This shows that denoising is critical for our model to generate grammatical responses.

4.5 Visualizing the semantic space

In order to verify that the shared latent space successfully encodes semantic information, we visualize the representations of some sentences in Figure 2. The dimension reduction is performed using t-SNE (van der Maaten, 2009) trained on 1 000 prompt representations and 1 000 response representations in the test set.

The light red point is the latent representation of the sentence *"what instruments do you play ?"* encoded by the prompt encoder F_x. The seven dark red points are possible responses encoded by the response encoder F_y, such as *"i practice the piano every day ."*, *"i am learning the guitar ."* Similarly, the light and dark blue, green, and yellow points show possible responses to three other questions.

We can see that semantically related responses to the same question are clustered, showing that the latent space is indeed able to capture semantic information. The questions' representation is close to the cluster of their corresponding responses, demonstrating that our model has successfully learned from the collection of semantically similar possible responses.

We also visualize *"i don't know ."* in black, and the most frequent generic response of the Seq2Seq model trained on PersonaChat, *"what do you do for a living ?"* in brown, using the response encoder F_y. Those generic responses are much farther away from the question than specific responses, thus they are unlikely to be generated. Note that the prompts and responses are encoded by separate encoders but plotted on the same space, so there are two points for "what do you do for a living ?", one as a prompt and the other as a response.

4.6 Grammaticality and comprehensibility

Since generating text from a continuous space was previously found to produce grammatical errors (Bowman et al., 2016), we show 500 PersonaChat

(a)

Prompt D_x (Light red)	**Prompt D_x (Light green)**
what instruments do you play ?	what do you do for a living ? (Encoded by prompt encoder)
Response D_y (Dark red)	**Response D_y (Dark green)**
i practice the piano every day . i can play anything on my electric violin . i am learning the guitar . i like the drums a lot i used to play clarinet . i play trombone , alto sax , baritone , and trumpet . you ? my parents taught me flute	i work as an elementary teacher . i am an olympic gymnast aside from nursing , i work at a bar to pay for school . i'm a janitor , but i also play music at night . you ? since i was fired i found a job in insurance . i work part time as a bartender , but i don't drink any alcohol mechanical engineering is my day job .
Prompt D_x (Light blue)	**Prompt D_x (Light yellow)**
what is your favorite color ?	ya , are you a female ?
Response D_y (Dark blue)	**Response D_y (Dark yellow)**
my favorite color is green and whats yours i like red too , with a bit of yellow . like a superhero ! blue color makes me happy mine is orange ! i like rainbow colors , you ? red , blue , green , and yellow . i am thinking purple too strangely my favorite is grey !	yes i am a woman . not much to tell , i'm an average male . tell me about you . female i am just a boy with a heart outside my body i am a 12 year old female
Response D_y (Brown)	**Response D_y (Black)**
what do you do for a living ? (Encoded by response encoder)	I don't know .

(b)

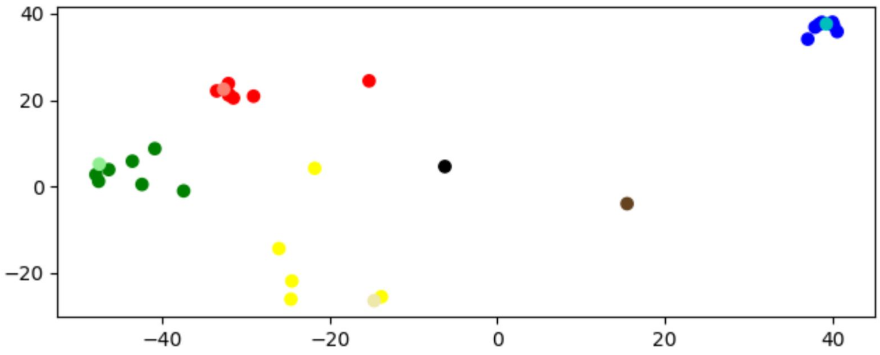

Figure 2: t-SNE Visualization of the semantic latent space. The representations of the sentences in (a) are plotted in (b). Prompts D_x and responses D_y are encoded by separate encoders F_x and F_y. Multiple semantically related responses are close to each other and close to the corresponding prompt, while generic responses are far away.

responses, each to 3 crowdworkers to evaluate the grammaticality and comprehensibility of our model. We asked them to choose between the following options: About 11% of sentences contain major grammatical errors that makes understanding the sentence difficult. 18% contain minor errors that do not affect the understanding of the sentence. 71% of the sentences are grammatically correct. This shows that most of the responses of our model are acceptable by humans, and comprehensibility is not a major problem for our latent space method.[6]

5 Conclusion

In this work, we pointed out that end-to-end cross entropy classification used in most previous methods is not able to integrate information from different semantically similar words responses, and designed a substitute method that is able to do so. Our method learns the pair relationship between prompts and responses as a regression task on a latent space, which is more suitable for the open-ended nature of this task. We performed ablation study to validate the components of our model. Human evaluation results concretely demonstrate that our latent space method significantly outperforms baselines using end-to-end cross entropy training, in terms of relevance and informativeness.

---

[6] MLE+beam search almost never makes grammatical errors as most responses are generic. While responses gets more informative and complicated, the issue of grammaticality becomes more probable.

Abstract

Dialogue participants often refer to entities or situations repeatedly within a conversation, which contributes to its cohesiveness. Subsequent references exploit the common ground accumulated by the interlocutors and hence have several interesting properties, namely, they tend to be shorter and reuse expressions that were effective in previous mentions. In this paper, we tackle the generation of first and subsequent references in visually grounded dialogue. We propose a generation model that produces referring utterances grounded in both the visual and the conversational context. To assess the referring effectiveness of its output, we also implement a reference resolution system. Our experiments and analyses show that the model produces better, more effective referring utterances than a model not grounded in the dialogue context, and generates subsequent references that exhibit linguistic patterns akin to humans.

1 Introduction

When speakers engage in conversation, they often refer to the same objects or situations more than once. Subsequent references (McDonald, 1978) are dependent on the shared knowledge that speakers accumulate during dialogue. For example, dialogue participants may first mention *"a white fuzzy dog with a wine glass up to his face"* and later refer to it as *"the wine glass dog"*, as shown in Figure 1, dialogue 1. Speakers establish 'conceptual pacts', i.e., particular ways of conceptualising referents that condition what is perceived as coherent in a given dialogue (Garrod and Anderson, 1987; Brennan and Clark, 1996). While *"the wine glass dog"* may be odd as a standalone description, it is an appropriate referring expression in the above conversational context. Yet, uttering it in a different context (such as dialogue 2 in Figure 1, after the participants had successfully referred to the image as *"the dog on the red chair"*) may disrupt the cohesion of the dialogue and lead to communication problems (Metzing and Brennan, 2003).

Referring utterances extracted from dialogue 1
A: a white fuzzy dog with a wine glass up to his face
⤳ B: I see the wine glass dog
⤳ A: no I don't have the wine glass dog

Referring utterances extracted from dialogue 2
C: white dog sitting on something red
⤳ D: yes I have the dog on the red chair
⤳ C: white dog on the red chair

Figure 1: Two chains of referring utterances from two games with different participants, including the first description of the target image in that dialogue and two subsequent references (⤳). In the game, each participant sees 5 additional images besides the target shown here. The distractor images change at every round of the game, i.e., each co-referring utterance within a dialogue is produced in a slightly different visual context.

In this paper, we tackle the generation of referring utterances—i.e., utterances that contain referring descriptions, as in Figure 1—grounded both in the visual environment and the dialogue context. These utterances have several interesting properties that make their automatic generation challenging. First, they are produced with the communicative goal of helping the addressee identify the intended referent. Second, because humans operate under cognitive and time-bound constraints, dialogue participants will aim to fulfil this communicative goal while optimising the use of their limited cognitive resources. This results in two common fea-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4350–4368,
November 16–20, 2020.

tures of subsequent mentions: (1) *Reduction:* Utterances tend to become shorter—a well attested phenomenon since the work of Krauss and Weinheimer (1967)—as a result of interlocutors' reliance on their common ground (Stalnaker, 2002): As more shared information is accumulated, it becomes predictable and can be left implicit (Grice, 1975; Clark and Wilkes-Gibbs, 1986; Clark and Brennan, 1991; Clark, 1996). Sentence compression also takes place in discourse, as predicted by the entropy rate principle (Genzel and Charniak, 2002; Keller, 2004). (2) *Lexical entrainment:* Speakers tend to reuse words that were effective in previous mentions (Garrod and Anderson, 1987; Brennan and Clark, 1996) possibly due to priming effects (Pickering and Garrod, 2004). Thus, besides being a challenging problem intriguing from a linguistic and psycholinguistic point of view, computationally modelling the generation of subsequent references can contribute to better user adaptation in dialogue systems and to more natural human-computer interaction.

For our study, we use data from the PhotoBook dataset (Haber et al., 2019), developed to elicit subsequent references to the same images within task-oriented dialogue. To isolate the issue we are interested in, we extract, from each dialogue, the utterances that refer to a given image. This results in a dataset of dialogue-specific chains of co-referring utterances: For example, Figure 1 shows two chains of co-referring utterances from two different dialogues, both referring to the same image. Figure 2 shows another example. We then formulate the problem as the generation of the next utterance in a chain given the current visual context and the common ground established in previous co-referring utterances (whenever these are available). To computationally model this problem, we propose three variants of a generation system based on the encoder-decoder architecture (Sutskever et al., 2014). We evaluate their output with metrics commonly used in the domain of Natural Language Generation and with several linguistic measures. In addition, to assess the communicative effectiveness of the generated references, we implement a reference resolution agent in the role of addressee.

We find that conditioning the generation of referring utterances on previous mentions leads to better, more effective descriptions than those generated by a model that does not exploit the conversational history. Furthermore, our quantitative and qualitative analysis shows that the context-aware model generates subsequent references that exhibit linguistic patterns akin to humans' regarding markers of new vs. given information, reduction, and lexical entrainment, including novel noun-noun compounds.

Our data, code, and models are available at `https://dmg-photobook.github.io`.

2 Related Work

Generation of distinguishing expressions Our work is related to Referring Expression Generation (REG), a task with a long tradition in computational linguistics that consists in generating a description that distinguishes a target from a set of distractors—Krahmer and van Deemter (2012) provide an overview of early approaches. Follow-up approaches focused on more data-driven algorithms exploiting datasets of simple visual scenes annotated with symbolic attributes (e.g., Mitchell et al., 2013a,b, among others). More recently, the release of large-scale datasets with real images (Kazemzadeh et al., 2014) has made it possible to test deep learning multimodal models on REG, sometimes in combination with referring expression comprehension (Mao et al., 2016; Yu et al., 2017). While REG typically focuses on describing objects within a scene, a few approaches at the intersection of REG and image captioning (Bernardi et al., 2016) have aimed to generate discriminative descriptions of full images, i.e., image captions that can distinguish the target image from a pool of related ones (Andreas and Klein, 2016; Vedantam et al., 2017; Cohn-Gordon et al., 2018). Similarly to these approaches, in the present work, we generate utterances that refer to a full image with the aim of distinguishing it from other distractor images. In addition, our setup has several novel aspects: The referring utterances are the result of interactive dialogue between two participants and include subsequent references.

Generation of subsequent references Follow-up work within the REG tradition has extended the early algorithms to deal with subsequent references (Gupta and Stent, 2005; Jordan and Walker, 2005; Stoia et al., 2006; Viethen et al., 2011). These approaches focus on content selection (i.e., on generating a list of attribute types such as `color` or `kind` using an annotated corpus) or on choosing the type of reference (definite or indefinite noun phrase, pronoun, etc.) and do not directly exploit visual representations. In contrast, we generate the surface realisation of first and subsequent referring utterances end-to-end, grounding them in continuous visual features of real images.

Our work is related to a recent line of research on reference *resolution* in visually-grounded dialogue, where previous mentions have been shown to be useful (Shore and Skantze, 2018; Haber et al., 2019; Roy et al., 2019). Here we focus on *generation*. To our knowledge, this is the first attempt at generating visually grounded referring utterances taking into account earlier mentions in the dialogue. Some work on generation has exploited dialogue history in order to make lexical choice decisions that align with what was said before (Brockmann et al., 2005; Buschmeier et al., 2009; Stoyanchev and Stent, 2009; Lopes et al., 2015; Hu et al., 2016; Dušek and Jurčíček, 2016). Indeed, incorporating entrainment in dialogue systems leads to an increase in the perceived naturalness of the system responses and to higher task success (Lopes et al., 2015; Hu et al., 2016). As we shall see, our generation model exhibits some lexical entrainment.

Dialogue history in visual dialogue Recent work in the domain of visually grounded dialogue has exploited dialogue history in encoder-decoder models trained on large datasets of question-answering dialogues (Das et al., 2017; De Vries et al., 2017; Chattopadhyay et al., 2017). Recently, Agarwal et al. (2020) showed that only 10% of the questions in the VisDial dataset (Das et al., 2017) genuinely require dialogue history in order to be answered correctly, which is in line with other shortcomings highlighted by Massiceti et al. (2018). More generally, visually grounded dialogue datasets made up of sequences of questions and answers lack many of the collaborative aspects that are found in natural dialogue. For our study, we focus on the PhotoBook dataset by Haber et al. (2019), where dialogues are less restricted and where the common ground accumulated over the dialogue history plays an important role.

3 Data

3.1 PhotoBook Dataset

The PhotoBook dataset (Haber et al., 2019) is a collection of task-oriented visually grounded English dialogues between two participants. The task is set up as a game comprised of 5 rounds. In each round, the two players are assigned private 'photo books' of 6 images, with some of those images being present in both photo books. The goal is to find out which images are common to both players by interacting freely using a chat interface. In each round, the set of 6 images available to each player changes, but a subset of images reappears, thus triggering subsequent references to previously described images. This feature of the PhotoBook dataset makes it a valuable resource to model the development of conversational common ground between interlocutors. The dataset consists of 2,500 games, 165K utterances in total, and 360 unique images from MS COCO (Lin et al., 2014).

