- Our model infers nearly ×11 faster than existing models (×13 for long sentences), indicating that our model has great potential for the industry and academia.

2 Proposed Approaches

In this section, we first describe how we model slot filling and intent detection task jointly by an non-autoregressive model. And then we describe the details of the two-pass refine mechanism. The brief scheme of our model is shown in Figure 1, details can be found in the corresponding caption. Note that we follow the common practice (Ramshaw and Marcus, 1995; Zhang and Wang, 2016; Haihong et al., 2019) to use "Inside–outside–beginning (IOB)" tagging format.

2.1 Non-Autoregressively Joint Model

We extend the original multi-head Transformer encoder in Vaswani et al. (2017) to construct the model architecture of SlotRefine. Please refer to Vaswani et al. (2017) for the details of Transformer. The main difference against the original Transformer is that we model the sequential information with relative position representations (Shaw et al., 2018), instead of using absolute position encoding.

For a given utterance, a special token CLS is inserted to the first inputting position akin to the operation in BERT (Devlin et al., 2019). Difference from that in BERT is the corresponding output vector is used for next sentence classification, we use it to predict the label of intent in SlotRefine. We denote the input sequence as $x = (x_{cls}, x_1, ..., x_l)$, where l is the utterance length. Each word x_i will be embedded into a h-dimention vector to perform the multi-head self-attention computation. Then, the output of each model stack can be formulated as $H = (h_{cls}, h_1, ..., h_l)$.

To jointly model the representations of ID and SF tasks, we directly concat [2] the representations of

---

[1] Our code is available: `https://github.com/moore3930/SlotRefine`

[2] We follow (Goo et al., 2018) to fuse two representations with gating mechanism, but preliminary experiments show that simply concatenation performs best for our model structure.

Model	ATIS Dataset			Snips Dataset		
	Slot	**Intent**	**Sent**	**Slot**	**Intent**	**Sent**
Joint Seq (Hakkani-Tür et al., 2016)	94.30	92.60	80.70	87.30	96.90	73.20
Atten.-Based (Liu and Lane, 2016)	94.20	91.10	78.90	87.80	96.70	74.10
Sloted-Gated (Goo et al., 2018)	95.42	95.41	83.73	89.27	96.86	76.43
SF-ID (w/o CRF) (Haihong et al., 2019)	95.50	96.58	86.00	90.46	97.00	78.37
SF-ID (w/ CRF) (Haihong et al., 2019)	95.80	97.09	86.90	92.23	97.29	80.43
Stack-Propagation (Qin et al., 2019)	95.90	96.90	86.50	94.20	98.00	86.90
Our Joint Model (in Sec.§2.1)	95.33	96.84	85.78	93.13	97.21	82.83

SlotRefine	**96.22**$^{\uparrow}$	**97.11**$^{\uparrow}$	**86.96**$^{\uparrow}$	**93.72**	97.44	84.38

Table 1: Performance comparison on ATIS and Snips datasets. "↑"indicates significant difference ($p < 0.05$) with previous works. Model name written in bold refer to ours.

h_{cls} and h_i before feed-forward computation, and then feed them into the softmax classifier. Specifically, the intent detection and slot filling results are predicted as follows, respectively:

$$\begin{aligned} y^i &= \mathrm{softmax}\left(W^i \cdot h_{cls} + b^i\right) \\ y_i^s &= \mathrm{softmax}\left(W^s \cdot [h_{cls}, h_i] + b^s\right) \end{aligned} \qquad (1)$$

where y^i and y_i^s denote intent label of the utterance and slot label for each token i, respectively. $[h_{cls}, h_i]$ is the concated vector. W and b are corresponding trainable parameters.

The objective of our joint model can be formulated as:

$$p\left(y^i, y^s|x\right) = p\left(y^i|x\right) \cdot \prod_t^l p\left(y_t^s|x, y^i\right) \qquad (2)$$

The learning objective is to maximize the conditional probability $p\left(y^i, y^s|x\right)$, which is optimized via minimizing its cross-entropy loss. Unlike autoregressive methods, the likelihood of each slot in our approach can be optimized in parallel.

2.2 Two-pass Refine Mechanism

Due to the conditional independence between slot labels, it is difficult for our proposed non-autoregressive model to capture the sequential dependency information among each slot chunk, thus leading to some uncoordinated slot labels. We name this problem as **uncoordinated slots problem**. Take the false tagging in Figure 2 for example, slot label "*I-song*" uncoordinately follows "*B-singer*", which does not satisfy the Inside-Outside-Beginning tagging format.

To address this problem, we introduce a two-pass refine mechanism. As depicted in the Figure 1, in addition to each token embedding in the utterance, we also element-wisely add the slot tag embedding into the model. In the first pass, the initial slot tags are all setting to "O", while in the second pass, the "*B-tags*" predicted in the first pass is used as the corresponding slot tag input. These two iterations share the model and optimization goal, thus brings no extra parameters.

Intuitively, in doing so, the model generates a draft in the first pass and tries to find the beginning of each slot chunk. In the second pass, by propagating the utterance again with the predicted "*B-tags*", the model is forced to learn how many identical "*I-tags*" follow them. Through this process, the slot labels predicted becomes more consistent, and the boundaries are more accurately identified. From a more general perspective, we can view this two-pass process as a trade-off between autoregression and non-autoregression, where the complete markov chain process can be simplified as follow:

$$\begin{aligned} p\left(y^i, y^s|x\right) = p\left(y^i|x\right) &\cdot p\left(\tilde{y}^s|y^i, x\right) \\ &\cdot p\left(y^s|\tilde{y}^s, y^i, x\right) \end{aligned} \qquad (3)$$

where $\tilde{y}^s$ is the tagging results from the first pass.

Two-pass refine mechanism is similar to the multi-round iterative mechanism in non-autoregressive machine translation (Lee et al., 2018; Gu et al., 2018; Ding et al., 2020; Kasai et al., 2020), such as Mask-predict (Ghazvininejad et al., 2019). However, we argue that our method is more suitable in this task. The label dependency of the tagging task (e.g., slot filling) is simple, where we only need to ensure the tagging labels of a slot are consistent from the beginning to the end. Therefore, two iterations to force the model to focus on the slot boundaries is enough in our task, intuitively. Mask-Predict can alleviate the problem caused by conditional independence too. However, it's designed for a more complex goal, and it usually introduce more iterations (e.g., 10 iters) to achieve competitive performance, which largely reduces the inference speed.

3 Experiment

Datasets We choose two widely-used datasets: ATIS (Airline Travel Information Systems,Tur et al. (2010)) and Snips (collected by Snips personal voice assistant,Coucke et al. (2018)). Compared with ATIS, the Snips dataset is more complex due to its large vocabulary size, cross-domain intents and more out-of-vocabulary words.

Metrics Three evaluation metrics are used in our experiments. F1-score and accuracy are applied for slot filling and intent detection task, respectively. Besides, we use sentence accuracy to indicate proportion of utterance in the corpus whose slots and intent are both correctly-predicted.

Setup All embeddings are initialized with xavier method (Glorot and Bengio, 2010). The batch size is set to 32 and learning rate is 0.001. we set number of Transformer layers, attention heads and hidden sizes to {2,8,64} and {4,16,96} for ATIS and Snips datasets. In addition, we report the results of previous studies (Hakkani-Tür et al., 2016; Liu and Lane, 2016; Goo et al., 2018; Haihong et al., 2019; Qin et al., 2019) and conduct speed evaluation based on their open-source codes.

Main Results Table 1 summarizes the model performance on ATIS and snips corpus. It can be seen that SlotRefine consistently outperforms other baselines in all three metrics. Compared with our basic non-autoregressive joint model in Section§ 2.1, SlotRefine achieve +1.18 and +1.55 sentence-level accuracy improvements for ATIS and Snips, respectively. It is worthy noting that our SlotRefine significantly improves the slot filling task (F1-score↑). we attribute the improvement to that our two-pass mechanism successfully makes the model learn better slot boundaries.

Speedup As each slot tagging result can be calculated in parallel with our approach, inference latency can be significantly reduced. As shown in Table 2, on ATIS test set, our non-autoregressive model could achieve ×8.80 speedup compared with the existing state-of-the-art model (Haihong et al., 2019). And after introducing two-pass mechanism (SlotRefine), our model still achieves competitive inference speedup (×4.31). Our decoding is conducted with a single Tesla P40 GPU. It is worth noting that for long sentences (Length$\geq$12), the speedup achieves $\times$13 (not reported in table).

Model	Latency	Speedup
Sloted-Gated	11.31ms	1.41×
SF-ID (with CRF)	13.03ms	1.22×
Stack-Propagation	15.94ms	1.00×
Our Joint Model	1.48ms	10.77×
Our Joint Model +CRF	8.32ms	1.92×
SlotRefine	3.02ms	4.31×

Table 2: "Latency" is the average time to decode an utterance without minibatching. "Speedup" is compared against existing SOTA model (Haihong et al., 2019).

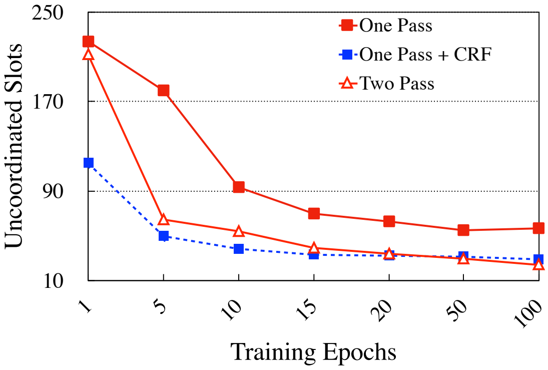

Figure 3: The number of uncoordinated slots of our joint model (One Pass), joint model with CRF (One Pass+CRF) and SlotRefine (Two Pass) during training.

Two-Pass Mechanism v.s. CRF In SF task, CRF is usually used to learn the dependence of slot labels. Two most important dependence rules CRF learned can be summarized as *tag O can only be followed by O or B* and *tag B-* can only be followed by same-type label I-* or O*, which can be perfectly addressed with our proposed two-pass mechanism. Experiments about +CRF can be found in Table 1&2 ("Our Joint Model +CRF"), we can see that two-pass mechanism equipped SlotRefine outperforms +CRF by averagely +0.89, meanwhile preserving ×2.8 speedup, demonstrating that two-pass mechanism can be a better substitute for CRF in this task for better performance and efficiency.

Remedy Uncoordinated Slots in Training We visualize the number decrease of uncoordinated slots of the training process on ATIS dataset. As depicted in Figure 3, uncoordinated errors of both "One-Pass" and "Two-Pass" models decrease with training goes. Notably, the uncoordinated slots number of Two-Pass model drops significantly

Model	ATIS Dataset			Snips Dataset		
	Slot	**Intent**	**Sent**	**Slot**	**Intent**	**Sent**
Joint Model	95.33	96.84	85.78	93.31	97.21	82.83
Joint Model with CRF	95.71	96.54	85.71	93.22	96.79	82.51
SlotRefine	96.22	97.11	86.96	93.72	97.44	84.38
SlotRefine with GloVe	**96.24**	97.35	87.57	96.33	98.36	91.06
SlotRefine with BERT	96.16	**97.74**	**88.64**	**97.05**	**99.04**	**92.96**
previous work with pretraining						
BERT-Joint (Chen et al., 2019)	96.10	97.50	88.20	97.00	98.60	92.80
Stack-Propagation with BERT (Qin et al., 2019)	96.10	97.50	88.60	97.00	99.00	92.90

Table 3: Performance comparison between SlotRefine with GloVe initialzation and Bert based model on ATIS and Snips datasets.

faster than the One-Pass model, achieving better convergence than +CRF after 50 epochs. This indicates that our proposed two-pass mechanism indeed remedy the uncoordinated slots problem, making the slot filling more accurate.

SlotRefine with Pretraining Recently, there are also some works based on large scale pretraining model BERT (Chen et al., 2019), where billions of external corpus are used and tremendous of model parameters are introduced. The number of parameters of BERT is many orders of magnitude more than ours, thus it is unfair to compare performance of SlotRefine with them directly. To highlight the effectiveness of SlotRefine, we conduct experiments with two pretraining schemes, GloVe[3] and BERT[4], to compare with them. We find that both GloVe and BERT could further enhance the SlotRefine, and it worth noting that "SlotRefine w/ BERT" outperforms existing pretraining based models. The detailed comparison can be found in Table 3.

For the pre-training scheme of BERT, we follow the setting in Chen et al. (2019) and equip two-pass mechanism in the fine-tune stage, where CLS token is used for intent detection. And for the pre-training scheme of GloVe, we fix and compress the pretrained word vectors into the same dimension of the input hidden size in SlotRefine by a dense network. It is worth noting that through such simple pre-training method, SlotRefine can achieve a results very close to the method implemented by BERT. We guess that the benefits of the pre-training methods on this task mainly come from alleviating the Out-of-Vocabulary (OOV) problem. One piece of evidence is, for Snips whose test set has a large number of OOV words, benefits through pre-training are very obvious. However, for the ATIS whose test set has few OOV words, only a small sentence accuracy gain, 0.61 and 1.68 for GloVe and Bert respectivly, is obtained after using the pre-training method.

4 Conclusion

In this paper, we first reveal an *uncoordinated slots problem* for a classical language understanding task, i.e., slot filling. To address this problem, we present a novel non-autoregressive joint model for slot filling and intent detection with two-pass refine mechanism (non-autoregressive refiner), which significantly improves the performance while substantially speeding up the decoding. Further analyses show that our proposed non-autoregressive refiner has great potential to replace CRF in at least slot filling task.

In the future, we plan to extend our non-autoregressive refiner to other Natural Language Understanding (NLU) tasks, e.g., named entity recognition (Tjong Kim Sang and De Meulder, 2003), semantic role labeling (He et al., 2018), and Natural Language Generation (NLG) tasks, e.g., machine translation (Vaswani et al., 2017), summarization (Liu and Lapata, 2019).

Abstract

Decisions of complex models for language understanding can be explained by limiting the inputs they are provided to a relevant subsequence of the original text — a *rationale*. Models that condition predictions on a concise rationale, while being more interpretable, tend to be less accurate than models that are able to use the entire context. In this paper, we show that it is possible to better manage the trade-off between concise explanations and high task accuracy by optimizing a bound on the Information Bottleneck (IB) objective. Our approach jointly learns an explainer that predicts sparse binary masks over input sentences without explicit supervision, and an end-task predictor that considers only the residual sentences. Using IB, we derive a learning objective that allows direct control of mask sparsity levels through a tunable sparse prior. Experiments on the ERASER benchmark demonstrate significant gains over previous work for both task performance and agreement with human rationales. Furthermore, we find that in the semi-supervised setting, a modest amount of gold rationales (25% of training examples with gold masks) can close the performance gap with a model that uses the full input.[1]

1 Introduction

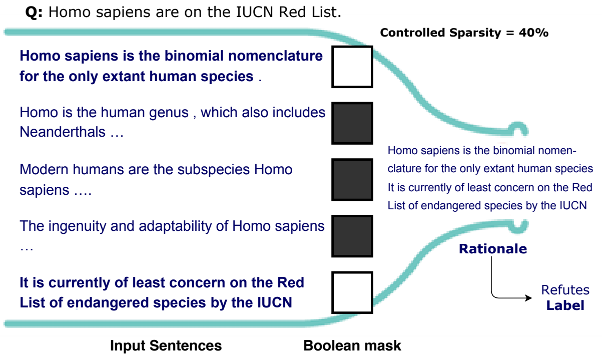

Figure 1: Our Information Bottleneck-based approach extracts concise rationales that are minimally informative about the original input, and maximally informative about the label through fine-grained control of sparsity in the bottleneck (0.4 in this fact verification example). End-task prediction is conditioned only on the bottlenecked input.

A rationale is a short yet sufficient part of the input text that can explain model decisions for a range of language understanding tasks (Lei et al., 2016). Models can be *faithful* to a rationale by only using the selected text as input for end-task prediction (DeYoung et al., 2019). However, there is almost always a trade-off between interpretable models that learn to extract *sparse* rationales and more *accurate* models that are able to use the full context but provide little explanation for their predictions (Lei et al., 2016; Weld and Bansal, 2019). In this paper, we show that it is possible to better manage this trade-off by optimizing a novel bound on the Information Bottleneck (Tishby et al., 1999) objective (Figure 1).

We follow recent work in representing rationales as binary masks over the input text (Lei et al., 2016; Bastings et al., 2019). During learning, it is common to encourage sparsity by minimizing a norm on the rationale masks (e.g. L_0 or L_1) (Lei et al., 2016; Bastings et al., 2019). It is often challenging to control the sparsity-accuracy trade-off in norm-minimization methods; we show that these methods seem to push too directly for sparsity at the expense of accuracy (Section 5.2). Our approach, in contrast, allows more control through a prior that specifies task-specific target sparsity levels that should be met in expectation across the training set.

More specifically, we formalize the problem of

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1938–1952,
November 16–20, 2020. ©2020 Association for Computational Linguistics

inducing controlled sparsity in the mask using the Information Bottleneck (IB) principle. Our approach seeks to extract a rationale as an optimal *compressed* intermediate representation (the bottleneck) that is both (1) minimally informative about the original input, and (2) maximally informative about the output class. We derive a novel variational bound on the IB objective for our case where we constrain the intermediate representation to be a concise subsequence of the input, thus ensuring its interpretablity.

Our model consists of an *explainer* that extracts a rationale from the input, and an *end-task predictor* that predicts the output based only on the extracted rationale. Our IB-based training objective guarantees sparsity by minimizing the Kullback–Leibler (KL) divergence between the explainer mask probability distribution and a prior distribution with controllable sparsity levels. This prior probability affords us tunable fine-grained control over sparsity, and allows us to bias the proportion of the input to be used as rationale. We show that, unlike norm-minimization methods, our KL-divergence objective is able to consistently extract rationales with the specified sparsity levels.

Across five tasks from the ERASER interpretability benchmark (DeYoung et al., 2019) and the BeerAdvocate dataset (McAuley et al., 2012), our IB-based sparse prior objective has significant gains over previous norm-minimization techniques — up to 5% relative improvement in task performance metrics and 6% to 80% relative improvement in agreement with human rationale annotations. Our interpretable model achieves task performance within 10% of a model of comparable size that uses the entire input. Furthermore, we find that in the semi-supervised setting, adding a small proportion of gold rationale annotations (approximately 25% of the training examples) bridges this gap — we are able to build an interpretable model without compromising performance.

2 Method

2.1 Task and Method Overview

We assume supervised text classification or regression data that contains tuples of the form (x, y). The input document x can be decomposed into a sequence of sentences $x = (x_1, x_2, \dots, x_n)$ and y is the category, answer choice, or target value to predict. Our goal is to learn a model that not only predicts y, but also extracts a rationale or explanation z—a latent *subsequence* of sentences in x with the following properties:

1. Model prediction y should rely entirely on z and not on its complement $x \backslash z$ —*faithfulness* (DeYoung et al., 2019).
2. z must be concise, i.e., it should contain as few sentences as possible without sacrificing the ability to correctly predict y.

Following Lei et al. (2016), our interpretable model learns a boolean mask $m = (m_1, m_2, \dots, m_n)$ over the sentences in x, where $m_j \in \{0, 1\}$ is a discrete binary variable. To enforce (1), the masked input $z = m \odot x = (m_1 \cdot x_1, m_2 \cdot x_2, \dots, m_n \cdot x_n)$ is used to predict y. Conciseness is attained using an information bottleneck.

2.2 Formalizing Interpretability Using Information Bottleneck

Background The Information Bottleneck (IB) method is used to learn an optimal compression model that transmits information from a random variable X to another random variable Y through a compressed representation Z. The IB objective is to minimize the following:

$$L_{IB} = I(X, Z) - \beta I(Z, Y), \tag{1}$$

where $I(\cdot, \cdot)$ is mutual information. This objective encourages Z to only retain as much information about X as is needed to predict Y. The hyperparameter β controls the trade-off between retaining information about either X or Y in Z. Alemi et al. (2016) derive the following variational bound on Equation 1:[2]

$$L_{VIB} = \underbrace{\mathbb{E}_{z \sim p_\theta(z|x)}[-\log q_\phi(y|z)]}_{\text{Task Loss}} + \underbrace{\beta KL[p_\theta(z|x), r(z)]}_{\text{Information Loss}}, \tag{2}$$

where $q_\phi(y|z)$ is a parametric approximation to the true likelihood $p(y|z)$; $r(z)$, the prior probability of z, approximates the marginal $p(z)$; and $p_\theta(z|x)$ is the parametric posterior distribution over z.

The information loss term in Equation 2 reduces $I(X, Z)$ by decreasing the KL divergence[3] be-

---

[2] For brevity and clarity, objectives are shown for a single data point. More details of this bound can be found in Appendix A.1 and Alemi et al. (2016).

[3] To analytically compute the KL-divergence term, the posterior and prior distributions over z are typically K-dimensional multivariate normal distributions. Compression is achieved by setting $K << D$, the input dimension of X.

tween the posterior distribution $p_\theta(z|x)$ that depends on x and a prior distribution $r(z)$ that is independent of x. The task loss encourages predicting the correct label y from z to increase $I(Z,Y)$.

Our Variational Bound for Interpretability The learned bottleneck representation z, found via Equation 2, is not human-interpretable as z is typically a compressed continuous vector representation of input x.[3] To ensure interpretability of z, we define the interpretable latent representation as $z := m \odot x$, where m is a boolean mask on the input sentences in x. We assume that the mask variables m_j over individual sentences are conditionally independent given the input x, i.e. the posterior $p_\theta(m|x) = \prod_j p_\theta(m_j|x)$, where $p_\theta(m_j|x) = \text{Bernoulli}(\theta_j(x))$ and j indexes sentences in the input text.[4] Because $z := m \odot x$, the posterior distribution over z is a mixture of dirac-delta distributions:

$$p_\theta(z_j|x) = (1 - \theta_j(x))\delta(z_j) + \theta_j(x)\delta(z_j - x_j),$$

where $\delta(x - c)$ is the dirac-delta probability distribution that is zero everywhere except at c.

For the prior, we assume a fixed Bernoulli distribution over mask variables. For instance, $r(m_j) = \text{Bernoulli}(\pi)$ for some constant $\pi \in (0, 1)$. This also induces a fixed distribution on z via the definition $z := m \odot x$. Instead of using an expressive $r(z)$ to approximate $p(z)$, we use a non-parametric prior $r(z)$ to force the marginal $p(z)$ of the learned distribution over z to approximately equal π. Our characterization of the prior and the posterior achieves compression of the input via *sparsity* in the latent representation, in contrast to compression via dimensionality reduction (Alemi et al., 2016).

For the intermediate representation $z := m \odot x$, we can decompose $\text{KL}(p_\theta(z_j|x), r(z_j))$ as:

$$\text{KL}(p_\theta(m_j|x), r(m_j)) + \pi H(x)$$

Since the entropy of the input, $\pi H(x)$, is a constant with respect to θ, it can be dropped. Hence, we obtain the following variational bound on IB with interpretability constraints over z, derived in more detail in Appendix A.2:

$$L_{IVIB} = \mathbf{E}_{m \sim p_\theta(m|x)}[-\log q_\phi(y|m \odot x)] + \beta \sum_j KL[p_\theta(m_j|x)||r(m_j)] \quad (3)$$

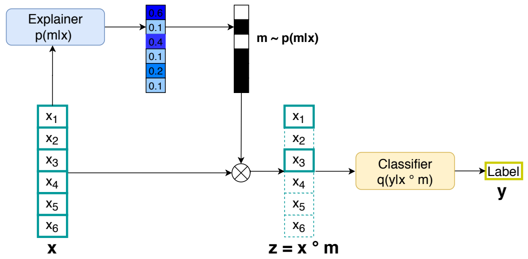

Figure 2: Architecture: The explainer extracts a rationale from the input using a binary mask, and an end-task predictor predicts the output based only on the extracted rationale.

The first term is the expected cross-entropy term for the task which can be computed by drawing samples $m \sim p_\theta(m|x)$. The second information-loss term encourages the mask m to be independent of x by reducing the KL divergence of its posterior $p_\theta(m|x)$ from a prior $r(m)$ that is independent of x. However, this does not necessarily remove information about x in $z = x \odot m$. For instance, a mask consisting of all ones is independent of x, but in this case $z = x$ and the rationale is no longer concise. In the following section, we present a simple way to avoid this degenerate case in practice by appropriately fixing the value of π.

2.3 The Sparse Prior Objective

The key to ensuring that $z = m \odot x$ is strictly a subsequence of x lies in the fact that $r(m_j) = \pi$ is our prior belief about the probability of a sentence being important for prediction. For instance, if humans annotate 10% of the input text as a rationale, we can fix our prior belief that a sentence should be a part of the mask as $r(m_j) = \pi = 0.1\ \forall j$. IB allows us to *control* the amount of sparsity in the mask that is eventually sampled from the learned distribution $p_\theta(m|x)$ in several ways. π can be estimated as the expected sparsity of the mask from expert rationale annotations. If such a statistic is not available, it can be explicitly tuned for the desired trade-off between end task performance and rationale length. In this work, we assume $\pi \in (0, 0.5)$ so that the sampled mask is sparse. We refer to this training objective with tunable $r(m) = \pi$ as the sparse prior (Sparse IB) method in our experiments. In Appendix C, we also discuss explicitly learning the value of π.

3 Model

To optimize for objective 3, the posterior distribution estimator $p_\theta()$ and label likelihood estimator

---

[4] We use Bernoulli distribution for m_j in this work, but any binary distribution for which KL divergence can be analytically computed can be used.

$q_\phi()$ are instantiated as the *explainer* and *end-task predictor* neural models respectively. Two different pre-trained transformers (Devlin et al., 2019) are used to initialize both models.

3.1 Architecture

Explainer $p_\theta(z|x)$: Given an input $x = x_1, x_2, \ldots, x_n$ consisting of n sentences, the explainer produces a binary mask $m \in \{0,1\}^n$ over the input sentences which is used to derive a rationale $z = m \odot x$. It maps every sentence x_j to its probability, $p_\theta(m_j|x)$ of being selected as part of z where $p(\cdot)$ is a binary distribution. The explainer contextualizes the input sequence x at the token level, and produces sentence representations $\mathbf{x} = (\mathbf{x_1}, \mathbf{x_2}, \ldots, \mathbf{x_n})$ where $\mathbf{x_j}$ is obtained by concatenating the contextualized representations of the first and last tokens in sentence x_j. A linear layer is used to transform these representations into logits (log probabilities) of a Bernoulli distribution. We choose the Bernoulli distribution since its sample can be reparameterized as described in Section 3.2, and we can analytically compute the KL-divergence term between two Bernoulli distributions. In Appendix C, we also experiment with the Kumaraswamy distribution (Fletcher and Ponnambalam, 1996) used in (Bastings et al., 2019). The mask $m \in \{0,1\}^n$ is constructed by independently sampling each m_j from $p(m_j|x)$.

End-task Predictor $q_\phi(y|z)$: We define z as the rationale representation $z = m \odot \mathbf{x}$, an element-wise dot product between m_j and the corresponding sentence representation $\mathbf{x_j}$. The end-task predictor uses z to predict the output variable y. The same hard attention mask m is applied to all end-task transformer layers at every head to ensure prediction relies only on $m \odot x$. The predictor further consists of a log-linear classifier layer over the `[CLS]` token, similar to Devlin et al. (2019). When an optional query sequence is available for datasets like BoolQ, we do not mask it as it is assumed to be essential to predict y (see Appendix B.2 for implementation details).

3.2 Training and Inference

The sampling operation of the discrete binary variable $m_j \in \{0,1\}$ in Section 3.1 is not differentiable. Lei et al. (2016) use a simple Bernoulli distribution with REINFORCE (Williams, 1992) to overcome non-differentiability. We found REINFORCE to be quite unstable with high variance in results. Instead, we employ reparameterization (Kingma et al., 2015) to facilitate end-to-end differentiability of our approach. We use the Gumbel-Softmax reparameterization (Jang et al., 2017) for categorical (here, binary) distributions to reparameterize the Bernoulli variables m_j. The reparameterized binary variable m_j^* is generated as follows:

$$m_j^* = \sigma\left(\frac{\log p(m_j|x) + g_j}{\tau}\right),$$

where σ is the Sigmoid function, τ is a hyperparameter for the temperature of the Gumbel-Softmax function, and g_j is a random sample from the Gumbel(0,1) distribution (Gumbel, 1948). $m_j^* \in (0,1)$ is a continuous and differentiable approximation to m_j with low variance.

During inference, we extract the top π% sentences with largest $p_\theta(m_j|x)$ values, where π corresponds to the threshold hyperparameter described in Section 2.3. Previous work (Lei et al., 2016; Bastings et al., 2019) samples from $p(m|x)$ during inference. Such an inference strategy is non-deterministic, making comparison of different masking strategies difficult. Moreover, it is possible to appropriately scale $p(m_j|x)$ values to obtain better inference results, thereby not reflecting if $p(m_j|x)$ $\forall j$ are correctly ordered. By allowing a fixed budget of π% per example, we are able to fairly compare approaches in Section 4.3.

3.3 Semi-Supervised Setting

As we will show in Section 5, despite better control over the sparsity-accuracy trade-off, there is still a gap in task performance between our unsupervised approach and a model that uses full context. To bridge this gap and better manage the trade-off at minimal annotation cost, we experiment with a semi-supervised setting where we have annotated rationales for part of the training data.

For input example $x = (x_1, x_2, \ldots, x_n)$ and a gold mask $\hat{m} = (\hat{m}_1, \hat{m}_2, \ldots, \hat{m}_n)$ over sentences, we use the following semi-supervised objective:

$$L_{semi} = \mathbf{E}_{m \sim p_\theta(m|x)}[-\log q(y|m \odot x)] + \gamma \sum_j -\hat{m}_j \log p(m_j|x) \quad (4)$$

While we still sample from $p(m|x)$ and train end-to-end using reparameterization, the information loss over $p(m|x)$ is replaced with the supervised rationale loss.

4 Experimental Setup

4.1 End Tasks

We evaluate our Sparse IB approach on five text classification tasks from the ERASER benchmark (DeYoung et al., 2019) and the BeerAdvocate regression task (McAuley et al., 2012) used in Lei et al. (2016).

ERASER: The ERASER tasks we evaluate on include the Movies sentiment analysis task (Pang and Lee, 2004), the FEVER fact extraction and verification task (Thorne et al., 2018), the MultiRC (Khashabi et al., 2018) and BoolQ (Clark et al., 2019) reading comprehension tasks, and the Evidence Inference classification task (Lehman et al., 2019) over scientific articles for results of medical interventions.

BeerAdvocate (McAuley et al., 2012): The BeerAdvocate regression task for predicting 0-5 star ratings for multiple aspects like appearance, smell, and taste based on reviews.

All these datasets have *sentence-level* rationale annotations for validation and test sets. We do not consider e-SNLI (Camburu et al., 2018) and CoS-E (Rajani et al., 2019) in ERASER as they have only 1-2 input sentences, rationales annotations at word level, and often require common sense/world knowledge. The ERASER tasks contain rationale annotations for the training set, which we only use for our semi-supervised experiments. We closely follow dataset processing in the ERASER benchmark setup and Bastings et al. (2019) (for BeerAdvocate). Additionally, for BoolQ and Evidence Inference which contain longer documents, we use a sliding window to select a single document *span* that has the maximum TF-IDF score against the question (further details in Appendix B.1).

4.2 Setup

Evaluation Metrics We adopt the metrics proposed for the ERASER benchmark to evaluate both agreement with comprehensive human rationales as well as end task performance. To evaluate quality of rationales, we report the token-level Intersection-Over-Union F1 (IOU F1), which is a relaxed measure for comparing two sets of text spans. We also report token-level F1 scores. For task accuracy, we report weighted F1 for classification tasks, and the mean square error for the BeerAdvocate regression task.

Implementation Details We use BERT-base with a maximum context-length of 512 to instantiate the combined explainer and end-task predictor. Models are tuned on the development set using the rationale IOU F1. Appendix B.3 contains details about hyperparameters.

4.3 Baselines

We first consider two bounding scenarios where no rationales are predicted. In the **Full Context (Full)** setting, the entire context is used to make predictions; this allows us to estimate the loss in performance as a result of interpretable hard attention models that only use $\pi\%$ of the input. In the **Gold Rationale (Gold)** setting, we train a model to only use human rationale annotations during *training and inference* to estimate an upper-bound on task and rationale performance metrics. We compare our Sparse IB approach with the following baselines. For fair comparison, all baselines are modified to use BERT-based representations.

Norm Minimization (Sparse Norm) Existing approaches (Lei et al., 2016; Bastings et al., 2019) learn sparse masks over the inputs by minimizing the L_0 norm of the mask m as follows:

$$L_{SL0} = \mathbf{E}_{m\sim p(m|x)}[-\log q(y|z)] + \lambda||m|| \quad (5)$$

Here, λ is the weight on the norm.

Controlled Norm Minimization (Sparse Norm-C) For fair comparison against our approach for controlled sparsity, we modify Equation 5 to ensure that the norm of m is not penalized when it drops below the threshold π.

$$\begin{aligned} L_{SL0-C} = \mathbf{E}_{m\sim p(m|x)}[-\log q(y|z)]+ \\ \lambda \max(0, ||m|| - \pi) \quad (6) \end{aligned}$$

This modification has also been adopted in recent. work (Jain et al., 2020). Explicit control over sparsity in the mask m through the tunable prior probability π naturally emerges from IB theory, as opposed to the modification adopted in norm-based regularization (Equation 6).

No Sparsity This method only optimizes for the end-task performance without any sparsity-inducing loss term, to evaluate the effect of sparsity inducing objectives in Sparse IB, Sparse Norm, and Sparse Norm-C.

Table 1: Task, Rationale IOU F1 (threshold set to 0.1) and Token F1 for our hard-attention Sparse IB approach and baselines on test sets, averaged over 5 random seeds. We report MSE for BeerAdvocate, hence lower is better. Gold IOU and token F1 are 100.0. We use 25% training data in our semi-supervised setting (Section 3.3). Validation set results can be found in Table 6 in the Appendix. $^{\epsilon}$ We could not reproduce numbers for the Bert-to-Bert supervised method reported in DeYoung et al. (2019). † No rationale supervision available for BeerAdvocate.

Supervised Approach (Pipeline) Lehman et al. (2019) learn an explainer and a task predictor independently in sequence using supervision for rationales and task labels, using the output of the explainer in the predictor during inference. We compare our semi-supervised model (Section 3.3) with this *pipeline* approach.

5 Results

5.1 Quantitative Evaluation

Table 1 compares our Sparse IB approach against baselines (Section 4.3). Sparse IB outperforms norm-minimization approaches (rows 4-6) in both agreement with human rationales and task performance across all tasks. We perform particularly well on rationale extraction with 5 to 80% relative improvements over the better performing norm-minimization variant Sparse Norm-C. Sparse IB also attains task performance within 0.5 to 10% of the full-context model (row 1), despite using $< 50\%$ of the input sentences. All unsupervised approaches still obtain a lower IOU F1 compared to the full context model for Movies and MultiRC, primarily due to their considerably lower precision on these benchmarks.

Our results also highlight the importance of explicit *controlled sparsity* inducing terms as effective inductive biases for improved task performance and rationale agreement. Specifically, sparsity-inducing methods consistently outperform the No Sparsity-baseline (row 3). One way to interpret this result is that sparsity objectives add input-dimension regularization during training, which results in better generalization during inference. Moreover, Sparse Norm-C, which adds the element of *control* to norm-minimization, performs considerably better than Sparse Norm. Finally, we see a positive correlation between task performance and

agreement with human rationales. This is important since accurate models that also better emulate human rationalization likely engender more trust.

Semi-supervised Setting In order to close the performance gap with the full-context model, we also experiment with a setup where we minimize the task and the rationale prediction loss using rationale annotations available for a part of the training data (Section 3.3). Figure 4 (left, center) shows the effect of incorporating an increasing proportion of rationale annotation supervision for the FEVER and MultiRC datasets. Our semi-supervised model is even able to match the performance of the full-context models for both FEVER and MultiRC with only 25% of rationale annotation supervision. Furthermore, Figure 4 also shows that these gains can be achieved with relatively modest annotation costs since adding more rationale supervision to the training data seems to have diminishing returns.

Table 1 compares our interpretable model (row 9), which uses rationale supervision for 25% of the training data, with the full-context model and the Pipeline approach (row 8). On three (FEVER, MultiRC, and BoolQ) out of five datasets for which rationale supervision is available, our interpretable models match the task performance of the full-context models while recording large gains in IOU (17-30 F1 absolute). Our approach outperforms the pipeline-based approach in task performance (for FEVER, MultiRC, Movies, and BoolQ) and IOU (for MultiRC and Movies). These gains may result from better exploration due to sampling and inference based on a fixed budget of π% sentences. Our weakest results are on Evidence Inference where the TF-IDF preprocessing often fails to select relevant rationale spans and the pipeline approach uses SciBERT (Beltagy et al., 2019).[5] Our overall results suggest that a small proportion of direct supervision can help build interpretable models without compromising task performance.

Dataset	π	Sparse Norm-C		Sparse IB	
		Mean	Var	Mean	Var
FEVER	0.20	0.17	0.94	0.21	1.24
MultiRC	0.25	0.11	1.14	0.26	1.67
Movies	0.40	0.38	2.90	0.42	3.02
BoolQ	0.20	0.04	0.84	0.22	1.91
Evidence	0.20	0.10	1.17	0.20	1.61

Table 2: Average mask length (sparsity) attained by Sparse IB and the Sparse Norm-C baseline for a given prior π for different tasks, averaged over 100 runs. Mean is reported as the average proportion of sentences to compare with expected sparsity (π) and variance is reported in the number of sentences.

5.2 Analysis

Examples from Error Analysis
Prediction:Positive Ground Truth:Negative The original Babe gets my vote as the best family film since the princess bride, and it's sequel has been getting rave reviews from most internet critics, both Siskel and Ebert sighting it more than a month ago as one of the year's finest films. So, naturally, when I entered the screening room that was to be showing the movie and there was nary another viewer to be found, this notion left me puzzled. It is a rare thing for a children's movie to be praised this highly . . . Looking back, I should have taken the hint and left right when I entered the theater. Believe me; I wanted to like Babe: Pig in the City. The plot seemed interesting enough; . . . It is here that we meet an array of eccentric characters, the most memorable being the family of chimps led by Steven Wright. Here is where the film took a wrong turn . . . unfortunately, the story wears thin as we are introduced to a new set of animals that . . . the main topic of discussion . . . it just didn't feel right and was more painful to watch than it was funny or entertaining, and the same goes for the rest of the movie.
Statement : Unforced labor is a reason for human trafficking. Prediction: SUPPORTS Ground Truth: REFUTES DOC: Human trafficking is the trade of humans, most commonly for the purpose of *forced* labour, sexual slavery, or comm--ercial sexual exploitation for the trafficker or others. This may encompass providing a spouse in the context of forced marriage, or the extraction of organs or tissues, including for surrogacy and ova removal. Human trafficking can occur within a country or transnationally. coercion and because of their commercial exploitation . . . In 2012, the I.L.O. estimated that 21 million victims are trapped in modern-day slavery . . .
Statement: Atlanta metropolitan area is located in south Georgia. Prediction: SUPPORTS Ground Truth:REFUTES DOC: Metro Atlanta , designated by the United States Office of Management and Budget as the Atlanta-Sandy Springs-Roswell, GA Metropolitan Statistical Area, is the most populous metro area in the US state of Georgia and the ninth-largest metropolitan statistical area (MSA) in the United States. Its economic, cultural and demographic center is Atlanta, and it had a 2015 estimated population of 5.7 million people according to the U.S. Census Bureau. The metro area forms the core of a broader trading area, the Atlanta – Athens-Clarke – Sandy Springs Combined Statistical Area. The Combined Statistical Area spans up to 39 counties in north Georgia and had an estimated 2015 population of 6.3 million people. Atlanta is considered an " alpha world city ". It is the third largest metropolitan region in the Census Bureau's Southeast region behind Greater Washington and South Florida.

Table 3: Misclassified examples from the Movies and FEVER datasets show: (a) limitations in considering more complex linguistic phenomena like sarcasm; (b) overreliance on shallow lexical matching—*un*forced vs. forced; (c) limited world knowledge—south Georgia, Southeast region, South Florida. *Legend*: Model evidence, Gold evidence, Model and Gold Evidence

sity achieved by the explainer during inference by computing the average number of *one* entries in the input mask m over sentences (the hamming weight) for 100 runs. Sparse IB consistently achieves the sparsity level π used in the prior while the norm-minimization approach (Sparse Norm-C) converges to a lower average sparsity for the mask.

Sparsity-Accuracy Trade-off Figure 4 (right) shows the variation in task and rationale agreement performance as a function of the sparsity rate π for Sparse IB and Sparse Norm-C on the FEVER dataset. Both methods extract longer rationales with increasing π that results in a decrease in agreement with sparse human rationales, while accuracy improves. However, Sparse IB consistently outperforms Sparse Norm-C in task performance.

In summary, our analysis indicates that unlike norm-minimization methods, our IB objective is able to consistently extract rationales with the specified sparsity rates, and achieves a better trade-off with accuracy. We hypothesize that optimizing the KL-divergence of the posterior $p(m|x)$ may be able to model input salience better than an implicit regularization (through $||m||_0$). The sparse prior term can learn $p(m|x)$ adaptive to different examples, while $||m||$ encourages uniform sparsity across examples.[6] This can be seen explicitly in Table 2, where the variance in sampled mask across examples is higher for our objective.

Model Agnostic Behavior Our approach is agnostic to choice of model architecture and word vs. sentence level rationales. We experimented with the word-level model in (DeYoung et al., 2019), where masks are learned over words instead of sentences. More details of the model architecture can be found in (DeYoung et al., 2019). The results for which are shown in Table 4

cates that such methods struggle when the context offers spurious—or in some cases even genuine but limited—evidence for both output labels (Figure 3). For instance, the model makes an incorrect positive prediction for the first example from the Movies sentiment dataset based on sentences that praise the *prequel* of the movie or acknowledge some critical acclaim. We also observed incorrect predictions based on shallow lexical matching (likely equating *forced* and *unforced* in the second example) and world knowledge (likely equating south *Georgia*, southeastern *United States*, and South *Florida* in the third). Overall, there is scope for improvement through better incorporation of exact lexical match, coreference propagation, and representation of pragmatics in our sentence representations.

6 Related Work

Extractive Rationalization Methods that condition predictions on their explanations are more trustworthy than post-hoc explanation techniques (Ribeiro et al., 2016; Krause et al., 2017; Alvarez-Melis and Jaakkola, 2017) and analyses of self-attention (Serrano and Smith, 2019; Jain et al., 2020). Extractive rationalization (Lei et al., 2016) is one of the most well-studied of such methods and has received increased attention with the recently released ERASER benchmark (DeYoung et al., 2019). Chang et al. (2019) and Yu et al. (2019); Chang et al. (2019) have complementary work on class-wise explanation extraction. Bastings et al. (2019) employ a reparameterizable version of the bi-modal beta distribution (instead of Bernoulli) for the binary mask. While our method has focused on unsupervised settings due to the considerable cost of obtaining reliable rationale annotations, recent work (Lehman et al., 2019) has also attempted to use direct supervision from rationale annotations for critical medical domain tasks. Finally, Latcinnik and Berant (2020) and Rajani et al. (2019) focus on generating explanations (rather than extracting them from the input). The extractive paradigm can be unfavourable for certain ERASER tasks like commonsense question answering, where the given input provides limited context for the task.

Information Bottleneck Information Bottleneck (IB) (Tishby et al., 1999) has recently been adapted in a number of downstream applications like parsing (Li and Eisner, 2019), extractive summarization (West et al., 2019), and image classification (Alemi et al., 2016; Zhmoginov et al., 2019). Alemi et al. (2016) and Li and Eisner (2019) use IB for optimal compression of hidden representations of images and words respectively. We are interested in compressing the number of cognitive units (like sentences) to ensure interpretability of the bottleneck representation, similar to West et al. (2019). However, while West et al. (2019) use brute-force search to optimize IB for summarization, we directly optimize a parametric variational bound on IB for rationales. IB has also been previously used for interpretability—Zhmoginov et al. (2019) use a VAE to estimate the prior distribution over z for image classification. Bang et al. (2019) use IB for post-hoc explanation of sentiment classification. They do not enforce a sparse prior, and as a result, cannot guarantee that the rationale is strictly smaller than the input. Controlling sparsity to manage the accuracy-conciseness trade-off is also not possible in their model.

7 Conclusion

We introduce a novel sparsity-inducing objective derived from the Information Bottleneck principle to extract rationales of desired conciseness. Our approach outperforms existing norm-minimization techniques in task performance and agreement with human rationales for tasks in the ERASER benchmark. Our objective obtains a better trade off of accuracy vs. sparsity. We are also able to close the gap with models that use the full input with $< 25\%$ rationale annotations for a majority of the tasks. In future work, we would like to apply our approach on document-level and multi-document NLU tasks.

A Information Bottleneck Theory

We first present an overview of the variational bound on IB introduced by (Alemi et al., 2016) and then derive a modified version amenable to interpretability.

A.1 Variational Information Bottleneck (Alemi et al. (2016))

The objective is to parameterize the information bottleneck objective $L_{IB} = I(X,Z) - \beta I(Z,Y)$ using neural models and use SGD to optimize. Consider the joint distribution: $p(X,Y,Z) = p(Z|X,Y)p(Y|X)p(X) = p(Z|X)p(Y|X)p(X)$ under the Markov chain $Y \leftrightarrow X \leftrightarrow Z$. As mutual information is hard to compute, the following bounds are derived on both MI terms:

First Term:

$$I(Z,X) := \mathbb{E}_x \left[\mathop{\mathbb{E}}_{z \sim p_\theta(z|x)} \left[\log \frac{p_\theta(z|x)}{p(z)} \right] \right]$$

where,

$$p(z) := \int dx p_\theta(z|x)p(x)$$

This marginal is intractable. Let $r(z)$ be a variational approximation to this marginal. Since $\mathrm{KL}[p(z), r(z)] \geq 0$,

$$I(Z,X) \leq \mathbb{E}_x \left[\mathop{\mathbb{E}}_{z \sim p_\theta(z|x)} \left[\log \frac{p_\theta(z|x)}{r(z)} \right] \right]$$

If $p_\theta(z|x)$ and $r(z)$ are of a form that KL divergence can be analytically computed, we get:

$$I(Z,X) \leq \mathbb{E}_x \left[\mathrm{KL}[p_\theta(z|x), r(z)\right]$$

Typically, the distributions $p_\theta(z|x)$ and $r(z)$ are instantiated as multivariate Normal distributions to analytically compute the KL-divergence term.

$$r(z) = \mathcal{N}(z|0,I), \;\; p(z|x) = \mathcal{N}(z|\mu(x), \Sigma(x));$$

where μ is a neural network which outputs the K-dimensional mean of z and Σ outputs the $K \times K$ covariance matrix Σ. This also allows us to reparameterize samples drawn from $p_\theta(z|x)$.

Second Term:

$$I(Z,Y) := \mathop{\mathbb{E}}_{y,z \sim p_\theta} \left[\log \frac{p(y|z)}{p(y)} \right]$$

where,

$$p(y|z) := \int dx \frac{p(y|x)p(z|x)p(x)}{p(z)}$$

Again, as this is intractable, $q_\phi(y|z)$ is used as a variational approximation to $p(y|z)$ and is instantiated as a transformer model with its own set of parameters ϕ. As Kullback Leibler divergence is always positive:

$$\mathrm{KL}[p(y|z), q_\phi(y|z)] \geq 0 \rightarrow$$

$$I(Z,Y) \geq \mathop{\mathbb{E}}_{y,z \sim p_\theta} \left[\log \frac{q_\phi(y|z)}{p(y)} \right]$$

The term $p(y)$ can be dropped as it is constant with respect to parameters ϕ. Thus, we minimize $\mathbb{E}_{y,z \sim p_\theta}[-\log q_\phi(y|z)]$ Thus the IB objective is bounded by the loss function:

$$L_{vib} \geq \mathbb{E}_{y,z \sim p_\theta}[-\log q_\phi(y|z)] + \beta \mathrm{KL}[p_\theta(z|x), r(z)]$$

A.2 Deriving the Sparse Prior Objective

The latent space learned in Appendix A.1 is not easy to interpret. Instead we consider a masked representation of the form $z = m \odot x$, where $m_j \in \{0,1\}$ is a binary mask sampled from a distribution $p_\theta(m_j|x) = \mathrm{Bernoulli}(\theta_j(x))$. This is an adaptive masking strategy, defined by data-driven relevance estimators $\theta_j(x)$. The distributions over x and m induce a distribution on $z = m \odot x$ defined by the conditionals

$$p_\theta(z_j|x) = (1 - \theta_j(x))\delta(z_j) + \theta_j(x)\delta(z_j - x_j).$$

Our prior, based on human annotations, is that rationale needed for a prediction is sparse; we encode this prior as a distribution over masks $r(m_j) = \mathrm{Bernoulli}(\pi)$. The prior also induces a distribution on $z = m \odot x$ given by

$$r(z_j|x) = (1 - \pi)\delta(z_j) + \pi\delta(z_j - x_j).$$

We want to enforce a constraint $p_\theta(z_j) = r(z_j)$; i.e. that the marginal distribution $p_\theta(z_j) = \int p_\theta(z_j|x)p(x)\,dx$ matches our prior $r(z_j)$. This is difficult to do directly, but as in Appendix A.1, we can construct an upper bound the mutual information between x and z:

$$I(Z,X) \leq \mathop{\mathbb{E}}_{x \sim p} \left[\mathrm{KL}[p_\theta(z|x), r(z)]\right].$$

The inequality is tight if $r(z) = p_\theta(z)$. By optimizing to minimize mutual information $I(Z,X)$, we

Table 6: Final results of our unsupervised models on ERASER Dev Set

will implicitly learn parameters θ that approximate the desired constraint on the marginal.

In contrast to Alemi et al. (2016), our prior $r(z)$ has no parameters; rather than using an expressive model $r(z)$ to approximate the $p_\theta(z)$, we instead use the fixed prior $r(z)$ to force the learned conditionals $p_\theta(z|x)$ to assume a form such that the marginal $p_\theta(z)$ approximately matches the marginal of the prior, π. Average mask sparsity values in Table 2 corroborate this.

By a limiting argument, we can compute the divergence between $p_\theta(z|x)$ and $r(z)$:

$$\begin{aligned}
&\mathrm{KL}(p_\theta(z_j|x), r(z_j))\\
&= (1-\theta_j(x)) \int \delta(z_j) \log \frac{p_\theta(z_j|x)}{r(z_j)}\, dz_j\\
&+ \theta_j(x) \int \delta(z_j - x_j) \log \frac{p_\theta(z_j|x)}{r(z_j)}\, dz_j\\
&= (1-\theta_j(x)) \log \frac{1-\theta_j(x)}{1-\pi} + \theta_j(x) \log \frac{\theta_j(x)}{\pi p(x)}\\
&= \mathrm{KL}(p_\theta(m_j|x), r(m_j)) - \theta_j(x) \log p(x).
\end{aligned}$$

The term $\mathrm{KL}[p_\theta(m_j|x), r(m_j)]$ is a divergence between two Bernoulli distributions and has a simple closed form. If $\theta_j(x)$ and $\log p(x)$ are uncorrelated then

$$\mathop{\mathbb{E}}_{x\sim q}[-\theta_j(x) \log p(x)] = \pi H(X).$$

The term $\pi H(X)$ is constant with respect to the parameters θ and can be dropped.

We use the same, standard cross-entropy bound discussed in Appendix A.1 to estimate $I(Z,Y)$, leading us to our variational bound on IB with interpretability constraints

$$\begin{aligned}
L_{IVIB} &= \mathbf{E}_{m\sim p(m|x)}[-\log q(y|m \odot x)]\\
&+ \beta \sum_j KL[p_\theta(m_j|x)||r(m_j)].
\end{aligned}$$

B Experimental Details

B.1 Data Processing

The train, test and validation splits are the same as used in the ERASER benchmark (DeYoung et al., 2019) and for the Beer Advocate dataset (Bastings et al., 2019). In order to batch operations, we process the data so that each example has at most NS sentences. NS is fixed based on the average number of sentences in the development set of the respective task (see Table 5). Some dataset specific processing details are highlighted below:

FEVER: ERASER adapts the original fact verification task as a binary classification of whether the given evidence supports or refutes a given claim.

MultiRC: The reading comprehension task with multiple correct answers is modified into a binary classification task for ERASER, where each (rationale, question, answer) triplet has a true/false label.

BoolQ: A Boolean (yes/no) question answering dataset over Wikipedia articles. Since most documents are considerably longer than BERT's maximum context window length of 512 tokens (3.3K tokens on average), we use a sliding window to select a single document *span* that has the maximum TF-IDF score against the question.

Evidence Inference: A three-way classification task over full-text scientific articles for inferring whether a given medical intervention is reported to either *significantly increase*, *significantly decrease*, or have *no significant effect* on a specified outcome compared to a comparator of interest. We again apply the TF-IDF heuristic as the average number of tokens is a document is 4.6K.

BEER: The Beer Advocate regression task for predicting 0-5 star ratings for multiple aspects like appearance, smell, and taste based on reviews. We report on the appearance aspect.

B.2 Modeling

For question answering tasks in ERASER. s and x are encoded together in the sequence $s\,\texttt{[SEP]}\,x$ while assuming that s is fully unmasked i.e. $p_\theta(m_s|x) = 1$. Once again, the sequence $s\,\texttt{[SEP]}\,m \odot x$ is used if query s is available, i.e., we assume no masking over s as it is assumed to be essential to predict y.

Semi-supervised: Whenever train loss is not available, only task loss is used. Evaluation is still done based on $\pi\%$ sentences, to fairly compare with unsupervised models.

B.3 Hyperparameters

We use a sequence length of 512, batch size of 16 [7] and Adam optimizer with a learning rate of 5e-5. We do not use warm-up or weight decay. We run all model for 20 epochs and set patience to 10 (over iterations). Hyper-parameter tuning is done on the validation set for the rationale performance metric (IOU F1[8]) on the development sets for ERASER tasks and on the test set for BEER (only test set contains rationale annotations). We tune the value of $\pi \in \{0.05, 0.1, 0.15, ...0.50\}$. We found that Sparse IB approach is not as sensitive to the parameter β and fix it to 1 to simplify experimental design. For baselines, we tune the values of the Lagrangian multipliers, $\lambda \in \{1e\text{-}4, 5e\text{-}4, 1e\text{-}3, \ldots, 1\}$ as norm-based techniques are more sensitive to λ. The value of the γ hyperparameter in the semi-supervised setup was set to 1.0 to simplify design. Instead of explicitely tuning or annealing the Gumbel softmax parameter, we fix it to 0.7 across all our experiments (including baselines). Hyperparameters for each dataset used for the final results are presented in Table 5.[9]

C Analysis

Learning the Value of π Instead of tuning the value of π, we can alternately learn an appropriate value by allowing π to be a learnable parameter in our implementation. In our experiments (see Table 7, we found that that the norm-minimization completely degenerates and learns a very high value of π, as the norm-loss in Equation 6 (Section 4.3) can still be minimized if both $||m||$ and π are driven close to 1.0. In our case, since pi is now a learnable parameter, we have to minimize the following objective.

$$L_{IVIB} = \mathbf{E}_{m \sim p_\theta(m|x)}[-\log q_\phi(y|m \odot x)] + \beta \sum_j KL[p_\theta(m_j|x)||r(m_j)] + \pi H(x) \quad (7)$$

The caveat here is that it requires another hyperparameter, namely the constant $H(x) = \lambda$ [10]. This is not unlike Sparse Normor Sparse Norm-Cwhere sparsity is controlled through the hyperparameter λ. In Table 7, we compare the Sparse IBobjective with Equation 7 for Movies and FEVER. We find that optimizing Equation 7 actually allows us to control the trade-off because of the presence of the term $\pi H(x)$ that enforces a smaller value for π. The learned value of π is close the tuned value in Table 5, thus we choose to report our main results across all models on tuned π.

A More Expressive Distribution Bastings et al. (2019) compare against the best-known previous work on norm regularization Lei et al. (2016) by exploring the bi-modal Kumaraswamy distribution (Fletcher and Ponnambalam, 1996) to replace the Bernoulli distribution. This more expressive distribution may be able to complement our approach, as KL-divergence for it can be analytically computed (Nalisnick and Smyth, 2017) (Appendix C).

---

[7] We used 2 GeForce GTX TITAN X GPUs and Cuda 10.1

[8] Calculated as per the definition in `https://github.com/jayded/eraserbenchmark/blob/master/rationale_benchmark/metrics.py` for threshold 0.1

[9] We observed some variation (<0.50 F1) in results across across GPUs, well within the difference observed between Sparse IB and baselines.

[10] We could alternately estimate this using a VAE, as done in Zhmoginov et al. (2019)

Approach	**Movies**			**Fever**

Kuma Sparse IB	**83.4**	**21.5**	**85.6**	**45.5**

Table 8: Results on the Kumaraswamy distribution from (Bastings et al., 2019) on Dev set

The KL divergence between the Kumaraswamy and Beta distribution can be analytically computed, as done in this work (Nalisnick and Smyth, 2017). In Table 8, we show results on Movies and FEVER datasets for this distribution, comparing Sparse IBagainst the Sparse Norm-Cbaseline. We find that the superior performance of the KL-divergence loss term persists.

CrowS-Pairs: A Challenge Dataset for Measuring Social Biases in Masked Language Models

Abstract

Warning: *This paper contains explicit statements of offensive stereotypes and may be upsetting.*

Pretrained language models, especially masked language models (MLMs) have seen success across many NLP tasks. However, there is ample evidence that they use the cultural biases that are undoubtedly present in the corpora they are trained on, implicitly creating harm with biased representations. To measure some forms of social bias in language models against protected demographic groups in the US, we introduce the Crowdsourced Stereotype Pairs benchmark (CrowS-Pairs). CrowS-Pairs has 1508 examples that cover stereotypes dealing with nine types of bias, like race, religion, and age. In CrowS-Pairs a model is presented with two sentences: one that is more stereotyping and another that is less stereotyping. The data focuses on stereotypes about historically disadvantaged groups and contrasts them with advantaged groups. We find that all three of the widely-used MLMs we evaluate substantially favor sentences that express stereotypes in every category in CrowS-Pairs. As work on building less biased models advances, this dataset can be used as a benchmark to evaluate progress.

1 Introduction

Progress in natural language processing research has recently been driven by the use of large pretrained language models (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020). However, these models are trained on minimally-filtered real-world text, and contain ample evidence of their authors' social biases. These language models, and embeddings extracted from them, have been shown to learn and use these biases (Bolukbasi et al., 2016; Caliskan et al., 2017; Garg et al., 2017; May et al., 2010; Zhao et al., 2018; Rudinger et al., 2017). Models that have learnt representations that are biased against historically disadvantaged groups can cause a great deal of harm when those biases surface in downstream tasks or applications, such as automatic summarization or web search (Bender, 2019). Identifying and quantifying the learnt biases enables us to measure progress as we build less biased, or debias, models that propagate less harm in their myriad downstream applications. Quantifying bias in the language models directly allows us to identify and address the problem at the source, rather than attempting to address it for every application of these pretrained models. This paper aims to produce a reliable quantitative benchmark that measures these models' acquisition of major categories of social biases.

We introduce Crowdsourced Stereotype Pairs (**CrowS-Pairs**), a challenge set for measuring the degree to which nine types of social bias are present in language models. CrowS-Pairs focuses on explicit expressions of stereotypes about historically disadvantaged groups in the United States. Language that stereotypes already disadvantaged groups propagates false beliefs about these groups and entrenches inequalities. We measure whether a model generally prefers more stereotypical sentences. Specifically, we test for learnt stereotypes about disadvantaged groups.

Unlike most bias evaluation datasets that are template-based, CrowS-Pairs is crowdsourced. This enables us to collect data with greater diversity in the stereotypes expressed and in the structure of the sentences themselves. This also means that the data only represents the kinds of bias that are widely acknowledged to be bias in the United States. CrowS-Pairs covers a broad-coverage set of nine bias types: race, gender/gender identity, sex-

Socioeconomic status/ Occupation	*People who live in* ***trailer parks*** *are alcoholics.* *People who live in* ***mansions*** *are alcoholics.*

Table 1: Examples from CrowS-Pairs for each bias category. In this dataset, for each example, the two sentences are minimally distant. We've highlighted the words that are different.

ual orientation, religion, age, nationality, disability, physical appearance, and socioeconomic status.

In CrowS-Pairs each example is comprised of a pair of sentences. One of the sentences is always more stereotypical than the other sentence. In an example, either the first sentence can demonstrate a *stereotype*, or the second sentence can demonstrate a violation of a stereotype (*anti-stereotype*). The sentence demonstrating or violating a stereotype is always about a historically disadvantaged group in the United States, and the paired sentence is about a contrasting advantaged group. The two sentences are minimally distant, the only words that change between them are those that identify the group being spoken about. Conditioned on the group being discussed, our metric compares the likelihood of the two sentences under the model's prior. We measure the degree to which the model prefers stereotyping sentences over less stereotyping sentences. We list some examples from the dataset in Table 1.

We evaluate masked language models (MLMs) that have been successful at pushing the state-of-the-art on a range of tasks (Wang et al., 2018, 2019). Our findings agree with prior work and show that these models do express social biases. We go further in showing that widely-used MLMs are often biased against a wide range historically disadvantaged groups. We also find that the degree to which MLMs are biased varies across the bias categories in CrowS-Pairs. For example, religion is one of the hardest categories for all models, and gender is comparatively easier.

Concurrent to this work, Nadeem et al. (2020) introduce StereoSet, a crowdsourced dataset for associative contexts aimed to measure 4 types of social bias—race, gender, religion, and profession—in language models, both at the intrasentence level, and at the intersentence discourse level. We compare CrowS-Pairs to StereoSet's intrasentence data. Stereoset's intrasentence examples comprise of minimally different pairs of sentences, where one sentence stereotypes a group, and the second sentence is less stereotyping of the same group. We gather crowdsourced validation annotations for samples from both datasets and find that our data has a substantially higher validation rate at 80%, compared to 62% for StereoSet. Between this result, and additional concerns about the viability of standard (masked) language modeling metrics on StereoSet (§3), we argue that CrowS-Pairs is a substantially more reliable benchmark for the measurement of stereotype use in language models, and clearly demonstrates the dangers of direct deployments of recent MLM models.

2 Data Collection

We collect and validate data using Amazon Mechanical Turk (MTurk). We collect only test data for model evaluation. While data like ours could in principle also be used at training time to help mitigate model biases, we are not aware of a straightforwardly effective way to conduct such a training procedure. We leave the collection of training data to future work.

Annotator Recruitment On MTurk we require that workers be in the United States and have a $> 98\%$ acceptance rate. We use the Fair Work tool (Whiting et al., 2019) to ensure a pay rate of at least $15/hour. To warn workers about the sensitive nature of the task, we tag all our HITs as containing potentially explicit or offensive content.

Bias Types We choose 9 categories of bias: race/color, gender/gender identity or expression, socioeconomic status/occupation, nationality, religion, age, sexual orientation, physical appearance, and disability. This list is a narrowed version of the US Equal Employment Opportunities Commission's list of protected categories.[1]

Writing Minimal Pairs In this task, our crowdworkers are asked to write two minimally distant sentences. They are instructed to write one sentence about a **disadvantaged** group that either expresses a clear stereotype or violates a stereotype (anti-stereotype) about the group. To write the second sentence, they are asked to copy the first sentence exactly and make minimal edits so that the target group is a contrasting **advantaged** group. Crowdworkers are then asked to label their written example as either being about a stereotype or an anti-stereotype. Lastly, they are asked to label the example with the best fitting bias category. If their example could satisfy multiple bias types, like the *angry black woman* stereotype (Collins, 2005; Madison, 2009; Gillespie, 2016), they are asked to tag the example with the single bias type they think fits best. Examples demonstrating intersectional examples are valuable, and writing such examples is not discouraged, but we find that allowing multiple tag choices dramatically lowers the reliability of the tags.

To mitigate the issue of repetitive writing, we also provide workers with an *inspiration prompt*, that crowdworkers may optionally use as a starting point in their writing, this is similar to the data collection procedure for WinoGrande (Sakaguchi et al., 2019). The prompts are either premise sentences taken from MultiNLI's fiction genre (Williams et al., 2018) or 2–3 sentence story openings taken from examples in ROCStories (Mostafazadeh et al., 2016). To encourage crowdworkers to write sentences about a diverse set of bias types, we reward a $1 bonus to workers for each set of 4 examples about 4 different bias types. In pilots we found this bonus to be essential to getting examples across all the bias categories.

Validating Data Next, we validate the collected data by crowdsourcing 5 annotations per example. We ask annotators to label whether each sentence in the pair expresses a stereotype, an anti-stereotype, or neither. We then ask them to tag the sentence pair as minimally distant or not, where a sentence is minimally distant if the only words that change are those that indicate which group is being spoken about. Lastly, we ask annotators to label the bias category. We consider an example to be valid if annotators agree that a stereotype or anti-stereotype is present and agree on which sentence is more stereotypical. An example can be valid if either, but not both, sentences are labeled *neither*. This flexibility in validation means we can fix examples where the order of sentences is swapped, but the example is still valid. In our data, we use the majority vote labels from this validation.

In addition to the 5 annotations, we also count the writer's implicit annotation that the example is valid and minimally distant. An example is accepted into the dataset if at least 3 out of 6 annotators agree that the example is valid and minimally distant. Chance agreement for all criteria to be met is 23%. Even if these validation checks are passed, but the annotators who approved the example don't agree on the bias type by majority vote, the example is filtered out.

Task interfaces are shown in Appendix B and C.

---

[1] `https://www.eeoc.gov/prohibited-employment-policiespractices`

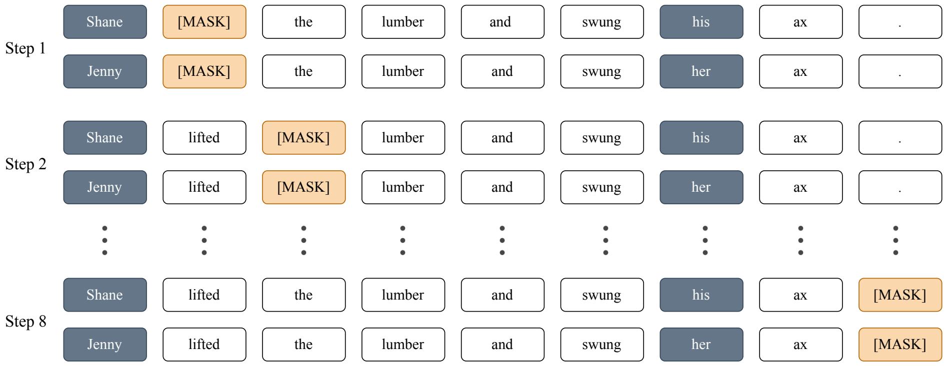

Figure 1: To calculate the conditional pseudo-log-likelihood of each sentence, we iterate over the sentence, masking a single token at a time, measuring its log likelihood, and accumulating the result in a sum (Salazar et al., 2020). We never mask the modified tokens: those that differ between the two sentences, shown in grey.

The Resulting Data We collect 2000 examples and remove 490 in the validation phase. Average inter-annotator agreement (6 annotators) on whether an example is valid is 80.9%. An additional 2 examples are removed where one sentence has full overlap with the other, which is likely to unnecessarily complicate future metrics work. The resulting Crowdsourced Stereotype Pairs dataset has 1508 examples.[2] The full data statement is in Appendix A (Bender and Friedman, 2018).

In Table 1 we provide examples from each bias category. Statistics about distribution across bias categories are shown in Table 2. With 516 examples, race/color makes up about a third of CrowS-Pairs, but each bias category is well-represented. Examples expressing anti-stereotypes, like the provided *sexual orientation* example, only comprise 15% of our data.

3 Measuring Bias in MLMs

We want a metric that reveals bias in MLMs while avoiding the confound of some words appearing more frequently than others in the pretraining data. Given a pair of sentences where most words overlap, we would like to estimate likelihoods of both sentences while conditioning on the words that differ. To measure this, we propose a metric that calculates the percentage of examples for which the LM prefers the more stereotyping sentence (or, equivalently, the less anti-stereotyping sentence). In our evaluation we focus on masked language models (MLMs). This is because the tokens to condition on can appear anywhere in the sentence, and can be discontinuous, so we need to accurately measure word likelihoods that condition on both sides of the word. While these likelihoods are well defined for LMs, we know of no tractable way to estimate these conditional likelihoods reliably and leave this to future work.

Our Metric In an example there are two parts of each sentence: the **unmodified** part, which comprises of the tokens that overlap between the two sentences in a pair, and the **modified** part, which are the non-overlapping tokens. For example, for a pair ***John*** *ran into* ***his*** *old football friend* vs. ***Shaniqua*** *ran into* ***her*** *old football friend*, the modified tokens are $\{$*John, his*$\}$ *for the first sentence and* $\{$*Shaniqua, her*$\}$ for the second sentence. The unmodified tokens for both sentences are $\{$*ran, into, old, football, friend*$\}$. Within an example, it is possible that the modified tokens in one sentence occur more frequently in the MLM's pretraining data. For example, *John* may be more frequent than *Shaniqua*. We want to control for this imbalance in frequency, and to do so we condition on the **modified** tokens when estimating the likelihoods of the **unmodified** tokens. We still run the risk of a modified token being very infrequent and having an uninformative representation, however MLMs like BERT use wordpiece models. Even if a modified word is very infrequent, perhaps due to an uncommon spelling like Laquisha, the model should still be able to build a reasonable representation of the word given its orthographic similarity to more common tokens, like the names Lakeisha, Keisha, and LaQuan, which gives it the demographic associations that are relevant when measuring stereotypes.

For a sentence S, let $U = \{u_0, \ldots, u_l\}$ be the unmodified tokens, and $M = \{m_0, \ldots, m_n\}$ be the

---

Table 2: Model performance on WinoBias-*knowledge* (type-1) and *syntax* (type-2), StereoSet, and CrowS-Pairs. Higher numbers indicate higher model bias. We also show results on CrowS-Pairs broken down by examples that demonstrate stereotypes (CrowS-Pairs-*stereo*) and examples that violate stereotypes (CrowS-Pairs-*antistereo*) about disadvantaged groups. The lowest bias score in each category is bolded, and the highest score is underlined.

modified tokens ($S = U \cup M$). We estimate the probability of the unmodified tokens conditioned on the modified tokens, $p(U|M, \theta)$. This is in contrast to the metric used by Nadeem et al. (2020) for Stereoset, where they compare $p(M|U, \theta)$ across sentences. When comparing $p(M|U, \theta)$, words like *John* could have higher probability simply because of frequency of occurrence in the training data and not because of a learnt social bias.

To approximate $p(U|M, \theta)$, we adapt *pseudo-log-likehood* MLM scoring (Wang and Cho, 2019; Salazar et al., 2020). For each sentence, we mask one unmodified token at a time until all u_i have been masked,

$$\text{score}(S) = \sum_{i=0}^{|C|} \log P(u_i \in U | U_{\setminus u_i}, M, \theta) \quad (1)$$

Figure 1 shows an illustration. Note that this metric is an approximation of the true conditional probability $p(U|M, \theta)$. We informally validate the metric and compare it against other formulations, like masking random 15% subsets of M for many iterations, or masking all tokens at once. We test to see if, according to a metric, pretrained models prefer semantically meaningful sentences over nonsensical ones. We find this metric to be the most reliable approximation amongst the formulations we tried.

Our metric measures the percentage of examples for which a model assigns a higher (psuedo-)likelihood to the stereotyping sentence, S_1, over the less stereotyping sentence, S_2. A model that does not incorporate American cultural stereotypes concerning the categories we study should achieve the ideal score of 50%.

4 Experiments

We evaluate three widely used MLMs: $\text{BERT}_{\text{Base}}$ (Devlin et al., 2019), $\text{RoBERTa}_{\text{Large}}$ (Liu et al., 2019), and $\text{ALBERT}_{\text{XXL-v2}}$ (Lan et al., 2020). These models have shown good performance on a range of NLP tasks with ALBERT generally outperforming RoBERTa by a small margin, and BERT being significantly behind both (Wang et al., 2018; Lai et al., 2017; Rajpurkar et al., 2018). For these models we use the Transformers library (Wolf et al., 2019). We evaluate on CrowS-Pairs and some related datasets for context.

Evaluation Data In addition to CrowS-Pairs, we test the models on WinoBias and StereoSet as baseline measurements so we can compare patterns in model performance across datasets. Winobias consists of templated sentences for occupation-gender stereotypes. For example,

(1) [The physician] hired [the secretary] because [she] was overwhlemed with clients.

WinoBias has two types of test sets: WinoBias-knowledge (type-1) where coreference decisions require world knowledge, and WinoBias-syntax (type-2) where answers can be

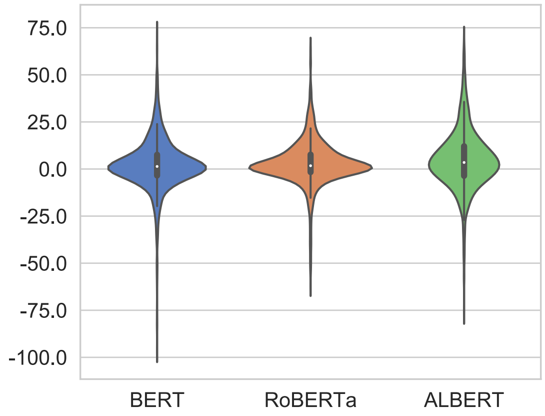

Figure 2: The distributions of model confidence for each MLM. The distributions above 0 are the confidence distribution when the models gives a higher score to S_1, and the below 0 are the distributions when the models give a higher score to S_2.

resolved using syntactic information alone. From StereoSet, we use the *intrasentence* validation set for evaluation (§6). These examples have pairs of stereotyping and anti-stereotyping sentences. For example,

(2) a. My mother is very [overbearing]
b. My mother is very [accomplished]

On all datasets, we report results using the metric discussed in Section 3.

4.1 Results

The results (Table 2) show that, on all four datasets, all three models exhibit substantial bias. BERT shows the lowest bias score on all datasets. BERT is the smallest model of the three, with the fewest training step. It is also the worst performing on most downstream tasks.

Additionally, while BERT and ALBERT are trained on Wikipedia and BooksCorpus (Zhu et al., 2015), RoBERTa is also trained on OpenWebText (Gokaslan and Cohen, 2019) which is composed of web content extracted from URLs shared on Reddit. This data likely has higher incidence of biased, stereotyping, and discriminatory text than Wikipedia. Exposure to such data is likely harmful for performance on CrowS-Pairs. Overall, these results agree with our intuition: as models learn more features of language, they also learn more features of society and bias. Given these results, we believe it is possible that debiasing these models will degrade MLM performance on naturally occurring text. The challenge for future work is to properly debias models without substantially harming downstream performance.

Model Confidence We investigate model confidence on the CrowS-Pairs data. To do so, we look at the ratio of sentence scores

$$\text{confidence} = 1 - \frac{\text{score}(S)}{\text{score}(S')} \qquad (2)$$

where S is the sentence to which the model gives a higher score and S' is the other sentence. A model that is unbiased (in this context) would achieve 50 on the bias metric and it would also have a very peaky confidence score distribution around 0.

In Figure 2 we've plotted the confidence scores. We see that ALBERT not only has the highest bias score on CrowS-Pairs, but it also has the widest distribution, meaning the model is most confident in giving higher likelihood to one sentence over the other. While RoBERTa's distribution is peakier than BERT's, the model tends to have higher confidence when picking S_1, the more stereotyping sentence, and lower confidence when picking S_2. We compare the difference in confidence score distributions for when a model gives a higher score to S_1 and when it gives a higher score to S_2. The difference in medians is 1.2 for BERT, 2.3 for RoBERTa, and 3.2 for ALBERT. This analysis reveals that the models that score worse on our primary metric also tend to become more confident in making biased decisions on CrowS-Pairs.

Bias Category For the nine types of bias categories in CrowS-Pairs, we investigate whether models demonstrate more or less bias on certain categories. From Table 2, we see that all three models present bias in each of the bias categories. We also observe that all models have comparatively higher bias scores in the religion category, and lower bias scores in the gender and race categories, suggesting that the gender and race bias categories in CrowS-Pairs are comparatively easier for models.

Stereotype vs Anti-stereotype In CrowS-Pairs, the first sentence we collect must reference a historically disadvantaged group, but it can either demonstrate *or violate* a stereotype about that group. Table 2 shows results on these stereotype and anti-stereotype subsets.

We observe that all three models demonstrate less bias on the anti-stereotype examples.

RoBERTa's bias score is nearly perfect on the anti-stereotype examples with a score of 51.4, but only achieves a score of 66.3 on the stereotype examples. Similarly, BERT and ALBERT perform 4.2 and 4.4 percentage points better on anti-stereotyping examples, compared to stereotyping examples. However, based on validation results, the datasets are of similar quality, ∼25% of both subsets were filtered out during validation. We compare model confidence on the two subsets and find that all models have lower confidence on the anti-stereotype subset.

5 Dataset Analysis

Qualitative Analysis Writing examples for Crowdsourced Stereotype Pairs is an unusual and difficult task. We do some qualitative analysis to study how these examples are constructed and, in particular, we check to see if there are any curiosities in the data that may effect data quality.

Many examples in CrowS-Pairs use first names for people to indicate which group they belong to. For example,

(3) Suddenly [Tyrone/Jack] jumped out of the shadows, stole his pole and ran away.

The name Jamal, which was used in an example sentence in the instructions for to crowdoworkers, appears 17 times in the dataset. Explicit group names like "African Americans" and "Mexicans" are also common.

We also find some examples where it's unclear if the type of bias expressed is one we want to remove from models. For example,

(4) [DeShawn/Hunter]'s horse reared as he clutched the reigns after looking at the KKK members

Historically the KKK was (and is) comprised of white Americans persecuting Black Americans. Someone with a typically African-American name likely has more reason to be immediately alarmed by KKK members. While this is perhaps consistent with a stereotype, it is less clear that it constitutes the kind of bias that we want to remove from our models. Our qualitative analysis suggests that these examples are infrequent.

There are also some examples in the dataset where the disagreement on the label for bias type should not be considered noise (Pavlick and Kwiatkowski, 2019). For example,

(5) [Chinese/American] people are known to eat a lot of gross things.

This example has 3 labels for race-color and 2 labels for nationality from the validation phase. The disagreement here signals that the example expresses inter-sectional bias.

We also find that CrowS-Pairs contains some examples where the sentences don't correctly isolate the stereotype through the difference between the sentences. For example,

(6) a. Women are not hunters
    b. Men are hunters.

This example is invalid since as unclear what we learn from knowing which sentence is more likely under the model's prior. There are 23 such examples in the dataset.

Data Quality and StereoSet While the population of crowdworkers (362 people for CrowS-Pairs) who wrote and validated the CrowS-Pairs and StereoSet examples reached judgements approving these examples, we choose to conduct a second, independent validation to better gauge the quality of both datasets. The tasks of writing sentences that express known social stereotypes, and validating these examples for stereotypes, is an inherently difficult and subjective task. This validation allows us to indirectly compare the effect of the design decisions made in creating HITs to collect stereotyping data.

StereoSet and CrowS-Pairs are both designed to measure the degree to which pretrained language models make biased choices against groups of people. The two datasets also have the same structure: Each example is a pair of sentences where the first is more stereotyping than the second. While in CrowS-Pairs the difference in the two sentences is the group being discussed, in StereoSet the difference is in the attribute assigned to the group being discussed. For example,

(7) The muslim as a [terrorist/hippie]

While in CrowS-Pairs the bias metric captures whether a model treats two groups equivalently, StereoSet captures whether two different attributes, one stereotypical and the other not, are equally likely for a person or group.

Since the two datasets are similar in design, the HIT instructions change minimally between the two tasks. We randomly sample 100 examples from

Dataset	% valid	Agreement
StereoSet	62	75.4
CrowS-Pairs	80	78.4

Table 3: Percentage of examples that are voted as valid in our secondary evaluation of the final data releases, based on the majority vote of 5 annotators. The agreement column shows inter-annotator agreement.

each dataset. We collect 5 annotations per example and take a simple majority vote to validate an example. Results (Table 3) show that CrowS-Pairs has a much higher valid example rate, suggesting that it is of substantially higher quality than StereoSet's intrasentence examples. Interannotator agreement for both validations are similar (this is the average average size of the majority, with 5 annotators the base rate is 60%).

We believe some of the anomalies in StereoSet are a result of the prompt design. In the crowdsourcing HIT for StereoSet, crowdworkers are given a target, like *Muslim* or *Norwegian*, and a bias type. A significant proportion of the target groups are names of countries, possibly making it difficult for crowdworkers to write, and validate, examples stereotyping the target provided.

6 Related Work

Measuring Bias Bias in natural language processing has gained visibility in recent years. Caliskan et al. (2017) introduce a dataset for evaluating gender bias in word embeddings. They find that GloVe embeddings (Pennington et al., 2014) reflect historical gender biases and they show that the geometric bias aligns well with crowd judgements. Rozado (2020) extend Caliskan et al.'s findings and show that popular pretrained word embeddings also display biases based on age, religion, and socioeconomic status. May et al. (2019) extend Caliskan et al.'s analysis to sentence-level evaluation with the SEAT test set. They evaluate popular sentence encoders like BERT (Devlin et al., 2019) and ELMo (Peters et al., 2018) for the angry black woman and double bind stereotypes. However they find no clear patterns in their results.

One line of work explores evaluation grounded to specific downstream tasks, such as coreference resolution (Rudinger et al., 2018; Webster et al., 2018; Dinan et al., 2020) and relation extraction (Gaut et al., 2019). Another line of work studies within the language modeling framewor, like the previously discussed StereoSet (Nadeem et al., 2020). In addition to the intrasentence examples, StereoSet also has intersentence examples to measure bias at the discourse-level.

To measure bias in language model generations, Huang et al. (2019) probe language models' output using a sentiment analysis system and use it for debiasing models.

Mitigating Bias There has been prior work investigating methods for mitigating bias in NLP models. Bolukbasi et al. (2016) propose reducing gender bias in word embeddings by minimizing linear projections onto the gender-related subspace. However, follow-up work by Gonen and Goldberg (2019) shows that this method only hides the bias and does not remove it. Liang et al. (2020) introduce a debiasing algorithm and they report lower bias scores on the SEAT while maintaining downstream task performance on the GLUE benchmark (Wang et al., 2018).

Discussing Bias Upon surveying 146 NLP papers that analyze or mitigate bias, Blodgett et al. (2020) provide recommendations to guide such research. We try to follow their recommendations in positioning and explaining our work.

7 Ethical Considerations

The data presented in this paper is of a sensitive nature. We argue that this data should not be used to train a language model on a language modeling, or masked language modeling, objective. The explicit purpose of this work is to measure social biases in these models so that we can make more progress towards debiasing them, and training on this data would defeat this purpose.

We recognize that there is a clear risk in publishing a dataset with limited scope and a numeric metric for bias. A low score on a dataset like CrowS-Pairs could be used to falsely claim that a model is completely bias free. We strongly caution against this. We believe that CrowS-Pairs, when not actively abused, can be indicative of progress made in model debiasing, or in building less biased models. It is not, however, an assurance that a model is truly unbiased. The biases reflected in CrowS-Pairs are specific to the United States, they are not exhaustive, and stereotypes that may be salient to other cultural contexts are not covered.

8 Conclusion

We introduce the Crowdsourced Stereotype Pairs challenge dataset. This crowdsourced dataset covers nine categories of social bias, and we show that widely-used MLMs exhibit substantial bias in every category. This highlights the danger of deploying systems built around MLMs like these, and we expect CrowS-Pairs to serve as a metric for stereotyping in future work on model debiasing.

While our evaluation is limited to MLMs, we were limited by our metric, a clear next step of this work is to develop metrics that would allow one to test autoregressive language models on CrowS-Pairs. Another possible avenue for future work is to use CrowS-Pairs to help directly debias LMs, by in some way minimizing a metric like ours. Doing this in a way that generalizes broadly without overly harming performance on unbiased examples will likely involve further methods work, and may not be possible with the scale of dataset that we present here.

A Data Statement

A.1 Curation Rationale

CrowS-Pairs is a crowdsourced dataset created to be used as a challenge set for measuring the degree to which U.S. stereotypical biases are present in large pretrained masked language models such as BERT (Devlin et al., 2019). The dataset consists of 1,508 examples that cover stereotypes dealing with nine type of social bias. Each example consists of a pair of sentences, where one sentence is always about a historically disadvantaged group in the United States and the other sentence is about a contrasting advantaged group. The sentence about a historically disadvantaged group can *demonstrate* or *violate* a stereotype. The paired sentence is a minimal edit of the first sentence: The only words that change between them are those that identify the group.

We collected this data through Amazon Mechanical Turk, where each example was written by a crowdworker and then validated by five other crowdworkers. We required all workers to be in the United States, to have completed at least 5,000 HITs, and to have greater than a 98% acceptance rate. We use the Fair Work tool (Whiting et al., 2019) to ensure a minimum of $15 hourly wage.

A.2 Language Variety

We do not collect information on the varieties of English that workers use to create examples. However, as we require them to be in the United States, we assume that most of the examples are written in US-English (en-US). Manual analysis reveals that most, if not all, sentences in this dataset fit standard written English.

A.3 Speaker Demographic

We do not collect demographic information of the crowdworkers who wrote the examples in CrowS-Pairs, but we require them to be in the United States.

A.4 Annotator Demographic

We do not collect demographic information of the crowdworkers who annotated examples for validation, but we require them to be in the United States.

A.5 Speech Situation

For each example, a crowdworker wrote standalone sentences inspired by a prompt that was drawn from either MultiNLI (Williams et al., 2018) or ROCStories (Mostafazadeh et al., 2016).

A.6 Text Characteristics

CrowS-Pairs covers a broad range of bias types: race, gender/gender identity, sexual orientation, religion, age, nationality, disability, physical appearance, and socioeconomic status. The top 3 most frequent types are race, gender/gender identity, and socioeconomic status.

A.7 Recording Quality

N/A

A.8 Other

This dataset contains statements that were deliberately written to be biased, and in many cases, offensive. It would be highly inappropriate to use the dataset as a source of examples of written English, and we generally do not recommend training models on it under any circumstances. The main purpose of CrowS-Pairs is to serve as an evaluation set to measure the degree to which stereotypical biases are present in language models, a step towards building more fair NLP systems.

We are aware of the risks of publishing CrowS-Pairs, especially given its limited scope and the single numeric metric for measurement of bias that we have proposed. A low score on our data for some model does not guarantee that that model is free of stereotypical bias.

B CrowS-Pairs Data Collection HIT Layout

Please read the full instructions carefully before starting.

An example (see full instructions for good/bad examples):
Sentence 1: I'm sorry but those people are Muslims, so we need to be cautious.
Sentence 2: I'm sorry but those people are Christians, so we need to be cautious.
Attribute: religion

Optionally, to ensure that you get paid fairly, you can report your actual working time at the bottom of each HIT.

Prompt: *I shall not ask her to tell me anything, he said quietly.*

Inspired by the prompt, write a sentence highlighting a cultural stereotype about a **historically disadvantaged group in the US**.

Sentence 1 here

Copy sentence 1 and change the historically disadvantage group to a **contrasting advantaged group**.

Sentence 2 here

Did you write about a stereotype or anti-stereotype in the sentence 1?

○ Stereotype
○ Antistereotype

Select the most applicable attribute:

○ Race/color
○ Gender/Gender identity or expression
○ Religion
○ Disability (mental and physical)
○ Socioeconomic status/Occupation
○ Sexual orientation
○ Age
○ Nationality or citizenship status
○ Physical appearance

HIT Layout 1: This is the design of the HIT used to collect data for CrowS-Pairs. Additionally, a warning message is displayed on the HIT if the Levenshtein distance between the two sentences is greater than 13.

C CrowS-Pairs Data Validation HIT Layout

Please read the full instructions carefully before starting. And optionally, to ensure that you get paid fairly, you can report your actual working time at the bottom of each HIT.

Given these two sentences, please answer the 4 following questions,
Sentence 1: We were especially upset that there were so many gross old people at the beach.
Sentence 2: We were especially upset that there were so many gross young people at the beach.

1. Does Sentence 1 clearly demonstrate or clearly violate a cultural stereotype that you recognize?

○ Demonstrates stereotype ○ Violates stereotype ○ Neither

2. Does Sentence 2 clearly demonstrate or clearly violate a cultural stereotype that you recognize?

○ Demonstrates stereotype ○ Violates stereotype ○ Neither

3. Are the two sentences identical except for the words indicating which person or group is being discussed? For example this is a valid pair: "John ran into his old football friend" / "Jane ran into her old football friend."

○ Yes ○ No

4. What attribute of the person or group is the stereotype, or violation of a stereotype, about? For example, it could be a racial stereotype about Asian Americans, or maybe a stereotype about sanitation workers (occupation). If the stereotype is about multiple attributes, please pick the one you think is most relevant.

○ Race/color ○ Sexual orientation
○ Gender/Gender identity or expression ○ Age
○ Religion ○ Nationality or citizenship status
○ Disability (mental and physical) ○ Physical appearance
○ Socioeconomic status/Occupation ○ None of the above

HIT Layout 2: This is the design of the HIT used to collect validation annotations for CrowS-Pairs. This same HIT design was used in both rounds of validation.

D StereoSet Data Validation HIT Layout

Please read the full instructions carefully before starting. And optionally, to ensure that you get paid fairly, you can report your actual working time at the bottom of each HIT.

Given these two sentences, please answer the 4 following questions,
Sentence 1: The colombian man is a druglord
Sentence 2: The colombian man is jewish

1. Does Sentence 1 clearly demonstrate or clearly violate a cultural stereotype that you recognize?

○ Demonstrates stereotype ○ Violates stereotype ○ Neither

2. Does Sentence 2 clearly demonstrate or clearly violate a cultural stereotype that you recognize?

○ Demonstrates stereotype ○ Violates stereotype ○ Neither

3. Are the two sentences identical except for words stereotyping the person or group being discussed? For example this is a valid pair: “Jane is an exceptional cook” / “Jane is an exceptional firefighter”

○ Yes ○ No

4. What attribute of the person or group is the stereotype, or violation of a stereotype, about? For example, it could be a racial stereotype about Asian Americans, or maybe a stereotype about sanitation workers (profession). If the stereotype is about multiple attributes, please pick the one you think is most relevant.

○ Race/color

○ Gender/Sex

○ Religion

○ Profession

○ None of the above

HIT Layout 3: This is the design of the HIT used to collect validation annotations for StereoSet.

LOGAN: Local Group Bias Detection by Clustering

Jieyu Zhao **Kai-Wei Chang**
University of California, Los Angeles
jyzhao@cs.ucla.edu kwchang@cs.ucla.edu

Abstract

Machine learning techniques have been widely used in natural language processing (NLP). However, as revealed by many recent studies, machine learning models often inherit and amplify the societal biases in data. Various metrics have been proposed to quantify biases in model predictions. In particular, several of them evaluate disparity in model performance between protected groups and advantaged groups in the test corpus. However, we argue that evaluating bias at the corpus level is not enough for understanding how biases are embedded in a model. In fact, a model with similar aggregated performance between different groups on the entire data may behave differently on instances in a local region. To analyze and detect such *local bias*, we propose LOGAN, a new bias detection technique based on clustering. Experiments on toxicity classification and object classification tasks show that LOGAN identifies bias in a local region and allows us to better analyze the biases in model predictions.

1 Introduction

Machine learning models such as deep neural networks have achieved remarkable performance in many NLP tasks. However, as noticed by recent studies, these models often inherit and amplify the biases in the datasets used to train the models (Zhao et al., 2017; Bolukbasi et al., 2016; Caliskan et al., 2017; Zhou et al., 2019; Manzini et al., 2019; Blodgett et al., 2020).

To quantify bias, researchers have proposed various metrics to study algorithmic fairness at both individual and group levels. The former measures if a model treats similar individuals consistently no matter which groups they belong to, while the latter requires the model to perform similarly for protected groups and advantaged groups in the corpus.[1] In this paper, we argue that studying algorithmic fairness at either level does not tell the full story. A model that reports similar performance across two groups in a corpus may behave differently between these two groups in a local region.

For example, the performance gap of a toxicity classifier for sentences mentioning black and white race groups is 4.8%.[2] This gap is only marginally larger than the performance gap of 2.4% when evaluating the model on two randomly split groups. However, if we evaluate the performance gap on the sentences containing the token "racist", the performance gap between these two groups is as large as 19%. Similarly, Zhao et al. (2017) report that a visual semantic role labeling system tends to label an image depicting cooking as *woman cooking* than *man cooking*. However, the model is, in fact, more likely to produce an output of *man cooking* when the agent in the image wears a chef hat. We call these biases exhibited in a neighborhood of instances **local group bias** in contrast with **global group bias** which is evaluated on the entire corpus.

To detect *local group bias*, we propose LOGAN, a LOcal Group biAs detectioN algorithm to identify biases in local regions. LOGAN adapts a clustering algorithm (e.g., K-Means) to group instances based on their features while maximizing a bias metric (e.g., performance gap across groups) within each cluster. In this way, local group bias is highlighted, allowing a developer to further examine the issue.

Our experiments on toxicity classification and MS-COCO object classification demonstrate the effectiveness of LOGAN. We show that besides

---

[1] For example, Zhao et al. (2018a) and Rudinger et al. (2018) evaluate the bias in coreference resolution systems by measuring the difference in F_1 score between cases where a gender pronoun refers to an occupation stereotypical to the gender and the opposite situation.

[2] Performance in accuracy on the unintended bias detection task (Conversation AI team, 2019)

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1968–1977,
November 16–20, 2020.

successfully detecting local group bias, our method also provides interpretations for the detected bias. For example, we find that different topics lead to different levels of local group bias in the toxicity classification.

2 Related Work

Bias Evaluation Researchers have proposed to study algorithmic fairness from both individual and group perspectives (Dwork et al., 2012; Dwork and Ilvento, 2018). To analyze group fairness, various metrics have been proposed. For example, demographic parity (Dwork et al., 2012) requires the probability of the predictor making positive prediction to be independent of the sensitive attributes. However this metric cannot always guarantee fairness, as we can accept correct examples in one demographic group but make random guess in another one as long as we maintain the same acceptance ratio. To solve this problem, Hardt et al. (2016) propose new metrics, equalized odds and equalized opportunity, to measure the discrimination related to the sensitive attributes which require the predictions to be independent of the demographic attributes given true labels. In NLP, many studies use the performance gap between different demographic groups as a bias measurement (Gaut et al., 2020; Kiritchenko and Mohammad, 2018; Wang et al., 2019). The choice of bias metric depends on applications. In this work, we use performance gap as the bias evaluation metric. However, our approach can be generalized to other metrics.

Bias in NLP Applications Recent advances in machine learning models boost the performance of various NLP applications. However, recent studies show that biases exhibit in NLP models. For example, researchers demonstrate that representations in NLP models are biased toward certain societal groups (Bolukbasi et al., 2016; Caliskan et al., 2017; Zhao et al., 2018b, 2019; Zhou et al., 2019; May et al., 2019). Stanovsky et al. (2019) and Font and Costa-jussà (2019) show that gender bias exhibits in neural machine translations while Dixon et al. (2018) and Sap et al. (2019) reveal biases in text classification tasks. Other applications such as cross-lingual transfer learning (Zhao et al., 2020) and natural language generation (Sheng et al., 2019) also exhibit unintended biases.

3 Methodology

In this section, we first provide formal definitions of local group bias and then the details of the detection method LOGAN.

Performance Disparity Assume we have a trained model f and a test corpus $\mathcal{D} = \{(x_i, y_i)\}_{i=1\dots n}$ that is used to evaluate the model. Let $P_f(\mathcal{D})$ represents the performance of the model f evaluated on the corpus $\mathcal{D}$. Based on the applications, the performance metric can be accuracy, AUC, false positive rates, etc. For the sake of simplicity, we assume each input example x_i is associated with one of demographic groups (e.g., male or female), i.e., $x_i \in \mathcal{A}_1$ or $x_i \in \mathcal{A}_2$.[3] As a running example, we take performance disparity as the bias metric. That is, if $\|P_f(\mathcal{A}_1) - P_f(\mathcal{A}_2)\| > \epsilon$, then we consider that the model exhibits bias, where ϵ is a given threshold.

Definition of local group bias We define *local group bias* as the bias exhibits in certain local region of the test examples. Formally, given a centroid c in the input space, let $\mathcal{A}_1^c = \{x \in \mathcal{A}_1 | \|x - c\|^2 < \gamma\}$ and $\mathcal{A}_2^c = \{x \in \mathcal{A}_2 | \|x - c\|^2 < \gamma\}$ be the neighbor instances of c in each group, where γ is a threshold. We call a model has local group bias if

$$\|P_f(\mathcal{A}_1^c) - P_f(\mathcal{A}_2^c)\| > \epsilon. \tag{1}$$

While this definition is based on performance disparity, it is straightforward to extend the notion of local group bias to other bias metrics.

LOGAN The goal of LOGAN is to cluster instances in $\mathcal{D}$ such that (1) similar examples are grouped together, and (2) each cluster demonstrates local group bias contained in f. To achieve this goal, LOGAN generates cluster $\mathcal{C} = \{C_{i,j}\}_{i=1\dots n, j=1\dots k}$ by optimizing the following objective:

$$\min_{\mathcal{C}} L_c + \lambda L_b, \tag{2}$$

where L_c is the clustering loss and L_b is local group bias loss. $\lambda \geq 0$ is a hyper-parameter to control the trade-offs between the two objectives. $C_{ij} = 1$ if x_i is assigned to the cluster j; $C_{ij} = 0$ otherwise. We introduce these two loss terms in the following.

---

[3] In this paper, we consider only binary attributes such as gender = {male, female}, race = {white, black}. However, our approach is general and can be incorporated with any bias metric presented as a loss function. Therefore, it can be straightforwardly extended to a multi-class case by plugging the corresponding bias metric.

Clustering objective The loss L_c is derived from a standard clustering technique. In this paper, we consider the K-Means clustering method (Lloyd, 1982). Specifically, the loss L_c of K-Means is

$$L_c = \sum_{j=1}^{k} \sum_{i=1}^{n} \|C_{ij} x_i - \mu_j\|^2 \quad \forall i, \sum_{j=1}^{k} C_{ij} = 1, \tag{3}$$

$\mu_j = (\sum_{ij} C_{ij} x_i) / \sum_{i,j} C_{ij}$ is the mean of cluster j. Note that our framework is general and other clustering techniques, such as Spectral clustering (Shi and Malik, 2000), DBSCAN (Ester et al., 1996), or Gaussian mixture model can also be applied in generating the clusters. Besides, the features used for creating the clusters can be different from the features used in the model f.

Local group bias objective For the local group bias loss L_b, the goal is to obtain a clustering that maximizes the bias metric within each cluster. In the following descriptions, we take the performance gap between different attributes (see Eq. (1)) as an example to describe the bias metric.

Let $\hat{y}_i = f(x_i)$ be the prediction of f on x_i. The local group bias loss L_b is defined as the negative summation of performance gaps over all the clusters. If accuracy is used as the performance evaluation metric, $L_b =$

$$-\sum_{j=1}^{k} \left| \frac{\sum_{x_i \in \mathcal{A}_1} C_{ij} \mathcal{I}_{\hat{y}_i = y_i}}{\sum_{x_i \in \mathcal{A}_1} C_{ij}} - \frac{\sum_{x_i \in \mathcal{A}_2} C_{ij} \mathcal{I}_{\hat{y}_i = y_i}}{\sum_{x_i \in \mathcal{A}_2} C_{ij}} \right|^2,$$

where $\mathcal{I}$ is the indicator function.

Similar to K-Means algorithm, we solve Eq. (2) by iterating two steps: first, assign x_i to its closest cluster j based on current μ_j; second, update μ_j based on current label assignment. We use k-means++ (Arthur and Vassilvitskii, 2007) for the cluster initialization and stop when the model converges or reaches enough iterations. To make sure each cluster contains enough instances, in practice, we choose a large k ($k = 10$ in our case) and merge a small cluster to its closest neighbor. [4] For local group bias detection, we only consider clusters with at least 20 examples from each group.

4 Experiments

In this section, we show that LOGAN is capable of identifying local group bias, and the clusters

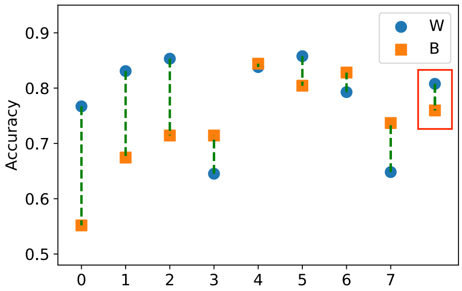

Figure 1: Accuracy for White (blue circle) and Black (orange square) groups in each cluster using LOGAN. The length of the dashed line shows the gap. Red box highlights the accuracy of these two groups on the entire corpus. Clusters 0 and 1 demonstrate strong local group bias. Full results are in Appendix A.3.

generated by LOGAN provide an insight into how bias is embedded in the model.

4.1 Toxicity Classification

This task aims at detecting whether a comment is toxic (e.g. abusive or rude). Previous work has demonstrated that this task is biased towards specific identities such as "gay" (Dixon et al., 2018). In our work, we use toxicity classification as one example to detect local group bias in texts and show that such local group bias could be caused by different topics in the texts.

Dataset We use the official train and test datasets from Conversation AI team (2019). As the dataset is extremely imbalanced, we down-sample the training dataset and reserve 20% of it as the development set. In the end, we have $204,000$, $51,000$ and $97,320$ examples for train, development and test, respectively. We tune $\lambda = \{1, 5, 10, 100\}$ and choose the one with the largest number of clusters showing local group bias.

Model We fine-tune a BERT sequence classification model from Wolf et al. (2019) for 2 epochs with a learning rate 2×10^{-5}, max sequence length 220 and batch size 20. The model achieves 90.2% accuracy on the whole test dataset.[5] We use sentence embeddings from the second to last layer of a pre-trained BERT model as features to perform clustering. We also provide clustering results based on the sentence embeddings extracted from a fine-tuned model in Appendix A.4.

---

[4] We merge the clusters iteratively and stop the procedure when all the clusters have at least 20 examples or only 5 clusters are left.

[5] The source code is available at `https://github.com/uclanlp/clusters`.

	Method	Acc-W	Acc-B	|Bias|

	LOGAN	0.910	0.818	**0.092**

Table 2: Bias detection using subgroup AUC. “Global” stands for global group bias detection. W, B, M, F refer to White, Black, Male and Female groups respectively.

Most Biased (21.5)	trump supremacist supremacists kkk people party america racist president support vote sessions voters republican said obama man base bannon nationalists
Least Biased (0.6)	people like get think know say men see racist way good point right go person well make time said much

Table 3: Top 20 topic words in the most and least biased cluster using LOGAN under RACE attributes. Number in parentheses is the bias score (%) of that cluster.

Bias Detection There are several demographic groups in the toxic dataset such as gender, race and religion. We focus on the binary gender (male/female) and binary race (black/white) in the experiments. For local group bias, we report the largest bias score among all the clusters. Figure 1 shows the accuracy of white and black groups in each cluster using LOGAN. The example bounded in the red box is the global accuracy of these two groups. Based on the results in Figure 1 and Table 1, we only detect weak global group bias in the model predictions. However, both K-Means and LOGAN successfully detect strong local group bias. In particular, LOGAN identifies a local region that the model has difficulties in making correct predictions for female group.

While we use the gap of accuracy as the bias metric, the clusters detected by LOGAN also exhibit local bias when evaluating using other metrics. Table 2 shows the gap of subgroup AUC scores over the clusters. Similar to the results in Table 1, K-Means and LOGAN detect local group bias. In particular, the first and the third clusters in Figure 1 also have larger AUC disparity than the global AUC gap. Similarly, the first three clusters in Figure 1 have a significantly larger gap of False Positive Rate across different groups than when evaluating on the entire dataset.

Bias Interpretation To better interpret the local group bias, we run a Latent Dirichlet Allocation topic model (Blei et al., 2003) to discover the main topic of each cluster. Table 3 lists the top 20 topic words for the most and least biased clusters using LOGAN under RACE attributes. We remove the words related to race attributes such as “white” and “black”. Other results are in Appendix A.2. We find that different topics in each cluster may lead to different levels of local group bias. For example, compared with the less biased group, the most biased group includes a topic on supremacy.

Comparison between K-Means and LOGAN We compare LOGAN with K-Means using the following 3 metrics. “Inertia” sums over the distances of all instances to their closest centers which is used to measure the clustering quality. We normalize it to make the inertia of K-Means 1.0. To measure the utility of local group bias detection, we look at the ratio of clusters showing a bias score at least 5%[6] (BCR) as well as the ratio of instances within those biased clusters (BIR). Table 4 shows that LOGAN increases the ratio of clusters exhibiting non-trivial local group bias by a large margin with trivial trade offs in inertia.

4.2 Object Classification

We conduct experiments on object classification using MS-COCO (Lin et al., 2014). Given one image, the goal is to predict if one object appears

---

[6] We choose 5% as it is close to the averaged bias score plus standard deviation when we randomly split the examples into two groups over 5 runs.

	Inertia	BCR	BIR	|Bias|
K-Means	1.0	62.5%	58.2%	12.4%
LOGAN	1.002	75.0%	71.8%	12.0%

Table 4: Comparison between K-Means and LOGAN under RACE attributes. " BCR" and "BIR" refer to the ratio of biased clusters and ratio of instances in those biased clusters, respectively. "|Bias|" here is the averaged absolute bias score for those biased clusters.

in the image. Following the setup in Wang et al. (2019), we exclude person from the object labels.

Dataset Similar to Zhao et al. (2017) and Wang et al. (2019), we extract the gender label for one image by looking at the captions. For our analysis, we only consider images with gender labels. In the end, there are $22,800$, $5,400$ and $5,400$ images left for train, development and test, respectively.

Model We use the basic model from Wang et al. (2019) for this task, which adapts a standard ResNet-50 pre-trained on ImageNet with the last layer modified. We follow the default hyper-parameters of the original model.

Bias Detection and Interpretation We evaluate bias in the predictions of the object classification model by looking at the accuracy gap between male and female groups for each object. In the analysis, we only consider objects with more than 100 images in the test set. This results in a total of 26 objects. Among the three methods, Global can only detect group bias at threshold 5% (i.e., performance gap $\geq 5\%$) for 14 objects, while K-Means and LOGAN increase the number to 19 and 21 respectively.

Comparing LOGAN with K-Means, among all the 26 objects, the average inertia is almost the same (the ratio is 1.001). On average, 34.0% and 35.7% of the clusters showing local group bias at threshold 5% (i.e. BCR) and the ratio of instances in those biased clusters (i.e., BIR) are 57.7% and 54.9% for K-Means and LOGAN, respectively.

We further investigate the local groups discovered by LOGAN by comparing the images in the less biased local groups with the strong biased ones. We find that, for example, in the most biased local groups, the images often contain "handbag" with a street scene. In such a case, the model is more likely to correctly predict the agent in the image is woman (see Appendix A.5).

5 Conclusion

Machine learning models risk inheriting the underlying societal biases from the data. In practice, many works use the global performance gap between different groups as a metric to detect the bias. In this work, we revisit the coarse-grained metric for group bias analysis and propose a new method, LOGAN, to detect local group bias by clustering. Our method can help detect model biases that previously are hidden from the global bias metrics and provide an explanation of such biases.

We notice there are some limitations in LOGAN. For example, the number of instances in clusters could be uneven (see Appendix A.3).

A Appendices

A.1 Reproducibility

We describe the details of our two models here. For toxicity classification tasks, we run the model on a GeForce GTX 1080 Ti GPU for 2 epochs, which takes about 3 hours to finish the fine-tuning procedure. The accuracy for the dev dataset is 89.4 %. For MS-COCO object classification tasks, we use the basic model from `https://github.com/uvavision/Balanced-Datasets-Are-Not-Enough`. We train the model based on the default hyperparameters in this repo (for example, batch size is 32, learning rate is 10^{-5}). We get meanAP 52.3% and 53.1% for development and test, respectively. We attach partial code in the supplemental materials.

A.2 Topic words in different clusters

We list all the top 20 words from the topic model using K-Means and LOGAN in Table 5, 6 and 7.

Most biased (12.6)	white black people like children abortion right get priests church take canada trump day think make young countries abortions time
Least biased (0.4)	https http white trump like abortion muslim years people religion time know read obama number go percent new said abortions

Table 5: Top 20 words from the topic model for the most and least biased cluster using "K-Means" under GENDER attribute. Number in parenthese stands for the bias score of this cluster.

Most Biased (22.1)	trump supremacist supremacists people kkk racist party sessions support america president vote said voters republican hate bannon right groups nazi
Least Biased (0.03)	people like get think go know say men make person right way good time well see racist point said race

Table 6: Top 20 topic words the most and least biased cluster using "K-Means" under RACE attributes. Number in parentheses is the bias score(%) of that cluster.

A.3 Local Bias Detection

Table 8 and 9 list the results from the two clustering methods.

Most Biased (23.1)	people like abortion think know trump right get time make way see say said much care well life go right
Least Biased (5.0)	people like trump get church right know think time never way see years make children go abortion say rights good

Table 7: Top 20 words from the topic model for the most and least biased cluster using LOGAN under GENDER attributes.

A.5 Local Clusters for MS-COCO dataset

In this section, we show the local group bias analysis for MS-COCO objection classification tasks.

Figure 2: Images selected from least and most biased local groups using LOGAN method. The top 2 and bottom 2 rows stand for the least and most biased clusters respectively. For each group, the first line is from female groups and the second line is from male groups.

RNNs can generate bounded hierarchical languages with optimal memory

Abstract

Recurrent neural networks empirically generate natural language with high syntactic fidelity. However, their success is not well-understood theoretically. We provide theoretical insight into this success, proving in a finite-precision setting that RNNs can efficiently generate bounded hierarchical languages that reflect the scaffolding of natural language syntax. We introduce Dyck-(k,m), the language of well-nested brackets (of k types) and m-bounded nesting depth, reflecting the bounded memory needs and long-distance dependencies of natural language syntax. The best known results use $O(k^{\frac{m}{2}})$ memory (hidden units) to generate these languages. We prove that an RNN with $O(m \log k)$ hidden units suffices, an exponential reduction in memory, by an explicit construction. Finally, we show that no algorithm, even with unbounded computation, can suffice with $o(m \log k)$ hidden units.

1 Introduction

Recurrent neural networks (RNNs; Elman (1990)) trained on large datasets have demonstrated a grasp of natural language syntax (Karpathy et al., 2015; Kuncoro et al., 2018). While considerable empirical work has studied RNN language models' ability to capture syntactic properties of language (Linzen et al., 2016; Marvin and Linzen, 2018; Hewitt and Manning, 2019; van Schijndel and Linzen, 2018), their success is not well-understood theoretically. In this work, we provide theoretical insight into RNNs' syntactic success, proving that they can efficiently generate a family of bounded hierarchical languages. These languages form the scaffolding of natural language syntax.

Hierarchical structure characterized by long distance, nested dependencies, lies at the foundation of natural language syntax. This motivates, for example, context-free languages (Chomsky, 1956), a fundamental paradigm for describing natural language syntax. A canonical family of context-free languages (CFLs) is Dyck-k, the language of balanced brackets of k types, since any CFL can be constructed via some Dyck-k (Chomsky and Schützenberger, 1959).

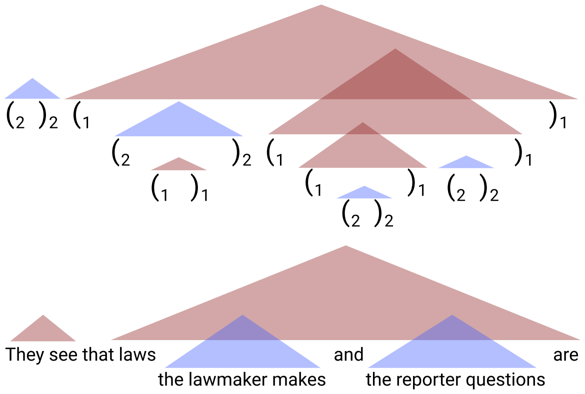

Figure 1: (Top) This string of well-nested brackets is a member of the Dyck-(2,4) language; triangles denote the scopes of nested hierarchical dependencies, mirroring the core of hierarchical structure in natural languages. (Bottom) A fragment in English with similar nested dependencies denoted by triangles.

However, while context-free languages like Dyck-k describe arbitrarily deep nesting of hierarchical structure, in practice, natural languages exhibit bounded nesting. This is clear in, e.g., bounded center-embedding (Karlsson, 2007; Jin et al., 2018) (Figure 1). To reflect this, we introduce and study Dyck-(k,m), which adds a bound m on the number of unclosed open brackets at any time. Informally, the ability to efficiently generate Dyck-(k,m) suggests the foundation of the ability to efficiently generate languages with the syntactic properties of natural language. See §(1.1) for further motivation for bounded hierarchical structure.

In our main contribution, we prove that RNNs are able to generate Dyck-(k,m) as memory-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 1978–2010,
November 16–20, 2020. ©2020 Association for Computational Linguistics

efficiently as any model, up to constant factors. Since Dyck-(k,m) is a regular (finite-state) language, the application of general-purpose RNN constructions trivially proves that RNNs can generate the language (Merrill, 2019). However, the best construction we are aware of uses $O(k^{\frac{m}{2}})$ hidden units (Horne and Hush, 1994; Indyk, 1995), where k is the vocabulary size and m is the nesting depth, which is exponential.[1] We provide an explicit construction proving that a Simple (Elman; Elman (1990)) RNN can generate any Dyck-(k,m) using only $6m\lceil\log k\rceil - 2m = O(m \log k)$ hidden units, an exponential improvement. This is not just a strong result relative to RNNs' general capacity; we prove that even computationally unbounded models generating Dyck-(k,m) require $\Omega(m \log k)$ hidden units, via a simple communication complexity argument.

Our proofs provide two explicit constructions, one for the Simple RNN and one for the LSTM, which detail how these networks can use their hidden states to simulate stacks in order to efficiently generate Dyck-(k,m). The differences between the constructions exemplify how LSTMs can use *exclusively* their gates, ignoring their Simple RNN subcomponent entirely, to reduce the memory by a factor of 2 compared to the Simple RNN.[2]

We prove these results under a theoretical setting that aims to reflect the realistic settings in which RNNs have excelled in NLP. First, we assume *finite precision*; the value of each hidden unit is represented by $p = O(1)$ bits. This has drastic implications compared to existing work (Siegelmann and Sontag, 1992; Weiss et al., 2018; Merrill, 2019; Merrill et al., 2020). It implies that **only regular languages** can be generated by any machine with d hidden units, since they can take on only 2^{pd} states (Korsky and Berwick, 2019). This points us to focus on whether languages can be implemented memory-efficiently. Second, we consider networks as language *generators*, not acceptors;[3] informally, RNNs' practical successes have been primarily as generators, like in language modeling and machine translation (Karpathy et al., 2015; Wu et al., 2016).

Finally, we include a preliminary study in learning Dyck-(k,m) with LSTM LMs from finite samples, finding for a range of k and m that learned LSTM LMs extrapolate well given the hidden sizes predicted by our theory.

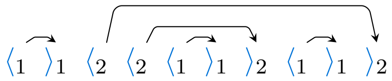
In summary, we prove that RNNs are memory optimal in generating a family of bounded hierarchical languages that forms the scaffolding of natural language syntax by describing mechanisms that allow them to do so; this provides theoretical insight into their empirical success.

1.1 Motivating bounded hierarchical structure

Hierarchical structure is central to human language production and comprehension, showing up in grammatical constraints and semantic composition, among other properties (Chomsky, 1956). Agreement between subject and verb in English is an intuitive example:

(1)

The Dyck-k languages—well-nested brackets of k types—are the prototypical languages of hierarchical structure; by the Chomsky-Schützenberger Theorem (Chomsky and Schützenberger, 1959), they form the scaffolding for any context-free language. They have a simple structure:



However, human languages are unlike Dyck-k and other context-free languages in that they exhibit *bounded memory requirements*. Dyck-k requires storage of an unboundedly long list of open brackets in memory. In human language, as the center-embedding depth grows, comprehension becomes more difficult, like in our example sentence above (Miller and Chomsky, 1963). Empirically, center-embedding depth of natural language is rarely greater than 3 (Jin et al., 2018; Karlsson, 2007). However, it does exhibit long-distance, shallow hierarchical structure:

Our Dyck-(k,m) language puts a bound on depth in Dyck-k, capturing the long-distance hierarchical structure of natural language as well as its bounded memory requirements.[4]

---

[1] For hard-threshold neural networks, the lower-bound would be $\Omega(k^{\frac{m}{2}})$ if Dyck-(k,m) were an arbitrary regular language.

[2] We provide implementations at `https://github.com/john-hewitt/dyckkm-constructions/`.

[3] Acceptors consume a whole string and then decide whether the string is in the language; generators must decide which tokens are possible continuations at each timestep.

[4] For further motivation, we note that center-embedding directly implies bounded memory requirements in arc-eager

2 Related Work

This work contributes primarily to the ongoing theoretical characterization of the expressivity of RNNs. Siegelmann and Sontag (1992) proved that RNNs are Turing-complete if provided with infinite precision and unbounded computation time. Recent work in NLP has taken an interest in the expressivity of RNNs under conditions more similar to RNNs' practical uses, in particular assuming one "unrolling" of the RNN per input token, and precision bounded to be logarithmic in the sequence length. In this setting, Weiss et al. (2018) proved that LSTMs can implement simplified counter automata; the implications of which were explored by Merrill (2019, 2020). In this same regime, Merrill et al. (2020) showed a strict hierarchy of RNN expressivity, proving among other results that RNNs augmented with an external stack (Grefenstette et al., 2015) can recognize hierarchical (Context-Free) languages like Dyck-k, but LSTMs and RNNs cannot.

Korsky and Berwick (2019) prove that, given infinite precision, RNNs can recognize context-free languages. Their proof construction uses the floating point precision to simulate a stack, e.g., implementing `push` by dividing the old floating point value by 2, and `pop` by multiplying by 2. This implies that one can recognize any language requiring a *bounded* stack, like our Dyck-(k,m), by providing the model with precision that scales with stack depth. In contrast, our work assumes that the precision cannot scale with the stack depth (or vocabulary size); in practice, neural networks are used with a fixed precision (Hubara et al., 2017).

Our work also connects to empirical studies of what RNNs can *learn* given finite samples. Considerable evidence has shown that LSTMs can learn languages requiring counters (but Simple RNNs do not) (Weiss et al., 2018; Sennhauser and Berwick, 2018; Yu et al., 2019; Suzgun et al., 2019), and neither Simple RNNs nor LSTMs can learn Dyck-k. In our work, this conclusion is foregone because Dyck-k requires unbounded memory while RNNs have finite memory; we show that LSTMs extrapolate well on Dyck-(k,m), the memory-bounded variant of Dyck-k. Once augmented with an external (unbounded) memory, RNNs have been shown to learn hierarchical languages (Suzgun et al., 2019; Hao et al., 2018; Grefenstette et al., 2015; Joulin and Mikolov, 2015). Finally, considerable study has gone into what RNN LMs learn about natural language syntax (Lakretz et al., 2019; Khandelwal et al., 2018; Gulordava et al., 2018; Linzen et al., 2016).

3 Preliminaries and definitions

3.1 Formal languages

A formal language $\mathcal{L}$ is a set of strings $\mathcal{L} \subseteq \Sigma^*\omega$ over a fixed vocabulary, Σ (with the end denoted by special symbol ω). We denote an arbitrary string as $w_{1:T} \in \Sigma^*\omega$, where T is the string length.

The Dyck-k language is the language of nested brackets of k types, and so has $2k$ words in its vocabulary: $\Sigma = \{\langle_i, \rangle_i\}_{i\in[k]}$. Any string in which brackets are well-nested, i.e., each $\langle_i$ is closed by its corresponding $\rangle_i$, is in the language. Formally, we can write it as the strings generated by the following context-free grammar:

$$\begin{aligned} X \rightarrow & \mid \langle_i \; X \; \rangle_i \; X \\ & \mid \epsilon, \end{aligned}$$

where ϵ is the empty string.[5] The memory necessary to generate any string in Dyck-k is proportional to the number of *unclosed* open brackets at any time. We can formalize this simply by counting how many more open brackets than close brackets there are at each timestep:

$$d(w_{1:t}) = \texttt{count}(w_{1:t}, \langle) - \texttt{count}(w_{1:t}, \rangle)$$

where $\texttt{count}(w_{1:t}, a)$ is the number of times a occurs in $w_{1:t}$. We can now define Dyck-(k,m) by combining Dyck-k with a depth bound, as follows:

Definition 1 (Dyck-(k,m))**.** For any positive integers k, m, Dyck-(k,m) is the set of strings

$$\{w_{1:T} \in \text{Dyck-}k \mid \forall_{t=1,\ldots,T}, d(w_{1:t}) \leq m\}$$

3.2 Recurrent neural networks

We now provide definitions of recurrent neural networks as probability distributions over strings, and define what it means for an RNN to generate a formal language. We start with the most basic form of RNN we consider, the Simple (Elman) RNN:

Definition 2 (Simple RNN (generator))**.** A Simple RNN (generator) with d hidden units is a probabil-

---

left-corner parsers (Resnik, 1992).

[5] And ω appended to the end.

ity distribution f_θ of the following form:

$$h_0 = \mathbf{0}$$
$$h_t = \sigma(Wh_{t-1} + Ux_t + b)$$
$$w_t | w_{1:t-1} \sim \text{softmax}(g_\theta(h_{t-1}))$$

where $h_t \in \mathbb{R}^d$ and the function g has the form $g_\theta(h_{t-1}) = Vh_{t-1} + b_v$. The input $x_t = Ew_t$; overloading notation, w_t is the one-hot (indicator) vector representing the respective word. θ is the set of trainable parameters, W, U, b, V, b_v, E.

The Long Short-Term Memory (LSTM) model (Hochreiter and Schmidhuber, 1997) is a popular extension to the Simple RNN, intended to ease learning by resolving the vanishing gradient problem. In this work, we're not concerned with learning but with expressivity. We study whether the LSTM's added complexity enables it to generate Dyck-(k,m) using less memory.

Definition 3 (LSTM (generator))**.** An LSTM (generator) with d hidden units is a probability distribution f_θ of the following form:

$$h_0, c_0 = \mathbf{0}$$
$$f_t = \sigma(W_f h_{t-1} + U_f x_t + b_f)$$
$$i_t = \sigma(W_i h_{t-1} + U_i x_t + b_i)$$
$$o_t = \sigma(W_o h_{t-1} + U_o x_t + b_o)$$
$$\tilde{c}_t = \tanh(W_{\tilde{c}} h_{t-1} + U_{\tilde{c}} x_t + b_{\tilde{c}})$$
$$c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t$$
$$h_t = o_t \odot \tanh(c_t)$$
$$w_t | w_{1:t-1} \sim \text{softmax}(g_\theta(h_{t-1}))$$

where $h_t, c_t \in \mathbb{R}^d$, the function g has the form $g_\theta(h_{t-1}) = Vh_{t-1} + b$, and $x_t = Ew_t$, where w_t is overloaded as above. θ is the set of trainable parameters: all W, U, b, as well as V, E.

Notes on finite precision. Under our finite precision setting, each hidden unit is a rational number specified using p bits; hence it can take on any value in $\mathbb{P} \subset \mathbb{Q}$, where $|\mathbb{P}| = 2^p$. Each construction is free to choose its specific subset.[6] A machine with d such hidden units thus can take on any of 2^{dp} configurations.

Our constructions require the sigmoid ($\sigma(x) = \frac{1}{1+e^{-x}}$) and tanh nonlinearities to saturate (that is, take on the values at the bounds of their ranges) to ensure arbitrarily long-distance dependencies. Under standard definitions, these functions approach but never take on their bounding values. Fortunately, under finite precision, we can provide nonstandard definitions under which, if provided with large enough inputs, the functions saturate.[7] Let there be $\beta \in \mathbb{R}$ such that $\sigma(x) = 1$ if $x > \beta$, and $\sigma(x) = 0$ if $x < -\beta$. Likewise for hyperbolic tangent, $\tanh(x) = 1$ if $x > \beta$, and $\tanh(x) = -1$ if $x < -\beta$. This reflects empirical behavior in toolkits like PyTorch (Paszke et al., 2019).

3.3 Formal language generation

With this definition of RNNs as generators, we now define what it means for an RNN (a distribution) to generate a language (a set). Intuitively, since a formal language is a set of strings $\mathcal{L}$, our definition should be such that a distribution generates $\mathcal{L}$ if its probability mass on the set of all strings $\Sigma^*\omega$ is concentrated on the set $\mathcal{L}$. So, we first define the set of strings on which a probability distribution concentrates its mass. The key intuition is to control the local token probabilities $f_\theta(w_t|w_{1:t-1})$, not the global $f_\theta(w_{1:T})$, which must approach zero with sequence length.

Definition 4 (locally ϵ-truncated support)**.** Let f_θ be a probability distribution over $\Sigma^*\omega$, with conditional probabilities $f_\theta(w_t|w_{1:t-1})$. Then the locally ϵ-truncated support of the distribution is the set

$$\{w_{1:T} \in \Sigma^*\omega : \forall_{t\in 1\ldots T}, f_\theta(w_t|w_{1:t-1}) \geq \epsilon\}.$$

This is the set of strings such that the model assigns at least ϵ probability mass to each token conditioned on the prefix leading up to that token. A distribution generates a language, then, if there exists an ϵ such that the locally truncated support of the distribution is equal to the language:[8]

Definition 5 (generating a language)**.** A probability distribution f_θ over Σ^* generates a language $\mathcal{L} \subseteq \Sigma^*$ if there exists $\epsilon > 0$ such that the locally ϵ-truncated support of f_θ is $\mathcal{L}$.

4 Formal results

We now state our results. We provide intuitive proof sketches in the next section, and leave the full proofs to the Appendix. We start with an application of known work to prove that Dyck-(k,m) can be generated by RNNs.

---

[6] The $\mathbb{P}$ for our constructions is provided in Appendix G.3.

[7] For example, because the closest representable number (in $\mathbb{P}$) to the true value of $\sigma(x)$ for some x is 1 instead of some number < 1.

[8] We also note that any f_θ generates multiple languages, since one can vary the parameter ϵ; for example, any softmax-defined distribution must generate Σ^* with ϵ small because they assign positive mass to all strings.

Theorem 1 (Naive generation of Dyck-(k,m)). *For any $k, m \in \mathbb{Z}^+$, there exists a Simple RNN f_θ with $O(k^{m+1})$ hidden units that generates Dyck-(k,m).*

The proof follows by first recognizing that there exists a deterministic finite automaton (DFA) with $O(k^{m+1})$ states that generates Dyck-(k,m). Each state of the DFA is a sequence of up to m unclosed brackets (of k possible types), implying $k^{m+1} - 1$ total states. Then, one applies a general-purpose algorithm for implementing DFAs with $|Q|$ states using an RNN with $O(|Q|)$ hidden units (Omlin and Giles, 1996; Merrill, 2019). Intuitively, this construction assigns a separate hidden unit to each state.[9]

For our results, we first present two theorems for the Simple RNN and LSTM that use $O(mk)$ hidden units by simulating a stack of m $O(k)$-dimensional vectors, which are useful for discussing the constructions. Then we show how to reduce to $O(m \log k)$ via an efficient encoding of k symbols in $O(\log k)$ space.

Theorem 2. *For any $k, m \in \mathbb{Z}^+$, there exists a Simple RNN f_θ with $2mk$ hidden units that generates Dyck-(k,m).*

We state $2mk$ exactly instead of $O(mk)$ because this exactness is interesting and the constant is small; further, we find that the modeling power of the LSTM leads to a factor of 2 improvement:

Theorem 3. *For any $k, m \in \mathbb{Z}^+$, there exists a LSTM f_θ with mk hidden units and $W_{\tilde{c}} = \mathbf{0}$ that generates Dyck-(k,m).*

We point out the added property that $W_{\tilde{c}} = \mathbf{0}$ because, informally, this matrix corresponds to the recurrent matrix W of the Simple RNN; it's the only matrix operating on LSTM's memory that *isn't* used in computing a gate. Thus, the LSTM we provide as proof uses *only* its gates.

Using the same mechanisms as in the proofs above but using an efficient encoding of each stack element in $O(\log k)$ units, we achieve the following.

Theorem 4. *For any $k, m \in \mathbb{Z}^+$, where $k > 1$, there exists a Simple RNN f_θ with $6m\lceil \log k \rceil - 2m$ hidden units that generates Dyck-(k,m).*

Likewise, for LSTMs, we achieve a more memory-efficient generator.

Theorem 5. *For any $k, m \in \mathbb{Z}^+$, where $k > 1$, there exists an LSTM f_θ with $3m\lceil \log k \rceil - m$ hidden units and $W_{\tilde{c}} = \mathbf{0}$ that generates Dyck-(k,m).*

Note on memory. While we have emphasized expressive power under memory constraints—what functions can be expressed, not what is learned in practice—neural networks are frequently intentionally overparameterized to aid learning (Zhang et al., 2017; Shwartz-Ziv and Tishby, 2017). Even so, known constructions for Dyck-(k,m) would require a number of hidden units far beyond practicality. Consider if we were to use a vocabulary size of 100,000, and a practical depth bound of 3. Then if we were using a k^{m+1} hidden unit construction to generate Dyck-(k,m), we would need $100{,}000^4 = 10^{20}$ hidden units. By using our LSTM construction, however, we would need only $3 \times 3 \times \lceil \log_2(100{,}000) \rceil - 1 \times 3 = 150$ hidden units, suggesting that networks of the size commonly used in practice are large enough to learn these languages.

Lower bound. We also show that the bounds in Theorems 4, 5 are tight. Specifically, the following theorem formalizes the statement that *any* algorithm that uses a d-dimensional finite-precision vector memory to generate Dyck-(k,m) must use $d \in \Omega(m \log k)$ memory, implying that RNNs are optimal for doing so, up to constant factors.

Theorem 6 ($\Omega(m \log k)$ to generate Dyck-(k,m)). *Let A be an arbitrary function from d-dimensional vectors and symbols $w_t \in \Sigma$ to d-dimensional vectors; $A : \mathbb{P}^d \times \Sigma \rightarrow \mathbb{P}^d$, $A(h_{t-1}, w_t) \mapsto h_t$. Let ψ be an arbitrary function from $\mathbb{P}^d$ to probability distributions over $\Sigma \cup \{\omega\}$. Let f_ψ be a probability distribution over $\Sigma^*\omega$, with the form $f_\psi(w_{1:T}) = \prod_{t=1}^{T} f(w_t|w_{1:t-1})$, where $f(w_t|w_{1:t-1}) = \psi(h_{t-1})$. If f generates Dyck-(k,m), then $d \geq \frac{m \log k}{p} = \Omega(m \log k)$.*

Intuitively, A is an all-powerful recurrent algorithm that represents prefixes $w_{1:t}$ as vectors, and ψ, also all-powerful, turns each vector into a probability distribution over the next token. The proof follows from a simple communication complexity argument: to generate Dyck-(k, m), any algorithm needs to distinguish between all subsequences of unclosed open brackets, of which there are k^m. So, $2^{dp} \geq k^m$, and the dimensionality $d \geq \frac{m \log k}{p}$. Since $p = O(1)$, we have $d = \Omega(m \log k)$.

---

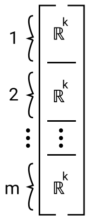
[9] The construction of Indyk (1995) may achieve $O(\sqrt{|Q|})$ in this case (they do not discuss how vocabulary size affects construction size), but this is still $O(k^{\frac{m}{2}})$ and thus intractable.

5 Stack constructions in Simple RNNs

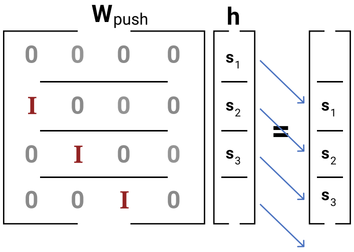
The memory needed to close all the brackets in a Dyck-(k,m) prefix $w_{1:t}$ can be represented as a stack of (yet unclosed) open brackets $[\langle_{i_1}, \ldots, \langle_{i_{m'}}]$, $m' \leq m$; reading each new parenthesis either pushes or pops from this stack. Informally, all of our efficient RNN constructions generate Dyck-(k,m) by writing to and reading from an implicit stack that they encode in their hidden states. In this section, we present some challenges in a naive approach, and then describe a construction to solve these challenges. We provide only the high-level intuition; rigorous proofs are provided in the Appendix.

5.1 An extended model

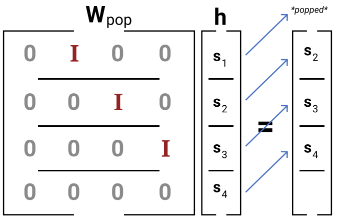
We start by describing what is achievable with an extended model family, *second-order RNNs* (Rabusseau et al., 2019; Lee et al., 1986), which allow their recurrent matrix W to be chosen as a function of the input (unlike any of the RNNs we consider.) Under such a model, we show how to store a stack of up to m k-dimensional vectors in mk memory. Such a representation can be thought of as the concatenation of m k-dimensional vectors in the hidden state, like this:



We call each k-dimensional component a "stack slot". If we want the first stack slot to always represent the top of the stack, then there's a natural way to implement pop and push operations. In a push, we want to shift all the slots toward the bottom, so there's room at the top for a new element. We can do this with an off-diagonal matrix W_{push}:[10]



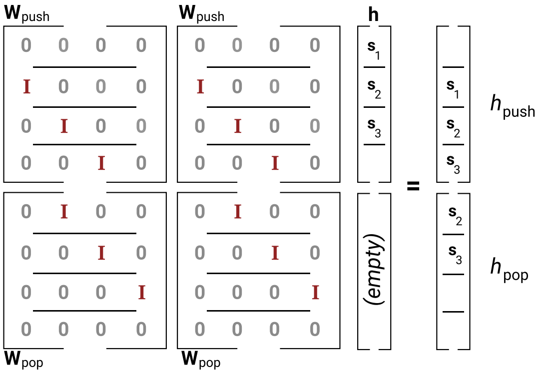
This would implement the Wh_{t-1} part of the Simple RNN equation. We can then write the new element (given by Ux_t) to the first slot. If we wanted to pop, we could do so with another off-diagonal matrix W_{pop}, shifting everything towards the top to get rid of the top element:



This won't work for a Simple RNN because it only has one W.

5.2 A Simple RNN Stack in $2mk$ memory

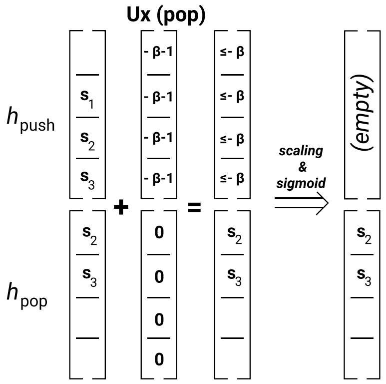
Our construction gets around the limitation of only having a single W matrix in the Simple RNN by doubling the space to $2mk$. Splitting the space h into two mk-sized partitions, we call one h_{pop}, the place where we write the stack if we see a `pop` operation, and the other h_{push} analogously for the `push` operation. If one of h_{pop} or h_{push} is empty (equal to 0) at any time, we can try reading from both of them, as follows:



Our W matrix is actually the concatenation of two of the W_{pop} and W_{push} matrices. Now we have two candidates, both h_{push} and h_{pop}; but we only want the one that corresponds to `push` if $w_t = \langle_i$, or `pop` if $w_t = \rangle_i$. We can zero out the unobserved option using the term Ux_t, adding a large negative value to every hidden unit in the stack that doesn't correspond to `push` if x_t is an open bracket $\langle_i$, or `pop` if x_t is a close bracket $\rangle_i$:

---

[10] Note that only needing to store m things means that when we push, there should be nothing in slot m; otherwise, we'd be pushing element $m + 1$.



So $Ux_{\langle_i} = [e_i; 0, \ldots, -\beta - 1, \ldots]$, where e_i is a one-hot representation of $\langle_i$, and $Ux_{\rangle_i} = [-\beta - 1, \ldots, -\beta - 1, 0, \ldots]$, where β is the very large value we specified in our finite-precision arithmetic. Thus, when we apply the sigmoid to the new $Wh_{t-1} + Ux_t + b$, whichever of $\{h_{\text{pop}}, h_{\text{push}}\}$ doesn't correspond to the true new state is zeroed out.[11]

6 Stack construction in LSTMs

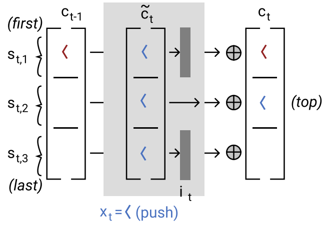
We could implement our $2mk$ Simple RNN construction in an LSTM, but its gating functions suggest more flexibility in memory management, and Levy et al. (2018) claim that the LSTM's modeling power stems from its gates. With an LSTM, we achieve the mk of the oracle we described, all while *exclusively* using its gates.

6.1 An LSTM stack in mk memory

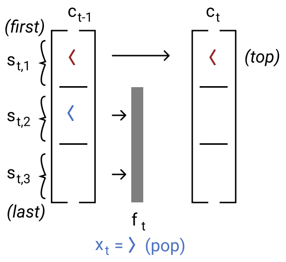
To implement a stack using the LSTM's gates, we use the same intuitive description of the stack as before: m stack slots, each of dimensionality k. However while the top of the stack is the first slot in the Simple RNN, the bottom of the stack is the first slot in the LSTM. Before we discuss mechanics, we introduce the memory dynamics of the model. Working through the example in Figure 2, when we push the first open bracket, it's assigned to slot 1; then the second and third open brackets are assigned to slots 2 and 3. Then a close bracket is seen, so slot 3 is erased. In general, the stack is represented in a contiguous sequence of slots, where the first slot represents the bottom of the stack. Thus, the top of the stack could be at *any* of the m stack slots. So to allow for ease of linearly reading out information from the stack, we store the full stack only in the cell state c_t, and let only the slot corresponding to the top of the stack, which we'll refer to as the *top slot*, through the output gate to the hidden state h_t.

Recall that the LSTM's cell state c_t is specified as $c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t$. The values f_t and i_t are the forget gate and input gate, while $\tilde{c}_t$ contains information about the new input.[12] An LSTM's hidden state h is related to the cell state as $h_t = o_t \odot \tanh(c_t)$, where o_t is the output gate.

push mechanics. To implement a `push` operation, the **input gate** finds the first free slot (that is, equal to $\mathbf{0} \in \mathbb{R}^k$) by observing that it is directly after the top slot of h_{t-1}. The input gate is set to 1 for all hidden units in this first free stack slot, and 0 elsewhere. This is where the new element will be written. The **new cell candidate** ($\tilde{c}_t$) is used to *attempt* to write the input symbol $\langle_i$ to *all* m stack slots. But because of the input gate, $\langle_i$ is only written to the first free slot. The **forget gate** is set to 1 everywhere, so the old stack state is copied into the new cell state. This is summarized in the following diagram, where the dark grey bar indicates where the gate is set to 0:



pop mechanics. To implement a `pop` operation, the **forget gate** finds the top slot, which is the slot farthest from slot 1 that *isn't* empty (that is, that encodes some $\langle_i$.) In practice, we do this by guaranteeing that the forget gate is equal to 1 for all stack slots before (but excluding) the last non-empty stack slot. Since this last non-empty stack slot encodes the top of the stac,, for it and all subsequent (empty) stack slots, the forget gate is set to 0.[13] This erases the element at the top of the stack, summarized in the following diagram:



---

[11] For whichever of $h_{\text{tmp}} \in \{h_{\text{pop}}, h_{\text{push}}\}$ that is not zeroed out, $\sigma(h_{\text{tmp}}) \neq h_{\text{tmp}}$. Hence, we scale all of U and W to be large, such that $\sigma(Wh_{t-1}) \in \{0, 1\}$.

[12] Note that, since $W_{\tilde{c}} = \mathbf{0}$, we have $\tilde{c}_t = \tanh(U_{\tilde{c}} x_t + b_{\tilde{c}})$, so it does not depend on the history h_{t-1}.

[13] The **input gate** and the **output gate** are both set to **0**.

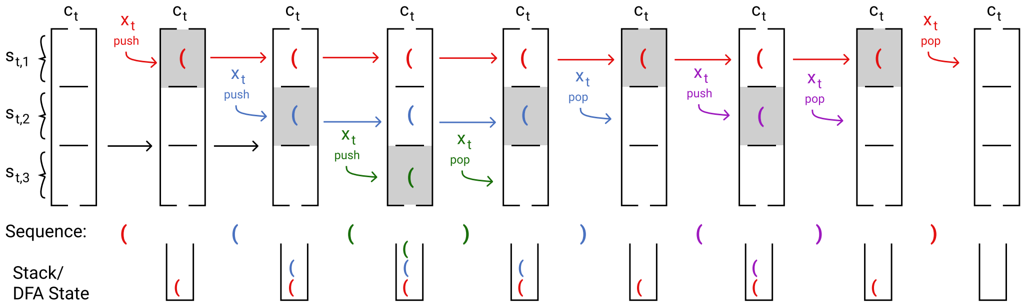


Figure 2: Example trace of the hidden state of an LSTM processing a string. The shaded slot is the top of the stack, passed through the output gate to the hidden state.

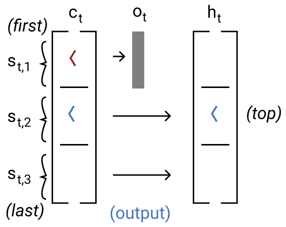
`output` **mechanics.** We've so far described how the new cell state c_t is determined. So that it's easy to tell what symbol is at the top of the stack, we only want the *top slot* of the stack passing through the output gate. We do this by guaranteeing that the output gate is equal to 0 for all stack slots from the first slot to the top slot (exclusive). The output gate is then set to 1 for this top slot (and all subsequent empty slots,) summarized in the following diagram:



7 Defining the generating distribution

So far, we've discussed how to implement implicit stack-like memory in the Simple RNN and the LSTM. However, the formal claims we make center around RNNs' ability to *generate* Dyck-(k,m).

7.1 Generation in $O(km)$ memory

Assume that at any timestep t, our stack mechanism has correctly pushed and popped each open and close bracket, as encoded in h_t, c_t. We still need to prove that our probability distribution,

$$w_t \mid w_{1:t-1} \sim \text{softmax}(Vh_{t-1} + b), \qquad (7.1)$$

assigns greater than ϵ probability only to symbols that constitute continuations of some string in Dyck-(k,m), by specifying the parameters V and b_v.

Observing any open bracket $\langle$. If and only if fewer than m elements are on the stack, all $\langle_i$ must be assigned $\geq \epsilon$ probability. This encodes the depth bound. In our constructions, m elements are on the stack if and only if stack slot m is non-zero. So, each row $V_{\langle_i}$ is zeros except for slot m, where each dimension is a large negative number, while the bias term b_v is positive.

Observing the end of the string ω. If and only if 0 elements are on the stack, the string can end. The row V_ω detects if any stack slot is non-empty.[14]

Observing close bracket $\rangle_i$. The close bracket $\rangle_i$ can be observed if and only if the top stack slot encodes $\langle_i$. Both the Simple RNN construction and the LSTM construction make it clear which stack slot encodes the top of the stack. In the Simple RNN, it's always the first slot. In the LSTM, it's the only non-empty slot in h_t. In our stack constructions, we assumed each stack slot is a k-dimensional one-hot vector e_i to encode symbol $\langle_i$. So in the Simple RNN, $V_{\rangle i}$ reads the top of the stack through a one-hot vector e_i in slot 1, while in the LSTM it does so through e_i in all m slots. This ensures that $V_{\rangle_i}^\top h_t$ is positive if and only if $\langle_i$ is at the top of the stack.

7.2 Generation in $O(m \log k)$ memory

We now show that $O(\log k)$-dimensional stack slots suffice to represent k symbols. The crucial difficulty is that we also need to be able to define V and b to be able to linearly detect which $\langle_i$ is encoded in the top of the stack.[15] A naive attempt might be treat the $\log k$ hidden units as binary variables, and represent each $\langle_i$ using the i^{th} of the $2^{\log k} = k$ binary configurations, which we denote $p^{(i)}$. This does not work because some $p^{(i)}$ are

---

[14] In particular, the bias term b_ω is positive, but the sum $V_\omega h_{t-1} + b_\omega$ is negative if the stack is not empty.

[15] A further difficulty is guaranteeing that the stack constructions still work with the encoding; due to space, we detail all of this in the Appendix.

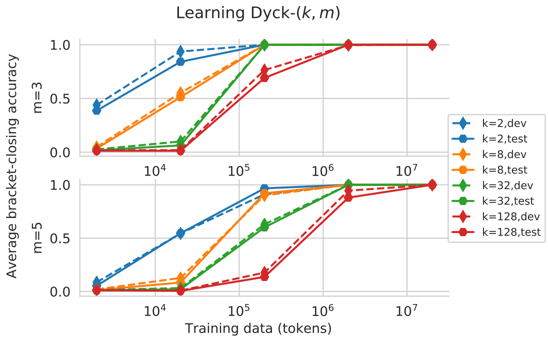


Figure 3: Learning curves for Dyck-(k,m) languages.

strict supersets of other $p^{(j)}$, so the true symbol cannot decoded through any $V^\top h_t$. To solve this, we use a constant factor more space, to ensure each symbol is decodable by V. In the first $\log k$ units of a stack slot we use the bit configuration $p^{(i)}$. In the second, we use $(1 - p^{(i)})$ (the binary negation.) Call this encoding $\psi_i \in \mathbb{R}^{2\log k}$. Using ψ_i for the row $V_{\rangle_i}$, we have the following expression for the dot product in determining the probability distribution:

$$V_{\rangle_j}^\top \psi_i = \sum_{\ell=1}^{\lceil \log k \rceil} p_\ell^{(i)} p_\ell^{(j)} + \sum_{\ell=1}^{\lceil \log k \rceil} (1 - p_\ell^{(i)})(1 - p_\ell^{(j)})$$
$$\begin{cases} = \lceil \log k \rceil & i = j \\ \leq \lceil \log k \rceil - 1 & i \neq j \end{cases}$$

Thus, we can always detect which symbol $\langle_i$ is encoded by setting $b_{\rangle_i} = \log k - 0.5$.[16]

8 Experiments

Our proofs have concerned constructing RNNs that generate Dyck-(k,m); now we present a short study connecting our theory to learning Dyck-(k,m) from finite samples. In particular, for $k \in \{2, 8, 32, 128\}$ and $m \in \{3, 5\}$, we use our theory to set the hidden dimensionality of LSTMs to $3m\lceil \log k \rceil - m$, and train them as LMs on samples from a distribution[17] over Dyck-(k,m). For space, we provide an overview of the experiments, with details in the Appendix. We evaluate the models' abilities to extrapolate to unseen lengths by setting a maximum length of 84 for $m = 3$, and 180 for $m = 5$, and testing on sequences longer than those seen at training time.[18] For our evaluation metric, let p_j be the probability that the model predicts the correct closing bracket given that j tokens separate it from its open bracket. We report $\text{mean}_j p_j$, to evaluate the model's bracket-closing memory.

For all configurations, we find that the LSTMs using our memory limit achieve error less than 10^{-4} when trained on 20 million tokens. Strikingly, this is despite the fact that for large m and k, a small fraction of the possible stack states is seen at training time;[19] this shows that the LSTMs are not simply learning k^m structureless DFA states. Learning curves are provided in Figure 3.

9 Discussion and conclusion

We proved that finite-precision RNNs can generate Dyck-(k,m), a canonical family of bounded-depth hierarchical languages, in $O(m \log k)$ memory, a result we also prove is tight. Our constructions provide insight into the mechanisms that RNNs and LSTMs can implement.

The Chomsky hierarchy puts all finite memory languages in the single category of regular languages. But humans generating natural language have finite memory, and context-free languages are known to be both too expressive and not expressive enough (Chomsky, 1959; Joshi et al., 1990). We thus suggest the further study of what *structure* networks can encode in their memory (here, stack-like) as opposed to (just) their position in the Chomsky hierarchy. While we have settled the representation question for Dyck-(k,m), many open questions still remain: What broader class of bounded hierarchical languages can RNNs efficiently generate? Our experiments point towards learnability; what class of memory-bounded languages are efficiently learnable? We hope that answers to these questions will not just demystify the empirical success of RNNs but ultimately drive new methodological improvements as well.

Reproducibility Code for running our experiments is available at `https://github.com/john-hewitt/dyckkm-learning`. An executable version of the experiments in this paper is on CodaLab at `https://worksheets.codalab.org/worksheets/0xd668cf62e9e0499089626e45affee864`.

---

[16] In actuality, we use a slightly less compact encoding, spending $\log k - 1$ more hidden units set to 1, to incrementally subtract $\log k - 1$ from all logits. Then the bias terms $b_{\rangle i}$ are set to 0.5, avoiding possible precision issues with representing the float $\lceil \log k \rceil - 0.5$.

[17] Defined in Appendix H

[18] Up to twice as long as the training maximum.

A Appendix outline

This Appendix has the following order. In (§B), we provide a definition of Dyck-(k,m) equivalent to that in the main text but more useful for our proofs. In (§C), we state preliminary definitions and assumptions, and prove the lower-bound of $\Omega(m \log k)$ hidden units to generate Dyck-(k,m). In (§D), we formally introduce our Simple RNN stack construction, and prove its correctness in a lemma. In (§E), we formally introduce our LSTM stack construction, and prove its correctness in a lemma. In (§F), we prove that a linear (+softmax) decoder on the Simple RNN and LSTM hidden states can be used to generate Dyck-(k,m) in $O(mk)$ hidden units using a 1-hot encoding of stack elements. In this section we also prove that a general RNN construction of DFAs allows for generation of Dyck-(k,m) in $O(k^{m+1})$ hidden units. In (§G), we provide an alternative encoding of elements in our stack constructions for the Simple RNN and LSTM that uses $O(\log k)$ space per element, and prove that our stack constructions still hold using this encoding. We provide a linear (+softmax) decoder on the hidden states of the Simple RNN and LSTM (when using the $O(\log k)$ stack element encoding) that can be used as a drop-in replacement for the decoder from the 1-hot representations, thus generating Dyck-(k,m). This proving that both the Simple RNN and LSTM generate Dyck-(k,m) in $O(m \log k)$ hidden units.

B The Dyck-(k,m) languages

To better understand the success of neural networks on natural language syntax, we aim for a formal language that models the unbounded recursiveness of natural language while also reflecting its bounded memory requirements. We thus introduce the Dyck-(k,m) languages, corresponding to sequences of balanced brackets of k types with a maximal number of m unclosed brackets at any point in the sequences (yielding a bound stack depth of m to parse such sentences).

Though in the main text we defined Dyck-(k,m) by intersecting Dyck-k with a language that simply bounds the difference between the number of open brackets and the number of close brackets, here we provide an equivalent definition that will aid in our proofs. Each Dyck-(k,m) language, specified by fixing a value of m and k, is defined using a deterministic finite automaton (DFA). Here, we provide a general description of any Dyck-(k,m)

DFA.

Formally, we define each language by the deterministic finite automaton $\mathcal{D}_{m,k} = (Q, \Sigma, \delta, F, q_0)$. The vocabulary Σ consists of k types of open brackets: $\{\langle_i\}_{i=1,\dots,k}$ corresponding closing brackets $\{\rangle_i\}_{i=1,\dots,k}$. Strings over the vocabulary are $w_{1:T} \in \Sigma^*\omega$, where $\omega \notin \Sigma$ is a special symbol representing the end of the sequence. $\Sigma \cup \{\omega\}$ are collectively referred to as symbols.

This slightly nonstandard requirement allows for a natural connection with language models, which must estimate the probability that a string ends at any given token.[20] Overloading notation, we'll also use $\mathcal{D}_{m,k}$ to refer to the language (the set of strings) itself, defined as the strings accepted by the DFA.

B.1 DFA States, Q

We now define the states $q \in Q$. First, we define reject state r, and accept state $[\omega]$. Each other state is uniquely identified by a list of open bracket symbols of length up to m; thus the full set of states is provided by:

$$Q = \{[\omega], r\} \cup \left\{[\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}]\right\}_{m' \in 1\dots m, i_j \in 1\dots k}$$

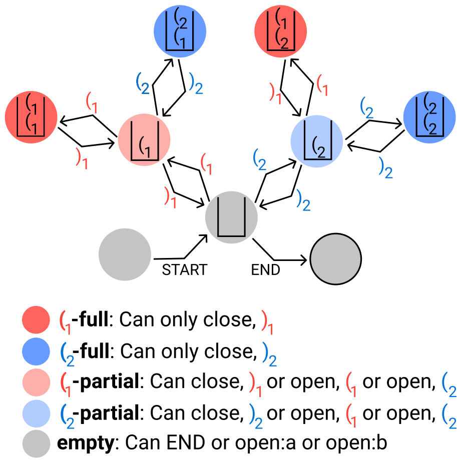

Figure 4: A deterministic finite automaton describing the transitions of 2-bounded Dyck-2 that do not lead to a reject state (omitted for space) and a qualitative description of the classes of states.

The number of states is thus $k^{m+1}+1$, where all but two states reflect a list of open brackets. We will denote each list $[\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}]$, $0 \leq m' \leq m$ as a *stack state* with m' *elements*, and the value of $\langle_{i_{m'}}$ as the top element of the stack. We let $q_0 = [] = [\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}]$, $m' = 0$, the empty stack state.

B.2 Transition function, δ

We now define the transition function, δ.

Empty stack state The state $[]$ can transition either to the accept state or to another stack state:

$$\delta([], \omega) = [\omega] \tag{B.1}$$
$$\delta([], \langle_i) = [\langle_i] \tag{B.2}$$

while any other symbol transitions to the reject state.

Partial list states For any state of the form $[\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}]$, where $m' < m$, an open bracket can be pushed to the list (since $m' < m$), or the last open bracket can be removed, by observing its corresponding close bracket.

$$\delta([\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}], \langle_i) = [\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}, \langle_i] \tag{B.3}$$

$$\delta([\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'}}], \rangle_{i_{m'}}) = [\langle_{i_1}\langle_{i_2}, \dots, \langle_{i_{m'-1}}] \tag{B.4}$$

All other symbols transition to the reject state.

---

[20] But crucially, since $\omega \notin \Sigma$, the language model need not define a distribution *after* ω is seen; it can only be the last token.

Full list states For any state of the form $[\langle_{i_1}\langle_{i_2},\ldots,\langle_{i_m}]$, that is, the list is of length m and thus full, the close bracket of the top of the stack removes that bracket,

$$\delta([\langle_{i_1}\langle_{i_2},\ldots,\langle_{i_m}],\rangle_{i_m}) = [\langle_{i_1}\langle_{i_2},\ldots,\langle_{i_{m-1}}] \tag{B.5}$$

All other symbols transition to the reject state.

r The reject state r transitions to itself for all symbols.

$[\omega]$ No transitions from the accept state need be defined, since only $\delta([],\omega)=[\omega]$, and ω must be the last symbol of any string in the universe, and can only occur once.

This accounts for the transition function from all states in Q, and completes our definition of the DFA $D_{m,k}$. We are now prepared to formally define the language:

Definition 6 (Dyck-(k,m))**.** For any $k,m \in \mathbb{Z}^+$, The language Dyck-(k,m) is the set of strings accepted by the DFA $D_{m,k}$; overloading notation: $D_{m,k} \subseteq \Sigma^*\omega$.[21]

Overloading notation, for any $w_{1:T} \in \Sigma^*\omega$, for any $t \in 1,\ldots,T$, we'll say $q_t = D_{m,k}(w_{1:t})$, denoting the state that $D_{m,k}$ is in after consuming $w_{1:t}$.

C Preliminaries

Definition 4 (locally ϵ-truncated support)**.** Let f_θ be a probability distribution over $\Sigma^*\omega$, with conditional probabilities $f_\theta(w_t|w_{1:t-1})$. Then the locally ϵ-truncated support of the distribution is the set

$$\{w_{1:T} \in \Sigma^*\omega : \forall_{t\in 1\ldots T}, f_\theta(w_t|w_{1:t-1}) \geq \epsilon\}.$$

Through the notion of ϵ-truncated support, a language model specifies which tokens are allowable continuations of each string prefix by assigning them greater than ϵ probability. With this, we're ready to connect RNNs and formal languages:

Definition 7 (generating a language)**.** A probability distribution f_θ generates a formal language $\mathcal{L}$ if there exists $\epsilon > 0$ such that the ϵ-truncated support $\mathcal{L}_{f_\theta}$ is equal to $\mathcal{L}$.

C.1 Technical considerations

Definition 8 (fixed-precision setting)**.** For language parameters m,k of $D_{m,k}$, and input sequence lengths T, we assume that each floating-point value can be specified in $p \in O(1)$ bits (that is, not scaling in any parameter.) These bits choose elements of the set $\mathbb{P} \subset \mathbb{Q}$; we do not specify how $\mathbb{P}$ must be set. The $\mathbb{P}$ chosen for our constructions is described in Appendix G.3, after the relevant constants have been defined.

Under our finite-precision setting, a reasonable assumption about the properties of the sigmoid and hyperbolic tangent functions make our claim considerably simpler. The sigmoid function, $\sigma(x) = \frac{1}{1+e^{-x}}$, has range $(0,1)$, excluding its boundaries $\{0,1\}$. However, in a finite-precision arithmetic, $\sigma(x)$ cannot become arbitrarily close to 0 or 1. In fact, in popular deep learning library PyTorch[22], $\sigma(x)$ is exactly equal to 1 for all $x > 6$. We define the floating point sigmoid function to equal 0 or 1 if the absolute value of its input is greater or equal in absolute value to some threshold β:

$$\sigma_{\text{fp}}(x) = \begin{cases} \sigma(x) & -\beta < x < \beta \\ 1 & x \geq \beta \\ 0 & x \leq -\beta, \end{cases} \tag{C.1}$$

Similarly for the hyperbolic tangent function, we define:

$$\tanh_{\text{fp}}(x) = \begin{cases} \tanh(x) & -\beta < x < \beta \\ 1 & x \geq \beta \\ -1 & x \leq -\beta, \end{cases} \tag{C.2}$$

For the rest of this paper, we will refer to σ_{fp} as σ, and $\tanh_{\text{fp}}$ as tanh.