3.2 Dataset of Referring Utterance Chains

As mentioned above, in PhotoBook participants can freely interact via chat. The dialogues thus include different types of dialogue act besides referring utterances. While utterances performing other functions are key to the dialogue and may provide useful information, in the present work we abstract away from this aspect and concentrate on referring utterances.[1] To create the data for our generation task, we extract utterances that contain an image description and their corresponding image target from the dialogues as follows. Within a game round, we consider all the utterances up to the point where a given image i has been identified by the participants[2] as candidate referring utterances for i – see Figure 2. We then compare each candidate against a reference set of descriptions made up of the MS COCO (Lin et al., 2014) captions for i and the attributes and relationship tokens of i in the Visual Genome (Krishna et al., 2017). We score each candidate utterance with the sum of its BERTScore[3] (Zhang et al., 2020) for captions and its METEOR score (Banerjee and Lavie, 2005) for attributes and relationships. The top-scoring utterance in the game round is selected as a referring utterance for i and used as an additional caption for extracting subsequent references in the following game rounds. As a result of this procedure, for a given dialogue and an image i, we obtain a reference chain made up of the referring utterances—maximum one per round—that refer to i in the dialogue. Since images do not always reappear in each round, chains can have different

---

[1] Haber et al. (2019) extracted co-reference chains made up of multi-utterance dialogue excerpts. Our chains include single utterances, which is more suitable for generation.

[2] Image identification actions are part of the metadata.

[3] BERTScore uses contextualised embeddings (Devlin et al., 2019) to assess similarity between a target sentence and one or more reference sentences.

Dialogue fragment and images visible to participant A in the first round of a game

A: Hi
B: Hello.
B: do you have a white cake on multi colored striped cloth?
A: **I see a guy taking a picture. What about you?**
B: is it of a cake with construction trucks on it?
A: Yeah. I don't see the cake you mentioned.
A: `<common img_4>`

Resulting referring utterance chain with subsequent references extracted from the following game rounds

1. I see a guy taking a picture. What about you?
2. guy with camera
3. I have the guy with camera
4. The last one is the camera guy.

Figure 2: Example from our new dataset of referring utterance chains. Given a target image selected by a participant (here `<common img_4>`), the utterances in the dialogue prior to that selection action are scored by their likelihood of referring to the target. In this example, the utterance in bold is selected as the first description. To construct the reference chain, subsequent references are extracted in a similar manner from the dialogue in the following game rounds. The set of distractor images available to a participant changes across rounds.

length. Two examples of chains of length 3 are shown in Figure 1 and a chain of length 4 in Figure 2. Given that each utterance in a chain belongs to a different game round, each utterance was produced in a slightly different visual context with different distractor images. Figure 2 shows the visual context available to participant A in the first round of a game, when the participant produced the first description in the dialogue for target image number 4. The other three descriptions in the chain were produced while seeing different distractors.

We evaluate the referring utterance extraction procedure and the resulting chains using 20 dialogues hand-annotated by Haber et al. (2019) with labels linking utterances to the target image they describe. Using our best setup, we obtain a precision of 0.86 and a recall of 0.61. The extracted chains are very similar to the human-annotated ones in terms of chain and utterance length.

Our new dataset is made up of 41,340 referring utterances and 16,525 chains (i.e., there are 16,525 first descriptions and 24,815 subsequent references). The median number of utterances in a chain is 3. We use the splits defined by Haber et al. (2019) to divide the dataset into Train, Validation, and Test, and all hand-annotated dialogues are excluded from these splits. Table 1 reports relevant descriptive statistics of the dataset. More details about the extraction procedure and the dataset are available in Appendix A. Appendix B describes how the dataset is further processed to be used in our models.

Split	**Games**	***First***		***Later***	
		N	**Length**	**N**	**Length**
Train	1725	11540	10.52 (4.80)	17393	7.52 (4.15)
Val	373	2503	10.49 (4.81)	3749	7.70 (4.22)
Test	368	2482	10.52 (4.85)	3673	7.59 (4.17)

Table 1: Number of games and referring utterances in the splits of our dataset with their average length in tokens (standard deviation in brackets) broken down by first mentions vs. subsequent ('Later') references.

4 Models

With the new dataset of referring utterance chains in place, we operationalise the problem of generating a referring utterance taking into account the visual and conversational context as follows. The model aims to generate a referring utterance given (a) the *visual context* in the current game round made up of 6 images from the perspective of the player who produced the utterance, (b) the *target* among those images, and (c) the *previous co-referring utterances* in the chain (if any). Besides being contextually appropriate, the generated utterance has to be informative and discriminative enough to allow an addressee to identify the target image. We thus also develop a reference resolution model that plays the role of addressee. The two models are trained independently.

4.1 Generation Models

We propose three versions of the generation model, which all follow the encoder-decoder architecture (Sutskever et al., 2014). These versions differ from each other with respect to whether and how they exploit earlier referring utterances for the target image: (1) a baseline model that does not use the dialogue context at all (hence, **Ref**); (2) a model that conditions the generation on the previous referring utterance, if available, and operates attention over it (hence, **ReRef**); (3) a model that builds on (2) by adding a 'copy' mechanism (See et al., 2017) (hence, **Copy**). We describe them below and provide further details in Appendix C.

Ref This model is provided only with the information about the visual context in the current game round–and not with the linguistic context in previous rounds. We encode each image in the context by means of visual features extracted from the penultimate layer of ResNet-152 (He et al., 2016) pretrained on ImageNet (Deng et al., 2009). First, the visual features of the 6 candidate images are concatenated. This concatenated vector goes through dropout, a linear layer and ReLU (Nair and Hinton, 2010). The same process is applied for the single target image. We then concatenate the final visual context vector with the target image vector, apply a linear transformation, and use the resulting hidden representation h_d to initialise an LSTM decoder, which generates the referring utterance one word at a time. At each timestep, the input to the decoder is a multimodal vector, i.e., the concatenation of h_d and the word embedding of token t_t. The weights of the embeddings are initialised uniformly in the range $(-0.1, 0.1)$ and learned from scratch for the task at hand.

ReRef With this model, we aim to simulate a speaker who is able to *re-refer* to a target image in accordance with what has been established in the conversational common ground (Clark, 1996; Brennan and Clark, 1996). The model enriches **Ref** by incorporating linguistic information into the encoder (in addition to visual information) and an attention mechanism applied over the hidden states of the encoder during decoding. The model thus generates a new utterance conditioned on both the visual and the linguistic context.

The encoder is a one-layer bidirectional LSTM initialised with the same visual input fed to **Ref**. In addition, it receives as input the previous referring utterance used in the dialogue to refer to the target image,[4] or else is fed the special <nohs> token, indicating that there is no conversational history for the target image yet. We utilise the attention mechanism proposed by Bahdanau et al. (2018) and used by See et al. (2017). During decoding, attention contributes to determining which aspects of the multimodal context are most critical in generating the next referring utterance. We expect this attention mechanism to be able to identify the words in a previous utterance that should be present in a subsequent reference, resulting in lexical entrainment.

Copy This model builds on **ReRef** and incorporates a means of simulating lexical entrainment more explicitly, by regulating when a word used in the previous mention should be used again in the current referring utterance (i.e., should be produced by the decoder). Given the shortening property of subsequent references mentioned in the Introduction, our task bears some similarity to text summarisation. We thus draw inspiration from the summarisation model proposed by See et al. (2017). In particular, we equip the model with their 'copy' mechanism, which combines the probability of copying a word present in the encoded input with the probability of generating that word from the vocabulary. We expect this mechanism to contribute to generating rare words present in preceding referring utterances that are part of a 'conceptual pact' (Brennan and Clark, 1996) between the dialogue participants, but may have low generation probability overall.

4.2 Reference Resolution Model

Given an utterance referring to a target image and a 6-image visual context, our reference resolution model predicts the target image among the candidates. This model is similar to the resolution model proposed by Haber et al. (2019) for the PhotoBook dataset, but includes several extensions: (1) We use BERT embeddings from the uncased base BERT model (Devlin et al., 2019; Wolf et al., 2019) to represent the linguistic input rather than LSTMs;[5] (2) The input utterance is encoded taking into account the visual context: We compute a multimodal representation of the utterance by concatenating each BERT token representation with the visual context representation, obtained in the same way as for the generation models;[6] (3) We apply at-

---

[4] The latest description seems to contain the most relevant information. Including all referring utterances in the chain up to that point in the dialogue did not lead to improvements.

[5] In the generation models, we did not use BERT due to the difficulties of using contextualised embeddings in the decoder, and the desirability of using the same word embeddings in both the encoder and the decoder.

[6] We also tried using multimodal representations obtained via LXMERT (Tan and Bansal, 2019). No improvements were

tention over the multimodal representations of the utterance in the encoder instead of using the output from a language-only LSTM encoder. The utterance's final representation is given by the weighted average of these multimodal representations with respect to the attention weights.

Each candidate image is represented by its ResNet-152 features (He et al., 2016) or, if it has been previously referred to in the dialogue, by the sum of the visual features and the representation of the previous utterance (obtained via averaging its BERT embeddings).[7] To pick a referent, we take the dot product between the representation of the input utterance and each of the candidate image representations. The image with the highest dot-product value is the one chosen by the model.

4.3 Model Configurations

For each model, we performed hyperparameter search for batch size, learning rate, and dropout; also, the search included different dimensions for the embedding, attention, and hidden layers. All models were trained for up to 100 epochs (with a patience of 50 epochs in the case of no improvement to the validation performance) using the Adam optimiser (Kingma and Ba, 2015) to minimise the Cross Entropy Loss with sum reduction. BERTScore F1 (Zhang et al., 2020) in the validation set was used to select the best model for the generation task, while we used accuracy for the resolution task. In the next section, we report average scores and standard deviations over 5 runs with different random seeds. Further details on hyperparameter selection, model configurations, and reproducibility can be found in Appendix E.

5 Results

5.1 Evaluation Measures

We evaluate the performance of the reference resolution model by means of both accuracy and Mean Reciprocal Rank (MRR). As for the generation models, we compute several metrics that are commonly used in the domain of Natural Language Generation. In particular, we consider three measures based on n-gram matching: BLEU-2 (Papineni et al., 2002),[8] ROUGE (Lin, 2004), and CIDEr (Vedantam et al., 2015). We also compute BERTScore F1 (Zhang et al., 2020) (used for model selection), which in our setup compares the contextual embeddings of the generated sentence to those of the set of referring utterances in the given *chain*. Further details of the metrics are in Appendix D.

All these measures capture the degree of similarity between generated referring utterances and their human counterparts. In addition, to assess the extent to which the generated utterances fulfil their communicative goal, we pass them to our reference resolution model and obtain accuracy and MRR. While this is not a substitute for human evaluation, we take it to be an informative proxy. In Section 6, we analyse the generated utterances with respect to linguistic properties related to phenomena that are not captured by any of these metrics.

5.2 Reference Resolution Results

Our reference resolution model achieves an accuracy of 85.32% and MRR of 91.20% on average over 5 runs. This is a substantial result. A model that predicts targets at random would yield an accuracy of roughly 16.67% (as the task is to pick one image out of 6 candidates), while a baseline that simply takes one-hot representations of the image IDs in the context achieves 22.37% accuracy.[9]

Subset	ACC	MRR	Instances
First	80.27 (0.46)	87.78 (0.28)	2482
Later	88.74 (0.18)	93.51 (0.09)	3673
Overall	85.32 (0.19)	91.20 (0.10)	6155

Table 2: Test set scores of the reference resolution model: averages of 5 runs with the best configuration, with the standard deviations in parentheses.

In Table 2, the results are presented by breaking down the test set into two subsets: the *first* referring utterances in a chain, and *later* referring utterances, i.e., subsequent references where the target image among the candidates has linguistic history associated with it. The model performs better on subsequent references. Exploiting dialogue history plays a role in this boost: an ablated version of the model that does not have access to the linguistic history of subsequent references yields an accuracy of 84.82% for the *Later* subset, which is significantly lower than the 88.74% obtained with

---

observed.

[7] Thus, some of the candidate images have multimodal representations (if they were already mentioned in the dialogue), while others do not.

[8] BLEU-2, which is based on bigrams, appears to be more informative than BLEU with longer n-grams in dialogue response generation (Liu et al., 2016)

[9] In this simple baseline, one-hot vectors are projected to scalar values, and a softmax layer assigns probabilities over them. The fact that this is slightly higher than random accuracy seems due the different frequencies of images being the target.

our model ($p < 0.01$ independent samples t-test). This confirms the importance of accessing information about previous mentions in visually grounded reference resolution (Haber et al., 2019).

We use the best model run to assess the communicative effectiveness of our generation models.

5.3 Generation Model Results

As we did for the reference resolution model, we break down the test set into first referring utterances in a chain and subsequent references, for which generation is conditioned on a previous utterance. The outcomes of this breakdown are provided in Table 3, where we report the test set performances of our three generation models. Overall results on the validation set are available in Appendix F.

ReRef obtains the highest scores across all measures, followed by **Copy**, while **Ref** achieves substantially lower results. Regarding the comparison between first and subsequent references, the context-aware models **ReRef** and **Copy** attain significantly higher results when generating later mentions vs. first descriptions ($p < 0.001$, independent samples t-test). As expected, no significant differences are observed in this respect for **Ref**.[10]

As for the communicative effectiveness of the generated utterances as measured by our resolution model, both accuracy and MRR are particularly high (over 90%) for **ReRef**. Across all model types, generated subsequent references are easier to resolve by the model, in line with the pattern observed in Table 2 for the human data.

All in all, the addition of the copy mechanism does not provide improvements over **ReRef**'s performance that can be detected with the current evaluation measures. We do find, however, that the **Copy** model uses a substantially larger vocabulary than **ReRef**: 1,791 word types vs. 760 (the human vocabulary size on the test set is 2,332, while **Ref** only uses 366 word types). An inspection of the vocabularies shows that **Copy** does generate a good deal of low-frequency words, in line with what is expected from the dedicated copy mechanism (less desirably, this also includes words with spelling errors). Further analysis also shows that **Copy** generates utterances that include more repetitions: 18% of the utterances generated by **Copy** in the test set contain two identical content words e.g. *"do you have the runway runway woman?"*, while only 7% of those generated by **ReRef** do.[11] Adding a means to control for repetitions, such as the 'coverage' mechanism by See et al. (2017), could be worth exploring in the future.

We compare our best performing model **ReRef** to a baseline consisting in reusing the first generated utterance verbatim in later mentions. In this case, the model does not learn how to reuse previous referring utterances taking into account the changing visual context, but simply keeps repeating the first description it has generated. We expect this baseline to be relatively strong given that experiments in the lab have shown that dialogue participants may stick to an agreed description even when some properties are not strictly needed to distinguish the referent in a new visual context (Brennan and Clark, 1996; Brown-Schmidt et al., 2015). The results (reported in Table 3 *baseline*) show that the model significantly outperforms this baseline when generating later mentions.

Overall, our results confirm that referring utterances do evolve during a dialogue and indicate that the models that exploit the conversational context are able to learn some of the subtle modifications involved in the re-referring process. In the next section, we look into the linguistic patterns that characterise this process.

6 Linguistic Analysis

We analyse the linguistic properties of the utterances generated by the best performing run of each of our models and compare them with patterns observed in the human data. Extensive descriptive statistics are available in Appendix G.