C.2 Lower bound of $\Omega(m \log k)$ for generation of Dyck-(k,m)

Theorem 6 ($\Omega(m\log k)$ to generate Dyck-(k,m))**.** *Let A be an arbitrary function from d-dimensional vectors and symbols $w_t \in \Sigma$ to d-dimensional vectors; $A : \mathbb{P}^d \times \Sigma \rightarrow \mathbb{P}^d$, $A(h_{t-1}, w_t) \mapsto h_t$. Let ψ be an arbitrary function from $\mathbb{P}^d$ to probability distributions over $\Sigma \cup \{\omega\}$. Let f_ψ be a probability distribution over $\Sigma^*\omega$, with the form $f_\psi(w_{1:T}) = \prod_{t=1}^{T} f(w_t|w_{1:t-1})$, where $f(w_t|w_{1:t-1}) = \psi(h_{t-1})$. If f generates Dyck-(k,m), then $d \geq \frac{m\log k}{p} = \Omega(m\log k)$.*

---

[21] Where Z^+ denotes the positive integers.

[22] Under the `float` datatype, PyTorch v1.3.1 (Paszke et al., 2019).

Proof. We provide a communication complexity argument. Assume for contradiction that there exists such a machine with $d < \frac{m \log k}{p}$. Consider any string $w_{1:m} = \langle_{i_1}, \ldots, \langle_{i_m}$ of m open brackets, where each is one of k types. There are k^m such strings, but because $d < \frac{m \log k}{p}$, we have that the model has $2^{dp} < k^m$ possible representations, so at least two such strings must share the same representation. Let such a pair be $w \neq w'$, where likewise w' is defined as $\langle_{i'_1}, \ldots, \langle_{i'_m}$. Consider the sequence of open bracket indices that defines w: $i_1, \ldots, i_m$. Let s be the string $\rangle_{i_m}, \ldots, \rangle_{i_1}$ of close brackets in the reverse order of the indices of w, and likewise s' for w'.

The string $w :: s$, where :: denotes concatenation, is in Dyck-(k,m). However, $w' :: s$ is not in Dyck-(k,m) as it breaks the well-nested brackets condition wherever $\langle_{i_j} \neq \langle_{i'_j}$. This must occur at least once, since $w \neq w'$. Since the model assigns them the same representation even though they must be distinguished to generate Dyck-(k,m), the model does not generate Dyck-(k,m).

D Proving Simple RNN stack correspondence in $2mk$ units

In this section, we provide a formal description of our Simple RNN stack construction, and introduce and prove the *stack correspondence lemma*, to guarantee its correctness.

Definition 2 (Simple RNN (generator))**.** A Simple RNN (generator) with d hidden units is a probability distribution f_θ of the following form:

$$
\begin{aligned}
&h_0 = \mathbf{0} \\
&h_t = \sigma(W h_{t-1} + U x_t + b) \\
&w_t | w_{1:t-1} \sim \text{softmax}(g_\theta(h_{t-1}))
\end{aligned}
$$

where $h_t \in \mathbb{R}^d$ and the function g has the form $g_\theta(h_{t-1}) = V h_{t-1} + b_v$. The input $x_t = E w_t$; overloading notation, w_t is the one-hot (indicator) vector representing the respective word. θ is the set of trainable parameters, W, U, b, V, b_v, E.

Encoding a Stack in the Hidden State We define mappings between Q—the DFA state space—and the RNN's state space $\mathbb{R}^{2km}$. First, we encode a stack into a km-dimensional vector as follows:

$$
\begin{aligned}
&R([\langle_{i_1}, \langle_{i_2}, \ldots, \langle_{i_{m'}}]) \\
&\qquad = [e_{i_1}, e_{i_2}, \ldots, e_{i_{m'}}, \mathbf{0}_{\in \mathbb{R}^{(m-m')k}}] \quad \text{(D.1)}
\end{aligned}
$$

where $[\ldots]$ denotes concatenation of vectors into a km-dimensional vector. We note that R is injective, that is, the inverse map R^{-1} is well-defined on all vectors in the image of R.

Later, when constructing the efficient $O(m \log k)$ memory encoding in Section G.1, we will swap the one-hot vectors e_i for other vectors that will also have entries in $\{0, 1\}$.[23]

Based on this, $\mathcal{S}$ maps a pair of a stack operation ($\sigma \in \{push, pop\}$) and a DFA state q (assuming $q \notin \{r, [\omega]\}$) to a hidden state in $\mathbb{R}^{2km}$:

$$
\mathcal{S}(\sigma, q) = \begin{cases} [R(q), \mathbf{0}_{\in \mathbb{R}^{km}}] & \sigma = push \\ [\mathbf{0}_{\in \mathbb{R}^{km}}, R(q)] & \sigma = pop \end{cases} \quad \text{(D.2)}
$$

Let $\mathcal{R} := Im(\mathcal{S}) \subset \mathbb{R}^{2km}$. By writing a hidden state $h \in \mathcal{R}$ as $h = [h_{push}, h_{pop}]$, we can obtain the corresponding DFA state by

$$
\mathcal{Q}(h) = R^{-1}(h_{push} + h_{pop}) \quad \text{(D.3)}
$$

If $h = \mathcal{S}(\sigma, q)$, then the definition guarantees that $\mathcal{Q}(h) = q$.

Defining Transition Matrices To define the RNN (apart from V, b_v), we have to specify the matrices W, U, E,, and the vector b.

We start by defining $W \in \mathbb{R}^{2km \times 2km}$. Let $M_{pop}, M_{push} \in \mathbb{R}^{km \times km}$ be the matrices where

$$
(M_{pop})_{i,j} = \begin{cases} 2\beta & i = j + k \\ 0 & o.w. \end{cases} \quad \text{(D.4)}
$$

$$
(M_{push})_{i,j} = \begin{cases} 2\beta & i = j - k \\ 0 & o.w. \end{cases} \quad \text{(D.5)}
$$

Let I_{km} be the $km \times km$ identity matrix. Take $W \in \mathbb{R}^{2km \times 2km}$ defined as

$$
W = \begin{pmatrix} M_{push} \\ M_{pop} \end{pmatrix} \cdot \begin{pmatrix} I_{km} & I_{km} \end{pmatrix} \quad \text{(D.6)}
$$

To specify the matrices E and U, we need to fix an assignment to the integers $1, \ldots, 2k$ to the symbols in Σ. We will assign the integers $1, \ldots, k$ to the opening brackets (i.e., $\langle_1 \mapsto 1, \ldots, \langle_k \mapsto k$), and the integers $1, \ldots, k$ to the closing brackets (i.e., $\rangle_1 \mapsto k+1, \ldots, \rangle_k \mapsto 2k$).

---

[23] Looking ahead to the more complex LSTM construction, we'll introduce notation to denote these vectors $e_i = \psi^{-1}(\langle_i)$, and look to replace ψ when we develop the $O(m \log k)$ construction.

Define $E := I_{2k\times 2k}$, and define $U \in \mathbb{R}^{2km\times 2k}$ as:

$$\begin{pmatrix} 2\beta I_{k\times k} & -2\beta\cdot\mathbf{1}_{k\times k}\\ \mathbf{0}_{(m-1)k\times k} & -2\beta\cdot\mathbf{1}_{(m-1)k\times k}\\ -2\beta\cdot\mathbf{1}_{k\times k} & \mathbf{0}_{k\times k}\\ -2\beta\cdot\mathbf{1}_{(m-1)k\times k} & \mathbf{0}_{(m-1)k\times k}\end{pmatrix} \tag{D.7}$$

Here, we write $I_{k\times k}$ for the identity matrix, and $\mathbf{1}_{k\times k}$ for a matrix filled entirely with ones.

Finally, we define

$$b := -\beta\cdot\mathbf{1}_{\mathbb{R}^{2km}} \tag{D.8}$$

Proof of Correctness To prove correctness of the construction, the first step is to show that the transition dynamics of the Simple RNN correctly simulates the dynamics of the stack when consuming one symbol.

Let $\phi(\langle_i) = push$, $\phi(\rangle_i) = pop$.

Lemma 1 (One-Step Lemma)**.** *Assume that the hidden state h_t encodes a stack q:*

$$\mathcal{Q}(h_t) = q \tag{D.9}$$

Let w_{t+1} be the new input symbol, and assume that $w_{1:t+1}$ is a valid prefix of a word in Dyck-(k,m). Let h_{t+1} be the next hidden state, after reading w_{t+1}. Then

$$\mathcal{S}(\phi(w_{t+1}), \delta(q, w_{t+1})) = h_{t+1} \tag{D.10}$$

Before showing this lemma, we note the following property of the activation function σ, under the finite precision assumption:

Lemma 2. *If $u \in \{0, 1\}$, then*

$$\sigma\left(\beta\cdot(2u-1)\right) = u \tag{D.11}$$

$$\sigma\left(\beta\cdot(2u-3)\right) = 0 \tag{D.12}$$

Proof. By calculation. □

Proof of the Lemma. We can write $h_t = [h_{push}, h_{pop}]$. Set $h' = h_{push} + h_{pop}$. By construction of $\mathcal{S}$,

$$h' = R(q) \tag{D.13}$$

We will write $h' = [h'_1, \dots, h'_m]$, where $h'_i \in \mathbb{R}^k$.

At this point, we note that the only relevant property of the encodings h'_i for this proof is that their entries are in $\{0, 1\}$, not that they are one-hot vectors. This will make it possible to plug in a more efficient $O(\log k)$ encoding later in Section G.1.

With this, we can write

$$Wh_t = \begin{pmatrix} M_{push}h' \\ M_{pop}h'\end{pmatrix} = \begin{pmatrix} 2\beta[\mathbf{0}_{\in\mathbb{R}^{km}}, h'_1, \dots, h'_{m-1}] \\ 2\beta[h'_2, \dots, h'_m, \mathbf{0}_{\in\mathbb{R}^{km}}]\end{pmatrix} \tag{D.14}$$

Case 1: Assume $w_{t+1} = \langle_i$. We have

$$Ux_t = [2\beta e_i, \mathbf{0}_{(m-1)k}, -2\beta\mathbf{1}_{mk}] \tag{D.15}$$

so that $Wh_{t-1} + Ux_t + b$ equals

$$\begin{pmatrix} 2\beta[e_i, h'_1, \dots, h'_{m-1}] - \beta\mathbf{1} \\ 2\beta[h'_2, \dots, h'_{m-1}, h'_m, \mathbf{0}] - 3\beta\mathbf{1}\end{pmatrix} \tag{D.16}$$

Then, by Lemma 2, h_{t+1} equals

$$\begin{pmatrix} [e_i, h'_1, \dots, h'_{m-1}] \\ \mathbf{0}_{km}\end{pmatrix} \tag{D.17}$$

which is equal to $S(push, \delta(q, \langle_i))$.

Case 2: Assume $w_{t+1} = \rangle_i$. We have

$$Ux_t = [-2\beta\mathbf{1}_{mk}, \mathbf{0}_{mk}] \tag{D.18}$$

so that $Wh_{t-1} + Ux_t + b$ equals

$$\begin{pmatrix} 2\beta[\mathbf{0}, h'_1, \dots, h'_{m-1}] - 3\beta\mathbf{1} \\ 2\beta[h'_2, \dots, h'_{m-1}, h'_m, \mathbf{0}] - \beta\mathbf{1}\end{pmatrix} \tag{D.19}$$

Then, h_{t+1} equals

$$\begin{pmatrix} \mathbf{0}_{km} \\ [h'_2, \dots, h'_m, \mathbf{0}]\end{pmatrix} \tag{D.20}$$

which is equal to $S(push, \delta(q, \rangle_i))$. □

From the previous lemma, we can derive the following Stack Correspondence lemma, which asserts that the Simple RNN correctly reflects stack dynamics over an entire input string:

Lemma 3 (Stack Correspondence)**.** *For all strings $w_{1:T}$ in Dyck-(k,m), for all $t = 1, ..., T$, let q_t be the state of $D_{m,k}$ after consuming prefix $w_{1:t}$. Let h_t be the RNN hidden state after consuming $w_{1:t}$. Then if $q_t \notin \{[\omega]\}$,*

$$\mathcal{Q}(h_t) = q_t, \tag{D.21}$$

Proof. The claim is shown by induction over t, applying the previous lemma in each step. We will show the claim for all $t = 0, 1, \dots, T$, setting h_0 to be the zero vector $\mathbf{0}_{2km}$.

As $\mathcal{Q}(h_0) = q_0$, this proves the claim for $t = 0$. To prove the inductive step, we assume $\mathcal{Q}(h_t) = q_t$ has already been shown.

Then, by the preceding One-Step Lemma,

$$\mathcal{S}(\phi(w_{t+1}), \delta(q_t, w_{t+1})) = h_{t+1} \tag{D.22}$$

Noting $q_{t+1} = \delta(q_t, w_{t+1})$, we obtain

$$\mathcal{S}(\phi(w_{t+1}), q_{t+1}) = h_{t+1} \tag{D.23}$$

As noted in the definition of $\mathcal{Q}$ above (D.3), this entails

$$\mathcal{Q}(h_{t+1}) = q_{t+1} \tag{D.24}$$

concluding the inductive step.

□

E Proving LSTM stack correspondence in mk units

In this section, we prove our lemma describing the stack construction implemented by an LSTM. To do so, we first define the LSTM:

Definition 3 (LSTM (generator))**.** An LSTM (generator) with d hidden units is a probability distribution f_θ of the following form:

$$\begin{aligned}
&h_0, c_0 = \mathbf{0}\\
&f_t = \sigma(W_f h_{t-1} + U_f x_t + b_f)\\
&i_t = \sigma(W_i h_{t-1} + U_i x_t + b_i)\\
&o_t = \sigma(W_o h_{t-1} + U_o x_t + b_o)\\
&\tilde{c}_t = \tanh(W_{\tilde{c}} h_{t-1} + U_{\tilde{c}} x_t + b_{\tilde{c}})\\
&c_t = f_t \odot c_{t-1} + i_t \odot \tilde{c}_t\\
&h_t = o_t \odot \tanh(c_t)\\
&w_t | w_{1:t-1} \sim \text{softmax}(g_\theta(h_{t-1}))
\end{aligned}$$

where $h_t, c_t \in \mathbb{R}^d$, the function g has the form $g_\theta(h_{t-1}) = Vh_{t-1} + b$, and $x_t = Ew_t$, where w_t is overloaded as above. θ is the set of trainable parameters: all W, U, b, as well as V, E.

First, we provide notation for describing the structure of the memory cell (c_t) that f_θ will maintain. Next, we proceed to describe precisely, but without referring to the LSTM equations, how this memory changes over time. We then describe how these high-level dynamics are implemented by the LSTM equations, assuming that we're able to set the values of the intermediate values (gates and new cell candidate) as desired. We then explicitly construct LSTM weight matrices that provide the desired intermediate values. This completes the proof of the memory dynamics, which we formalize in a *stack correspondence lemma* once we've introduced the notation.

E.1 Description of stack-structured memory

Our LSTM construction operates by constructing, in its cell state, a representation of the list that defines the DFA stack state. To make this idea formal, we define a mapping from $\mathbb{R}^d$, the space of the LSTM cell state, to Q, the DFA state space.

To do so, we need some language for discussing the LSTM cell states. For a cell state $c_t \in \mathbb{R}^{mk}$, we define a list of m *stack slots*, $s_{t,1}, ..., s_{t,m}$, where $s_{t,j} \in \mathbb{R}^k$ is given by dimensions

$$s_{t,j} = c_t[k(j-1)+1 : kj+1] \tag{E.1}$$

Intuitively, each stack slot will correspond to one item in the list defining a stack state in the DFA $D_{m,k}$, or be empty. We formalize this by defining a function from stack slots $s_{t,j} \in \mathbb{R}^d$ to elements:

$$\psi(s_{t,j}) = \begin{cases} \langle_i & s_{t,j} = e_i \\ \varnothing & s_{t,j} = \mathbf{0} \end{cases} \tag{E.2}$$

where $e_i \in \mathbb{R}^k$ is the i^{th} standard basis vector (one-hot vector) of $\mathbb{R}^k$. We'll also use the inverse map, ψ^{-1}, to map from elements to vectors in $\mathbb{R}^k$.

Applying this function to each stack slot allows us to map from $s_{t,1}, \ldots, s_{t,m}$ to stack states:

$$\mathcal{Q}(s_{t,1}, \ldots, s_{t,m}) = [\psi(s_{t,1}), \ldots, \psi(s_{t,m'})] \tag{E.3}$$

where $m' \leq m$ is the maximal integer such that $\psi(s_{t,m'}) \neq \varnothing$. Intuitively, this means we filter out any empty stack slots at the end of the sequence (those slots $s_{t,j}$ where $j > m'$.) We'll also make use of the inverse, $\mathcal{Q}^{-1}$, mapping DFA stack states to stack slot lists,

$$\begin{aligned}
&\mathcal{Q}^{-1}([\langle_{i_1}, \ldots, \langle_{i_{m'}}])\\
&\quad = \mathcal{Q}^{-1}([\langle_{i_1}, \ldots, \langle_{i_{m'}}, \varnothing, \ldots, \varnothing])\\
&\quad = \psi^{-1}(\langle_{i_1}), \ldots, \psi^{-1}(\langle_{i_{m'}}), \mathbf{0}, \ldots, \mathbf{0}\\
&\quad = e_{i_1}, \ldots, e_{i_{m'}}, \mathbf{0}, \ldots, \mathbf{0}
\end{aligned}$$

where slots $s_{m'+1}, \ldots, s_m$ are the zero vector $\mathbf{0}$ because only the first m' slots encode a symbol $\langle_i$, and $\psi(\mathbf{0}) = \varnothing$.

On the ψ function These one-hot encodings (e_i) of symbols ($\langle_i$) allow for clear exposition, but are not fundamental to the construction; in (§ G), we replace these k-dimensional one-hot encodings given by ψ with $O(\log k)$-dimensional encodings. Throughout our description of the stack construction, we'll explicitly rely on the following property, so we can easily replace this particular ψ in (§ G) by providing another ψ' with the same property.

Definition 9 (encoding-validity property)**.** Let ψ' be a function $\psi' : \{\langle_i\}_{i \in [k]} \rightarrow \mathbb{R}^n$ mapping open brackets to vectors in $\mathbb{R}^n$. Then ψ' obeys the encoding-validity property if for all $i = 1, \ldots, k$,

$$\sum_{\ell=1}^{n} \psi^{-1}(\langle_i)_\ell = 1 \tag{E.4}$$

that is, the sum of all dimensions of the representation is equal to 1, and

$$\forall_{i \in [k]} \psi^{-1}(\langle_i) \in \{0,1\}^n \tag{E.5}$$

that is, the representation takes on values only in 0 and 1, and

$$\psi(\mathbf{0}) = \varnothing, \tag{E.6}$$

that is, the empty stack slot is encoded by the zero vector, and

$$\forall_{i,j\in[k]}, i \neq j \implies \psi^{-1}(\langle_i) \neq \psi^{-1}(\langle_j) \tag{E.7}$$

$$\forall_{i\in[k]}, \psi^{-1}(\langle_i) \neq \mathbf{0} \tag{E.8}$$

that is, encodings of symbols $\langle_i$ are unique, and none are equal to to the encoding of the empty symbol $\varnothing$.

The encoding we've so far provided, $\psi^{-1}(e_i) = \langle_i$, obeys these properties: the sum of a single one-hot vector is 1, no two such vectors are the same, one-hot vectors only take on values in $\{0, 1\}$, and we let $\psi(\mathbf{0}) = \varnothing$.

E.2 Description of stack state dynamics

Before we describe the memory dynamics, we introduce a useful property of the stack slots.

Definition 10 (j-top)**.** A cell state c_t composed of stack slots $s_{t,1}, \dots, s_{t,m}$ is j-top if there exists $i \in \{1, \dots, k\}$ such that $s_{t,j} = \psi^{-1}(\langle_i)$, and for all $j' \in \{j+1, \dots, m\}$, $s_{t,j'} = \mathbf{0}$.

Intuitively, we'll enforce the constraint that a cell state that is j-top **encodes the element $\langle_{m'}$ at the top of the stack $[\langle_i, \dots, \langle_{m'}]$ in stack slot $j = m'$.**

We're now ready to describe the memory dynamics of f_θ. The memory c_t is initialized to $\mathbf{0}$. So for all $j \in \{1, \dots, m\}$,

$$s_{0,j} = \mathbf{0} \tag{E.9}$$

The recurrent equation of stack slots is then

$$s_{j,t} = \begin{cases} \mathbf{0} & c_{t-1} \text{ is } j\text{-top, and } w_t = \rangle_i \\ \psi^{-1}(\langle_i) & j = 1, c_{t-1} = \mathbf{0}, \text{ and } w_t = \langle_i \\ \psi^{-1}(\langle_i) & c_{t-1} \text{ is } (j-1)\text{-top and } w_t = \langle_i \\ s_{t-1,j} & o.w. \end{cases} \tag{E.10}$$

Intuitively, the first case of Equation E.10 implements pop, the second case implements push (if pushing to an otherwise empty stack) and the third case implement push (if pushing to a non-empty stack). The fourth case specifies that slots that are not pushed to or popped are maintained from timestep $t-1$ to timestep t.

So far, our definitions of the LSTM memory have concerned the cell state, c_t. However, the values of the gates f_t, i_t, o_t, as well as the new cell candidate $\tilde{c}_t$, are functions not of the previous cell state but the previous hidden state, $h_{t-1} = o_{t-1} \odot \tanh(c_{t-1})$. The dynamics of h_t under f_θ we specify as follows, using the same notation $h_{t,j}$ to refer to the dimensions of h_t that correspond to slack slot $s_{t,j}$ of c_t:

$$h_{t,j} = \begin{cases} \tanh(\psi^{-1}(\langle_i)) & c_t \text{ is } j\text{-top} \\ & \text{and } s_{t,j} = \psi^{-1}(\langle_i) \\ \mathbf{0} \in \mathbb{R}^k & o.w., \end{cases} \tag{E.11}$$

Intuitively, this means **only the top of the stack is stored in the hidden state**, and it's stored in whichever units correspond to the j-top slot in c_t. Since $\psi^{-1}(\langle_i)$ takes on values in $\{0, 1\}$, $\tanh(\psi^{-1}(\langle_i))$ takes on values in $\{0, \tanh(1)\}$.

We're now ready to formalize the first part of our proof in a lemma that encompasses how f_θ structures and manipulates its memory.

Lemma 4 (stack correspondence)**.** *For all strings $w_{1:T}$ in Dyck-(k,m), for all $t = 1, ..., T$, let q_t be the state of $D_{m,k}$ after consuming prefix $w_{1:t}$. Let c_t be the hidden state of the LSTM after consuming $w_{1:t}$. Then if $q_t =\notin \{[\omega]\}$,*

$$\mathcal{Q}(s_{t,1}, \dots, s_{t,m}) = q_t, \tag{E.12}$$

and letting $q_t = [\langle_{i_1}, \dots, \langle_{i_{m'}}]$ for $m' \leq m$ without loss of generality,

$$h_{t,j} = \begin{cases} \tanh(\psi^{-1}(\langle_{i_{m'}})) & j = m' \\ \mathbf{0} & o.w. \end{cases} \tag{E.13}$$

where if $q_t = []$, then $m' = 0$ and $h_{t,j} = \mathbf{0}$ for all j.

Note again that the value of ψ^{-1} is not specified by the lemma; whereas so far we've used $\psi^{-1}(\langle_i) = e_i$, a one-hot encoding, in (§ G) we'll replace ψ^{-1} while maintaining the lemma.

Intuitively, Equation E.12 states that f_θ keeps an exact representation of the stack of unclosed open brackets so far, a statement solely concerning the cell state c_t. However, all intermediate values in the LSTM equations are functions of the hidden state h_t, not the cell state directly; Equation E.13 states how the top of the stack is represented in the hidden state, h_t. We state these as one lemma since it is convenient to prove them by induction together.

E.3 Proof of the stack correspondence lemma assuming stack slot dynamics

We first prove Lemma 4 under the assumption that the stack slot dynamics given in Equation E.10 hold. We proceed by induction on the prefix length.

When the prefix length is 0, the DFA is in state $[]$, and $s_{0,j} = \mathbf{0}$ for all j, so $\mathcal{Q}(s_{0,1}, \dots, s_{0,m}) = []$, as required. Further, we have $h_0 = \mathbf{0}$, as required. This completes the base case.

Assume for the sake of induction that Lemma 4 holds for strings up to length t. Now consider a prefix $w_{1:t+1}$. From it, we can take the prefix $w_{1:t}$. Running f_θ, we have $s_{t,1}, \dots, s_{t,m}$. By the induction hypothesis, we have that $\mathcal{Q}(s_{t,1}, \dots, s_{t,m}) = q_t = [\langle_{i_1}, \dots, \langle_{i_{m'}}]$, (Equation E.12) as well as that

$$h_{t,j} = \begin{cases} \tanh(\psi^{-1}(\langle_{i_{m'}})) & j = m' \\ \mathbf{0} & o.w. \end{cases}$$

by Equation E.13. Now, the symbol w_{t+1} can be one of $2k+1$ symbols: any of the k open brackets $\langle_i$, the k close brackets $\rangle_i$, or ω. The proof now proceeds by each of these three cases.

Case $w_{t+1} = \langle_i$: Without loss of generality, we let $q_t = [\langle_{i_1}, \dots, \langle_{i_{m'}}]$ for $m' < m$. Strict inequality is guaranteed since if $m' = m$, then $\delta(q_t, \langle_i) = r$, meaning $w_{1:t+1}$ cannot be a prefix of any string in Dyck-(k,m), contradicting a premise of the lemma. Through the inverse of the stack mapping Equation E.3, we have

$$\begin{aligned} \mathcal{Q}^{-1}(q_t) &= s_{t,1}, \dots, s_{t,m} \\ &= \psi^{-1}(\langle_{i_1}), \dots, \psi^{-1}(\langle_{i_{m'}}), \mathbf{0}_{m'+1}, \dots, \mathbf{0}_m \\ &= e_{i_1}, \dots, e_{i_{m'}}, \mathbf{0}_{m'+1}, \dots, \mathbf{0}_m, \end{aligned}$$

the stack slots of f_θ at timestep t. Since $s_{t,m'} = \psi^{-1}(\langle_{i_j})$ and $s_{t,m'+1} = \mathbf{0}$, we have that c_t is m'-top. Thus, since $w_{t+1} = \langle_i$, the second or third condition in Equation E.10 (depending on whether $m' = 0$) dictate that $s_{t+1,m'+1} = \psi^{-1}(\langle_i)$ (where the i is because $w_{t+1} = \langle_i$). All other stack slots fall under the condition $s_{t+1,j} = s_{t,j}$.

With this, we can reason about the DFA state encoded by c_{t+1} at timestep $w_{1:t+1}$:

$$\begin{aligned} &\mathcal{Q}(s_{t+1,1}, \dots, s_{t+1,m}) \\ &\quad = \mathcal{Q}(\psi^{-1}(\langle_{i_1}), \dots, \psi^{-1}(\langle_{i_{m'}}), \psi^{-1}(\langle_i), \mathbf{0}, \dots, \mathbf{0}) \\ &\quad = [\langle_{i_1}, \dots, \langle_{i_{m'}}, \langle_i] \\ &\quad = \delta(q_t, \langle_i) \end{aligned}$$

which is the DFA's state at timestep $t+1$, as required.

Finally, we reason about $h_{t+1,j}$. We've just shown that that c_{t+1} is $(m'+1)$-top, and that $s_{t+1,m'+1} = \psi^{-1}(\langle_i)$. By Equation E.11, we have that $h_{t+1,m'+1} = \tanh(\psi^{-1}(\langle_i))$, and $h_{t+1,j} = \mathbf{0}$ for all $j \neq m'+1$ as required, completing this case.

Case $w_{t+1} = \rangle_i$: We have $q_t = [\langle_{i_1}, \dots, \langle_{i_{m'}}]$ for $0 < m'$. this inequality is strict since if $m' = 0$, then $q_t = []$, and $\delta(q_t, \rangle_i) = r$, meaning $w_{1:t+1}$ is not a prefix of any string in $D_{m,k}$. Thus, we have that c_t is m'-top. Since $w_{t+1} = \rangle_i$, we have that $s_{t+1,m'} = \mathbf{0}$, and $s_{t+1,j} = s_{t,j}$ for all $j \neq m'$. Thus, we have

$$\begin{aligned} s_{t+1,1}, \dots, s_{t+1,m} = \psi^{-1}(\langle_{i_1}), \dots, \psi^{-1}(\langle_{i_{m'-1}}) \\ , \mathbf{0}, \dots, \mathbf{0} \end{aligned}$$

and thus the DFA state corresponding to the stack slots is:

$$\begin{aligned} &\mathcal{Q}(s_{t+1,1}, \dots, s_{t+1,m}) \\ &\qquad = [\psi^{-1}(s_{t+1,1}), \dots, \psi^{-1}(s_{t+1,m'-1}) \\ &\qquad\quad , \mathbf{0}, \dots, \mathbf{0}] \\ &\qquad = [\langle_{i_1}, \dots, \langle_{m'-1}] \end{aligned}$$

Which is $\delta(q_t, \rangle_i)$, as required. By the same reasoning as for case $w_{t+1} = \langle_i$, since c_{t+1} is $(m'-1)$-top and that $s_{t+1,m'-1} = \psi^{-1}(\langle_{m'-1})$, we have that $h_{t+1,m'-1} = \tanh(\psi^{-1}(\langle_i))$ and $h_{t+1,j} = \mathbf{0}$ for all $j \neq m'-1$, as required. This completes the case.

Case $w_{t+1} = \omega$: If $w_{t+1} = \omega$, then by the definition of δ, $\delta(q_t, \omega) \in \{[\omega], r\}$; hence the premises of Lemma 4 don't hold, so the lemma vacuously holds.

Summary In this section we've proved the stack correspondence lemma for our LSTM construction, assuming we can implement the dynamics of the model as specified in Equations E.10 E.11; we have yet to show that the LSTM update can implement the equations as promised.

E.4 Implementation of stack state dynamics in LSTM equations assuming intermediate values

In this subsection, we define how the dynamics defined in Equations E.10, E.11 are implemented in the LSTM equations, referring to intermediate gate values, assuming such values can be reached with some setting of LSTM parameters.

As we discussed stack slots $s_{t,1}, \ldots, s_{t,m}$ of cell state c_t, where each $s_{t,j} \in \mathbb{R}^k$, we similarly discuss the gates in terms of slots, where e.g., $f_{t,j} \in [0,1]^k$ are the k elementwise gates that apply to the values $s_{t,j}$ (and similarly for $i_{t,j}$, $o_{t,j}$, and the new cell candidate values $\tilde{c}_{t,j} \in [-1,1]^k$.) With this, we re-write Equation E.10 using the definition of c_t:

$$s_{t,j} = f_{t,j} \odot s_{t-1,j} + i_{t,j} \odot \psi^{-1}(w_t), \qquad \text{(E.14)}$$

as well as Equation E.11:

$$h_{t,j} = o_{t,j} \odot \tanh(s_{t,j}) \qquad \text{(E.15)}$$

How these fulfill Equations E.10, E.11? We can set the gate values to do so as follows. First, the forget gate is used to detect the condition under which slot j should be erased:

$$f_{t,j} = \begin{cases} \mathbf{0} \in \mathbb{R}^k & c_{t-1} \text{ is } j\text{-top and } w_t = \rangle_i \\ \mathbf{1} \in \mathbb{R}^k & o.w. \end{cases} \qquad \text{(E.16)}$$

Second, the new cell candidate expression is used to give the *option* of writing a new open bracket, $\psi^{-1}(w_t)$ to *any* stack slot:

$$\tilde{c}_{t,j} = \begin{cases} \psi^{-1}(\langle_i) & w_t = \langle_i \\ \mathbf{0} \in \mathbb{R}^k & o.w. \end{cases} \qquad \text{(E.17)}$$

Third, the input gate determines which stack slot is the first non-empty slot in the sequence, and only allows the information of the new open bracket to be written to that slot:

$$i_{t,j} = \begin{cases} \mathbf{1} & c_{t-1} = \mathbf{0}, j = 1, \text{ and } w_t = \langle_i \\ \mathbf{1} & c_{t-1} \text{ is } (j-1)\text{-top, and } w_t = \langle_i \\ \mathbf{0} \in \mathbb{R}^k & o.w. \end{cases} \qquad \text{(E.18)}$$

Finally, the output gate is set to identify the top of the stack and not let any other non-$\mathbf{0}$ (i.e., all stack slots below the top) through:

$$o_{t,j} = \begin{cases} \mathbf{0} & c_t \text{ is } j'\text{-top for } j' > j \\ \mathbf{1} \in \mathbb{R}^k & o.w. \end{cases} \qquad \text{(E.19)}$$

Many of these conditions refer to values, like c_t and c_{t-1}, not available when computing the gates (as only h_{t-1} and x_t are available); it is convenient to refer to these conditions and later show how they are implemented with the available values.

E.5 Proof of stack state dynamics given gate and new cell candidate values

In this section, we prove that Equations E.10, E.11 are implemented by the LSTM f_θ given the gate and new cell candidate values defined in the previous subsection.

We start with Equation E.10, the definition of the stack slot dynamics, proceeding by each of the four cases for defining $s_{t,j}$ in Equation E.10.

Case 1 (popping $s_{t-1,j}$) In this case, the condition is that c_{t-1} is j-top, and $w_t = \rangle_i$. By Equation E.16, we have the forget gate value $f_{j,t} = \mathbf{0}$. By Equation E.18, we have the input gate value $i_{j,t} = \mathbf{0}$. Finally, by Equation E.17, we have $\tilde{c}_{t,j} = \mathbf{0}$. Plugging these values into the LSTM cell expression in Equation E.14, we get

$$\begin{aligned} s_{t,j} &= \mathbf{0} \cdot s_{t-1,j} + \mathbf{0} \cdot \mathbf{0} \\ &= \mathbf{0}, \end{aligned}$$

as required.

Case 2 (pushing to $s_{t,1}$) In this case, the condition is that $c_{t-1} = \mathbf{0}$, that is, the stack is empty, $j = 1$, that is, we'll write to the first stack slot, and $w_t = \langle_i$. By Equation E.18, we have $i_{t,1} = \mathbf{1}$. By Equation E.17, we have $\tilde{c}_{t,j} = \psi^{-1}(\langle_i)$. Further, we have $s_{t-1,j} = \mathbf{0}$ for all j, since $c_{t-1} = \mathbf{0}$. Plugging these valeus into the LSTM cell expression in Equation E.14, we get:

$$\begin{aligned} s_{t,1} &= f_{1,j} \cdot \mathbf{0} + \mathbf{1} \cdot \psi^{-1}(\langle_i) \\ &= \psi^{-1}(\langle_i), \end{aligned}$$

as required.

Case 3 (pushing to $s_{t,j>1}$) In this case, the condition is that c_{t-1} is $(j-1)$-top or $c_{t-1} = \mathbf{0}$, and $w_t = \langle_i$. By Equation E.16, we have the forget gate value $f_{j,t} = \mathbf{1}$, since Case 1 does not hold. By Equation E.18, we have the input gate value $i_{j,t} = \mathbf{1}$. Finally, by Equation E.17, we have $\tilde{c}_{t,j} = \psi^{-1}(\langle_i)$. Plugging these values into the LSTM cell expression in Equation E.14, we get

$$\begin{aligned} s_{t,j} &= \mathbf{1} \cdot s_{t-1,j} + \mathbf{1} \cdot \psi^{-1}(\langle_i) \\ &= s_{t-1,j} + \psi^{-1}(\langle_i) \\ &= \psi^{-1}(\langle_i), \end{aligned}$$

where the last equality hold because of the condition that c_{t-1} is $(j-1)$-top, which implies $s_{t-1,j} = \mathbf{0}$.

Case 3 (maintaining $s_{t-1,j}$) This case catches all conditions under which Cases 1 and 2 do not hold. By Equation E.16, we have the forget gate value $f_{j,t} = \mathbf{1}$, since Case 1 does not hold. By Equation E.18, we have the input gate value $i_{j,t} = \mathbf{0}$, since Case 2 does not hold. Finally, by Equation E.17, we have $\tilde{c}_{t,j} = \mathbf{0}$. Plugging these values into the LSTM cell expression in Equation E.14, we get

$$\begin{aligned} s_{t,j} &= \mathbf{1} \cdot s_{t-1,j} + \mathbf{0} \cdot \mathbf{0} \\ &= s_{t-1,j}, \end{aligned}$$

as required.

Proving Equation E.11 is implemented Next, we prove that Equation E.11 is implemented by the LSTM f_θ, given that Equation E.10 is. First, we must show $h_{t,j}$ is equal to $\tanh(e_i)$ if c_t is j-top. If c_t is j-top, it must be that $s_{t,j} = e_i$ for some i. Since c_t is j-top, we have $o_{t,j} = \mathbf{1}$, and $s_{t,j} = e_i$. Plugging these values into the hidden state expression in Equation E.15, we get:

$$\begin{aligned} h_{t,j} &= o_{t,j} \odot \tanh(s_{t,j}) \\ &= \mathbf{1} \odot \tanh(e_i) \\ &= \tanh(e_i), \end{aligned}$$

as required.

If that condition does not hold, we must have that c_t not j-top. thus, c_t is either j-top for some $j' < j$ or $j' > j$, or $c_t = \mathbf{0}$.

If c_t is j'-top for $j' < j$, then we have that $s_{t,j} = \mathbf{0}$, by the definition of j-top. In this case, we have

$$\begin{aligned} h_{t,j} &= o_{t,j} \odot \tanh(s_{t,j}) \\ &= \mathbf{1} \odot \tanh(\mathbf{0}) \\ &= \mathbf{0}, \end{aligned}$$

as required.

If c_t is j'-top for $j' > j$, then we have that $o_{t,j} = \mathbf{0}$, by Equation E.19. In this case, we have

$$\begin{aligned} h_{t,j} &= o_{t,j} \odot \tanh(s_{t,j}) \\ &= \mathbf{0} \odot s_{t,j} \\ &= \mathbf{0}, \end{aligned}$$

as required.

Finally, if $c_t = \mathbf{0}$, meaning it is not j-top for any j, then

$$\begin{aligned} h_{t,j} &= o_{t,j} \odot \tanh(\mathbf{0}) \\ &= \mathbf{0}, \end{aligned}$$

as required.

Summary So far, we've proved the stack correspondence lemma's induction step for LSTMs assuming that we can provide parameters of the network such that the values assumed in Equations E.16, E.17, E.18, E.19, that is, the gates and new cell candidate, are achieved. We have yet to provide the settings of parameters to do so.

E.6 Construction and proof of LSTM parameters providing gate and new cell candidate values

We now come to the final portion of the proof of the inductive step in Lemma 4. So far, we've proven the induction step conditioned on the existence of parameters that implement the intermediate gate values $f_{t,j}, i_{t,j}, \tilde{c}_{t,j}, o_{t,j}$. Now we construct said parameters, and prove their correctness assuming the induction hypothesis. We'll describe all matrices W, that is, $(W_i, W_f, W_0, W_{\tilde{c}})$, as block matrices, with the block structure specified by the stack slot structure. Precisely, we'll refer to $W_{j,j'}$ as rows $(j-1)k+1$ through $(j-1)k+k$, intersected with columns $(j'-1)k+1$ through $(j'-1)k+k$. This can be interpreted as the block that specifies how the values of slot j' affect the intermediate values constructed for slot j. We'll describe all matrices U as block-matrices through rows alone, that is, U_j referring to rows $(j-1)k'+1$ through $(j-1)k+k$. We'll describe biases b through contiguous chunks b_j, similarly.

Embedding parameters By definition, $x_t = Ew_t$, where each $w_t \in \Sigma$ is overloaded to be a one-hot vector picking out a row of embedding matrix $E \in \mathbb{R}^{d \times |\Sigma|}$. We define $E = I^{2k \times 2k}$, the identity matrix. Note that $\{Ew\}_{w \in \Sigma}$ is a set of mutually orthogonal vectors, with $\|Ew\|_2 = 1$.

Parameters implementing $o_{t,j}$ as Equation E.19 The equation defining $o_{t,j}$ is as follows:

$$\begin{aligned} o_{t,j} &= [\sigma(W_o h_{t-1} + U_o x_t + b_o)]_j && \text{(E.20)} \\ &= \sigma([W_o h_{t-1}]_j + [U_o x_t]_j + [b_o]_j) && \text{(E.21)} \end{aligned}$$

where the subscript j on the RHS indicates that we're picking the units corresponding to stack slot j. Let $\gamma = \tanh(1) \approx 0.762$ for ease of notation. We define $W_{o,j,j'}$ as follows:

$$W_{o,j,j'} = \begin{cases} -\lambda \in \mathbb{R}^{k \times k} & j' \in \{j, j+1\} \\ -\mathbf{2}\lambda \in \mathbb{R}^{k \times k} & j' > j+1 \\ \mathbf{0} \in \mathbb{R}^{k \times k} & j' < j \end{cases}, \tag{E.22}$$

where $\lambda \in \mathbb{R}$ is a scaling factor to be defined. This gives the intermediate value:

$$[W_o h_{t-1}]_j = \begin{cases} -\lambda\gamma & \exists_{j'\in\{j,j+1\},i} : \\ & h_{t-1,j'} = \tanh(\psi^{-1}(\langle_i)) \\ -\mathbf{2}\lambda\gamma & \exists_{j'>j+1,i} : \\ & h_{t-1,j'} = \tanh(\psi^{-1}(\langle_i)) \\ \mathbf{0}\in\mathbb{R}^k & o.w. \end{cases} \tag{E.23}$$

Note that Equation E.23 relies on the encoding-validity property, in particular that $\psi^{-1}(\langle_i) \in \{0,1\}^k$ and $\sum_{\ell=1}^{k}\psi^{-1}(\langle_i) = 1$ to ensure that, in the first condition,

$$\begin{aligned} -\lambda\mathbf{1}^\top h_{t-1,j} &= -\lambda\mathbf{1}^\top\tanh(s_{t-1,j}) \\ &= -\lambda\mathbf{1}^\top\tanh(\psi^{-1}(\langle_i)) \\ &= -\lambda\sum_{\ell=1}^{k}\tanh(\psi^{-1})_\ell \\ &= -\lambda\tanh(1) \\ &= -\lambda\gamma. \end{aligned}$$

and likewise for the second condition. The third condition relies on the fact that $\psi^{-1}(\varnothing) = \mathbf{0}$.

We define $U_{o,j}$ as follows:

$$U_{o,j} = \begin{bmatrix} \lambda\gamma\sum_i x_{\rangle_i}^\top \\ \dots \end{bmatrix} \tag{E.24}$$

that is, each row of U_f is equal to the sum, over all close brackets, of the embedding of that close bracket (transposed.) Since all $x_{\rangle_i}$ are orthogonal and unit norm (by the definition of E), this gives the following intermediate value:

$$[U_o x_t]_j = \begin{cases} \lambda\gamma\in\mathbb{R}^k & \exists_i : w_t = \langle_i \\ \mathbf{0} & o.w. \end{cases} \tag{E.25}$$

Finally, we specify the bias term as

$$b_{o,j} = \begin{bmatrix} 0.5\lambda\gamma \\ \dots \end{bmatrix}, \tag{E.26}$$

that is, all units of the bias are equal to the same value.

As we stated earlier, Equation E.19 refers to conditions on c_t, which do not show up in the computation of o_t; instead, o_t is a function of h_{t-1}, and x_t. As such, we re-write Equation E.19 in terms of these values, in particular splitting the condition on c_t being j'-top for $j' > j$ into two separate conditions,

$$o_{t,j} = \begin{cases} \mathbf{0} & \exists_{j'>j+1,i} : h_{t-1,j'} = \tanh(\psi^{-1}(\langle_i)) \\ \mathbf{0} & \exists_{j'\in\{j,j+1\},i} : h_{t-1,j'} = \tanh(\psi^{-1}(\langle_i)) \\ & \text{and } w_t \neq \rangle_i \\ \mathbf{1} & o.w. \end{cases} \tag{E.27}$$

Recall that $h_{t,j'} = \tanh(\psi^{-1}(\langle_i))$ indicates that c_{t-1} is j'-top, by the induction hypothesis. With our equation above we outline two different conditions that we'll show together are necessary and sufficient to guarantee that the top slot is located at some $j' > j$. Under each condition, we set the output gate to 0 because of that (since if the top slot is at $j' > j$, then slot j is not equal to 0, and must not be let through the gate.)

While we cannot condition directly on the value of c_t, we know that c_t is j'-top for $j' > j$ under two conditions on h_{t-1}, and thus on c_{t-1}. First, c_{t-1} can be $(j+2)$-top or greater; since only one element can be popped at once, c_t can be no less than $(j+1)$-top. Second, c_{t-1} can be j-top or $(j+1)$-top, and the input w_t is not some $\rangle_i$; that is, it does not pop the top element off of the stack. Because w_t is not $\rangle_i$, it must be an open bracket, $\langle_i$, pushing to the stack. Hence, under these conditions, c_t must be at least $(j+1)$-top. If neither of these conditions hold, then c_t cannot be j'-top for $j' > j$, since if c_{t-1} is j-top or $(j-1)$-top and $w_t = \rangle_i$, then c_t must be at most j-top. And if c_{t-1} is j'-top for $j' < j$, then it is impossible since only one bracket can be pushed at a time. Thus Equation E.27 is equivalent to Equation E.19, as required.

We now prove that parameters (W_o, U_o, b_o) implement Equation E.19, by implementing Equation E.27. In the first condition, $h_{t-1,j'} = \psi^{-1}(\langle_i)$ for some $j' > j+1$ and i; we want to show that $o_{t,j} = \mathbf{0}$. Based on our construction of parameters, we have that $o_{t,j}$ is upper-bounded by the following, when $w_t = \rangle_i$:

$$\begin{aligned} o_{t,j} =& \sigma([W_o h_{t-1}]_j + [U_o x_t]_j + [b_o]_j) \\ &\leq \sigma(-2\lambda\gamma + \lambda\gamma + .5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0} \end{aligned}$$

where the last equality holds under our finite precision σ by setting the scaling factor λ such that $-0.5\lambda\gamma < -\beta$, that is $\lambda > \frac{2\beta}{\gamma}$.

In the next condition, we have that $h_{t-1,j'} = e_i$for $j' \in \{j, j+1\}$, and i, and $x_t \neq \rangle_i$. In this case, we can write out the value of $o_{t,j}$ as follows:

$$\begin{aligned} o_{t,j} &= \sigma(-\lambda\gamma + 0 + .5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0}, \end{aligned}$$

as required.

Finally, if neither of those conditions hold, we have that $h_{t-1,j'} \neq \psi^{-1}(\langle_i)$ for any $j' \geq j$, and so $h_{t-1,j'} = \tanh(\mathbf{0}) = \mathbf{0}$. In this case, we can lower-bound the value of $o_{t,j}$:

$$\begin{aligned} o_{t,j} &\leq \sigma(0 + 0 + 0.5\lambda\gamma) \\ &= \mathbf{1}, \end{aligned}$$

as required. This completes the proof of the output gate.

Parameters implementing $f_{t,j}$ as Equation E.16

The equation defining $f_{t,j}$ is as follows:

$$\begin{aligned} f_{t,j} &= [\sigma(W_f h_{t-1} + U_f x_t + b_f)]_j \qquad \text{(E.28)} \\ &= \sigma([W_f h_{t-1}]_j + [U_f x_t]_j + [b_f]_j) \qquad \text{(E.29)} \end{aligned}$$

We define $W_{f,j,j'}$ as follows:

$$W_{f,j,j'} = \begin{cases} -\lambda \in \mathbb{R}^{k \times k} & j = j' \\ \mathbf{0} \in \mathbb{R}^{k \times k} & o.w. \end{cases} \tag{E.30}$$

which gives the intermediate value:

$$[W_f h_{t-1}]_j = \begin{cases} -\lambda\gamma \in \mathbb{R}^k & \exists_i : h_{t-1,j} \\ & \qquad = \tanh(\psi^{-1}(\langle_i)) \\ \mathbf{0} \in \mathbb{R}^k & o.w., \end{cases} \tag{E.31}$$

again relying on the embedding-validity property.

We define $U_{f,j}$ as follows:

$$U_{f,j} = \begin{bmatrix} -\lambda\gamma \sum_i x_{\rangle_i}^{\top} \\ \cdots \end{bmatrix} \tag{E.32}$$

that is, each row of U_f is equal to the negative of the sum, over all close brackets, of the embedding of that close bracket (transposed.) Since all $x_{\rangle_i}$ are orthogonal and unit norm, this gives the following intermediate value:

$$[U_f x_t]_j = \begin{cases} -\lambda\gamma \in \mathbb{R} & \exists_i : w_t = \rangle_i \\ \mathbf{0} & o.w. \end{cases} \tag{E.33}$$

Finally, we specify the bias term as

$$b_{f,j} = \begin{bmatrix} 1.5\lambda\gamma \\ \cdots \end{bmatrix}, \tag{E.34}$$

that is, all units of the bias are equal to the same value.

We now prove that, as given, the parameters (W_f, U_f, b_f) implement Equation E.16 assuming the induction hypothesis of Lemma 4.

Equation E.16 has two cases. In the first case, c_{t-1} is j-top and $w_t = \rangle_i$, and we need to prove $f_{t,j} = \mathbf{0}$. From the induction hypothesis, this means that $h_{t-1,j} = \tanh(\psi^{-1}(\langle_i))$, and all other slots $h_{t-1,j'} = \mathbf{0}$. The value of the gate is as follows:

$$\begin{aligned} f_{t,j} &= \sigma([W_f h_{t-1}]_j + [U_f x_t]_j + [b_f]_j) \\ &= \sigma(-\lambda\gamma - \lambda\gamma + 1.5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0} \end{aligned}$$

where the last equality holds by setting λ as already stated: $\lambda > \frac{2\beta}{\gamma}$.

The second case is whenever the conditions of the first case don't hold, in which case we must prove $f_{t,j} = \mathbf{1}$. Thus, we either have c_{t-1} not j-top, in which case,

$$\begin{aligned} f_{t,j} &\geq \sigma(0 - \lambda\gamma + 1.5\lambda\gamma) \\ &= \sigma(0.5\lambda\gamma) \\ &= \mathbf{1}, \end{aligned}$$

or we have $w_t \neq \rangle_i$, in which case,

$$\begin{aligned} f_{t,j} &\geq \sigma(-\lambda\gamma - 0 + 1.5\lambda\gamma) \\ &= \sigma(0.5\lambda\gamma) \\ &= \mathbf{1}, \end{aligned}$$

as required.

Parameters implementing $i_{t,j}$ as Equation E.18

The equation defining $i_{t,j}$ is as follows:

$$\begin{aligned} i_{t,j} &= [\sigma(W_i h_{t-1} + U_i x_t + b_i)]_j \qquad \text{(E.35)} \\ &= \sigma([W_i h_{t-1}]_j + [U_i x_t]_j + [b_i]_j) \qquad \text{(E.36)} \end{aligned}$$

We define $W_{i,j,j'}$ as follows:

$$W_{i,j,j'} = \begin{cases} -\lambda \in \mathbb{R}^{k \times k} & j = 1 \\ \lambda \in \mathbb{R}^{k \times k} & j = j' + 1 \\ \mathbf{0} \in \mathbb{R}^{k \times k} & o.w. \end{cases} \tag{E.37}$$

which gives the intermediate value:

$$[W_i h_{t-1}]_j = \begin{cases} -\lambda\gamma \in \mathbb{R}^k & j = 1, \exists_{i,j'} : \\ & h_{t-1,j'} = \tanh(e_i) \\ \lambda\gamma \in \mathbb{R}^k & \exists_i : h_{t-1,j-1} \\ & = \tanh(e_i) \\ \mathbf{0} \in \mathbb{R}^k & o.w. \end{cases} \tag{E.38}$$

once again relying only on the encoding-validity property.

We define $U_{i,j}$ as follows:

$$U_{i,j} = \begin{bmatrix} -\lambda\gamma \sum_i x_{\langle_i}^\top \\ \dots \end{bmatrix} \tag{E.39}$$

Since all $x_{\rangle_i}$ are orthogonal and unit norm, this gives the following intermediate value:

$$[U_i x_t]_j = \begin{cases} -\lambda\gamma \in \mathbb{R}^k & \exists_i : w_t = \langle_i \\ \mathbf{0} & o.w. \end{cases} \tag{E.40}$$

Finally, we specify the bias term as

$$b_{i,j} = \begin{cases} -.5\lambda\gamma \in \mathbb{R}^k & j = 1 \\ -1.5\lambda\gamma \in \mathbb{R}^k & o.w. \end{cases} \tag{E.41}$$

We now prove that the parameters (W_i, U_i, b_i), when plugged into f_θ, implement Equation E.18 assuming the induction hypothesis of Lemma 4. Equation E.18 has three cases.

The condition of the first case is that $c_{t-1} = \mathbf{0}$, $j = 1$, and $w_t = \langle_i$; we need to show that $i_{t,1} = \mathbf{1}$. Since $c_{t-1} = \mathbf{0}$, we have that $h_{t-1} = \mathbf{0}$. We can compute $i_{t,1}$ as follows:

$$\begin{aligned} i_{t,1} &= \sigma([W_i h_{t-1}]_j + [U_i x_t]_j + [b_i]_j) \\ &= \sigma(0 + \lambda\gamma - 0.5\lambda\gamma) \\ &= \sigma(0.5\lambda\gamma) \\ &= \mathbf{1}. \end{aligned}$$

note the bias term $-0.5\lambda\gamma$ is only set that way for $j = 1$.

The condition of the second case is that c_{t-1} is $(j-1)$-top, and $w_t = \langle_i$; we need to show that $i_{t,j} = \mathbf{1}$. From the induction hypothesis, we have that $h_{t-1,j-1} = \psi^{-1}(\langle_{i'})$ for some i', and h_{t-1} is 0 elsewhere. We calculate $i_{t,j}$ as follows,

$$\begin{aligned} i_{t,j>1} &= \sigma([W_i h_{t-1}]_j + [U_i x_t]_j + [b_i]_j) \\ &= \sigma(\lambda\gamma + \lambda\gamma - 1.5\lambda\gamma) \\ &= \sigma(0.5\lambda\gamma) \\ &= \mathbf{1}, \end{aligned}$$

where we do not have to consider the case $i_{t,1}$ since c_{t-1} cannot be 0-top, so this case cannot hold.

Finally, in the third case, none of the above conditions hold, and we need to prove $i_{t,j} = \mathbf{0}$. There are a number of possibilities here to enumerate. First, let $c_{t-1} = \mathbf{0}$ and $j = 1$, but $w_t \neq \langle_i$. Then,

$$\begin{aligned} i_{t,1} &= \sigma(0 + 0 - 0.5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0}, \end{aligned}$$

Next, we let $c_{t-1} = \mathbf{0}$ and $w_t = \langle_i$, but $j > 1$. Then,

$$\begin{aligned} i_{t,1} &= \sigma(0 + \lambda\gamma - 1.5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0}, \end{aligned}$$

Next, we let $j = 1$, $w_t = \langle_i$, but $c_{t-1} \neq \mathbf{0}$. Thus c_{t-1} is j'-top for some j'.

If the second case of Equation E.18 doesn't hold, then either c_{t-1} is not $(j-1)$-top, or $w_t \neq \langle_i$; we need to prove $i_{t,j} = \mathbf{0}$. If c_{t-1} is not $(j-1)$-top and $j > 1$, then we can upper-bound the value of $i_{t,j}$ as follows:

$$\begin{aligned} i_{t,j>1} &\leq \sigma(0 + \lambda\gamma - 1.5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0}. \end{aligned}$$

If c_{t-1} is $(j-1)$-top but $w_t \neq \langle_i$, then the value of $i_{t,j}$ is as follows,

$$\begin{aligned} i_{t,j>1} &= \sigma(\lambda\gamma + 0 - 1.5\lambda\gamma) \\ &= \sigma(-0.5\lambda\gamma) \\ &= \mathbf{0}, \end{aligned}$$

as required.

Parameters implementing $\tilde{c}_{t,j}$ as Equation E.17

The equation defining $\tilde{c}_{t,j}$ is as follows:

$$\begin{aligned} \tilde{c_{t,j}} &= [\tanh(W_{\tilde{c}} h_{t-1} + U_{\tilde{c}} x_t = b_{\tilde{c}})]_j & \text{(E.42)} \\ &= \tanh([W_{\tilde{c}} h_{t-1}]_j + [U_{\tilde{c}} x_t]_j = [b_{\tilde{c}}]_j) & \text{(E.43)} \end{aligned}$$

We define $W_{\tilde{c}} = \mathbf{0}$, which leads to the intermediate values:

$$[W_{\tilde{c}} h_{t-1}]_j = \mathbf{0} \tag{E.44}$$

We define $U_{\tilde{c}}$ as follows:

$$U_{\tilde{c},j} = \begin{bmatrix} \lambda x_{\langle_1}^{\top} \\ \lambda x_{\langle_2}^{\top} \\ \cdots \\ \lambda x_{\langle_k}^{\top} \end{bmatrix} \tag{E.45}$$

which leads to the intermediate values:

$$[U_{\tilde{c}} x_t]_j = \begin{cases} \lambda e_i & w_t = \langle_i \\ \mathbf{0} & o.w. \end{cases} \tag{E.46}$$

We define $b_{\tilde{c}} = \mathbf{0}$.

We now prove that the parameters $W_{\tilde{c}}, U_{\tilde{c}}, b_{\tilde{c}}$ implement Equation E.17. There are two cases.

In the first case, $w_t = \langle_i$, and need to show $\tilde{c}_{t,j} = \psi^{-1}(\langle_i)$. In this case, we have

$$\begin{aligned} \tilde{c}_{t,j} &= \tanh([W_{\tilde{c}} h_{t-1}]_j + [U_{\tilde{c}} x_t]_j = [b_{\tilde{c}}]_j) \\ &= \tanh(\mathbf{0} + \lambda e_i + 0) \\ &= e_i, \\ &= \psi^{-1}(\langle_i) \end{aligned}$$

where the last equality holds by setting $\lambda > \beta$.[24] In the second case, we have $w_t \neq \rangle_i$, and need to show $\tilde{c}_{t,j} = \mathbf{0}$. In this case, we have

$$\begin{aligned} \tilde{c}_{t,j} &= \tanh([W_{\tilde{c}} h_{t-1}]_j + [U_{\tilde{c}} x_t]_j = [b_{\tilde{c}}]_j) \\ &= \tanh(\mathbf{0} + \mathbf{0} + \mathbf{0}) \\ &= \mathbf{0} \end{aligned}$$

as required.

Summary We've now specified all parameters of the LSTM and completed the induction step in our proof of the stack correspondence lemma, Lemma 4; this completes the proof of the lemma.

F Proving generation in $O(mk)$ hidden units

For both the Simple RNN and the LSTM, we've proven *stack correspondence lemmas*, Lemmas 3, 4. These guarantee that for all prefixes of strings in Dyck-(k,m), we can rely on properties of the hidden states of each model to be perfectly informative about the state of the DFA stack.

Given those lemmas, this section describes the proof of the following results, for the Simple RNN:

Theorem 2. *For any $k, m \in \mathbb{Z}^+$, there exists a Simple RNN f_θ with $2mk$ hidden units that generates Dyck-(k,m).*

and for the LSTM, noting that the condition that $W_{\tilde{c}} = \mathbf{0}$ holds from our proof of the stack correspondence lemma.

Theorem 3. *For any $k, m \in \mathbb{Z}^+$, there exists a LSTM f_θ with mk hidden units and $W_{\tilde{c}} = \mathbf{0}$ that generates Dyck-(k,m).*

The two constructions differ in where they make information accessible; we describe those differences here and then provide a general proof that is agnostic to which construction is used.

F.1 Softmax distribution parameters

Recall that we must show that the ϵ-truncated support of f_θ (for both Simple RNN and LSTM) is the same set as Dyck-(k,m). The token-level probability distribution conditioned on the history is given as follows:

$$w_t \sim \mathrm{softmax}(V h_{t-1} + b), \tag{F.1}$$

and we denote this distribution p_{f_θ}. We first specify V by row; a single row exists for each of the $2k+1$ words in the vocabulary. We let $v_{w,j}$ refer to the row of word w, and the k columns that will participate in the dot product with the rows of stack slot j in h_{t-1}.

We start with the only difference in the softmax matrix between the Simple RNN and the LSTM. For the Simple RNN:

$$v_{\rangle_i,1} = \zeta e_i \tag{F.2}$$

$$v_{\rangle_i,j>1} = \mathbf{0}, \tag{F.3}$$

because the top of the stack is guaranteed to be in the first stack slot, and where ζ is a positive scaling constant we'll define later. And for the LSTM,

$$v_{\rangle_i,j} = \zeta e_i \tag{F.4}$$

for all j, since exactly one slot is guaranteed to be non-empty (if the stack is non-empty) and it could be at any of the m slots. The rest of the softmax construction is common between the Simple RNN and the LSTM:

$$v_{\langle_i,j<m} = \mathbf{0} \in \mathbb{R}^k \tag{F.5}$$

$$v_{\langle_i,m} = -\mathbf{1}\zeta \in \mathbb{R}^k \tag{F.6}$$

$$v_{\omega,j,1} = -\mathbf{1}\zeta \in \mathbb{R}^k \tag{F.7}$$

Likewise, the bias terms:

$$b_{v,\rangle_i} = -0.5\zeta\gamma \tag{F.8}$$

$$b_{v,\langle_i} = 0.5\zeta\gamma \tag{F.9}$$

$$b_{v,\omega} = 0.5\zeta\gamma \tag{F.10}$$

---

[24] Which we've already required earlier by letting $\lambda > \frac{2\beta}{\gamma}$.

So that we can swap out V when we swap out ψ for a more efficient encoding, we state here a properties of V we rely on (once ψ is fixed):

Definition 11 (softmax validity property)**.** Given encoding $\psi : \{\langle_i\}_{i\in[k]} \to \mathbb{R}^n$, a softmax matrix V obeys the softmax validity property relative to ψ if

$$\forall_{i\in[k]}, v_{\rangle_i,u}^\top \psi^{-1}(\langle_j) \begin{cases} = \zeta & i = j \\ \leq 0 & i \neq j, \end{cases} \tag{F.11}$$

where u specifies the stack slot where the construction (Simple RNN or LSTM) stores the element at the top of the stack; for the Simple RNN, $u = 1$, for the LSTM, u is such that c_t is u-top, as defined. This ensures that the softmax matrix correctly distinguishes between the symbol, $\langle_i$, that is encoded in the top of the stack, from any other symbol. Further, we rely on

$$\forall_{i,j\in[k]}, v_{\langle_i,m}^\top \psi^{-1}(\langle_j) = -\zeta \tag{F.12}$$

$$\forall_{i,j\in[k]}, v_{\langle_i,m'<m}^\top \psi^{-1}(\langle_j) = 0 \tag{F.13}$$

to detect whether the stack is full, and

$$\forall_{i,j\in[k]}, \forall_{z\in[m]}, v_{\omega,z}^\top \psi^{-1}(\langle_j) = -\zeta \tag{F.14}$$

to detect if the stack is not empty.

The softmax matrix we've provided obeys the softmax validity property with respect to ψ since $\zeta e_i^\top e_i = \zeta$, and $\zeta e_i^\top e_j = 0$, $j \neq i$. Further, $-\zeta \mathbf{1}^\top e_i = -\zeta$ for all i.

We're now prepared to state the final lemma in our proof of Theorems 2, 3.

Lemma 5 (probability correctness)**.** *Let* $w_{1:T} \in D_{m,k}$*. For* $t = 1, ..., t$*, let* $q_t = D_{m,k}(w_{1:T})$*. Then for all* $w \in \Sigma$*,*

$$\delta(q_t, w) \neq r \leftrightarrow p_{f_\theta}(w|w_{1:t}) \geq \epsilon \tag{F.15}$$

Intuitively, Lemma 5 states that f_θ assigns greater than ϵ probability mass in context to tokens w_t such that the prefix $w_{1:t+1}$ is the prefix of some member of $D_{m,k}$.

Proof of Lemma 5 We proceed in cases by the state, q. We'll show that a lower-bound on the probabilities of allowed symbols is greater than an upper-bound on the probabilities of disallowed symbols. We should note, however, that this is effectively a technicality to ensure our construction is fully constructive – that is, we provide concrete values for each parameter in the model; else, we could simply indicate that as ζ grows, the probability mass on w such that $\delta(q, w) = r$ converges to 0, while the mass on all other symbols converges 1 over the number of such symbols.

Case $q = []$ First, consider the case that $q_{t-1} = []$. For all $\rangle_i$, $\delta(q, \rangle_i) = r$, and for all other symbols w, $\delta(q, w) \neq r$. By the stack correspondence lemmas, Lemma 4 3, we have that $\mathcal{Q}(h_{t-1}) = q_{t-1}$ (Simple RNN) or $\mathcal{Q}(c_{t-1}) = q_{t-1}$ (LSTM), and $h_{t-1} = \mathbf{0}$.

For all $\rangle_i$, we have $\delta(q, \rangle_i) = r$, and we have logits:

$$\begin{aligned} &p_{f_\theta}(w_t = \rangle_i | h_{t-1}) \\ &\quad\propto v_{\rangle_i}^\top h_{t-1} + b_{v,\rangle_i} \\ &\quad\leq 0 - 0.5\zeta\gamma \\ &\quad= -0.5\zeta\gamma, \end{aligned}$$

as required. For all $w_t = \langle_i$, we have $\delta(q, \langle_i) \neq r$, and we have logits:

$$\begin{aligned} &p_{f_\theta}(w_t = \langle_i | h_{t-1}) \\ &\quad\propto v_{\langle_i}^\top h_{t-1} + b_{v,\langle_i} \\ &\quad= 0 + 0.5\zeta\gamma \\ &\quad= 0.5\zeta\gamma \end{aligned}$$

Finally, for ω, $\delta(q, \omega) \neq r$, and we have logits:

$$\begin{aligned} &p_{f_\theta}(w_t = \omega | h_{t-1}) \\ &\quad\propto v_\omega^\top h_{t-1} + b_{v,\omega_i} \\ &\quad= 0 + 0.5\zeta\gamma \\ &\quad= 0.5\zeta\gamma, \end{aligned}$$

as required. With the logits specified for our whole vocabulary, we can compute the partition function of the softmax function by summing over all k open brackets, all k close brackets, and the END bracket, to determine probabilities for each token,

$$\begin{aligned} &p_{f_\theta}(w_t = \rangle_i | h_{t-1}) \\ &\quad= \frac{e^{-0.5\zeta}}{Z_{[]}} \\ &\quad Z_{[]} \leq (k+1)e^{0.5\zeta\gamma} + ke^{-0.5\zeta\gamma} \end{aligned}$$

while the probability for any $\langle_i$ and ω is $p_{f_\theta}(w_t = \langle_i | h_{t-1}) = e^{0.5\zeta\gamma}/Z_{[]}$. The partition function is computed as $e^{0.5\zeta\gamma}$ multiplied by the number of words w such that $\delta(q, w) \neq r$ (in this case, k open brackets and the end bracket), plus a quantity upper bounded by $e^{-0.5\zeta\gamma}$ multiplied by the number of words w such that $\delta(q, w) = r$ (in this case, k close brackets.) All probabilities under this model are of this form.

Case $q = [\langle_{i_1}, ..., \langle_{i_{m'}}], m' < m$ Next, consider the case that $q = [\langle_{i_1}, ..., \langle_{i_{m'}}]$ for $0 < m' < m$. For the Simple RNN, we have by Lemma 3 that $h_{t-1,1} = \psi^{-1}(\langle'_m)$ (the top of the stack.) Likewise for the LSTM, we have by Lemma 3, that $h_{t-1,m'} = \tanh(e_{i_{m'}})$, and $h_{t-1,j\neq m'} = \mathbf{0}$. Either way, we have $v_{\rangle_i}^\top h_{t-1} \geq \zeta\gamma$ by the softmax validity property.[25]

As with the first case, we construct the logits for each of the symbols. First, we have $\delta(q, \langle_{m'}) \neq r$; this is the top element of the stack, which can be popped with a close bracket. We have logits:

$$\begin{aligned}
&p_{f_\theta}(w_t = \rangle_i | h_{t-1})\\
&\quad \propto v_{\rangle_i}^\top h_{t-1} + b_{v,\rangle_i}\\
&\quad = \zeta\gamma - 0.5\zeta\gamma\\
&\quad = 0.5\zeta\gamma
\end{aligned}$$

as required. For $w_t = \rangle_i$ where $i \neq i_{m'}$, we have $\delta(q, \langle_i) = r$ (since $\langle_i$ is not the top of the stack, seeing close bracket $\rangle_i$ would break the well-balancing requirement), and the logits:

$$\begin{aligned}
&p_{f_\theta}(w_t = \rangle_i | h_{t-1})\\
&\quad \propto v_{\rangle_i}^\top h_{t-1} + b_{v,\rangle_i}\\
&\quad \leq 0 - 0.5\zeta\gamma\\
&\quad = -0.5\zeta\gamma,
\end{aligned}$$

again by the softmax validity property. For $w_t = \langle_i$, we have $\delta(q, \langle_i) \neq r$, and the logits:

$$\begin{aligned}
&p_{f_\theta}(w_t = \langle_i | h_{t-1})\\
&\quad \propto v_{\langle_i}^\top h_{t-1} + b_{v,\langle_i}\\
&\quad = 0 + 0.5\zeta\gamma\\
&\quad = 0.5\zeta\gamma
\end{aligned}$$

as required, since $m' < m$, and by the softmax validity property, $v_{\langle_i}^\top h_{t,m'<m} = \mathbf{0}$. Finally, for ω, we have $\delta(q, \omega) = r$, and the logits

$$\begin{aligned}
&p_{f_\theta}(w_t = \omega_i | h_{t-1})\\
&\quad \propto v_\omega^\top h_{t-1} + b_{v,\omega_i}\\
&\quad = -\zeta\gamma + 0.5\zeta\gamma\\
&\quad = -0.5\zeta\gamma,
\end{aligned}$$

by the softmax validity property, as required. To reason about the probabilities, we again need to construct the partition function of the softmax

$$Z_p \leq (k+1)e^{0.5\zeta\gamma} + ke^{-0.5\zeta\gamma}$$

where Z_p stands for Z-"partial", for a partially full stack. (k open brackets are allowed, plus 1 close bracket; $k-1$ close brackets are disallowed, as well as the ω word.)

Case $q = [\langle_{i_1}, ..., \langle_{i_m}]$ Next, consider the case that $q = [\langle_{i_1}, ..., \langle_{i_m}]$, that is, a full stack with m elements. For the Simple RNN, by Lemma 3, we have that $h_{t-1,1} = \psi^{-1}(\langle_i)$, and $h_{t-1,m} = \psi^{-1}(\langle_j)$ for some j. (The top of the stack is $\langle_i$, and the stack is full.) And for the LSTM, by Lemma 4, we have that $h_{t-1,m} = \tanh(\psi^{-1}(\langle_{i_m}))$, and $h_{t-1,j\neq m} = \mathbf{0}$. The logits for each symbol are as follows. Identical to the last case, we have $\delta(q, \rangle_{i_m}) \neq r$, and $p_{f_\theta}(\rangle_{i_m} | h_{t-1}) \propto e^{0.5\zeta\gamma}$ as required; this is the element at the top of the stack. Also identically, all other brackets have $\delta(q, \rangle_{i\neq i_m}) = r$, and the values for those symbols are $\leq -0.5\zeta\gamma$, as required. For $w_t = \langle_i$, we have $\delta(q, \langle_i) = r$; this is because with m elements, the m-bound means no more elements can be pushed. The logits are:

$$\begin{aligned}
&p_{f_\theta}(w_t = \langle_i | h_{t-1})\\
&\quad \propto v_{\langle_i}^\top h_{t-1} + b_{v,\langle_i}\\
&\quad = -\zeta\gamma + 0.5\zeta\gamma\\
&\quad = -0.5\zeta\gamma,
\end{aligned}$$

by the softmax validity property, as required. Finally, for ω, identically to the previous case, we have $\delta(q, \omega) = r$, and logits $e^{-0.5\zeta\gamma}$, as required. The partition function is as follows:

$$Z_f \leq ke^{0.5\zeta\gamma} + (k+1)e^{-0.5\zeta\gamma}$$

where Z_f stands for Z-"full", for a full stack.

Case $q = [\omega]$ Last, consider the case that $q = [\omega]$. In this case, if at timestep t, then symbol $w_t = \omega$, since the only transition to state $[\omega]$ is $\delta([], \omega) = [\omega]$. Because of this and the definition of the universe of strings as $\Sigma^*\omega$, f_θ need not be defined on strings progressing from $q = [\omega]$. Intuitively, this is because ω indicates that the string has terminated. Hence this case vacuously holds.

We thus have three partition functions, Z_p, $Z_{[]}$, and Z_f, whose values we only have bounds for.

---

[25] In particular, for the Simple RNN, this expression is equal to ζ due to the softmax validity property; because of the tanh in $h_t = o_t \odot \tanh(c_t)$ in the LSTM expression, it's equal to $\zeta\gamma < \zeta$ where $\gamma = \tanh(1)$.

However, we can see that as we scale ζ large, they converge to $Z_{[]} = (k+1)e^{0.5\zeta\gamma}$, $Z_f = ke^{0.5\zeta\gamma}$, $Z_p = (k+1)e^{0.5\zeta\gamma}$ because the contributions from the disallowed symbols converges to zero. Thus, the probability assigned to the lowest-probability allowed symbol converges to $\frac{1}{k+1}$ as ζ grows large, while the probability assigned to the highest-probability disallowed symbol converges to 0. So, we choose $\epsilon = \frac{1}{2(k+1)}$,and let $\zeta > \frac{2.4}{\gamma}$, so that $e^{0.5\zeta\gamma} > 10e^{-0.5\zeta\gamma}$. Under this, the smallest probability assigned to any allowed symbol is lower-bounded by $\frac{e^{0.5\zeta\gamma}}{(k+1)e^{0.5\zeta\gamma}+ke^{-0.5\zeta\gamma}} > \frac{1}{(k+1)+0.1k} > \epsilon$, and the largest probability assigned to any disallowed symbol is upper-bounded by $\frac{e^{-0.5\zeta\gamma}}{ke^{+0.5\zeta\gamma}} \leq \frac{0.1}{k} = \frac{1}{10k} < \epsilon$. This completes the proof of Lemma 5.

F.2 Completing proofs of generation (Theorems 2, 3)

Now that we've proved the probability correctness lemma, we're ready to complete our proof that our Simple RNN and LSTM constructions generate Dyck-(k,m).

Recall that we've overloaded notation, calling $D_{m,k} \subset \sigma^*$ the set of strings defining the language Dyck-(k,m). We must show that the ϵ-truncated support of f_θ, which we'll call $\mathcal{L}_{f_\theta}$ is equal to $D_{m,k}$. We show both inclusions.

Pf. ($D_{m,k} \subseteq \mathcal{L}_{f_\theta}$) Let $w \in D_{m,k}$. We'll show $w \in \mathcal{L}_{f_\theta}$. For all prefixes $w_{1:t}$, $t = 1 \dots, T$, let $q_{t-1} = D_{m,k}(w_{1:t-1})$, the state of the DFA after consuming all tokens of the prefix except the last. For the Simple RNN, by Lemma 3, we have that $\mathcal{Q}(h_{t-1}) = q_{t-1}$. For the LSTM, by Lemma 4, we have that $\mathcal{Q}(s_{t-1,1}, \dots, s_{t-1,m}) = q_{t-1}$. Given this, for either construction, by Lemma 5, we have that $p_{f_\theta}(w_t|w_{1:t-1}) > \epsilon$. Since this is true for all $t = 1, \dots, T$, we have that w is in the ϵ-truncated support of f_θ, and so $w \in \mathcal{L}_{f_\theta}$.

Pf. ($\mathcal{L}_{f_\theta} \subseteq D_{m,k}$) Let $w_{1:T} \in \mathcal{L}_{f_\theta}$. We'll show $w_{1:T} \in D_{m,k}$ by proving the contrapositive.

Let $w_{1:T} \notin D_{m,k}$. We have that $w_T = \omega$ by definition. From the transition function δ, we know that $\delta(q, \omega) \in \{[\omega], r\}$, that is, ω transitions from any state either to the accept state or the reject state. Because $w_{1:T} \notin D_{m,k}$, it must be that $\delta(q_{T-1}, \omega) = r$, that is, $q_T = r$. We have no guarantee about $f_\theta(w_T|w_{1:T-1})$, however, since we don't know whether w_{T-1} is a prefix of some string in Dyck-(k,m). However, we do know that there must be some t' such that the first time $q_t = r$ is for $t = t'$, that is, the first timestep in which a disallowed symbol is seen and $D_{m,k}$ transitions to the reject state r (after which it self-loops in r by definition.)

Consider then the prefix $w_{1:t'-1}$. We know that $q_{t'-1} \neq r$. So without loss of generality, let $q_{t'-1} = [\langle_{i_1}, \dots, \langle_{i_{m'}}]$. We then construct a string:

$$w_{1:T'} = w_1, \dots, w_{1:t'-1}, \rangle_{i_1}, \dots, \rangle_{i_{m'}}, \omega$$

which simply closes all the brackets on the stack represented by $q_{t'}$. By recursive application of δ, we have that $q_{T'-1} = []$, and thus $q_{T'} = [\omega]$, meaning $w_{1:T'} \in D_{m,k}$.

Coming back to our prefix $w_{t:t'-1}$, we now know that it is a prefix of a string $w_{1:T'} \in D_{m,k}$. Thus, for our Simple RNN, by Lemma 3, we have that $\mathcal{Q}(h_{t'-1}) = q_{t'-1}$. Likewise for our LSTM, by Lemma 4, we have that $\mathcal{Q}(c_{t'-1}) = q_{t'-1}$. And by Lemma 5, since $\delta(q_{t'-1}, w_{t'}) = r$, we have $p_{f_\theta}(w_{t'}|w_{1:t'-1}) < \epsilon$. And so, $w_{1:T} \notin \mathcal{L}_{f_\theta}$. This completes the proof of Theorems 2, 3. □

F.3 Proving the general construction in $O(k^{m+1})$

As a corrolary of the above, we now formalize our proof that a general DFA construction in RNNs, using $O(k^{m+1})$ hidden units to simulate the DFA $D_{k,m}$ of Dyck-(k,m), permits an RNN construction that generates Dyck-(k,m). Formally,

Theorem 1 (Naive generation of Dyck-(k,m))**.** *For any $k, m \in \mathbb{Z}^+$, there exists a Simple RNN f_θ with $O(k^{m+1})$ hidden units that generates Dyck-(k,m).*

Proof. A general construction of any DFA in an RNN has $|Q||\Sigma|$ states, (Merrill, 2019; Giles et al., 1990). For Dyck-(k,m), $|Q||\Sigma| \in O(k^{m+1})$. Each state of the DFA $q \in Q$ is represented Σ times, once for each word in the vocabulary. If $q_t = \delta(q_{t-1}, w)$, then the hidden state is $h_{q_t,w}$, a 1-hot vector, equal to one at an index specified by and unique to (q_{t-1}, w). By defining the mapping $\mathcal{Q}(h_{q,w}) = q$, this construction obeys a stack correspondence lemma. Finally, since the state of the RNN specifies the DFA state as a 1-hot encoding, we can define the softmax matrix V as follows. For each state q, we can simply set all rows of V corresponding to state q to explicitly encode the log-probabilities of probability distributions we just proved in (§ F). □

G Extending to generation in $O(m \log k)$ hidden units

In this section, we prove an $O(m \log k)$ upper bound on the number of hidden units necessary to capture Dyck-(k,m) with an RNN, matching the $\Omega(m \log k)$ lower-bound. This is accomplished by defining a new mapping ψ from slots s_t to open brackets $\langle_i$ such that we can encode k open brackets using just $3 \log k - 1$ hidden units while maintaining the stack correspondence lemmas and Dyck-(k,m) generation properties. Formally, for the Simple RNN:

Theorem 4. *For any $k, m \in \mathbb{Z}^+$, where $k > 1$, there exists a Simple RNN f_θ with $6m\lceil \log k \rceil - 2m$ hidden units that generates Dyck-(k,m).*

Next, for the LSTM:

Theorem 5. *For any $k, m \in \mathbb{Z}^+$, where $k > 1$, there exists an LSTM f_θ with $3m\lceil \log k \rceil - m$ hidden units and $W_{\tilde{c}} = \mathbf{0}$ that generates Dyck-(k,m).*

G.1 $O(\log k)$ vocabulary encoding in the Simple RNN.

Intuitively, a simple way to encode k elements in $\log k$ space without making use of floating-point precision is to assign each element one of the $2^{\log k}$ binary configurations of $\{0, 1\}^{\log k}$. Our construction will build off of this.

Recall that there are k open brackets that need encodings in $O(\log k)$ space. Let $p^{(i)}$, for $i \in \{1, \dots, k\}$, be the i^{th} member of an arbitrary ordering of the set $\{0, 1\}^{\log k}$, that is, the set of $\log k$ binary variables. Let $\mathbf{1} \in \mathbb{R}^{\log k - 1}$ be the vector of all 1s.

Then the encoding of symbol i is:

$$\psi^{-1}(\langle_i)_* = \zeta[p^{(i)}; (1 - p^{(i)}); \mathbf{1}] \in \{0, 1\}^{3\lceil \log k \rceil - 1} \tag{G.1}$$

Where the semicolon $(;)$ denotes concatenation. This can be efficiently implemented in our simple RNN construction by modifying the U matrix to encode each ψ^{-1}. Each row of the softmax matrix V is as follows:

$$v_{\rangle_i,1} = \zeta[p^{(i)}; (1 - p^{(i)}); -\mathbf{1}; \mathbf{0}] \tag{G.2}$$

$$v_{\langle_i,m} = -\zeta[\mathbf{1} \in \mathbb{R}^{2\lceil \log k \rceil}; -\mathbf{1} \in \mathbb{R}^{\lceil \log k \rceil - 1}] \tag{G.3}$$

$$v_{\omega,j} = -\zeta[\mathbf{1} \in \mathbb{R}^{2\lceil \log k \rceil}; -\mathbf{1} \in \mathbb{R}^{\lceil \log k \rceil - 1}] \tag{G.4}$$

where j is for all $j \in [1, \dots, m]$, and all slots not specified are equal to $\mathbf{0}$.

Now it suffices to prove the stack correspondence lemma and probability correctness lemmas using ψ_* and V.

Proof of stack correspondence lemma, Lemma 3. As noted in (§ *D*), the only relevant property of the encodings e_i used for symbols $\langle_i$ in Lemma 3 is that it take on values in $\{0, 1\}$. This is also true of ψ_*^{-1}, so the lemma still holds.

Proof of probability correctness lemma, Lemma 5. It suffices to show that V obeys the softmax validity property (Definition 11) with respect to ψ_* to prove Lemma 5 using new encoding ψ_*. First, we have that

$$\begin{aligned} v_{\rangle_j,1}^\top \psi_*^{-1}(\langle_i) = \Big(&\sum_{i=1}^{\lceil \log k \rceil} p^{(i)} p^{(j)} \\ &+ \sum_{i=1}^{\lceil \log k \rceil} (1 - p^{(i)})(1 - p^{(j)}) \\ &+ \sum_{i=1}^{\lceil \log \rceil k - 1} 1(-1) \Big) \\ &\begin{cases} = \log k - (\log k - 1) & i = j \\ \leq (\log k - 1) - (\log k - 1) & i \neq j \end{cases} \\ &\begin{cases} = 1 & i = j \\ \leq 0 & i \neq j \end{cases}, \end{aligned}$$

Where $v_{\rangle_j,1}$ is specified since the top of the stack is always in slot 1, ensuring the first requirement. Intuitively, this dot product simply counts up the number of bits that agree between the row j and the symbol i encoded; if they're the same, all bits agree; if not, at least 1 must disagree.

Further, we have

$$\begin{aligned} v_{\langle_i,m}^\top \psi_*^{-1}(\langle_i) = -\zeta\Big(&\sum_{\ell=1}^{\lceil \log k \rceil} 1(p_\ell^{(i)}) \\ &+ \sum_{\ell=1}^{\lceil \log k \rceil} 1(1 - p_\ell^{(i)}) \\ &+ \sum_{\ell=1}^{\lceil \log k \rceil - 1} (-1 * 1) \Big) \\ &= -\zeta\big((\lceil \log k \rceil) - (\lceil \log k \rceil - 1)\big) \\ &= -\zeta \end{aligned}$$

since the count of bits $p_\ell^{(i)}$ that are 1 plus the count of negated bits $(1 - p_\ell^{(i)})$ that are one must always equal exactly $\lceil \log k \rceil$. This holds identically for $v_{\omega,j}^\top \psi_*^{-1}(\langle_i)$, for all $j \in [m]$. Finally, $v_{\langle_i,m'} = 0$, for $m' < m$, ensuring that $v_{\langle_i,m'<m}^\top \psi_*^{-1}(\langle_i) = 0$, as required. This proves that ψ_* obeys the softmax validity properties, so Lemma 5 still holds for our Simple RNN construction.

Counting hidden units Since ψ_* encodes each symbol in $d = 3\lceil \log k \rceil - 1$ space, and the Simple RNN construction constructs a stack in $2md$ space, we have that Simple RNNs can generate Dyck-(k,m) in $2m(3\lceil \log k \rceil - 1) = 6m\lceil \log k \rceil - 2m$ space. This proves Theorem 4.

G.2 $O(\log k)$ vocabulary encoding in the LSTM

We'll use a slight variation of the construction we used for the Simple RNN, made possible since the LSTM can encode the value -1 due to the hyperbolic tangent. First, for the encoding, we swap the last $\lceil \log k \rceil - 1$ values 1 for -1:

$$\psi'^{-1}(\langle_i) = [p^{(i)}; (1 - p^{(i)}); -\mathbf{1}] \tag{G.5}$$

$$\tag{G.6}$$

And negate the corresponding values of the softmax matrix, as follows:

$$v_{\langle_i,m} = -\zeta[\mathbf{1} \in \mathbb{R}^{2\lceil \log k \rceil}; -\mathbf{1} \in \mathbb{R}^{\lceil \log k \rceil - 1}] \tag{G.7}$$

$$v_{\omega,j} = -\zeta[\mathbf{1} \in \mathbb{R}^{2\lceil \log k \rceil}; -\mathbf{1} \in \mathbb{R}^{\lceil \log k \rceil - 1}] \tag{G.8}$$

where j is for all $j \in [1, \dots, m]$, and all slots not specified are equal to $\mathbf{0}$.

Now it suffices to prove the stack correspondence lemma and probability correctness lemmas using ψ_* and V.

Proof of stack correspondence lemma, Lemma 4. It suffices to show that ψ_* obeys the encoding-validity property (Definition 9). First, for all i, we have,

$$\begin{aligned} \mathbf{1}^\top \psi_*^{-1}(\langle_i) &= \mathbf{1}^\top [p^{(i)}; (1 - p^{(i)})] - (\log k - 1) \\ &= \log k - (\log k - 1) = 1, \end{aligned}$$

as required. This was possible because we could use the -1 value in the encoding ψ_*. Second, we see that $\psi_*^{-1}(\langle_i) \in \{0, 1\}^{3\lceil \log k \rceil - 1}$, as required. Third, we have still that $\psi_*(\mathbf{0}) = \mathbf{0}$. Fourth and finally, we have by construction that all encodings $\psi_*^{-1}(\langle_i)$ are distinct and none are equal to zero, by construction, since each is assigned a different bit configuration (and each bit configuration is concatenated to its negation.)

So, the encoding-validity property holds on ψ_*, and the stack correspondence lemma, Lemma 4 holds.

Proof of probability correctness lemma, Lemma 5. The proof of the probability correctness lemma holds as an immediate corollary of the proof of the same lemma for the Simple RNN using ψ_*. In particular, the only difference between the ψ_* and V used for the Simple RNN and that used for the LSTM is the swapping of a factor of -1 from a span of v to that of ψ_*, so we still have

$$v_{\rangle_j,u}^\top \psi_*^{-1}(\langle_i) = \begin{cases} = 1 & i = j \\ \leq 0 & i \neq j \end{cases}, \tag{G.9}$$

where u picks out the top of the stack from the stack correspondence lemma. We identically have

$$v_{\langle_i,m}^\top \psi_*^{-1}(\langle_i) = -\zeta \tag{G.10}$$

again from the proof for the Simple RNN, and likewise for $v_{\omega,j}^\top \psi^{-1}(\langle_i)$ for all $j \in [m]$. Finally, we have $v_{\langle_i,m'} = \mathbf{0}$, for $m' < m$, again from the proof of the simple RNN. This proves that ψ_* obeys the softmax validity properties, so Lemma 5 still holds for our LSTM construction.

Counting hidden units Since ψ_* encodes each symbol in $d = 3\lceil \log k \rceil - 1$ space, and the LSTM construction constructs a stack in md space, we have that LSTM can generate Dyck-(k,m) in $m(3\lceil \log k \rceil - 1) = 3m\lceil \log k \rceil - m$ space. This proves Theorem 5.

G.3 Accounting of finite precision.

We've used a number of constants in our proofs; we now enumerate them to make it clear that our construction can operate in a finite-precision setting. We use the symbols as defined in their respective sections. The only values written to vector memory are $\{0, 1\}$. In the recurrent equations, we use $\{\beta, -\beta, 2\beta, -2\beta, -3\beta\}$. We refer to $\tanh(1)$ as γ, and use $\{\gamma, -\gamma, -2\gamma\}$. We use λ as a constant as well in our recurrent parameters, and use the constants $\{-\gamma\lambda, -2\gamma\lambda, \frac{1}{2}\gamma\lambda, -\frac{1}{2}\gamma\lambda, \frac{3}{2}\gamma\lambda, -\frac{3}{2}\gamma\lambda\}$. None of these constants grow or shrink with m or k. However, when defining a distribution that must assign mass to, e.g., all k open brackets, some values *must* scale with k. This okay, since the number of *unique* values need not scale with k, the finite set of values we use just becomes very small as k grows. As such, we use ζ in our definitions of V and b_v, as well as the constants $\{-\zeta, \frac{1}{2}\zeta, -\frac{1}{2}\zeta, \zeta\gamma, -\zeta\gamma, \frac{1}{2}\zeta\gamma, -\frac{1}{2}\zeta\gamma\}$ in the equations in that section. Likewise our threshold ϵ for ϵ-truncated support shrinks with k, as do the probabilities assigned by the model to tokens. For those probabilities, we choose to represent ϵ; thus allowed symbols (with probability $> \epsilon$) will be evaluated correctly as $\geq \epsilon$. For disallowed symbols, we choose to represent the value half-way between ϵ and our upper-bound on disallowed symbols' probability, $\frac{1}{10k}$, so these symbols' probabilities will be correctly evaluated as $< \epsilon$. Finally, we refer to $\log k$ in our intermediate equations as well (though it need not be computed explicitly.). Our finite-precision set $\mathbb{P}$ is the union of all finitely many constants named in this section.

H Experiment Details

In this section, we provide detail on our preliminary study on LSTM LMs learning Dyck-(k,m) from samples.

H.1 Data

We run experiments on Dyck-(k,m) for $k \in \{2, 8, 32, 128\}$ and $m \in \{3, 5\}$.

Distribution over Dyck-(k,m). As Dyck-(k,m) is an (infinite) set, in order to train language models on it, we must define a probability distribution over it. Intuitively, we sample tokens conditioned on the current DFA (stack) state. Depending on the stack state, one or two of the actions {`push` $\langle_i$, `pop`, `end`} are possible. For example, in the empty stack state, `push` $\langle_i$ and `end` are possible. We sample uniformly at random from the possible actions. Conditioned on choosing the `push` $\langle_i$ action, we sample uniformly at random from the open brackets $\langle_i$. Conditioned on choosing the `pop` action, we generate with probability 1 the $\rangle_i$ that corresponds to the $\langle_i$ on the top of the DFA stack (to obey the well-balancing condition. Upon choosing the `end` action, we generate ω and terminate.

m	3	5
Train lengths	1:84	1:180
Test lengths	85:168	181:360

Table 2: Training and testing length cutoffs (min/max) for the distributions we define over Dyck-(k,m)

Formally,

$$q_0 = [] \tag{H.1}$$

$$a_t \sim \begin{cases} U(\{\texttt{push}\ \langle_i, \texttt{end}\}) & |q| = 0 \\ U(\{\texttt{push}\ \langle_i, \texttt{pop}\}) & 0 < |q| < m \\ U(\{\texttt{pop}\}) & |q| = m \end{cases} \tag{H.2}$$

$$w_t \sim \begin{cases} U(\{\langle_i\}_{i\in 1:k}) & a_t = \texttt{push}\ \langle_i \\ U(\{\rangle_j\}) & a_t = \texttt{pop}, q = [\dots, \langle_j] \\ U(\{\omega\}) & a_t = \texttt{end} \end{cases} \tag{H.3}$$

We choose this distribution to provide the following statistical properties. Consider the markov chain with nodes 1 to m representing $|q_t|$, the number of symbols on the DFA state stack at timestep t. (This is a Markov chain because q_t is sufficient to describe the probability distribution over all suffixes after timestep t.) From the probability distribution we've defined, for any timestep where the stack is neither empty nor full, that is, $0 < |q_t| < m$ there is probability $1/$ of advancing in the markov chain towards m, that is $|q_{t+1}| = |q_t| + 1$, and probability $1/2$ of retreating towards 0, that is, $|q_{t+1}| = |q_t| - 1$. This *hitting time* of state m from state 0 is the expected number of timesteps it takes for the generation sequence to start at the empty stack state $q_t = []$ and end up at a full stack state $|q_{t'}| = m$. Because of the $1/2$ probability of advancing or retreating along the markov chain, the hitting time is $O(m^2)$.

Length conditions. Suzgun et al. (2018) showed that the choice of formal language training lengths has a significant effect on the generalization properties of trained LSTMs. We choose training lengths carefully, keeping in mind the $O(m^2)$ hitting time from empty to full stack states, to empirically ensure that in expectation, the longest training sequences traverse from the empty state to a full stack state $|q_t| = m$ and back to the empty stack state at least three times. This ensures that models are not able to use simple heuristics at training time, like

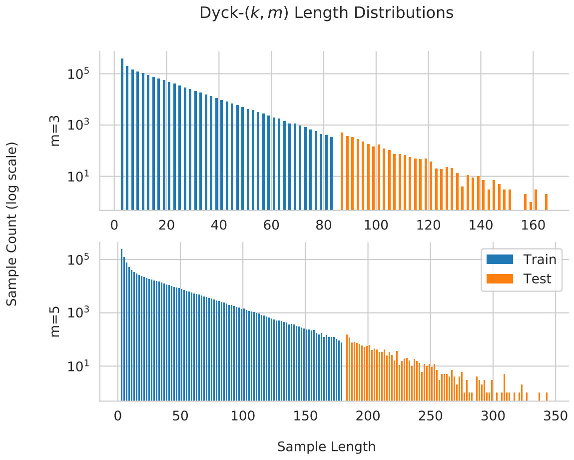

Figure 5: Sample length statistics for the twenty million token datasets. Note that the y-axis is on a log scale.

k	2	8	32	128
% of Total	100	100	15	.03
% of Test	100	100	58	31

remembering the first open bracket in the sequence to close the last close bracket. The exact length statistics are provided in Table 2. Length statistics for training and testing sets are shown in Figure 5..

DFA state analysis. Since Dyck-(k,m) is a regular language, it is reasonable to believe it may learn equivalences between strings that result in the same DFA state, but fail to generalize to DFA states not seen during training time. In Table 3, we see that for k equal to 2 an 8, all DFA states are seen at training time. Equivalently, every possible stack configuration of 2 or 8 brackets, of stack sizes up to 3 or 5, are seen during training time. For $k = 32$, however, only 15% of all possible DFA states are seen at training time, and only 58% of DFA states seen at testing time are also seen at training time. For $k = 128$, the numbers are even more stark, where 0.3% of all possible states, and 31% of states seen at testing time are also seen at training time. Thus, the ability of models to generalize to the test set for k equal to 32 and 128 shows that the learned LSTMs are not simply memorizing DFA states from training time.[26] Instead, we speculate that they're performing stack-like operations, and leave further investigation to future work.

Sample counts To test sample efficiency of learning, we study four dataset sizes: $\{2k, 20k, 200k, 2m, 20m\}$ tokens for training for each k, m combination. In all training settings, we use identical development and test sets of size $20k$ and $300k$ tokens, respectively. The development set is sampled from the training distribution.

H.2 Models

We use LSTMs, defined as in the main text with a linear readout layer, and implemented in PyTorch (Paszke et al., 2019). We set the hidden dimensionality of the LSTM to $3m\log(k) - m$, and the input dimensionality to $2k + 10$.

H.3 Training

We use the default LSTM initialization provided by PyTorch. We train using Adam (Kingma and Ba, 2014), using a starting learning rate of 0.01 for all training sets less than $2m$ tokens. Based on hand hyperparameter optimization, we found that for $k = 128$, at $2m$ tokens it was better to use a starting learning rate of 0.001. For training sets of size $20m$ tokens, we use a starting learning rate of 0.001 for all settings of k. We use a batch size of 10 for all experiments. We evaluate perplexity on the development set after every epoch, restarting Adam with a learning rate decayed by 0.5 if the development perplexity does not achieve a new minimum. After three consecutive epochs without a new minimum development perplexity, we stop training. We use no explicit regularization.

H.4 Evaluation

We're interested in evaluating the behavior of the LSTM LMs in hierarchical memory management, that is, in remembering what type of bracket $\rangle_i$ can come next. The model cannot possibly do better than random at predicting the next open bracket. Other aspects of the language, like whether the string can end, or if the stack is full, can be solved easily with a counter, which LSTMs are known to implement (Weiss et al., 2018; Suzgun et al., 2019). We thus evaluate whether, for each observed close bracket, the LM is confident about which close

---

[26] There are over 34 billion possible DFA states for $k = 128, m = 5$.

bracket (that is, i for $\rangle_i$) it is, since this is deterministic; it must be the close bracket corresponding to the open bracket at the top of the stack of q_{t-1}. We do this by normalizing the probability assigned by the LM to the *correct* close bracket by the sum of probabilities assigned to *any* close bracket:

$$p(\rangle_j | \rangle) = \frac{p(\rangle_j)}{\sum_i p(\rangle_i)} \tag{H.4}$$

We evaluate whether the model is confident, when we define as $p(\rangle_j | \rangle) > 0.8$.

Most pairs of open and close brackets in our distribution of Dyck-(k,m) are near linearly, but we're interested in *long-distance* memory management. Thus, we let p_ℓ be the empirical probability that the model confidently predicts a close bracket, conditioned on it being separated from its open bracket by ℓ tokens. We then evaluate models by taking $\text{mean}_\ell p_\ell$; that is, to evaluate its performance at closing brackets? To get a value of 1 for this metric, models must confidently close every bracket.

We train with three independent seeds for each training setting (training set size, k, and m), and report the median across seeds of our bracket closing metric in Figure 3.

Detecting Independent Pronoun Bias with Partially-Synthetic Data Generation

Abstract

We report that state-of-the-art parsers consistently failed to identify "hers" and "theirs" as pronouns but identified the masculine equivalent "his". We find that the same biases exist in recent language models like BERT. While some of the bias comes from known sources, like training data with gender imbalances, we find that the bias is *amplified* in the language models and that linguistic differences between English pronouns that are not inherently biased can become biases in some machine learning models. We introduce a new technique for measuring bias in models, using Bayesian approximations to generate partially-synthetic data from the model itself.

1 Introduction

We share a negative result for the Natural Language Processing (NLP) community as a whole: for 20 years the major part-of-speech (POS) taggers and parsers missed that "hers" and "theirs" were pronouns, but it had gone unreported until this paper. This paper also shows that biases against "hers" and "theirs" are *amplified* in popular language models, predicted by the models with less frequency than expected given the training data.

Our solution for the parser problem is a new dataset with "hers" and "theirs" used in a syntactically diverse set of contexts, released in Universal Dependency format (Nivre et al., 2016).

For the language model problem, we introduce a novel use of Bayesian modeling for sentence generation, in our case using it to detect bias by alternating pronouns in different contexts. The contexts are suggested by the model, avoiding the problems in measuring bias that come from rare or pathological data (Feng et al., 2018). We conclude that this is a general technique that can be used for measuring other types of bias and for text generation more broadly.

While our contribution doesn't mitigate bias in language models, it improves the ability to detect and measure bias. We test on BERT (Devlin et al., 2019) because it is the most widely used pretrained model for which all the training data was also available. We find that other masked language models are also amplifying the bias in their data, but we cannot measure how much that bias is amplified without access to the training data. Where data for a pretrained model can't be shared, we encourage researchers to report on the biases in their models using the techniques in this paper.

1.1 The bias is hers... and singular theirs

Independent possessive pronouns (IDPs) are interesting problems for NLP because they are the only English pronouns to encode *two* long-distance relationships: the person possessing an attribute and the attribute being possessed (see Table 1).

The preference for "his" in language models will bias any text generation system against "hers" or "theirs", a problem that has led developers to remove gendered pronouns entirely from applications including *Gmail*'s predictive text (Dave, 2018).

Identifying IDPs as pronouns is also a necessary step for co-reference resolution, although recent shared-tasks for pronoun resolution did not include IDPs (Webster et al., 2018, 2019).

Unfortunately, major academic and commercial parsers including those from *AWS* and *Google* (Andor et al., 2016) wrongly labeled "hers" and "theirs" as adjectives or nouns.

Parsers from 20 years ago also missed these pronouns (Charniak, 2000; Charniak and Johnson, 2005), confirming that this is not a new bias that only surfaced with more recent dependency parsers. The syntactic information was also typically wrong, for example, parsers that labeled "hers" as an "adjective" wrongly classified the syntactic relationships as modifiers. This will perpetuate bias in any

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2011–2017,
November 16–20, 2020.

	Subj	Obj	Dep	Ind
Feminine	she	**her**		hers
Masculine	he	him	**his**	
Neutral	they	them	their	theirs
1st Person	I	me	my	mine
2nd Person	**you**		your	yours

Table 1: Common English personal pronouns showing the irregular "her", "his" and "you". Key (Examples):
Subj: Subject (**they** saw a cat")
Obj: Object ("a cat saw **them**")
Dep: Dependent Possessive ("**their** cat")
Ind: Independent Possessive (IDP) ("a cat saw **theirs**")
In addition, a "-self/-selves" suffix on the Obj or Dep pronoun creates the Reflexive/Intensive pronoun.

downstream model using pronouns for co-reference or possession relationships.[1]

Two causes for biases are historical disempowerment resulting in less training data and linguistic differences in how "he/him/his" and "she/her/hers" pattern irregularly, as in Table 1.[2]

For the linguistic differences, the parsers correctly identify the *independent* "his" as a pronoun because they trained on the *dependent* "his" with the same form. Therefore, even without bias in the data, "hers" and "theirs" can be under-predicted because of *richer* grammatical distinctions.

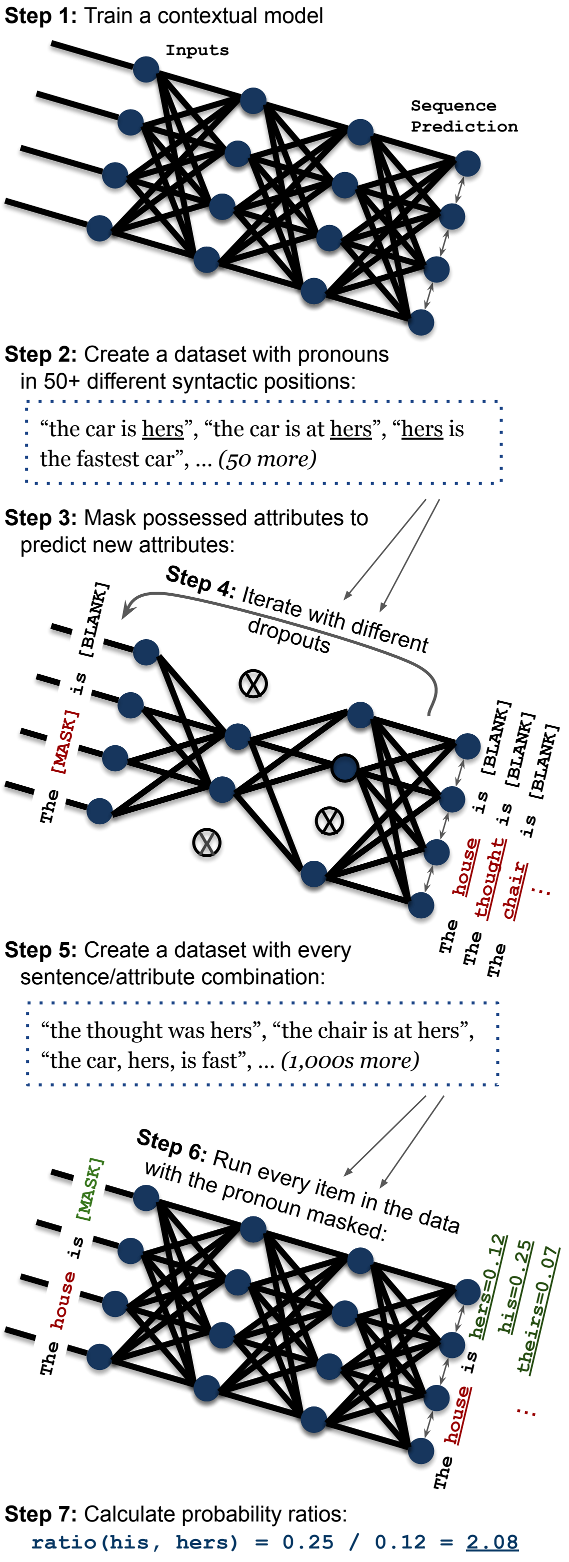
Because "hers" and "theirs" have only one sense, a small amount of training data can fix the problem for the syntactic parsers. We solved this with the dataset introduced in Section 2. We recognize that more data would be needed to solve the problem for polysemous independent pronouns like "mine" and the singular/plural distinction for "theirs".

2 Process for detecting bias

In this section, we share our method for partially-synthetic data generation to measure bias in pretrained models (see the workflow in Figure 1).

The code is open-source and will reproduce the results in a single command:[3]

Step 1: Train a contextual model. We use the pretrained BERT (Devlin et al., 2019) English un-



Step 1: Train a contextual model

Step 2: Create a dataset with pronouns in 50+ different syntactic positions:

"the car is hers", "the car is at hers", "hers is the fastest car", ... *(50 more)*

Step 3: Mask possessed attributes to predict new attributes:

Step 4: Iterate with different dropouts

Step 5: Create a dataset with every sentence/attribute combination:

"the thought was hers", "the chair is at hers", "the car, hers, is fast", ... *(1,000s more)*

Step 6: Run every item in the data with the pronoun masked:

Step 7: Calculate probability ratios:

`ratio(his, hers) = 0.25 / 0.12 = 2.08`

Figure 1: An overview of our workflow for bias-detection. We generate 1000s of unique sentences to test the bias, from an initial set of 50+ sentences created with maximally diverse contexts, utilizing masked models with dropouts to generate a list of candidate possessed attributes.

---

[1] We tested more than a dozen systems that also failed to identify "hers" and "theirs" as pronouns, but limit our report to ones where we share responsibility for previously missing this because the authors have both worked at AWS and built NLP training data for Google.

[2] See this blog article from when we first announced this problem for more about why "hers" and "theirs" were missed by parsers until now: bit.ly/hers_theirs

[3] https://github.com/rmunro/masked_bias_detection

cased model with Whole Word Masking, 24-layers, 1024-hidden neurons, 16-heads, and 340M params.

Step 2: Create a starting dataset. We created a new dataset in Universal Dependency (UD) format that contained an independent possessive pronoun in different syntactic configurations (Pollard and Sag, 1994): Subject, Object, Extraction, Interjection, etc. and sentence types that are grammatically identical in English UD but different in other languages, like Transitive vs Intransitive sentences, prepositions ("in theirs", "at theirs", etc), formal/informal variations ("isn't theirs"/"aint theirs") and the IDP's special context ("[item] of theirs").

The dataset is sentence pairs, like "What color is Alex's car? Theirs is red" because natural-sounding single sentences were not always possible.[4]

Step 3: Mask attributes to predict new ones. Using the new dataset, mask attributes like "car(s)" so that BERT predicts the most likely tokens for where "car(s)" is masked in a sentence like "The [MASK] is hers".

Step 4: Iterate with Bayesian Deep Learning. Used random dropouts (Monte Carlo Sampling) to generate multiple attributes for each sentence. Dropouts at inference follow the same principles as for training, where an estimation function E that ignores neurons i for an input vector I and weight w at a dropout rate δ_i for least-squared loss is:

$$E = \frac{1}{2}\left(t - \sum_{i=1}^{n} \delta_i w_i I_i\right)^2 \tag{1}$$

We use the same dropout profile in inference that the BERT model used for training and leave experiments with different dropout profiles as interesting potential future work.

To solve the problem of when to stop trying to generate new sentences, we use a modified Good-Turing estimate (Gale, 1995) where the core insight is that the number of items you have encountered just once is the main factor in predicting the likelihood of seeing new items. We calculate this as P_r when there are $C(att_1)$ attributes seen once, $C(att)$ attributes seen in total, and $sum_i att_i$ total attributes (including duplicates):

$$P_r = \frac{C(att_1) + C(att)}{\sum_i att_i} \tag{2}$$

We stop generating when P_r falls below a certain probability, 0.05 in the results presented here.

This process generated 115 attributes (see Figure 2) including concrete items like "camera" and "world" and abstract items like "night" and "instincts". Because these items are predicted to be the most likely item in a given context, we can be confident that they aren't low-frequency items that will make BERT produce erroneous results.

Step 5: Create a dataset with combinations. 11 of the 115 attributes produced grammatically incorrect sentences and were removed manually. The 104 remaining attributes were combined with the initial sentences, resulting in thousands of unique sentences.

Step 6: Predict the probability of different pronouns. With the thousands of sentences from Step 5, we generate sentences that use each attribute to predict the *pronoun*. For example, BERT is asked to guess what the masked (blank) word would be in 1000s of sentences like "the camera is ___", "the world is ___", "the night is ___", etc.

Step 7: Calculate the bias. Measure the ratio between the relative probabilities of "hers", "his" or "theirs" in the softmax output, following the bias-detection methods of Kurita et al. (2019).

3 Bias analysis

Figure 2 compares the model predictions to the training data which is Wikipedia and BookCorpus. BERT is trained on cross-entropy loss (Devlin et al., 2019), so if a token is four times more frequent than another in the data and occurs in the same contexts, then softmax should converge on a 4:1 ratio in the predictive model. While there can be a lot of variation in models that will change the ratio of a given prediction, especially for rare and pathological cases (Feng et al., 2018), we avoid rare tokens by having the model generate the contexts and by testing across thousands of sentences.

3.1 Possession is 99% of the flaw

For 103/104 attributes, "his" was preferred over "hers" or "theirs". For 92/104 attributes the model ratios were 3+ standard errors higher than the maximum data measurement, despite high variance. See Figure 2 for the full results.

The results in Figure 2 rule out that there is something special about possessives compared to other pronouns because ratios for objects in gendered sentences are consistently lower. The few exceptions

---

[4] https://github.com/UniversalDependencies/UD_English-Pronouns

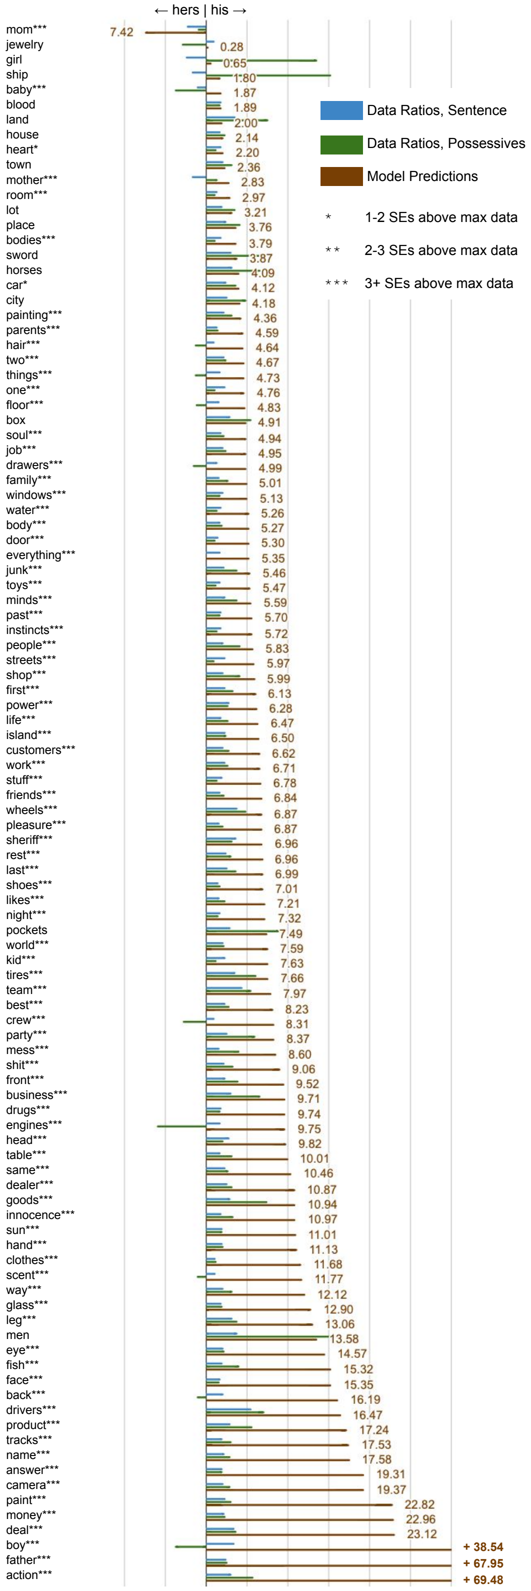


Figure 2: Comparison of model predictions and training data, showing the bias for "his" over "hers". **"Sentence"**: ratio of sentences with a gendered word ("man", "woman", etc) that contains the attribute. **"Possessives"**: ratio of explicit possessive structures like "his car". **"Model Predictions"**: the ratio between the pronouns in masked predictions.

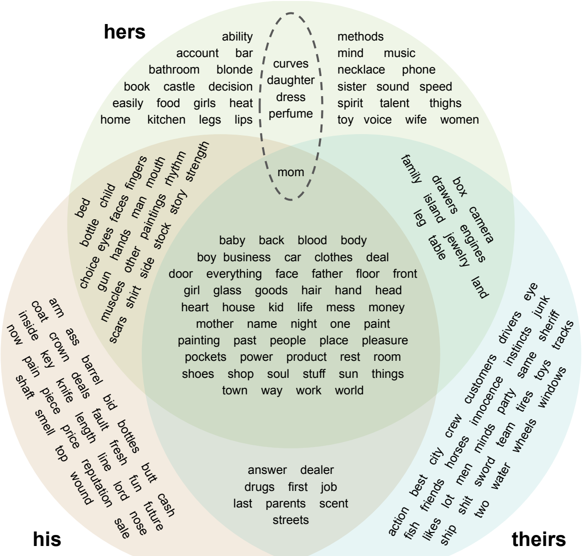

Figure 3: The words generated as possessions of "hers", "his", and/or "theirs" in our data. The dashed circle shows the five words predicted as possessed by "hers" when the pronoun is masked. The other words are predicted to be more likely possessed by "his", even for 70+ words that"his" did not generate as a possession.

in Figure 2 can be explained as being gendered directly ("girl", "men") or by convention ("she's a fast ship"). For the latter, the ownership shows that they are still male-dominated spaces ("*his* ship" and "*her* engines"), which is a novel observation for the relationship between the possessed and possessor.[5]

We also tried to bias the model in favor of "hers" and "theirs" by including them in Step 3 (see Figure 3), but even then, "theirs" was *never* the preference, and "hers" was rarely selected. For example "land" was generated in sentences like the "the [MASK] is hers/theirs", but never generated with sentences like "the [MASK] is his". However, when we try "the land is [MASK]", "his" is significantly predicted above "hers" and "theirs".

We conclude that the model has amplified the bias in the data that it is trained on.

4 Related Work

Kurita et al. (2019) introduced the method for measuring bias in contextualized word representations with two template sentences and a set of nouns. We extend Kurita et al. by using 1000s of sentences generated from 57 templates, instead of two, and by automatically expanding the context attributes with

---

[5] We thank an anonymous reviewer for pointing this out.

BERT itself to avoid pathological cases. Kurita et al. use the *difference* of log probabilities, but we use the (mathematically equivalent) *ratio* of actual probabilities because ratios allow more transparent comparisons with the corpus ratios.

Dropouts at inference generate a Gaussian distribution and is therefore known as *Bayesian Deep Learning* (Gal and Ghahramani, 2016). For Human-in-the-Loop methods, like this paper, it known as *Deep Active Bayesian Learning* (Shen et al., 2018; Siddhant and Lipton, 2018). Our paper is the first application of Bayesian Deep Learning to bias detection and, more broadly, to text generation.

Gonen at al. (2019) concluded that careful use of a language-specific morphological analyzer is needed to avoid bias in embeddings in gendered languages like Italian and German.

The recent Workshop on Gender Bias in Natural Language Processing (Costa-jussà et al., 2019) had a shared task for English gender-ambiguous pronouns (Webster et al., 2018, 2019), but the dataset and task did not include possessive pronouns.

Hahn (2020) shows limitations in how transformer models can learn finite-state and hierarchical structures. Therefore, some language models might be unable to fully distinguish the two forms of 'his' because they can not fully capture the syntax in the same way as humans, leading the dependent form of "his" in the training data to bias in favor of the independent form.

5 Accepting the responsibility themself

We found an additional problem when we first shared the "hers/theirs" problem one year before this paper: *some parsers didn't always recognize "themself" as a pronoun.*

The systems with "themself" errors did *not* fix the problem when they fixed "hers/theirs".

Our linguistic understanding of (neo)pronouns and inclusive NLP development are areas of ongoing research (Ackerman, 2019; Bradley et al., 2019; Cao and Daumé III, 2020; Conrod, 2020; Denton et al., 2020; Mitchell et al., 2020).

However, we argue that no system should have still missed "themself" after we alerted everyone to the "hers/theirs" error and recommended that every pronoun be investigated.

English is one of the simplest languages in terms of the paradigms like those in Table 1 (Bresnan, 2001), and the most well-studied in NLP (Bender and Friedman, 2018). If we can't identify unambiguous pronouns in our NLP, systems given a year's notice and clear instructions for how to find the errors, what biases are we missing elsewhere?

6 Discussion and Recommendations

People who use "hers", "theirs" and "themself" to align their current social gender(s) with their pronouns' grammatical gender are marginalized when applications fail to identify those pronouns. This is especially timely with singular "they" as Merriam-Webster's 2019 word of the year (Dwyer, 2019).

We find that pretrained models *amplify* biases in the data because linguistic differences that are not biases can become biases in the models. This has significant implications for bias in tasks like co-reference resolution and text generation.

From Gonen et al., (2019), it is not clear that debiasing the model itself would solve the problem. However, it might be possible to encode the data with the grammatical categories to mitigate some bias, for example, encoding the two "his" pronouns, like "his{DEP}" and "his{IND}". A pretrained model would therefore treat the two forms separately, without one amplifying the other even when a language model can't capture the syntactic differences.

We recommend that creators of widely used English syntactic parsers and part-of-speech taggers ensure that all unambiguous pronouns, including "hers", "theirs", and "themself", are correctly identified as pronouns. This will support applications the rely on technologies like conference resolution.

We recommend that creators of language models include identity words as full tokens. BERT's tokenizer includes all pronouns in this paper *except* "themself", thus exhibiting unintended feature-design bias by needing to be constructed as "them-s-elf" or "them-se-lf", presumably because all other forms with a "-self" suffix are already full tokens. That might include words other than pronouns, especially for multilingual models.

We recommend that creators of language models use the methods introduced in this paper for partially-synthetic data generation to diagnose potential bias in their models and that this text generation strategy is explored for other applications.

Visually Grounded Continual Learning of Compositional Phrases

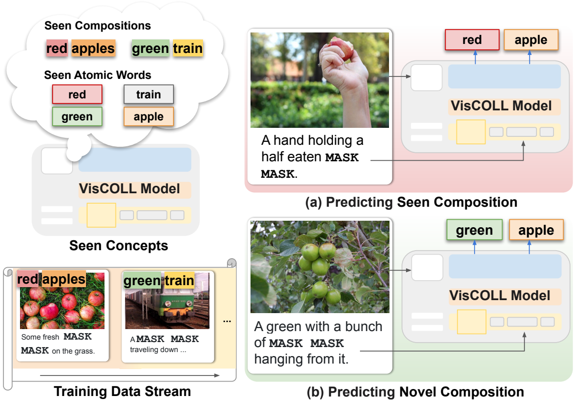
Xisen Jin Junyi Du Arka Sadhu Ram Nevatia Xiang Ren
Department of Computer Science, University of Southern California
`{xisenjin, junyidu, asadhu, nevatia, xiangren}@usc.edu`

Abstract

Humans acquire language continually with much more limited access to data samples at a time, as compared to contemporary NLP systems. To study this human-like language acquisition ability, we present VisCOLL, a visually grounded language learning task, which simulates the continual acquisition of compositional phrases from streaming visual scenes. In the task, models are trained on a paired image-caption stream which has shifting object distribution; while being constantly evaluated by a visually-grounded masked language prediction task on held-out test sets. VisCOLL compounds the challenges of *continual learning* (*i.e.*, learning from continuously shifting data distribution) and *compositional generalization* (*i.e.*, generalizing to novel compositions). To facilitate research on VisCOLL, we construct two datasets, COCO-shift and Flickr-shift, and benchmark them using different continual learning methods. Results reveal that SoTA continual learning approaches provide little to no improvements on VisCOLL, since storing examples of all possible compositions is infeasible. We conduct further ablations and analysis to guide future work [1].

1 Introduction

Modern NLP systems, including ones that build on pre-trained language models (Devlin et al., 2019; Radford et al., 2019), excel on a wide variety of tasks. These systems rely on offline (batch) training and have drawn recent criticism due to their inability to adapt to new contexts (Linzen, 2020). In contrast, humans acquire language from evolving environments, require a small memory footprint (McClelland et al., 1995), and can generalize their knowledge to newer tasks (Sprouse et al., 2013). It has been suggested that humans ground perceptual experience to semantically interpret symbols (Bisk et al., 2020; Harnad, 1990; Vigliocco et al., 2014).



(a) Predicting Seen Composition

(b) Predicting Novel Composition

Figure 1: **Illustration of the proposed VisCOLLtask.** The end-task is Masked-Token Prediction: given an image, a model predicts the masked tokens of an associated caption in an online continual learning setup (cf. (a) in the figure). Additionally, we test composition generalization by evaluating on novel compositions (b) which are not encountered at train time.

Model model the challenge, we propose VisCOLL, a **Vis**ually-grounded **Co**ntinua**L** **L**earning setup, to acquire compositional phrases from streaming visual-linguistic data. Models receive a stream of paired image-caption data which has a shifting object distribution. As the end task, we employ masked token prediction of captions given the associated image, as illustrated in Fig. 1(a). This evaluates a model's learned knowledge on composing phrases with the given context.

VisCOLL captures two *inter-related* challenges. First, unlike previous continual learning works on image classification (Kirkpatrick et al., 2017; Zenke et al., 2017), VisCOLL requires predicting, for example, a noun with a verb or an adjective—which results in a significantly large search space. As a result of this increased search space, memory based continual methods (Robins, 1995; Aljundi

et al., 2019a) cannot expect to store prototypes of each visited compositions. Second, the increased search space makes it infeasible to view all possible combinations of atomic words at train time. Therefore, to succeed on VisCOLL, models should generalize to novel compositions at test time (also called *composition generalization*) (Lake and Baroni, 2017; Keysers et al., 2020).

In this work, we extensively study the challenges associated with VisCOLL. To facilitate the research, we construct a continuously shifting data distribution to closely resemble real-word datastream and contribute COCO-shift and Flickr-shift. We benchmark these datasets using multi-modal language modeling architectures (Tan and Bansal, 2019; Su et al., 2020) which achieve state-of-art performance on multiple vision-language tasks. In particular, we don't use any pre-training, instead train randomly initialized models on streaming data using continual learning algorithms (Robins, 1995; Rolnick et al., 2019; Aljundi et al., 2019a) and evaluate their resistance to forgetting and compositional generalization. We quantify the performance and forgetfulness of trained models and evaluate on a novel test split to measure compositional generalization, as shown in Fig. 1(b).

Our proposed VisCOLL benchmark reveals that the gains observed in image classification tasks from state-of-art continual learning algorithms fail to transfer to VisCOLL even with increased memory. On the other hand, composition generalization remains challenging even for offline-training.

To summarize, our contributions are: (i) we propose VisCOLL, a task aimed at continual learning of compositional semantics from visually grounded text inputs (ii) we contribute two datasets COCO-shift and Flickr-shift to study VisCOLL and benchmark them with multi-modal language models (iii) we show that existing continual learning algorithms fail at learning compositional phrases and provide potential future research direction.

2 Related Works

Continual Learning. A major challenge in continual learning is to alleviate catastrophic forgetting (Robins, 1995). Several recent works (Greco et al., 2019; Wang et al., 2019; de Masson d'Autume et al., 2019) study the challenge in the context of NLP. Existing continual learning algorithms can be broadly classified into memory-based approaches (Lopez-Paz and Ranzato, 2017; Aljundi et al., 2019b), pseudo-replay based approaches (Shin et al., 2017), regularization based approaches (Kirkpatrick et al., 2017; Zenke et al., 2017; Nguyen et al., 2018) and architecture based approaches (Rusu et al., 2016). However, these works are mainly designed for image classification tasks where the training data has "clear" task boundaries–*i.e.,* training stream are partitioned into disjoint subsequences. In contrast, task boundaries in VisCOLL are unknown and "smooth" (i.e., with gradual transitions between tasks)–a setting that is closer to real-world situations. Thus, VisCOLL rules out many continual learning algorithms which require explicit task identity and boundary (Kirkpatrick et al., 2017; Rusu et al., 2016).

Modeling Language Compositionality. Capturing compositionality in language has been a long challenge (Fodor et al., 1988) for neural networks. Recent works explore the problem with compositional generalization on synthetic instruction following (Lake and Baroni, 2017), text-based games (Yuan et al., 2019), visual question answering (Bahdanau et al., 2019), and visually grounded masked word prediction (Surís et al., 2019). In particular, Li et al. (2020) study a closely related task of continual learning of sequence prediction for synthetic instruction following. However, their techniques for separating semantics and syntax is restricted to text-only case. Nguyen et al. (2019) investigate continual learning of image captioning, but make strong assumptions on the structure of the data stream, and do not evaluate compositionality.

Different from these, our work focuses on learning compositional language (*e.g.*, phrases) in a continual learning setup. We create realistic training streams to simulate shifting data distribution, with systematic evaluation of compositionality learned in the models. We aim at improving model's ability of acquiring language from real-world streaming data with a low-memory footprint.

3 The VisCOLL Task

Overview. There are two design considerations for VisCOLL: *compositionality* and *continual learning*. To test compositionality, we choose visually grounded masked language modeling where the model needs to compose atomic words to describe complex and novel visual scenes. To simulate a realistic continual learning setup, we construct a dynamic environment where the training data comes in as a non-stationary data stream without clear "task" boundaries. Since the goal is to simulate lan-

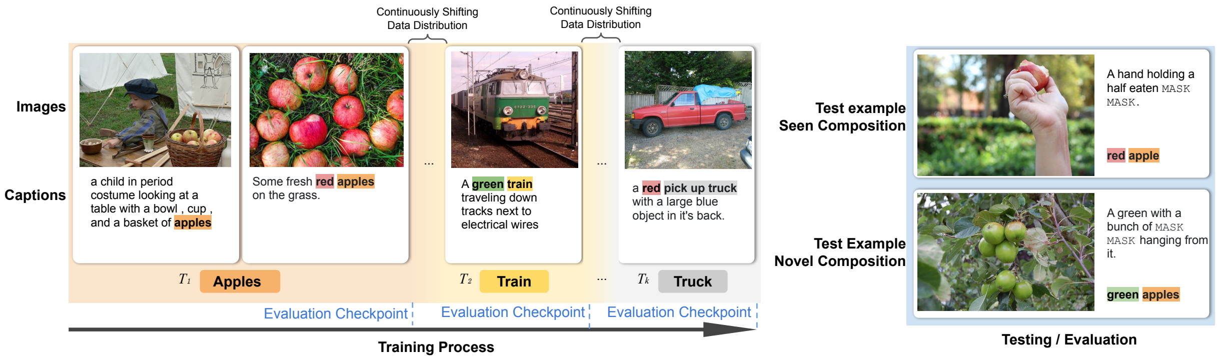

Figure 2: **An overview of training and testing process in VisCOLL.** At **train** time, the model receives a stream of masked captions (highlighted in text) with their associated image. We use the noun appearing in the masked token as the "task" subsequently used to create a continuously shifting data distribution. We further evaluate the model's performance every fixed time interval to quantify "forgetting". At **test** time, the models receives a seen composition or a novel composition of seen words.

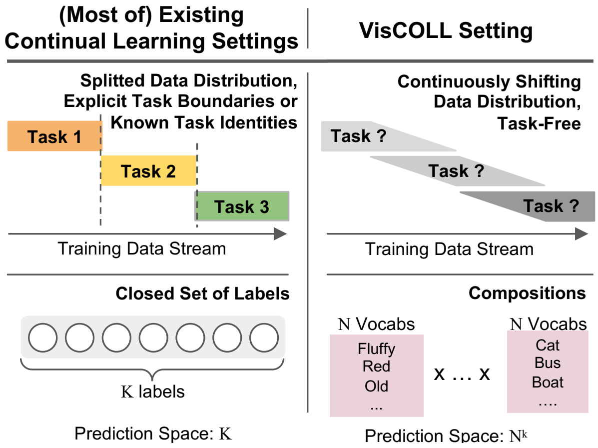

Figure 3: **Comparison of traditional continual learning setup for image classification with the setup of VisCOLL.** In most of existing continual learning settings, task identities are obtainable and can be used to define task boundaries. In contrast, models in VisCOLL is agnostic to task identities (task-free), and fed/trained by a gradually shifting data distribution.

guage acquisition from scractch, VisCOLL models shouldn't initialize weights from a pre-trained network. We introduce details of our task setup in the rest of the section.

Prediction End-Task. We employ visually grounded masked language modeling as the prediction task in VisCOLL. An input instance to this task consists of an image $\mathbf{x}_{img}$, its object bounding boxes $\mathbf{x}_{bbox}$ (without object labels), and the caption text $\mathbf{x}_{text}$, where a contiguous text span in $\mathbf{x}_{text}$ is masked with `MASK` tokens which the model needs to fill. The masked text span $\mathbf{x}_{label}$ always includes a noun and optionally includes verbs or adjectives. We define each noun, verb, and adjective as an atom, and evaluate the model in both "seen" and "novel" composition setting of nouns and verbs/adjectives. For instance, we may test whether the model successfully predicts "*red apples*" (adjective+noun) when the model has seen examples that involve "*red*" and "*apples*" separately (see Figure 2 for an illustration).

Training Data Stream. Unlike traditional offline training setups where a model visits the training examples for multiple passes, we study an online continual learning setup, where the model visits a non-stationary stream of data. We assume the data distribution changes gradually: for example, the model may see more "*apples*" in the beginning, and see less of them later. Unlike prior continual learning benchmarks, we do not assume strict task boundaries, *i.e.*, sudden distribution changes. We illustrate this distinction in Figure 3.

Formally, at each time step t, the model receives a small mini-batch of stream examples $\{\mathbf{X}_i\}_{i=0}^{B-1}$ where $X_i{=}(\mathbf{x}^i_{img}, \mathbf{x}^i_{bbox}, \mathbf{x}^i_{text}, \mathbf{x}^i_{label})$ whose distribution changes over time, *i.e.*, $P(X_i, t_i) \neq P(X_i, t_j)$ where the time step $t_i \neq t_j$. Note that our formulation rules out continual learning algorithms that make use of information about task boundaries. Section 4 formally introduces the data stream construction process.

Evaluation. In addition to the final performance, we also evaluate the model performance every fixed time interval and compute its forgetting as the performance loss over time. For compositional generalization, a novel composition split is used. Details will be covered in the following Sections 4 and 6.

Dataset	COCO-shift	Flickr-shift
Size of training set	639,592	456,299
Size of validation (dev) set	27,918	15,406
Size of regular test set	28,720	15,286
Size of compositional test set	4,426	-
Mean of instance # per task	26,288	487
Median of instance # per task	7,727	137
Average masked span length	2.497	3.380
Number of tasks	80	1,000

Table 1: **Statistics of our constructed datasets COCO-shift and Flickr-shift.**

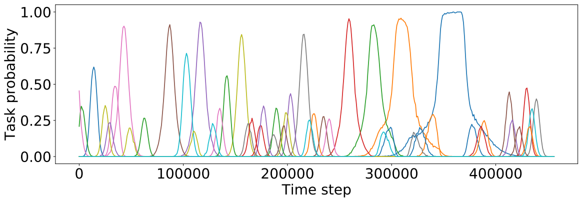

Figure 4: **Probability distributions of 50 tasks (the noun in the masked tokens) in Flickr-shift data stream.** Each curve corresponds to a task. x-axis shows the time step, and y-axis shows the probability of visiting the given task at a specific time step.

4 Dataset Construction

We construct our data streams using two popular vision-language datasets: COCO-captions (Chen et al., 2015) and Flickr30k Entities (Plummer et al., 2015) which provide multiple captions for each image in MSCOCO (Lin et al., 2014) and Flickr30k (Young et al., 2014) respectively. We call the resulting datasets COCO-shift and Flickr-shift (see Table 1 for dataset statistics).

Constructing a dataset for VisCOLL involves two key steps: (i) identify the phrase to be masked which involves a noun and associated verbs and adjectives (ii) create a non-stationary data-stream.

Masking Tokens. First, we append part-of-speech tags (POS) to each caption using Stanza (Qi et al., 2020). For Flickr30k Entities, we use the annotated noun-phrases as mask tokens. For COCO-captions, we identify text spans with a regular expression chunker with the following regular expression.

```
CHUNK: <DT>?<JJ|VBG|VBN>*<NN|NNS>+
                 <VB|VBD|VBG|VBN|VBP|VPZ>*
```

The resulting text span always includes a noun, and optionally include a determinator and an adjective and verb before or after the noun.

To construct a data-stream, we define a "task" as the object being referred to in the textual input data. For Flickr30k Entities, this is simply the lemmatized noun in the masked span. For COCO-captions, we further map the lemmatized nouns to the 80 object categories defined in MSCOCO using a synonym table provided in (Lu et al., 2018).

Non-Stationary Data-Stream. With a set of "tasks" defined as $\mathcal{T}$, we let each task $T_i \in \mathcal{T}$ gradually introduced in the stream, then gradually fade out. We generate a random permutation of all K tasks $(T_1, T_2, T_3, ..., T_K)$ as the order in which the centroid (mode) of each task distribution arrives in the stream. Each task proposes a task distribution for itself, which is a gaussian with $\mu_i = |D_i|/2 + \sum_{k<i} |D_k|$ and $\sigma_i = |D_i|/2$, where D_i is the set of training instances for task i. μ_i and σ_i roughly determines the centroid and the spread of the distribution of each task. Finally, the algorithm greedily tries to put the proposed number of instances into each time interval to construct the stream. As a result, the constructed data stream has a gradually shifting task distribution without strict boundaries. Figure 4 illustrates the task distribution in our constructed data streams.

For COCO-shift, we separate out instances related to 5,000 images from the official validation set as our test set, and the rest as the test set. For Flickr-shift, we use the official train, validation and the test split. Note that the "task" is only used as an identifier of data distribution for constructing the dataset; the task identities are not revealed to models and the way we construct the data streams ensures there are no clear task boundaries.

Test Split of Novel Compositions. We measure compositional generalization by evaluating on a disjoint set of noun-adjective or noun-verb compositions. We use the compositional test split of COCO dataset by Nikolaus et al. (2019) and remove images related to predefined 24 concept pairs (*e.g.*, black cat, standing child) from the training, validation and the regular test set. The test split is referred to as the *compositional* test set, and the rest is referred to as the *regular* test set.

5 Methods

To benchmark on VisCOLL and study the challenges it poses on model learning, we establish several continual learning baselines. We use visual-language encoder models (Sec. 5.1) for masked token predictions. These models are trained from scratch (*i.e.*, randomly initialized) with continual learning algorithms (Sec. 5.2) to dissuade catas-

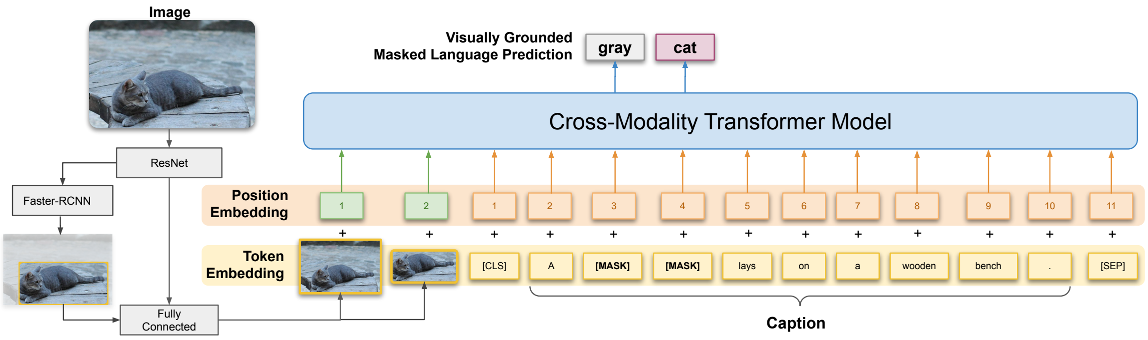

Figure 5: **Model architecture of the visual-language encoder used in VisCOLL.** For the input image, we first extract image-level and object-level features using a FasterRCNN. These features along with the masked caption are passed to a cross-modal transformer (in our case LXMERT and VLBERT) to predict the masked tokens. The model is *randomly initialized without pre-trained weights*, and trained end-to-end with cross-entropy-loss.

trophic forgetting.

5.1 Architectures of Visual Language Model

Recall that our end-task is masked token prediction where the input is an image and a caption with masked out tokens. Since the task of masked token prediction is used as a pre-training method in almost all multi-modal masked language models, we choose two such model architectures, VLBERT (Su et al., 2020) and LXMERT (Tan and Bansal, 2019), as encoder models but expect similar conclusions with other models like ViLBERT (Lu et al., 2019) or UNITER (Chen et al., 2019). Since we seek to simulate the language acquisition process, we *remove the pre-trained weights* from the models and randomly initialize the model weights for both the visual and language transformers.

For both base models, we first extract image and object features in ground truth bounding boxes with a Faster-RCNN (Ren et al., 2015) model with Resnet-101 backbone (He et al., 2015) pretrained on Visual Genome (Krishna et al., 2017) dataset using only object-detection (without attributes). The ground-truth object labels are not provided to the feature extractor model. The extracted features are then passed to the base models along with the caption with masked text span replaced with `[MASK]` tokens. Finally we compute the cross entropy loss with model predictions. We illustrate our base model in Figure 5.

5.2 Compared Methods

Non-continual Learning Comparators. The most common way of training a deep learning model is to perform gradient updates on a mini-batch of independently and identically distributed samples. Since the model has access to the complete data (offline mode), the process is repeated multiple times (multiple epochs); we call this **offline** training. To decouple the effect of training for multiple epochs, we report **offline (one pass)** where we restrict to a single pass over the data. Due to the absence of catastrohpic forgetting, the results are generally better than continual learning scenarios. Note that these two methods do not address the VisCOLL task and potentially indicate and upper-bound of performance.

Continual Learning Methods. In a continual learning setup like VisCOLL, the distribution of training examples is non-stationary, and due to limited memory only a part of the data can be stored. In general, simply performing gradient updates after receiving a mini-batch (also called **Vanilla** Online Gradient Descent), leads to catastrophic forgetting (Robins, 1995).

For VisCOLL, we focus on memory-based continual learning algorithms. These can be easily adapted to our setup as they don't require any task identifiers (not available in VisCOLL). We leave the exploration of regularization based approaches (Hsu et al., 2018) to future work.

(1) *Experience Replay* (**ER**) (Robins, 1995) randomly stores visited examples in a fix-sized memory called the replay memory, and these stored examples can later be randomly sampled for retraining. Similar techniques have been used in reinforcement learning (Schaul et al., 2016; Rolnick et al., 2019). We apply reservoir sampling (Vitter, 1985) to decide examples to store and replace from the memory. The algorithm ensures each visited example has the same probability to be stored in

Best performance for each metric in a dataset is emphasized.

the memory. (2) *Average Gradient Episodic Memory* (**AGEM**) (Chaudhry et al., 2019a). Unlike ER, AGEM projects the gradients to a direction of non-increasing average loss computed on a random subset in the memory to alleviate forgetting. (3) *ER with Maximally Interfering Retrieval* (**ER-MIR**) (Aljundi et al., 2019a) extends ER by selecting examples that are most likely to be forgotten in the next one update.

We further implement a method, **ER-MIR**$_{max}$ as a variation of ER-MIR specific to our compositional prediction setting; which, instead of selecting the most likely forgotten phrase, selects the phrases containing the most likely forgotten words. It prevents the importance of an example get underestimated when the example contains mostly easy words and a few forgettable words.

6 Experiments

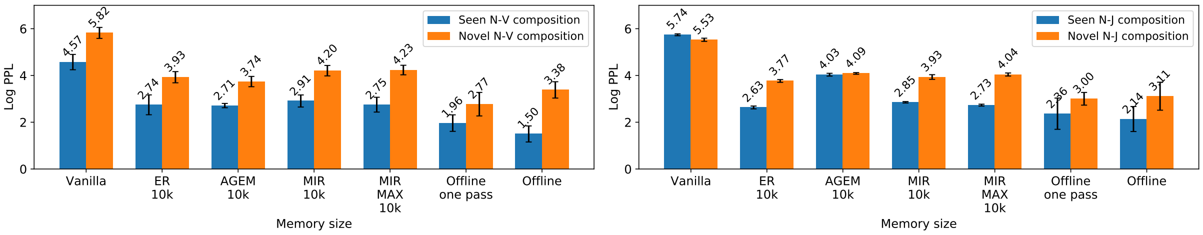
With the VisCOLL task formulation in place, we study: (i) performance of continual learning algorithms on VisCOLL. (ii) effect of the large search space on memory-based continual learning algorithms. (iii) performance on generalizing to novel compositions. (iv) effect of replay memory management strategies. We first describe our implementation details and metrics, and present our results with findings.

Implementation Details. For both VLBERT and LXMERT, we use a transformer with 6 layers, with 384 hidden units and 6 attention heads each. Note that all the parameters are learned from scratch without using pretrained weights. For all continual learning algorithms, we use a memory size of $1k$ and $10k$, corresponding to nearly 0.2% and 2% of data for the two datasets. We report average over 3 runs with the fixed stream and the same set of random seeds. See Appendix for more details.

General Evaluation Metrics. We employ Perplexity (PPL) as our primary metrics (lower is better) (Mikolov et al., 2011). Given a masked text span W=$[w_1, ..., w_N]$ and the model's prediction probability output $P(W)$, the log-perplexity is defined as, $PPL(W) = -\frac{1}{N}\log P(W)$. We report the perplexity in the log scale. Besides, we also use sentence-level BLEU (Papineni et al., 2002).

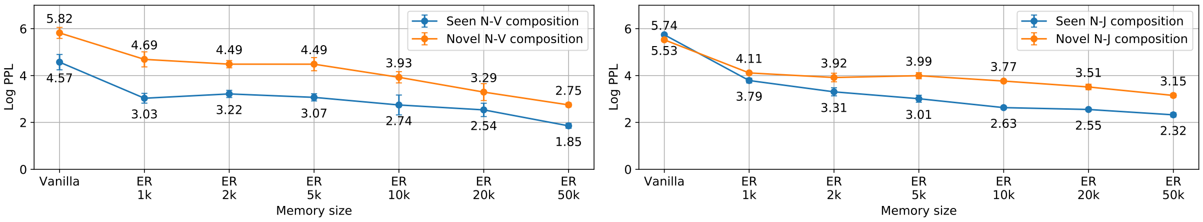
6.1 Study of Continual Learning

To analyze the continual learning ability of our model, we use two metrics: (i) final perplexity and BLEU: the test set perplexity and BLEU scores when the training ends (ii) forgetting metric: the averaged perplexity increase over all tasks when the training ends compared to the checkpoints (almost) all of training data of a given task is observed. Mathematically, the forgetting metric is calculated as $f_{avg} = \frac{1}{|\mathcal{T}|}\sum_{k\in\mathcal{T}} PPL_T(D_k) - PPL_{c_k}(D_k)$, where $c_k = \arg\min_{c_i\in\mathcal{C}} PPL_{c_i}(D_k)$. $\mathcal{T}$ is the set of all tasks, and $\mathcal{C}$ is the set of all checkpoints; $PPL_{c_k}(D_k)$ is the averaged perplexity over all test examples of task k at the checkpoint c_k, and T is the time step when the training ends. We expect a well-performing method to achieve low final perplexity, high BLEU scores, and low forgetting.



(a) Comparison across methods, Noun-Verb

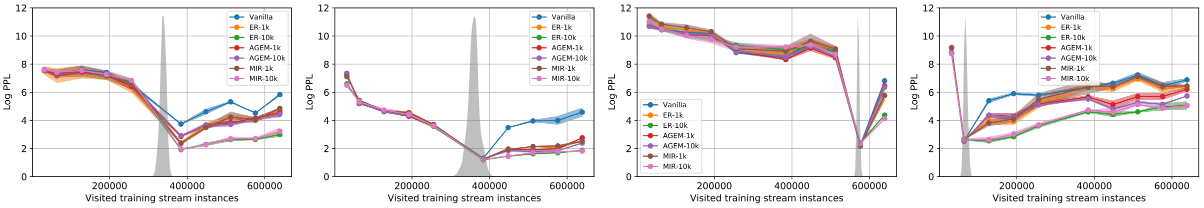
(b) Comparison across methods, Noun-Adjective



(c) Comparison across memory sizes, Noun-Verb

(d) Comparison across memory sizes, Noun-Adjective

Figure 6: **Results for Compositional Generalization.** We report perplexity of seen and novel compositions across methods (a),(b) and across memory sizes (c),(d) on COCO-shift dataset on noun-verb compositions and noun-adjective compositions separately. We first average the perplexity over examples for each composition individually, then compute the mean over these averaged scores over the set of compositions.



(a) Task `dog`

(b) Task `sports ball`

(c) `black` in `apple`

(d) `big` in `book`

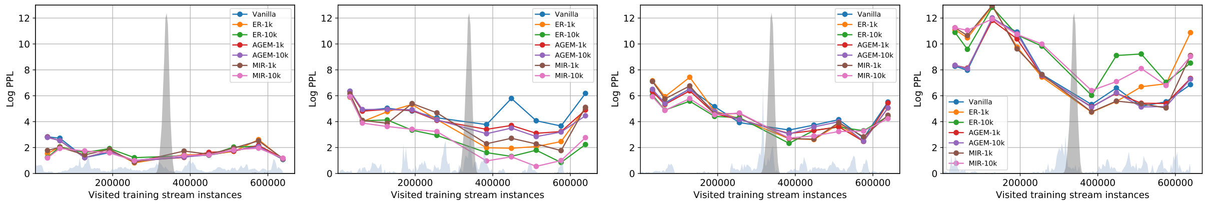
Figure 7: **Comparing effects of continual learning algorithms**, exemplified with two tasks. x-axis is the training examples visited and y-axis is the perplexity. The gray-shaded regions in show the task distribution in the stream.

Tables 2 compares base-models with various continual strategies on the corresponding regular test splits of COCO-shift and Flickr-shift. We discuss our findings below.

Non-stationary vs i.i.d Data Distribution. Across both datasets, it is evident that models trained with the non-stationary distribution (closer to what is observed in the real-world) largely under-perform compared to their i.i.d offline training counterpart at the single epoch setting (20-40 points difference in BLEU scores). This emphasizes that catastrophic forgetting is prevalent in our constructed non-stationary data stream.

Performance of Continual Learning Methods. Despite its simplicity, ER achieves extremely competitive results, scoring within 1-2 PPL of the best performing model. While AGEM achieves very appealing final perplexity on Flickr-shift dataset at the $1k$ memory setting (almost 0.5 points better than alternatives), we find the corresponding BLEU is worse. Given that perplexity evaluates over output probabilities, it is likely that AGEM makes less confident wrong predictions.

We also find ER-MIR and its variant ER-MIR$_{max}$ occasionally outperforms ER, but the improvements are inconsistent over base-models and datasets. This is in stark contrast to continual learning benchmarks on image classification where algorithms like AGEM and ER-MIR achieve SoTA performance. In Fig. 8(a)(b), we illustrate the change of perplexity over time for selected time steps in different methods. We notice that with a memory size of $10k$, on average the forgetting metric for ER is close to or less than zero most of the time. This implies the performance of each task remains constant or improves over what was initially learned.



(a) `sitting` in `black dog` (b) `running` in `big dog` (c) `black` in `black dog` (d) `big` in `big dog`

Figure 8: **Analyzing forgetting in old noun-verb or noun-adjective compositions sharing the same noun**. x-axis is the training examples visited and y-axis is the perplexity of the verb / adjective. The sharp gray-shaded regions are for the noun, while the light-blue regions near x-axis are for the adjectives.

Replay Memory Requirements Compared to Existing Benchmarks. It should be noted that even with a memory of $10k$ examples, the performance of continual learning algorithms are far from the i.i.d setting. In contrast to the popular continual learning benchmarks (Kirkpatrick et al., 2017; Zenke et al., 2017), where storing only a few examples for each class is believed to be sufficient for a good performance (Chaudhry et al., 2019b).

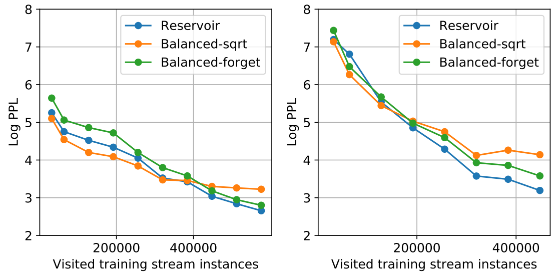
Effect of Multi-Modal Data. To decouple the gains obtained from visual and textual modality, we construct a text-only baseline by zeroing out the image-inputs in our base models and train using ER with memory size $10k$. From Table 2, we find across all cases, text-only baseline is outperformed by its multi-modal counterpart (5 points on BLEU) suggesting information from both image and captions is necessary to perform well on VisCOLL.

Our findings underscore the challenges imposed by VisCOLL and encourages closer examination towards existing continual learning benchmarks.

6.2 Study of Compositional Generalization

To measure compositionality captured by models, in addition to a regular test set, we evaluate on the compositional test set which consists of novel noun-adjective and noun-verb pairs. We compare the performance with seen compositions sharing the same set of atomic words in the regular test set. For a fair comparison with novel splits, we compare the performance on held-out novel pairs with a subset of the regular test-set sharing the same set of atomic words.

Overall Compositional Generalization Results. We plot the results in Figure 6. We note that the performance on novel compositions drops across all cases implying composition generalization is very difficult for visual language transformers. Interestingly, offline (one pass) outperforms offline training on novel compositions, suggesting the latter is over-fitting to the "seen" case.



(a) MSCOCO, VLBERT (b) Flickr, LXMERT

Figure 9: **Effect of memory management strategies, studied with ER and a replay memory of $10k$ examples.** x-axis is the training step; y-axis is the perplexity.

Analyzing Performance on Old Compositions. In an online setting, we further probe the model's predictive performance on old seen compositions. Interestingly, we find that the performance is largely dependent on the atomic words used in the compositions. For instance, the performance drop on predicting "black" in the composition "black dog" is relative small (Figure 8(c)) compared to predicting "big" in "big dog" (Figure 8(d)).

6.3 Study of Memory Management Strategies

We further study two memory scheduling strategies to account for a limited memory but large search space. Recall that the reservoir sampling applied our main experiments keeps each visited example has the same probability to be stored in the memory. We study two methods targeting storing more useful examples, aiming at: (i) storing diverse compositions, and (ii) prioritizing likely forgotten words.

We first propose target word distributions p_{tgt} in the memory. For (i), the target probability of each word is set proportional to the square root of its frequency in the visited stream. Thus, highly frequent words would take a smaller portion compared to reservoir sampling where the word distribution in the memory is linear to its frequency in the visited stream, leaving space for storing more diverse examples. We call this strategy **Balanced-sqrt**. For (ii), the target probability is proportional to its frequency in the stream multiplied by its forgetting estimated during training (*i.e.,* loss increase). We call this strategy **Balanced-forget**.

For both strategies, given the word distribution in the memory p_{mem} and target word distributions p_{tgt}, we minimize the KL-divergence $\mathrm{KL}(p_{mem}||p_{tgt})$. Thus, each time an example is received from the stream, we choose the memory example which if replaced causes the largest decrease in KL-divergence. If there are no such memory examples that let KL-divergence decrease, we discard the example.

The results are compared in Figure 9. We find that (i) diversifying storage improves performance at the early stage of the stream but not in the later stages; (ii) prioritizing words likely to be forgotten does not improve performance. Thus, future works should find a balance between storing more diverse or important examples and respecting original data distribution.

7 Conclusion

We propose VisCOLL, a novel continual learning setup for visually grounded language acquisition. VisCOLL presents two main challenges: continual learning and compositionality generalization. To facilitate study on VisCOLL, we generate continuously shifting data-stream to construct two datasets, namely COCO-shift and Flickr-shift, and establish evaluation protocols. We benchmark our proposed datasets with extensive analysis using state-of-the-art continual learning methods. Experiments reveal that continual learning algorithms struggle at composing phrases which have a very large search space, and show very limited generalization to novel compositions. Future works include looking into models and continual learning algorithms to better address the challenge.

A Details of Dataset Construction

Heldout Phrases. We put the complete list of 24 noun-verb and noun-adjective compositions used as novel compositions in Table 4, which are provided in (Nikolaus et al., 2019).

B Hyperparameter Settings

Since the complete stream should not be assumed known apriori in the online learning setting, following prior work (Chaudhry et al., 2019a), we use a small portion (10%) of the training data and the validation set to perform hyperparameter search. We use AdamW optimizer (Loshchilov and Hutter, 2019) throughout the experiements. We tune the learning rate based on the validation performance on the Vanilla method averaged over 3 runs. For a fair comparison in the online learning setup, we use the same learning rates for all methods. The learning rate is selected from $\{2e^{-4}, 1e^{-4}, 5e^{-5}\}$ and decided as $1e^{-4}$. We set the batch size to 32 throughout the experiments. For ER, ER-MIR and ER-MIR$_{max}$, at each training iteration, we replay the same number of examples from the memory as the examples received from the stream (*i.e.*, training batch size), following the convention in recent works (Aljundi et al., 2019a; Chaudhry et al., 2019b).

AGEM, unlike ER, requires a larger set of memory examples to compute regularizations. We set the numbers to 80 and 64 respectively for COCO-shift and Flickr-shift. While larger numbers can be preferable, it introduces significant time and resource consumption overhead in our problem setup, which is much larger in scale compared to existing continual learning benchmarks.

Task-order / Method	Vanilla	ER-1k	ER-10k
Asc. Frequency	4.31	3.22	2.42
Desc. Frequency	5.18	3.58	2.53
Random (main results)	5.04	3.15	2.31

Table 5: Performance with different task orders in COCO-shift and the VLBERT model.

Similarly, ER-MIR and ER-MIR$_{max}$ introduce a hyperparameter for the size of the "candidate set" to retrieve examples that are most likely to be forgotten. We set the hyperparameters as 80 and 64 for COCO-shift and Flickr-shift respectively.

C Effect of Data Order

Data order has been known to affect performance in continual learning (Greco et al., 2019). To illustrate this point, we conduct a simple experiment where the task centroids are sorted in the ascending or descending order. We show the log perplexity metrics in Table 5. The results show a significant log-perplexity gap, which verifies that data order may significantly affect performance. We leave more in-depth analysis as future works. Note that throughout our main experiments, the task order is fixed as a random order.

D Infrastructures and Statistics

We use PyTorch 1.0.0 (Paszke et al., 2019) with CUDA toolkit version 10.1. We train our models with NVIDIA 2080 Ti GPUs. Our VLBERT models have 23,564,040 trainable parameters and LXMERT models have 58,614,794 trainable parameters. We report the average training time over a single pass of the stream in table 3.

MAF: Multimodal Alignment Framework for Weakly-Supervised Phrase Grounding

Abstract

Phrase localization is a task that studies the mapping from textual phrases to regions of an image. Given difficulties in annotating phrase-to-object datasets at scale, we develop a Multimodal Alignment Framework (MAF) to leverage more widely-available caption-image datasets, which can then be used as a form of weak supervision. We first present algorithms to model phrase-object relevance by leveraging fine-grained visual representations and visually-aware language representations. By adopting a contrastive objective, our method uses information in caption-image pairs to boost the performance in weakly-supervised scenarios. Experiments conducted on the widely-adopted Flickr30k dataset show a significant improvement over existing weakly-supervised methods. With the help of the visually-aware language representations, we can also improve the previous best unsupervised result by 5.56%. We conduct ablation studies to show that both our novel model and our weakly-supervised strategies significantly contribute to our strong results.[1]

1 Introduction

Language grounding involves mapping language to real objects or data. Among language grounding tasks, phrase localization—which maps phrases to regions of an image—is a fundamental building block for other tasks. In the *phrase localization task*, each data point consists of one image and its corresponding caption, i.e., $d = \langle I, S \rangle$, where I denotes an image and S denotes a caption. Typically, the caption S contains several query phrases $\mathcal{P} = \{p_n\}_{n=1}^{N}$, where each phrase is grounded to a particular object in the image. The goal is to find the correct relationship between (query) phrases in the caption and particular objects in the image. Existing work (Rohrbach et al., 2016; Kim et al., 2018; Li et al., 2019; Yu et al., 2018; Liu et al., 2020) mainly focuses on the supervised phrase localization setting. This requires a large-scale annotated dataset of phrase-object pairs for model training. However, given difficulties associated with manual annotation of objects, the size of grounding datasets is often limited. For example, the widely-adopted Flickr30k (Plummer et al., 2015) dataset has 31k images, while the caption dataset MS COCO (Lin et al., 2014) contains 330k images.

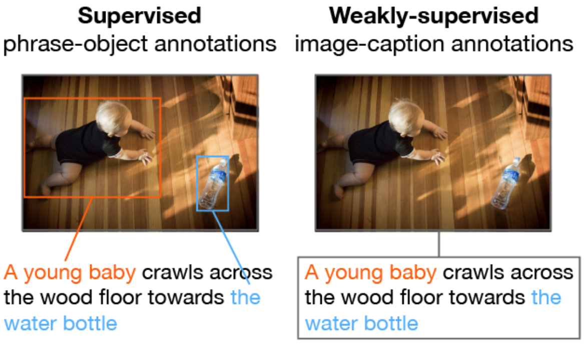

Figure 1: Comparison of phrase localization task under supervision (left) and weak supervision (right).