6.1 Main Trends

Givenness markers We first look into the use of markers of new vs. given information, in particular indefinite and definite articles as well as particles such as *again* or *before* (as in *"I have the X one again"* or *"the X from before"*), which are anaphoric and presuppose that an image has been discussed previously in the dialogue. Figure 3a shows the proportion of givenness markers (*the, one, same, again, also, before*) in first vs. subsequent references. Not surprisingly, this proportion increases in the human subsequent references. **ReRef** and **Copy** both display an amplified version

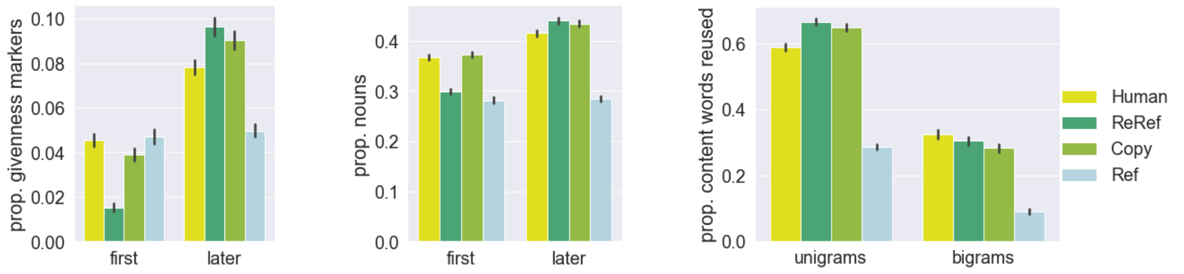
---

[10] While first descriptions do not require linguistic context, **ReRef** and **Copy** perform better on first description generation than **Ref**. This is likely due to their higher complexity.

[11] The **Ref** model is even more repetitive: 21% of the generated utterances contain repeated content words.

Model	Subset	BLEU-2	ROUGE	CIDEr	BERT-F1	ACC	MRR
Ref	**First**	20.80 (1.02)	29.74 (1.59)	41.26 (3.14)	54.48 (1.38)	57.12 (4.85)	72.47 (3.19)
	Later	23.06 (1.20)	31.88 (1.66)	40.79 (2.83)	55.54 (1.40)	60.94 (2.67)	75.34 (1.59)
ReRef	**First**	33.09 (0.79)	42.32 (0.42)	94.63 (2.12)	62.55 (0.12)	90.36 (1.73)	94.49 (1.14)
	Later	52.15 (1.19)	56.74 (0.63)	143.59 (5.84)	71.25 (0.39)	92.21 (0.73)	95.62 (0.45)
	baseline	36.66 (0.92)	45.37 (0.57)	96.41 (2.69)	64.13 (0.24)	90.14 (2.28)	94.38 (1.41)
Copy	**First**	25.25 (0.40)	33.31 (0.50)	60.51 (1.21)	57.61 (0.36)	81.36 (0.53)	88.70 (0.49)
	Later	43.08 (0.36)	48.79 (0.41)	128.45 (1.98)	66.07 (0.17)	83.96 (0.53)	90.60 (0.32)

Table 3: Test set scores of the generation models (averaged over 5 runs) for first vs. subsequent references, including word-overlap metrics, BERTScore F1, and accuracy/MRR obtained by our resolution model on the generated utterances. ReRef *baseline* uses the first generated description verbatim in all later mentions. All differences across model types are statistically significant ($p < 0.001$, independent samples t-test).



(a) Givenness markers (b) Proportion of nouns (c) Lexical entrainment in later references

Figure 3: Linguistic patterns in human referring utterances and in referring utterances generated by our three models. Givenness markers and proportion of nouns per utterance are displayed for first and later references.

of this trend, while **Ref**, which cannot capture any given information, shows no difference.

Reduction Regarding referring utterance length, we observe a significant shortening in subsequent mentions in human dialogues (11.3 vs. 8.3 tokens on average in first and subsequent mentions, respectively). This shortening is also observed in the utterances generated by **ReRef** (11.3 vs. 7.2) and **Copy** (10.8 vs. 7.8). **Ref** tends to generate longer utterances across the board (13.7 vs. 13.6).

Shortening may be linked to compression, i.e., to an increase in information density (Shannon, 1948). To analyse this aspect, we consider the proportion of content words in the utterances, since such proportion can capture mechanisms such as syntactic reduction (e.g., the removal of the complementiser *that*), which has been shown to be a good predictor of information density increase (Levy and Jaeger, 2006). Haber et al. (2019) reported a rise in the proportion of content words for all utterance types in later rounds of the PhotoBook games. We also observe such an increase in our referring utterance chains, and a similar trend is exhibited as well by the output of the **ReRef** and **Copy** models: In particular, generated subsequent references contain a significantly higher proportion of nouns and adjectives compared to first descriptions. Figure 3b shows this pattern for nouns, which are the most prominent type of content word in our data.

Entrainment In order to analyse the presence of lexical entrainment, we compute the proportion of expressions in subsequent references that are reused from the previous mention. We compare reuse at the level of unigrams and bigrams. Figure 3c shows this information focusing on content words. Around 60% of content tokens are reused by humans. The proportion is even higher in the utterances generated by our context-aware models. Digging deeper into the types of content tokens being reused, we find that nouns are reused significantly more than other parts of speech by humans. This is also the case in the subsequent references generated by the **ReRef** and **Copy** models.

Humans also reuse a substantial proportion of content word bigrams—as do, to a smaller degree, the context-aware models. For example, given the gold description *"pink bowls rice and broccoli salad next to it"*, **ReRef** generates the subsequent reference *"pink bowls again"*. Noun-noun compounds are a particularly interesting case of such bigrams, which we qualitatively analyse below.

6.2 A Case Study: Noun-Noun Compounds

A partial manual inspection of the human utterances in our chains reveals that, as they proceed in the dialogue, participants tend to produce referring expressions consisting of a noun-noun compound.[12] For example, in Figure 2 we observe the compound *"camera guy"* being uttered after the previous mention *"guy with camera"*. (reused nouns are underlined). Another example is *"wine glass dog"* in Figure 1. This is in line with Downing (1977), who argues that novel (i.e., not yet lexicalised) noun-noun compounds can be built by speakers on the fly based on a temporary, implicit relationship tying the two nouns, e.g., 'the guy *taking a picture with* a camera'. Such noun-noun compounds are thus prototypical examples of reuse and reduction: On the one hand, the novel interpretation (which needs to be pragmatically informative, diagnostic, and plausible; Costello and Keane, 2000) can only arise from the established common ground between speakers; on the other hand, compounds are naturally shorter than the 'source' expression since they leave implicit the relation between the nouns.

We check whether our best performing generation models produce compounds as humans do, i.e., by reusing nouns that were previously mentioned while compressing the sentence. We perform the analysis with a qualitative focus, by manually inspecting a subset of the generated utterances.[13] In Figure 4, we show two noun-noun compounds generated by **ReRef** (similar cases were observed for **Copy**). The example on the left is a noun-noun compound, *"basket lady"*, that is consistent with the dialogue context: both nouns are indeed reused from the previous mention. In contrast, the compound on the right does not build on the conversational history; the noun *"tattoo"* is not in the previous mention and never uttered within the reference chain (not reported), and thus may be perceived as breaking a conceptual pact (Metzing and Brennan, 2003). The compound is grounded in the image, but not in the conversational context.

P: lady with basket? ⇝ **ReRef:** basket lady?

P: do you have headband guy? ⇝ **ReRef:** tattoo guy?

Figure 4: Two examples from the test set where **ReRef** generates a noun-noun compound based on the previous human mention (***P***). Left: a genuine *reuse* case; right: a *non-reuse* case. Reused words are underlined.

7 Conclusion

We have addressed the generation of descriptions that are (1) discriminative with respect to the visual context and (2) grounded in the linguistic common ground established in previous mentions. To our knowledge, this is the first attempt at tackling this problem at the level of surface realisation within a multimodal dialogue context.

We proposed an encoder-decoder model that is able to generate both first mentions and subsequent references by encoding the dialogue context in a multimodal fashion and dynamically attending over it. We showed that our best performing model is able to produce better, more effective referring utterances than a variant that is solely grounded in the visual context. Our analysis revealed that the generated utterances exhibit linguistic properties that are similar to those observed in the human utterances regarding reuse of words and reduction. Generating subsequent references with such properties has the potential to enhance user adaptation and successful communication in dialogue systems.

Yet, in our approach we abstracted away from important interactive aspects such as the collaborative nature of referring in dialogue (Clark and Wilkes-Gibbs, 1986), which was considered by Shore and Skantze (2018) for the task of reference resolution. In the present work, we simplified the interactive aspects of reference by extracting referring utterances from the PhotoBook dialogues and framing the problem as that of generating the next referring utterance given the previous mention. We believe that the resulting dataset of referring utterance chains can be a useful resource to analyse and model other dialogue phenomena, such as saliency or partner specificity, both on language alone or on the interaction of language and vision.

---

[12] This is consistent with the fact that the proportion of noun-noun bigrams is significantly higher in subsequent references (0.05 vs. 0.08 on average in first and subsequent references, respectively; $p < 0.001$ independent sample t-test).

[13] The subset is obtained by applying simple heuristics to the set of generated utterances, such as length and PoS tags.

A Reference chain extraction

For our generation task, we extract reference chains of single referring utterances from the PhotoBook dataset (Haber et al., 2019). Given a dialogue and a target image, a reference chain is comprised of utterances—maximum one per round—that refer to the target image in that dialogue. Due to the size of the PhotoBook dataset (see Section 3.1), we perform this procedure automatically, with a three-step heuristic method described in the following sections. The chain extraction code is available at `https://dmg-photobook.github.io`.

Extracting dialogue segments The goal of segment extraction is to identify all utterances that may include a description of a given target image. To identify relevant segments, we leverage the participants' recorded actions, i.e. selecting an image as common or different (more details on the available metadata in Haber et al., 2019). When an image is selected by a participant as *common* in a dialogue round, we extract all utterances up to that point in the round as candidate referring expressions. We collect referring expressions for a given image in a dialogue starting from the round when *both* speakers observe it. The speakers are then more likely to have established a conceptual pact (see Section 1).

Scoring referring utterances In this second step, we assign a score to each utterance in the extracted segments indicating how likely it is for that utterance to be a description of a given image. To produce these scores, we use as reference the MS COCO image captioning dataset (Lin et al., 2014) and the Visual Genome dataset of scene graphs (Krishna et al., 2017). All 360 pictures in PhotoBook are taken from MS COCO, so we have access to at least 5 captions for each target image. Instead, the Visual Genome dataset provides detailed scene graphs for 37% of the PhotoBook images.

To measure the similarity of a candidate utterance to a reference MS COCO caption, we use the BERTScore (Zhang et al., 2020). We experiment with BERTScore Precision, Recall, F1, and select BERTScore F1. As, in our dialogue setting, utterances often contain lexical material that is not part of a referring expression, we filter out stopwords from both the captions and the utterances. We use spaCy's stop-word list for English from which we remove numerals and prepositions that encode spatial information.[14]. Furthermore, to capture dyad-specific variation in referring language, we add the utterance with the highest BERTScore in a round to the reference set, and use it as an additional caption for the following rounds.

To take into account visual attributes and relationships, for each image we collect attribute tokens $T_A(i)$ (e.g. *leafy*, *tree* from *leafy(tree)*) and relationship tokens $T_R(i)$ (e.g. *man*, *playing*, *frisbee* from *playing(man, frisbee)*) from the Visual Genome dataset of scene graphs. We only consider the intersection $T_{VG}(i) = T_A(i) \cap T_R(i)$ between the sets of attribute and relationship tokens to retain only the most relevant tokens. The set difference $T_{VG}(i*) \setminus \bigcup_{i=1, i \neq i*}^{12}$ between the Visual Genome tokens of the target image and the tokens of the 11 distractors is then used as a reference set. To score an utterance, we compute its METEOR score (Banerjee and Lavie, 2005) with respect to this reference set. For all images annotated in the Visual Genome dataset, the final utterance score is the sum of BERTScore and METEOR.[15]

---

[14] The English stop-word list is available at `https://github.com/explosion/spaCy/blob/master/spacy/lang/en/stop_words.py` and our edits at `https://dmg-photobook.github.io`.

[15] We implement BERTScore and use NLTK's code for METEOR (`https://www.nltk.org/api/nltk.translate.html`). We set METEOR's alignment penalty to 0 as our references are unordered collections of tokens.

	Chains	Utterances	Unique utterances	Target images	Image domains	Chain length	Utterance length
Train	11540	28933	27288	360	30	2.51(0.85)	8.71(4.66)
Validation	2503	6252	6009	360	30	2.50 (0.85)	8.82 (4.67)
Test	2482	6155	5876	360	30	2.48 (0.86)	8.77(4.68)
Extracted-20	327	824	807	199	24	2.52 (0.85)	9.50 (4.75)
Gold-20	327	756	740	199	24	2.31 (0.94)	9.47 (4.77)

Table 4: Descriptive statistics of all portions of the extracted dataset of reference utterance chains. Gold-20 is a set of 20 hand-annotated PhotoBook dialogues, with referent labels linking utterances to the target image they describe (see Section 3.2) whereas Extracted-20 are the reference chains extracted from the same 20 dialogues, as if they were not annotated. Duplicate utterances are due to chance: PhotoBook participants have uttered them in different dialogues, potentially to describe the same target image. Image domains refers to the number of MS COCO image categories covered by a dataset portion; the 360 PhotoBook images come from a total of 30 domains.

Selecting referring utterances The last step, utterance selection, produces reference chains consisting of single utterances—maximum one per round. As PhotoBook dialogues are made up of five rounds, reference chains will have a minimum length of 1 and a maximum possible length of 5. First, given an extracted dialogue segment, we discard all utterances produced by speakers who do not have that image in their visual context. Then, for each target image in the corresponding dialogue round, we collect a ranked candidate list of n top-scoring utterances. As an utterance can be selected as a candidate for multiple images in the same round, we discard a candidate *(utterance, image)* pair if its score is lower than that of any other *(utterance', image)* pair in the same round. Finally, we pick the utterance with the highest score among the remaining candidates. For some images, all of the n top-scoring utterances are assigned to other images, and with higher scores. This causes a slight decrease in the number of utterances in the extracted dataset. We set $n = 4$ to minimise the number of discarded utterances. Table 4 reports relevant statistics for the dataset splits of our extracted reference utterance chains.

B Data processing for models

We further process the dataset of automatically extracted utterance chains. Every utterance is uniquely identified by the game ID, round number, message number and the ID of the image that they refer to. From these utterances and their contexts, we build the data we feed into our models.

While providing the 6 candidate images to the reference resolution models, we also keep track of the respective histories of candidates (the last utterance up to that time in the game).

As the distribution of the 6 images and the positions of the target is not uniform for each target-context pair, this may constitute a bias in the reference resolution model. Therefore, to overcome this, we shuffle the images in the context for all splits at the beginning of each epoch. In the generation models, this shuffling is done once at the beginning of training for all splits.

B.1 BERT representations

Since utilising pre-trained BERT models and representations has proven to be beneficial to many NLP tasks (Devlin et al., 2019), we also decided to use BERT to encode the linguistic input in the reference resolution models. For this purpose, we use the BERT-base-uncased model and the tokeniser as provided in the HuggingFace's Transformers library (Wolf et al., 2019). The utterances are first encoded into the correct format for BERT models. Afterwards, they go through the BERT model to produce the hidden states that correspond to the representations of each of the input wordpieces. Finally, all utterances are fed into the reference resolution model in the form of a set of BERT representations.

We also experimented with using BERT-large-uncased model as well as extracting hidden states from multiple layers and aggregating them. Neither option provided further improvements on the results we obtained with the final hidden states from the BERT-base-uncased model. Hence, we opted to use the base model's outputs, where each hidden state is of size 768.

B.2 Embeddings from scratch

For the generation models where we do not use BERT representations, we create a vocabulary of tokens from the training set with the help of TweetTokenizer from the NLTK library[16]. We then map the words that occurred only once in the training

---

[16] `https://www.nltk.org/api/nltk.tokenize.html`

split to '<unk>'. This results in a vocabulary of size 2816 (including <pad>, <unk>, <sos>, and <eos>). In addition to these special tokens, we also add <nohs> to point out that there was **no** **his**tory (no previous utterance) for the target image at that point in the game. This token is utilised in the models that base their generation on the previous utterance. An input of <nohs> means that what the generation model is expected to produce is the very first utterance for that image in the game.

The tokens in all 3 splits are converted to indices using this final vocabulary. For the copy model, we need to keep track of what the actual form of an <unk> token is. For this purpose, we build a full vocabulary from the whole dataset to have access to every word in all splits in their actual surface forms. This vocabulary is of size 5793 (including all 5 special tokens mentioned above).

Since we do not want the generation model to output the <nohs> token, the search space of the decoder does not include this token. The Copy model needs to keep track of unknown tokens in the previous utterance and map the previous utterance using an extended vocabulary so that the decoder would be able to 'copy' from the input itself, rather than only generating words from the reduced vocabulary. Mapped expected next utterance is used in calculating the loss. Actual inputs to the encoder and the decoder still contain unknown words, as we do not maintain special embeddings for the surface forms of each of the unknown tokens.

C Model architectures

Below are more details about our generation models and our reference resolution model.

C.1 Generation models

In these models, we apply teacher forcing during training; therefore, a token embedding at timestep t is the embedding of the expected token from the ground-truth utterance. During validation, the models use the embedding of the word they generated in the previous timestep.

C.1.1 ReRef model

This model obtains the visual input as in the Ref model (consisting of the context and the target). However, instead of initialising the decoder as in the prior model, here, this visual representation initialises the encoder. The encoder receives as input a sentence that was previously used in the same game to refer to the target image (or simply <nohs>, if there was no history for the target image in the game at that point). The embeddings of this input go through dropout.

We concatenate the last hidden states of the forward and backwards directions of the BiLSTM encoder. This concatenated vector is then projected to hidden dimensions and used to initialise the decoder. The input to the decoder during training is an embedding of the ground-truth utterance.

For the attention mechanism, each hidden output of the encoder ${h_{enc}}^t$ (concatenation of forward and backward hidden states for timestep t) goes through a linear layer that projects it from double the size of hidden dimensions to the attention dimensions. In addition, the current hidden state of the decoder ${h_{dec}}^c$ is projected from the hidden dimensions to the attention dimensions.

$$enc^t = W_e {h_{enc}}^t \tag{1}$$

$$dec^c = W_d {h_{dec}}^c \tag{2}$$

$$e_t = v_a(tanh(enc^t + dec^c)) \tag{3}$$

Attention weights are calculated based on the sum of enc^t and dec^c, on which we apply $tanh$ non-linearity and a linear layer. Padded tokens are masked and softmax is applied over all remaining encoder timesteps i:

$$a_i = softmax(e_i) \tag{4}$$

$$h^* = \sum_i a_i h^i_{enc} \tag{5}$$

To predict the word that the decoder will generate, we concatenate the decoder's current hidden state ${h_{dec}}^c$ with the weighted average from the encoder, i.e. encoder context vector h^*. This concatenation is projected to the size of the vocabulary minus 1, as we do not want the model to predict the <nohs> token.

C.1.2 Copy model

The encoder part of this model is the same as that of the model explained in the previous subsection. However, this model uses various versions of the input and the decoder is altered to accommodate the copy mechanism.

First of all, we keep track of the unknown tokens in the input to provide the ability to predict them in the decoder phase. For this, we map the input utterance to temporary indices in a new extended vocabulary. This extended vocabulary contains the unknown words existing in the input utterance in their original forms appended to the end of the original vocabulary. Since we do not want <nohs> to be predicted, we take additional precautions when it exists in the encoder input. The decoder input stays the same with unknown embeddings; nevertheless, the target utterance can include temporary indices assigned to unknown words encountered in the given input utterance, so that we can calculate the loss according to them as well.

The attention mechanism works in the same manner as in the previous model. However, we change what comes afterwards in line with the copy mechanism, where the attention for each word in the input utterance is added to their generation probabilities in the vocabulary. Here, we scatter the attention scores for the temporary indices of unknown words onto the distribution of the extended vocabulary, as well. For this reason, we maintain multiple versions of the input and output (mapped to the reduced vocabulary and mapped to the full vocabulary), as well as keeping track of the set of unknown words in the previous utterance and their temporary indices. Crucial here is the calculation of the generation probability p_{gen}, which requires the addition of several more linear layers that process the encoder context vector h_t^*, decoder input x_t, and the current decoder state s_t. As compared to the calculation of p_{gen} by See et al. (2017), we altered the formula for this value by adding $tanh$ non-linearities: $p_{gen} = \sigma(\tanh(w_{h^*}^T h_t^*) + \tanh(w_s^T s_t) + \tanh(w_x^T x_t))$.

C.2 Reference resolution model

In this model, BERT embeddings go through a dropout layer, then a linear layer projecting the size to hidden dimensions. Finally, ReLU is applied (Nair and Hinton, 2010).

All 6 images in the context are concatenated and the concatenation goes through dropout, a linear layer and ReLU to produce the final visual context vector. We then concatenate each of the BERT representations with the visual context vector to obtain multimodal token representations. This multimodal vector goes through a linear layer and ReLU, which finalises the multimodal input vectors. The model then determines the attention to be paid to each of the multimdal vectors as indicated below:

$$e_i = v_a(tanh(W_e h_i)) \qquad (6)$$

h_i is the multimodal output for each token, W_e is a linear layer projecting from hidden dimensions to attention dimensions, v_a is a linear layer that projects the output from the attention dimensions to a scalar. The model than masks the pad tokens before applying softmax over e_i scores to obtain the attention weights a_i:

$$a_i = softmax(e_i) \qquad (7)$$

The final multimodally-encoded utterance representation is then the weighted average of all h_i, given their attention weights a_i:

$$h_L = \sum_i a_i h_i \qquad (8)$$

Candidate images also separately go through dropout, a linear layer and ReLU. Finally, we normalise the outcomes for each image separately with L2 normalisation.

The history of each candidate image is determined by looking at their respective chains in the given game. Crucially, we only look at the chain items that were uttered before the current utterance we are trying to resolve. We take only the last utterance in the history, if such a history exists for a candidate image. In this case, we take the average of the BERT representations in the last utterance for that image. This average then goes through dropout, a linear layer and ReLU.

The final history representation for a candidate image is added to this image's final visual representation to obtain its final candidate representation. Please note that not all images in the context necessarily have histories associated with them. Therefore, some candidate representations will be multimodal, whereas the others will remain in the visual domain, with no linguistic history being added.

To determine the target image, we take the dot product between the candidate representations and the multimodally-encoded utterance representation. The candidate with highest value is then predicted to be the referent of the input utterance.

Ablation: As an ablation of the model described above, we train another type of model where the history is not added to the candidate images. Hence, the candidates are always represented only in the visual modality.

Baseline: This model only uses one-hot vectors based on image IDs. These vectors go through the same operations as the image features go through in the models described above (dropout, linear layer, ReLU and normalization). At the end, instead of a dot-product, the outputs for the candidates are

projected to scalar values and the model tries to predict the target via applying softmax directly over these scalars.

D Evaluation metrics

For the evaluation of the reference resolution models, we use accuracy and mean reciprocal rank (MRR) implemented by us. Accuracy is a stricter measure as it is either 0 or 1 for a given instance.

For the generation models, we use the *compute_metrics* function provided in the library at `https://github.com/Maluuba/nlg-eval` to obtain corpus-level BLEU, ROUGE, and CIDEr.

We also report BERTScore (Zhang et al., 2020) for the generation models. To obtain this score, we use the library provided by the authors at `https://github.com/Tiiiger/bert_score` and import the *score* function in our evaluation scripts. We use the BERT-uncased-model, we do not apply rescaling to baseline or importance weighting. The hash code for BERTScore that we used in evaluation is 'bert-base-uncased_L9_no-idf_version=0.3.2(hug_trans=2.6.0)'. We obtain precision, recall and F1 variants of BERTScore.

E Model configurations and reproducibility

The models are implemented in Python 3.7.5[17] and PyTorch 1.4.1[18]. In training our models, we use the Adam optimizer (Kingma and Ba, 2015) to minimize the Cross Entropy Loss with sum reduction.[19]

We experimented with learning rate (0.001, 0.0001, 0.00001), dimensions for the embeddings (512, 1024), hidden and attention dimensions (512, 1024), batch size (16, 32) and dropout probability (0.0, 0.3, 0.5). We selected the best configurations per model type via manual tuning.

We train each model type with their selected configuration with 5 different random seeds setting the random behaviour of PyTorch and NumPy. We also turn off the cuDNN benchmark and also set cuDNN to deterministic.

In all the models, the biases in linear layers were set to 0 and the weights were uniformly sampled from the range (-0.1, 0.1). In the models that learn embeddings from scratch, embedding weights were initialised uniformly in the range (-0.1, 0.1). The hidden and cell states of the LSTMs were initialised with task-related input at the first timestep.

Computing infrastructure: The models were trained and evaluated on a computer cluster with Debian Linux OS. No parallelization was implemented, each model used a single GPU GeForce 1080Ti, 11GB GDDR5X, with NVIDIA driver version 418.56 and CUDA version 10.1.

Average runtimes: Please see Table 5 and 6. These durations indicate the total approximate runtime of training. The best models are reached in a shorter amount of time.

Number of parameters in each model: Please see Table 7 and Table 8.

E.1 Configurations of the reference resolution models

We select the reference resolution models based on their performance in accurately predicting the correct target among 6 images. We also report MRR, as it also provides further information in terms of the ranking of the correct image among the distractors.

After hyperparameter search, we decided on a batch size of 32, a learning rate of 0.0001, atten-

[19] Copy model in fact uses the Negative Log-Likelihood Loss that receives log-softmax probabilities. This is equivalent to Cross Entropy Loss with logits.

Model	BLEU-2	ROUGE	CIDEr	BERT-F1	ACC	MRR
Ref	22.40 (1.22)	31.29 (1.56)	41.26 (3.18)	55.24 (1.38)	59.69 (3.48)	74.41 (2.21)
ReRef	45.41 (0.89)	51.14 (0.42)	127.08 (4.17)	67.94 (0.23)	91.70 (1.09)	95.32 (0.70)
Copy	36.44 (0.31)	43.00 (0.35)	104.27 (1.16)	62.93 (0.21)	83.28 (0.77)	90.07 (0.49)

Table 9: Average metric scores of the 3 generation models on the validation set. We report the average of 5 runs and standard deviations in parentheses. ACC is the reference resolution accuracy of the sentences generated by the generation models and MRR is their mean reciprocal rank as obtained through our best reference resolution model.

tion and hidden dimensions both set to 512, and a dropout probability of 0.5 for the proposed reference resolution model. We trained the ablation model with the same settings.

Subset	ACC	MRR	Instances
First	81.85 (0.45)	88.88 (0.29)	2503
Later	88.51 (0.19)	93.33 (0.12)	3749
Overall	85.85 (0.10)	91.55 (0.07)	6252

Table 10: Validation set scores of the reference resolution model: averages of 5 runs with the best configuration, with the standard deviations in parentheses.

E.2 Configurations of the generation models

Best-performing generation models for each model type were selected based on their performance with respect to the F1 component of BERTScore. We also performed hyperparameter search for beam width used in decoding, after which we decided to use a beam width of 3. The best-performing model for each model type outperformed the other models in its own category over all metrics.

As revealed by hyperparameter search, all reported generation models use 1024 dimensions for embeddings and 512 dimensions for hidden and attention layers. They all use a learning rate of 0.0001. Ref and Copy models use a batch size of 32 and the ReRef model, 16. Ref and ReRef models use a dropout probability of 0.3, whereas the Copy model yielded better results without dropout.

F Results on the validation set

For each model we report in the main text, we also provide the validation set performances in Table 9 for the generation and Table 10 for the resolution models.

G Linguistic measures

The linguistic measures used were chosen to quantitatively explore whether artefacts of the compression, reuse and grounding present in the human utterances, as well as other human-like linguistic patterns, can be seen in the generated utterances. We compare performance of the generation models with regards to the similarity of their generated sentences to human traits, namely a) whether there is a change in token use between first and last mention (Table 11) and b) whether this relative distance, or the values in the first mention differ significantly between human and model references (Table 12).

In the case of givenness markers, we measure this as the proportion of tokens which correspond to definite (*the*), indefinite (*some, a, an*) and other markers of the existence of shared context (*again, before, one, same, also*) which occur in the utterance. In the case of compression, we measure the lengths of the utterances in terms of tokens, and content tokens (tokens which are not in the stopword list from from nltk version 3.4.5 (Loper and Bird, 2002). We also measure the proportion of content words in an utterance which correspond to nouns, verbs and adjectives. Finally, for entrainment, examining only later utterances (not the first referent to an image), we measure firstly what proportion of the utterance in question consists of reused unigrams and bigrams from the previous utterance. We also measure within the reused tokens, the proportion of which is made up of nouns, adjectives and verbs, in order to discover their relative importance in terms of reuse. These measures can all be found in Tables 11 and 12. For these analyses we compared the generated output from the best seed for each model variant. These were seeds 1, 1, and 24 for the Ref, Copy and ReRef models respectively. We report both effect size (d) as measured by Cohen's d, and p-value (*$p < 0.05$, **$p < 0.005$, ***$p < 0.001$) for each comparison. We use the Scipy stats package (scipy version 1.3.3.) *ttest_ind* to perform the independent t-test, and our own implementation to calculate Cohen's d effect size.