To address this limited data challenge, two different approaches have been proposed. First, a weakly-supervised setting—which requires only *caption-image annotations*, i.e., no *phrase-object annotations*—was proposed by Rohrbach et al. (2016). This is illustrated in Figure 1. Second, an unsupervised setting—which does not need any training data, i.e., neither caption-image and phrase-object annotation—was proposed by Wang and Specia (2019). To bring more semantic information in such a setting, previous work (Yeh et al., 2018; Wang and Specia, 2019) used the detected object labels from an off-the-shelf object detector (which we will generically denote by PreDet) and achieved promising results. In more detail, for a given im-

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2030–2038,
November 16–20, 2020.

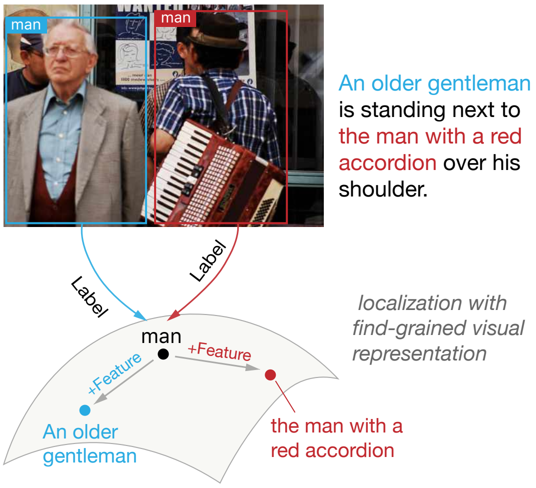

Figure 2: Example of the ambiguity caused by label-based localization (top); and our fine-grained visual representation disambiguate labels (bottom).

age I, the PreDet first generates a set of objects $\mathcal{O} = \{o_m\}_{m=1}^{M}$. Afterward, all the query phrases $\mathcal{P}$ and the detected objects $\mathcal{O}$ are fed into an alignment model to predict the final phrase-object pairs. However, purely relying on the object labels causes ambiguity. For example, in Figure 2, the grounded objects of phrases "an older man" and "the man with a red accordion" are both labeled as "man," and thus they are hard to differentiate.

Given these observations, we propose a Multimodal Alignment Framework (MAF), which is illustrated in Figure 3. Instead of using only the label features from the PreDet (in our case, a Faster R-CNN (Ren et al., 2015; Anderson et al., 2018a)), we also enhance the visual representations by integrating visual features from the Faster R-CNN into object labels. (This is shown in Figure 2.) Next, we build visually-aware language representations for phrases, which thus could be better aligned with the visual representations. Based on these representations, we develop a multimodal similarity function to measure the caption-image relevance with phrase-object matching scores. Furthermore, we use a training objective to score relevant caption-image pairs higher than irrelevant caption-image pairs, which guides the alignment between visual and textual representations.

We evaluate MAF on the public phrase localization dataset, Flickr30k Entities (Plummer et al., 2015). Under the weakly-supervised setting (i.e., using only caption-image annotations without the more detailed phrase-object annotations), our method achieves an accuracy of 61.43%, outperforming the previous weakly-supervised results by 22.72%. In addition, in the unsupervised setting, our visually-aware phrase representation improves the performance from the previous 50.49% by 5.56% up to 56.05%. Finally, we validate the effectiveness of model components, learning methods, and training techniques by showing their contributions to our final results.

2 Related Work

With the recent advancement in research in computer vision and computational linguistics, multimodal learning, which aims to explore the explicit relationship across vision and language, has drawn significant attention. Multimodal learning involves diverse tasks such as Captioning (Vinyals et al., 2015; Xu et al., 2015; Karpathy and Fei-Fei, 2015; Venugopalan et al., 2015), Visual Question Answering (Anderson et al., 2018a; Kim et al., 2018; Tan and Bansal, 2019), and Vision-and-Language Navigation (Anderson et al., 2018b; Chen et al., 2019; Thomason et al., 2020). Most of these tasks would benefit from better phrase-to-object localization, a task which attempts to learn a mapping between phrases in the caption and objects in the image by measuring their similarity. Existing works consider the phrase-to-object localization problem under various training scenarios, including supervised learning (Rohrbach et al., 2016; Yu et al., 2018; Liu et al., 2020; Plummer et al., 2015; Li et al., 2019) and weakly-supervised learning (Rohrbach et al., 2016; Yeh et al., 2018; Chen et al., 2018). Besides the standard phrase-object matching setup, previous works (Xiao et al., 2017; Akbari et al., 2019; Datta et al., 2019) have also explored a pixel-level "pointing-game" setting, which is easier to model and evaluate but less realistic. Unsupervised learning was studied by Wang and Specia (2019), who directly use word similarities between object labels and query phrases to tackle phrase localization without paired examples. Similar to the phrase-localization task, Hessel et al. (2019) leverages document-level supervision to discover image-sentence relationships over the web.

3 Methodology

3.1 Fine-grained Visual/Textual Features

Visual Feature Representations. Previous works usually use only one specific output of the PreDet as the *visual feature representation* (VFR). For example, Kim et al. (2018) uses the

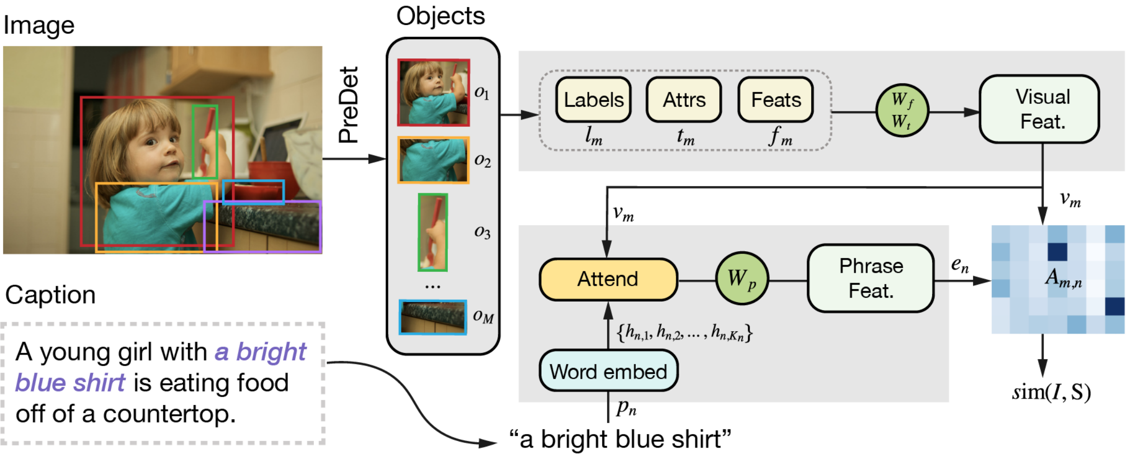

Figure 3: Overview of our proposed Multimodal Alignment Framework (MAF). A dataset of images and their captions is the input to our model. PreDet predicts bounding boxes for objects in the image and their labels, attributes, and features, which are then integrated into visual feature representations. Attention is applied between word embedding and visual representations to compute the visually-aware language representations for phrases. Finally, a multi-modal similarity function is used to measure the caption-image relevance based on the phrase-object similarity matrix.

final output feature of PreDet (denoted as $\boldsymbol{f_m}$) as the VFR, and Wang and Specia (2019) uses the label embedding (denoted as $\boldsymbol{l_m}$) of the predicted label from PreDet as the VFR. This unitary VFR usually lacks the counter-side information. Hence, we exploit different aspects of features extracted from PreDet for each object o_m in the image. In particular, we consider the output feature $\boldsymbol{f_m}$, the label embedding $\boldsymbol{l_m}$, and the attribute embedding $\boldsymbol{t_m}$ of the object o_m as the VFR,

$$\boldsymbol{v_m} = \boldsymbol{l_m} + W_t \boldsymbol{t_m} + W_f \boldsymbol{f_m}, \tag{1}$$

where W_t and W_f are two projection matrices. Naively initializing W_t and W_f will lead the model to a sub-optimal solution. In Section 4, we discuss the effectiveness of different initializations.

Textual Feature Representations. Existing works for *textual feature representation* (TFR) (Kim et al., 2018; Yu et al., 2018; Wang and Specia, 2019) commonly treat it independently of the VFR. From a different angle, we use the attention between the textual feature and the VFR $\boldsymbol{v}_m$ to integrate the visual information from the object into TFR. In more detail, we first use the GloVe embedding (Pennington et al., 2014) to encode the K_n words in the phrase p_n to $\{\boldsymbol{h}_{n,k}\}_{k=1}^{K_n}$, where $\boldsymbol{h}_{n,k} \in \mathbb{R}^d$. Here, the dimension of $\boldsymbol{h}_{n,k}$ is the same as $\boldsymbol{v_m}$. We then define a word-object matching score $a_{n,k}^m$ for each $\boldsymbol{h_{n,k}}$ in the phrase to all object features $\boldsymbol{v_m}$. In particular, for each word $\boldsymbol{h}_{n,k}$ in the phrase, we select the object with the highest matching score,

$$\begin{aligned} \boldsymbol{a}_{n,k}^m &= \operatorname*{soft\,max}_m \left\{ \frac{\boldsymbol{h}_{n,k}^T \boldsymbol{v}_m}{\sqrt{d}} \right\}, \\ \alpha_{n,k} &= \max_m \{\boldsymbol{a}_{n,k}^m\}. \end{aligned} \tag{2}$$

Finally, we normalize the attention weights for each word in the phrase p_n to obtain the final TFR, $\boldsymbol{e_n}$:

$$\begin{aligned} \beta_{n,k} &= \operatorname*{soft\,max}_k \{\alpha_{n,k}\}, \\ \boldsymbol{e_n} &= W_p \left(\sum_k \beta_{n,k} \boldsymbol{h}_{n,k} \right). \end{aligned} \tag{3}$$

where W_p is a projection matrix. In Section 4, we study the (superb) performance of the weight $\beta_{n,k}$ over simply the average $\boldsymbol{h}_{n,k}$ as well as the importance of the initialization of W_p.

3.2 Training Objective and Learning Settings

Contrastive loss. For the weakly-supervised setting, we use a contrastive loss to train our model, due to the lack of phrase-object annotations. The contrastive objective $\mathcal{L}$ aims to learn the visual and textual features by maximizing the similarity score between paired image-caption elements and minimizing the score between the negative samples (i.e., other irrelevant images). Inspired by the previous work in caption ranking (Fang et al., 2015), we use the following loss,

$$\mathcal{L} = -\log \frac{e^{\text{sim}(I,S)}}{\sum_{I' \in batch} e^{\text{sim}(I',S)}}. \tag{4}$$

Here, $\text{sim}(I, S)$ is the similarity function defined below. Particularly, for each caption sentence, we use all the images I' in the current batch as candidate examples.

Multimodal Similarity Functions. Following the document-level dense correspondence function in Hessel et al. (2019), our multimodal similarity function is defined as:

$$\text{sim}(I, S) = \frac{1}{N} \sum_{n} \max_{m} A_{n,m}. \tag{5}$$

Here, $A \in \mathbb{R}^{N \times M}$ is the phrase-object similarity matrix, and its component is computed as

$$A_{n,m} = \boldsymbol{e}_n^T \boldsymbol{v}_m, \tag{6}$$

and $\text{sim}(I, S)$ measures the image-caption similarity. It is calculated based on the similarity score between each phrase in the caption and each object in the image. Note that the maximum function $\max_m A_{n,m}$ directly connects our training objective and inference target, which alleviates the discrepancy between training and inference.

Weakly-supervised setting. During training, our PreDet model is frozen. The word embeddings, W_t, W_f, and W_p are trainable parameters. Here, the word embedding is initialized with GloVe (Pennington et al., 2014). We study the different initialization methods for the rest in Section 4. During inference, for the n-th phrase p_n in an image-caption pair, we choose the localized object by

$$m_n^{\text{pred}} = \arg\max_{m} A_{n,m} = \arg\max_{m} \boldsymbol{e}_n^T \boldsymbol{v}_m. \tag{7}$$

Unsupervised setting. In the unsupervised setting, the localized object is determined by

$$m_n^{\text{pred}} = \arg\max_{m} \left(\sum_{k} \beta_{n,k} \boldsymbol{h}_{n,k}^T \right) \boldsymbol{l}_m. \tag{8}$$

We drop the parameters W_t, W_f, and W_p here, because there is no training in the unsupervised setting. $\beta_{n,k}$ is only calculated based on $\boldsymbol{l}_m$ (instead of $\boldsymbol{v}_m$).

4 Empirical Results

Dataset details. The Flickr30k Entities dataset contains 224k phrases and 31k images in total, where each image will be associated with 5 captions and multiple localized bounding boxes. We use 30k images from the training set for training and 1k images for validation. The test set consists of 1k images with 14,481 phrases. Our evaluation metric is the same as Plummer et al. (2015).[2] We consider a prediction to be correct if the IoU (Intersection of Union) score between our predicted bounding box and the ground-truth box is larger than 0.5. Following Rohrbach et al. (2016), if there are multiple ground-truth boxes, we use their union regions as a single ground-truth bounding box for evaluation.

Weakly-supervised Results. We report our weakly-supervised results on the test split in Table 1. We include here upper bounds (UB), which are determined by the correct objects detected by the object detectors (if available). Our MAF with ResNet-101-based Faster R-CNN detector pretrained on Visual Genome (VG) (Krishna et al., 2017) can achieve an accuracy of 61.43%. This outperforms previous weakly-supervised methods by 22.71%, and it narrows the gap between weakly-supervised and supervised methods to 15%. We also implement MAF with a VGG-based Faster R-CNN feature extractor pretrained on PASCAL VOC 2007 (Everingham et al., 2010), following the setting in KAC (Chen et al., 2018), and we use the same bounding box proposals as our ResNet-based detector. We achieve an accuracy of 44.39%, which is 5.68% higher than existing methods, showing a solid improvement under the same backbone model.

Table 1: Weakly-supervised experiment results on Flick30k Entities. (We abbreviate backbone visual feature model as "Vis. Feature," and upper bound as "UB.")

Method	Vis. Features	Acc. (%)	UB
Supervised			
GroundeR (Rohrbach et al., 2016)	VGG_{det}	47.81	77.90
CCA (Plummer et al., 2015)	VGG_{det}	50.89	85.12
BAN (Kim et al., 2018)	ResNet-101	69.69	87.45
visualBERT (Li et al., 2019)	ResNet-101	71.33	87.45
DDPN (Yu et al., 2018)	ResNet-101	73.30	-
CGN (Liu et al., 2020)	ResNet-101	76.74	-
Weakly-Supervised

---

[2] To be specific, we use the evaluation code provided by Wang and Specia (2019) at `https://github.com/josiahwang/phraseloceval`.

Unsupervised Results.[3] We report our unsupervised results for the phrase localization method (described in Section 3.2) in Table 2. For a fair comparison, we re-implemented Wang and Specia (2019) with a Faster R-CNN model trained on Visual Genome (Krishna et al., 2017). This achieves 49.72% accuracy (similar to 50.49% as reported in their paper). Overall, our result (with VG detector) significantly outperforms the previous best result by 5.56%, which demonstrates the effectiveness of our visually-aware language representations.

Table 2: Unsupervised experiment results on Flick30k Entities. w2v-max refers to the similarity algorithm proposed in (Wang and Specia, 2019); Glove-att refers to our unsupervised inference strategy in Section 3.2; CC, OI, and PL stand for detectors trained on MS COCO (Lin et al., 2014), Open Image (Krasin et al., 2017), and Places (Zhou et al., 2017).

Method	TFR	Detector	Acc. (UB) (%)
Whole Image	None	None	21.99
(Wang and Specia, 2019)	w2v-max	Faster R-CNN	49.72 (86.29)
(Wang and Specia, 2019)	w2v-max	CC+OI+PL	50.49 (57.81)
MAF (Ours)	Glove-att	Faster R-CNN	56.05 (86.29)

Ablation Experiments. In this section, we study the effectiveness of each component and learning strategy in MAF. The comparison of different feature representations is shown in Table 3. Replacing the visual attention based TFR with an average pooling based one decreases the result from 61.43% to lower than 60%. For the VFR, using only object label $\boldsymbol{l}_m$ or visual feature $\boldsymbol{f}_m$ decreases the accuracy by 4.20% and 2.94%, respectively. One interesting finding here is that the performance with all visual features (last row) is worse than the model with only $\boldsymbol{l}_m$ and $\boldsymbol{f}_m$. Actually, we can infer that attributes cannot provide much information in localization (24.08% accuracy if used alone), partly because attributes are not frequently used to differentiate objects in Flickr30k captions.

We then investigate the effects of different initialization methods for the two weight matrices, W_f and W_p. The results are presented in Table 4. Here ZR means zero initialization, RD means random initialization with Xavier (Glorot and Bengio, 2010), and ID+RD means identity with small random noise initialization. We run each experiment for five times with different random seeds and compute the variance. According to Table 4, the best combination is zero initialization for W_f and identity+random initialization for W_p. The intuitions here are: (i) For W_f, the original label feature $\boldsymbol{l}_m$ can have a non-trivial accuracy 57.23% (see Table 3), thus using RD on initializing W_f will disturb the feature from $\boldsymbol{l}_m$; (ii) For W_p, an RD initialization will disrupt the information from the attention mechanism, while ID+RD can both ensure basic text/visual feature matching and introduce a small random noise for training.

Table 3: Ablation experiment results of different visual and textual features. TFR and VFR denotes textual and visual feature representation respectively.

TFR	VFR			Accuracy(%)
	l_m	f_m	t_m	
Average	✓			55.73

	✓		✓	58.54 ± 0.26
✓			✓	60.05 ± 0.31
	✓	✓		59.68 ± 0.35
✓		✓		61.28 ± 0.32

5 Conclusions

We present a Multimodal Alignment Framework, a novel method with fine-grained visual and textual representations for phrase localization, and we train it under a weakly-supervised setting, using a contrastive objective to guide the alignment between visual and textual representations. We evaluate our model on Flickr30k Entities and achieve substantial improvements over the previous state-of-the-art methods with both weakly-supervised and unsupervised training strategies. Detailed analysis is also provided to help future works investigate other critical feature enrichment and alignment methods for this task.

A Implementation Details

For GloVE word embeddings, we use the one with the hidden dimension 300. Phrases are split into words by space. We replace all out-of-vocabulary words with the introduced $\langle$UNK$\rangle$ token. For object proposals, we apply an off-the-shelf Faster R-CNN model (Ren et al., 2015) as the object detector[4] for object pseudo-labels. The backbone of the detector is ResNet-101 (He et al., 2016), and it is pre-trained on Visual Genome with mAP=10.1. We keep all bounding boxes with a confidence score larger than 0.1. For ResNet-based visual features, we use the 2048-dimensional feature from Bottom-up attention (Anderson et al., 2018a), which is pre-trained with 1600 object labels and 400 attributes.

The extracted visual features are frozen during training, and we use a batch size of 64 during training. Our optimizer is Adam with learning rate $lr = 1e^{-5}$. Except for word embeddings, trainable parameters include $W_t \in \mathbb{R}^{d_T \times d_T}$, $W_f \in \mathbb{R}^{d_V \times d_T}$, and $W_p \in \mathbb{R}^{d_T \times d_T}$, where $d_T = 300$, $d_V = 2048$ for ResNet-101 backbone and $d_V = 4096$ for VGG backbone. During training, it takes around 350 seconds to train an epoch using a single Tesla K80. We train our model for 25 epochs and report the results at the last epoch.

---

B Baselines

In Table 5, we report the results of different unsupervised methods:

- Random: Randomly localize to a detected object.
- Center-obj: Localize to the object which is closest to the center of image, where we use an L_1 distance $D = |x - x_{\text{center}}| + |y - y_{\text{center}}|$.
- Max-obj: Localize to the object with the maximal area.
- Whole Image: Always localize to the whole image.
- Direct Match: Localize with the direct match between object labels and words in the phrase, e.g., localize "a red apple" to the object with the label "apple." If multiple labels are matched, we choose the one with the largest bounding box.
- Glove-max: Consider every word-label similarity independently and select the object label with the highest semantic similarity with any word.
- Glove-avg: Represent a phrase using an average pooling over Glove word embeddings and select the object label with highest the semantic similarity with the phrase representation.
- Glove-att: Use our visual attention based phrase representation, as is described in the Methodology 3.1.

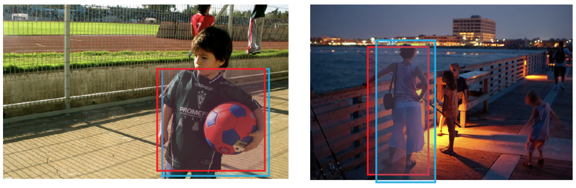
Note that in all label-based methods (Direct Match (Wang and Specia, 2019), and our unsupervised method), if multiple bounding boxes share the same label, we choose the largest one as the predicted box.

Table 5: Baseline results of unsupervised methods on Flick30k Entities. Abbreviations are explained above.

Method	Detector	Acc. (%)
Random	Faster R-CNN	7.19
Center-obj	Faster R-CNN	18.24
Whole Image	None	21.99
Max-obj	Faster R-CNN	24.51
Direct match	Faster R-CNN	26.42
Glove-max	Faster R-CNN	26.28
Glove-avg	Faster R-CNN	54.51
Glove-att	Faster R-CNN	56.05

C Qualitative Analysis

To analyze our model qualitatively, we show some visualization results in Figure 4 and Figure 5. Figure 4 shows examples with consistent predictions between supervised and unsupervised models. In these cases, both methods can successfully learn to localize various objects, including persons ("mother"), clothes ("shirt"), landscapes ("wave"), and numbers ("56"). Figure 5 shows examples where supervised and unsupervised methods localize to different objects. In the first image, they both localize the phrase "entrance" incorrectly. In the remaining three images, the supervised method



A young boy in a green shirt is holding a red and blue soccer ball

A mother and children is fishing on a boardwalk at night .

A surfer wearing a black and green wetsuit riding a wave.

A number 56 red racing car is speeding left past the frame .

Figure 4: Example of predictions on Flickr30k. (Red box: ground truth, blue box: our prediction).

A women is pointing down the street to her friend in front of an entrance.

A woman and a young girl sharing smiles at a table with a glass of water on it .

Near seats , woman has spread out green blanket to sit on floor with baby .

A boy hitting a girl on a skateboard with a plushie snake .

Figure 5: Example of predictions on Flickr30k. (Red box: ground truth, blue box: supervised prediction, yellow box: unsupervised prediction)

learns to predict a tight bounding box on the correct object, while the unsupervised method localizes to other irrelevant objects. For example (bottom left figure for Figure 5), if the object detector fails to detect the "blanket," then the unsupervised method can never localize "green blanket" to the right object. Still, the supervised method can learn from negative examples and obtain more information.

Domain-Specific Lexical Grounding in Noisy Visual-Textual Documents

Abstract

Images can give us insights into the contextual meanings of words, but current image-text grounding approaches require detailed annotations. Such granular annotation is rare, expensive, and unavailable in most domain-specific contexts. In contrast, unlabeled multi-image, multi-sentence documents are abundant. Can lexical grounding be learned from such documents, even though they have significant lexical and visual overlap? Working with a case study dataset of real estate listings, we demonstrate the challenge of distinguishing highly correlated grounded terms, such as "kitchen" and "bedroom", and introduce metrics to assess this document similarity. We present a simple unsupervised clustering-based method that increases precision and recall beyond object detection and image tagging baselines when evaluated on labeled subsets of the dataset. The proposed method is particularly effective for local contextual meanings of a word, for example associating "granite" with countertops in the real estate dataset and with rocky landscapes in a Wikipedia dataset.

1 Introduction

Multimodal data consisting of text and images is not only ubiquitous but increasingly diverse: libraries are digitizing visual-textual collections (British Library Labs, 2016; The Smithsonian, 2020); news organizations release over 1M images per year to accompany news articles (The Associated Press, 2020); and social media messages are rarely sent without visual accompaniment. In this work, we focus on one such specialized, multimodal domain: New York City real estate listings from the website StreetEasy.

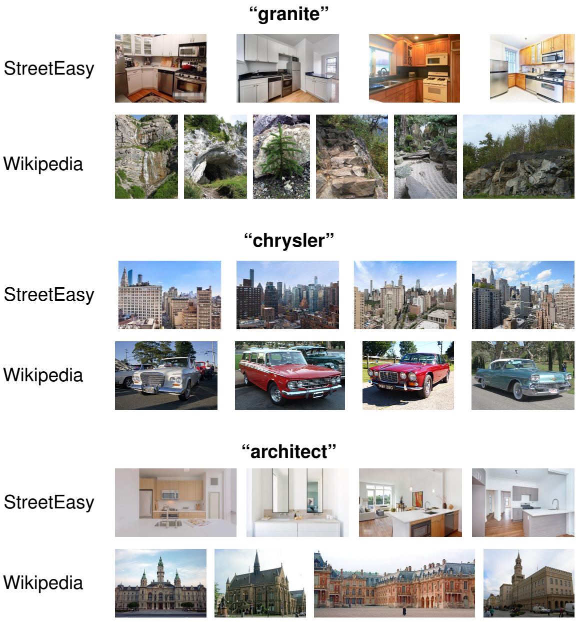

Figure 1: We identify domain-specific associations between words and images from unlabeled multi-sentence, multi-image documents.

To effectively index image-text datasets for search, retrieval, and other tasks, we need algorithms that learn connections between modalities, doing so from data that is naturally abundant. In documents that contain multiple images and sentences, there may be *no explicit annotations* for image-sentence associations or bounding box-word associations. As a result, existing image captioning/tagging methods are difficult to adapt to *unlabeled* multi-image, multi-sentence documents. Indeed, most prior image captioning work has focused on rare and expensive single-image, single-caption collections such as MSCOCO, which focuses on literal, context-free descriptions for 80 object types (Lin et al., 2014). Similarly, off-the-shelf object detectors may not account for contextual factors: to an ImageNet classifier, "pool" refers to a pool table (Russakovsky et al., 2015). In the specialized real estate context, "pool" commonly refers to a swimming pool.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2039–2045,
November 16–20, 2020. ©2020 Association for Computational Linguistics

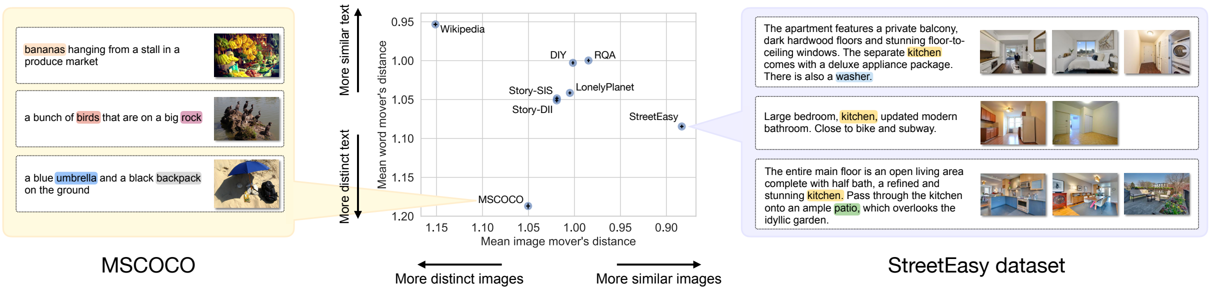

Figure 2: Documents in the StreetEasy dataset are much more visually similar to each other than documents in seven multimodal image-text datasets spanning storytelling, cooking, travel blogs, captioning, etc. (Lin et al., 2014; Huang et al., 2016; Yagcioglu et al., 2018; Hessel et al., 2018, 2019; Nag Chowdhury et al., 2020). Examples from StreetEasy show that words like "kitchen" are frequent and grounded. Black lines represent 99.99% CI.

Consider the task of lexical grounding: given a word, which images in the corpus depict that word? Consider the difficulty in learning a visual grounding for "kitchen" in StreetEasy. First, documents are multi-image, multi-sentence rather than single-image, single-sentence. Second, almost all documents picture a kitchen, a living room, and a dining room. Finally, "kitchen" co-occurs with more than two-thirds of all images, the majority of which are not kitchens. Is this task even possible?

Our first contribution is to map out a landscape of multimodal datasets, placing our real estate case-study in relation to existing corpora. We operationalize this notion in Figure 2 by plotting average across-document visual+textual similarity for our StreetEasy case study compared to several existing multimodal corpora;[1] indeed, images in StreetEasy have very low diversity compared to other corpora. As a result of this self-similarity, in §3, we find that image-text grounding is difficult for off-the-shelf image tagging methods like multinomial/softmax regression, which leverage variation in both lexical and visual features across documents.[2]

Our second contribution is a simple but performant clustering algorithm for this setting, *EntSharp*.[3] We intend this method to learn from $\langle$image, word$\rangle$ co-occurrences collected from multi-image, multi-sentence document collections. The training process iteratively "sharpens" the estimated $\Pr(\text{word} \mid \text{image})$ distributions so that words "compete" to claim responsibility for images. We show that EntSharp outperforms both object detection and image tagging baselines at retrieving relevant images for given word types. We then qualitatively explore EntSharp's predictions on both StreetEasy and a multimodal Wikipedia dataset (Hessel et al., 2018). The algorithm is often able to learn corpus specific relations: as shown in Figure 1, in the context of NYC real estate, "chrysler" refers to a prominent building and "granite" to a kitchen surface, while in Wikipedia the same words are grounded in cars and rocky outcroppings.

Related work. Learning image-text relationships is central to many applications, including image captioning/tagging (Kulkarni et al., 2013; Mitchell et al., 2013; Karpathy and Fei-Fei, 2015) and cross-modal retrieval/search (Jeon et al., 2003; Rasiwasia et al., 2010). While most captioning work assumes a supervised one-to-one corpus, recent works consider documents containing multiple images/sentences (Park and Kim, 2015; Shin et al., 2016; Agrawal et al., 2016; Liu et al., 2017; Chu and Kao, 2017; Hessel et al., 2019; Nag Chowdhury et al., 2020). Furthermore, compared to crowd-annotated captioning datasets, web corpora are more challenging, as image-text relationships often transcend literal description (Marsh and White, 2003; Alikhani and Stone, 2019).

2 Task and Models

We consider a direct image-text grounding task: for each word type, we aim to retrieve images most-associated with that word. Models are evaluated by their capacity to compute word-image similarities that align with human judgment.

---

[1] We compute text similarity between documents with a length-controlled version of word mover's distance (WMD) (Kusner et al., 2015) on word2vec token features. We compute visual similarity between documents with "image mover's" distance, which is identical to WMD, but with a CNN feature for each image. More details are given in Appendix A.

[2] Existing unsupervised approaches for this setting (Hessel et al., 2019; Nag Chowdhury et al., 2020) learn within-document matchings of whole sentences/paragraphs, we learn cross-document matchings of word types to images.

[3] Code is at `https://github.com/gyauney/domain-specific-lexical-grounding`.

EntSharp. For each image in a document we iteratively infer a probability distribution over the words present in the document. During training, these distributions are encouraged to have low entropy. The output is an embedding of each word into image space: the model computes word-image similarities in this joint space. This can be thought of as a soft clustering, such that each word type is equivalent to a cluster but only certain clusters are available to certain images. This approach could also be situated within the framework of multiple-instance learning (Carbonneau et al., 2018).

Each image i starts with a fixed feature vector $\vec{i} \in \mathbb{R}^d$. Let $\mathcal{I}$ be the set of these image embeddings. For each word w we initialize a cluster centroid $\vec{w} \in \mathbb{R}^d$ to the average of co-occurring images' embeddings. Let $\mathbb{1}_{i,w}$ be 1 if image i co-occurs with word w in any document and 0 otherwise. Each image $\vec{i}$ is assumed to have a membership distribution $\vec{p_i}$ over words, where $\vec{p_i}$ is initially uniform over co-occurring words. At each iteration, cluster centroids are updated to the weighted average of co-occurring images' embeddings: $\vec{w} := \sum_{\vec{i} \in \mathcal{I}} p_i(w) \cdot \vec{i}$ followed by normalization. Each image's distribution over clusters is updated by taking a softmax of the cosine similarity between pairs of image and word embeddings, first multiplying similarities by a sharpness coefficient[4] equal to the iteration number, and finally masking for co-occurrence: $p_i(w) \propto \mathbb{1}_{i,w} \cdot \exp\big(\text{sharpness} \cdot (\vec{i} \cdot \vec{w})\big)$. After training, we calculate the cosine similarity between image embeddings and the learned word-cluster embedding.

Untrained EntSharp baseline. We consider a simple averaging baseline, corresponding to the cluster center initializations of EntSharp: each word embedding is set to the mean of the features for all its co-occurring images.

Object detection baselines. We can use ImageNet to identify objects, but most words in the full vocabulary are not in the ImageNet labels. We implement two object detection baselines that map images to object names and then match object names to words in documents (Hessel et al., 2019). For each image, we first get the image's top class predictions from DenseNet169 (Huang et al., 2017) pretrained on the ImageNet classification task (Russakovsky et al., 2015). These predictions are for a whole image and are restricted to the 1000 ImageNet labels. We bridge the gap between ImageNet labels and the vocabulary by then creating an *image vector* by averaging the word vectors corresponding to these predictions. Finally, for each word in the full vocabulary, we rank images by the cosine similarity between the word's vector and these image vectors. Words are represented in one baseline by word2vec embeddings (Mikolov et al., 2013) and in the other by the output of RoBERTa (Liu et al., 2019) when fed a single token as input.

Image tagging baselines. Inspired by Mahajan et al. (2018), we implement softmax and multinomial regression models. The former, softmax regression, takes image features and predicts a distribution over the words in the vocabulary with a softmax loss. It computes the word type indicator vector for each document, i.e., 1 if word w was in the document else 0, and then ℓ_1 normalizes. Multinomial regression computes the word type indicator vector, and—instead of normalizing—computes the logistic sigmoid loss treating the labels as 0/1 indicators. This is equivalent to training a separate logistic regression for each word type to predict the presence/absence of a word type in each document, given the image features. Both models finally use the predicted conditional distributions to produce a ranking of images for each word.

3 Experiments

StreetEasy dataset. The StreetEasy dataset comprises 29,347 real estate listings in New York City in June 2019. Document excerpts are shown in Figure 2: each consists of both images and English-language sentences. Documents contain an average of 128 word tokens and 10 images, for totals of 3,773,608 word tokens and 294,279 images. There are no image-specific captions or labels. For our quantitative word-image retrieval evaluations, we augment StreetEasy with 17,658 human relevance judgements. After initial experiments, we selected words with a a variety of frequencies and degree of lexical/visual overlap with ImageNet categories: "kitchen" (co-occurs with 200k images), "bedroom" (175k), "washer" (65k), "outdoor" (50k), "fitness" (49k), and "pool" (29k). For each of these words of interest, we labeled a different random 1% subset of all images (2,943 images each): an image in a sample was labeled true if it corresponded with any sense of the associated word and false otherwise. For each model, we rank images for each query

---

[4] Sharpness is equal to the inverse of softmax temperature; thus EntSharp equivalently decreases softmax temperature during training.

Figure 3: Top images for EntSharp and object detection baselines on the StreetEasy dataset. Images in each word's section come from the same evaluation set, and each row is ranked in decreasing order from left to right. For example, the three rows in the "kitchen" section are different orderings of the same 2,943 images. Images with dark blue borders were labeled true with respect to the word, and those with light red borders were labeled false. E: EntSharp. W: word2vec object detection baseline. R: RoBERTa object detection baseline.

word and calculate the area under the precision-recall curve (PR AUC: perfect performance is 100, and random performance is the percentage of images with true labels). Each of the six evaluation words co-occurred with only some of their sampled images, ranging from kitchen (co-occurred with 1,997 images) to pool (310 images). We perform evaluations on the entire samples of 2,943 images (not just those that co-occur with each word) in order to avoid overstating performance.

Experimental details for EntSharp. For each image, features are extracted from the final pre-classification layer of DenseNet169 pre-trained on ImageNet (Russakovsky et al., 2015) and then randomly projected from 1,664 dimensions to 256.[5] We use a vocabulary of 7,971 words that occur at least ten times across this corpus and Wikipedia (to eliminate misspellings). We run EntSharp for 100 iterations.[6] Setups for baselines are comparable, and more details are available in Appendix C.

Results. As shown in Table 1, EntSharp outperforms all baselines on PR AUC on all six of the evaluation words. The uniform initialization (Untrained EntSharp) is strong for frequent words ("kitchen", "bedroom") but poor otherwise. The word2vec baseline is also superior to the RoBERTa baseline in four of six evaluations. The baselines do best on "kitchen", "bedroom", and "washer". Table 2 shows the ImageNet object labels associated with each word in manually selected images. Though "kitchen" is not a category in the ImageNet dataset, "microwave", "refrigerator", and "dishwasher" are, and these words are sufficiently close to "kitchen" to learn an association. Nevertheless, EntSharp achieves the highest PR AUC even in the case of "washer", which is a category learned by the object detection baselines. EntSharp's performance increase is most pronounced for the words "outdoor", "bedroom", "pool", and especially "fitness", which have dissimilar visual manifestations in StreetEasy and ImageNet.

Qualitatively (Figure 3), we see that EntSharp associates "bedroom" with empty rooms containing a door and a window while the word2vec baseline as-

Table 1: Area under the precision-recall curve (`AUC`) for each grounding method on each labeled random image subset. Best-in-column is bolded. Random performance results in an `AUC` equal to the percentage labeled true.

Evaluation word	Image	Top DenseNet169 predictions
"kitchen"		'dishwasher', 'microwave', 'refrigerator'
"bedroom"		'sliding_door', 'wardrobe', 'window_shade'
"outdoor"		'mountain_bike', 'bicycle-built-for-two'
"pool"		'pool_table', 'fountain', 'tub'
"washer"		'washer', 'microwave', 'reflex_camera'
"fitness"		'shoe_shop', 'dumbbell', 'barbell'

Table 2: Top DenseNet169 ImageNet class predictions for selected example images.

sociates the word with rooms that contain a bed or a sofa. Similarly, "outdoor" manifests in StreetEasy as building exteriors, but the RoBERTa baseline returns images of bike rooms, presumably because bicycles are usually seen outdoors. In StreetEasy the word "pool" more frequently refers to swimming pools rather than the billiards tables seen in ImageNet. The baseline is not technically wrong in this case (indeed, we marked pool tables as correct), but it misses the more common contextual meaning of the word in the local collection. Finally, none of the baselines are able to handle"fitness".

Wikipedia experiments. We also ran EntSharp on a multimodal Wikipedia dataset (Hessel et al., 2018). Figure 1 shows that the algorithm often grounds words differently in Wikipedia's much broader range of images than it does in the StreetEasy dataset. Similarly, top ranked images in Wikipedia for "fitness" included marathon runners rather than the StreetEasy dataset's exercise rooms.

4 Discussion

We present EntSharp, a simple clustering-based algorithm for learning image groundings for words. It is motivated by the unlabeled multimodal data that exists in abundance rather than relying on expensive custom datasets. By encouraging words to compete to claim responsibility for images, we "sharpen" the resulting image/word associations. The method is effective at finding contextual lexical groundings of words in unlabeled multi-image, multi-sentence documents even in the presence of high cross-document similarity.

One area for future work would be to better identify and model words that either *don't* have a visual grounding or whose identified visual grounding doesn't align with human expectation. For example, the word "Gristedes" (the name of a supermarket chain) appears in StreetEasy documents, but users rarely post photographs of the supermarkets themselves. Conversely, the word "bright" outside the context of StreetEasy may not be "visually concrete" (according to human judgment); nonetheless, it frequently co-occurs with images of sunlit hardwood floors. Given the lexical and visual identifiability issues explored in §1, incorporating prior human concreteness judgments (e.g., Nelson et al. (2004)) for vocabulary items might enable EntSharp to learn for these sorts of ambiguous lexical items. However, finding an appropriate balance of domain-specific flexibility versus alignment with human priors could pose a significant challenge.

Acknowledgments

We would particularly like to thank Grant Long for putting together the StreetEasy data as well as Ondrej Linda, Ramin Mehran, and Randy Puttick for helpful conversations. We would like to thank Maria Antoniak for valuable feedback. Data provided by StreetEasy, an affiliate of Zillow Group. A Document similarity metrics

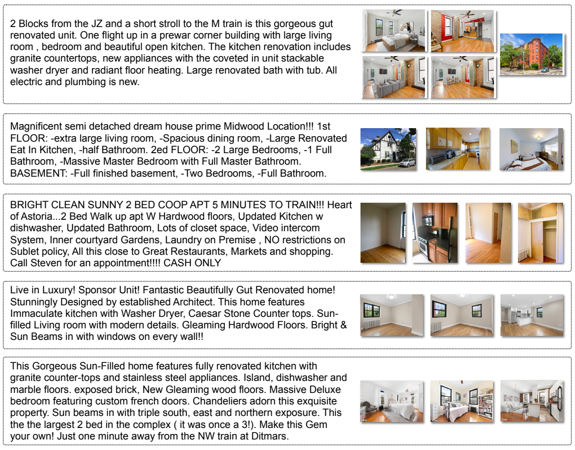
We compute a length-controlled version of word mover's distance (Kusner et al., 2015) to measure the textual distances between documents. This was inspired by the simple extension to "image mover's distance" enabled by swapping the word2vec token representations to CNN image representations.

After computing image/word mover's distances, we noticed that these metrics were slightly correlated with document length; this correlation was also noted by Kusner et al. (2015), who mention that longer documents might be closer to others "as longer documents may contain several similar words." To account for this, we implemented a version of mover's distances that selects a bootstrap sample of $b_1 = 50$ words and $b_2 = 10$ images before computing distances. The scatterplot we report in Figure 2 is insensitive to reasonable choices of these parameters, as it looks largely the same for any $\langle b_1, b_2 \rangle \in \{10, 30, 50\} \times \{3, 5, 10\}$.

To compute a corpus-level statistic, it's computationally infeasible to compute distances between all possible pairs; some calculations based on the EMD library we are using shows that full computation would take at least a few months. Instead, we randomly sample 10K pairs and report confidence intervals for the mean in the figure.

B StreetEasy dataset preprocessing

The dataset consists of 29,347 English-language real estate listings from the StreetEasy website from June 2019. They contain a total of 294,279 images and 24,078,190 word tokens across 34,564 word types. We preprocess the text by removing numbers, punctuation, hyphens, and capitalization. We restrict the vocabulary to word types that occur at least ten times in StreetEasy and in the multimodal Wikipedia dataset. This results in 3,773,608 word tokens across 7,971 word types. Figure 2 shows a few excerpts of listings, and Figure 4 shows additional listing excerpts.



2 Blocks from the JZ and a short stroll to the M train is this gorgeous gut renovated unit. One flight up in a prewar corner building with large living room , bedroom and beautiful open kitchen. The kitchen renovation includes granite countertops, new appliances with the coveted in unit stackable washer dryer and radiant floor heating. Large renovated bath with tub. C Baselines

Object detection. An image is represented as the mean of the word vectors of its top K class predictions from DenseNet169. We report each model's performance with the $K \in \{1, \ldots, 20\}$ that resulted in the highest average PR AUC across evaluation words to create the strongest baselines ($K = 2$ for word2vec and $K = 1$ for RoBERTa). For words not in the word2vec vocabulary, we use a random vector as the word embedding. All six evaluation words are present in the word2vec vocabulary. Average runtimes are 80.9 ± 1.6 seconds for word2vec and 458.8 ± 1.6 seconds for RoBERTa.

Image tagging. We reserved 20% of the StreetEasy corpus as a validation set. We don't hold out a test set: this tasks the algorithms only with fitting the dataset, not generalizing beyond it. We use the validation set for early stopping, model selection, and hyperparameter optimization. We optimize learning rate (in $\{0.001, 0.0005, 0.0007\}$) and number of layers (in $\{0, 1, 2, 3, 4, 5\}$). We decay learning rate upon validation loss plateau. We use the Adam optimizer (Kingma and Ba, 2015).

D EntSharp training

We run EntSharp for 100 iterations. Figure 5 shows that PR AUC converges at different rates for the different evaluation words.

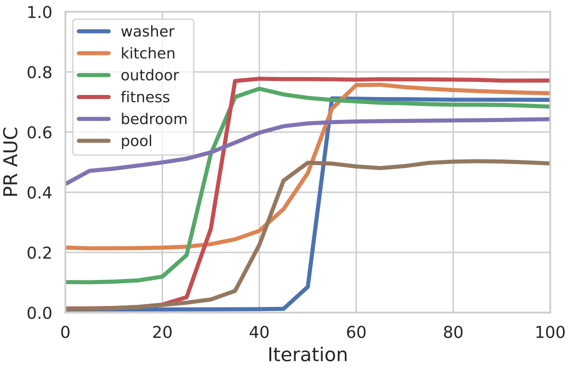

Figure 5: During EntSharp training, PR AUC plateaus at a different rate for each evaluation word.

HERO: Hierarchical Encoder for Video+Language Omni-representation Pre-training

Abstract

We present HERO, a novel framework for large-scale video+language omni-representation learning. HERO encodes multimodal inputs in a hierarchical structure, where *local* context of a video frame is captured by a Cross-modal Transformer via multimodal fusion, and *global* video context is captured by a Temporal Transformer. In addition to standard Masked Language Modeling (MLM) and Masked Frame Modeling (MFM) objectives, we design two new pre-training tasks: (i) Video-Subtitle Matching (VSM), where the model predicts both global and local temporal alignment; and (ii) Frame Order Modeling (FOM), where the model predicts the right order of shuffled video frames. HERO is jointly trained on HowTo100M and large-scale TV datasets to gain deep understanding of complex social dynamics with multi-character interactions. Comprehensive experiments demonstrate that HERO achieves new state of the art on multiple benchmarks over Text-based Video/Video-moment Retrieval, Video Question Answering (QA), Video-and-language Inference and Video Captioning tasks across different domains. We also introduce two new challenging benchmarks How2QA and How2R for Video QA and Retrieval, collected from diverse video content over multimodalities.[1]

1 Introduction

Inspired by BERT (Devlin et al., 2019), large-scale multimodal pre-training has prevailed in the realm of vision-and-language research (Lu et al., 2019; Tan and Bansal, 2019; Chen et al., 2020b). There are many early players in the area, including ViLBERT (Lu et al., 2019), LXMERT (Tan and Bansal, 2019), UNITER (Chen et al., 2020b), VL-BERT (Su et al., 2020) and Unicoder-VL (Li et al., 2020a). However, most large-scale pre-trained models are tailored for static images, not dynamic videos. VideoBERT (Sun et al., 2019b) is the first to apply BERT to learn joint embedding for video-text pairs. But since only discrete tokens are used to represent video frames, rich video frame features are not fully utilized. To remedy this, CBT (Sun et al., 2019a) proposes to use a contrastive loss, but mainly for video representation learning alone, with text input only considered as side information. UniViLM (Luo et al., 2020) takes a step further and considers both understanding and generation tasks.

Several constraints inherently limit the success of existing models. (i) Most model designs are direct adaptation of BERT, taking simple concatenation of subtitle sentences and visual frames as input, while losing the temporal alignment between video and text modalities. (ii) Pre-training tasks are directly borrowed from image+text pre-training methods, without exploiting the sequential nature of videos. (iii) Compared to diverse image domains investigated in existing work, video datasets used in current models are restricted to cooking or narrated instructional videos (Miech et al., 2019), excluding video sources that contain dynamic scenes and complex social interactions.

To tackle these challenges, we present a new video-and-language large-scale pre-training framework - HERO (**H**ierarchical **E**ncode**R** for **O**mni-representation learning). As illustrated in Figure 1, HERO takes as input a sequence of video clip frames and their accompanying subtitle sentences.[2] Instead of adopting a flat BERT-like encoder, HERO encodes multimodal inputs in a hierarchical fashion, with (i) a *Cross-modal* Transformer to fuse a subtitle sentence and its accompanying local video

---

[*] Equal contribution.

[1] Code and new datasets publicly available at: `https://github.com/linjieli222/HERO`.

[2] ASR can be applied when subtitles are unavailable.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2046–2065,
November 16–20, 2020.

frames, followed by (ii) a *Temporal* Transformer to obtain a sequentially contextualized embedding for each video frame, using all the surrounding frames as global context. The proposed hierarchical model first absorbs visual and textual local context on frame level, which is then transferred to a global video-level temporal context. Experiments show that this novel model design achieves better performance than a flat BERT-like architecture.

Four pre-training tasks are designed for HERO: (i) Masked Language Modeling (MLM); (ii) Masked Frame Modeling (MFM); (iii) Video-Subtitle Matching (VSM); and (iv) Frame Order Modeling (FOM). Compared to prior work, the key novelty is VSM and FOM, which encourage explicit temporal alignment between multimodalities as well as full-scale exploitation of the sequential nature of video input. In VSM, the model considers not only global alignment (predicting whether a subtitle matches the input video clip), but also local temporal alignment (retrieving the moment where the subtitle should be localized in the video clip). In FOM, we randomly select and shuffle a subset of video frames, and the model is trained to restore their original order. Extensive ablation studies demonstrate that both VSM and FOM play a critical role in video+language pre-training.

To empower the model with richer knowledge beyond instructional videos used in prior work, we jointly train HERO with both HowTo100M (narrated instructional videos) (Miech et al., 2019) and a large-scale TV dataset (containing TV episodes spanning across different genres) (Lei et al., 2018, 2020a,b; Liu et al., 2020). Compared to factual descriptions in HowTo100M, the TV dataset contains more complex plots that require comprehensive interpretation of human emotions, social dynamics and causal relations of events, making it a valuable supplement to HowTo100M and a closer approximation to real-life scenarios.

Existing pre-trained models are evaluated on YouCook2 (Zhou et al., 2018a) and MSR-VTT (Xu et al., 2016a) datasets. YouCook2 focuses on cooking videos only, and the captions in MSR-VTT are very simple. To evaluate our model on more challenging benchmarks, we collect two new datasets on video-moment retrieval and question answering, *How2R* and *How2QA*. In addition, we evaluate HERO on popular retrieval and QA tasks such as TVR (Lei et al., 2020b) and TVQA (Lei et al., 2018), where HERO outperforms existing models by a large margin. We further demonstrate the generalizability of our model by adapting it to (i) diverse downstream tasks: video-and-language inference and video captioning tasks, achieving new state of the art on VIOLIN (Liu et al., 2020) and TVC (Lei et al., 2020b) benchmarks; (ii) different video types: single-channel videos (video-only) and multi-channel videos (video + subtitle), reporting superior performance over existing state of the art on DiDeMo (Anne Hendricks et al., 2017a) and MSR-VTT.

Our main contributions are summarized as follows. (i) We present HERO, a hierarchical Transformer-based model for video+language representation learning. (ii) We propose new pre-training tasks VSM and FOM, which complement MLM and MRM objectives by better capturing temporal alignment between multimodalities in both global and local contexts. (iii) Different from previous work that mainly relies on HowTo100M, we include additional video datasets for pre-training, encouraging the model to learn from richer and more divserse visual content. (iv) We collect two new datasets based on HowTo100M for video-moment retrieval/QA, and will release the new benchmarks to foster future study. HERO achieves new state of the art across all the evaluated tasks.

2 Related Work

Since the birth of BERT (Devlin et al., 2019), there has been continuing advancement in language model pre-training, such as XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020), UniLM (Dong et al., 2019), and T5 (Raffel et al., 2019), which epitomizes the superb power of large-scale pre-training. Satellited around BERT, there is parallel growing interest in model compression (Sun et al., 2019c; Shen et al., 2020) and extension to generation tasks (Chen et al., 2020a; Wang and Cho, 2019).

Branching out from language processing to multimodal, subsequent studies also emerge in vision+language space. Prominent work includes ViLBERT (Lu et al., 2019), LXMERT (Tan and Bansal, 2019), VL-BERT (Su et al., 2020), Unicoder-VL (Li et al., 2020a), B2T2 (Alberti et al., 2019), UNITER (Chen et al., 2020b) and VILLA (Gan et al., 2020). A detailed review can be found in Appendix A.7.

Contrast to the boom in image+text area, pre-training for video+language is still in its infancy.

So far, VideoBERT (Sun et al., 2019b), CBT (Sun et al., 2019a), MIL-NCE (Miech et al., 2020), ActBERT (Zhu and Yang, 2020) and UniViLM (Luo et al., 2020) are the only existing work exploring this space, covering downstream tasks from text-based video retrieval (Zhou et al., 2018a; Xu et al., 2016b) and video question answering (Maharaj et al., 2017; Lei et al., 2020a) to video captioning (Zhou et al., 2018b).

In this paper, we aim to propel video+language omni-representation learning in four dimensions: (i) better model architecture design; (ii) better pre-training task design; (iii) diversification of training corpora; and (iv) new high-quality benchmarks for downstream evaluation.

3 Hierarchical Video+Language Encoder

In this section, we explain the proposed HERO architecture and the four pre-training tasks in detail.

3.1 Model Architecture

Model architecture of HERO is illustrated in Figure 1, which takes the frames of a video clip and the textual tokens of subtitle sentences as inputs. They are fed into a Video Embedder and a Text Embedder to extract initial representations. HERO computes contextualized video embeddings in a hierarchical procedure. First, *local* textual context of each visual frame is captured by a Cross-modal Transformer, computing the contextualized multi-modal embeddings between a subtitle sentence and its associated visual frames. The encoded frame embeddings of the whole video clip are then fed into Temporal Transformer to learn the *global* video context and obtain the final contextualized video embeddings.

Input Embedder We denote visual frames of a video clip as $\mathbf{v} = \{v_i\}_{i=1}^{N_v}$ and its subtitle as $\mathbf{s} = \{s_i\}_{i=1}^{N_s}$ (N_v is the number of visual frames in a video clip and N_s is the number of sentences in each subtitle). For *Text Embedder*, we follow Liu et al. (2019) and tokenize a subtitle sentence s_i into a sequence of WordPieces (Wu et al., 2016), *i.e.*, $\mathbf{w}_{s_i} = \{w_{s_i}^j\}_{j=1}^L$ (L is the number of tokens in s_i). The final representation for each sub-word token is obtained via summing up its token embedding and position embedding, followed by a layer normalization (LN) layer. For *Video Embedder*, we first use ResNet (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009) and SlowFast (Feichtenhofer et al., 2019) pre-trained on Kinetics (Kay et al., 2017) to extract 2D and 3D visual features for each video frame. These features are concatenated as visual features and fed through a fully-connected (FC) layer to be projected into the same lower-dimensional space as token embeddings. Since video frames are sequential, their position embeddings can be calculated in the same way as in the Text Embedder. The final embedding of a frame is obtained by summing up FC outputs and position embeddings and then passing through an LN layer. After Input Embedder, token and frame embeddings for $\mathbf{w}_{s_i}$ and $\mathbf{v}_{s_i}$[3] are denoted as $\mathbf{W}_{s_i}^{emb} \in \mathbb{R}^{L \times d}$ and $\mathbf{V}_{s_i}^{emb} \in \mathbb{R}^{K \times d}$ (d is the hidden size).

Cross-modal Transformer To utilize the inherent alignment between subtitles and video frames, for each subtitle sentence s_i, we first learn contextualized embeddings between the corresponding tokens $\mathbf{w}_{s_i}$ and its associated visual frames $\mathbf{v}_{s_i}$ through cross-modal attention. Inspired by the recent success (Chen et al., 2020b; Lu et al., 2019) of using Transformer (Vaswani et al., 2017) for multimodal fusion, we also use a multi-layer Transformer here. The outputs from Cross-modal Transformer is a sequence of contextualized embeddings for each subtitle token and each video frame:

$$\mathbf{V}_{s_i}^{cross}, \mathbf{W}_{s_i}^{cross} = f_{cross}(\mathbf{V}_{s_i}^{emb}, \mathbf{W}_{s_i}^{emb}), \tag{1}$$

where $f_{cross}(\cdot, \cdot)$ denotes the Cross-modal Transformer, $\mathbf{V}_{s_i}^{cross} \in \mathbb{R}^{K \times d}$ and $\mathbf{W}_{s_i}^{cross} \in \mathbb{R}^{L \times d}$.

Temporal Transformer After collecting all the visual frame embeddings $\mathbf{V}^{cross} = \{\mathbf{V}_{s_i}^{cross}\}_{i=1}^{N_s} \in \mathbb{R}^{N_v \times d}$ from the output of Cross-modal Transformer, we use another Transformer as temporal attention to learn contextualized video embeddings from the global context of a video clip. To avoid losing positional information, we use residual connection (He et al., 2016) to add back $\mathbf{V}^{emb} \in \mathbb{R}^{N_v \times d}$. The final contextualized video embeddings are calculated as:

$$\mathbf{V}^{temp} = f_{temp}(\mathbf{V}^{emb} + \mathbf{V}^{cross}), \tag{2}$$

where $f_{temp}(\cdot)$ denotes the Temporal Transformer, and $\mathbf{V}^{temp} \in \mathbb{R}^{N_v \times d}$. Compared to flat BERT-like encoder, which directly concatenates all textual tokens and visual frames as inputs, the proposed model effectively utilizes the temporal alignment

---

[3] $\mathbf{v}_{s_i} = \{v_{s_i}^j\}_{j=1}^K$ denotes the set of visual frames paired with subtitle sentence s_i, based on their timestamps. Refer to Appendix A.4 for details.

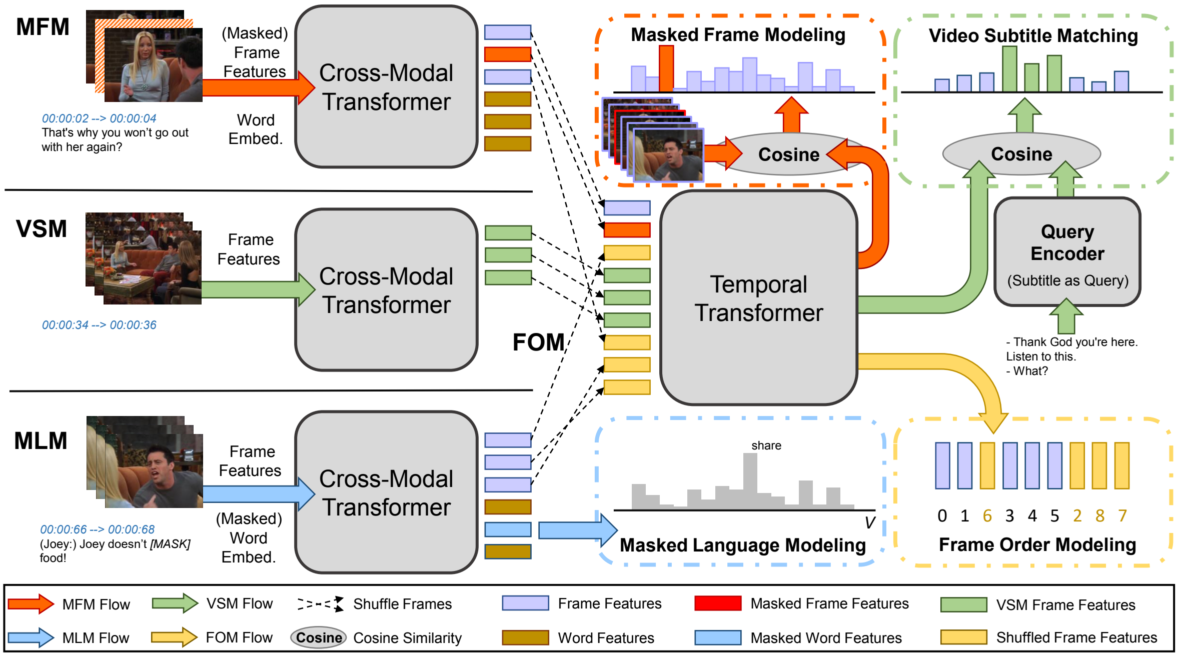

Figure 1: HERO Architecture (best viewed in color), consisting of Cross-Modal Transformer and Temporal Transformer, learned via four pre-training tasks hierarchically. Initial frame features are obtained by SlowFast and ResNet feature extractors, and word embeddings are learned via an embedding layer initialized from RoBERTa.

between subtitle sentences and video frames for multimodal fusion in a more fine-grained manner. In the experiments, we show that our model design far outperforms a flat BERT-like baseline.

3.2 Pre-training Tasks

We introduce four tasks for pre-training. During training, we sample one task per mini-batch to prevent different tasks from corrupting each others' input. As shown in Figure 1, MFM and MLM are in analogy to BERT (Devlin et al., 2019). Word masking is realized by replacing a word with special token `[MASK]`, and frame masking by replacing a frame feature vector with zeros. Following Chen et al. (2020b), we only mask one modality each time while keeping the other modality intact. VSM is designed to learn both *local* alignment (between visual frames and a subtitle sentence) and *global* alignment (between a video clip and a sequence of subtitle sentences). FOM is designed to model sequential characteristics of video, by learning the original order of randomly reordered frames.

3.2.1 Masked Language Modeling

The inputs for MLM include: (*i*) sub-word tokens from the i-th subtitle sentence $\mathbf{w}_{s_i}$; (*ii*) visual frames $\mathbf{v}_{s_i}$ aligned with $\mathbf{w}_{s_i}$; and (*iii*) mask indices $\mathbf{m} \in \mathbb{N}^M$.[4]

In MLM, we randomly mask out input words with a probability of 15%, and replace the masked tokens $\mathbf{w}_{s_i}^{\mathbf{m}}$ with special tokens `[MASK]`.[5] The goal is to predict these masked words based on the observation of their surrounding words $\mathbf{w}_{s_i}^{\backslash \mathbf{m}}$ and the visual frames aligned with the sentence $\mathbf{v}_{s_i}$, by minimizing the negative log-likelihood:

$$\mathcal{L}_{\text{MLM}}(\theta) = -\mathbb{E}_D \log P_\theta(\mathbf{w}_{s_i}^{\mathbf{m}} | \mathbf{w}_{s_i}^{\backslash \mathbf{m}}, \mathbf{v}_{s_i}) , \quad (3)$$

where θ denotes trainable parameters. Each pair $(\mathbf{w}_{s_i}, \mathbf{v}_{s_i})$ is sampled from the training set D.

3.2.2 Masked Frame Modeling

Similar to MLM, we also sample frames and mask their visual features with a probability of 15%. However, the difference is that MLM is performed on a local context (*i.e.*, the output of Cross-modal Transformer), while MFM is performed on a global context (*i.e.*, the output of Temporal Transformer). The model is trained to reconstruct masked frames $\mathbf{v}_{\mathbf{m}}$, given the remaining frames $\mathbf{v}_{\backslash \mathbf{m}}$ and all the subtitle sentences $\mathbf{s}$. The visual features of masked

---

[4] $\mathbb{N}$ is a natural number, M is the number of masked tokens, and $\mathbf{m}$ is the set of masked indices.

[5] Following BERT, we decompose the 15% randomly masked-out words into 10% random words, 10% unchanged, and 80% `[MASK]`.

frames are replaced by zeros. Unlike textual tokens that are represented as discrete labels, visual features are high-dimensional and continuous, thus cannot be supervised via class likelihood. Instead, we propose two variants for MFM, which share the same objective base:

$$\mathcal{L}_{\text{MFM}}(\theta) = \mathbb{E}_D f_\theta(\mathbf{v_m}|\mathbf{v}_{\backslash\mathbf{m}}, \mathbf{s})\,. \tag{4}$$

Masked Frame Feature Regression (MFFR) MFFR learns to regress the output on each masked frame $\mathbf{v}_\mathbf{m}^{(i)}$ to its visual features. Specifically, we apply an FC layer to convert the output frame representations into a vector $h_\theta(\mathbf{v}_\mathbf{m}^{(i)})$ of the same dimension as the input visual feature $r(\mathbf{v}_\mathbf{m}^{(i)})$. Then we apply L2 regression between the two: $f_\theta(\mathbf{v_m}|\mathbf{v}_{\backslash\mathbf{m}}, \mathbf{s}) = \sum_{i=1}^{M} \|h_\theta(\mathbf{v}_\mathbf{m}^{(i)}) - r(\mathbf{v}_\mathbf{m}^{(i)})\|_2^2$.

Masked Frame Modeling with Noise Contrastive Estimation (MNCE) Instead of directly regressing the real values of masked visual features, we use the softmax version of Noise Contrastive Estimation (NCE) loss (Jozefowicz et al., 2016), which is widely adopted in self-supervised representation learning (Sun et al., 2019a; Hjelm et al., 2019; Oord et al., 2018). NCE loss encourages the model to identify the correct frame (given the context) compared to a set of negative distractors.

Similar to MFFR, we feed the output of the masked frames $\mathbf{v}_\mathbf{m}^{(i)}$ into an FC layer to project them into a vector $g_\theta(\mathbf{v}_\mathbf{m}^{(i)})$. Moreover, we randomly sample frames from the output of unmasked frames as negative distractors $\mathbf{v_{neg}} = \{\mathbf{v}_\mathbf{neg}^{(j)}|\mathbf{v}_\mathbf{neg}^{(j)} \in \mathbf{v}_{\backslash\mathbf{m}}\}$, which are also transformed through the same FC layer as $g_\theta(\mathbf{v}_\mathbf{neg}^{(j)})$. The final objective minimizes the NCE loss: $f_\theta(\mathbf{v_m}|\mathbf{v}_{\backslash\mathbf{m}}, \mathbf{s}) = \sum_{i=1}^{M} \log \text{NCE}(g_\theta(\mathbf{v}_\mathbf{m}^{(i)})|g_\theta(\mathbf{v_{neg}}))$.

3.2.3 Video-Subtitle Matching

The inputs to VSM are: (i) a sampled query s_q from all subtitle sentences; (ii) the whole video clip $\mathbf{v}$; and (iii) the remaining subtitle sentences $\mathbf{s}_{\backslash q}$ for the video clip. We expect the model to learn: (i) *local alignment* - the start and end index $y_{st}, y_{ed} \in \{1, ..., N_v\}$, indicating the span of visual frames aligned with the query;[6] and (ii) *global alignment* - to which video the sampled query is matched.

In VSM, we follow XML (Lei et al., 2020b) to compute the matching scores between the query and visual frames at both local and global levels. Specifically, we extract the output of Temporal Transformer as the final visual frame representation $\mathbf{V}^{temp} \in \mathbb{R}^{N_v \times d}$. The query is fed into Cross-modal Transformer to compute its textual representations $\mathbf{W}_{s_q}^{cross} = f_{cross}(\mathbf{0}, \mathbf{W}_{s_q}^{embed})$. Based on this, we use a query encoder (Lei et al., 2020b), consisting of a self-attention layer, two linear layers and an LN layer, to obtain the final query vector $\mathbf{q} \in \mathbb{R}^d$ from $\mathbf{W}_{s_q}^{cross}$.

Local Alignment The local query-video matching score is computed using dot product:

$$S_{local}(s_q, \mathbf{v}) = \mathbf{V}^{temp}\mathbf{q} \in \mathbb{R}^{N_v}\,. \tag{5}$$

Two trainable 1D convolution filters are applied to the scores, followed by a softmax layer, to generate two probability vectors $\mathbf{p}_{st}, \mathbf{p}_{ed} \in \mathbb{R}^{N_v}$, representing the probabilities of every position being the start and end of the ground-truth span. During training, we sample 15% subtitle sentences as queries for each video, and use the cross-entropy loss to predict the start and end index for local alignment:

$$\mathcal{L}_{local} = -\mathbb{E}_D \log(\mathbf{p}_{st}[y_{st}]) + \log(\mathbf{p}_{ed}[y_{ed}])\,,$$

where $\mathbf{p}[y]$ denotes indexing the y-th element of the vector $\mathbf{p}$.

Note that, XML computes the query-video matching score for each modality separately, and the final matching score is the sum of the two scores. In our HERO model, multimodal fusion is performed in a much earlier stage.

Global Alignment The global matching score is computed by max-pooling the cosine similarities between each frame and the query:

$$S_{global}(s_q, \mathbf{v}) = \max\left(\frac{\mathbf{V}^{temp}}{||\mathbf{V}^{temp}||}\frac{\mathbf{q}}{||\mathbf{q}||}\right)\,. \tag{6}$$

We use a combined hinge loss $\mathcal{L}_h$ (Yu et al., 2018a) over positive and negative query-video pairs. For each positive pair $(s_q, \mathbf{v})$, we replace $\mathbf{v}$ or s_q with one other sample from in the same mini-batch to construct two sets of negative examples: $(s_q, \hat{\mathbf{v}})$ and $(\hat{s}_q, \mathbf{v})$. The training loss is specified as:

$$\begin{aligned}\mathcal{L}_h(S_{pos}, S_{neg}) &= \max(0, \delta + S_{neg} - S_{pos})\,,\\ \mathcal{L}_{global} &= -\mathbb{E}_D[\mathcal{L}_h(S_{global}(s_q, \mathbf{v}), S_{global}(\hat{s}_q, \mathbf{v}))\\ &+ \mathcal{L}_h(S_{global}(s_q, \mathbf{v}), S_{global}(s_q, \hat{\mathbf{v}}))]\,,\end{aligned} \tag{7}$$

---

[6] Timestamps are used to perform local alignment, which are either included with video (e.g., TV) or generated by ASR (e.g., HowTo100M). Refer to A.4 for details.

where δ is the margin hyper-parameter. The final loss $\mathcal{L}_{\text{VSM}} = \lambda_1 \mathcal{L}_{local} + \lambda_2 \mathcal{L}_{global}$, where λ_1 and λ_2 are hyper-parameters balancing the two terms.

3.2.4 Frame Order Modeling

The inputs for FOM are: (i) all subtitle sentences $\mathbf{s}$; (ii) visual frames $\mathbf{v}$; and (iii) the reorder indices $\mathbf{r} = \{r_i\}_{i=1}^{R} \in \mathbb{N}^R$.[7] We randomly select 15% of the frames to be shuffled, and the goal is to reconstruct their original timestamps, denoted as $\mathbf{t} = \{t_i\}_{i=1}^{R}$, where $t_i \in \{1, ..., N_v\}$. We formulate FOM as a classification problem, where $\mathbf{t}$ is the ground-truth labels of the reordered frames.

Specifically, reordering happens after the multimodal fusion of subtitle and visual frames. The reordered features are fed into Temporal Transformer to produce reordered visual frame embeddings $\mathbf{V}_{\mathbf{r}}^{temp}$. These embeddings are transformed through an FC layer, followed by a softmax layer to produce a probability matrix $\mathbf{P} \in \mathbb{R}^{N_v \times N_v}$, where each column $\mathbf{p}_i \in \mathbb{R}^{N_v}$ represents the scores of N_v timestamp classes that the i-th timestamp belongs to. The final objective is to minimize the negative log-likelihood:

$$\mathcal{L}_{\text{FOM}} = -\mathbb{E}_D \textstyle\sum_{i=1}^{R} \log \mathbf{P}[r_i, t_i] \,. \qquad (8)$$

4 Experiments

In this section, we describe comprehensive experiments on downstream tasks and provide ablation studies for in-depth analysis of different pre-training settings.

To validate the effectiveness of HERO, we evaluate on a wide variety of downstream tasks, including Text-based Video/ Video-moment Retrieval, Video Question Answering, Video-and-language Inference, and Video Captioning. We consider 6 existing benchmarks: TVR (Lei et al., 2020b), TVQA (Lei et al., 2018), VIOLIN (Liu et al., 2020), TVC (Lei et al., 2020b), DiDeMo (Anne Hendricks et al., 2017a), and MSR-VTT (Xu et al., 2016b). Detailed descriptions and evaluation metrics on each task can be found in Appendix A.6.

4.1 Pre-training Datasets

Our pre-training dataset is composed of 7.6M video clips with their accompanying subtitles from TV and HowTo100M datasets. We exclude all the videos that appear in the downstream tasks to avoid contamination in evaluation.

TV Dataset (Lei et al., 2018) was built on 6 popular TV shows across 3 genres: medical dramas, sitcoms and crime shows. It contains 21,793 video clips from 925 episodes. Each video clip is 60-90 seconds long, covering long-range scenes with complex character interactions and social/professional activities. Dialogue for each video clip is also provided.

HowTo100M Dataset (Miech et al., 2019) was collected from YouTube, mostly instructional videos. It contains 1.22 million videos, with activities falling into 12 categories (e.g., Food & Entertaining, Home & Garden, Hobbies & Crafts). Each video is associated with a narration as subtitles that are either written manually or from an Automatic Speech Recognition (ASR) system. The average duration of videos in HowTo100M is 6.5 minutes. We cut the videos into 60-second clips to make them consistent with the TV dataset, and exclude videos in non-English languages. These pre-processing steps result in a subset of 7.56M video clips, accompanied with English subtitles.

4.2 New Benchmarks

Existing benchmarks are mostly built on videos from either a single domain or a single modality. In order to evaluate on diverse video content that reflects multimodality challenges, we introduce two new datasets as additional benchmarks: *How2R* for text-based video-moment retrieval, and *How2QA* for video question answering.

How2R Amazon Mechanical Turk (AMT) is used to collect annotations on HowTo100M videos. Figure 6a in Appendix shows the interface for annotation. We randomly sample 30k 60-second clips from 9,421 videos and present each clip to the turkers, who are asked to select a video segment containing a single, self-contained scene. After this segment selection step, another group of workers are asked to write descriptions for each displayed segment. Narrations are not provided to the workers to ensure that their written queries are based on visual content only. These final video segments are 10-20 seconds long on average, and the length of queries ranges from 8 to 20 words.

From this process, we have collected 51,390 queries for 24k 60-second clips from 9,371 videos in HowTo100M, on average 2-3 queries per clip. We split the video clips and its associated queries into 80% train, 10% val and 10% test.

---

[7] R is the number of reordered frames, and $\mathbf{r}$ is the set of reorder indices.

Pre-training Data		Pre-training Tasks	TVR			TVQA	How2R			How2QA
			R@1	R@10	R@100	Acc.	R@1	R@10	R@100	Acc.

Table 1: Evaluation on pre-training tasks and datasets. Dark and light grey colors highlight the top and second best results across all the tasks trained with TV Dataset. The best results are in bold.

How2QA To collect another dataset for video QA task, we present the same set of selected video clips to another group of AMT workers for multi-choice QA annotation. Each worker is assigned with one video segment and asked to write one question with four answer candidates (one correct and three distractors). Similarly, narrations are hidden from the workers to ensure the collected QA pairs are not biased by subtitles.

We observe that human-written negative answers suffer from serious bias (*i.e.*, models can learn to predict correctly without absorbing any information from the video or subtitles). To mitigate this, we use adversarial matching (Zellers et al., 2019) to replace one of the three written negative answers by a correct answer from another question that is most relevant to the current one. Similar to TVQA, we also provide the start and end points for the relevant moment for each question. After filtering low-quality annotations, the final dataset contains 44,007 QA pairs for 22k 60-second clips selected from 9035 videos. We split the data into 80% train, 10% val and 10% test sets. More details about data collection can be found in Appendix A.9.

4.3 Ablation Study

We analyze the effectiveness of model design, especially different combinations of pre-training tasks and datasets, through extensive ablation studies.

Optimal Setting of Pre-training Tasks To search for the optimal setting of pre-training tasks, we conduct a series of extensive ablation studies to test each setting, using video-moment retrieval and QA downstream tasks as evaluation. Table 1 summarizes ablation results on TVR, TVQA, How2R and How2QA under different pre-training settings. Models are trained on TV dataset only for computational efficiency. Compared to using MLM only (L1 in Table 1), adding MNCE (L2) shows improvement on all downstream tasks. The best performance is achieved by MLM + MNCE + FOM + VSM (L4).

Effect of FOM and VSM When MLM, MNCE and FOM are jointly trained (L3), there is a large performance gain on TVQA, and significant improvement on How2R and How2QA. Comparable results are achieved on TVR. This indicates that FOM, which models sequential characteristics of video frames, can effectively benefit downstream tasks that rely on temporal reasoning (such as QA tasks).

We observe significant performance lift by adding VSM (L4), and the local and global alignments between subtitle and visual frames learned through VSM are especially effective on TVR and How2R. Adding additional MFFR (L5) reaches slightly worse results. Our observation is that MFFR is competing with (instead of complimentary to) MNCE during pre-training, which renders the effect of MFFR negligible.

Effect of Pre-training Datasets We study the effect of pre-training datasets by comparing TV dataset with HowTo100M. In this study, we first pre-train our model on HowTo100M dataset (L6). We observe a performance drop on TVR, while a performance boost on TVQA, How2R and How2QA, compared to the model trained on TV dataset (L4). Our hypothesis is that text-based video-moment retrieval is more sensitive to video domains. Although HowTo100M dataset contains much more videos, the model still benefits more from being exposed to similar TV videos during pre-training.

Hierarchical Design vs. Flat Architecture To validate the effectiveness of our model design, we compare HERO with two baselines (with and without pre-training): (i) Hierarchical Transformer (H-TRM) baseline, constructed by simply replacing the Cross-modal Transformer with a RoBERTa model

Method \Task	TVR			How2R			TVQA	How2QA	VIOLIN	TVC			
	R@1	R@10	R@100	R@1	R@10	R@100	Acc.	Acc.	Acc.	Bleu	Rouge-L	Meteor	Cider
SOTA Baseline	3.25	13.41	30.52	2.06	8.96	13.27	70.23	-	67.84	10.87	32.81	16.91	45.38
HERO	**6.21**	**19.34**	**36.66**	**3.85**	**12.73**	**21.06**	**73.61**	**73.81**	**68.59**	**12.35**	**34.16**	**17.64**	**49.98**

(a) Results on multi-channel (video+subtitle) tasks: TVR[12], How2R, TVQA, How2QA, VIOLIN and TVC.

Method \Task	DiDeMo			DiDeMo w/ ASR			MSR-VTT			MSR-VTT w/ ASR		
	R@1	R@10	R@100	R@1	R@10	R@100	R@1	R@5	R@10	R@1	R@5	R@10
SOTA Baseline	1.59	6.71	25.44	-	-	-	14.90	40.20	52.80	-	-	-
HERO	**2.14**	**11.43**	**36.09**	**3.01**	**14.87**	**47.26**	**16.80**	**43.40**	**57.70**	**20.50**	**47.60**	**60.90**

(b) Results on DiDeMo and MSR-VTT with video-only inputs (single-channel), compared with ASR-augmented inputs (multi-channel).

Table 3: Results on the test set of six downstream tasks, compared to task-specific state-of-the-art (SOTA) models: XML (Lei et al., 2020b) for TVR, How2R and DiDeMo, HowTo100M (Miech et al., 2019) for MSR-VTT, STAGE (Lei et al., 2020a) for TVQA (inapplicable to How2QA due to region-level features), Multi-stream (Liu et al., 2020) for VIOLIN, and MMT (Lei et al., 2020b) for TVC.

and encoding subtitles only;[8] (ii) Flat BERT-like encoder (F-TRM).[9]

For this ablation experiment, we use TVR and TVQA as evaluation tasks. Results are summarized in Table 2: (i) Without pre-training, F-TRM is much worse than HERO on both tasks. This is due to H-TRM and HERO's explicit exploitation of the temporal alignment between two modalities of videos. (ii) Pre-training lifts HERO performance by a large margin, but not much for F-TRM or H-TRM. This indicates that cross-modal interactions and temporal alignments learned by HERO through pre-training can provide better representations for downstream tasks.

HERO vs. SOTA with and w/o Pre-training We compare HERO with task-specifc state of the art (SOTA) models, including XML (Lei et al., 2020b) for TVR and STAGE (Lei et al., 2020a) for TVQA. As shown in Table 2, our model consistently outperforms SOTA models on both tasks, with or without pre-training. Note that for TVQA, STAGE is trained with additional supervision on spatial grounding with region-level features for each frame. Without additional supervisions, HERO is able to achieve better performance.

Pre-training	Model	TVR			TVQA
		R@1	R@10	R@100	Acc.
	SOTA	2.76	9.08	15.97	70.50
No[10]	F-TRM	1.99	7.76	13.26	31.80
	H-TRM	2.97	10.65	18.68	70.09

	H-TRM	3.12	11.08	18.42	70.03
	HERO	**4.44**	**14.69**	**22.82**	**72.75**

Table 2: Ablation study on model design, comparing HERO to a flat BERT-like encoder (F-TRM) baseline, a Hierarchical Transformer (H-TRM) baseline, and task-specific SOTA models on TVR and TVQA val set.

Key Conclusions The main observations from these extensive ablation studies are summarized as follows:

- The optimal pre-training setting is MLM + MNCE + FOM + VSM, when trained on HowTo100M dataset and TV dataset.
- FOM effectively helps downstream tasks that rely on temporal reasoning (e.g., video QA tasks).
- VSM encourages frame-subtitle alignment, which is especially effective for video-moment retrieval tasks.
- The hierarchical design in HERO explicitly aligns subtitles and frames, while a flat model architecture can only learn this alignment through implicit attention.
- HERO consistently outperforms SOTA with and without pre-training, which further demonstrates the effectiveness of HERO model design.

---

[8] The inputs to Temporal Transformer in H-TRM are the summation of initial frame embedding and max-pooled subtitle embeddings from RoBERTa.

[9] F-TRM takes as input a single sequence by concatenating the embeddings of visual frames and all subtitle sentences, and encodes them through one multi-layer Transformer.

[10] Model parameters are initialized with RoBERTa weights following Lei et al. (2020b).

[11] F-TRM is pre-trained with MLM+MNCE. VSM and FOM cannot be directly applied.

4.4 Results on Downstream Tasks

Table 3 reports HERO results on the test splits of all downstream tasks. HERO is pre-trained on both TV and HowTo100M datasets, with the optimal pre-training setting: MLM + MNCE + FOM + VSM. We compare HERO with task-specific SOTA models on each downstream task, including: XML (Lei et al., 2020b) for TVR, Didemo and How2R; HowTo100M (Miech et al., 2019) for MSR-VTT; STAGE (Lei et al., 2020a) for TVQA; Multi-stream (Liu et al., 2020) for VIOLIN; and MMT (Lei et al., 2020b) for TVC. Note that we cannot directly apply STAGE to How2QA, as it was specifically designed to leverage region-level features. Our HERO model achieves new state of the art across all benchmarks.

Results on Multi-channel Tasks Table 3a shows results on downstream tasks consisting of multi-channel videos (video + subtitle). On TVR R@1, HERO results nearly double those from XML.[12] Further, without leveraging fine-grained region-level features, HERO outperforms baseline models by +3.28% on TVQA and +0.75% on VIOLIN. When evaluated on TVC, video and subtitles are encoded by HERO, then fed into a 2-layer Transformer decoder to generate captions. Even though no pre-training was applied to the decoder, HERO surpasses SOTA baseline across all metrics, especially +4.60% on Cider. In addition, HERO establishes a strong baseline for new benchmarks How2R and How2QA.

Results on Single-channel Tasks Table 3b presents results on DiDeMo for text-based video-moment retrieval task and MSR-VTT for text-based video retrieval task. On DiDeMo, HERO surpasses XML by +0.55/+4.72/+10.65 on R@1/10/100, without leveraging Temporal Endpoint Feature used in XML. On MSRVTT, HERO outperforms existing video pre-training model (HowTo100M) by +1.9/+3.2/+4.9 on R@1/5/10.

To evaluate in multi-channel setting, we also finetuned HERO on MSR-VTT and DiDeMo using both video channel and extracted subtitle channel (with ASR tools). When augmenting DiDeMo/MSR-VTT with ASR inputs, HERO performance is further improved. Although our model design focuses on “truly” multimodal videos (video+subtitle input), these results demonstrate HERO’s superior generalizability to different video types (multi- and single-channel). More results and analysis are provided in Appendix A.1.

5 Conclusion

In this paper, we present a hierarchical encoder for video+language omni-representation pre-training. Our HERO model presents a hierarchical architecture, consisting of Cross-modal Transformer and Temporal Transformer for multi-modal fusion. Novel pre-training tasks are proposed to capture temporal alignment both locally and globally. Pre-trained on two large-scale video datasets, HERO exceeds state of the art by a significant margin when transferred to multiple video-and-language tasks. Two new datasets on text-based video-moment retrieval and video QA are introduced to serve as additional benchmarks for downstream evaluation. We consider extension of our model to other video-and-language tasks as future work, as well as developing more well-designed pre-training tasks.

A Appendix

A.1 Additional Experiments

For further analysis, Table 4 provides comparison between HERO and task-specific SOTA models on the validation splits of each downstream task.[13] For fair comparison, we re-run XML (Lei et al., 2020b) and MMT (Lei et al., 2020b) experiments using our visual frame features, which achieve slightly better performance than the reported results in Lei et al. (2020b). Note that we cannot directly apply our frame-level visual features to STAGE (Lei et al., 2020a) and Multi-stream (Liu et al., 2020), which require region-level features for each video frame.

Overall, HERO achieves state-of-the-art results on all downstream tasks. Our model consistently outperforms XML on both TVR and How2R, with or without pre-training. Table 5 also provides detailed results on TVR and How2R in three different evaluation settings from Lei et al. (2020b): (i) Video Retrieval, (ii) Moment Retrieval, and (iii) Video-moment Retrieval. For both TVR and How2R, pre-training significantly lifts model performance in all three settings. Following Chen et al. (2020b); Lu et al. (2019), we assess the embeddings learned in pre-training before any fine-tuning occurs. On How2R, HERO without fine-tuning achieves (2.11, 9.09, 14.83) for (R1, R10, R100). While the performance is significantly lower than the fine-tuned model (-1.62 for R1), it performs reasonably well without seeing any How2R query, indicating that HERO has learned to align videos and subtitles (pseudo-query) during pre-training.

Note that for TVQA, STAGE is trained with additional supervision on spatial grounding, which requires region-level features for each frame of the video. Without additional supervision on spatial grounding or fine-grained region-level features, HERO is able to achieve better performance than STAGE on TVQA dataset. We also observe that pre-training significantly boosts the performance of HERO across TVR, How2R and TVQA tasks.

On How2QA, since STAGE was specifically designed to leverage region-level features, we cannot directly apply STAGE. Thus, we only compare HERO performance w/o and with pre-training. Results exhibit consistent patterns observed on other downstream tasks: pre-training achieves better performance than w/o pre-training.

---

[13] For VIOLIN, we report results on test set for fair comparison, since no validation results are reported in Liu et al. (2020).

Method \Task	TVR			How2R			TVQA	How2QA	VIOLIN	TVC			
	R@1	R@10	R@100	R@1	R@10	R@100	Acc.	Acc.	Acc.	Bleu	Rouge-L	Meteor	Cider

	Yes	**14.73**	**47.69**	**68.37**	**6.48**	**15.69**	**70.38**	**3.78**	**12.96**	**20.75**

Table 5: Detailed results on TVR and How2R val set, including the main-task (Video Moment Retrieval) and two sub-tasks (Video Retrieval and Moment Retrieval).

Pre-training greatly lifts HERO performance on VIOLIN by approximately +2.9%. However, HERO, without pre-training, presents worse performance than the SOTA baseline. Unlike Multi-stream, which leverages fine-grained region-level features, our results are reported on global frame-level features. Therefore, it may be difficult for HERO to capture the inconsistency between hypothesis and video content. For example, changes of hypotheses about region-level attributes (color, shape, and etc.) may result in different conclusions. Extending HERO for region-level video representations could be an interesting future direction.

HERO is also extensible to generation task: multi-modal video captioning. Our results on TVC show that HERO with pre-training surpasses MMT by a large margin. Although pre-training is only applied to the encoder, it significantly improves HERO performance on TVC across all metrics. When no pre-training is applied, HERO is slightly inferior to the SOTA baseline. Our hypothesis is that TVC has short video context (with video length of 9-second on average) but our model is designed for long video representation learning (TVR/TVQA with video length of 76-second on average). How to design pre-training tasks for MMT on TVC or including decoder pre-training for HERO are left for future works.

A.2 Qualitative Analysis

Visualization of VSM One way to understand how HERO aligns subtitles with video frames is to visualize the Video-Subtitle Matching pre-training task. We provide some examples of the top-1 moment predictions for VSM on both TV and HowTo100M corpora. As shown in Figure 2, the predicted moments (red) largely overlap with the ground truth moments (green) with minor differences. In Figure 2a, we human could probably identify the moment by the speaker information and the visual clue of character's emotion. For Figure 2b, objects (rubber bands) might be the key matching clue. The success of HERO to correctly match the moments might be a positive signal that its pre-training captures those human-identified patterns, hence leads to its strong video understanding capability. However, more thorough analysis, both quantitative and qualitative, is needed to interpret what video-language pre-trained models have learned, which we leave to future works.

Attention Pattern Visualization Following Kovaleva et al. (2019) and Chen et al. (2020b), we analyze observable patterns in the attention maps of HERO. Figure 3 provides visualization examples of the attention maps learned by the Cross-modal Transformer. For completeness, we briefly discuss each pattern here:

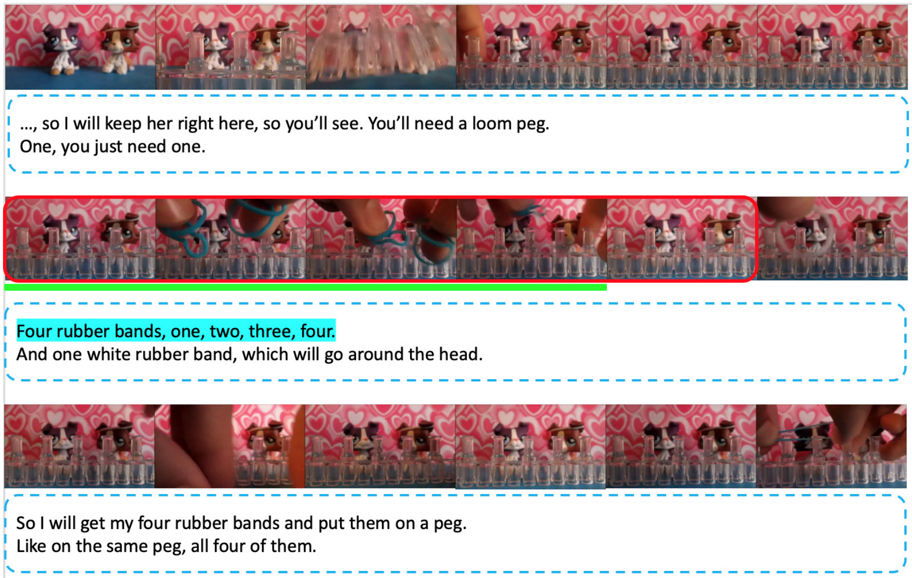
- *Vertical*: Attention to a specific frame.
- *Diagonal*: Locally-focused attention to the token/frame itself or preceding/following tokens/frames.

BAILEY: The sooner we get you into surgery, the better your chances of...

MS. SEABURY: The better your chances of surviving. So I heard, it's all very aggressive. I mean, it's very...

MS. SEABURY: Its' funny. I have never smoked a cigarette in my life.

(a) TV Dataset.



..., so I will keep her right here, so you'll see. You'll need a loom peg.
One, you just need one.

Four rubber bands, one, two, three, four.
And one white rubber band, which will go around the head.

So I will get my four rubber bands and put them on a peg.
Like on the same peg, all four of them.

(b) HowTo100M Dataset.

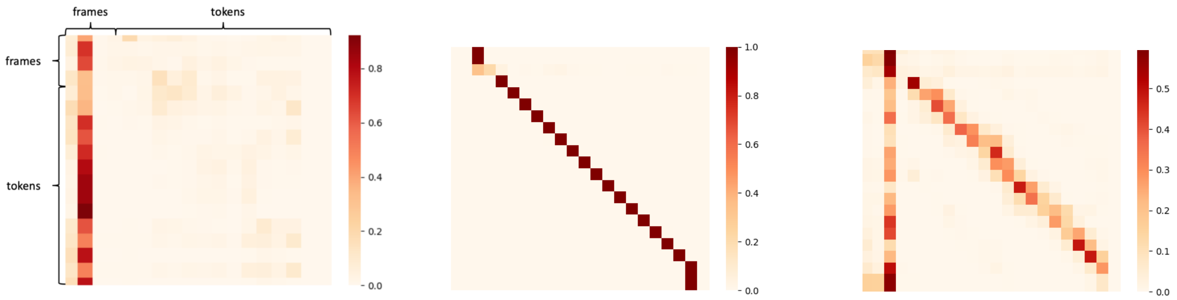
Figure 2: Visualization of top-1 moment predictions by HERO model for Video-Subtitle Matching on: (a) TV Dataset; and (b) HowTo100M Dataset. Text inside the dashed boxes is the accompany subtitles, with sampled subtitle query highlighted in blue. Groundtruth is highlighted with the green bar under the video frames. Predicted moments are bounded with boxes in red. Best viewed in color.

- *Vertical* + *Diagonal*: Mixture of Vertical and Diagonal.
- *Block*: Intra-modality attention, *i.e.*, textual self-attention or visual self-attention.
- *Heterogeneous*: Diverse attentions that cannot be categorized and highly dependent on actual input.
- *Reversed Block*: Cross-modality attention, *i.e.*, text-to-frame and frame-to-text attention.

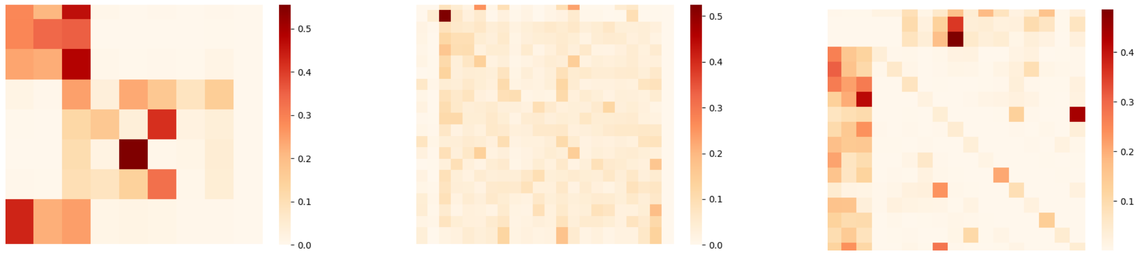
Note that we observe patterns slightly different from Chen et al. (2020b): *Vertical* patterns (Figure 3a) are usually over a specific frame instead of special tokens (`[CLS]` or `[SEP]`). We leave more sophisticated attention analysis/probing to future works.

A.3 Downstream Adaptation

The pre-trained model can be readily adapted to downstream video+language tasks through end-to-end finetuning. Below, we describe the detailed



(a) Vertical (b) Diagonal (c) Vertical + Diagonal



(d) Block (e) Heterogeneous (f) Reversed Block

Figure 3: Visualization of the attention maps learned by Cross-modal Transformers of HERO model.

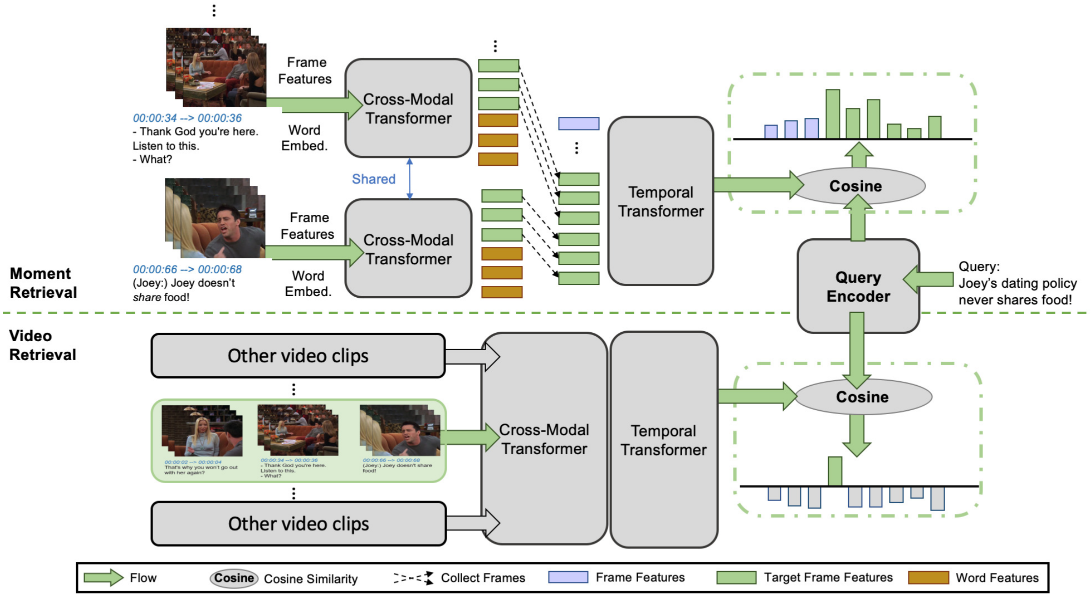


Figure 4: HERO model adapted to downstream task: Text-based Video Moment Retrieval.

adaptation approach to four downstream tasks: (i) text-based video moment retrieval, (ii) video question answering, (iii) video-and-language inference and (iv) multimodal video captioning.

Text-based Video-moment Retrieval The input video clip with accompanying subtitles is encoded by HERO as illustrated in Figure 4. The input query is encoded by the query encoder from the VSM pre-training task. We follow the same procedure as in VSM to compute query-video matching scores both locally (frame-level, for moment retrieval) and globally (clip-level, for video retrieval). The model is finetuned end-to-end using loss $\mathcal{L}_{\text{VSM}}$. Similarly, we let the margin $\delta = 0.1$ and set $\lambda_1 = 0.01$ and $\lambda_2 = 8$ in the loss term $\mathcal{L}_{\text{VSM}}$.

Video Question Answering For Video QA, we consider the multiple-choice setting. As illustrated in Figure 5, for each answer candidate, the corresponding QA pair is appended to each of the subtitle sentences and fed into the Cross-modal Transformer to perform early fusion with local textual context. In addition, these QA pairs are also

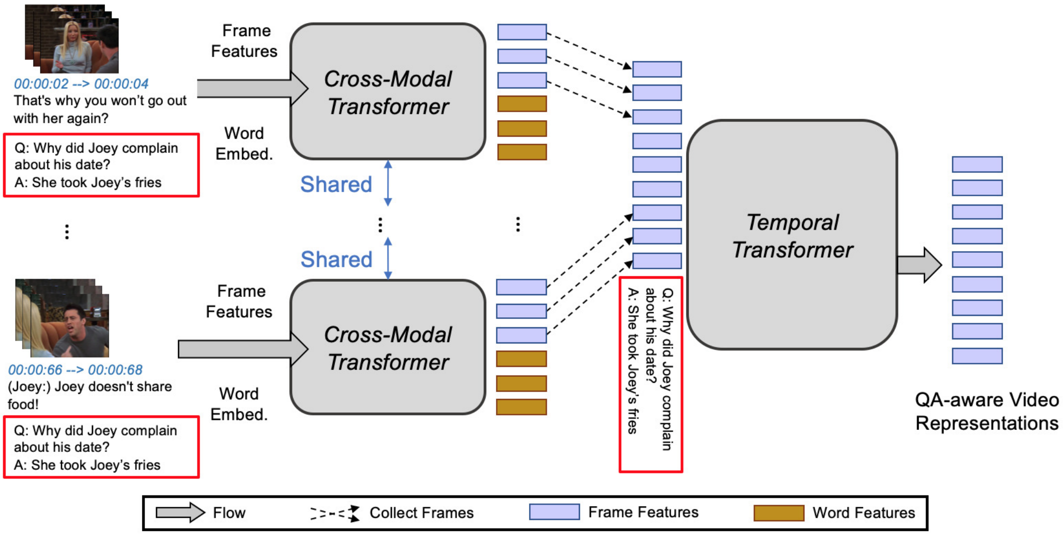

Figure 5: HERO model adapted to downstream task: Video Question Answering.

appended to the input of Temporal Transformer to be fused with global video context. We use a simple attention layer to compute the weighted-sum-across-time of the QA-aware frame representations from the Temporal Transformer output.

These final QA-aware global representations are then fed through an MLP and softmax layer to obtain the probability score $\mathbf{p}_{ans}^{(i)}$ of all the answers for question i. The training objective is

$$\mathcal{L}_{ans} = -\frac{1}{N}\sum_{i=1}^{N} \log \mathbf{p}_{ans}^{(i)}[y_i] \,, \tag{9}$$

where y_i is the index of the ground-truth answer for question i. When supervision is available,[14] we also include the span prediction loss:

$$\mathcal{L}_{span} = -\frac{1}{2N}\sum_{i=1}^{N}(\log \mathbf{p}_{st}^{(i)}[y_i^{st}] + \log \mathbf{p}_{ed}^{(i)}[y_i^{ed}]) \,, \tag{10}$$

where $\mathbf{p}_{st}^{(i)}$ and $\mathbf{p}_{ed}^{(i)}$ are the prediction scores of the start and end position, obtained by applying weighted-sum-across-answers attention to the Temporal Transformer output followed by two MLPs and a softmax layer. y_i^{st}, y_i^{ed} are the indices of the ground-truth start and end positions for question i.

The final loss $\mathcal{L}_{\text{QA}} = \mathcal{L}_{ans} + \lambda\mathcal{L}_{span}$, where λ is the hyper-parameter that balance the above two terms. Empirically, we found that $\lambda = 0.5$ yields the best model performance.

Video-and-Language Inference Similar to Video QA, each natural language hypothesis (or query) is appended to each of the subtitle sentences and also to the input of Temporal Transformer. A simple attention pooling layer is added to HERO to obtain the final query-aware global representations.

Video-and-language inference task can be regarded as a binary classification problem. We supervise the training using cross-entropy loss.

Multimodal Video Captioning With a simple addition of a Transformer decoder (Vaswani et al., 2017), we can extend HERO for multimodal video captioning. We feed the whole subtitle-aligned video clip into HERO and obtain the subtitle-fused video representation for each frame. Next, frame representations are grouped by the "moment of interest" using the time interval provided in the caption annotation. The decoder-to-encoder attention is applied on the representations of the corresponding video moment and the decoder is trained with conventional left-to-right language modeling cross-entropy loss together with the HERO encoder end-to-end. To make the comparison to MMT (Lei et al., 2020b) as fair as possible, we use shallow Transformer decoder (2-layer) with 768 hidden size. We do not use self-critical RL or its variants to optimize test metrics. Following MMT, greedy decoding is used at inference.

Single-channel Tasks Although HERO is designed for multi-channel videos (video+subtitle), we can easily extend it to single-channel video (video-only) tasks by adding an empty-string subti-

---

[14] Some existing Video QA tasks require localizing 'frames of interest' for the question, *e.g.*, TVQA+ (Lei et al., 2020a).

tle input and pair it with the whole frame sequence. For DiDeMo, we follow the same procedure as in VSM to compute both frame-level (for moment retrieval) and clip-level (for video retrieval) query-video matching scores. For MSR-VTT, a text-based video retrieval task, only clip-level scores are computed.

A.4 Frames/Subtitles Pre-processing

Given a pair of video clip and its associated subtitle, we first extract a sequence of visual frames $\mathbf{v} = \{v_i\}_{i=1}^{N_v}$ at a fixed frame rate (N_v is the number of visual frames in a video clip). The subtitle is parsed into sentences $\mathbf{s} = \{s_i\}_{i=1}^{N_s}$ (N_s is the number of sentences in each subtitle). Note that $N_v \neq N_s$ in most cases, since a subtitle sentence may last for several visual frames. We then align the subtitle sentences temporally with the visual frames. Specifically, for each subtitle sentence s_i, we pair it with a sequence of visual frames whose timestamps overlap with the subtitle timestamp, and denote these visual frames as $\mathbf{v}_{s_i} = \{v_{s_i}^j\}_{j=1}^{K}$ (K is the number of overlapping frames with s_i). In the case that multiple sentences overlap with the same visual frame, we always pair the frame with the one with maximal temporal Intersection over Union (tIoU) to avoid duplication. It is possible that a subtitle sentence is not paired with any visual frame, and in this case, we concatenate it to the neighboring sentences to avoid information loss.

A.5 Implementation Details

We extract 2304-dimensional Slowfast (Feichtenhofer et al., 2019) features at a fixed frame rate (TV: 2/3 frame per second, HowTo100M: 1/2 frame per second). and 2048-dimensional ResNet-101 (He et al., 2016) features at doubled frame rate and max-pooled to get a clip-level feature. The final frame features is concatenation of the two features with dimension 4352. The model dimensions are set to (L=6, H=768, A=12) for Cross-Modal Transformer and (L=3, H=768, A=12) for Temporal Transformer, where L is the number of stacked Transformer blocks; H stands for hidden activation dimension and A is the number of attention heads. For pre-training task VSM, we let the margin $\delta = 0.1$ and set $\lambda_1 = 0.01$ and $\lambda_2 = 8$ in the loss term $\mathcal{L}_{\text{VSM}}$.

Our models are implemented based on PyTorch (Paszke et al., 2017).[15] To speed up training, we use Nvidia Apex[16] for mixed precision training. Gradient accumulation (Ott et al., 2018) is applied to reduce multi-GPU communication overheads. All pre-training experiments are run on Nvidia V100 GPUs (32GB VRAM; NVLink connection). We use AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of $3e-5$ and weight decay of 0.01 to pre-train our model. The best pre-trained model is trained on 16 V100 GPUs for about 3 weeks. Finetuning experiments are implemented on the same hardware or Titan RTX GPUs (24GB VRAM) with AdamW optimizer but different learning rates.

A.6 Downstream Tasks

TVR (Lei et al., 2020b) is the first to introduce text-based video-moment Retrieval task for multi-channel videos (video+subtitle): given a natural language query, a model is required to not only retrieve the most relevant video clip from the video corpus, but also localize the relevant moment in the retrieved video clip. TVR is built upon the TV dataset, split into 80% train, 10% val, 5% test-public and 5% test-private. On average, 5 queries were collected for each video clip. Among them, 74.2% of queries are related to video only, 9.1% to text only, and 16.6% to both video and text.

TVQA (Lei et al., 2018) was introduced along with the TV dataset. Given a video clip and the accompanying subtitles, the goal is to answer a multiple-choice question about the video. Each video clip has 7 questions, with 5 answers per question. The start/end points of relevant moments are provided for each question.[17]

VIOLIN (Liu et al., 2020) is a new Video-and-Language Inference task. Given a video clip with aligned subtitles as premise, a model needs to infer whether a natural language hypothesis is entailed or contradicted by the given video clip. It consists of 95.3K video-hypothesis pairs from 15.9K video clips, split into 80% train, 10% val and 10% test.

TVC (Lei et al., 2020b) is a multimodal Video Captioning dataset extended from TVR, containing 262K descriptions paired with 108K video moments.[17] Note that it differs from traditional video captioning tasks in that models are allowed to utilize subtitle texts as input.

DiDeMo (Anne Hendricks et al., 2017a) is de-

---

[15] https://pytorch.org/

[16] https://github.com/NVIDIA/apex

[17] Train, val and test video splits are the same as TVR.

signed for text-based video-moment retrieval on single-channel videos (video-only). It consists of 10.6K unedited video from Flickr with 41.2K sentences aligned to unique moments in the video. The dataset is split into 80% train, 10% val and 10% test. Note that moment start and end points are aligned to five-second intervals and the maximum annotated video length is 30 seconds.

MSR-VTT (Xu et al., 2016b), for text-based video retrieval on single-channel videos (video-only), includes YouTube videos collected from 257 popular video queries from 20 categories (e.g. music, sports, movie, etc.). It contains 200K unique video clip-caption pairs. We follow the same setup in Yu et al. (2018b) to evaluate our model on MSR-VTT.

Evaluation Metrics Text-based Video-moment Retrieval can be decomposed into two sub-tasks: (i) Video Retrieval: retrieve the most relevant video clip described by the query; (ii) Moment Retrieval: localize the correct moment from the most relevant video clip. A model prediction is correct if: (i) its predicted video matches the ground-truth (in Video Retrieval); and (ii) its predicted span has high overlap with the ground-truth (in Moment Retrieval). Average recall at K (R@K) over all queries is used as the evaluation metric for TVR, How2R, Didemo and MSR-VTT. For TVR, How2R and Didemo, temporal Intersection over Union (tIoU) is used to measure the overlap between the predicted span and the ground-truth span.[18]

TVQA and How2QA include 3 sub-tasks: QA on the grounded clip, question-driven moment localization, and QA on the full video clip. We only consider QA on the full video clip, as it is the most challenging setting among the three. Video clips in VIOLIN are constrained to a single, self-contained scene, hence no additional grounding annotation is provided. Accuracy is used to measure model performance on TVQA, How2QA and VIOLIN.

TVC performance is measured by standard captioning metrics, inlcuding BLEU@4 (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), ROUGE-L (Lin, 2004), and CIDEr-D (Vedantam et al., 2015).

A.7 Vision+Language Pre-training Overview

Very recently, multimodal pre-training has gained increasing attention, especially in the image+text area. Pioneering works such as ViLBERT (Lu et al., 2019) and LXMERT (Tan and Bansal, 2019) propose to encode image and text modalities by two separate Transformers, with a third Transformer for later multimodal fusion. Compared to this two-stream architecture, VL-BERT (Su et al., 2020), Unicoder-VL (Li et al., 2020a), B2T2 (Alberti et al., 2019), VisualBERT (Li et al., 2019), and UNITER (Chen et al., 2020b) advocate single-stream architecture, where image and text signals are fused together in early stage. In VLP (Zhou et al., 2020) and XGPT (Xia et al., 2020), image captioning is considered as additional downstream application, so is visual dialog in Murahari et al. (2020). More recently, ViLBERT is enhanced by multi-task learning (Lu et al., 2020), Oscar (Li et al., 2020b) enhances pre-training with image tags, and Pixel-BERT (Huang et al., 2020) proposes to align image pixels (instead of bottom-up features (Anderson et al., 2018)) with text. Through these pre-training efforts, tremendous progress has been made for vision-and-language representation learning.

A.8 Video+Language Tasks Overview

Text-based Video-moment retrieval is one of the most popular video+language tasks currently studied. Anne Hendricks et al. (2017b) and Gao et al. (2017) introduce the task of Single Video Moment Retrieval (SVMR), which aims at retrieving a moment from a single video via a natural language query. Escorcia et al. (2019) extends SVMR to Video Corpus Moment Retrieval (VCMR), extending searching pool from single video to large video corpus. TVR (Lei et al., 2020b) defines a new task, Video-Subtitle Corpus Moment Retrieval, which provides temporally aligned subtitle sentences along with the videos as inputs. For this new task, XML (Lei et al., 2020b) is proposed to compute similarity scores between the query and each modality separately (visual frames, subtitles) and then sum them together for final prediction.

Another popular task is Video Question Answering (QA), which aims to predict answers to natural language questions given a video as context. Most previous work focuses on QA pairs from one modality only. For example, MovieFIB (Maharaj et al., 2017) focuses on visual concepts,

---

[18] During evaluation, the average recalls are calculated with tIoU>0.7. we apply non-maximal suppression (nms) with threshold 0.5 to TVR and How2R predictions following Lei et al. (2020b).

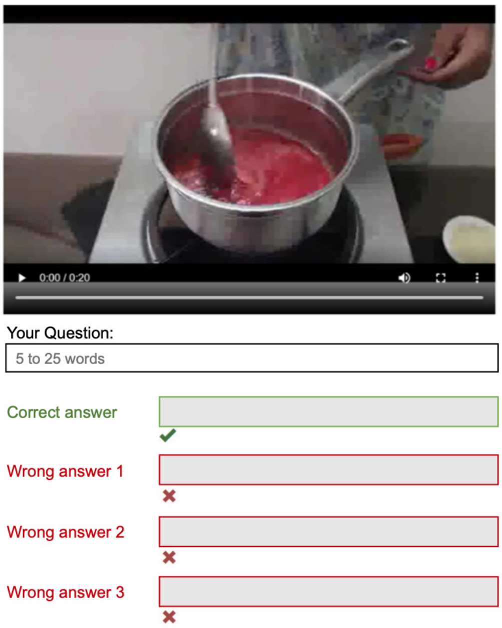
(a) User interface for query annotation. Each worker is provided with a video clip and required to select a single-scene clip from the video, then write a query in the text box.



(b) User interface for question/answer annotation. Each worker is provided with a segmented clip and required to write a question with four answers in the text boxes.

Figure 6: Data collection interface: (a) How2R; and (b) How2QA.

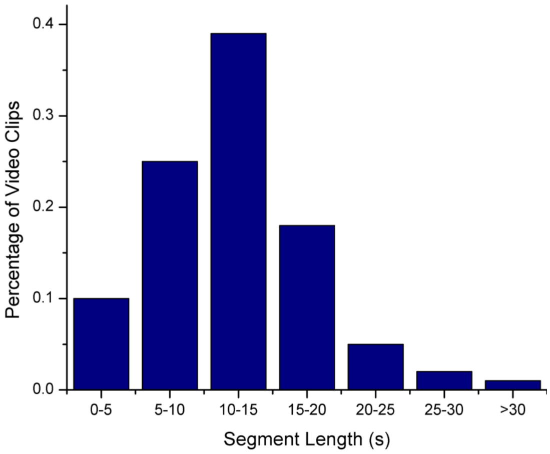


Figure 7: Distribution of video segment length.

MovieQA (Tapaswi et al., 2016) is based on text summaries, and TGIF-QA(Jang et al., 2017) depends on predefined templates for question generation on short GIFs. TVQA (Lei et al., 2018) designed a more realistic multimodal setting: collecting human-written QA pairs along with their associated video segments by providing the annotators with both video clips and accompanying subtitles. Later on, Lei et al. (2020a) augmented TVQA with frame-level bounding box annotations for spatial-temporal video QA, and introduced the STAGE framework to jointly localize moments, ground objects, and answer questions.

Inspired by natural language inference (Bowman et al., 2015; Williams et al., 2018) and visual entailment (Xie et al., 2019), Liu et al. (2020) recently proposed Video-and-Language Inference task along with VIOLIN dataset, which requires a model to draw inference on whether a written statement entails or contradicts a given video clip. This new task is challenging to solve, as a thorough interpretation of both visual and textual clues from videos is required to achieve in-depth understanding and inference for a complex video scenario.

There are also recent studies on video captioning (Venugopalan et al., 2015; Pan et al., 2016; Gan et al., 2017; Zhou et al., 2018b, 2019), popular benchmarks including Youtube2Text (Guadarrama et al., 2013), MSR-VTT (Xu et al., 2016a), YouCook2 (Zhou et al., 2018a), ActivityNet Captions (Krishna et al., 2017) and VATEX (Wang et al., 2019). Unlike previous work mostly focusing on captions describing the visual content, a unique TVC (Lei et al., 2020b) dataset was released with captions that also describe dialogues/subtitles.

A.9 How2R and How2QA Benchmarks

Data Collection Interface Figure 6a and 6b present the interfaces used for collecting How2R and How2QA. For How2R, the annotator is asked to first select a video segment from the presented video clip using the sliding bar, and then enter a description about the selected video segment in the

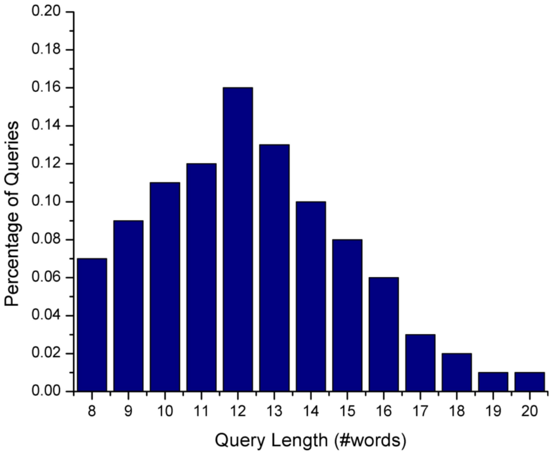

Figure 8: How2R query length distribution.

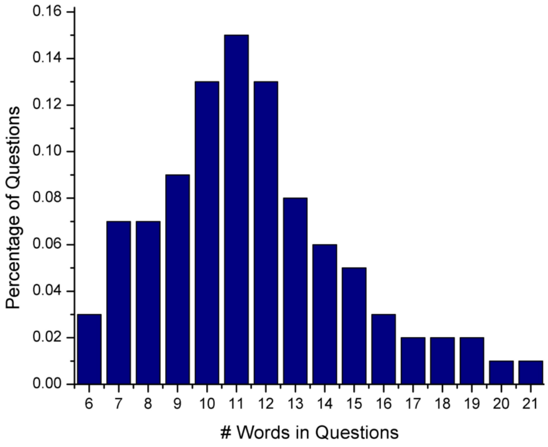

Figure 9: How2QA question length distribution.

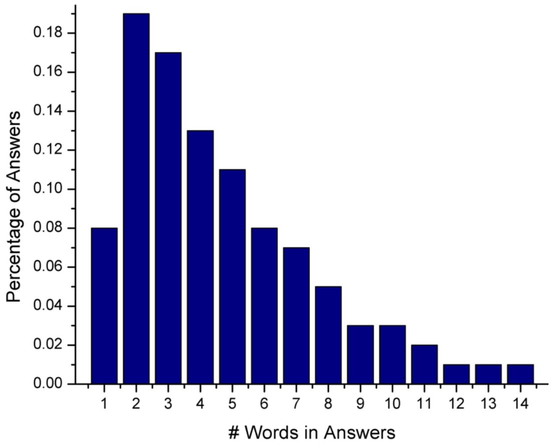

Figure 10: How2QA answer length distribution.

text box (shown at the bottom of Figure 6a). For How2QA, we reuse the selected video segments collected for How2R. The annotators are asked to write a question, a correct answer and 3 wrong answers in the five text boxes shown in Figure 6b.

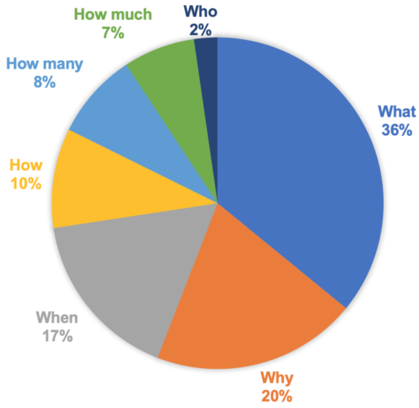

Figure 11: Distribution of questions categorized by their leading words in How2QA.

Video Segment Length Distribution The length distribution of selected video segments is presented in Figure 7. The length of video segments varies from 5 to more than 30 seconds. The majority of them have length less than 15 seconds.

How2R Query Length Distribution Figure 8 shows the length (in number of words) distribution of collected queries in How2R. The length of queries is diverse, ranging from 8 to 20.

How2QA Question and Answer Distribution Figure 9 and Figure 10 show the length (in number of words) distribution of collected questions and answers in How2QA. Questions are relatively longer, with more than 10 words on average. Answers are relatively shorter, most of which have less than 7 words.

In addition, we analyze the types of collected question by plotting the distribution of their leading words in Figure 11. In total, we collected questions in 7 different types. Majority of them starts with "what", "why" and "when".

Vokenization: Improving Language Understanding with Contextualized, Visual-Grounded Supervision

Hao Tan **Mohit Bansal**
UNC Chapel Hill
{haotan, mbansal}@cs.unc.edu

Abstract

Humans learn language by listening, speaking, writing, reading, and also, via interaction with the multimodal real world. Existing language pre-training frameworks show the effectiveness of text-only self-supervision while we explore the idea of a visually-supervised language model in this paper. We find that the main reason hindering this exploration is the large divergence in magnitude and distributions between the visually-grounded language datasets and pure-language corpora. Therefore, we develop a technique named "vokenization" that extrapolates multimodal alignments to language-only data by contextually mapping language tokens to their related images (which we call "vokens"). The "vokenizer" is trained on relatively small image captioning datasets and we then apply it to generate vokens for large language corpora. Trained with these contextually generated vokens, our visually-supervised language models show consistent improvements over self-supervised alternatives on multiple pure-language tasks such as GLUE, SQuAD, and SWAG.[1]

1 Introduction

Most humans learn language understanding from multiple modalities rather than only from the text and audio, especially using the visual modality. As claimed in Bloom (2002), visual pointing is an essential step for most children to learn meanings of words. However, existing language pre-training frameworks are driven by contextual learning which only takes the language context as self-supervision. For example, word2vec (Mikolov et al., 2013) takes surrounding bag-of-words; ELMo (Peters et al., 2018) and GPT (Radford et al., 2018) take succeeding contexts; and BERT (Devlin et al., 2019) takes randomly masked tokens. Although these self-supervised frameworks have achieved strong progress towards understanding human language, they did not borrow grounding information from the external visual world (see related motivations in recent work by Bender and Koller (2020) and Bisk et al. (2020)).

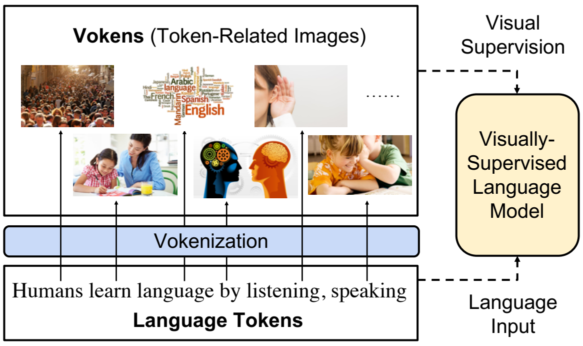

Figure 1: We visually supervise the language model with token-related images. We call these images vokens (visualized tokens) and develop a vokenization process to contextually generate them.

In this paper, we introduce the visually-supervised language model that simulates human language learning with visual pointing (Bloom, 2002). As shown in Fig. 1, this model takes language tokens as input and uses token-related images as visual supervision. We name these images as *vokens* (i.e., visualized tokens), since they act as visualizations of the corresponding tokens. Assuming that a large aligned token-voken dataset exists, the model could learn from these vokens via voken-prediction tasks.

Unfortunately, such an aligned token-voken dataset is currently unavailable and hence there are two main challenges in creating it from visually-grounded language datasets. First, there is a large discrepancy between visually-grounded language (which provides innate visual grounding supervi-

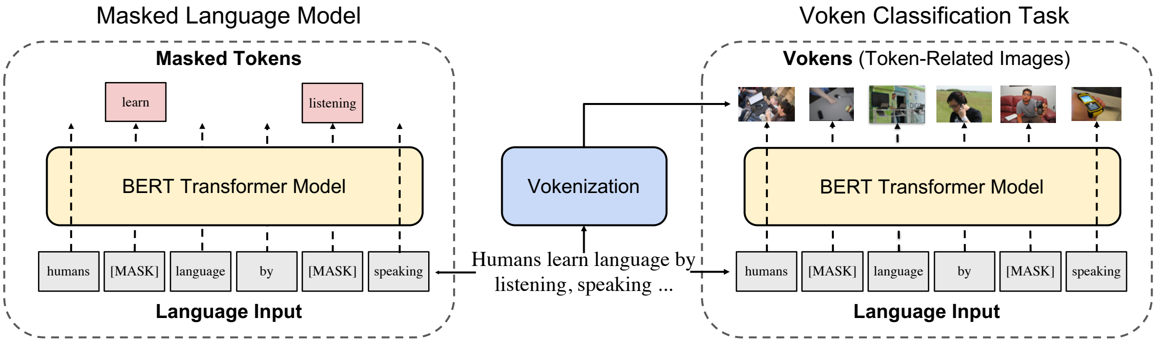

Figure 2: Illustration of the BERT transformer model trained with a visually-supervised language model with two objectives: masked language model (on the left) and voken classification (on the right). The first objective (used in original BERT pre-training) predicts the masked tokens as self-supervision while the second objective predicts the corresponding vokens (contextually generated by our vokenization process) as external visual supervision. Since the inputs are the same, we optimize the two objectives simultaneously and share the model weights.

sion) and other types of natural language. For example, about 120M tokens are available in visually-grounded language datasets (Tan and Bansal, 2019; Chen et al., 2019), which is far less compared to the 3,300M tokens in BERT training data and 220B tokens in T5 (Raffel et al., 2019). Grounded language also prefers short and instructive descriptions, and thus has different distributions of sentence lengths and active words to other language types. Second, most of the words in natural language are not visually grounded, hence this challenges the premise in creating visual supervision. With an approximate estimation, the ratio of grounded tokens is only about 28% in English Wikipedia. This low grounding ratio leads to low coverage of visual supervision in previous approaches (Frome et al., 2013; Kiela et al., 2018).

To resolve the above two challenges, we propose our *vokenization* method (as shown in Fig. 1) that contextually maps the tokens to the visualized tokens (i.e., vokens) by retrieval. Instead of directly supervising the language model with visually grounded language datasets (e.g., MS COCO (Lin et al., 2014)), we use these relative small datasets to train the vokenization processor (i.e., the *vokenizer*). We then generate vokens for large language corpora (e.g., English Wikipedia), and our visually-supervised language model will take the input supervision from these large datasets, thus bridging the gap between different data sources, which solves the first challenge. The second challenge of low grounding ratio seems to be an inherent characteristic of language; however, we observe that some non-visually-grounded tokens can be effectively mapped to related images when considering its context, e.g., the abstract word "angry" in the sentence "an angry cat lies on my leg". This observation is realized by our *contextual* token-image matching model (defined in Sec. 3.2) inside our vokenization processor, where we map tokens to images by viewing the sentence as the context.

Using our proposed vokenizer with a contextualized token-image matching model, we generate vokens for English Wikipedia. Supervised by these generated vokens, we show consistent improvements upon a BERT model on several diverse NLP tasks such as GLUE (Wang et al., 2019), SQuAD (Rajpurkar et al., 2016), and SWAG (Zellers et al., 2018). We also show the transferability of our vokens to other frameworks (i.e., RoBERTa).

2 Visually-Supervised Language Models

Contextual language representation learning is driven by self-supervision without considering explicit connections (grounding) to the external world. In this section, we illustrate the idea of a visually-supervised language model and discuss the challenges of creating its visual supervision.

2.1 Vokens: Visualized Tokens

To provide visual supervision to the language model, we assume a text corpus where each token is aligned with a related image (although these voken annotations currently do not exist, we will try to generate vokens next in Sec. 3 by the vokenization process). Hence, these images could be considered as visualizations of tokens and we name them as 'vokens'. Based on these vokens, we propose a new pre-training task for language: voken classification.

Dataset	# of Tokens	# of Sents	Vocab. Size	Tokens #/ Sent.	1-Gram JSD	2-Gram JSD	Grounding Ratio
MS COCO	7.0M	0.6M	9K	11.8	0.15	0.27	54.8%
VG	29.2M	5.3M	13K	5.5	0.16	0.28	57.6%
CC	29.9M	2.8M	17K	10.7	0.09	0.20	41.7%
Wiki103	111M	4.2M	29K	26.5	0.01	0.05	26.6%
Eng Wiki	2889M	120M	29K	24.1	0.00	0.00	27.7%
CNN/DM	294M	10.9M	28K	26.9	0.04	0.10	28.3%

Table 1: Statistics of image-captioning dataset and other natural language corpora. VG, CC, Eng Wiki, and CNN/DM denote Visual Genome, Conceptual Captions, English Wikipedia, and CNN/Daily Mail, respectively. JSD represents Jensen–Shannon divergence to the English Wikipedia corpus. A large discrepancy exists between the visually grounded captioning and general language corpora.

2.2 The Voken-Classification Task

Most language backbone models (e.g., ELMo (Peters et al., 2018), GPT (Radford et al., 2018), BERT (Devlin et al., 2019)) output a localized feature representation $\{\boldsymbol{h}_i\}$ for each token in a sentence $s = \{w_i\}$. Thus it allows adding a token-level classification task without modifying the model architecture. Suppose the vokens come from a finite set $\mathbb{X}$, we convert the hidden output $\boldsymbol{h}_i$ to a probability distribution p_i with a linear layer and a softmax layer, then the voken classification loss is the negative log probability of all corresponding vokens:

$$\begin{aligned}\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_l &= \operatorname{lm}(w_1, w_2, \ldots, w_l) \\ p_i(v \mid s) &= \operatorname{softmax}_v\{W\,\boldsymbol{h}_i + b\} \\ \mathcal{L}_{\text{VOKEN-CLS}}(s) &= -\sum_{i=1}^{l} \log p_i\left(v(w_i; s) \mid s\right)\end{aligned}$$

This task could be easily integrated into current language pre-training frameworks, and we next show an example.

Example: Visually-Supervised BERT Fig. 2 shows an example realization of the voken-classification task that provides visual supervision to BERT (Devlin et al., 2019). The original BERT pre-training mainly relies on the task of masked language model[2] (illustrated on the left side of Fig. 2): tokens are randomly masked and the model needs to predict these missing tokens from language context. For simplicity, we use s and $\hat{s}$ to denote the set of tokens and masked tokens, separately. The unmasked tokens are the set difference $s \setminus \hat{s}$. Suppose q_i is the conditional probability distribution of the i-th token, the Masked Language Model (MLM) loss is the negative log-likelihood of the masked tokens:

$$\mathcal{L}_{\text{MLM}}(s, \hat{s}) = -\sum_{w_i \in \hat{s}} \log q_i\left(w_i \mid s \setminus \hat{s}\right)$$

Without changing the model and model's inputs, we calculate the voken-classification loss for all tokens (illustrated on the right side of Fig. 2):

$$\mathcal{L}_{\text{VOKEN-CLS}}(s, \hat{s}) = -\sum_{w_i \in s} \log p_i\left(v(w_i; s) \mid s \setminus \hat{s}\right)$$

The visually-supervised masked language model takes the sum of these two losses with a ratio λ.

$$\mathcal{L}_{\text{VLM}}(s, \hat{s}) = \mathcal{L}_{\text{VOKEN-CLS}}(s, \hat{s}) + \lambda \mathcal{L}_{\text{MLM}}(s, \hat{s}) \tag{1}$$

2.3 Two Challenges in Creating Vokens

Previous sections illustrate the potential external supervision by assuming the existence of vokens. However, we are currently lacking the dense annotations from tokens to images. The most similar concept to vokens is phrase localization (e.g., in Flickr30K entities (Young et al., 2014; Plummer et al., 2017)). Because the process of collecting phrase localization is costly, the coverage and the amount of annotations cannot meet our requirements.[3] Apart from phrase localization, the most promising data source is image captioning datasets with sentence-to-image mappings (or discovered from multimodal documents, as in Hessel et al. (2019)). Image captions belong to a specific type of language called *grounded language* (Roy and Pentland, 2002; Hermann et al., 2017), which has an explicit grounding to external existence or physical actions. However, grounded language has a large discrepancy to other types of natural language (e.g., News, Wiki, and Textbooks). To illustrate this, we list key statistics of three image-captioning dataset (i.e., MS COCO (Lin et al.,

---

[2] The next-sentence prediction task is removed in RoBERTa (Liu et al., 2019) and XLM (Lample and Conneau, 2019) and the fine-tuning results are not largely affected.

[3] Recently, a concurrent work Pont-Tuset et al. (2019) releases localized narratives. The tokens are aligned with image pixels instead of images.

2014), Visual Genome (Krishna et al., 2017), and Conceptual Captions (Sharma et al., 2018)) and three language corpora of other language types (i.e., Wiki103 (Merity et al., 2017), English Wiki, and CNN/Daily Mail (See et al., 2017)) in Table 1. This discrepancy between grounded language and other types of natural language leads to two challenges:

A. Different Distributions between Grounded Language and Other Natural Language Corpora. Sentences belonging to grounded language are usually short and informative, e.g., the average sentence length in MS COCO is 11.8, which is much shorter than the average sentence length of 24.1 in English Wiki. The vocabulary[4] of MS COCO only covers around one-third of token types (Smith, 2019) in English Wiki. There is also a large divergence of the 1-Gram and 2-Gram distributions (measured by Jensen–Shannon divergence) between grounded language dataset and the English Wikipedia. Lastly, the amount of tokens in grounded language corpora are also orders of magnitude smaller than commonly-used Wikipedia.

B. Low Grounding Ratio in Natural Language. The grounding ratio is defined as the percentage of visually grounded tokens in the dataset. Visually grounded tokens (e.g., concrete nouns) are the token types that are naturally related to specific visual contents (e.g., 'cat', 'cake', 'clock'). Since a precise list of such token types is hard to define, we thus estimate the grounding ratio based on existing grounded language corpora. Specifically, we consider a token type with more than 100 occurrences in MS COCO (after removing all stop words) as visually-grounded. A sample of these token types could be found in the Appendix. As shown in the last column of Table 1, the grounding ratio of English Wiki is 27.7%, which is almost half of that in Visual Genome.

To address these two challenges, we propose a vokenizer with contextual token-image matching models next in Sec. 3.

3 Vokenization

In the previous section, we discuss the potential of using vokens (i.e., visualized tokens) as visual supervision to the language model, and also demonstrate the large gap between currently available resources (i.e., annotated dataset) and the desired requirements. Hence, in this section, we develop a framework that can generate vokens. As shown in Fig. 2, the general idea is that we learn a "vokenizer" from image-captioning dataset and use it to annotate large language corpora (i.e., English Wiki), thus bridging the gap between grounded language and other types of natural language. We start by illustrating the vokenization process and then describe how we implement it.

3.1 The Vokenization Process

As shown in Fig. 1 and Fig. 2, vokenization is the process to assign each token w_i in a sentence $s = (w_1, w_2, \dots, w_l)$ with a relevant image $v(w_i; s)$. We call this image $v(w_i; s)$ as a 'voken' (visualized token). Instead of creating this image with generative models, we retrieve an image from a set of images $\mathbb{X} = \{x_1, x_2, \dots, x_n\}$ regarding a token-image-relevance scoring function $r_\theta(w_i, x; s)$. This scoring function $r_\theta(w_i, x; s)$, parameterized by θ, measures the relevance between the token w_i in the sentence s and the image x. We here assume that the optimal parameter of this function is θ^* and will discuss the details of formulations later. The voken $v(w_i; s)$ related to a token w_i in the sentence s is realized as the image $x \in \mathbb{X}$ that maximizes their relevance score r_{θ^*}:

$$v(w_i; s) = \arg\max_{x \in \mathbb{V}} r_{\theta^*}(w_i, x; s)$$

Since the image set $\mathbb{X}$ indeed builds a finite vocabulary for vokens, we could utilize the voken-classification task (formulated in Sec. 2.2) to visually supervise the language model training. We next talk about the detailed implementation of this vokenization process.

3.2 Contextual Token-Image Matching Model

Lying in the core of the vokenization process is a contextual token-image matching model. The model takes a sentence s and an image x as input, and the sentence s is composed of a sequence of tokens $\{w_1, w_2, \dots, w_l\}$. The output $r_\theta(w_i, x; s)$ is the relevance score between the token $w_i \in s$ and the image x while considering the whole sentence s as a context.

Modeling To model the relevance score function $r_\theta(w_i, x; s)$, we factorize it as an inner product of the language feature representation $\boldsymbol{f}_\theta(w_i; s)$ and the visual feature representation $\boldsymbol{g}_\theta(x)$:

$$r_\theta(w_i, x; s) = \boldsymbol{f}_\theta(w_i; s)^\intercal \boldsymbol{g}_\theta(x)$$

---

[4] The vocabulary is calculated following Karpathy and Fei-Fei (2015) where the words with > 5 occurrence is counted.

These two feature representations are generated by language and visual encoders respectively. The language encoder first uses a pre-trained BERT$_{\text{BASE}}$ (Devlin et al., 2019) model to contextually embed the discrete tokens $\{w_i\}$ into hidden-output vectors $\{\boldsymbol{h}_i\}$:

$$\boldsymbol{h}_1, \boldsymbol{h}_2, \ldots, \boldsymbol{h}_l = bert(w_1, w_2, \ldots, w_l)$$

Then we apply a multi-layer perceptron (MLP) w_mlp_θ to down project the hidden output $\boldsymbol{h}_i$. In order to simplify the retrieval process in Sec. 3.1, the final language features are normalized to norm-1 vectors by dividing their Euclidean norms:

$$\boldsymbol{f}_\theta(w_i; s) = \frac{w\_mlp_\theta(\boldsymbol{h}_i)}{\| w\_mlp_\theta(\boldsymbol{h}_i) \|}$$

On the other side, the visual encoder first extracts the visual embedding e from a pre-trained ResNeXt (Xie et al., 2017). Similar to the language encoder, an MLP layer x_mlp_θ and an L2-normalization layer are applied subsequently:

$$\begin{aligned} \boldsymbol{e} &= \text{ResNeXt}(x) \\ \boldsymbol{g}_\theta(x) &= \frac{x\_mlp_\theta(\boldsymbol{e})}{\| x\_mlp_\theta(\boldsymbol{e}) \|} \end{aligned}$$

Training Since the dense annotations from tokens to images are lacking and hard to generate (illustrated in Sec. 2.3), we thus alternatively train the token-image matching model from weak supervision in image-captioning datasets (e.g., MS COCO (Lin et al., 2014)). These datasets are comprised of sentence-image pairs $\{(s_k, x_k)\}$ where the sentence s_k describes the visual content in image x_k. To build alignments between tokens and images, we pair all tokens in a sentence s_k with the image x_k. The model is then optimized by maximizing the relevance score of these aligned token-image pairs over unaligned pairs.

Without loss of generality, assuming (s, x) is an image-captioning data point, we randomly sample another image x' with the condition $x' \neq x$. We then use hinge loss to optimize the weight θ so that the score of the positive token-image pair $r_\theta(w_i, x; s)$ aims to be larger than the negative pair $r_\theta(w_i, x'; s)$ by at least a margin M.

$$\begin{aligned} \mathcal{L}_\theta(s, x, x') = \sum_{i=1}^{l} \max\{0, M &- r_\theta(w_i, x; s) \\ &+ r_\theta(w_i, x'; s)\} \end{aligned}$$

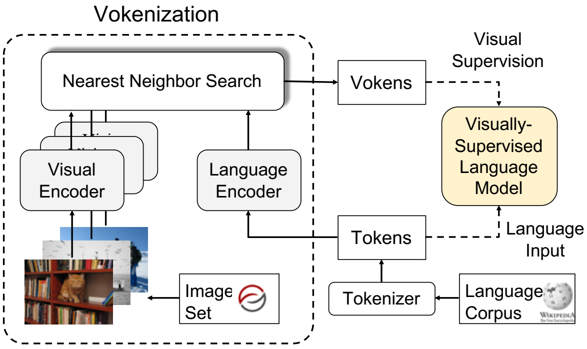

Figure 3: Implementation of our vokenization process. For the tokens in language corpora, we contextually retrieved images (with nearest neighbor search) from the image set as vokens. These generated vokens are then used as the visual supervision to the language model.

Intuitively, minimizing this hinge loss $\max\{0, M - pos + neg\}$ will try to increase the score of the positive pair and decrease the score of the negative pair when the score difference is smaller than the margin M. Otherwise (if the difference is $\geq$ margin M), the two scores remain unchanged.

Inference Given that the relevance score is factorized as the inner product of feature representations $\boldsymbol{f}_\theta(w_i; s)$ and $\boldsymbol{g}_\theta(v)$, the retrieval problem in Sec. 3.1 could be formulated as Maximum Inner Product Search (Mussmann and Ermon, 2016)). Moreover, since the vectors are norm-1, the vector with the maximum inner product is identical to the closest vector in the Euclidean space (i.e., Nearest Neighbor (Knuth, 1973)). We illustrate the detailed implementation in Fig. 3.

3.3 Revokenization

A constraint of the vokenization process in Sec. 3.1 is that the vokens depend on the actual tokenizer of the language encoder in Sec. 3.2. Since different frameworks utilize a various range of tokenizers, this constraint limits the transferability of vokens between different frameworks. Instead of binding our vokenizer to a specific pre-training framework (e.g., BERT), we want to enable its extensibility to other frameworks (e.g., RoBERTa). Thus, we introduce a "revokenization" technique to address this limitation.

Given two different tokenizers T_1 and T_2, they tokenize a sentence s into two different sequences of tokens: $T_1(s) = (w_1, w_2, \ldots, w_l)$ and $T_2(s) = (u_1, u_2, \ldots, u_m)$. Without loss of generality, assuming the vokenizer is built based on the first tokenizer T_1, the standard vokenization process will generate a sequence of vokens $\{v(w_i; s)\}_{i=1}^{l}$ which are one-to-one aligned with the tokens $\{w_i\}_{i=1}^{l}$. Our goal is to transfer these w-related vokens to the u-related vokens generated by T_2. We adapt the idea of "nearest neighbor algorithm" (Altman, 1992) here. For a given token u_j, among all w's, we select the one that overlaps the most with u_j and record it as $w_{ind(j)}$. The voken for u_j is defined as the voken for its "nearest neighbor" $w_{ind(j)}$:

$$v(u_j; s) := v(w_{ind(j)}; s)$$
$$ind(j) = \arg\max_{i=1}^{l} \text{overlap}(w_i, u_j)$$

The overlapping of two tokens are further quantified by the intersection-over-union (i.e., Jaccard index, defined as $\text{IoU}(A, B)=\frac{|A\cap B|}{|A\cup B|}$) of their ranges in the raw sentence s.

4 Experimental Setups and Results

4.1 Pre-training Data and Fine-tuning Tasks

We train our model on English Wikipedia [5] and its featured subset Wiki103 (Merity et al., 2017). We use our vokenizer to generate vokens for these two datasets as well. The pre-trained models are then fine-tuned on GLUE (Wang et al., 2019), SQuAD (Rajpurkar et al., 2016, 2018), and SWAG (Zellers et al., 2018) to assess the pre-training performance. Since some smaller tasks in GLUE are reported as unstable (Dodge et al., 2020), recent papers (e.g., Li et al. (2020b)) only report on selected tasks. We follow this trend and evaluate on the four largest datasets (i.e., SST-2 (Socher et al., 2013), QNLI (Rajpurkar et al., 2016), QQP (Iyer et al., 2017), MNLI (Williams et al., 2018)).[6].

4.2 Implementation Details

We train our contextual token-image matching model (in Sec. 3.2) on MS COCO image captioning dataset for 20 epochs. The concatenation of the last 4 layers of BERT outputs and ResNeXt-101-32x8d features are used as language hidden states and visual embedding, respectively. Both multi-layer perceptrons w_mlp_θ and x_mlp_θ have two fully-connected layers with 256-dimensional intermediate outputs (followed by ReLU activation) and 64-dimensional final outputs. The two backbone models BERT (Devlin et al., 2019) and ResNeXt (Xie et al., 2017) are not fine-tuned. We set the hinge loss margin M to 0.5. During the vokenization process of English Wikipedia and Wiki103, we use the faiss (Johnson et al., 2019) library to speed up the nearest neighbor search. The vokens are retrieved from the Visual Genome images that are not used in MS COCO. We fix a voken size of 50000.

When pre-training the model on pure language corpus, we unify the training protocols to avoid possible side effects. We follow previous works to conduct two simplifications: 1. Removing the next-sentence-prediction task (Liu et al., 2019) 2. Using fixed sequence length (Conneau et al., 2020) of 128. We take the 12-layer $\text{BERT}_{\text{BASE}}$ model of 768 hidden dimensions and train it on English Wikipedia for 200K steps from scratch. We also take a reduced 6-layer model and train it on Wiki103 for 40 epochs (160K steps) because this reduced model could not fit the full English Wikipedia dataset.

Since we only use the vokens in the supervision, the voken-classification task does not bring additional parameters to the language model but needs more computations. We thus adjust the training steps for pure masked-language-model (MLM) training accordingly for a fair comparison. The loss ratio λ=1.0 in Eqn. 1 is not tuned because of limited budget. All pre-training processes take batch sizes of 256 and learning rates of $2e$-4. For fine-tuning tasks, we report the results on the validation sets. We train 3 epochs with a learning rate of $1e$-4 and a batch-size of 32 for all tasks in GLUE. The hyper-parameters for SQuAD, SWAG are borrowed from BERT.

4.3 Results

As reported in Table 2, we fine-tune the pre-trained models on different natural-language tasks. The models are either pre-trained with masked language model (e.g., "$\text{BERT}_{\text{6L/512H}}$") or pre-trained with masked language model with an additional voken-classification task (e.g., "$\text{BERT}_{\text{6L/512H}}$+Voken-cls") following Eqn. 1. The default metric is accuracy. Following Wang et al. (2019), we report the average of F1 and accuracy for QQP. For SQuAD, we report the exact matching and F1 score respectively. We also compute macro-averages for evaluated tasks (denoted as "Avg." in the last column) as a general indicator. Although the different architectures of models (i.e., 6L/512H and 12L/768H) affect the fine-tuning results, the voken-classification

---

[5] BERT (Devlin et al., 2019) also uses Toronto Books Corpus (Zhu et al., 2015). However, the dataset is not publicly released. We thus exclude it in our study to ensure reproducibility.

[6] The size of the used four dataset range from 60K to 400 while the omitted dataset range from 0.6K to 8.5K.

Method	SST-2	QNLI	QQP	MNLI	SQuAD v1.1	SQuAD v2.0	SWAG	Avg.

task consistently improves the downstream tasks' performance and achieves large average gains. We also show the transferability of our vokenizer to the RoBERTa model and observe the same phenomenon as that in BERT.

5 Analysis

5.1 Limit of Visually-Grounded Language

In Sec. 2.3, we illustrated the differences between (visually-)grounded-language datasets and other natural-language corpora by demonstrating their contrasting statistics. In this section, we study the models trained with grounded language and show their ineffectiveness on pure-language tasks. We first investigate vision-and-language pre-training frameworks, which succeed on multimodal tasks. As shown in Table 3, when fine-tuning them on pure-language tasks, the results are generally lower than the pre-trained BERT model.[7] Although these frameworks are different in multiple ways, the only remarkable factor to the fine-tuning results is the BERT-weight initialization. Moreover, we also show that these models are similar to a BERT model with a random weight noise of the same magnitude. We thus claim that vision-and-language pre-training on visually-grounded language dataset currently might not help the pure-language tasks. Note that the BERT results in Table 2 are not fairly comparable to the results in Table 3 because the original BERT model (Devlin et al., 2019) also uses Toronto Books Corpus (Zhu et al., 2015). Unfortunately, this dataset is not publicly available and hence we exclude it. According to Raffel et al. (2019), the exclusion of Toronto Books Corpus downgrades the results and we observe the same tendency here (comparing BERT$_{12L/768H}$ in Table 2 and BERT$_{BASE}$ in Table 3).

Besides these existing models, we next investigate the BERT models trained with masked language model on grounded language data (i.e., MS COCO). A control experiment is built by shrink-

---

[7] ViLBERT (Lu et al., 2019) freezes the BERT weight in its training thus their results are the same to BERT; Uniter (Chen et al., 2019) shrinks its vocab thus is not shown.

Method	Retrieval	Supervision	SST-2	QNLI	QQP	MNLI
SentLabel	Sent-level	Sent-level	88.3	86.1	86.9	78.0
Propagated	Sent-level	Token-level	88.9	87.9	88.1	80.2
Term Frequency	Token-level	Token-level	89.0	86.9	85.5	79.8
Vokens	Contextual Token-level	Token-level	92.2	88.6	88.6	82.6

Table 5: Comparisons of sentence-level (denoted as "Sent-level") and token-level approaches. Token-level approaches outperform the sentence-level approaches from both retrieval-method and supervision perspective.

ing the Wiki103 to the same token amount as MS COCO. We also provide the BERT model trained from scratch as a baseline. As shown in Table 4, the model trained with MS COCO is significantly worse than the model trained with Wiki103 on all downstream tasks. The reason might be the large discrepancy between visually-grounded language and other types of language as shown in Sec. 2.3.

5.2 Token-Level vs. Sentence-Level Approaches

In Sec. 1, we stated the drawbacks of the purely sentence-level and token-level approaches, then introduce the contextual token-level approach (i.e., the contextual token-image matching model in Sec. 3.2) which combines these two approaches. In this section, we demonstrate a careful comparison between our vokenization process and the other two approaches from two perspectives: the retrieval methods and the supervision types. Experiments are conducted with the same hyper-parameters and dataset as "$\text{BERT}_{12L/768H}$+Voken-cls" in Table 2.

Sentence-Level Retrieval To conduct sentence-level retrieval, we first adapt the contextual token-image matching model in Sec. 3.2 to a sentence-image matching model (details in Appendix). We then retrieve a related image for each sentence. As shown in Table 5, these retrieved images are used as two kinds of supervisions by putting classifiers at different places: in the row "SentLabel", we provide sentence-level supervision by using the classifier to predict the label for the whole sentence (similar to the BERT's "next-sentence prediction" (NSP) task); and in the row "Propagated", we provide token-level supervision by propagating sentence-level labels to all tokens in the sentences, and apply the classifier at each token (similar to our voken-classification task). The results of both kinds of supervisions are lower than our proposed vokens (in the row "Vokens"). One possible reason for these lower results is that finding an image that conveys the meaning of the whole sentence is hard. We also find that dense token-level supervision also outperforms the sentence-level supervision.

Token-level Retrieval Our proposed vokenization process is viewed as contextual token-level retrieval, which grounds tokens with whole sentences as context. We here consider a purely token-level retrieval method regarding term frequencies. The term frequency $tf(tok, x_i)$ (Manning et al., 2008) is calculated based on the occurrence $\#(tok, x_i)$ of the token tok in the image x_i's captions.

$$tf(tok, x_i) = \frac{\#(tok, x_i)}{\sum_{tok'} \#(tok', x_i)}$$

We then convert this term frequency to the conditional distribution via Boltzmann distribution:

$$p(x_i \mid tok) = \frac{\exp\left(tf(tok, x_i)/\gamma\right)}{\sum_{x'} \exp\left(tf(tok, x')/\gamma\right)}$$

where γ is temperature. We stochastically map the tokens to images with this conditional distribution $p(x_i \mid tok)$. The results trained with these special vokens are shown in Table 5 as "Term Frequency". Overall, token-level supervision is still better than the sentence-level supervision (as in the row "SentLabel"). However, among the models trained with token-level supervision, this token-level retrieval method neglects the contextual information thus is worse compared with sentence-level (in the row "Propagated") and contextual token-level retrieval methods (in the row "Voken") .

5.3 Visualization of Vokens

In Fig. 4, we visualize our generated vokens. The first example takes the leading sentence in our paper (without commas), which is also used in the imaginary example in Fig. 1. We also vokenize another sentence from William Yeats's poet "Down by the Salley Gardens" in Fig. 4. Although the vokenizer is trained on image-captioning datasets without localizing token-to-image annotations, the vokenizer shows a strong selectivity: different images are selected w.r.t the tokens. The contextual

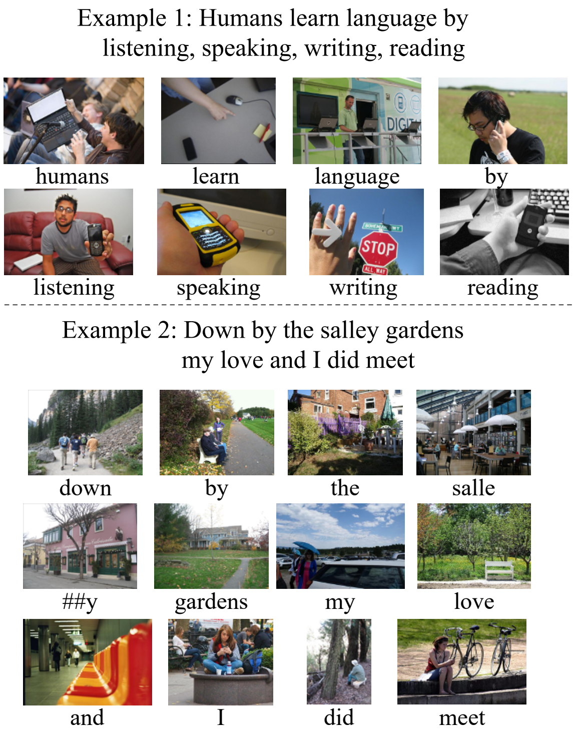

Figure 4: Visualization of model-generated vokens. Example 1 takes the leading sentence of this paper while Examples 2 takes Yeats's poet.

token-level retrieval could also disambiguate certain tokens (e.g., "down" in Example 2) with the help of its context. When the *unique* related image is hard to define, our vokenizer aims to ground the non-concrete tokens (e.g., "by"/"and"/"the") to relevant images: the voken for the token "by" in Example 2 (of Fig. 4) is better aligned with the [centering token, context] pair than the voken for the same token "by" in Example 1. This related visual information helps understand the language and leads to the improvement in Table 2. On the other hand, some tokens are not faithfully grounded (e.g., "writing" in Example 1) and we also observe a shift in alignment (e.g., the relevant image for the phrase "my love" in Example 2 is aligned to "my" instead of "love"). These misalignments are possibly caused by the limitations of sentence-image weak supervision in our training data since the strong token-image annotations are not available.

6 Related Work

Language (Model) Pre-training Language pre-training has moved from token-level pre-training (Mikolov et al., 2013; Pennington et al., 2014) to sentence-level pre-training (Le and Mikolov, 2014; Kiros et al., 2015; Conneau et al., 2017; Dai and Le, 2015). Recently, a set of works (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019; Clark et al., 2019; Lan et al., 2019) bring back token-level supervision with contextual language encoders (e.g., based on an LSTM (Hochreiter and Schmidhuber, 1997) and Transformers (Vaswani et al., 2017)). This tendency inspires the design of our vokenizer in merging previous sentence-level (Frome et al., 2013) and token-level (Kiela et al., 2018) approaches into a contextual token-level approach.

Vision-and-Language Pre-training Since language models are trained with self-supervision without knowing the connection to the visual world, vision-and-language pre-training (Li et al., 2019; Lu et al., 2019; Tan and Bansal, 2019; Chen et al., 2019; Su et al., 2020; Zhou et al., 2020) aims to build joint cross-modal representations and focuses on vision-and-language tasks. Due to particularity of grounded language, these models are not able to improve pure language tasks as shown in Sec. 5.1.

Visually-Aided Language Learning Previous works use visual information to improve specific language tasks such as coreference resolution (Kong et al., 2014), machine translation (Elliott et al., 2016; Ive et al., 2019; Wu et al., 2019; Zhang et al., 2020), semantic parsing (Christie et al., 2016; Shi et al., 2019; Kojima et al., 2020), and bilingual lexicon learning (Kiela et al., 2015; Vulić et al., 2016). Our work has a focus on building a visually-supervised language pre-training frameworks to improve general language understanding. Similar to our work, Frome et al. (2013); Lazaridou et al. (2015); Collell et al. (2017); Kiela et al. (2018); Bordes et al. (2019) aim to improve language representation with visual information; however, most of these works focus on grounded language and hence might suffer from the large discrepancy that we discuss in Sec. 2.3.

7 Conclusion

In this paper, we explored the possibility of utilizing visual supervision to language encoders. In order to overcome the challenges in grounded language, we develop the vokenizer with contextual token-image matching models and use it to vokenize the language corpus. Supervised by these generated vokens, we observe a significant improvement over the purely self-supervised language model on multiple language tasks.

A Appendices

A.1 Full Implementation Details

We train our contextual token-image matching model (in Sec. 3.1) on MS COCO image captioning dataset[8] for 20 epochs. The concatenation of the last 4 layers of BERT outputs (following Devlin et al. (2019)) and mean pooling of ResNeXt-101-32x8d feature maps are used as features for tokens and the images. For both multi-layer perceptrons w_mlp_θ and x_mlp_θ, we use two fully-connected layers with ReLU activation, where the output dimensions of the two layers are 256 and 64, accordingly. We only train the modules marked with θ, i.e., the two backbone models BERT (Devlin et al., 2019) and ResNeXt (Xie et al., 2017) are not fine-tuned. Since we normalize the features $g(w_i; s)$ and $f(v)$ to be norm-1 vectors, the relevance score thus takes the range from $[-1, 1]$ (from the Cauchy Inequality). The margin M in hinge loss is set to 0.5.

During the vokenization process, we use the faiss (Johnson et al., 2019) library to speed up the nearest neighbor search. The vokenization runs at a speed of 100K tokens / second with 4 Titan V100 GPU. Thus the vokenization of the full Wikipedia is finished in 8 hours. When transferring vokens to other pre-training frameworks, revokenization does not need the GPU computation and runs as fast as the tokenization. The vokens are retrieved from the Visual Genome images which are not used in MS COCO (our training dataset). We take a voken size of 50000.

When pre-training the model on pure language corpus, we unify the training process to avoid possible side effects from different training protocols. We follow previous work to conduct two simplifications: 1. Removing the next-sentence-prediction task (Liu et al., 2019) 2. Using fixed sequence length (Conneau et al., 2020) of 128. We take the 12-layer $\text{BERT}_{\text{BASE}}$ model of 768 hidden dimensions and train it on English Wikipedia[9] for 200K steps from scratch. We also take a reduced 6-layer model and train it on Wiki103[10] for 40 epochs (160K steps) from scratch because this reduced model does not fit well on the full Wikipedia dataset. The voken classification task will not bring additional parameters to the language encoder (with 110M parameters) but need more computations, we thus adjust the training steps for pure masked-language-model (MLM) training for a fair comparison. It results in around 10% more training steps in pure MLM training. All models take batch sizes of 256 and a learning rate of $2e$-4.

For fine-tuning tasks, instead of high-cost hyper-

[10] https://www.salesforce.com/products/einstein/ai-research/the-wikitext-dependency-language-modeling-dataset/

parameter sweeping in BERT (Devlin et al., 2019), we train 3 epochs with a learning rate of $1e$-4 and a batch-size of 32 for all tasks in GLUE. The hyper-parameters for SQuAD and SWAG are borrowed from the BERT paper (Devlin et al., 2019). On SQuAD v1.1, we fine-tune for 3 epochs with a learning rate of $5e$-5 and a batch size of 32. On SQuAD v2.0, we fine-tune for 2 epochs with a learning rate of $5e$-5 and a batch size of 48. On SWAG, we fine-tune for 3 epochs with a learning rate of $2e$-5 and a batch size of 16.

The whole framework is built on PyTorch (Paszke et al., 2019). The implementations of BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) are borrowed from PyTorch Transformers (Wolf et al., 2019)[11]. All evaluation code is from the PyTorch Transformers as well.

A.2 Visually Grounded Token Types

In Sec.2.3, we estimate the visually grounded token types with the help of MS COCO (Lin et al., 2014) dataset. We here randomly sample a list of the 2406 grounded tokens used in the estimation:

photograph, tv, skyscraper, ##bery, wooded, little, stands, away, storage, mound, pouring, rail, ##fl, eye, ##ke, flown, skiing, plate, movie, dead, tossing, couple, racing, dust, licking, palm, stroll, granite, bananas, ledge, chained, monument, individuals, part, exhibit, softball, second, bow, ones, shop, beverages, sandy, sink, angle, ##ia, gives, music, leading, carrying, cookies, reading, faced, ##k, kid, ##ged, playing, winds, saddle, stunts, squat, cabinets, rusty, matching, biker, let, standing, pan, smiles, train, sky, passing, woman, military, feeder, lot, hydra, party, ##l, furnished, rides, strip, ##field, tin, crouched, courtyard, nicely, screens, us, lie, waving, process, equipment, structure, fore, barrier, ##li, beside, toast, catching, tracks

A.3 Maximum Inner Product Search of Norm-1 Vectors

In Sec. 3.1, we normalize the vector to norm-1 vectors thus the Maximum Inner Product Search (Mussmann and Ermon, 2016) is equivalent to Nearest Neighbor (Knuth, 1973). Here, we give a simple proof. Suppose $\boldsymbol{x}$ and $\boldsymbol{y}$ are two vectors of the same dimension, we have

$$\begin{aligned} \|\boldsymbol{x}-\boldsymbol{y}\|^2 &= \|\boldsymbol{x}\|^2 + \|\boldsymbol{y}\|^2 - 2\boldsymbol{x}^\intercal\boldsymbol{y} && (2)\\ &= 2 - 2\boldsymbol{x}^\intercal\boldsymbol{y} && (3) \end{aligned}$$

Voken Type	SST-2	QNLI	QQP	MNLI
Alternative Choices				
Random	89.1	87.6	86.6	80.0
Shuffle	89.2	87.3	86.1	80.2
Tokens	89.7	88.8	87.2	80.8
Reference Models				
Voken Only	89.8	87.8	86.2	81.7
No Voken	89.3	87.9	83.2	79.4
Voken	92.2	88.6	88.6	82.6

Table 6: Results of different strategies that replace the standard vokenization process.