Additionally to check general fluency, we evaluate the coherence and vocabulary use of the models in comparison to humans. We measure *Type Token Ratio (TTR)*, the proportion of unique tokens

Table 12: Human comparison with ReRef, Copy and Ref for givenness markers and Compression. The presence of * indicates a significant difference between the human mean and that of the model. *(***: $p < 0.001$, **: $p < 0.005$, *: $p < 0.01$)*

in an utterance. This can capture ungrammatical repetition patterns in the generation, and, if following human trends, should increase in subsequent mentions. Although both models have significantly lower TTR than the human data, ReRef, unlike Copy, shows a significant increase in subsequent mentions, with much higher TTR than Copy, even though both models show similar average utterance length for later utterances *(ReRef: 7.22, Copy: 7.79)*. In terms of vocabulary, for the generated outputs, ReRef has a much smaller *(first: 492, later: 705)* vocabulary than Copy *(first: 1098, later: 1469)*, although these are both much lower than Human vocabulary size *(first: 1836, later: 1727)* and show an increase rather than a decrease in later mentions.

Overall, Tables 11 and 12 show that both of our context-aware speaker models ReRef and Copy are able to generate referring utterances which make use of the dialogue history in a manner akin to humans with respect to multiple aspects of language style.

Comparing the context-aware models, ReRef shows a stronger degree of shortening than Copy, with very similar levels of bigram reuse to humans while Copy shows more similar traits to humans in terms of proportion of markers and PoS tags (as revealed by smaller effect sizes). In general, both models are successful at generating human-like utterances as we measure them, however it seems that while Copy does generate utterances with the most similar proportional similarities to humans and exhibits similar proportions of unigram reuse, it does so at the expense of coherence. In terms of content bigram reuse, Copy seems to be less selective in what it repeats from previous referring utterances than ReRef, most likely due to the increased overall level of repetition in the generation. ReRef on the other hand shows amplified versions of the human trends, yet very similar content bigram and noun-noun bigram reuse proportion to humans, while maintaining low levels of same content word repetition as well as a high TTR, which indicates that coherence is also maintained.

Visually Grounded Compound PCFGs

Abstract

Exploiting visual groundings for language understanding has recently been drawing much attention. In this work, we study visually grounded grammar induction and learn a constituency parser from both unlabeled text and its visual groundings. Existing work on this task (Shi et al., 2019) optimizes a parser via REINFORCE and derives the learning signal only from the alignment of images and sentences. While their model is relatively accurate overall, its error distribution is very uneven, with low performance on certain constituents types (e.g., 26.2% recall on verb phrases, VPs) and high on others (e.g., 79.6% recall on noun phrases, NPs). This is not surprising as the learning signal is likely insufficient for deriving all aspects of phrase-structure syntax and gradient estimates are noisy. We show that using an extension of probabilistic context-free grammar model we can do fully-differentiable end-to-end visually grounded learning. Additionally, this enables us to complement the image-text alignment loss with a language modeling objective. On the MSCOCO test captions, our model establishes a new state of the art, outperforming its non-grounded version and, thus, confirming the effectiveness of visual groundings in constituency grammar induction. It also substantially outperforms the previous grounded model, with largest improvements on more 'abstract' categories (e.g., +55.1% recall on VPs).[1]

1 Introduction

Grammar induction is a task of finding latent hierarchical structure of language. As a fundamental problem in computational linguistics, it has been extensively studied for decades (Lari and Young, 1990; Carroll and Charniak, 1992; Clark, 2001; Klein and Manning, 2002). Recently, deep learning models have been shown very effective across NLP tasks and have also been applied to grammar induction, greatly advancing the area (Shen et al., 2018, 2019; Kim et al., 2019a,b; Jin et al., 2019). These neural grammar-induction approaches have been generally limited to relying on text, without considering learning signals from other modalities.

In contrast, the crucial aspect of natural language learning is that it is grounded in perceptual experiences (Barsalou, 1999; Fincher-Kiefer, 2001; Bisk et al., 2020). We thus anticipate improved language understanding by leveraging grounded learning. Promising results from grounded learning have been emerging in areas such as representation learning (Bruni et al., 2014; Kiela et al., 2018; Bordes et al., 2019). Typically, they use visual images as perceptual groundings of language and aim at improving *continuous vector representations* of language (e.g., word or sentence embeddings). In this work, we consider a more challenging problem: can visual groundings help us induce *syntactic structure*? We refer to this problem as *visually grounded grammar induction*.

Shi et al. (2019) propose a visually grounded neural syntax learner (VG-NSL) to tackle the task. Specifically, they learn a parser from aligned image-sentence pairs (e.g., image-caption data), where each sentence describes visual content of the corresponding image. The parser is optimized via REINFORCE, where the reward is computed by scoring the alignment of images and constituents. While straightforward, matching-based rewards can, as we will discuss further in the paper, make the parser focus only on more local and short constituents (e.g., 79.6% recall on NPs) and to perform poorly on longer ones (e.g., 26.2% recall on VPs) (Shi et al., 2019). While for the former it outperforms the text-only grammar induction methods, for the latter it substantially underachieves. This may not

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4369–4379,
November 16–20, 2020.

be surprising, as it is not guaranteed that every constituent of a sentence has its visual representation in the aligned image; the reward signals can be noisy and insufficient to capture all aspects of phrase-structure syntax. Consequently, Shi et al. (2019) have to rely on language-specific inductive bias to obtain more informative reward signals. Another issue with VG-NSL is that the parser does not admit tractable estimation of the partition function and the posterior probabilities for constituent boundaries needed to compute the expected reward in closed form. Instead, VG-NSL relies on Monte Carlo policy gradients, potentially suffering from high variance.

To alleviate the first issue, we propose to complement the image-text alignment-based loss with a loss defined on unlabeled text (i.e., its log-likelihood). As re-confirmed with neural models in Shen et al. (2019) and Kim et al. (2019a), text itself can drive induction of rich syntactic knowledge, so additionally optimizing the parser on raw text can be beneficial and complementary to visual grounded learning. To resolve the second issue, we resort to an extension of probabilistic context-free grammar (PCFG) parsing model, compound PCFG (Kim et al., 2019a). It admits tractable estimation of the posteriors, needed in the alignment loss, with dynamical programming and leads to a fully-differentiable end-to-end visually grounded learning. More importantly, the PCFG parser lets us complement the alignment loss with a language modeling objective.

Our key contributions can be summarized as follows: (1) we propose a fully-differentiable end-to-end visually grounded learning framework for grammar induction; (2) we additionally optimize a language modeling objective to complement visually grounded learning; (3) we conduct experiments on MSCOCO (Lin et al., 2014) and observe that our model has a higher recall than VG-NSL for five out of six most frequent constituent labels. For example, it surpasses VG-NSL by 55.1% recall on VPs and by 48.7% recall on prepositional phrases (PPs). Comparing to a model trained purely via visually grounded learning, extending the loss with a language modeling objective improves the overall F1 from 50.5% to 59.4%.

2 Background and Motivation

Our model relies on compound PCFGs (Kim et al., 2019a) and generalizes the visually grounded grammar learning framework of Shi et al. (2019). We will describe the relevant aspects of both frameworks in Sections 2.1-2.2, and then discuss their limitations (Section 2.3).

2.1 Compound PCFGs

Compound PCFGs extend context-free grammars (CFGs) and, to establish notation, we start by briefly introducing them. A CFG is defined as a 5-tuple $\mathcal{G} = (S, \mathcal{N}, \mathcal{P}, \Sigma, \mathcal{R})$ where S is the start symbol, $\mathcal{N}$ is a finite set of nonterminals, $\mathcal{P}$ is a finite set of preterminals, Σ is a finite set of terminals,[2] and $\mathcal{R}$ is a set of production rules in the Chomsky normal form:

$$\begin{aligned} S &\to A, & A &\in \mathcal{N}, \\ A &\to BC, & A &\in \mathcal{N}, B, C \in \mathcal{N} \cup \mathcal{P}, \\ T &\to w, & T &\in \mathcal{P}, w \in \Sigma\,. \end{aligned}$$

PCFGs extend CPGs by associating each production rule $r \in \mathcal{R}$ with a non-negative scalar π_r such that $\sum_{r:A\to\gamma} \pi_r = 1$, i.e., the probabilities of production rules with the same left-hand-side nonterminal sum to 1. The strong context-free assumption hinders PCFGs and prevent them from being effective in the grammar induction context. Compound PCFGs (C-PCFGs) mitigate this issue by assuming that rule probabilities follow a compound probability distribution (Robbins, 1951):

$$\pi_r = g_r(\mathbf{z}; \theta), \quad \mathbf{z} \sim p(\mathbf{z})\,,$$

where $p(\mathbf{z})$ is a prior distribution of the latent $\mathbf{z}$, and $g_r(\cdot;\theta)$ is parameterized by θ and yields a rule probability π_r. Depending on the rule type, $g_r(\cdot;\theta)$ takes one of these forms:

$$\begin{aligned} \pi_{S\to A} &= \frac{\exp(\mathbf{u}_A^T f_s([\mathbf{w}_S; \mathbf{z}]))}{\sum_{A'\in\mathcal{N}} \exp(\mathbf{u}_{A'}^T f_s([\mathbf{w}_S; \mathbf{z}]))}\,, \\ \pi_{A\to BC} &= \frac{\exp(\mathbf{u}_{BC}^T [\mathbf{w}_A; \mathbf{z}])}{\sum_{B',C'\in\mathcal{N}\cup\mathcal{P}} \exp(\mathbf{u}_{B'C'}^T [\mathbf{w}_A; \mathbf{z}])}\,, \\ \pi_{T\to w} &= \frac{\exp(\mathbf{u}_w^T f_t([\mathbf{w}_T; \mathbf{z}]))}{\sum_{w'\in\Sigma} \exp(\mathbf{u}_{w'}^T f_t([\mathbf{w}_T; \mathbf{z}]))}\,, \end{aligned}$$

where $\mathbf{u}$ is a parameter vector, $\mathbf{w}_N$ is a symbol embedding and $N \in \{S\} \cup \mathcal{N} \cup \mathcal{P}$. $[\cdot;\cdot]$ indicates vector concatenation, and $f_s(\cdot)$ and $f_t(\cdot)$ encode the input into a vector (parameters are dropped for simplicity).

---

[2] Strictly, CFGs do not distinguish nonterminals $\mathcal{N}$ (constituent labels) from preterminals $\mathcal{P}$ (part-of-speech tags). They are both treated as nonterminals. $\mathcal{N}, \mathcal{P}, \Sigma$ satisfy $\mathcal{N} \cap \mathcal{P} = \emptyset$ and $(\mathcal{N} \cup \mathcal{P}) \cap \Sigma = \emptyset$.

A C-PCFG defines a mixture of PCFGs (i.e., we can sample a set of PCFG parameters by sampling a vector $\mathbf{z}$). It satisfies the context-free assumption conditioned on $\mathbf{z}$ and thus admits exact inference for each given $\mathbf{z}$. Learning with C-PCFGs involves maximizing the log-likelihood of every observed sentence $\boldsymbol{w} = w_1 w_2 \ldots w_n$:

$$\log p_\theta(\boldsymbol{w}) = \log \int_{\mathbf{z}} \sum_{t \in \mathcal{T}_{\mathcal{G}}(\boldsymbol{w})} p_\theta(t|\mathbf{z}) p(\mathbf{z}) \, d\mathbf{z} \,,$$

where $\mathcal{T}_{\mathcal{G}}(\boldsymbol{w})$ consists of all parses of the sentence $\boldsymbol{w}$ under a PCFG $\mathcal{G}$. Though for each given $\mathbf{z}$ the inner summation over parses can be efficiently computed using the inside algorithm (Baker, 1979), the integral over $\mathbf{z}$ makes optimization intractable. Instead, C-PCFGs rely on variational inference and maximize the evidence lower bound (ELBO):

$$\begin{aligned} &\log p_\theta(\boldsymbol{w}) \geq \mathrm{ELBO}(\boldsymbol{w}; \phi, \theta) = \\ &\mathbb{E}_{q_\phi(\mathbf{z}|\boldsymbol{w})}[\log p_\theta(\boldsymbol{w}|\mathbf{z})] - \mathrm{KL}[q_\phi(\mathbf{z}|\boldsymbol{w}) || p(\mathbf{z})] \,, \end{aligned} \tag{1}$$

where $q_\phi(\mathbf{z}|\boldsymbol{w})$ is a variational posterior, a neural network parameterized with ϕ. The expected log-likelihood term is estimated via the reparameterization trick (Kingma et al., 2014); the KL term can be computed analytically when $p(\mathbf{z})$ and $q_\phi(\mathbf{z}|\boldsymbol{w})$ are normally distributed.

2.2 Visually grounded neural syntax learner

The visually grounded neural syntax learner (VG-NSL) comprises a parsing model and an image-text matching model. The parsing model is an easy-first parser (Goldberg and Elhadad, 2010). It builds a parse greedily in a bottom-up manner while at the same time producing a semantic representation for each constituent in the parse (i.e., its 'embedding'). The parser is optimized through REINFORCE (Williams, 1992). The reward encourages merging two adjacent constituents if the merge results in a constituent that is *concrete*, i.e., if its semantic representations is predictive of the corresponding image, as measured with a matching function. We omit details of the parser and how the semantic representations of constituents are computed, as they are not relevant to our approach, and refer the reader to Shi et al. (2019).