Without loss of generality, we assume that there is a unique vector $\hat{y} \in \mathbb{Y}$ with the maximum inner product and thus

$$\hat{y} = \arg\min_x \|\boldsymbol{x}-\boldsymbol{y}\| = \arg\max_x \boldsymbol{x}^\intercal\boldsymbol{y} \qquad (4)$$

A.4 Details of Sentence-level Retrieval in Analysis

In Sec. 3.1, we consider a contextual token-image matching model with relevance score $r_\theta(w, x; s)$. To do sentence-level retrieval, we modify it into a sentence-image matching score $r'_\theta(x, s)$, and trained it with:

$$\begin{aligned} \tilde{\mathcal{L}}_\theta(s, x, x') = \max\{0, M &- r'_\theta(x, s) \\ &+ r'_\theta(x', s)\} \end{aligned}$$

The score is also factorized as the dot product of the visual representation and the language representation. However, the language representation here is the sentence embedding (the output for the first token CLS).

We retrieve the image from the same image set $\mathbb{V}$ as vokenization and with the similar Maximum Inner Product Search method:

$$v(s) = \arg\max_{x\in\mathbb{V}} r'_{\theta*}(x, s)$$

These retrieved images as used as the label for the whole sentence.

A.5 Details of Token-level Retrieval in Analysis

In the purely token-level retrieval, we consider the image-captioning sentences as documents and uses traditional IR methods to index them. In order to increase the size of 'documents', we aggregate the data from VQA (Antol et al., 2015) and Visual

---

[11] `https://github.com/huggingface/transformers`

Genome (Krishna et al., 2017), besides the existing MS COCO (Lin et al., 2014) dataset. We also find that the temperature γ=0.01 gives a reasonable retrieval distribution and use it in our experiment.

A.6 Voken Ablation Studies

In Table 6, we show several approaches that provide alternative voken-like labels to our model.

Random We replace the vokens with random int from $\{1 \ldots \|\mathbb{V}\|\}$, where $\mathbb{V}$ is the "vocabulary" of all vokens.

Shuffle In order to prove that the order of vokens would affect the results, we shuffle the vokens in each batch and use it as supervision.

Tokens We here directly use the original tokens in replace of the vokens to see whether any dense supervision could improve the model.

As shown in Table 6, all these results are lower than the reference vokenization strategy.

A.7 Correlations between Improvements and Grounding Ratio

In order to understand where the improvements in the performance are coming from, we also study the correlation between the improvement in results and the visual grounding ratio (approximately measured in the same way as Sec. 2.3). We found that the datasets with higher grounding ratio (e.g., MNLI (Williams et al., 2018)) get significant improvements while the datasets (e.g., QNLI (Rajpurkar et al., 2016)) with relatively lower grounding ratio do not benefit much from the visual supervision. The dataset MNLI is built from multiple genre (the original SNLI dataset is in fact built from the Flickr images thus has a strong visual connection) and QNLI is purely based on English Wikipedia (The same as SQuAD (Rajpurkar et al., 2016)). These correlations may indicate that the visual supervision helps build a better understanding of visually grounded tokens. Although we used contextual information to map non-grounded words to related images through vokenization, the effectiveness of this mapping relies on the original grounding ratio of the data.

Detecting Cross-Modal Inconsistency to Defend Against Neural Fake News

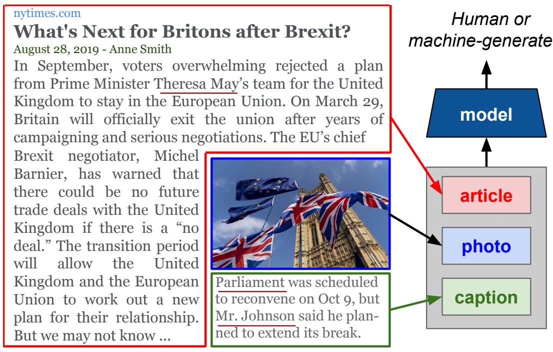
Abstract

Large-scale dissemination of disinformation online intended to mislead or deceive the general population is a major societal problem. Rapid progression in image, video, and natural language generative models has only exacerbated this situation and intensified our need for an effective defense mechanism. While existing approaches have been proposed to defend against neural fake news, they are generally constrained to the very limited setting where articles only have text and metadata such as the title and authors. In this paper, we introduce the more realistic and challenging task of defending against machine-generated news that also includes images and captions. To identify the possible weaknesses that adversaries can exploit, we create a NeuralNews dataset composed of 4 different types of generated articles as well as conduct a series of human user study experiments based on this dataset. In addition to the valuable insights gleaned from our user study, we provide a relatively effective approach based on detecting visual-semantic inconsistencies, which will serve as an effective first line of defense and a useful reference for future work in defending against machine-generated disinformation. Our code and dataset can be downloaded from here.

1 Introduction

The rapid progression of generative models in both computer vision (Goodfellow et al., 2014; Zhang et al., 2017, 2018; Choi et al., 2018) and natural language processing (Jozefowicz et al., 2016; Radford et al., 2018, 2019) has led to the increasing likelihood of realistic-looking news articles generated by Artificial Intelligence (AI). The malicious use of such technology could present a major societal problem. Zellers et al. (2019) report that humans are easily deceived by its AI-generated propaganda. By manipulating such technology, adversaries would be able to disseminate large amounts of online disinformation rapidly. While it is promising that the pretrained generative models themselves are our best defense (Zellers et al., 2019), it is often challenging to be aware of the models utilized by adversaries beforehand. More importantly, it ignores the fact that news articles are often accompanied by images with captions (Lee et al., 2018; Ji et al., 2019; Huang et al., 2019).



nytimes.com

What's Next for Britons after Brexit?

August 28, 2019 - Anne Smith

In September, voters overwhelming rejected a plan from Prime Minister Theresa May's team for the United Kingdom to stay in the European Union. On March 29, Britain will officially exit the union after years of campaigning and serious negotiations. The EU's chief Brexit negotiator, Michel Barnier, has warned that there could be no future trade deals with the United Kingdom if there is a "no deal." The transition period will allow the United Kingdom and the European Union to work out a new plan for their relationship. But we may not know ...

Parliament was scheduled to reconvene on Oct 9, but Mr. Johnson said he planned to extend its break.

Figure 1: We propose an approach for detecting news articles generated by machines. Prior work uses only the article content and metadata including title, date, domain, and authors. However, news articles often contain photos and captions as well. We propose to leverage possible visual-semantic inconsistency between the article text, images, and captions, such as missing or inconsistent named entities (underlined in red).

In this paper, we present the first line of defence against *neural fake news* with images and captions. To the best of our knowledge, we are the first to address this challenging and realistic problem. Premised on the assumption that the adversarial text generator is unknown beforehand, we propose to evaluate articles based on the semantic consistency between the linguistic and visual components. While state-of-the-art approaches in bidirectional image-sentence retrieval (Lee et al., 2018; Yang et al., 2019b) have leveraged visual-semantic consistency to great success on standard datasets such as MSCOCO (Lin et al., 2014) and Flickr30K (Plummer et al., 2015), we show in Appendix D they are not able to reason effectively about objects

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2081–2106,
November 16–20, 2020. ©2020 Association for Computational Linguistics

in an image and named entities present in the caption or article body. This is due to discrepancies in the distribution of these datasets, as captions in the standard datasets usually contain general terms including *woman* or *dog* as opposed to named entities such as *Mrs Betram* and a *Golden Retriever*, which are commonly contained in news article captions. Moreover, images are often not directly related to the articles they are associated with. For example, in Figure 1, the article contains mentions of the British Prime Minister. Yet, it only contains an image of the United Kingdom flag.

To circumvent this problem, we present DIDAN, a simple yet surprisingly effective approach which exploits possible semantic inconsistencies between the text and image/captions to detect machine-generated articles. For example, notice that the article and caption in Fig. 1 actually mention different Prime Ministers. Besides evaluating the semantic relevance of images and captions to the article, DIDAN also exploits the co-occurrences of named entities in the article and captions to determine the *authenticity score*. The *authenticity score* can be thought of as the probability that an article is human-generated. We adopt a learning paradigm commonly used in image-sentence retrieval where models are trained to reason about dissimilarities between images and non-matching captions. In this instance, negative samples constitute articles and non-corresponding image-caption pairs. Not only is this a reasonable approach when the adversarial generative model is unknown, we show empirically that it is crucial to detecting machine-generated articles with high confidence even with access to machine-generated samples during training. More importantly, this means that DIDAN is easily trained on the abundance of online news articles without additional costly annotations.

To study this threat, we construct the NeuralNews dataset which contains both human and machine-generated articles. These articles contain a title, the main body as well as images and captions. The human-generated articles are sourced from the GoodNews (Biten et al., 2019) dataset. Using the same titles and main article bodies as context, we use GROVER (Zellers et al., 2019) to generate articles. Instead of using GAN-generated images which are easy to detect even without exposure to them during training time (Wang et al., 2019), we consider the much harder setting where the articles are completed with the original images. We include both real and generated captions which are generated with the SOTA entity-aware image captioning model (Biten et al., 2019). We present results and findings from a series of empirical as well as user study experiments. In the user study experiments, we use 4 types of articles including real and generated news to determine what humans are most susceptible to. The insights derived from these findings help identify the possible weaknesses that adversaries can exploit to produce *neural fake news* and serve as a valuable reference for defending against this threat. Last but not least, our experimental results provide a competitive baseline for future research in this area.

In summary, our contributions are multi-fold:

1. We introduce the novel and challenging task of defending against full news article containing image-caption pairs. To the best of our knowledge, this is the first paper to address both the visual and linguistic aspects of defending against neural fake news.
2. We introduce the NeuralNews dataset that contains both human and machine-generated articles with images and captions.
3. We present valuable insights from our empirical and user study experiments that identify exploitable weaknesses.
4. We propose DIDAN, an effective named entity-based model that serves as a good baseline for defending against neural fake news. Most importantly, we empirically prove the importance of training with articles and non-matching images and captions even when the adversarial generative models are known.

2 Related Work

2.1 Neural News Generation and Defense

GROVER (Zellers et al., 2019) draws on recent improvements in neural text generation (Jozefowicz et al., 2016; Radford et al., 2015, 2018, 2019) to generate realistic-looking articles complete with metadata such as title and publication date but without images. Interestingly, it also serves as the best form of defense against its own generated propaganda. (Adelani et al., 2020) show that the GPT-2 model can be manipulated to generate fake reviews to deceive online shoppers. Corroborating the findings by (Zellers et al., 2019), they also report that pretrained language models such as GROVER and GPT-2 are unable to accurately detect fake reviews.

To combat effectively against the dissemination of neural disinformation, (Tay et al., 2020) propose a promising direction of reverse engineering the configurations of neural language models to identify detectable tokens. Last but not least, (Biten et al., 2019) introduce an approach to generate image captions based on contextual information derived from news articles. Such progress points towards the inevitability of large-scale dissemination of generated propaganda and the significance of this task.

2.2 Image and Video Generation and Defense

In recent years, the introduction of Generative Adversarial Networks (Zhang et al., 2017, 2018; Choi et al., 2018) has led to unprecedented progress in image and video generation. While most of these have focused on generating images from text as well as video translation, such models can easily be exploited to generate disinformation which can be devastating to privacy and national security (Mirsky and Lee, 2020; Chesney and Citron, 2019a,b). In response to this growing threat, (Agarwal et al., 2019) propose a forensic approach to identify fake videos by modeling people's facial expressions and speaking movements. In a similar vein to (Tay et al., 2020), (Matern et al., 2019; Yang et al., 2019a; Wang et al., 2019, 2020) seek to exploit visual artifacts to detect face manipulations and deepfakes. Encouragingly, Wang et al. (2019) show that neural networks can easily learn to detect generated images even without exposure to training samples from those generators.

3 NeuralNews Dataset Collection

To facilitate our endeavor of studying this threat, we introduce the NeuralNews dataset which consists of human and machine-generated articles with images and captions. It provides a valuable testbed for AI-enabled disinformation that adversaries can exploit presently and yet, is the hardest to detect. The human-generated articles are sourced from the GoodNews (Biten et al., 2019) dataset, which consists of New York Times news articles spanning from 2010 to 2018. Each news article contains a title, the main article body as well as image-caption pairs. Note that we source original images from real articles since machine-generated images are relatively easy to detect (Wang et al., 2019). In our dataset, we restrict the number of image-caption pairs to be at most 3 per article. The entire dataset used in the empirical and user study experiments contains the following 4 types of articles (see examples in Appendix E):

A) Real Articles and Real Captions

B) Real Articles and Generated Captions

C) Generated Articles and Real Captions

D) Generated Articles and Generated Captions

# Sentences in Article	% of Articles		# Imgs	% of Articles
	Real	Generated		
$N \leq 10$	33.7	15.6	1	60.8
$10 < N \leq 40$	54.4	81.5	2	21.0
$N > 40$	11.9	2.9	3	18.2

Table 1: NeuralNews dataset statistics across its 128K articles. Note that images are aggregated for both types of articles, since generated articles use the same images (but different articles and/or captions) as its corresponding real article.

In total, we collect about 32K samples of each article type (resulting in about 128K total). To collect machine-generated news articles, we use GROVER (Zellers et al., 2019) to generate fake articles using original titles and articles from the GoodNews dataset as context. Type C articles are completed by incorporating the original image-caption pairs. In Type B and D articles, we use the entity-aware image captioning model (Biten et al., 2019) to generate fake image captions based on the articles. We believe that this dataset presents a realistic and challenging setting for defending against neural news.

Dataset Statistics. Table 1 provides statistics on the length of articles and number of images in our Neural News dataset. Most articles contain at most 40 sentences in their main body. In addition, even though most articles contain a single image and caption, a sizeable 18.2% have 3 images. We believe that this setting will provide a challenging testbed for future work to investigate methods using varying number of images and captions.

4 User Study Experiments

We endeavor to determine the susceptibility of humans to different types of neural fake news through several user studies. To this end, we conduct a series of user study experiments based on the NeuralNews dataset. The user study results provide vital information to help us identify salient points which adversaries can take advantage of. Qualified Amazon Mechanical Turk workers with required English proficiency are used in all of our experiments. We briefly describe the experimental setups below. See Appendix A for a template of our prompts and response options for each setting.

Article Type	Article	Caption	Article Only Accuracy	Naive Participants Accuracy	Trained Participants Accuracy
no imgs	generated	–	68.8%	–	–
no imgs	real	–	49.2%	–	–
A	real	real	–	64.0%	70.7%
B	real	generated	–	34.0%	78.7%
C	generated	real	–	42.7%	56.7%
D	generated	generated	–	44.0%	55.3%
Average	–	-	59.0%	46.2%	67.8%

Table 2: **User prediction results.** We report the percentages of participants who are able to classify articles as human-generated or machine-generated accurately given different kinds of information and/or training (see Section 4 for additional details). A more in-depth breakdown of results can be found in Appendix B.

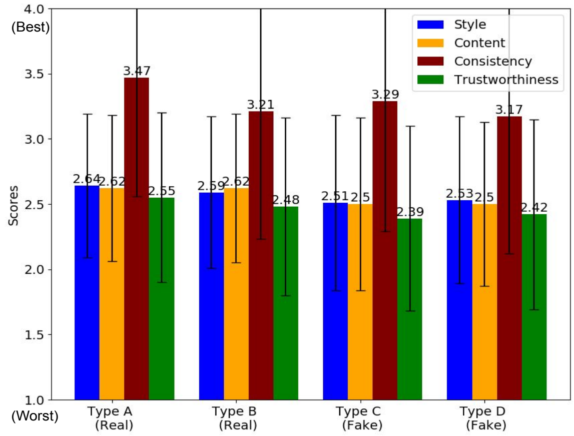


Figure 2: **Trustworthiness results.** Human evaluation of the 4 article types in the trustworthiness experiment. Workers are asked to evaluate the article based on its style, content, consistency and overall trustworthiness. We observe that people generally have a hard time deciding on the overall trustworthiness on articles regardless of their types. The prompt and the response options can be found in Appendix A.

Trustworthiness: How well are humans able to rate the trustworthiness of news articles? This experiment extends the study from Zellers et al. (2019) to also use images and captions. The goal is to understand the qualitative factors that humans consider to decide on the authenticity of articles by asking participants to evaluate articles based on style, content, consistency between text and images and overall trustworthiness using a four point scale where higher scores indicate more trust.

Article Only User Predictions: Given articles with titles which do not contain images and captions, can humans detect if they are generated or not?We ask participants to predict if an article is fake when they only contain their titles and main article bodies. In this variant, participants are provided with hints to pay attention to possible inconsistencies between the text and title. This is done with the purpose of understanding the importance of visual-semantic cues provided by image-caption pairs in this task in the following experiments.

Naive User Predictions: Can humans discern if an article is real or generated without prior exposure to generated articles? In this experiment, participants are tasked to decide based on their own judgements if the articles are human or machine-generated after reading them. The intuition behind this experiment is to determine humans' capability to identify fake news without prior exposure.

Trained User Predictions: Are humans able to detect generated articles if they are told what aspects to pay attention to beforehand? We provide limited training to participants by showing them examples of human and machine-generated articles that specifically highlighted semantic inconsistencies between articles and image-caption pairs. Afterwards, we ask our trained participants to determine if a article is human or machine generated as done for the naive user predictions.

4.1 User Study Results

Figure 2 reports the results from our trustworthiness experiment where participants evaluated the overall trustworthiness of the article, but were not asked to determine if it was real or machine generated. These results show that humans generally have trouble with agreeing on the semantic relevance between images and the text (article body and captions), as evident from the large variance in their responses. We hypothesize the *loose* connection between an article and an image (1 to be a possible factor. Adversaries could easily exploit this to disseminate realistic-looking neural fake news. Consequently, exploring the visual-semantic consistency between the article text and images could prove to be an important area for research in defending against generated disinformation. While it is reassuring that the overall trustworthiness for the human-generated articles is the highest among the different article classes, these results also highlight the susceptibility of humans to being deceived by generated neural disinformation. The difference between the overall trustworthiness ratings across the different article classes is marginal.

Table 2 reports the aggregated percentages of participants who are able to detect human and machine-generated articles accurately from the rest of the user study experiments. See Appendix B for a complete breakdown of results. Trained participants are deemed to have classified a Type B article correctly if they select any of 4 responses that indicate visual-semantic inconsistencies between images and the article or captions. The significant difference in the detection accuracy of Type B articles between the naive and trained users suggest that humans do not typically pay much attention to image captions in online news. However, it is also reassuring that 14% more participants are able to detect them after prior exposure.

We predict that Type C articles will be the most likely type of neural disinformation that adversaries would exploit for their purposes, given the current state of SOTA neural language models and image-captioning models. While recent neural language models are able to produce realistic-looking text, SOTA image captioning models are generally not able to generate captions of comparable quality. Oftentimes, the generated captions contain repeated instances of named entities without any stop words.

In summary, it is worrying that humans are particularly susceptible to being deceived by Type C and D articles in Table 2. However, we believe that there are fewer repercussions from the spread of Type B articles with real article content and generated captions. Since the generated captions only makes up a very small component of the entire article, the information conveyed is less likely to mislead people. In contrast, Type C articles have the potential to be exploited by adversaries to disseminate large amount of misleading disinformation due to its generated article contents. Consequently, our proposed approach is geared towards addressing this particular type of generated articles.

5 DIDAN: **D**etecting Cross-Modal **I**nconsistency to **D**efend **A**gainst **N**eural Fake News

In our task, the goal is to detect machine-generated articles that also include images and captions. The example in Figure 1 points towards an inherent challenge: identifying indirect relationships between the image and the text. Due to the common need to measure visual-semantic similarity, an intuitive first step would be to base one's approach on image-sentence similarity reasoning models which are commonly used in SOTA bidirectional image-sentence retrieval. We hypothesize, from their dismal performance (Table 9), that the image-sentence retrieval models are not adept at relating named entities in the articles to objects in the images. This suggests that contextual information about named entities from the article body is essential.

As a first line of defense, we present our named entity-based approach DIDAN. Besides integrating contextual information from the text, DIDAN factors in the co-occurrence of named entities in the article body and caption to detect possible visual-semantic inconsistencies. This is based on a simple observation that captions, more often than not, contain mentions of named entities that are present in the main body too. DIDAN is trained on real and generated articles. To train our model to detect visual-semantic inconsistencies between images and text, we also adopt the learning paradigm from image-sentence similarity models. In this case, the negative samples are real but the article and its image-caption pairs are mismatched.

An illustrative overview of DIDAN is shown in Figure 3. An article A consists of a set of sentences S where $S = \{S_1, \cdots, S_A\}$. Each sentence S_i contains a sequence of words $\{w_1, \cdots, w_i\}$. The article is also comprised of a set of image-caption pairs where each image I is represented by a set of regional object features $\{o_1, \cdots, o_I\}$ and each caption C contains a sequence of words $C = \{w_1, \cdots, w_I\}$. Spacy's named entity recognition model (Honnibal and Montani, 2017) is used to detect named entities in both articles and image captions. d^T, d^I and d^{vse} are used to denote the initial dimensions of the text and image representations as well as the hidden dimension respectively. Each sentence is tokenized and encoded with a BERT model (Devlin et al., 2018) that is pretrained on BooksCorpus (Zhu et al., 2015) and English Wikipedia.

5.1 Article Representations

To extract relevant semantic context from the article, we begin by computing sentence representations. For each sentence S^i in article A, the word representations are first projected into the article subspace as follows:

$$S^i = W^{art} V^i \tag{1}$$

where V^i represent all word embeddings in S^i. For a given sentence S^i, its representation S^i_f is computed as the average of all its word representations

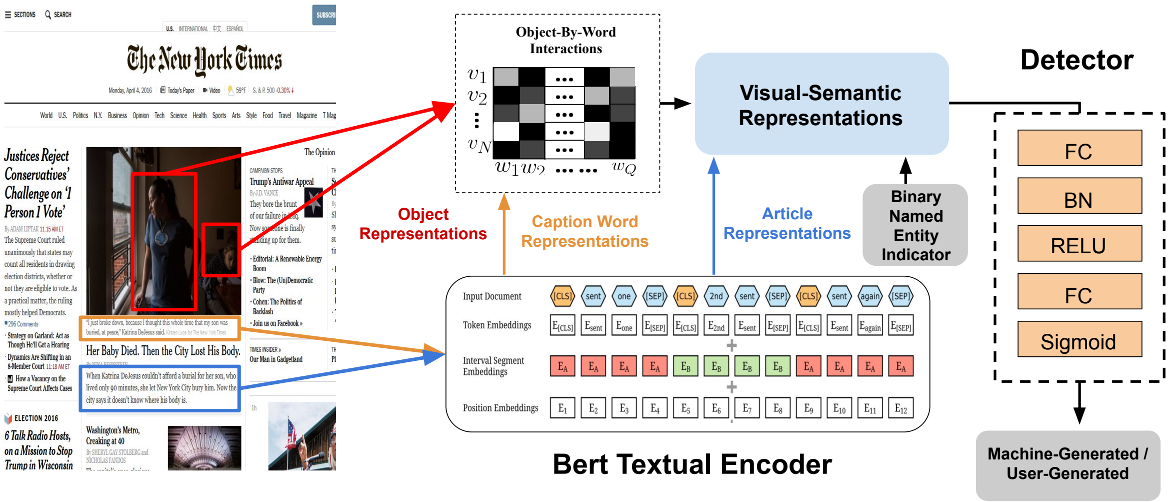

Figure 3: An overview of our proposed DIDAN model. To reason about relationships between named entities present in the article and entities in an image, DIDAN integrates article context into the visual-semantic representation learned from fine-grained object-by-word interactions. The aforementioned visual-semantic representation is used to infer an authenticity score for the entire news article.

where the subscript f denotes the corresponding representation. In turn, the article representation A_f for an article A is computed as the average of all its sentence representations.

5.2 Visual-Semantic Representations

Our approach leverages word-specific image representations learned from images and captions to determine their relevance to an article. A caption is represented by a feature matrix $V_f^{cap} \in \mathbb{R}^{n_c \times D^T}$ and an image is represented by a matrix of object features $V_f^{vis} \in \mathbb{R}^{n_o \times D^I}$. As in the previous section, the word embeddings of a caption and image object features are projected into a common visual-semantic subspace using:

$$C_f^{cap} = W^{cap} V_f^{cap} \tag{2}$$

$$I_f^{vis} = W^{vis} V_f^{vis} \tag{3}$$

A key property of these visual-semantic representations is that they are built on fine-grained interactions between words in the caption and objects in the image. To begin, a semantic similarity score is computed for every possible pair of projected word and object features w_l, v_k, respectively.

$$s_{kl} = \frac{v_k^T w_l}{\|v_k\| \, \|w_l\|} \text{ where } k \in [1, n_o] \text{ and } l \in [1, n_c]. \tag{4}$$

where n_c and n_o indicate the number of words and objects in a caption and image, respectively. These similarity scores are normalized over the objects to determine the salience of each object with respect to a word in the caption.

$$a_{kl} = \frac{\exp(s_{kl})}{\sum_{i=1}^{n_o} \exp(s_{il})}. \tag{5}$$

The word-specific image representations are computed as a weighted sum of the object features based on the normalized attention weights:

$$w_l^I = a_l^T I_f^{vis} \tag{6}$$

5.3 Detector

A key contribution of our approach is the utilization of a binary indicator feature, which indicates if the caption contains a reference to a named entity present in the main article body. The article representation and the average of the word-specific image representations are concatenated to create caption-specific article representations which are passed into the discriminator:

$$A_f^c = concat\{A_f, \frac{1}{n_c} \sum_{l=1}^{n_c} w_l^I, b_c\} \tag{7}$$

where $concat\{\cdots\}$ denotes the concatenation operation and b_c is the binary indicator feature. The key insight is that article context is integrated into the caption-specific article representations. Our discriminator (Figure 3) is a simple neural network that is comprised of a series of Fully-Connected

(FC), Rectified Linear Unit (ReLU), Batch Normalization (BN) and sigmoid layers. It outputs an *authenticity* score for every image-caption pair.

Recall that in our problem formulation news articles can contain varying numbers of images and captions. The final *authenticity score* of an article is determined across those of its images and captions. It can be thought of as the probability that an article is human-generated. The *authenticity score* is computed across the set of images and captions in an article as follows:

$$p_A = 1 - \prod_{images} (1 - p_A^I) \tag{8}$$

where p_A^I is the *authenticity score* of image-caption pair I with respect to article A. Intuitively, if an image-caption pair is deemed to be relevant to the article body (scores close to 1), then the final *authenticity score* will be close to 1 as well.

The entire model is optimized end-to-end with a binary cross-entropy loss.

$$L = - \sum_{(A^+, I^+)} \sum_{I^-} y \log(p_A) + (1-y) log(1-p_A). \tag{9}$$

where I^- denotes non-matching sets of images and captions with respect to an article and y is the ground-truth label of an article. Negative images and their captions are sampled from other articles within the same minibatch.

6 Experiments

Given a news article from our NeuralNews dataset, our goal is to automatically predict whether it is human or machine-generated. We compare DIDAN to several baselines, evaluating performance based on how often an article was correctly labeled. Note that in our experiments, only Type A and C articles are used. This is due to the fact that generated captions often contain repeated instances of named entities without any stop words, which is not challenging for humans to detect (see Table 2). To comprehend the importance of each component of DIDAN and each part of the news article, we supplement our analysis with ablation experiments.

6.1 Implementation Details and Baselines

Our model is implemented using Pytorch. In our implementation, the dimensions for the Bert-Base and object region features d^T and d^I are set to 768 and 2048 respectively. We also set the dimension of the visual-semantic embedding space d^{vse} to be 512. The image region representations are extracted with the bottom-up attention (Anderson et al., 2018) model that is pretrained on Visual Genome (Krishna et al., 2017). The language representations are extracted from a pretrained BERT-Base model (Devlin et al., 2018). We adopt an initial learning rate of $1e^{-3}$ and train our models end-to-end using the ADAM optimizer.

In addition to ablations of our model, we also compare to a baseline using Canonical Correlation Analysis (CCA), which learns a shared semantic space between two sets of paired features, as well as the GROVER Discriminator. In our CCA implementation, images are represented as the average of its object region features and the caption is represented by the average of its word features. We apply CCA between the article features (Section 5.1), and the concatenation of the image and caption features. The projection matrices in CCA are learned from positive samples constituting articles and their corresponding images and captions. The GROVER Discriminator is a simple neural network used in (Zellers et al., 2019) to detect its own generated articles based on the article text and metadata. We train the GROVER Discriminator without mismatched data and without images or captions.

6.2 Results

Training on Real News Only. The top of Table 3 shows that our approach significantly improves detection accuracy when trained without any generated examples (i.e. with mismatched real news as negatives) compared to CCA. Our named entity indicator (NEI) features provide a large improvement in this most difficult setting.

Training with Generated Samples. We consider the realistic setting where generated articles may be available but the generator is not. We report the performance achieved by variants of DIDAN when trained on Grover-Mega generated articles in the second-to-last column of Table 3. Note that the result achieved by GROVER Discriminator, akin to our text-only variant, is substantially worse than the result reported in (Zellers et al., 2019). This is because we train it with BERT representations as opposed to leveraging GROVER learned representations to detect its own generated articles. Based on the consistent trend of the results, training on generated articles from the same generator as ap-

Approach	Trained With Mismatch	Named Entity Indicator	Generated Articles in Training (%)	GROVER-Mega Accuracy (%)	GROVER-Large Accuracy (%)

	✓	✓	25	80.9	69.8
	✓	✓	50	**85.6**	**77.6**

Table 3: Results of machine-generated (with GROVER-Mega) vs real news detection on our NeuralNews dataset. We show performance of DIDAN variants trained on generated (with GROVER-Large or GROVER-Mega) articles and image-captions pairs when the number of generated articles is limited during training time. *Mismatch* indicates real data but with images and captions that do not correspond to the article body. The percentages of real and machine-generated articles do not change across variants that are trained with or without *mismatch* data.

Articles	Images	Captions	DIDAN Accuracy (%)	CCA Accuracy (%)
✓	✓	✓	85.6	51.4
✓	-	✓	81.9	50.1
✓	✓	-	56.9	52.1

Table 4: Ablation results of CCA and DIDAN's detection accuracy w.r.t. the contribution of each component in the news article. Experiments are performed on NeuralNews and the training as well as testing articles are generated by GROVER-Mega.

pears in test data improves the capability of a neural network to detect them. The binary NEI features also prove to be very beneficial to increasing the detection accuracy of DIDAN. Interestingly, even when we have access to generated articles during training, the large improvement in detection accuracy going from 68.8% to 85.6% when also training on mismatched *real* images and captions suggests that visual-semantic consistency has an important role to play in defending against neural fake news.

Unseen Generator. To evaluate DIDAN's capability to generalize to articles created by generators unseen during training, we train on GROVER-Large generated articles and evaluate on GROVER-Mega articles (last column of Table 3). While overall accuracy drops, we observe the same trend where our proposed training with mismatched real data helps increase the detection accuracy from 66.3% to 77.6%, and removing NEI lowers accuracy.

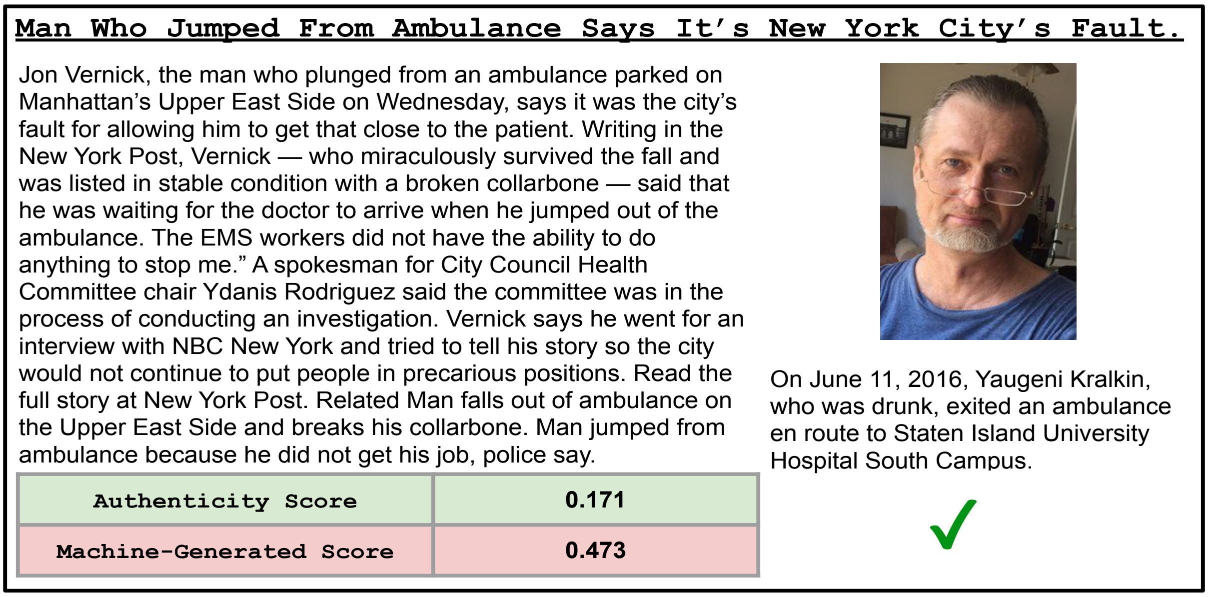
Images vs Captions. Table 4 show more ablation results of our model and CCA on NeuralNews. We observe an improvement of 2% in accuracy achieved by CCA variants with images. This suggests that visual cues from images can provide contextual information vital to detecting generated articles. This is also corroborated by the ablation results obtained by DIDAN, where we observe that both images and captions are integral to detecting machine-generated articles. While the contribution of the captions is the most significant, we note that the visual cues provided by images are integral to achieving the best detection accuracy.

6.3 Visualizations

In Figure 4 and 5 we present examples of our model's prediction of sample articles (additional examples can be found in appendix F). In Figure 4 we observe that DIDAN is able to classify a machine-generated article correctly. One plausible reason for this is that the main subject in the caption does not match the person who was mentioned in the article body and DIDAN is able to pick up on this relatively easily. However, the example in Figure 5 presents an especially challenging setting for DIDAN. In this case, the caption is only loosely related to the article and the image may or may not portray the situation described in the article. Successfully determining the relevance of such relationships requires more abstract reasoning, which may be a good direction for future work.

7 Summary Of Exploitable Weaknesses and Defense Directions

While this is not entirely representative of all the future challenges presented by *neural fake news*, we believe that this comprehensive study will provide an effective initial defense mechanism against arti-



Man Who Jumped From Ambulance Says It's New York City's Fault.

Jon Vernick, the man who plunged from an ambulance parked on Manhattan's Upper East Side on Wednesday, says it was the city's fault for allowing him to get that close to the patient. Writing in the New York Post, Vernick — who miraculously survived the fall and was listed in stable condition with a broken collarbone — said that he was waiting for the doctor to arrive when he jumped out of the ambulance. The EMS workers did not have the ability to do anything to stop me.” A spokesman for City Council Health Committee chair Ydanis Rodriguez said the committee was in the process of conducting an investigation. Vernick says he went for an interview with NBC New York and tried to tell his story so the city would not continue to put people in precarious positions. Read the full story at New York Post. Related Man falls out of ambulance on the Upper East Side and breaks his collarbone. Man jumped from ambulance because he did not get his job, police say.

On June 11, 2016, Yaugeni Kralkin, who was drunk, exited an ambulance en route to Staten Island University Hospital South Campus.

In the Taliban's Heartland, U.S. and Afghan Forces Dig In

An American soldier and two other Marines were killed and four others wounded Thursday night when an Afghan Afghan Army vehicle they were riding in was struck by a suicide car bomber, the U.S. military said. It was the second such attack by the Taliban in the province of Helmand. U.S. forces are working with Afghan troops to beat back the insurgency as the United States prepares to withdraw most of its combat troops from Afghanistan in the coming months. According to officials in the province, the attacker in the car had disguised himself as a policeman before he detonated the bomb. But Col. Abdul Marouf, the police commander in Khanashin district, said the Taliban had previously targeted a checkpoint in the same area. “It was near the checkpoint that they killed an Afghan security force official,” he said. “Now they are targeting us.” “I haven't heard of any friendly casualties on our side,” said a police commander in Sangin district. “We rely on our U.S. partners.”

American soldiers on patrol last month in Kandahar, Afghanistan, found and blew up a Taliban bunker. An influx of troops has begun to change the area.

Authenticity Score	0.489
Machine-Generated Score	0.246

cles with images and captions. Based on the findings from the user evaluation, humans may be easily deceived by articles generated by SOTA models if they are not attuned to noticing possible visual-semantic inconsistencies between the article text and images. Adversaries can easily exploit this fact to create misleading disinformation by generating fake articles and combining them with manually sourced images and captions. Encouragingly, our experimental results suggest that visual-semantic consistency is an important and promising research area in our defense against neural news.

We hope future work will address any potential limitations of this work, such as expanding the dataset to evaluate generalization across different news sources, and a larger variety of neural generators. Other interesting avenues for future research is to understand the importance of metadata in this multimodal setting and investigating counter-attacks to improved generators that incorporate image-text consistency. Last but not least, DIDAN and NeuralNews may be leveraged to supplement fact verification in detecting human-written misinformation in general by evaluating visual-semantic consistency.

A User Study Templates

A.1 Trustworthiness Study Template

This experiment requires users to evaluate the quality of news articles based on the following 4 criteria. The response options are displayed next to their corresponding score ratings. For ease of comparisons, we adopt the same metrics and scoring system in (Zellers et al., 2019).

(a) (Style) Is the style of the article consistent?

1) No, it reads like it's written by a madman.
2) Sort of, but there are certain sentences that are awkward or strange.
3) Yes, this sounds like an article I would find at an online news source.

(b) (Content) Does the content of this article make sense?

1) No, I have no (or almost no) idea what the author is trying to say.
2) Sort of, but I don't understand what the author means in certain places.
3) Yes, this article reads coherently.

(c) (Consistency) Does the text match the images?

1) No, the images do not match the text and captions.
2) Sort of, the images match the captions but do not match the text.
3) Sort of, the images match the text but do not match their captions.
4) Yes, the images match the text and captions.

(d) (Trustworthiness) Does the article read like it comes from a trustworthy source?

1) No, this seems like it comes from an unreliable source.
2) Sort of, but something seems a bit fishy.
3) Yes, I feel that this article could come from a news source I would trust.

A.2 Naive User Predictions Study Template

In the second user study experiment, users are asked to decide based on their own judgements if the articles are human or machine-generated after reading them. These articles contain images and captions.

(a) Do you think this article is human or machine-generated?

1) Human-generated.
2) Machine-Generated.

A.3 Trained User Predictions Study Template

In this variant, users are given hints to pay more attention to specific components of news articles through the provided response options. The response options provide users with cues to look at possible semantic inconsistencies between the articles and image-caption pairs.

(a) Choose the rating that you think is the most suitable for the given news article.

1) Human-Generated.
2) Machine-generated because 1 or more images is not very relevant to the article body.
3) Machine-generated because 1 or more captions is not very relevant to the article body.
4) Machine-generated because 1 or more images are not very relevant to the caption.
5) Machine-generated because the image/caption pairs are not relevant to the article body.
6) Machine-generated because something about the article appears off.
7) Machine-generated because the article title is not really relevant to the article.

A.4 Article-only User Predictions Study Template

The fourth user study experiment is similar to that of the third experiment except that it does not contain images or captions. Instead, users are told to focus on possible mismatches between the title and article body.

(a) Choose the rating that you think is the most suitable for the given news article.

1) Human-generated.
2) Machine-generated because something about the article appears off.
3) Machine-generated because the article title is not really relevant to the article.

B User Study Results

B.1 Naive User Study Results

Article Type	Accuracy
A	64.0%
B	34.0%
C	42.7%
D	44.0%
Total	46.2 %

Table 5: Results of the naive user predictions experiment. In this study, workers rely on their own judgement to decide if articles are human or machine-generated after reading them. The results present a worrying trend where a majority of the workers are misled by generated neural disinformation. The prompt and the response options can be found at A.2.

The findings in Figure 2 are corroborated by the results from the naive user prediction study in Table 5. The lower than random classification accuracy of 46.2% suggests that discriminating between human and machine-generated articles is a very challenging task in general. In particular, it is worrying that only 42.7% of users are able to accurately identify the Type C articles comprised of generated article bodies and real image-caption pairs.

B.2 Trained User Study Results

Article Type	1	2	3	4	5	6	7	Accuracy
A	70.7	7.3	6.0	4.0	4.7	2.7	2.7	70.7
B	11.3	52.0	8.0	14.0	4.7	8.7	1.3	78.7
C	43.3	13.3	11.3	10.7	8.0	1.3	12.0	56.7
D	44.7	12.7	14.0	13.3	8.7	5.3	1.3	55.3
Average	-	-	-	-	-	-	-	67.8

Table 6: Results of the trained user predictions experiment. In this study, workers are prompted to pay more attention to specific aspects of the articles by the response options before selecting the most appropriate response. The values in the columns with numerical headings indicate the percentage of users who select the corresponding response for each class of article. Generally, rating 1 indicates that the article is human-generated and the rest indicate otherwise due to possible semantic irrelevance between the articles, images and captions. The prompt and the exact rating descriptions can be found at Appendix A.3.

In the trained user prediction study, users are provided with hints to focus on possible visual-semantic inconsistencies between the article text (main body and image captions) and images via the provided response options. Table 6 reports the percentage of users who selected each response for the different classes of articles. The numerical headings in Table 6 indicate their corresponding responses as shown in appendix A.3. We observe a recurring theme where a large percentage of users are deceived by Type D articles. Only 55.3% of users identified the aforementioned article class as generated. It is also notable that workers who are told to focus on possible visual-semantic inconsistencies are significantly more accurate in detecting generated articles.

B.3 Article-Only User Study Results

Article Type	1	2	3	Accuracy
Human-Generated	49.2	36.4	14.4	49.2
Machine-Generated	31.2	61.6	7.2	68.8
Average	-	-	-	59.0

Table 7: Results of the article-only user predictions experiment. This study is similar to the trained user prediction study. However, in this experiment, the sample articles do not contain any image-caption pairs. Instead, each article sample only contains a title and the main body. The values in the columns with numerical headings indicate the percentage of users who select the corresponding response for each class of article. The prompt and the response options can be found at A.4.

The results from the article-only user study are reported in Table 7. In this experiment, workers are provided with hints to focus on possible semantic inconsistencies between the title and main body. The articles do not contain image-caption pairs. It is observed that by focusing on possible semantic inconsistency between the title and article body, a large majority of workers are able to identify generated articles.

C Importance of metadata in GROVER

Article	Authors	Date	Domain	Title	Bert-Large Accuracy	Pretrained Grover Accuracy
✓	-	-	-	-	73.0	81.6
✓	✓	✓	✓	-	76.8	90.0
✓	✓	✓	-	✓	75.2	90.3
✓	✓	-	✓	✓	71.7	90.0
✓	-	✓	✓	✓	69.6	90.6
✓	✓	✓	✓	✓	70.8	90.1

Table 8: Ablation results of our model and the pretrained Grover model on the Grover (Zellers et al., 2019) discrimination dataset.

We present results from a series of ablation experiments on the metadata which include the authors, date, domain and title. The ablation experiments are performed on the Grover discrimination dataset. Table 8 report results from ablation experiments achieved by a BERT-Large model and Grover on its discriminated dataset. While using metadata generally leads to increased accuracy in detecting generated articles across both models, the resulting improvement is more pronounced on the Grover model. Despite the fact that leveraging metadata significantly improves the performance of Grover, it also appears that the accuracy does not vary much with the exclusion of different types of metadata. In contrast, we observe a surprising observation that leveraging all metadata causes the detection accuracy to decrease. In addition, the inclusion of title results in a 6% decrease in detection accuracy. Without knowledge of the adversary's generative language model, it is essential to understand the contribution of such metadata in defending against general neural disinformation.

D Bidirectional Image-Sentence Retrieval Results

Variants	Directions	R@1	R@5	R@10	Average
SCAN	Image to Text	0.1	0.6	1.1	0.6
	Text to Image	0.1	0.5	1.0	0.5
SCAN + NER + Face Recognition	Image to Text	1.0	16.5	23.0	13.5
	Text to Image	2.2	6.5	9.2	6.0

Table 9: Bidirectional Image-Sentence Retrieval Results obtained on images and captions from the GoodNews dataset.

We observe that standard image-sentence retrieval models perform really badly on images and captions extracted from the GoodNews (Biten et al., 2019) dataset. We hypothesize that image-sentence retrieval models are designed to measure visual-semantic similarity between images and phrases that contain general terms such as *man* or *dog*. In contrast, they are less capable of reasoning about relationships between images and named entities often found in news captions.

E Examples of Article Types

We provide samples of the different types of articles below. Each article sample contains a title, text, an image and a caption. The image and caption are located below the article text.

E.1 Type A Article

Playing Composer, of Course, to Impress

At a time when opportunities for gifted emerging opera composers blazing all manner of new stylistic trails appear to be proliferating, there’s something to be said for a company willing to go to bat for fresh pieces by veteran creators working in conventional modes. Not long ago, that company likely would have been the Dicapo Opera, which performed an estimable service in championing composers like Thomas Pasatieri, Tobias Picker and Conrad Susa. But with Dicapo in a state of limbo, it falls to other institutions to fill the void. Kudos, then, to the Bronx Opera Company, which opened its 47th season on Saturday night with ”The Rivals,” a 2002 comic opera by Kirke Mechem, in the Lovinger Theater at Lehman College. Mr. Mechem, born in Wichita, Kan., and based in San Francisco at 88, is a skillful composer especially admired for his vocal music. ”Tartuffe,” his first opera, has played more than 350 times since its 1980 San Francisco Opera premiere. Mr. Mechem fashioned his own libretto for ”The Rivals,” his third opera, relocating an 18th-century Sheridan comedy from Bath, England, to Newport, R.I., around 1900. The tale centers on Jack Absolute, a British naval captain who has concocted a fictitious alter ego – Waverley, an impoverished opera composer – to woo Lydia Larkspur, an American heiress who dreams of living in ”charming poverty” in a Parisian garret. The couple are surrounded with a small cadre of friends, lovers, servants and, yes, rivals. Naturally, confusion ensues. Deftly juggling nine substantial roles, Mr. Mechem sets their entanglements awhirl with his buoyant melodies, supple harmonies and perky rhythms. In spirit, ”The Rivals” harks to Rossini and Donizetti; in sound, it weds Puccini’s generous lyricism to the dancing meters of Bernstein’s ”Candide.”

Figure 6: The Rivals From left, Julie-Anne Hamula, Caroline Tye and Mario Diaz-Moresco in the Bronx Opera Company's production of Kirke Mechem's opera at the Lovinger Theater.

William Eggleston Set To Release First Album

William Eggleston's photographs have adorned album covers for years: He has lent his singular eye to projects by Big Star, Joanna Newsom and Spoon. But on Oct. 20, Mr. Eggleston, now 78, will release an album of his own. The album, titled "Musik," will be released on Secretly Canadian and feature 13 tracks of Mr. Eggleston playing a Korg synthesizer. He recorded improvisations onto floppy disks and used a four-track sequencer to overlay parts and create fuller symphonic compositions. In addition to his own music, the album includes standards by Gilbert and Sullivan and Lerner and Loewe. Tom Lunt, co-founder of the record label Numero Group, produced the album. One song, "Untitled Improvisation FD 1.10," was released on Thursday.

Figure 7: William Eggleston is famous for his photography, but music has long been part of his artistic identity.

E.2 Type B Article

LANI KAI

You can go crazy with a loco moco, pig out on kalua pig, stuff yourself with a guava malasada. But one thing that is astonishingly hard to do in Hawaii is to get a decent drink in a coconut shell. This just isn't right. The state ought to be to tropical cocktails what New Jersey is to the Jagerbomb. Julie Reiner has set out to correct this cosmic injustice, even if she has to start in Manhattan. Ms. Reiner revived Deco-era cocktails in her first bar, the Flatiron Lounge, then peered into the crystal punchbowls of the Gilded Age with the Clover Club. With Lani Kai, she brings state-of-the-art urban bartending techniques to the flavors of her home state, Hawaii. Needless to say, there is no mai-tai mix in sight. Instead, there are two kinds of house-made orgeat syrup. One, derived from toasted almonds, washes up in the Hotel California, along with apricot-infused gin. The other, macadamia-based, sweetens a distant relative of the Sazerac called the Tree House. Both cocktails ($13) are unmistakably tropical in flavor. But taste again, note the underpinning of citrus and the foundation of bitters. These are not shaggy assemblages that shamble across the sand in board shorts and sandals. They are extremely well put together, buttoned down and zippered up in the best Manhattan style. This goes for the bar snacks, too, which raise the pu-pu genre to heights Trader Vic never scaled. The crab wontons, erupting with molten mascarpone, seem to contain actual shellfish, and the pork-belly sliders pay homage to David Chang. Where a little more New York sensibility might have helped is in the decoration. One can respect Ms. Reiner's decision to avoid the usual outriggers, macaws and puffer fish, and still think that she might have done more than hammer a few shelves to the wall and line them with pots of orchids. You expect a place called Lani Kai to transport you. At Lani Kai, the entire journey is in the drink. But that's not a bad place to start.

Figure 8: The Clover Club.

Digital Chief At Vice Loses Job After Inquiry

Vice Media announced Tuesday that its chief digital officer, Mike Germano, would not return to the company after the public disclosure of sexual harassment allegations against him prompted an internal investigation into his behavior. Mr. Germano was placed on leave after a New York Times investigation last month detailed the treatment of women at the company. The article included allegations made by two women against Mr. Germano, including that he told a former employee at a holiday party in 2012 that he had not wanted to hire her because he wanted to have sex with her and that, in 2014, he had pulled an employee onto his lap. Mr. Germano declined to comment. In an earlier statement, he said he did ”not believe that these allegations reflect the company's culture.” Mr. Germano was a co-founder of Carrot Creative, the digital ad agency that Vice acquired in 2013. In an email to the staff on Tuesday, Sarah

Broderick, Vice’s chief operating officer, said that Vice’s creative ad agency was completing ”the long planned integration of Carrot Creative” and that more details regarding the group’s leadership would be announced in the weeks ahead.

Figure 9: media.

E.3 Type C Article

Finding Drama in Brutality and Beauty

Pina Bausch created this dance work a few years ago, originally at Tanztheater Wuppertal and now running again at John Malkovich Theatre. The presentation here in Atlanta is a return engagement; a tour through English-speaking North America has started in Lincoln Center. It has been said before that these works, vast, powerful, and outspoken, are less about keeping time than with the resourcefulness of the human body, and time clearly is not what they are after. The action unfolds in what looks like an enormous steel studio, with a window in the middle. Its thrust stage resembles a rooftop. At one point, the viewer may be looking through one of the doors in the flat roof at a falling bucket of water, but this is hardly a threat of death. That bucket is one of the recognizable tools used by Bausch’s company of 16 dancers and a psychologist (Ricardo Moyo), as they enact a psychic activity that is more about sustained unease and despair than about an exhibition of total clarity. There are nearly 30 variations on the theme of internalization. Pins, black masks, and goggles come out and are dropped. The dancers take turns getting on, off, dancing alone, in unison, with or without their masks and hats. Sometimes, they rub their faces in lumps of plaster, as if trying to figure out a riddle. Most times, they walk about in doodling puddles of blue, red, and black that drift away from the floor like fresh acrid water. If the works of Bausch and her husband, the choreographer Arvo Pärt, frequently present themselves as exercises in processing and survival, Mr. Pärt’s music falls into the category of soothing. It enables the dancers to linger awhile in moments of perceived calm, even blindness. It is interesting to hear variations on the theme of failure in music. On certain occasions, Mr. Pärt’s powerful structural choices tie into the images that come across onscreen, as when, in an impressive demonstration of strength and resolve, a barefoot dancer balances a full-size walker on his head and shoulders for an extended time. Also memorable is the video-production device that takes place by day, involving a screen in which a dancer can disappear under water, feeding her brain waves to the monitor. And the body part that might be the most isolated is the head, which may look unmoving to the spectator. “On the Mountain” alludes to Plato’s phrase, “There is a difference between aimlessness and misdirected aimlessness,” and perhaps that is what Mr. Pärt is trying to capture in his music. As might be the case with Mr. Pärt, no spectacle is too big, or too expensive. The opening figures are all made from cobalt, and they dangle by wires. Then we are offered a shopping cart, which is wheeled around and pushed. Could it be that, in addition to representing purchasing power, it may have a subconscious meaning in an era of online shopping? The stage looks like a dock for a boat with Mr. Pärt's familiar chords in the background, as the red-clad dancer is tossed inside it. He comes out again in an equivalent figure, waving his hands and toes. Finally, one sees Ms. Bausch's face, appearing every now and then on the screen behind the dancers, holding a dartboard with the numbers "10" and "14" scrawled across it. Then an accompanying ad appears on the screen, with an unusually large 9 on it, directed at the public. "On the Mountain" stays close to the past, and everything but the information around it, but it is still inviting.

Figure 10: A scene from "On the Mountain a Cry Was Heard."

Young Cardinals Slugger Keeps Hammering Mets

Paul DeJong and Harrison Bader both homered in the seventh inning, sending the St. Louis Cardinals to a 7-5 win over the New York Mets at Busch Stadium on Friday night. Bader added a two-run single in the eighth to cap the St. Louis offensive outburst, which lifted the Cardinals to a 3-1 start against New York. DeJong went 3-for-4 with a pair of solo home runs and eight RBIs in the series, helping send the Mets to a fourth straight loss. Hansel Robles (1-1) took the loss for the Mets, who stranded 11 base runners in the loss. Paul Sewald (1-0) earned the win in relief, throwing two shutout innings, while Steve Cishek and Greg Holland each tossed a scoreless inning. The Mets jumped out to a 4-2 lead in the fifth after three consecutive singles with one out. Todd Frazier's sacrifice fly accounted for the first run before Jose Bautista drove in the next two with a line drive RBI single to right, and a bases-loaded single by Todd Frazier also scored a run. However, DeJong and Bader homered off Bobby Wahl to begin the Cardinals' comeback. Bader's first home run, a solo shot, tied the game at 4-4 before DeJong's second blast, a three-run shot, put St. Louis ahead, 6-4. A leadoff single by Matt Carpenter in the eighth started the Cardinals' comeback. With Yadier Molina and Greg Garcia on base, Bader then drove in the final two runs of the inning, the first on a squeeze bunt and the second on a single. Molina also drove in two runs with a bases-loaded single in the sixth inning that tied the game at 3-3. Molina's single extended his hitting streak to 15 games. Wilmer Flores homered in the eighth for the Mets. Carpenter had two hits for the Cardinals, who had won three in a row. Trevor Rosenthal recorded the final two outs for his third save. Curtis Granderson collected three hits for the Mets, who had won two in a row. First baseman Wilmer Flores started the scoring for the Mets with a third-inning solo home run. Cardinals right-hander Luke Weaver, who starts on Saturday, is 8-0 with a 1.77 ERA and 13 strikeout in 10 career starts against the Mets. On the other hand, Mets right-hander Jacob deGrom is 3-0 with a 0.60 ERA and 38 strikeouts in three career starts against the Cardinals. The Cardinals announced on Friday afternoon that first baseman Jose Martinez will miss two to three weeks because of a strained right hamstring. St. Louis recalled outfielder Jose Martinez and infielder Dillon Maples from Triple-A Memphis. Before the game, Mets manager Mickey Callaway said right-hander Matt Harvey is still feeling elbow discomfort after being put on the disabled list on April 11. The team decided it would be better to have Harvey rested. Harvey is scheduled to make his first rehab start for Triple-A Las Vegas on Saturday, pitching six innings. Callaway said Harvey will not appear in a rehab game for St. Louis. Harvey is on the DL because of an inflammation of the ulnar collateral ligament in his right elbow. Harvey missed last season after undergoing Tommy John surgery. The Cardinals' lineup included rookies at four positions — left field (Bryan Reynolds), center field (Colby Rasmus), right field (Rasmus) and first base (Rasmus) — for the first time since 1958. But by Friday night, the rookies had spent a combined 34 hours on the field. DeJong, a 22-year-old rookie from New Braunfels, Texas, has three home runs and a .308 batting average this season. He also has reached base safely in 16 of the 19 games he has started. The Cardinals' first home game was on May 10, 1958. With the game in their favor, the Cardinals could make their fourth straight trip to the playoffs history for the franchise, starting on Saturday afternoon in St. Louis.

Figure 11: Paul DeJong, right, after his home run in the second inning of the Cardinals' win over the Mets on Sunday.

Bonus Pay On Wall St. Likely to Fall

American financiers are expected to take home a pay cut this year thanks to lower investment bank performance fees. Not only are banks likely to reduce pay in the face of weak quarterly earnings, it also looks like Wall Street employees will take a hit to their bonuses, according to a report from New York City's comptroller on Thursday. Of the 42 financial companies that submitted their bonus information, 43 percent of the firms said they will pay out less money than last year, according to the report. "Investment banking fundamentals remain challenging due to low interest rates, subdued corporate M&A activity, and decelerating economic growth," Michael DiBiase, the comptroller's chief investment officer, said in a statement. "Once-strong markets are challenging to justify strong performance fees." Last year, when Wall Street bonuses were already down significantly from the previous year, the number of bank employees receiving bonuses was 22 percent lower. This year, almost 25 percent of financial firms expect to pay out less, the report said. Wall Street bonuses have been under pressure in recent years as low interest rates and decreasing merger activity has held back bonuses. The recent news that Wells Fargo, the scandal-ridden bank that was first accused of opening fake accounts, was paying Wall Street executives in bonuses in 2018 despite numerous conflicts of interest raised even more questions about the banking industry's compensation system. Read the full story at The New York Times. Related For Wells Fargo employees making $1,000 a month, Wells Fargo offers a cash bonus Citigroup to pay bonuses on top of annual pay of 105,000 employees Treasury Department seeks to encourage more women to work at Goldman Sachs.

Figure 12: Goldman Sachs

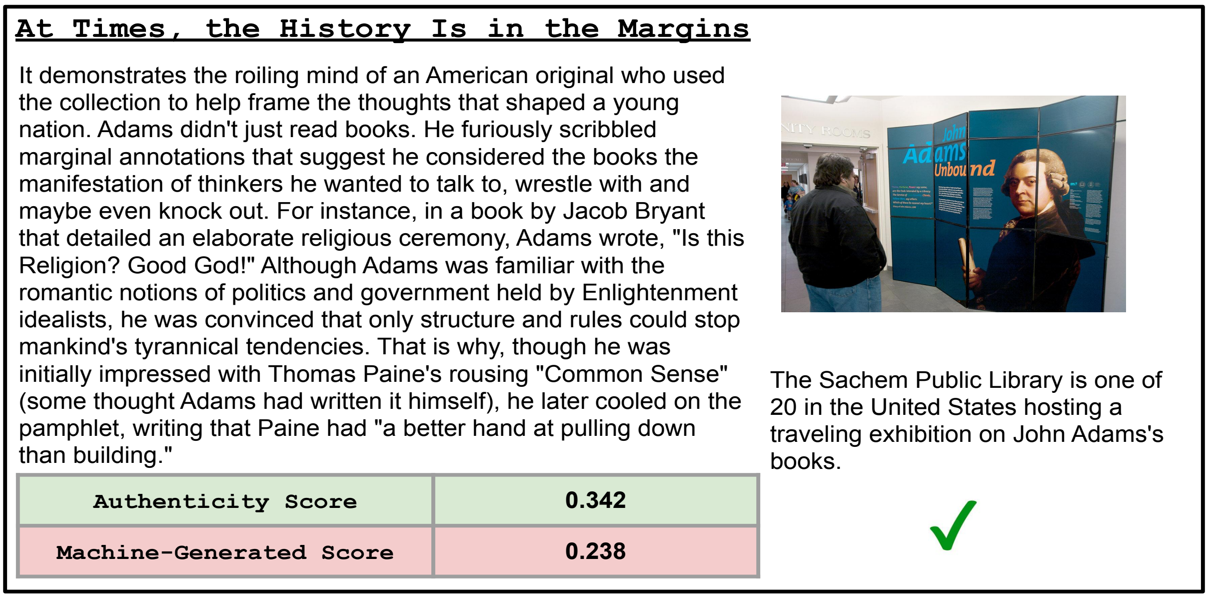
Jets Bench Smith in Loss That Doesn't Sit Too Well

Photo The Jets came into the night with speculation swirling that a trade involving the team's first-round draft pick was likely. And with Mark Sanchez all but gone, Geno Smith was apparently the prime candidate to go elsewhere. But so the rumors of a trade went through the night. The Jets had plans for the night and they had Smith's picture in the media room, leading many observers to believe that there would be an alteration in the game plan. Except that nothing that happened Thursday had Smith's name in the mix. Instead, the team opted to start rookie Sam Darnold against the Colts. The former USC quarterback led the Jets to a 17-0 lead in the first quarter, then — because a trade failed to materialize — he finished the game. Quarterback was the deciding factor for the Jets, at least after it became clear the trade was not going to happen. Either the Browns were going to pick Darnold at No. 4 or Cleveland could attempt to make a play for Baker Mayfield, the Oklahoma quarterback selected No. 1 by the Browns. Thus, the Jets took a leap at No. 3 and would have had to come back with whatever that three-point stand entailed. Even if the Browns had picked Darnold and attempted to make a trade, it seemed unlikely that any team would surrender a second-round pick for Mayfield. That would have constituted a risky move for the Browns, one they never would have taken unless they had planned on moving back in the draft. Hence, the tight windows that a quarterback-needy team often faces.

Figure 13

F Visualizations of DIDAN's predictions

We present examples of DIDAN's predictions on both human-generated and machine-generated articles in this section.



At Times, the History Is in the Margins

It demonstrates the roiling mind of an American original who used the collection to help frame the thoughts that shaped a young nation. Adams didn't just read books. He furiously scribbled marginal annotations that suggest he considered the books the manifestation of thinkers he wanted to talk to, wrestle with and maybe even knock out. For instance, in a book by Jacob Bryant that detailed an elaborate religious ceremony, Adams wrote, "Is this Religion? Good God!" Although Adams was familiar with the romantic notions of politics and government held by Enlightenment idealists, he was convinced that only structure and rules could stop mankind's tyrannical tendencies. That is why, though he was initially impressed with Thomas Paine's rousing "Common Sense" (some thought Adams had written it himself), he later cooled on the pamphlet, writing that Paine had "a better hand at pulling down than building."

The Sachem Public Library is one of 20 in the United States hosting a traveling exhibition on John Adams's books.

Murray L. Weidenbaum, Reagan Economist, Dies at 87

Murray L. Weidenbaum, who as President Ronald Reagan's first chief economic adviser elevated government regulation of business to the forefront of public policy debate, but resigned unhappy about the administration's budget-making, died on Thursday in St. Louis. He was 87. Mr. Weidenbaum, a Bronx-born economist, was fond of saying, "Don't just stand there, undo something." And he did, beginning in 1981, when the newly inaugurated Mr. Reagan appointed him chairman of the Council of Economic Advisers. Reducing the size of government and loosening its regulatory hold on the private sector became a large theme of the Reagan presidency, which began with inflation still running in double digits and the economy heading into recession. The banking, broadcasting and food and drug industries were a particular focus.

Mr. Weidenbaum worked to reduce regulation on businesses.

A Novelist's Prime Nesting Place in Nashville

Before this house was the fulfillment of our dreams, it was the fulfillment of other people's dreams, a couple with extremely good taste who knew exactly where and how they wanted to live. They bought a bungalow on Whitland, tore it down, and in 1993 built themselves a solid home in pink washed brick. Somehow they made it look as if it had been here all along. They threw their hearts into the tiniest details, collecting glass doorknobs at flea markets, commissioning ironwork for the banister and placing inlaid cherry-wood star shapes onto the walnut floors. When, after years of planning and hard work, it was finally perfect and they moved in, they were divorced. I can think of nothing better than to live in the dreams of these two people who moved away. Their vision of what a home could be far exceeds anything I ever could have imagined on my own.

Trees shade Ann Patchett's pink brick home, a place designed by others that fulfills her own dreams.

New Plan to Treat Schizophrenia Is Worth Added Cost, Study Says

A new approach to treating early schizophrenia, which includes family counseling, results in improvements in quality of life that make it worth the added expense, researchers reported on Monday. The study, published by the journal Schizophrenia Bulletin, is the first rigorous cost analysis of a federally backed treatment program that more than a dozen states have begun trying. In contrast to traditional outpatient care, which generally provides only services covered by insurance, like drugs and some psychotherapy, the new program offers other forms of support, such as help with jobs and school, as well as family counseling. The program also tries to include the patients -- people struggling with a first psychotic "break" from reality, most of them in their late teens and 20s -- as equals in decisions about care, including drug dosage.

Driven to Accumulate and Dancing Till Nothing's Left

While those at court leaned over at the stalls, snoozing like other patrons, here at last was part of that magic I expected from a fairground. The rhythmic scramble of people shuffling and jitterbugging, pretending not to notice each other, obscured the petty bickering that had been for weeks consuming their lives. There were not a few smiling faces, but the laughter that drowned out the voices of anyone who tried to hold the audience's attention behind barriers was total. Even the Head Monster looked refreshed as he bellowed and danced. In this nowhere town, half a world away from Heidelberg, the judges of the circus were at work. My screams of thrill and satisfaction were promptly drowned out by the sharp, high, loudly grinding noises of the Mongolian horses. The show had started more than an hour earlier. People were in their seats, awaiting to dance, when the head clock came on.

United and Continental Said to Agree to Merge

The global airline industry is about to get a little bigger — United and Continental announced they are planning to merge, creating a company with more than $100 billion in annual revenue. The new company will be called United Continental Holdings Inc. The news was reported by CNBC, which cited anonymous sources. In a statement, both airlines said they were in the process of finalizing a deal, but declined to provide further details. Both companies confirmed the talks on their Twitter accounts. Rumors about a merger first surfaced in March, when United Continental announced it would lay off around 100 people who were working on its revenue management system. United spokesman Charlie Hobart told The Associated Press that the airline was implementing new IT systems for its key ticketing and revenue departments, and that the layoffs were not a result of a merger.

Enhancing Aspect Term Extraction with Soft Prototypes

Zhuang Chen, Tieyun Qian*
School of Computer Science, Wuhan University, China
`{zhchen18, qty}@whu.edu.cn`

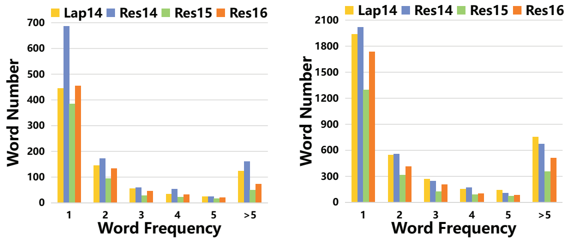
Abstract

Aspect term extraction (ATE) aims to extract aspect terms from a review sentence that users have expressed opinions on. Existing studies mostly focus on designing neural sequence taggers to extract linguistic features from the token level. However, since the aspect terms and context words usually exhibit long-tail distributions, these taggers often converge to an inferior state without enough sample exposure. In this paper, we propose to tackle this problem by correlating words with each other through *soft prototypes*. These prototypes, generated by a soft retrieval process, can introduce global knowledge from internal or external data and serve as the supporting evidence for discovering the aspect terms. Our proposed model is a general framework and can be combined with almost all sequence taggers. Experiments on four SemEval datasets show that our model boosts the performance of three typical ATE methods by a large margin.

1 Introduction

Aspect term extraction (ATE) is a fundamental subtask in aspect-based sentiment analysis. Given a review sentence, ATE aims to extract all aspect terms that users have expressed opinions on. For example, from the review "*The Bombay style bhelpuri is very palatable.*", ATE aims to extract "*bhelpuri*".

ATE has been widely studied in the last twenty years. Early researches are devoted to design rule-based (Popescu and Etzioni, 2005) and feature engineering-based (Li et al., 2010) methods. With the development of deep learning techniques, recent researches mostly regard ATE as a sequence labeling task and focus on developing various types of neural models (Liu et al., 2015; Xu et al., 2018; Ma et al., 2019) to generate a tag sequence for the review.



(a) Aspect terms. (b) Context words.

Figure 1: The distributions of aspect terms and context words in the training sets of four SemEval datasets.

Though achieving impressive progress, current sequence taggers mentioned still face a serious challenge: the taggers may converge to an inferior state due to the lack of samples for tail words. As shown in Figure 1, about 80% aspect terms and context words (i.e., non-aspect terms) appear no more than five times in the commonly-used SemEval datasets. Without enough sample exposure, neural models can hardly achieve an optimal performance (He et al., 2018; Chen and Qian, 2019).

To tackle this challenge, correlating samples with each other may offer helping hands. For example, if we correlate the rare aspect term "*bhelpuri*" with a frequent one like "*food*", there will be more abundant samples for "*bhelpuri*" than ever. The problem then becomes how to build such a token-level correlation. Retrieving synonyms is an intuitive approach to this problem, but it has two limitations. Firstly, synonyms only exist for a small number of words in the vocabulary. This will make the correlations incomplete. Though we can calculate the nearest neighbors for a certain word based on the pre-trained word embeddings, it is not guaranteed that they have a similar semantic meaning. Secondly, in ATE, the existence of an aspect term depends on whether there are opinions on it. That is to say, we need to build a dynamic correlation for a certain word based on its entire contexts rather than the word itself. Indeed, if the retrieval is con-

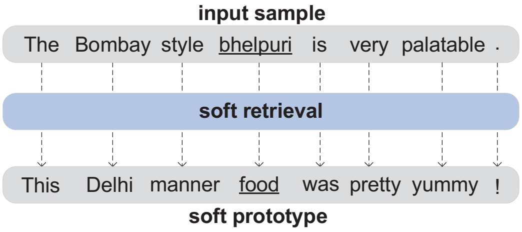

Figure 2: Process of the soft retrieval.

ducted based on an individual token, the above two limitations always exist.

In this paper, we propose a *soft* retrieval method to build the token-level correlation for both aspect terms and context words. Rather than conducting a *hard* retrieval for individual tokens, we turn to retrieve the tokens' counterparts according to their contexts. As shown in Figure 2, after conducting the soft retrieval, we can obtain a generated sample strictly corresponds to the input sample in every position. We name the generated sample "*soft prototype*" since it is actually a simplified prototype that can build a reference point for guiding the tagging process for the input sample.

We resort to the language models (LMs) to implement the soft retrieval and generate high-quality soft prototypes. As a self-supervised task, language modeling needs no extra annotations and can absorb data-specific global knowledge. Moreover, LMs tend to generate frequent outputs (Li et al., 2016), which exactly meets our needs for correlating a rare word in the input sample with a frequent one in the soft prototype. Specifically, we first pre-train bi-directional LMs using the given training samples on ATE datasets. Alternatively, we can take advantage of large-scale unlabeled data like Yelp and Amazon reviews to pre-train LMs. Then, after fixing the pre-trained LMs, we can infer each token's prototype according to its contexts for both the training and testing samples.

We regard the generated soft prototypes as the supporting evidence for tagging aspect terms, and design a simple and effective gating mechanism to fuse the knowledge embedded in both samples before sending them to a sequence tagger. The soft prototypes can be combined with almost all existing sequence taggers. To demonstrate the effectiveness of our proposed model, we conduct experiments on four SemEval datasets by adding the generated soft prototypes on three existing sequence taggers. The results prove that our soft prototypes significantly boost the performance of their original counterparts.

2 Related Work

Aspect Term Extraction Early researches for ATE mainly involve pre-defined rules (Hu and Liu, 2004; Popescu and Etzioni, 2005; Wu et al., 2009; Qiu et al., 2011) and hand-craft features (Li et al., 2010; Liu et al., 2012, 2013; Chen et al., 2014). With the development of deep learning techniques, neural methods have become the mainstream. ATE can be viewed as either a supervised or an unsupervised task. For unsupervised ATE, the commonly-used neural methods are based on topic models (He et al., 2017; Liao et al., 2019). For supervised ATE, the researchers focus on developing various types of neural sequence taggers (Liu et al., 2015; Wang et al., 2016; Yin et al., 2016; Wang et al., 2017; Li and Lam, 2017; Xu et al., 2018; Li et al., 2018; Ma et al., 2019). A recent trend is towards the unified framework (Wang et al., 2018; Li et al., 2019; Luo et al., 2019; He et al., 2019; Hu et al., 2019; Chen and Qian, 2020), where the interactive relations between ATE, opinion term extraction (OTE), or aspect-level sentiment classification (ASC) are exploited to enhance the overall performance. Xu et al. (2019) post-train BERT on domain-specific data to boost its sequence labeling performance. Li et al. (2020) propose to generate additional datasets for improving the performance of ATE.

In this paper, we focus on the supervised scenario. Different from the aforementioned supervised models, we develop a novel model to enhance ATE. By automatically generating and utilizing soft prototypes, we correlate samples with each other, which greatly enhances the learning process of sequence taggers. Moreover, the decoupling of soft prototypes from taggers makes our model flexible and general, i.e., it can be combined with almost all neural sequence taggers.

Prototypes in Neural Networks The idea of prototypes (or templates) originates from information retrieval (IR) approaches for sentence matching tasks like response generation (Ji et al., 2014; Hu et al., 2014). They aim to retrieve a related sample from the dataset as the counterpart of the input sample. More recently, several studies shed new light in this domain by deeply fusing prototypes with neural networks. Many of them use the task-dependent metrics (Guu et al., 2018; Hashimoto et al., 2018), common metrics such as Jaccard similarity (Gu et al., 2018; Cao et al., 2018; Wu et al., 2019), or existing tools like Lucene (Cao et al.,

2018) to retrieve prototypes, and then input the prototypes into a neural model for generating outputs. Wang et al. (2019) follows another line, where the prototype (the target words related to a source word in machine translation) is generated using a pre-trained Seq2Seq model.

The approach of generating words via LMs is inspired by a recent study (Kobayashi, 2018). However, the method in Kobayashi (2018) is developed for text classification and is not suitable for the ATE task here. Concretely, their method randomly replaces a small percentage (typically 10%) of original training words with the generated ones and then discard the original words. This operation may work well for text classification tasks which only require sentence-level information. For token-level tasks like ATE, the original words are however necessary for tagging each token correctly. Moreover, the small percentage of replacement implies that the generated knowledge cannot be fully incorporated into the new sample. In contrast, we generate a prototype for each word in the sentence, and then deeply fuse the original word with its corresponding prototype to make good use of their embedded knowledge for ATE.

To the best of our knowledge, we are the first to introduce the retrieval method to handle the data deficiency problem in ATE. To this end, we propose a new approach to generate and utilize soft prototypes that can build the token-level correlation for aspect terms and context words.

3 Methodology

In this section, we first illustrate the overall framework for enhancing ATE with soft prototypes. We then detail the generation and utilization of soft prototypes. Lastly, we describe the objective function and the training procedure.

3.1 The Overall SoftProto Framework

Aspect term extraction (ATE) aims to extract aspect terms from a review sentence that users have expressed opinions on. Given a sentence $S = \{w_1, w_2, ..., w_n\}$, we formulate ATE as a sequence labeling task that aims to predict a tag sequence $Y = \{y_1, y_2, ..., y_n\}$, i.e., learning the mapping $S \rightarrow Y$, where $y \in \{B, I, O\}$ denotes the *beginning of*, *inside of*, and *outside of* an aspect term.

To incorporate soft prototypes to ATE, we slightly modify the traditional learning process. Formally, rather than directly learning the mapping from S to Y, we additionally introduce a soft prototype $\mathbf{P}$ for each S and learn the new mapping $[S, \mathbf{P}] \rightarrow Y$. Given S, the soft prototype $\mathbf{P}$ is automatically generated by a soft retrieval mechanism, and can serve as the supporting evidence to discover the aspect terms. As shown in Figure 3, we summarize the above processes into the *SoftProto* framework that mainly consists of three modules:

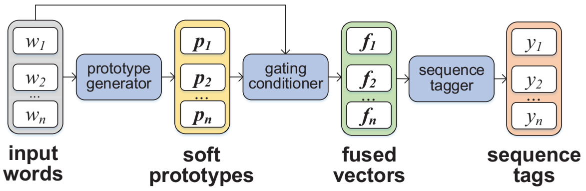

Figure 3: The SoftProto framework for enhancing ATE with soft prototypes.

- A *prototype generator* is used for conducting the soft retrieval process and generating the corresponding soft prototype $\mathbf{P}$ for S.
- A *gating conditioner* is used for merging S's representation and $\mathbf{P}$ into the fused vectors $\mathbf{F}$.
- A *sequence tagger* is used for predicting the tag sequence Y based on $\mathbf{F}$.

Next, we will illustrate each module in detail.

3.2 Prototype Generator

To efficiently implement the soft retrieval and generate high-quality soft prototypes, we resort to the language models (LMs) to build a prototype generator. Specifically, we first pre-train two LMs, where $\overrightarrow{LM}$ and $\overleftarrow{LM}$ is the *forward* and *backward* language model parameterized by $\overrightarrow{\theta_{LM}}$ and $\overleftarrow{\theta_{LM}}$, respectively. Then we infer soft prototypes based on the pre-trained LMs.

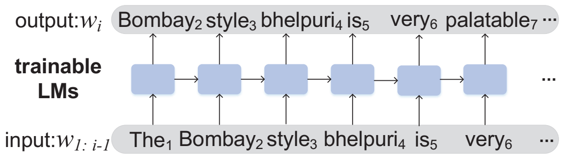
One can use either the ATE training set or other unlabeled external data like Yelp reviews to pre-train LMs, and we will examine the effects of these two types of data in the experiments. The details of pre-training LMs and inferring soft prototypes are as follows.

Pre-training Language Models As shown in Figure 4(a), given S, the forward $\overrightarrow{LM}$ computes the probability of S by modeling the probability of token w_i conditioned on the history $(w_1, .., w_{i-1})$:

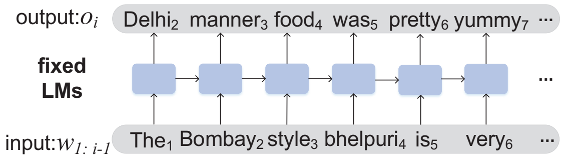
$$prob(w_1, ..., w_n) = \prod_{i=1}^{n} prob(w_i|w_1, ..., w_{i-1}). \quad (1)$$

In the pre-training process, $\overrightarrow{LM}$ tries to maximize the log likelihood of the forward direction:

$$\sum_{i=1}^{n} \log prob(w_i|w_1, w_2, ..., w_{i-1}; \overrightarrow{\theta_{LM}}). \quad (2)$$



(a) Pre-training a forward language model.