However, as we will extend their image-text matching model, we explain this component of their approach more formally. In their work, this loss is used to learn the textual and visual representations. For every constituent $c^{(i)}$ of a sentence $\boldsymbol{w}^{(i)}$, they define the following triplet hinge loss:

$$\begin{aligned} h(\mathbf{c}^{(i)}, \mathbf{v}^{(i)}) &= \mathbb{E}_{\mathbf{c}'} \left[m(\mathbf{c}', \mathbf{v}^{(i)}) - m(\mathbf{c}^{(i)}, \mathbf{v}^{(i)}) + \epsilon \right]_+ \\ &+ \mathbb{E}_{\mathbf{v}'} \left[m(\mathbf{c}^{(i)}, \mathbf{v}') - m(\mathbf{c}^{(i)}, \mathbf{v}^{(i)}) + \epsilon \right]_+ \,, \end{aligned} \tag{2}$$

where $[\cdot]_+ = \max(0, \cdot)$, ϵ is a positive margin, $m(\mathbf{c}, \mathbf{v}) \triangleq \cos(\mathbf{c}, \mathbf{v})$ is the matching function measuring similarity between the constituent representation $\mathbf{c}$ and the image representation $\mathbf{v}$. The expectation is taken with respect to 'negative examples', $\mathbf{c}'$ and $\mathbf{v}'$. In practice, for efficiency reasons, a single representation of an image $\mathbf{v}'$ and a single representation of a constituent (span) $\mathbf{c}'$ from another example in the same batch are used as the negative examples. Intuitively, an aligned image-constituent pair $(\mathbf{c}^{(i)}, \mathbf{v}^{(i)})$ should score higher than an unaligned one ($(\mathbf{c}', \mathbf{v}^{(i)})$ or $(\mathbf{c}^{(i)}, \mathbf{v}')$).

The total loss for an image-sentence pair $(\mathbf{v}^{(i)}, \boldsymbol{w}^{(i)})$ is obtained by summing losses for all constituents in a tree $t^{(i)}$, sampled from the parsing model (we write $c^{(i)} \in t^{(i)}$):

$$\hat{s}(\mathbf{v}^{(i)}, \boldsymbol{w}^{(i)}) = \sum_{c^{(i)} \in t^{(i)}} h(\mathbf{c}^{(i)}, \mathbf{v}^{(i)}) \,. \tag{3}$$

In their work, training alternates between optimizing the parser using rewards (relying on image and text representations) and optimizing the image-text matching model to refine image and text representations (relying on the fixed parsing model). Once trained, the parser can be directly applied to raw text, i.e., images are not used at test time.

2.3 Limitations of the VG-NSL framework

While straightforward, there are several practical issues inhibiting the visually grounded learning framework. First, contrastive learning implicitly assumes that every constituent of a sentence has its visual representation in the aligned image. However, it is not guaranteed in practice and would result in noisy reward signals. Besides, the loss in Equation 2 (and a similar component in the reward, see Shi et al. (2019)) focuses on constituents corresponding to short spans. Long spans, independently of their syntactic structure, tend to be sufficiently discriminative to distinguish the aligned image $\mathbf{v}^{(i)}$ from an unaligned one. This implies that there is not much learning signal for such constituents. The tendency to focus on short spans and those more easily derivable from an image is evident from the results (Shi et al., 2019; Kojima et al., 2020). For example, their parser is accurate for noun phrases (recall 79.6%), which are often short for captions, but performs poorly on verb phrases (recall 26.2%) which have longer spans, more complex compositionally and also harder to predict from images (see our analysis in Section 4.3.2). While there may be ways to mitigate some of these issues, we believe that any image-text matching loss alone is unlikely to provide sufficient learning signal to accurately captures all aspects of syntax. Instead of resorting to language-specific inductive biases as done by Shi et al. (2019) (i.e., head-initial bias (Baker, 2008) of English), we propose to complement the image-text matching loss with the objective derived from the unaligned text (i.e., log-likelihood), jointly training a parser to both explain the raw language data and the alignment with images.

Moreover, their learning is likely to suffer from large variance in gradient estimation as their parser does not admit tractable estimation of the partition function, and thus they have to rely on sampling decisions. This will be even more of a problem if we would attempt to use it in the joint learning set-up. Also note that similar parsing models do not yield linguistically-plausible structures when used in the conventional (i.e., non-grounded) grammar-induction set-ups (Williams et al., 2018; Havrylov et al., 2019).

In the next section, we will use compound PCFGs and describe an improved visually grounded learning framework that can tackle these issues neatly.

3 Visually grounded compound PCFGs

We use compound PCFGs (Kim et al., 2019a) and develop visually-grounded compound PCFGs (VC-PCFGs) within the contrastive learning framework. Instead of sampling a tree and computing a point estimate of the image-text matching loss, we can compute the expected image-text matching loss under a tree distribution and use end-to-end contrastive learning (Section 3.1). Since it is inefficient to compute constituent representations relying on the chart, we will introduce an additional textual representation model to encode constituents (Section 3.2). Moreover, VC-PCFGs let us additionally optimize a language modeling objective, complementing the visually grounded contrastive learning (Section 3.3).

3.1 End-to-end contrastive learning

In the visually grounded grammar induction framework, the parsing model is optimized through learning signals derived from the alignment of images and constituents, as scored by the image-text matching model. Denoting a set of image representations by $\mathcal{V} = \{\mathbf{v}^{(i)}\}$ and the corresponding set of sentences by $\mathcal{W} = \{\boldsymbol{w}^{(i)}\}$, the image-text matching model is optimized via contrastive learning:

$$\mathcal{L}(\mathcal{V}, \mathcal{W}; \phi, \theta) = \sum_{i} s(\mathbf{v}^{(i)}, \boldsymbol{w}^{(i)}) \,. \tag{4}$$

We define $s(\mathbf{v}^{(i)}, \boldsymbol{w}^{(i)})$ as the loss of aligning $\mathbf{v}^{(i)}$ and $\boldsymbol{w}^{(i)}$. In VG-NSL, it is estimated via point estimation (see Equation 3). While in VC-PCFGs, given an aligned image-sentence pair $(\mathbf{v}, \boldsymbol{w})$, we compute the expected image-sentence matching loss under a tree distribution $p_\theta(t|\boldsymbol{w})$, leading to an end-to-end contrastive learning:

$$s(\mathbf{v}, \boldsymbol{w}) = \mathbb{E}_{p_\theta(t|\boldsymbol{w})} \sum_{c \in t} h(\mathbf{c}, \mathbf{v}) \,, \tag{5}$$

where $h(\mathbf{c}, \mathbf{v})$ is the hinge loss of aligning the unlabeled constituent c and the image $\mathbf{v}$ (defined in Equation 2). Minimizing the hinge loss encourages an aligned image-constituent pair to rank higher than any unaligned one. Expanding the right-hand side of Equation 5

$$\begin{aligned} s(\mathbf{v}, \boldsymbol{w}) &= \sum_{t \in \mathcal{T}_{\mathcal{G}}(\boldsymbol{w})} p_\theta(t|\boldsymbol{w}) \sum_{c \in t} h(\mathbf{c}, \mathbf{v}) \\ &= \sum_{c \in \boldsymbol{w}} \underbrace{\sum_{t \in \mathcal{T}_{\mathcal{G}}(\boldsymbol{w})} \mathbb{I}_{\{c \in t\}} p_\theta(t|\boldsymbol{w})}_{p(c|\boldsymbol{w})\text{: marginal of the span } c} \; h(\mathbf{c}, \mathbf{v}) \\ &= \sum_{c \in \boldsymbol{w}} p(c|\boldsymbol{w}) h(\mathbf{c}, \mathbf{v}) \,, \end{aligned} \tag{6}$$

where $p(c|\boldsymbol{w})$ is the conditional probability (i.e., marginal) of the span c given $\boldsymbol{w}$. It can be efficiently computed with the inside algorithm and automatic differentiation (Eisner, 2016).

3.2 Span representation

Estimation of the expected image-text matching scores relies on span representations. Ideally, a span representation should encode semantics of a span with its computation guided by its syntactic structure (Socher et al., 2013). The reliance on the predicted tree structure will result in propagating learning signals derived from the alignment of images and sentences back to the parser. To realize this desideratum, we could follow the inside algorithm and recursively compose span representations (Le and Zuidema, 2015; Stern et al., 2017; Drozdov et al., 2019), which is, however, time- and memory-inefficient in practice.

Instead, we produce span representations largely independently of the parser, as we will explain below. The only way the parser model influences this representation is through the predicted constituent label: we use its distribution to compute the representation.[3]

Specificially, as a trade-off for a better training efficiency, we adopt a single-layer BiLSTM to encode spans. A mean-pooling layer is applied over the hidden states $\mathbf{h}$ of the BiLSTM and followed by a label-specific affine transformation $f_k(\cdot)$ to produce a label-specific span representation $\mathbf{c}_k$. Take a span $c_{i,j} = w_i \dots w_j$ $(0 < i < j \le n)$:

$$\mathbf{c}_k = f_k\Big(\frac{1}{j-i+1}\sum_{l=i}^{j}\mathbf{h}_l\Big)\,. \tag{7}$$

The BiLSTM encoding model operates at the span level and encodes semantics of a span. Unlike using a single sentence-level (Bi)LSTM encoder, it guarantees that no information from words outside of the span leaks into its representations. More importantly, it can run in $\mathcal{O}(n)$ for a sentence of length n with a parallel implementation. While the produced representation does not reflect the structural decisions made by the parser, it can be sensitive to word order and may be affected by its syntactic structure (Blevins et al., 2018).

In order to compute the representation of unlabeled constituent $\mathbf{c}$, we average the label-specific span representation $\mathbf{c}_k$ under the distribution of labels defined by the parser:

$$\mathbf{c} = \sum_{k=1}^{K} p(k|c,\boldsymbol{w})\mathbf{c}_k\,, \tag{8}$$

where $p(k|c,\boldsymbol{w})$ is the probability that the span $\mathbf{c}$ has label k, conditioned on having this constituent span in the tree.

To further reduce computation we estimate the matching loss only using the $\frac{n(n-1)}{4}$ shortest spans for a sentence of length n. Thus the image-text alignment loss will focus on small constituents. This is the case anyway (see discussion in Section 2.3), so we expect that this simplification would not hurt model performance significantly.

3.3 Joint objective

Rather than simply optimizing the contrastive learning objective, we additionally maximize the log-likelihood of text data. As with C-PCFGs, we optimize the ELBO:

$$\mathcal{L}(\mathcal{W};\phi,\theta) = -\sum_{\boldsymbol{w}\in\mathcal{W}} \text{ELBO}(\boldsymbol{w};\phi,\theta)\,. \tag{9}$$

This learning objective complements contrastive learning. As contrastive learning optimizes a parser by solely matching images and constituents, the parser would only focus on simple and local constituents (e.g., short NPs). Moreover, in practice, since not every constituent can be grounded in an image, contrastive learning would suffer from misleading or ambiguous learning signals.

To summarize, the overall loss function is

$$\mathcal{J}(\phi,\theta) = \mathcal{L}(\mathcal{W};\phi,\theta) + \alpha\cdot\mathcal{L}(\mathcal{V},\mathcal{W};\phi,\theta)\,, \tag{10}$$

where α is a hyper-parameter balancing the relative importance of the contrastive learning.

3.4 Parsing

The parser can be directly used to parse raw text after training, without requiring access to visual groundings. Parsing seeks for the most probable parse t^* of $\boldsymbol{w}$:

$$t^* = \text{argmax} \int_{\mathbf{z}} p_\theta(t|\mathbf{w},\mathbf{z})p_\theta(\mathbf{z}|\boldsymbol{w})\,d\mathbf{z}\,.$$

Still, though the maximum a posterior (MAP) inference over $p_\theta(t|\boldsymbol{w})$ can be solved by the CYK algorithm (Kasami, 1966; Younger, 1967), inference becomes intractable when introducing into $\mathbf{z}$. The MAP inference is instead approximated by

$$t^* \approx \text{argmax} \int_{\mathbf{z}} p_\theta(t|\mathbf{w},\mathbf{z})\delta(\mathbf{z}-\boldsymbol{\mu}_\phi(\boldsymbol{w}))\,d\mathbf{z}\,,$$

where $\delta(\cdot)$ is the Dirac delta function and $\boldsymbol{\mu}_\phi(\boldsymbol{w})$ is the mean vector of the variational posterior $q_\phi(\mathbf{z}|\boldsymbol{w})$. As $\delta(\cdot)$ has zero mass everywhere but at the mode $\boldsymbol{\mu}_\phi(\boldsymbol{w})$, it is equivalently solving $\text{argmax}_t\, p_\theta(t|\boldsymbol{w},\boldsymbol{\mu}_\phi(\boldsymbol{w}))$.

---

[3] Intuitively, the key learning signal for the parser in our model comes through the marginals in Equation 6, not through the span representation.

4 Experiments

4.1 Datasets and evaluation

Datasets: We use MSCOCO (Lin et al., 2014). It consists of 82,783 training images, 1,000 validation images, and 1,000 test images. Each image is associated with 5 caption sentences. We encode images into 2048-dimensional vectors using the pre-trained ResNet-101 (He et al., 2016). At test time, only captions are used. We follow Shi et al. (2019) and parse test captions with Benepar (Kitaev and Klein, 2018). We use the same data preprocessing[4] as in Shen et al. (2019) and Kim et al. (2019a), where punctuation is removed from all data, and the top 10,000 frequent words in training sentences are kept as the vocabulary.

Evaluation: We mainly compare VC-PCFGs with VG-NSL (Shi et al., 2019). To verify the effectiveness of the use of visual groundings, we also compare our model with a C-PCFG trained only on the training captions. All models are run four times with different random seeds and for at most 15 epochs with early stopping (i.e., the image-caption loss / perplexity on the validation captions does not decrease). We report both averaged corpus-level F1 and averaged sentence-level F1 numbers as well as the unbiased standard deviations.

4.2 Settings and hyperparameters

We adopt parameter settings suggested by the authors for the baseline models. For VG-NSL we run the authors' code.[5] We re-implement C-PCFG using automatic differentiation (Eisner, 2016) to speed up training. Our VC-PCFG comprises a parsing model and an image-text matching model. The parsing model has the same parameters as the baseline C-PCFG; the image-text matching model has the same parameters as the baseline VG-NSL. Concretely, the parsing model has 30 nonterminals and 60 preterminals. Each of them is represented by a 256-dimensional vector. The inference model $q_\phi(\mathbf{z}|\boldsymbol{w})$ uses a single-layer BiLSTM. It has a 512-dimensional hidden state and relies on 512-dimensional word embeddings. We apply a max-pooling layer over the hidden states of the BiLSTM and then obtain 64-dimensional mean vectors $\boldsymbol{\mu}_\phi(\boldsymbol{w})$ and log-variances $\log \sigma_\phi(\boldsymbol{w})$ by using an affine layer. The image-text matching model projects visual features into 512-dimensional feature vectors and encodes spans as 512-dimensional vectors. Our span representation model is another single-layer BiLSTM, with the same hyperparameters as in the inference model. α for visually grounded learning is set to 0.001. We implement VC-PCFG relying on Torch-Struct (Rush, 2020), and optimize it using Adam (Kingma and Ba, 2015) with the learning rate set to 0.01, $\beta_1 = 0.75$, and $\beta_2 = 0.999$. All parameters are initialized with Xavier uniform initializer (Glorot and Bengio, 2010).

4.3 Results and analysis

4.3.1 Main results

Our model outperforms all baselines according to both corpus-level F1 and sentence-level F1 (see Table 1). Notably, it surpasses VG-NSL+HI by 10% F1.[6] The right branching model is a strong baseline on image captions, as observed previously on the WSJ corpus, including in recent work (Shen et al., 2018; Kim et al., 2019a). Comparing with C-PCFG, which is trained solely on captions, VC-PCFG achieves a much higher mean F1 (+5.7% F1), demonstrating the informativeness of visual groundings. However, VC-PCFG suffers from a larger variance presumably because the joint objective is harder to optimize. Visually grounded contrastive learning (w/o LM) has a mean F1 50.5%. It is further improved to 59.4% when additionally optimizing the language modeling objective.

Moreover, we show recall on six frequent constituent labels (NP, VP, PP, SBAR, ADJP, ADVP) in the test captions. Unsurprisingly, VG-NSL is best on NPs because the matching-based reward signals optimize it to focus only on short and concrete NPs (recall 64.3%). It performs poorly on other constituent labels such as VPs (recall 28.1%). In contrast, VC-PCFG exhibits a relatively even performance across constituent labels, e.g., it is most accurate on SBARs and ADVPs and works fairly well on VPs (recall 83.2%). Meanwhile, it improves over C-PCFG for NPs, which are usually short and 'concrete', once again confirming the benefits of using visual groundings. Visually grounded contrastive learning (w/o LM) tends to behave like

[5] `https://git.io/Jf3nn`.

[6] We run the code of Shi et al. (2019) and train VG-NSL and VG-NSL+HI on the training captions with punctuation removed. This is considered a more challenging setting as punctuation signals the boundaries of constituents and makes it easy for parsers to derive constituents. At test time, as a common practice (Shen et al., 2018, 2019; Kim et al., 2019a), we discard punctuation and ignore trivial single-word and sentence-level spans. We notice that including sentence-level spans can improve the F1 of VG-NSL to around 49%.

Model	NP	VP	PP	SBAR	ADJP	ADVP	C-F1	S-F1

Table 1: Recall on six frequent constituent labels (NP, VP, PP, SBAR, ADJP, ADVP) in the MSCOCO test captions and corpus-level F1 (C-F1) and sentence-level F1 (S-F1) results. The best mean number in each column is in bold. † indicates results reported by Shi et al. (2019). ⋆ denotes results obtained by running their code. Notice that the results from Shi et al. (2019) are not comparable to ours because they keep punctuation and include trivial sentence-level spans in evaluation.

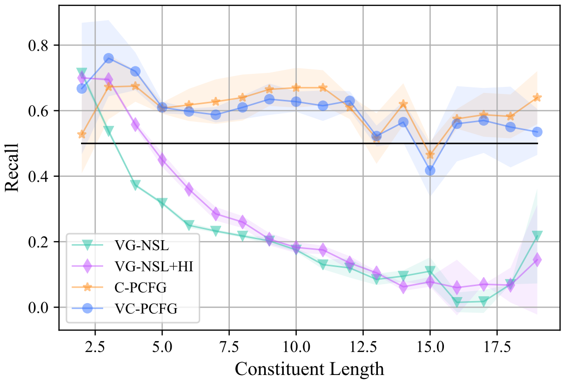

Figure 1: Recall broken down by constituent length.

the right branching baseline. Additionally optimizing the language modeling objective brings a huge improvement for NPs (+19.3% recall).

4.3.2 Analysis

We analyze model performance for constituents of different lengths (Figure 1). As expected, VG-NSL becomes weaker as constituent length increases, and the drop is very dramatic. C-PCFG and its grounded version VC-PCFG consistently outperform VG-NSL on constituents longer than four tokens and display a more even performance across constituent lengths. Meanwhile, VC-PCFG beats C-PCFG on constituents of length below 5, confirming that visual groundings are beneficial for short spans. We further plot the distribution over constituent length for different phrase types (Figure 2) and find that around 75% constituents in our dataset are shorter than six tokens, and 60% of them are NPs. Thus, it is not surprising that the improvement on NPs, brought by visually grounded learning, has a large impact on the overall performance.

	2	3	4	5	6	7	8
NP	0.25	0.10	0.05	0.04	0.02	0.01	0.01
VP	0.01	0.01	0.03	0.03	0.03	0.03	0.02
PP	0.04	0.09	0.05	0.02	0.02	0.01	0.01
SBAR	0.00	0.00	0.00	0.00	0.00	0.00	0.00
ADJP	0.01	0.00	0.00	0.00	0.00	0.00	0.00
ADVP	0.00	0.00	0.00	0.00	0.00	0.00	0.00
All	0.31	0.22	0.13	0.09	0.08	0.06	0.04

Figure 2: Label distribution over constituent length. *All* denotes frequencies of constituent lengths. Zero frequencies are due to the limited numerical precision.

Next, we analyze induced tree structures. We compare model predictions against gold trees, left branching trees, and right branching trees. As there is little performance difference between corpus-level F1 and sentence-level F1, we focus on sentence-level F1 in this analysis. We report self F1 (Williams et al., 2018) to show model consistency across runs. The self F1 is computed by averaging over six model pairs from four different runs. All results are presented in Table 2. Overall, all models have self F1 above 70%, indicating a relatively high consistency. We observe that using the head-initial bias pushes VG-NSL closer to the right-branching baseline, while visual grounded learning

Model	Gold	Left	Right	Self
VG-NSL	41.8	28.3	20.6	84.3
VG-NSL+HI	49.4	24.5	29.2	88.6
C-PCFG	53.7	1.3	53.6	77.3
VC-PCFG	59.4	4.4	48.5	71.1

Table 2: Average sentence-level F1 results against gold trees (Gold), left branching trees (Left), right branching trees (Right), and self F1 (Self) (Williams et al., 2018).

leads to improvements over C-CPFG, forcing VC-PCFG to deviate from the default right-branching behaviour.

Finally, we test VG-NSL+HI and VC-PCFG on 50 manually annotated captions released by Shi et al. (2019). VC-PCFG achieves a mean F1 62.7%, surpassing VG-NSL+HI by 12.1% F1. In Figure 3 we visualize a parse tree predicted by the best run of VC-PCFG. We can see that VC-PCFG identifies most NPs but makes mistakes in PP attachement and consequently fails to identify the VP.

5 Related work

Grammar Induction has a long history in computational linguistics. Following observations that direct optimization of log-likelihood with the Expectation Maximization algorithm (Lari and Young, 1990) is not effective at producing effective grammars, a number of approaches have been developed, emboding various inductive biases or assumption about the language structure and its relation to surface realizations (Klein and Manning, 2002; Smith and Eisner, 2005; Cohen and Smith, 2009; Spitkovsky et al., 2010). The recent advances in the area have been brought by flexible neural models (Jin et al., 2019; Kim et al., 2019a,b; Drozdov et al., 2019). All these methods, with the exception of Shi et al. (2019), rely solely on text.

Visually grounded learning is motivated by the observation that natural language is grounded in perceptual experiences (Steels, 1998; Barsalou, 1999; Fincher-Kiefer, 2001; Roy, 2002; Bisk et al., 2020). It has been shown effective in word representation learning (Bruni et al., 2014; Silberer and Lapata, 2014; Lazaridou et al., 2015) and sentence representation learning (Kiela et al., 2018; Bordes et al., 2019). All this work uses visual images as perceptual experience of language and exploits visual semantics derived from images to improve continuous vector representatios of language. In contrast, we induce structured representations, discrete tree structure of language, by using visual groundings. We propose a model for the task within the contrastive learning framework. Learning involves estimating *concreteness* of spans, which generalizes word-level concreteness (Turney et al., 2011; Kiela et al., 2014).

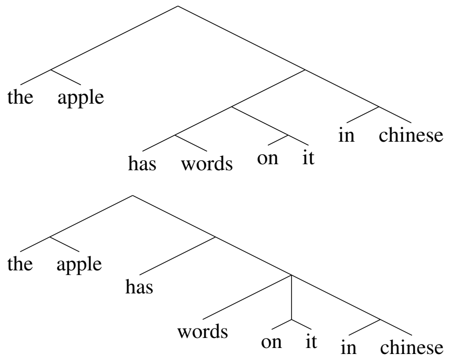

Figure 3: Upper: A parse output by the best run of VC-PCFG. Bottom: The corresponding gold tree.

In the vision and machine learning community, unsupervised **induction of structured image representations** (aka scene graphs or world models) has been receiving increasing attention (Eslami et al., 2016; Burgess et al., 2019; Kipf et al., 2020). However, they typically rely solely on visual signal. An interesting extension of our work would be to consider joint induction of structured representations of images and text while guiding learning by an alignment loss.

6 Conclusion

We have presented visually-grounded compound PCFGs (VC-PCFGs) that use compound PCFGs and generalize the visually grounded grammar learning framework. VC-PCFGs exploit visual groundings via contrastive learning, with learning signals derived from minimizing an image-text alignment loss. To tackle the issues of misleading and insufficient learning signals from purely agreement-based learning, we propose to complement the image-text alignment loss with a loss defined on unlabeled text. We resort to using compound PCFGs which enables us to complement the alignment loss with a language modeling objective, resulting in a fully-differentiable end-to-end visually grounded learning. We empirically show that our VC-PCFGs are superior to models that are trained only through visually grounded learning or only relying on text.

Abstract

Training a supervised neural network classifier typically requires many annotated training samples. Collecting and annotating a large number of data points are costly and sometimes even infeasible. Traditional annotation process uses a low-bandwidth human-machine communication interface: classification labels, each of which only provides a few bits of information. We propose Active Learning with Contrastive Explanations (ALICE), an expert-in-the-loop training framework that utilizes contrastive natural language explanations to improve data efficiency in learning. ALICE learns to first use active learning to select the most informative pairs of label classes to elicit contrastive natural language explanations from experts. Then it extracts knowledge from these explanations using a semantic parser. Finally, it incorporates the extracted knowledge through dynamically changing the learning model's structure. We applied ALICE in two visual recognition tasks, bird species classification and social relationship classification. We found by incorporating contrastive explanations, our models outperform baseline models that are trained with 40-100% more training data. We found that adding 1 explanation leads to similar performance gain as adding 13-30 labeled training data points.

1 Introduction

The de-facto supervised neural network training paradigm requires a large dataset with annotations. It is time-consuming, difficult and sometimes even infeasible to collect a large number of data-points due to task nature. A typical example task is medical diagnosis. In addition, annotating datasets also is costly, especially in domains where experts are difficult to recruit. In a traditional annotation process, the human-machine communication bandwidth is narrow. Each label provides $\log C$ bits per sample for a C-class classification problem. However, humans don't solely rely on such low bandwidth communication to learn. They instead learn through natural language communication, which grounds on abstract concepts and knowledge. Psychologists and philosophers have long posited natural language explanations as central, organizing elements to human learning and reasoning (Chin-Parker and Cantelon, 2017; Lombrozo, 2006; Smith, 2003). Following this intuition, we explore methods to incorporate natural language explanations in learning paradigms to improve learning algorithm's data efficiency.

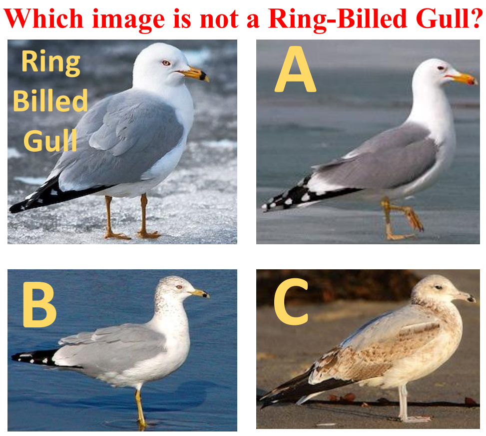

Figure 1: An example task that would benefit from learning with natural language explanation. The top-left corner shows an example image of a ring-billed gull. In the other three images (A), (B), (C), which one is not a ring-billed gull but a California gull? Given the natural language explanation *"Ring-billed gull has a bill with a black ring near the tip while California gull has a red spot near the tip of lower mandible"*, it would be easier to find that (A) is the correct choice.

Let's take a bird species classification task as an example to illustrate the advantage of learning with natural language explanation. Figure 1 shows several bird images. Based on visual dissimilarity, many people mistakenly thought Image C is not a ring-billed gull as it has a different colored coat

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 4380–4391,
November 16–20, 2020.

compared to the example. However, ring-billed gulls change their coat color from light yellow to grey after the first winter. So color is not the deciding factor to distinguish California gull and ring-billed gull. If we receive abstract knowledge from human experts through a natural language format, such as *"Ring-billed gull has a bill with a black ring near the tip while California gull has a red spot near the tip of lower mandible"* and incorporate it in the model, then the model will discover that Image A is a California gull instead of a ring-billed gull based on its bill.

Previous work has shown that incorporating natural language explanation into the classification training loop is effective in various settings (Andreas et al., 2018; Mu et al., 2020). However, previous work neglects the fact that there is usually a limited time budget to interact with domain experts (e.g., medical experts, biologists) (Liang et al., 2019, 2020) and high-quality natural language explanations are expensive, by nature. Therefore, we focus on eliciting fewer but more informative explanations to reduce expert involvement.

We propose Active Learning with Contrastive Explanations (ALICE), an expert-in-the-loop training framework that utilizes contrastive natural language explanations to improve data efficiency in learning. Although we focus on image classification in this paper, our expert-in-the-loop training framework could be generalized to other classification tasks. ALICE learns to first use active learning to select the most informative query pair to elicit contrastive natural language explanations from experts. Then it extracts knowledge from these explanations using a semantic parser. Finally, it incorporates the extracted knowledge through dynamically updating the learning model's structure. Our experiments on bird species classification and social relationship classification show that our method that incorporates natural language explanations has better data efficiency compared to methods that increase training sample volume.

2 Related Work

Learning with Natural Language Explanation Psychologists and philosophers have long posited natural language explanations as central organizing elements to human learning and reasoning (Chin-Parker and Cantelon, 2017). Several attempts have been made to incorporate natural language explanations into supervised classification tasks. Andreas et al. (2018); Mu et al. (2020) adopt a multi-task setting by learning classification and captioning simultaneously. Murty et al. (2020); He and Peng (2017) encode natural language explanations as additional features to assist classification. Orthogonal to their approaches, we focus on eliciting fewer but more informative explanations to reduce expert involvement with class-based active learning. Another line of research collects heuristic rules as explanations (e.g., 'honey month' for predicting SPOUSE relationship) to automatically label unlabeled data (Srivastava et al., 2017; Zhou et al., 2020; Hancock et al., 2018). Different from their settings, we assume no additional training datapoints. In addition, we leverage natural language explanations by extracting knowledge and incorporate the knowledge into classifiers. Distantly related to our work, Hendricks et al. (2016) propose to generate explanations for image classifiers but they do not explore improving the classifiers with the explanations.

Active Learning The key hypothesis of active learning is that, if the learning algorithm is allowed to choose the data from which it learns, it will perform better than randomly selecting training samples (Settles, 2009). Existing work in active learning focuses primarily on exploring sampling methods to select additional data-points to label from a pool of unlabeled data (Sener and Savarese, 2018; Settles, 2011, 2009). Luo and Hauskrecht (2017) propose group-based active learning where the annotator could label a group of data points each time rather than one data point. However, they still rely on classification labels as the interface for human-machine communication. Instead, we focus on incorporating natural language explanations into the classification training framework. Contrastive learning has previously been shown to substantially improve unsupervised learning (Abid et al., 2018), feature learning (Zou et al., 2015), and learning probabilistic models (Zou et al., 2013). However, it has not been applied to the setting of active learning with explanations as we explore here.

Hierarchical Visual Recognition Categorical hierarchy is inherent in visual recognition (Biederman, 1987; Feng et al., 2019). Xiao et al. (2014) propose to expand the model based on category hierarchy for incremental learning. Yan et al. (2015) decompose classification task into a coarse category classification and a fine category classifica-

tion. Different from previous work, we focus on incorporating contrastive natural language explanations into the model hierarchy to achieve better data efficiency.

3 Problem Formulation

Contrastive Natural Language Explanations Existing research in social science and cognitive science (Miller, 2019; Mittelstadt et al., 2019) suggests contrastive explanations are more effective in human learning than descriptive explanations. Therefore, we choose contrastive natural language explanations to benefit our learners. An example contrastive explanation is like "Why P rather than Q?", in which P is the target event and Q is a counterfactual contrast case that did not occur (Lipton, 1990). In the example in Figure 1, if we ask the expert to differentiate between Ring-billed gull against California gull, the expert would output the following natural language explanation: *"Ring-billed gull has a bill with a black ring near the tip while California gull has a red spot near tip of lower mandible"*. Our explanations are class-based and are not specifically associated with any particular images.

Problem Setup We are interested in a C class classification problem defined over an input space X and a label space $Y = \{1, ..., C\}$. Initially, the training set $D_{train} = \{(x_i, y_i)\}_1^{N_{train}}$ is small, since our setting is restricted to be low resource. We also assume that there is a limited budget to ask domain experts to provide explanations during training. Specifically, we consider k rounds of interactions with domain experts and each round has a query budget b. For each query, we need to specify two classes y^p, y^q for domain experts to compare. Domain experts would return a contrastive natural language explanation e. Each explanation e would guide us to focus on the most discriminating semantic segments to differentiate between y^p and y^q. In this paper, a *semantic segment* refers to a semantic segment of an object (e.g., "bill" in bird species classification) or a semantic object (e.g., "soccer" in social relationship classification).

To make our framework more general, we start from a standard image classification neural architecture. We formulate our initial model as $M(\phi, g_{pool}, f) = f(g_{pool}(\phi(x)))$: Here ϕ is an image encoder that maps each input image x to an activation map $\phi(x) \in \mathbb{R}^{H \times W \times d}$. g_{pool} is a global pooling layer $g_{pool}(\phi(x)) \in \mathbb{R}^{d_{pool}}$. f is a fully connected layer that performs flat C way classification. This formulation covers most of the off-the-shelf pre-trained image classifiers.

4 ALICE: Active Learning with Contrastive Explanations

4.1 Overview

ALICE is an expert-in-the-loop training framework that utilizes contrastive natural language explanations to improve data efficiency in learning. ALICE performs multiple rounds of interaction with domain experts and dynamically updates the learning model's structure during each round. Figure 2 describes ALICE's three-step workflow for each round: **(A) Class-based Active Learning**: ALICE first projects each class's training data into a shared feature space. Then ALICE selects b most confusing class pairs to query domain experts for explanations. **(B) Semantic Explanation Grounding**:

ALICE then extracts knowledge from b contrastive natural language explanations by semantic parsing. ALICE grounds the extracted knowledge on the training data of b class pairs by cropping the corresponding semantic segments. **(C) Neural Architecture Morphing**: ALICE finally allocates b new local classifiers and merges b class pairs in the global classifier. The cropped image patches are used as additional training data for a newly added local classifier to emphasize these patches' importance. The model is re-trained after each round.

4.2 Class-based Active Learning

ALICE optimizes towards requesting the most informative explanations to reduce expert involvement. Since each explanation provides knowledge to distinguish a class pair, we aim to identify the class pairs that confuse the model most and the explanations on these class pairs would intuitively help the model a lot. ALICE identifies confusing class pairs by first projecting each class's training data into a shared feature space $g_{pool}(\phi(x))$. As shown in Figure 2 (A), if the training data of two classes are close in the feature space, it is usually hard for the model to distinguish them and thus it would be helpful to solicit an explanation on this class pair. Based on this intuition, we first define the distance between two classes and then select the class pairs with the lowest distance. We first profile each class j by fitting a multivariate Gaussian distribution $\mathcal{N}_j(\mu_j, \Sigma_j)$ on class j's training sample features. We define the distance between class j and class k as the Jensen–Shannon Divergence (JSD) between $\mathcal{N}_j$ and $\mathcal{N}_k$.

$$\mathbb{D}_{\mathsf{J}}(\mathcal{N}_j, \mathcal{N}_k) \triangleq \frac{1}{2}\mathbb{D}_{\mathsf{KL}}(\mathcal{N}_j||(\mathcal{N}_{jk})) + \frac{1}{2}\mathbb{D}_{\mathsf{KL}}(\mathcal{N}_k||\mathcal{N}_{jk})$$

where $\mathcal{N}_{jk} = \frac{1}{2}(\mathcal{N}_j + \mathcal{N}_k)$ and $\mathbb{D}_{\mathsf{KL}}(\mathcal{N}_j||\mathcal{N}_k)$ is the Kullback-Liebler (KL) divergence:

$$\begin{aligned}\mathbb{D}_{\mathsf{KL}}(\mathcal{N}_j||\mathcal{N}_k) =& \frac{1}{2}\Big(tr(\Sigma_k^{-1}\Sigma_j - I) + \log(\frac{|\Sigma_k|}{|\Sigma_j|}) \\ &+ (\mu_j - \mu_k)^T\Sigma_k^{-1}(\mu_j - \mu_k)\Big)\end{aligned}$$

After calculating the distance between all possible class pairs, we select the b class pairs with the lowest JSD distance to query domain experts.

4.3 Semantic Explanation Grounding

After identifying b class pairs that the model is most confused about, we send b query to domain experts. We ask the expert the following question for each query, "How would you differentiate class P and class Q?". Since we want the expert to provide general class-level knowledge, each query only contains text information, and no visual examples are provided to the experts. We obtain b contrastive natural language explanations after the query. Next, we parse the natural language explanations into machine-understandable form.

Query Expert: "How to differentiate *Ring-billed Gulls* and *California Gulls*?"
Parse Expert Explanation: "*Ring-billed Gull* has a bill with a black ring near the tip while *California Gull* has a red spot near the tip of lower mandible. " **Extracted Knowledge:** Pay attention to **[Bill]** when classifying *Ring-billed Gull* v.s. *California Gulls*
Ground Extracted Knowlwdge: Crop **[Bill]** in every training image of *Ring-billed Gulls* and *California Gulls* 
Table 1: Semantic Explanation Grounding Workflow

We choose a simple rule-based semantic parser for simplicity, following Hancock et al. (2018). The simple rule-based semantic parser can be used without any additional training and requires minimum effort to develop. Formally, the parser uses a set of rules in the form $\alpha \rightarrow \beta$, which means that α can be replaced by the token(s) in β. Our rules focus primarily on identifying the discriminating semantic segments (§ 3) mentioned in the explanations (e.g., "bill" for differentiating between ring-billed gull and California gull). We also allow the parser to skip unexpected tokens so that the parser could always succeed in generating a valid output.

Since each explanation e provides class-level knowledge to distinguish class y^p, y^q, we need to propagate the knowledge to all the training datapoints in class y^p, y^q so that the learning model could incorporate the knowledge later during training. We denote the semantic segments mentioned in an explanation e as $S = \{s_1, s_2, ..., \}$. For each training data-point of class y^p, y^q, we apply off-the-shelf semantic segment localization models to crop out the image patch(es) of the semantic segment(s) mentioned $S = \{s_1, s_2, ..., \}$ (Figure 2 (B)). The number of patches cropped from each image equals the number of mentioned semantic segments (i.e., $|S|$). We then resize the image patches to full resolution. The intuition behind our crop-and-resize approach comes from the popular image crop data augmentation: it augments the training data with "sampling of various sized patches of the image whose size is distributed evenly between 8% and 100% of the image area" (Szegedy et al., 2015). This data augmentation technique is widely-adopted and is supported by common deep learning frameworks like PyTorch[1].

ALICE does not need the localization model during testing (More details in § 4.4). The off-the-shelf semantic segment localization models could be the pre-trained localization models on various large-scale datasets like Visual Genome (Krishna et al., 2017) and PASCAL-Part (Chen et al., 2014). If there is no available off-the-shelf localization model, we could recruit non-expert annotators to annotate the location of the semantic segments given that our training set D_{train} is small.

4.4 Neural Architecture Morphing

Overview ALICE incorporates contrastive natural language explanations through dynamically updating the learning model's structure. The high-level idea is to allocate a number of local classifiers to help the origin model guided by the explanations. Specifically, for each explanation e that provides knowledge to distinguish two classes y_p, y_q, we allocate a local classifier that is dedicated to the binary classification between y_p, y_q. We incorporate the extracted knowledge from explanation e to the local classifier so that the local classifier learns to focus on the discriminating semantic segments pointed out by the domain experts. We first discuss the case where all local classifiers perform binary classification and then discuss how to extend them to support general m-ary classification.

Progressive Architecture Update The initial flat C-way classification architecture could be viewed as a composition of an image encoder ϕ and a global classifier $f \circ g_{pool}$. We discuss how the local classifiers are progressively added to assist the global classifier. As shown in Figure 2 (C), we first merge b class pairs into b super-classes in the global classifier. For example, in the first round, the global classifier would change from C-way to $(C-2b+b)$-way. We then allocate b new local classifiers, each for performing binary classification for one class pair. Each local classifier is only called when the global classifier predicts its super-class as the most confident. We delay more complex conditional execution schemes as future work. We also note that the conditional execution schemes have potential for reducing computation runtime (Chen et al., 2020; Mailthody et al., 2019). During training, we fine-tune the image encoder ϕ and reset the global classifier after each round since it is only a linear layer.

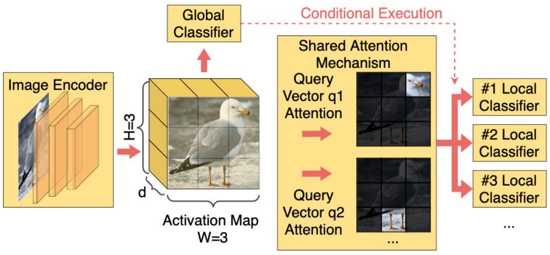

Figure 3: Local classifiers with shared attention mechanism

Knowledge Grounded Training The global classifier is trained on D_{train}, with labels adjusted according to the class pair merging. For a local classifier corresponding to the class pair y^p, y^q, its training data consists of two parts. One part of the training data is the training data-points of classes y^p, y^q in D_{train}. The other part is the resized image patches of class y^p, y^q obtained in semantic explanation grounding (§ 4.3). We use the resized image patches as additional training data to to emphasize these patches' importance. Take the local classifier distinguishing ring-billed gull and California gull as an example (Figure 2 (B, C)). This local classifier is trained on the training images of ring-billed gull and California gull, as well as the bills' patches of each training image of ring-billed gull and California gull. During testing, we only feed the whole image into the model.

Supporting m-ary local classifier So far we have assumed that the local classifier is always a binary classifier. An implicit assumption is that the b class pairs have no overlap. We could support overlapping class pairs as follows. If some class pairs have overlap (e.g., class pair (P, Q), class pair (P, T), class pair (T, U)), we only allocate one local classifier for them (e.g., a 4-ary local classifier for class (P, Q, T, U)). We also merge all the relevant classes in the global classifier into only one super-class (e.g., super-class $\{P, Q, T, U\}$). The local classifier is trained on the union of the overlapping class pairs' training data including patches.

Local Classifier Design Our framework is agnostic to the design choice of the local classifiers. Any design could be plugged into ALICE. We provide a default design as follows. Ideally, each local classifier should learn which semantic segments to focus and how to detect them. Since

---

[1] `torchvision.transforms.RandomResizedCrop`

different local classifier might need to detect the same semantic segments (e.g., bill), the knowledge of detecting semantic segments could be shared among all local classifiers. Therefore, we introduce a shared attention mechanism, which is parameterized using M learnable latent attention queries $q_1, q_2, ..., q_M \in \mathbb{R}^d$ that represent M different latent semantic segments. To keep our design general, we do *not* bind each latent attention queries to any concrete semantic segments (e.g., we do not assign binding like q_1 to "bill") and these queries are trained in a weakly-supervised manner. Following Lin et al. (2015); Hu and Qi (2019), we view the activation map $\phi(x) \in \mathbb{R}^{H \times W \times d}$ of each image x as $H \times W$ attention keys $k_1, ..., k_{H \times W} \in \mathbb{R}^d$. We compute the attention by:

$$Q = \begin{bmatrix} q_1^T \\ ... \\ q_M^T \end{bmatrix}, K = V = \begin{bmatrix} k_1^T \\ ... \\ k_{H \times W}^T \end{bmatrix}$$

$$A = \text{Attention}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d}})V$$

Where $Q \in \mathbb{R}^{M \times d}$, $K = V \in \mathbb{R}^{(H \times W) \times d}$. Each row in the attention output matrix $A \in \mathbb{R}^{M \times d}$ is the attention output for each attention query q_i, which is a descriptor of the i^{th} latent semantic segments. After the shared attention mechanism, each local classifier applies a private fully-connected layer on $\text{flattened}(A)$ to make predictions. Each local classifier could ignore irrelevant semantic segments by simply setting the corresponding weights in its fully-connected layer to zero.

Implementation Our image encoder ϕ could be any off-the-shelf visual backbone model and we use Inception v3 (Szegedy et al., 2016). We implement our semantic parser on top of the Python-based SippyCup (Liang and Potts, 2015) following previous work Hancock et al. (2018). Our framework could support applications in other languages by changing a semantic parser for corresponding languages. We provide more details in Appendix.

5 Bird Species Classification Task