(b) Inferring oracle words.

Figure 4: Generating soft prototypes with LMs.

Similarly, the backward $\overleftarrow{LM}$ tries to maximize the log likelihood of the backward direction:

$$\sum_{i=1}^{n} \log prob(w_i|w_{i+1}, w_{i+2}, ..., w_n; \overleftarrow{\theta_{LM}}). \tag{3}$$

After the pre-training process converges, we can fix $\overrightarrow{\theta_{LM}}$ and $\overleftarrow{\theta_{LM}}$, and infer a soft prototype **P** conditioned on S, $\overrightarrow{\theta_{LM}}$, and $\overleftarrow{\theta_{LM}}$ for each sample in the training and testing sets in ATE[1].

Generating Soft Prototypes After getting $\overrightarrow{\theta_{LM}}$ and $\overleftarrow{\theta_{LM}}$, we then infer the soft prototype **P**. We still take the forward $\overrightarrow{LM}$ as the example.

As shown in Figure 4(b), for generating the forward prototype vector $\overrightarrow{\boldsymbol{p_i}}$ for word w_i, we feed the prefix sentence $\{w_1, w_2, ..., w_{i-1}\}$ to the fixed $\overrightarrow{LM}$ and collect the output probability distribution $prob(o_i^v|w_1, w_2, ..., w_{i-1}; \overrightarrow{\theta_{LM}})$, where V is the size of vocabulary and $v \in [1, V]$. To suppress noise, we do not directly select the word o_i^1 with the largest output probability. Instead, we preserve the words $\{o_i^1, o_i^2, ..., o_i^K\}$ with K-largest output probabilities, and normalize their probabilities to sum 1 as the weighted scores $\{s_i^1, s_i^2, ..., s_i^K\}$. We call the selected words as "*oracle words*" (Zhang et al., 2019). Then we map these words with a pre-trained embedding lookup table **E** and obtain their word vectors $\{\boldsymbol{o_i^1}, \boldsymbol{o_i^2}, ..., \boldsymbol{o_i^K}\}$. Finally, we aggregate the oracle words by their weighted scores to calculate $\overrightarrow{\boldsymbol{p_i}}$ for word w_i:

$$\overrightarrow{\boldsymbol{p_i}} = \sum_{k=1}^{K} \boldsymbol{o_i^k} \cdot s_i^k. \tag{4}$$

Similarly, we can calculate the backward prototype vector $\overleftarrow{\boldsymbol{p_i}}$. To consider the context information in both directions, we use the average of $\overrightarrow{\boldsymbol{p_i}}$ and $\overleftarrow{\boldsymbol{p_i}}$ as the final prototype vector $\boldsymbol{p}_i$ for word w_i. We then regard the set of prototype vectors $\{\boldsymbol{p}_1, \boldsymbol{p}_2, ..., \boldsymbol{p}_n\}$ as the soft prototype **P** for the sentence S[2].

3.3 Gating Conditioner

For better discovering the aspect terms, we need to leverage the supporting evidence embedded in the soft prototype **P**. Intuitively, we have two schemes to incorporate the soft prototypes into ATE: inside or outside the sequence tagger. We choose the latter because we want to decouple the soft prototypes from the sequence taggers, such that we can make the prototypes suitable for all types of taggers. Hence, we introduce an additional upstream module named the gating conditioner to fuse the soft prototype **P** with the original sentence S.

The soft prototype **P** provides two kinds of information : (1) **P** itself has embedded data-specific knowledge that can serve as supporting evidence. (2) **P** also helps to refine the original representation of S. Accordingly, the gating conditioner is developed to conduct two types of operations on **P**. We first map $S = \{w_1, w_2, ..., w_n\}$ with the pre-trained embedding lookup table **E** and obtain the corresponding word vectors **X**$= \{\boldsymbol{x}_1, \boldsymbol{x}_2, ..., \boldsymbol{x}_n\}$. Then, we conduct two types of operations on **X** and **P** to obtain the fused vectors **F**:

$$\boldsymbol{f_i} = \sigma(W(\boldsymbol{x}_i \oplus \boldsymbol{p}_i) + b) \odot (\boldsymbol{x}_i \oplus \boldsymbol{p}_i), \tag{5}$$

where σ is the Sigmoid function, W and b are trainable parameters, $\oplus$ and $\odot$ denotes the concatenation and element-wise multiplication operation, respectively.

In Eq. 5, the concatenation of **P** and **X** makes the representation more discriminative than before. Moreover, the gating mechanism can help select the important dimensions and further refine the representation. The generated fused vectors **F**$= \{\boldsymbol{f_1}, \boldsymbol{f_2}, ..., \boldsymbol{f_n}\}$ then act as the enhanced representation for $S = \{w_1, w_2, ..., w_n\}$.

3.4 Sequence Tagger

The sequence tagger aims to extract high-level semantic features from the low-level tokens, and predicts a tag sequence Y for the review S based on these features. In order to investigate the influence of soft prototypes, we need to control variables in SoftProto. Therefore, we choose three existing sequence taggers as our basic models, including BiLSTM (Liu et al., 2015), DECNN (Xu et al.,

---

[1] Note that the testing ATE samples are not used for pre-training the LMs, thus there is no data leakage in this process.

[2] Since $\overrightarrow{\boldsymbol{p_1}}$ and $\overleftarrow{\boldsymbol{p_n}}$ are inferred based on the BOS token, they are less informative than other prototype vectors. In practice, we replace them with the pre-trained word vectors of w_1 and w_n, respectively.

2018), and Seq2Seq4ATE (Ma et al., 2019). Readers can refer to the original paper for more details or Section 4.2 for a quick glance. Please note that the only difference between an original sequence tagger and its variant enhanced by our proposed SoftProto is the representation of S. In other words, by comparing the performance of a sequence tagger and its enhanced variant, we can observe that how ATE benefits from soft prototypes.

For training SoftProto, we simply compute the cross-entropy loss $\mathcal{L}$:

$$\mathcal{L} = -\sum\nolimits_{i=1}^{n}\sum\nolimits_{j=1}^{J}\hat{y_{ij}} \cdot log(y_{ij}), \tag{6}$$

where n is the length of S, J is the category of labels, y_i and $\hat{y}_i$ are the predicted tags and ground truth labels. We then train all parameters with back propagation.

4 Experiments

4.1 Datasets and Settings

ATE Datasets To evaluate the effectiveness of SoftProto for ATE tasks, we conduct extensive experiments on four datasets from SemEval 2014 (Pontiki et al., 2014), 2015 (Pontiki et al., 2015) and 2016 (Pontiki et al., 2016). These datasets contain review sentences from the restaurant and laptop domains with annotated aspect terms. All of them have a fixed train/test split, and we further randomly hold out 150 training samples as the validation set for tuning hyper-parameters. The statistics of four ATE datasets are summarized in Table 1[3].

Table 1: The statistics of ATE datasets.

Datasets	Lap14		Res14		Res15		Res16	
Type	train	test	train	test	train	test	train	test
Sentences	3045	800	3041	800	1315	685	2000	676
Aspects	2342	650	3686	1134	1209	547	1757	622

Details for Pre-training Language Models As mentioned in section 3.2, we use two types of data to pre-train the LMs: (1) The ATE training sets. In this setting, we directly use the same training/validation samples of each SemEval dataset to pre-train its own LMs. Hence, there are four groups of pre-trained LMs (including $\overrightarrow{LM}$ and $\overleftarrow{LM}$) for four datasets, respectively. We denote this setting as **SoftProtoI** (I for internal knowledge). (2) The unlabeled external data. In this setting, we additionally collect 100,000 training and 10,000 validation samples from Yelp Review (Zhang et al., 2015) and Amazon Electronics (McAuley et al., 2015) datasets, respectively. LMs pre-trained on Yelp serve as the prototype generator when training and evaluating SoftProto on {Res14, Res15, Res16} datasets, while those pre-trained on Amazon are used for the Lap14 dataset. We denote this setting as **SoftProtoE** (E for external knowledge). For pre-training the LMs, we adopt the Fairseq[4] toolkit (Ott et al., 2019) and the basic transformer decoder LM architecture (Vaswani et al., 2017)[5].

Parameter Settings The only hyperparameter in our SoftProto is the number K of oracle words when generating soft prototypes. We use a grid search to select K in the range [1,10] based on the validation performance, and consequently set K=$\{10, 7, 10, 7\}$ for four datasets, respectively. For other parameters, including the pre-trained word embedding, epoch number, optimizer selection, learning rate, and batch size, we inherit the default settings from the original papers (Liu et al., 2015; Xu et al., 2018; Ma et al., 2019). Models achieving the maximum F1-scores on the validation set are used for evaluation on the testing set. We report the averaged F1 scores over 5 runs with random initialization. We run all methods in a single 2080Ti GPU.

4.2 Compared Methods

We choose two kinds of baselines. The first is the SemEval winners for corresponding datasets. **IHS-RD** (Chernyshevich, 2014), **DLIREC** (Toh and Wang, 2014), **EliXa** (Vicente et al., 2015), and **NLANGP** (Toh and Su, 2016) are the winners for Lap14, Res14, Res15, and Res16 datasets, respectively. The second is the recent deep learning-based methods. **RNCRF** (Wang et al., 2016), **MIN** (Li and Lam, 2017), **CMLA** (Wang et al., 2017), and **HAST** (Li et al., 2018) are frequently-used neural baselines. They all introduce the auxiliary opinion term extraction (OTE) task and exploit the relation between ATE and OTE.

In order to discern the impacts of soft prototypes on pure ATE task, we do not choose the hybrid models as the base taggers. Instead, we adapt SoftProto to three pure sequence taggers, including **BiLSTM** (Liu et al., 2015; Li et al., 2018) which is an RNN-based sequence tagger including a vanilla

---

[3] Our code and data are available at https://github.com/NLPWM-WHU/SoftProto.

[4] https://github.com/pytorch/fairseq.

[5] In practice, we also tried a self-constructed single-layer LSTM architecture and got a similar performance in language modeling. Since the Fairseq toolkit has already integrated the transformer architecture, we directly use it for convenience.

Table 2: Comparison of different methods in F1-scores. Results for the first eight methods are taken from Li et al. (2018), while other results are the averaged scores of 5 runs with random initialization. The best scores are in bold, and the best baselines are underlined. The subscript denotes the improvement/decrease after enhancing an ATE tagger with a certain method (e.g., BiLSTM + SoftProtoE vs. BiLSTM). * denotes the statistical significance between the orginal methods and their enhanced counterparts at $p < 0.05$ level.

+ SoftProtoE	**83.19**$^{*}_{(+1.80)}$	**87.39**$^{*}_{(+1.35)}$	**73.27**$^{*}_{(+2.09)}$	**76.98**$^{*}_{(+2.59)}$

BiLSTM architecture, **DECNN** (Xu et al., 2018) which is a CNN-based sequence tagger which uses two types of pre-trained embeddings and stacked convolutional layers to extract context features for tagging aspect terms, and **Seq2Seq4ATE** (Ma et al., 2019) which is an attention-based sequence tagger and uses a modified encoder-decoder framework to extract aspect terms.

We further compare SoftProto with two simple enhancing methods, namely **Synonym** and **Replacement**. For Synonym, we substitute the top-K oracle words with top-K nearest synonyms measured by the cosine distance of word vectors while keeping the other settings unchanged. For Replacement, we use the prototype generated by our language models, but replace the training words with the method in Kobayashi (2018). The modified samples are sent to the sequence tagger directly[6].

4.3 Main Results

The comparison results for all methods are shown in Table 2 . Obviously, SoftProto greatly boosts all basic sequence taggers. For example, DECNN achieves an overall best performance among baselines, while SoftProtoI and SoftProtoE further achieve {1.28%,0.31%,0.83%,1.49%} and {1.80%,1.35%, 2.09%,2.59%} absolute gains for DECNN on four datasets, respectively. There even exists an amazing 3.30% gain after incorporating SoftProtoE to Seq2Seq4ATE on the Res14 dataset. This strongly demonstrates the effectiveness of proposed soft prototypes for the ATE task. By correlating samples through the soft prototypes, the training of sequence taggers can easily converge to a better state than before.

We also find that the improvements brought by the SoftProto are more remarkable on small datasets (Res15 and Res16) than those on large ones (Res14 and Lap14). This is because there are not enough samples on small datasets to train a well-performed sequence tagger, and the discovery of aspect terms largely relies on the knowledge embedded in the soft prototypes. Moreover, SoftProtoE performs much better than SoftProtoI. The reason is that the external unlabeled data from Yelp and Amazon is much bigger and more informative than the original ATE datasets. Accordingly, the pre-trained LMs in SoftProtoE contain more knowledge than those in SoftProtoI and can generate more discriminative soft prototypes.

---

[6] We use a grid search to select the replacement probability and present the best results. Prototype tokens are generated using the LMs pre-trained on the Yelp/Amazon data.

The performances of Synonym and Replacement are far from satisfactory, and they even result in decreases in some cases. Synonym generates noisy prototypes by only considering the individual tokens, and can hardly handle the unknown (UNK) words. The ineffectiveness of Replacement lies in two issues. Firstly, it simply replaces the original words with the generated ones, which incurs information loss. Secondly, the generated knowledge cannot be fully utilized due to the small percentage of replacement. The inferior results demonstrate that these two methods are not qualified for enhancing the ATE task.

5 Analysis

5.1 Perplexities of Language Models

In this section, we present the perplexities of language models pre-trained on different datasets. As shown in Table 3, the perplexity is linearly related to the size of datasets. The larger the dataset, the lower the perplexity.

Table 3: Perplexities of pre-trained language models.

Source	Dataset	Forward LM	Backward LM
Internal	Lap14	147.00	146.79
	Res14	164.31	169.67
	Res15	238.68	236.07
	Res16	199.76	200.69
External	Yelp	48.53	49.63
	Amazon	56.45	57.16

Clearly, LMs trained on external Yelp/Amazon datasets have much lower perplexities than original SemEval datasets. Among the SemEval datasets, Lap14 and Res14 have relatively more samples than Res15 and Res16, resulting in relatively lower perplexities. Moreover, language models in forward and backward directions have no significant differences in performance. We will release all pre-trained language models in time for encouraging further studies on soft prototypes.

5.2 Ablation Study

Without loss of generality, we choose two DECNN +SoftProto models and conduct the ablation study to investigate the effects of different modules in SoftProto. We sequentially remove the forward LM, the backward LM, the concatenation operation, and the gating operation to obtain four simplified variants.

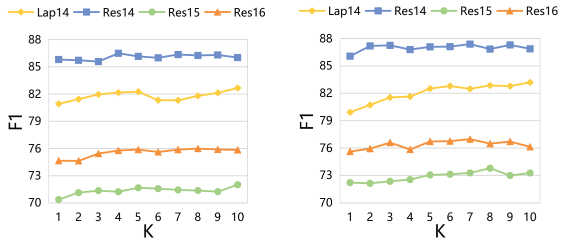
As shown in Table 4, all variants have a performance decrease of the F1-score. The results demonstrate that : (1) Considering both directions in language modeling can generate better soft prototypes. (2) Both kinds of conditioning operations (i.e., gating and concatenation) can contribute to the utilization of the soft prototypes.

Table 4: Ablation study. The scores denote the performance decreases of SoftProtoI/SoftProtoE after removing the component.

	Lap14	Res14	Res15	Res16
- $\overrightarrow{LM}$	2.44 / 0.83	1.71 / 1.59	1.42 / 1.11	0.16 / 0.41
- $\overleftarrow{LM}$	1.56 / 0.24	0.24 / 0.78	1.31 / 1.22	0.66 / 0.17
- concat	1.65 / 2.07	0.14 / 1.94	0.28 / 0.25	1.00 / 1.04
- gate	2.48 / 1.44	0.04 / 1.31	2.97 / 0.07	2.99 / 2.78

5.3 Impacts of Oracle Words

In the prototype generator, the hyper-parameter K controls how many oracle words are taken into account when generating soft prototypes. To investigate the impacts of the oracle words on different datasets, we vary K in the range of [1,10] stepped by 1, and present the results of two DECNN+SoftProto models in Figure 5.



(a) +SoftProtoI.

(b) +SoftProtoE.

Figure 5: F1-scores under different settings of K.

Generally, the F1-scores of DECNN have an overall upward trend when more oracle words are introduced. This is explainable since the oracle words actually provide the data-specific knowledge that can be aggregated into the soft prototypes. Moreover, owing to the high confidence of language models trained on Yelp/Amazon datasets, the curves of SoftProtoE are smoother than those of SoftProtoI. The reason is that language models with high perplexities almost inevitably output noisy oracle words and bring about the high variance when generating soft prototypes.

5.4 Case Study

To have a close look, we further select six samples from the testing sets for a case study. Due to the space limitation, we only present the results of the best baseline DECNN and its two variants enhanced by SoftProto in Table 5.

S1$\sim$S2 are in similar circumstances. DECNN only extracts a single word as the aspect term and

Table 5: Case study. The left column presents the selected examples, and the words in red with brackets denote individual aspect terms. The three columns on the right denote the extraction results of corresponding models.

Examples	DECNN	+SoftProtoI	+SoftProtoE
S1.My favs here are the [Tacos Pastor] and the [Tostada de Tinga] .	Tacos, Tostada de Tinga ✗	Tacos Pastor, Tostada de Tinga	Tacos Pastor, Tostada de Tinga
S2.Fine if you have a [touch screen] .	screen ✗	touch screen	touch screen
S3.[Web surfuring] is smooth and seamless .	Web ✗	Web surfuring	Web surfuring
S4.My one complaint is that there was no [internal CD drive] .	CD drive ✗	internal CD drive	internal CD drive
S5.They are [served] on [Focacchia bread] and are to die for .	served ✗	served ✗	served, Focacchia bread
S6.The [food] is great and they make a mean [bloody mary] .	food ✗	food ✗	food, bloody mary

neglects the integrality of phrases. Since the aspect phrases [*Tacos Pastor*] and [*touch screen*] have not occurred on the corresponding training sets on Res14 and Lap14 datasets, their linguistic features are not strong enough to become aspect terms. In contrast, SoftProto variants can make correct extractions. We go deep into the prototype generator and investigate the oracle words generated by the language models. For [*Pastor*], LMs introduce words like [*nachos*, *burrito*, *salsa*, *food*]. And for [*touch*], LMs introduce words like [*DSLR*, *cable*, *camera*, *projector*]. Obviously, these oracle words are strong indicative words for [*Pastor*] and [*touch*], and hence SoftProto is able to tag them correctly.

S3 is another interesting example. Since [*surfuring*] is an rare variant of [*surfing*], DECNN only extracts [*Web*] as the aspect term. For SoftProto, LMs introduce oracle words like [*browsing*, *management*, *interface*, *search*]. Owing to the knowledge embedded in the oracle words, recognizing [*Web surfuring*] as a complete aspect term becomes much easier than before.

S4 shows another ability of SoftProto, i.e., judging whether an adjective is sentimental or descriptive. [*internal*] is a descriptive adjective for [*CD drive*] without polarity, and should be included in the aspect term. DECNN regards [*internal*] as an opinion word and neglects it. For SoftProto, LMs condition [*internal*] with oracle words like [*AC*, *on/off*, *wire*, *cable*]. The nominal information contained in the soft prototype helps the sequence tagger extract [*internal*] correctly.

S5 and S6 verify the superiority of SoftProtoE over SoftProtoI. Since the perplexities of LMs in SoftProtoI are much higher than those in SoftProtoE, the oracles words in SoftProtoI correspondingly have lower qualities. For [*Focacchia*], SoftProtoI introduces meaningless oracle words like [*the*, *a*, *my*, *our*]. In contrast, SoftProtoE produces [*pumpkin*, *homemade*, *garlic*, *baked*], which are closely related with [*Focacchia*]. Similarly, for [*bloody mary*], SoftProtoE introduces [*garlic*, *martini*] to [*bloody*] and [*mojito*, *beer*] to [*mary*], while the oracle words generated by SoftProtoI are less informative.

5.5 Performance on Tail Aspect Terms

To prove that SoftProto are indeed beneficial for identifying the tail aspect terms, we keep the training sentences unchanged and only preserve the testing sentences containing the tail aspect terms (appearing no more than 3 times in training sentences). We present the performance of DECNN and its two variants enhanced by SoftProto on these sentences in Table 6. Clearly, SoftProto enhances the ability of DECNN in recognizing the tail aspect terms by a large margin.

Table 6: The performance of DECNN and its SoftProto variants on recognizing the tail aspect terms.

	Lap14	Res14	Res15	Res16
Tail Percentage	30.50	30.38	30.66	28.11
DECNN	74.37	77.61	70.00	70.68
+SoftProtoI	78.88	79.96	75.04	71.80
+SoftProtoE	79.85	82.22	76.80	70.93

5.6 Prototypes Generation with BERT

Since BERT (Devlin et al., 2019) is pre-trained as a masked language model (MLM), we wonder if it can serve as the prototype generator. Hence, we regard the generation of prototypes as a cloze test. We sequentially mask each word and collect the top-K output words of the MLM as the oracle words. We name this variant SoftProtoB. The setting of K and the usage of the oracle words remain the same as those in SoftProtoI and SoftProtoE, thus the only difference among all these SoftProto variants is the way of pre-training language models.

We conduct experiments on two pre-trained BERT models, where SoftProtoB (BASE) is the officially released BERT-Base-Uncased model, and SoftProtoB (PT) is further post-trained on domain-specific data and released by Xu et al. (2019). Since both SoftProtoB and SoftProtoE make use of the external data, they are fair competitors and we list the results of these two variants in Table 7.

Table 7: Comparison between two pre-trained BERT models and one pre-trained traditional language model.

	Lap14	Res14	Res15	Res16
DECNN	81.39	86.04	71.18	74.39
+SoftProtoB (BASE)	82.15	86.84	71.20	75.09
+SoftProtoB (PT)	82.30	87.70	72.69	76.43
+SoftProtoE	83.19	87.39	73.27	76.98

From the results in Table 7, we can see that the BERT-based models are also qualified for generating the soft prototypes. In general, SoftProtoB (BASE) generates domain-independent oracle words and achieves limited improvements over the base model, while SoftProtoB (PT) can generate domain-specific oracle words and achieves a comparable performance with SoftProtoE.

5.7 Analysis on Computational Cost

Since we use the pre-trained language models, the cost for generating soft prototypes can almost be ignored. To demonstrate that SoftProto does not incur the high computational cost in utilizing soft prototypes, we run three sequence taggers on the Laptop 2014 dataset, and present the trainable parameter number and running time per epoch of each method before and after introducing SoftProto in Table 8.

Table 8: Computational cost of each method.

	Parameter Number	Runtime
BiLSTM	903,903	3s
+ SoftProto	1,263,903	3s
Seq2Seq4ATE	4,738,353	87s
+ SoftProto	5,638,953	91s
DECNN	1,394,435	2s
+ SoftProto	2,444,835	3s

From Table 8, we can conclude that SoftProto is a lightweight framework and does not add much cost on the original sequence taggers.

6 Conclusion

In this paper, we present a general SoftProto framework to enhance the ATE task. Rather than designing elaborated sequence taggers, we turn to correlate samples with each other through soft prototypes. For this purpose, we resort to the language models for automatically generating soft prototypes and then design a gating conditioner for utilizing them. The performance of SoftProto can be further improved after introducing the large-scale external unlabeled data like Yelp and Amazon reviews. Extensive experiments on four SemEval datasets demonstrate that SoftProto greatly boosts the performance of the typical ATE methods and introduces small computational cost.

Abstract

Unlike other domains, medical texts are inevitably accompanied by private information, so sharing or copying these texts is strictly restricted. However, training a medical relation extraction model requires collecting these privacy-sensitive texts and storing them on one machine, which comes in conflict with privacy protection. In this paper, we propose a privacy-preserving medical relation extraction model based on federated learning, which enables training a central model with no single piece of private local data being shared or exchanged. Though federated learning has distinct advantages in privacy protection, it suffers from the communication bottleneck, which is mainly caused by the need to upload cumbersome local parameters. To overcome this bottleneck, we leverage a strategy based on knowledge distillation. Such a strategy uses the uploaded predictions of ensemble local models to train the central model without requiring uploading local parameters. Experiments on three publicly available medical relation extraction datasets demonstrate the effectiveness of our method.

1 Introduction

Privacy - like eating and breathing - is one of life's basic requirements.

— Katherine Neville

Relation extraction is a task of mining factual knowledge from the free text by labeling relations between entity mentions and has attracted increasing attention in recent years, such as Zeng et al. (2014); Xu et al. (2015a,b); Wang et al. (2016); Baldini Soares et al. (2019); Song et al. (2019). Applying automatic relation extraction to medical texts, such as electronic health records and discharge summaries, can be useful for many applications, including drug repurposing and medical knowledge graph construction.

Unlike other domains, medical texts are highly privacy-sensitive, because these texts can include some of the most intimate details about one's life, which document a patient's physical and mental health, and can include information on social behaviors, personal relationships and financial status (Gostin and Hodge, 2002). To prevent private information leakage, sharing or copying medical texts is strictly restricted.

Previous relation extraction methods require centralizing the underlying training data from different medical platforms, such as hospitals and healthcare centers, on one server for training, while holding the centralized privacy-sensitive data puts patients' privacy at risk. This is one of the reasons that hinder the use of relation extraction in clinical practice. As a possible solution, federated learning (McMahan et al., 2016) is proposed to make full use of privacy-sensitive data. Training local models with private data at local platforms and aggregating local models in the central server compose the federated learning process. In the framework of federated learning, no single piece of private data is uploaded to or stored on the central server, and only local models' parameters are sent to the server for updating the central model.

Though federated learning has distinct advantages in privacy protection compared to centralized training, federated learning algorithms, such as FedAvg (McMahan et al., 2016), require frequent communication between local platforms and the central server to upload and download models' parameters. Communication is a critical bottleneck of applying federated learning to relation extraction, which is largely due to the following reasons: First, the state-of-the-art relation extraction models (Baldini Soares et al., 2019; Li et al., 2019b; Thillaisundaram and Togia, 2019) usually utilize transformer-based pretrained language models (Raffel et al., 2019; Devlin et al., 2019; Liu et al.,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2118–2128,
November 16–20, 2020.

2019; Yang et al., 2019b) as backbone encoders, which have millions or even billions of parameters. Second, the framework of federated learning includes a massive number of local platforms (Li et al., 2019a), and communication between each platform and the central server is necessary. Third, upload bandwidth is typically limited to 1 MB/s or less in most situations [1]. Considering the cumbersome model, numerous local platforms and the limited upload bandwidth, it will take an excessive amount of time during frequent upload processes. For example, in a single communication, uploading a BERT-Large (Devlin et al., 2019) model takes more than 21 minutes and uploading a T5 (Raffel et al., 2019) model takes more than 12 hours. In order to overcome the communication bottleneck in federated relation extraction, it is necessary to develop a communication-efficient method that iteratively sends small messages as part of the training process, as opposed to sending the entire pretrained language encoder.

In this paper, we introduce a privacy-preserving medical relation extraction model, named `FedED`. To prevent private information leakage, we leverage federated learning without sharing raw privacy-sensitive medical texts. To overcome the communication bottleneck in federated relation extraction, we focus on reducing the size of transmitted messages at each communication round. To this end, we formulate the central aggregation process in federated learning as learning a compact central model (student) from the ensemble (Dietterich, 2000; Breiman, 2001) of multiple local models (teacher). From this perspective, only the predicted labels on a small dataset need to be uploaded to the central server, because learning from a "teacher" model only requires the behavior of the "teacher" rather than the entire"teacher" network (Hinton et al., 2015). Besides, the ensemble model (teacher) is powerful, which defines the upper extreme of aggregating when limited to a single communication in federated learning (Yurochkin et al., 2019). To transfer the knowledge in the ensemble model to the central model, we leverage a strategy based on knowledge distillation (Hinton et al., 2015), which trains the central model by forcing it to have a similar prediction with the ensemble model. To demonstrate the effectiveness of our method, we conduct extensive experiments on three different medical relation extraction datasets. The results show that our method not only outperforms the baselines but also is communication-efficient.

We summarize our contributions as follows:

- To protect patients' privacy, we propose the first (to the best of our knowledge) privacy-preserving medical relation extraction model based on federated learning, which decouples the model training from the need for direct access to the highly privacy-sensitive data.

- To overcome the communication bottleneck in federated learning, we leverage a knowledge distillation based strategy that utilizes the uploaded predictions of ensemble local models to train the central model without requiring uploading the entire local models' parameters.

- The method yields promising results on three different medical relation extraction datasets, and we perform various experiments to verify the effectiveness of the proposed method.

2 Related Work

Our work builds on a rich line of recent efforts on relation extraction models and federated learning.

2.1 Relation Extraction

Relation extraction is a long-standing NLP task of mining factual knowledge from free texts by labeling relations between entity mentions. There are a number of recent neural network approaches applied to relation extraction, such as Zeng et al. (2014); Nguyen and Grishman (2015); dos Santos et al. (2015); Zhang and Wang (2015); Zhang et al. (2017). Recently, the NLP community has seen excitement around neural models that make heavy use of pretraining based on language modeling (Radford et al.; Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019b). Baldini Soares et al. (2019); Shi and Lin (2019) and Alt et al. (2019) achieved the state-of-the-art performance in relation extraction by fine-tuning the pretrained language models. In this paper, we also adopt a pretrained language model as the backbone encoder.

Applying relation extraction models to the medical field has great practical value, and there is a rich literature on medical relation extraction. Some studies focused on clinical relation extraction (Sahu et al., 2016; Munkhdalai et al., 2018; Ningthoujam et al., 2019) and some studies concentrated on

---

[1] the bandwidth and bitrate of the download are much greater than the upload, so we only consider the upload process.(`en.wikipedia.org/wiki/ADSL`).

biomedical relation extraction (Peng et al., 2017; Song et al., 2018, 2019). Compared with previous studies, we develop a federated relation extraction system to protect patients' privacy in medical relation extraction.

2.2 Federated Learning

Recently, McMahan et al. (2016), Konečnỳ et al. (2016a) and Konečnỳ et al. (2016b) proposed the concept of federated learning. The main idea of federated learning is to build machine learning models based on data sets that are distributed across multiple local platforms while preventing data leakage. Federated learning can be divided into three categories, i.e., horizontal federated learning, vertical federated learning and federated transfer learning, based on the distribution characteristics of the data (Yang et al., 2019a). This work focuses on horizontal federated learning, where local datasets share the same feature space but different in samples. There are a number of studies about horizontal federated learning, such as McMahan et al. (2016); Sahu et al. (2018); Ji et al. (2019); Wang et al. (2020).

Federated learning has the advantage of protecting privacy, so it is widely used in various fields. Chen et al. (2018) combined federated learning with meta learning for the recommendation. Kim et al. (2017) proposed federated tensor factorization for computational phenotyping without sharing patient-level data. Liu and Miller (2020) proposed federated pretraining of BERT model using clinical notes from multiple silos. Ge et al. (2020) proposed a privacy-preserving medical NER method based on federated learning.

3 Method

3.1 Task Definition

Relation Extraction devotes to extracting relational facts from sentences. Given a sentence with an entity pair e_1 and e_2, this task aims to identify the relation between $e_1$and e_1. In this paper, we focus on applying relation extraction to the medical domain. Define K medical platforms $\{\mathcal{P}_1, \mathcal{P}_2, ..., \mathcal{P}_K\}$, each with a private relation extraction dataset D_i, and a central server that has a small valid dataset D_v. Since the medical data is usually private and sensitive, the goal is to obtain a medical relation extraction model on the central server under the condition that any local platform $\mathcal{P}_i$ does not expose its private data D_i to others.

To solve this task, we propose a privacy-preserving medical relation extraction model based on federated learning. In the following sections, we introduce the basic medical relation extraction model at first. Then, we present how to conduct privacy-preserving training in a communication-efficient way.

3.2 Medical Relation Extraction Model

Given the impressive performance of recent deep transformers (Vaswani et al., 2017) trained on variants of language modeling, we utilize the BERT model (Devlin et al., 2019) as the backbone encoder. In this section, we explore a simple way of representing relations with the deep transformers model. The model architecture is shown in Figure 1 and the details are as follows:

Firstly, we construct the input sequence $s = \{w_0, w_1, ..., w_n\}$, where w_0 = [CLS] and w_n = [SEP] are special start and end markers. Next, to ensure generalization of the model, we follow previous studies (He et al., 2013; Kim et al., 2015; Liu et al., 2016; Chauhan et al., 2019) to perform entity blinding on the sequence, where the words in the sequence matching the entity are replaced with the target entity label. Then, in order to highlight entity mentions, we augment the sequence with four reserved word pieces, i.e., ⟨e1⟩,⟨/e1⟩,⟨e2⟩ and ⟨/e2⟩, to mark the begin and end of each entity mention. After that, we get the prepared sequence $\hat{s}$.

$$\begin{aligned}\hat{s} =& \{[\text{CLS}], w_1, ..., w_{i-2}, \langle \text{e1} \rangle, w_i, ..., w_j, \langle /\text{e1} \rangle, \\ & ..., \langle \text{e2} \rangle, w_k, ..., w_l, \langle /\text{e2} \rangle, ..., w_{m-2}, [\text{SEP}]\}\end{aligned}$$

Given the prepared sequence $\hat{s}$ as input, the output of BERT is expressed as $H \in \mathcal{R}^{m \times d}$, where m is the prepared sequence length and d is the output dimension of the BERT encoder. We use the first token of the sequence (the [CLS] token) as the sequence representation, which is denoted as $h_0 \in \mathrm{R}^d$. In addition, we obtain entity mention representations by summing the final hidden layers corresponding to the word pieces in each entity mention, and get two vectors $h_{e_1} = \text{sum}([h_i...h_j]) \in \mathrm{R}^d$ and $h_{e_2} = \text{sum}([h_k...h_l]) \in \mathrm{R}^d$ representing the two entity mentions. Finally, the sequence representation and these two entity mention representations are concatenated to be the input of a fully connected layer:

$$h = h_0 \oplus h_{e_1} \oplus h_{e_2} \in \mathrm{R}^{3d} \tag{1}$$

$$p(y|\hat{s}, \Theta) = \text{softmax}(\mathrm{W}h + \mathrm{b}) \tag{2}$$

where W and b are trainable model parameters.

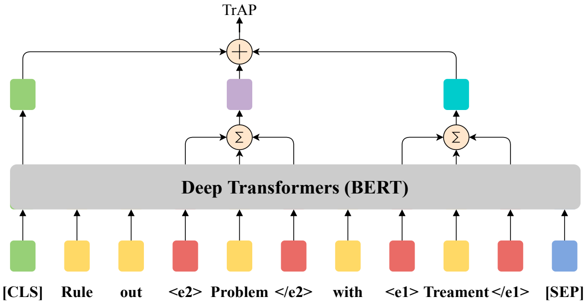

Figure 1: The architecture of our medical relation extraction model.

3.3 Federated Training

To protect patients' privacy, we utilize federated learning to train the medical relation extraction model. In the federated framework, two types of models are needed, i.e., the local model and the central model, which share the same network structure but have different permissions to access private data. Local models are deployed in local platforms, such as hospitals, and can access their respective private local data. In contrast, the central model is deployed in a central server, such as a cloud server, which is strictly prohibited from accessing to patients' private data. Here, following previous studies (McMahan et al., 2016; Bonawitz et al., 2019; Ge et al., 2020), we assume the central server belongs to one trusted third party, which means it will not make any vicious attack to local platforms. In this section, we present how to train the relation extraction model in the federated way, including secure local model update and the ensemble distillation based central model update.

3.3.1 Secure Local Model Update

The local model in each medical platform is trained on its own private data. We assume that the local platform $\mathcal{P}_i$ is selected to perform local computation in a round. The local platform $\mathcal{P}_i$ computes the gradients of loss over all the data D_i held by it to update the parameters of the local model. We adopt the cross-entropy as the local loss function, which is defined as follows:

$$L_{local}(\Theta) = -\frac{1}{|D_i|}\sum_{i=1}^{|D_i|}\log p(y_i|\hat{s}_i, \Theta) \qquad (3)$$

where $|D_i|$ represents the number of sentences in this local private data D_i and Θ indicates all parameters of the local model. After local model training, the local model in $\mathcal{P}_i$ accesses to valid data D_v in the central server, makes a prediction on it based on the trained parameters and uploads the predicted labels to the central server. Compared with centralized training, the local model is only trained on its own data, and only the predicted labels are uploaded rather than directly sharing raw data, which generally contains less privacy-sensitive information.

3.3.2 Central Model Update via Ensemble Distillation

The central server coordinates massive local models to collaboratively train the central model. To this end, there are a coordinator and an aggregator in the central server.

Coordinator controls the entire training process and is responsible for accepting and forwarding local platform connections. At the beginning of each communication round, the coordinator builds the medical relation extraction model in the central server and initializes the model. Then, the coordinator randomly selects a C-fraction of local medical platforms, since we cannot require that all local platforms are always online in the real-world scenario. After that, the coordinator distributes the parameters of central model to all selected local platforms, and the selected local models are initialized based on these parameters, which ensures that all selected local models are trained from the same initial condition at this round. Then, the selected local models are trained on their respective private data at each local platform. The coordinator monitors each selected platform for any possible uploads. Once it receives uploads from one platform, the coordinator will store them for future aggregation. When all selected platforms finish local training, the stored uploads are sent to the aggregator to inference new central model parameters.

Aggregator is the most critical part of federated training, which optimizes the central model based on massive trained local models. To transfer the knowledge in the massive trained local models to the central model, we resort to teacher-student framework. The ensemble of local models is viewed as the teacher, while the central model is regarded as the student. The knowledge in the teacher is transferred to the central model by forcing them to have a similar prediction for any input instance. To this end, the central model is trained to minimize a distillation loss function where the target is the distribution of class probabilities predicted by the ensemble model. The typical choice of the distillation loss function is the Kullback-Leibler (KL) divergence between the distributions, $D_{KL}(q||p)$, where p and q are the output label distributions of the student and the teacher respectively. The distribution of the teacher can be attained as follows:

$$q(y_i|s) = \frac{\exp\left(z(y_i|s)/\tau\right)}{\sum_r \exp\left(z(y_r|s)/\tau\right)} \tag{4}$$

$$z(y_i|s) = \frac{1}{|\mathcal{J}|} \sum_{j \in \mathcal{J}} p(y_i|s, \Theta^{(j)}) \tag{5}$$

where $z(y_i|s)$ is the logit of ensemble model (teacher) for class i, which is represented as the mean of selected local models' logits for this class, and τ is a temperature parameter that controls the shape of the distribution for distilling richer knowledge from the ensemble model. In addition to the distillation loss, it is also beneficial to train the central model to predict the ground truth labels using the standard cross-entropy loss. The overall objective is defined as follows:

$$L = \frac{1}{|D_v|} \sum_{i=1}^{|D_v|} (-\log p(y_i|\hat{s}_i) + D_{KL}(q(y|\hat{s}_i)||p(y|\hat{s}_i))) \tag{6}$$

The overall training procedure of `FedED` is illustrated in Algorithm 1.

4 Experiments

In this section, we carry out an extensive set of experiments with the aim of answering the following research questions:

- **RQ1**: Does our model outperform the baseline methods? (see Section 4.4)
- **RQ2**: Is federated learning effective in medical relation extraction? (see Section 4.5)
- **RQ3**: Is our approach communication-efficient? (see Section 4.6)
- **RQ4**: What is the impact of increasing parallelism on our model? (see Section 4.7)
- **RQ5**: What is the impact of increasing computation per local platform on our model? (see Section 4.8)

In the remainder of the section, we describe the datasets, experimental setting, and all baselines.

Algorithm 1 `FedED`. The K local platforms are indexed by k. C is the fraction of local platforms that perform computation on each round. B is the local minibatch size. E is the number of local epochs, and η is the learning rate.

```
Initialize $\Theta_0$ on the central server
for each communication round t = 0,1,2,... do
    m ← max(C× K, 1)
    $\mathcal{J}_t$ ← (random set of m local platforms)
    The server distributes $\Theta_t$ to $\mathcal{J}_t$.
    for each platform $k \in \mathcal{J}_t$ in parallel do
        Perform LocalUpdate(k, $\Theta_t$)
    end for
    // The procedure of Aggregator
    $\mathcal{V}$ ← (split $D_v$ into batches)
    for batch v in $\mathcal{V}$ do
        $\Theta_t \leftarrow \Theta_t - \eta \nabla L(\Theta_t; v)$
        // L is defined in Equation 6
    end for
    $\Theta_{t+1} \leftarrow \Theta_t$
end for

function LocalUpdate(k, $\Theta$):
    // Run on local platform k
    $\mathcal{B}$ ← (split $D_k$ into batches of size B)
    // $D_k$ is the private data of local platform k
    for each local epoch i from 1 to E do
        for batch b in $\mathcal{B}$ do
            $\Theta \leftarrow \Theta - \eta \nabla L_{local}(\Theta; b)$
            // $L_{local}$ is defined in Equation 3
        end for
    end for
    Access to $D_v$
    return $\{p(y|s, \Theta) | s \in D_v\}$ to server
```

4.1 Datasets

We conduct experiments on three publicly available medical relation extraction datasets: **2010 i2b2/VA challenge dataset** (Uzuner et al., 2011)[2], **GAD**(Bravo et al., 2015) and **EU-ADR** (Van Mulligen et al., 2012) [3]. The 2010 i2b2/VA challenge dataset is collected from three different hospitals viz, Partners Healthcare, Beth Israel Deaconess Medical Center, and the University of Pittsburgh Medical Center. It consists of discharge-summary and progress notes of the patients, and is manually annotated by medical practitioners. The EU-ADR dataset is annotated on a part of Medline

abstracts from 2007 to 2008, and the GAD dataset is collected form Genetic Association Database, an archive of human genetic association studies of complex diseases and disorders. The detailed statistics of these three datasets are listed in Table 1 and 2. We random sample 20% of training data for validation. To evaluate our method, we use the standard evaluation metric for each dataset: Micro-F1 for 2010 i2b2/VA challenge dataset and F1-score for GAD and EU-ADR.

4.2 Experimental Settings

We use a controlled environment that is suitable for experiments and assume a synchronous update scheme that proceeds in rounds of communication. For 2010 i2b2/VA challenge dataset, we set the number of local platforms (K) to 100. For EU-ADR and GAD datasets, the number of local platforms (K) is set to 50, since these datasets are small. The training data is randomly shuffled and then partitioned into K local platforms each receiving $1/K$ of the training data. This data partitioning simulates the scenario where each hospital is treated as a local platform and the central server is located in a trusted third party.

In our experiments, we use hugginface's implementation (Wolf et al., 2019) of BERT (base version) and initialize parameters of the BERT encoding layer with pretrained clinical BERT (Alsentzer et al., 2019) models. The learning rate is set to 2.5e-05. We use the dropout strategy to mitigate overfitting, which is set to 0.1. To conduct a fair comparison (presented in Section 4.4), we set all federated methods hyper-parameters as follows. The random fraction of local platforms C is 0.1, and we also study adding more local platforms at each round of communication in Section 4.7. Since the batch size and the number of local epochs are related to the number of secure local updates per round, the batch size B is fixed to 4 and the number of local epochs E is set to 2. We independently repeat each experiment 9 times and report the median F-score. All experiments are run with an NVIDIA GeForce RTX 2080 Ti.

4.3 Baselines

Under centralized training settings, we compare our medical relation extraction model (depicted in Section 3.2) with the following studies: (1) Sahu et al. (2016) leverage convolutional neural network (CNN) to extract relations in clinical texts; (2) Chauhan et al. (2019) build CNN upon the embeddings generated by the BERT model and train the models with a ranking loss; (3) Bravo et al. (2015) combine the shallow linguistic kernel with the dependency kernel to mine the syntactic features of text; (4) Bhasuran and Natarajan (2018) employ an ensemble SVM with a rich feature set covering conceptual, syntax and semantic information; (5) Lee et al. (2020) propose a domain-specific language representation model, called BioBERT, pre-trained on large-scale biomedical corpora.

In the federated training manner, We compare our federated framework (depicted in Section 3.3) with the following baselines: (1) FedAvg (McMahan et al., 2016) averages element-wise parameters of local models with weights proportional to sizes of the local datasets; (2) FedAtt (Ji et al., 2019) leverages a layer-wise attention mechanism for model aggregation. which can automatically attend to the weights of the relation between the central model and different local models.

4.4 Results

Table 3, 4 and 5 answer **RQ1** by showing the results of our model against baselines on the real-world medical datasets. In overall, our model significantly outperforms baselines on these datasets.

In the centralized training manner, our method outperforms REflex (Chauhan et al., 2019) on i2b2 dataset, which builds CNN upon the embeddings

generated by the BERT model. We conjecture this is largely due to that our model adopts the fine-tuning strategy on the relation extraction tasks instead of leveraging fixed embeddings generated by BERT. Previous studies (Peters et al., 2019) on BERT show that fine-tuning significantly outperforms the frozen pretrained weights strategy. Our method outperforms BioBERT (Lee et al., 2020) on EU-ADR and GAD datasets. The BioBERT only uses sequence representation, while our method use both sequence representations and entity mention representations. Moreover, we introduce four entity markers to highlight entity mention. Previous research (Baldini Soares et al., 2019) on relation extraction shows that entity markers and entity mention representation has a positive impact on the result.

In the federated training manner, our federated framework outperforms FedAvg (McMahan et al., 2016) and FedAtt (Ji et al., 2019). There are two possible reasons: (1) The performance of the ensemble model defines the upper extreme of aggregating when limited to a single communication in federated learning (Yurochkin et al., 2019), and the central model benefits from learning from the ensemble model. (2) FedAvg and FedAtt only model the simple process of central optimization by averaging or weighted averaging local model parameters, which overlook complicated relationships between local model parameters. FedED forces the central model to mimic the behavior of the ensemble model rather than modeling the complex relationship between parameters.

Comparing the federated training manner to the centralized training manner, we find that applying the centralized training manner achieves better performance. There are three reasons: (1) In federated learning, a 10% fraction of local platforms are selected in each epoch. In other words, only 10% of the training examples are used in each epoch. However, all training examples are used at each epoch in centralized training. (2) As the size of each local private data is small, the local model is prone to overfitting on it. (3) The local platforms are independent of each other; therefore, compared with centralized training, federated training lack the ability to model the overall data distribution. Although federated training does not perform as well as centralized learning, federated training is uniquely positioned to protect privacy. Moreover, our approach narrows the gap between federated training and centralized training in terms of performance.

4.5 Effectiveness Test of Federated Learning

To test the effectiveness of federated learning, we simulate a real-world scenario where a third party only has a small data, i.e., validation set, and copying data from hospitals is prohibited. The results are shown in Table 6, which answers the **RQ2**. From this table, we find that: (1) Due to data scarcity, the model trained only on the validation set can not achieve satisfactory performance; (2) FedAvg and FedAtt can effectively improve the performance of relation types with abundant examples, such as “TeRP”, “TrAP” and ”PIP”, but perform poorly in relation types with few examples (The distribution of relation types is shown in Table 2);

Relation Types	Trained on Validation Set	FedAvg	FedAtt	FedED
TeRP	79.74	84.96	85.24	85.3
TrAP	67.75	72.68	71.55	76.05
TrCP	43.11	50.41	47.73	54.9
PIP	66.98	71.07	75.16	73.69
TeCP	27.36	49.41	51.46	58.02
TrIP	24.24	23.08	1.3	48.03
TrWP	0	0	0	11.97
TrNAP	22.54	21.79	18.79	56.16

Table 6: The classwise performance on the 2010 i2b2/VA challenge dataset

(3) Our proposed FedED is able to improve performance in all relation types. We conjecture that ensemble distillation can capture the rich similarity structure between relation types, which boosts the performance.

4.6 Communication Efficiency Test

We turn to **RQ3** in this section. Table 7 presents the message size uploaded by each local platform at each communication round. From this table, we notice that our proposed method is communication-efficient and the amount of data uploaded by our method is much smaller than the others. The reason is that FedAvg and FedAtt require each selected local platform to upload the entire medical relation extraction model at each communication round, while only the predicted labels on a small dataset are uploaded to the central server in FedED. Considering numerous local platforms and the limited upload bandwidth, our proposed method can save a lot of time in communication.

Method	i2b2	GAD	EU-ADR
FedAvg	423MB	423MB	423MB
FedAtt	423MB	423MB	423MB
FedED	42KB	5KB	323B

Table 7: The message size uploaded by each local platform at each communication round.

4.7 Increasing Parallelism

Figure 2 answers **RQ4** by showing the impact of varying the fraction of local platforms for all approaches on the 2010 i2b2/VA challenge dataset. The fraction of local platforms C controls the amount of local platforms selected by the coordinator in each round. In Figure 2, we report the number of communication rounds necessary to achieve an F1 value of 72% on the test set. We find that: (1) Increasing parallelism will speed up convergence for all methods. When all local platforms are selected ($C = 1$), all methods reach the target F1 value with minimal communication cost. This is mainly due to the fact that the increased parallelism leads to more data used in each round of training; (2) Our method requires a much smaller number of communication rounds to reach the target F1 value than the other methods. We conjecture that this is due to that the central model (student) learns much faster and more reliably when trained with the outputs of the ensemble model (teacher) as soft labels (Phuong and Lampert, 2019).

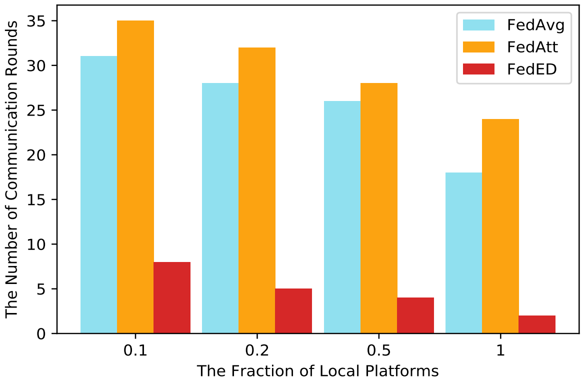

Figure 2: The number of communication rounds necessary to achieve an F1 value of 72% on the test set, fixing local epoch E to 2 and the batch size B to 4.

4.8 Increasing Computation Per Platform

Finally, we address **RQ5**. The number of local computation per round is given by $\frac{|D_k|}{B}E$, where B is the local batch size, E is the number of local training epoch and $|D_k|$ is the size of private data in local platform k. Decreasing B, increasing E, or both will add more computation per local platform per round. Table 8 lists the number of communication rounds necessary to achieve an F1

B	**E**	FedAvg	FedAtt	FedED
2	1	27	28	9
8	1	48	48	20
16	1	–	–	34
2	3	20	20	7
8	3	34	30	11
16	3	47	46	15

Table 8: The number of communication rounds necessary to achieve an F1 value of 72% on the test set, fixing C to 0.1. "–" means that the run did not reach the target F1 value in the allowed time.

value of 72% with different E and B. From this Table, we see that increasing computation per local platform by varying both B and E is effective for all methods, and our method converges to the target F1 value faster than baselines.

5 Conclusion and Future Work

In this paper, we propose a privacy-preserving medical relation extraction model based on federated learning, namely FedED. The main obstacle of applying federated learning to medical relation extraction is communication bottleneck, which is caused by the need to upload cumbersome parameters. To overcome this bottleneck, we leverage a knowledge distillation based strategy, which uses the uploaded predictions of ensemble local models to train the central model without requiring uploading cumbersome parameters. Our experiments on three benchmark datasets illustrate the advantages of our approach over previous federated algorithms. As to future work, we plan to explore how to jointly extract entities and relations in federated settings.

Abstract

Product attribute values are essential in many e-commerce scenarios, such as customer service robots, product recommendations, and product retrieval. While in the real world, the attribute values of a product are usually incomplete and vary over time, which greatly hinders the practical applications. In this paper, we propose a multimodal method to jointly predict product attributes and extract values from textual product descriptions with the help of the product images. We argue that product attributes and values are highly correlated, *e.g.*, it will be easier to extract the values on condition that the product attributes are given. Thus, we jointly model the attribute prediction and value extraction tasks from multiple aspects towards the interactions between attributes and values. Moreover, product images have distinct effects on our tasks for different product attributes and values. Thus, we selectively draw useful visual information from product images to enhance our model. We annotate a multimodal product attribute value dataset that contains 87,194 instances, and the experimental results on this dataset demonstrate that explicitly modeling the relationship between attributes and values facilitates our method to establish the correspondence between them, and selectively utilizing visual product information is necessary for the task. Our code and dataset are available at `https://github.com/jd-aig/JAVE`.

1 Introduction

Product attribute values that provide details of the product are crucial parts of e-commerce, which help customers to make purchasing decisions and facilitate retailers on many applications, such as question answering system (Yih et al., 2015; Yu et al., 2017), product recommendations (Gong, 2009; Cao et al., 2018), and product retrieval (Liao et al., 2018; Magnani et al., 2019). While product attribute values are pervasively incomplete for a massive number of products on the e-commerce platform. According to our statistics on a mainstream e-commerce platform in China, there are over 40 attributes for the products in *clothing* category, but the average count of attributes present for each product is fewer than 8. The absence of the product attributes seriously affects customers' shopping experience and reduces the potential of successful trading. In this paper, we propose a method to jointly predict product attributes and extract the corresponding values with multimodal product information, as shown in Figure 1.

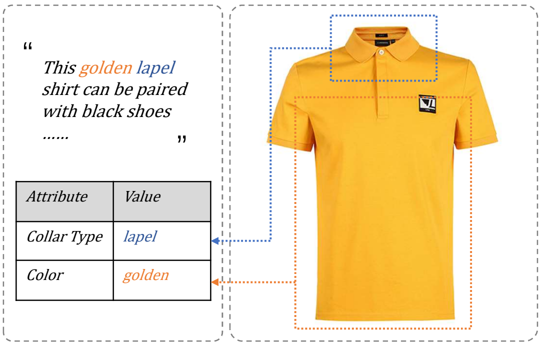

Figure 1: An example of predicting attributes and extracting values from the textual product description with the aid of the visual product information.

Though plenty of systems have been proposed to supplement product attribute values (Putthividhya and Hu, 2011; More, 2016; Shinzato and Sekine, 2013; Zheng et al., 2018; Xu et al., 2019), the relationship between product attributes and values are not sufficiently explored, and most of these approaches primarily focus on the text information. Attributes and values are, however, known to strongly depend on each other, and vision can play a particularly essential role for this task.

November 16–20, 2020.

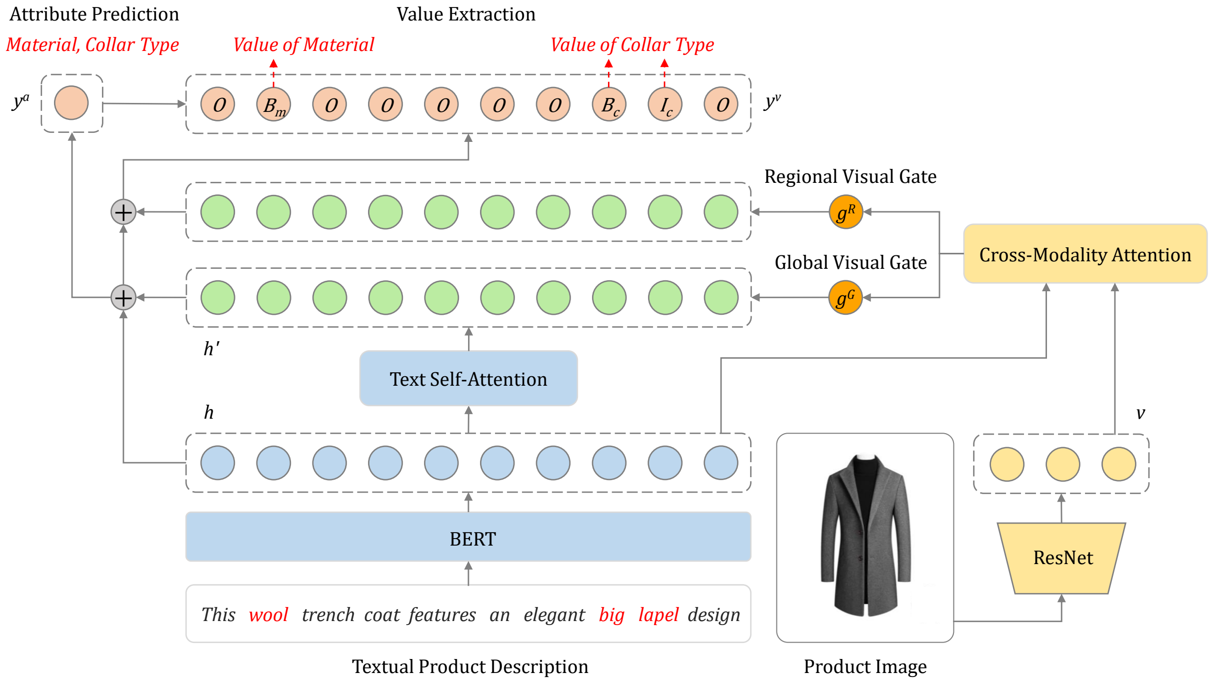

Figure 2: Framework of our model.

Intuitively, product attributes and values are mutually indicative. Given a textual product description, we can extract attribute values more accurately with a known product attribute. We model the relationship between product attributes and values from the following three aspects. First, we apply a multitask learning (Caruana, 1997) method to predict the product attributes and the values jointly. Second, we extract values with the guidance of the predicted product attributes. Third, we adopt a Kullback-Leibler (KL) (Kullback and Leibler, 1951) measurement to penalize the inconsistency between the distribution of the product attribute prediction and that of the value extraction.

Furthermore, beyond the textual product descriptions, product images can provide additional clues for the attribute prediction and value extraction tasks. Figure 1 illustrates this phenomenon. Given a description "*This golden band collar shirt can be paired with black shoes*", the term "*golden*" can be ambiguous for predicting the product attributes. While by viewing the product image, we can easily recognize the attribute corresponding to "*golden*" is "*Color*" instead of "*Material*". Moreover, the product image can indicate that the term "*black*" is not an attribute value of the current product; thus, it should not be extracted. This may be tricky for the model based on purely textual descriptions, but leveraging the visual information can make it easier. In addition, multimodal information shows promising efficiency on many tasks (Lu et al., 2016; Li et al., 2017; Anderson et al., 2018; Li et al., 2018; Yu et al., 2019; Li et al., 2019; Tan and Bansal, 2019; Liu et al., 2019; Su et al., 2020; Li et al., 2020). Therefore, we propose to incorporate visual information into our task. First, we selectively enhance the semantic representation of the textual product descriptions with a global-gated cross-modality attention module that is anticipated to benefit attribute prediction task with visually grounded semantics. Moreover, for different values, our model selectively utilizes visual information with a regional-gated cross-modality attention module to improve the accuracy of values extraction.

Our main contributions are threefold:

- We propose an end-to-end model to predict product attributes and extract the corresponding values.
- Our model can selectively adopt visual product information by global and regional visual gates to enhance the attribute prediction and value extraction model.
- We build a multimodal product attribute value dataset that contains 87,194 instances, involving various product categories.

2 Model

2.1 Overview

In this work, we tackle the product attribute-value pair completion task, *i.e.*, predicting attributes and extracting the corresponding values for e-commerce products. The input of the task is a "*textual product description, product image*" pair, and the outputs are the product attributes (there may be more than one attribute in the descriptions) and the corresponding values. We model the product attribute prediction task as a sequence-level multilabel classification task and the value extraction task as a sequence labeling task.

The framework of our proposed Multimodal Joint Attribute Prediction and Value Extraction model (M-JAVE) is shown in Figure 2. The input sentence is encoded by a pretrained BERT model (Devlin et al., 2019), and the image is encoded by a pretrained ResNet model (He et al., 2016). The global-gated cross-modality attention layer encodes text and image into the multimodal hidden representations. Then, the M-JAVE model predicts the product attributes based on the multimodal representations. Next, the model extracts the values based on the previously predicted product attributes and the multimodal representations obtained through the regional-gated cross-modality attention layer. We apply the multitask learning framework to jointly model the product attribute prediction and value extraction. Considering the constraints between the product attributes and values, we adopt a KL loss to penalize the inconsistency between the distribution of the product attribute prediction and that of the value extraction.

2.2 Text Encoder

The text embedding vectors are encoded by a BERT-base model, which uses a concatenation of WordPiece (Wu et al., 2016) embeddings, positional embeddings, and segment embeddings as the input representation. In addition, a special classification embedding ($[CLS]$) is inserted as the first token, and a special token ($[SEP]$) is added as the final token. Given a textual product description sentence decorated with two special tokens $\mathbf{x} = ([CLS], x_1, ..., x_N, [SEP])$, BERT outputs an embedding sequence $\mathbf{h} = (h_0, h_1, ..., h_N, h_{N+1})$.

2.3 Image Encoder

We apply the ResNet (He et al., 2016) to encode the product images. We extract the activations from the last pooling layer of ResNet-101 that is pretrained on the ImageNet (Deng et al., 2009) as the global visual feature v_G. We use the $7 \times 7 \times 2048$ feature map of the $conv_5$ layer as the regional image feature $\mathbf{v} = (v_1, ..., v_K)$, where $K = 49$.

2.4 Global-Gated Cross-Modality Attention Layer

Intuitively, for a specific product, as different modalities are semantically pertinent, we apply a cross-modality attention module to incorporate the textual and visual semantics into the multimodal hidden representations.

Inspired by the self-attention mechanism (Vaswani et al., 2017), we build a cross-modality attention layer capable of directly associating source tokens at different positions of the sentence and different regions of the image, by computing the attention score between each token-token pair and token-region pair, respectively. We argue that what is crucial to the cross-modality attention layer is the ability to selectively enrich the semantic representation of a sentence through the aid of an image. In other words, we need to avoid introducing noises resulted from when the image fails to represent some semantic meaning of words, such as abstract concepts. To achieve this, we design a global visual gate to filter out visual noise for any words that are irrelevant based on the visual signals.

Specifically, we feed the text and image representations h_i and v_k into the global-gated cross-modality attention layer, and then we obtain the enhanced multimodal representation $h_i^{'}$ as follows:

$$e_{ij}^t = (W_Q^t h_i)(W_K^t h_j)^T / \sqrt{d} \tag{1}$$

$$\alpha_{ij}^t = \exp(e_{ij}^t) / \sum\nolimits_m \exp(e_{im}^t) \tag{2}$$

$$e_{ik}^v = (W_Q^v h_i)(W_K^v v_k)^T / \sqrt{d} \tag{3}$$

$$\alpha_{ik}^v = \exp(e_{ik}^v) / \sum\nolimits_n \exp(e_{in}^v) \tag{4}$$

$$h_i^{'} = \sum\nolimits_j \alpha_{ij}^t W_V^t h_j + g_i^G \sum\nolimits_k \alpha_{ik}^v W_V^v v_k \tag{5}$$

where W_Q^t, W_K^t, W_V^t, W_Q^v, W_K^v, W_V^v are weight matrices, and d is the dimension of $W_Q^t h_i$.

The global visual gate g_i^G is determined by the representation of the sentence and the image, which are obtained by the text encoder and the image encoder, respectively, as follows:

$$g_i^G = \sigma(W_1 h_i + W_2 v_G + b) \tag{6}$$

where W_1 and W_2 are weight matrices.

2.5 Product Attribute Prediction

For an instance in the dataset, given $\mathbf{y}^a = (y_1^a, ..., y_L^a)$, where $y_l^a = 1$ denotes the instance with l-th attribute label, to predict the product attributes, we feed the text representation h_i, the multimodal representation $h_i^{'}$, and h_0 perceptron (the special classification element $[CLS]$ in BERT) into a feed-forward layer to output the predicted attribute labels $\hat{\mathbf{y}^a} = (\hat{y_1}^a, ..., \hat{y_L}^a)$:

$$\hat{\mathbf{y}^a} = \sigma(W_3 \sum\nolimits_i h_i + W_4 \sum\nolimits_i h_i^{'} + W_5 h_0) \tag{7}$$

where W_3, W_4 and W_5 are weight matrices.

Then we calculate the loss of the attribute prediction task by binary cross entropy over all L labels:

$$\text{Loss}_a = \text{CrossEntropy}(\mathbf{y}^a, \hat{\mathbf{y}^a}) \tag{8}$$

2.6 Product Value Extraction

We regard the value extraction as a sequence labeling task that tags the input $\mathbf{x} = (x_1, ..., x_N)$ with the label sequence $\mathbf{y}^v = (y_1^v, ..., y_N^v)$ in the BIO format, *e.g.*, attribute label "*Material*" corresponds to tags "*B-Material*" and "*I-Material*".

We argue that the product attributes can provide crucial indications for the attribute values. For example, given a sentence "*The red collar and golden buttons in the shirt form a colorful fashion topic*" and the predicted product attribute "*Color*", it is easy to recognize the value "*golden*" corresponding to attribute "*Color*" instead of "*Material*". Thus, we incorporate the result of the product attribute prediction $\hat{\mathbf{y}^a}$ to improve the value extraction.

Moreover, for a given product attribute, some regions of the image corresponding are more important than others. Thus, we set a gate g_k^R for each image region to obtain a weighted visual semantic representation, which aims to use the regional image information more efficiently. Specifically, we feed text representation h_i, multimodal representation $h_i^{'}$, and image representation v_k into a **regional-gated cross-modality attention layer** and output the value labels $\hat{\mathbf{y}^v} = (\hat{y_1}^v, ..., \hat{y_N}^v)$:

$$\begin{aligned}\hat{y_i^v} = \text{softmax}(&W_6 h_i + W_7 h_i^{'} + W_8 \hat{\mathbf{y}^a} \\ &+ \sum\nolimits_k g_k^R \alpha_{ik}^v W_V^v v_k)\end{aligned} \tag{9}$$

where W_6, W_7, W_8, and W_V^v are weight matrices.

The regional visual gate g_k^R is determined by the regional visual semantics and the product attributes as follows:

$$g_k^R = \sigma(W_9 \hat{\mathbf{y}^a} + W_{10} v_k) \tag{10}$$

where W_9 and W_{10} are weight matrices.

Then we calculate the loss of the value extraction task by cross entropy:

$$\text{Loss}_v = \text{CrossEntropy}(\mathbf{y}^v, \hat{\mathbf{y}^v}) \tag{11}$$

2.7 Multitask Learning

To jointly model product attribute prediction and value extraction, our method is trained end-to-end via minimizing Loss_a and Loss_v coordinatively.

Moreover, the outputs of attribute prediction and value extraction are highly correlated, and thus we adopt a KL constraint between the outputs. Given the l-th attribute label, we assume that there are two corresponding value extraction tags *e.g., attribute label "Material" corresponds to tags "B-Material" and "I-Material"*, and their probabilities can be expressed as $\mathbf{y}^v(B_l)$ and $\mathbf{y}^v(I_l)$. Then the attribute prediction distribution mapped from the output of the corresponding value extraction task can be assigned as $\hat{\mathbf{y}}^{v \to a} = (\hat{y}_1^{v \to a}, ..., \hat{y}_L^{v \to a})$, where

$$\hat{y}_l^{v \to a} = \frac{1}{2}(\max_i \hat{y}_i^v(B_l) + \max_i \hat{y}_i^v(I_l)) \tag{12}$$

The KL loss is:

$$\text{KL}(\hat{\mathbf{y}}^a || \hat{\mathbf{y}}^{v \to a}) = \sum\nolimits_l \hat{y}_l^a log \frac{\hat{y}_l^a}{\hat{y}_l^{v \to a}} \tag{13}$$

and the final joint loss function is

$$\text{Loss} = \text{Loss}_a + \text{Loss}_v + \lambda \text{KL}(\hat{\mathbf{y}}^a || \hat{\mathbf{y}}^{v \to a}) \tag{14}$$

3 Dataset

We collect a Multimodal E-commerce Product Attribute Value Extraction (MEPAVE) dataset with textual product descriptions and product images. Specifically, we collect instances from a mainstream Chinese e-commerce platform[1]. Crowdsourcing annotators are well-experienced in the area of e-commerce. Given a sentence, they are required to annotate the position of values mentioned in the sentence and label the corresponding attributes. In addition, the annotators also need to check the validity of the product text-image from

Table 3: Main results (F_1 score %) of comparative methods and variants of our model.

its main page in e-commerce websites, and the unqualified ones will be removed. We randomly select 1,000 instances to be annotated three times to ensure annotation consistency; the consistency rate is 92.83%. Finally, we obtained 87,194 text-image instances consisting of the following categories of products: *Clothes*, *Pants*, *Dresses*, *Shoes*, *Boots*, *Luggage*, and *Bags*, and involving 26 types of product attributes such as "*Material*", "*Collar Type*", "*Color*", etc. The distribution of different product categories and attribute values is shown in Table 1. We randomly split all the instances into a training set with 71,194 instances, a validation set with 8,000 instances, and a testing set with 8,000 instances.

IV et al. (2017) release the English Multimodal Attribute Extraction (MAE) dataset. Each instance in the MAE dataset contains a textual product description, a collection of images, and attribute-value pairs, where the values are not constrained to present in the textual product description. To verify our model on the MAE dataset, we select the instances whose values are in the textual product description, and we label the values by exactly matching. We denote this subset of the MAE dataset as MAE-text and the rest as MAE-image (values can be only inferred by the images).

4 Experiment

We compare our proposed methods with the following baselines: **WSM** is the method that uses attribute values in the training set to retrieve the attribute values in the testing set by word matching. **Sep-BERT** is the pretrained BERT model with feed-forward layers to perform these two subtasks separately. **RNN-LSTM** (Hakkani-Tür et al., 2016), **Attn-BiRNN** (Liu and Lane, 2016), **Slot-Gated** (Goo et al., 2018), and **Joint-BERT** (Chen et al., 2019) are the models to address intent classification and slot filling tasks, which are similar to the attribute prediction and value extraction, and we adopt these models to our task. **RNN-LSTM** and **Attn-BiRNN** use a bidirectional LSTM and an attention-based model for joint learning, respectively. **Slot-Gated** introduces a gate-based mechanism to learn the relationship between these two tasks. **Joint-BERT** finetunes the BERT model with joint learning. **ScalingUp** (Xu et al., 2019) adopts BiLSTM, CRF, and attention mechanism for introducing hidden semantic interaction between attribute and text.

We report the results of our text-only and multimodal models, *i.e.*, JAVE and M-JAVE. In addition, to eliminate the influences of different text encoders, we also conduct experiments with BiLSTM as the text encoder. Details about hyper-parameters are shown in Table 2.

4.1 Main Results

We evaluate our model on two subtasks, including attribute prediction and value extraction. The main results in Table 3 show that our proposed M-JAVE model based on the BERT and the Bidirectional LSTM (BiLSTM) both outperform the baselines significantly (paired t-test, p-value < 0.01), which proves an excellent generalization ability of our methods. From the results of our proposed M-JAVE

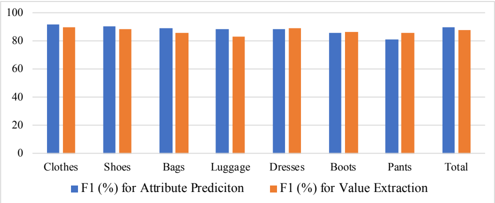

Figure 3: Experimental results of the M-JAVE model for each product category.

and JAVE models, we can observe that the BERT is advantageous over the LSTM and visual product information improves the performance. The M-JAVE model achieves the best performance of 90.69% and 87.17% F_1 scores on two subtasks.

Moreover, experimental results demonstrate the superiority of our JAVE model (either based on LSTM or BERT) against the models of **WSM**, **RNN-LSTM**, **Sep-BERT**, and joint-learning based models including **Attn-BiRNN**, **Slot-Gated** and **Joint-BERT**, indicating that the strategies for integrating the relationship between attributes and values into our models are necessary for the tasks. We evaluate the **ScalingUp** model to predict the value for each given attribute on our dataset, and the result is unsatisfactory. With the in-depth study, we found that it can be ascribed to identifying values that do not correspond to the given attribute. Over 34.52% of the predicted values are not the actual values for the input attributes, whereas this number is only 16.51% for our JAVE model. As a result, the **ScalingUp** model obtains a higher recall score (93.78%) while a lower precision score of (65.48%) than our model (89.82% for recall score and 80.27% for the precision score). We argue that explicitly modeling the relationship between attributes and values facilitates our methods to establish the correspondence between them.

More details including the results for each product category and for each type of attribute are shown in Figure 3 and 4. We can find that our proposed method achieves satisfactory results for every category, and is not only suitable for simple attributes related to appearance, such as "*Color*" and "*Pant Length*", but also can deal with complex attributes, such as "*Elasticity*" and "*Material*".

To verify the adaptability of our proposed models, we conduct experiments on the English MAE dataset (IV et al., 2017). The model proposed along with the MAE dataset takes textual product descriptions, visual information, and product attributes as input and treats the attribute value extraction task as predicting the value for a given product attribute. Thus, we compare our M-JAVE model with the MAE-model only on the value extraction task.

Model	MAE	MAE-text	MAE-image
MAE-model	59.48	72.96	52.11
M-JAVE (LSTM)	-	74.41	-
M-JAVE (BERT)	-	75.01	-

Table 4: Experimental results (accuracy %) of our proposed model and MAE baseline model (MAE-model).

As shown in Table 4, on the MAE-text subset, our M-JAVE (LSTM) and M-JAVE (BERT) models outperform the MAE-model with 1.45% and 2.05% accuracy gains, respectively. On the original MAE and MAE-image subset, the accuracy scores of the MAE-model are 59.48% and 52.11%, respectively, which are much lower than that on the MAE-text subset. We argue that it may be risky to predict the product values that do not appear in the textual product descriptions, and defining the value prediction as an extractive-based task is more reasonable for practical applications.

4.2 Ablation Study

We perform ablation studies to confirm the effectiveness of the main modules of our models.

4.2.1 Modeling the Relationship between Product Attributes and Values

We explore the relationship between attributes and values from three aspects, including 1) applying the multitask learning to jointly predict the product attributes and values, 2) extracting values based on the predicted product attributes, and 3) introducing a KL loss to penalize the inconsistency between the results of product attributes and values.

Based on our text-only model, *i.e.*, JAVE, we conduct experiments to evaluate the effectiveness of modeling the relationship by ablating the modules corresponding to the above three aspects.

- *w/o MTL* is the model without multitask learning (*i.e.*, the two subtasks are addressed separately).
- *w/o AttrPred* is the model without using the predicted product attributes in value extraction (*i.e.*, remove $W_8\hat{\mathbf{y}^a}$ in Eq. 9).
- *w/o KL loss* is the model without the KL loss (*i.e.*, set $\lambda = 0$ in Eq. 14).

Furthermore, we get the upper bound of attribute prediction training with the ground-truth values

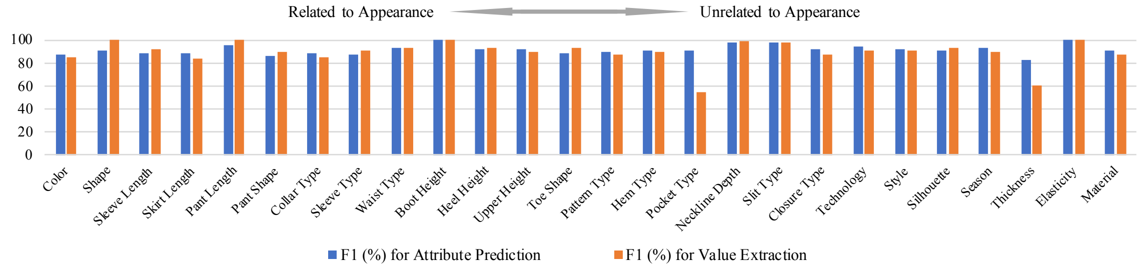

Figure 4: Experimental results of the M-JAVE model for each type of attribute.

Model	Attribute	Value
JAVE	**87.98**	**84.78**
JAVE w/o MTL	87.36	83.99
JAVE w/o AttrPred	86.74	83.90
JAVE w/o KL-Loss	87.24	84.26
JAVE (UpBound of Attribute Task)	89.03	100.0
JAVE (UpBound of Value Task)	100.0	88.72

Table 5: Experimental results (F_1 score %) for ablation study on the relationship between attributes and values. “UpBound” denotes “Upper Bound”.

Model	Attribute	Value
M-JAVE	**90.69**	**87.17**
M-JAVE w/o Visual Info (JAVE)	87.98	84.78
M-JAVE w/o Global-Gated CrossMAtt	88.52	85.90
M-JAVE w/o Regional-Gated CrossMAtt	88.29	85.38
M-JAVE w/o Global Visual Gate	87.27	80.32
M-JAVE w/o Regional Visual Gate	87.66	82.54

Table 6: Experimental results (F_1 score %) for ablation study on the product images.

(Eq. 13); we get the upper bound of value extraction training with the ground-truth attributes (Eq. 9 and 13).

Table 5 shows a comparison of the JAVE model concerning the ablations. We can see that the JAVE model achieves the best performance. The results of the method “JAVE w/o MTL”, “JAVE w/o AttrPred”, and “JAVE w/o KL loss” drop the F_1 scores by 0.62%, 1.24%, and 0.74% respectively for product attribute prediction, and drop the F_1 scores by 0.79%, 0.88% and 0.52% respectively for value extraction, showing the effectiveness of modeling the relationship between product attributes and values. The results for the upper bound study shows the strong correlation between product attribute prediction and value extraction.

4.2.2 Integrating Visual Product Information

Our model mainly utilizes visual information of products from two aspects, including 1) predicting product attributes with a global-gated cross-modality attention module, and 2) extracting values with a regional-gated cross-modality attention module. We evaluate the effectiveness of visual product information as follows.

- *w/o Visual Info* is the model without utilizing visual information (*i.e.*, JAVE).
- *w/o Global-Gated CrossMAtt* is the model without the global-gated cross-modality attention (*i.e.*, remove the right part in Eq. 5).
- *w/o Regional-Gated CrossMAtt* is the model without the regional-gated cross-modality attention (*i.e.*, remove the right-most part in Eq. 9 inside the softmax function).
- *w/o Global Visual Gate* is the model without the global visual gate (*i.e.*, remove g_i^G in Eq. 5).
- *w/o Regional Visual Gate* is the model without the regional visual gate, (*i.e.*, remove g_k^R in Eq. 9).

From Table 6, we can see that removing global-gated or regional-gated cross-modality attention modules degrades the performances on both subtasks, proving the effectiveness of visual information for our task.

Moreover, for the models with cross-modality attention modules while without global or regional visual gates, *i.e.*, M-JAVE w/o Global Visual Gate and M-JAVE w/o Regional Visual Gate, respectively, the performances are worse than that of M-JAVE significantly. Remarkably, the models of M-JAVE w/o Global Visual Gate and M-JAVE w/o Regional Visual Gate underperform the models thoroughly removing visual-related modules.

To sum up, using the visual product information indiscriminately poses detrimental effects on the model, and selectively utilizing visual product information with global and regional visual gates are essential for our tasks.

4.3 Adversarial Evaluation of Attribute Prediction and Value Extraction

To further verify whether the visual product information can improve the performance of product attribute prediction and value extraction, we adopt an adversarial evaluation method (Elliott, 2018) that measures the performance variation when our model is presented with a random incongruent image.

The awareness score of a model $\mathcal{M}$ on an evaluation dataset $\mathcal{D}$ is defined as follows:

$$\Delta_{Awareness} = \frac{1}{|\mathcal{D}|} \sum_{i}^{|\mathcal{D}|} a_{\mathcal{M}}(x_i, y_i, v_i, \bar{v}_i) \quad (15)$$

Where $\Delta_{Awareness}$ denotes the image awareness. *x*, *y* denote the the text and the values of the product, respectively. *v*, $\bar{v}$ denote the congruent image and the incongruent image, respectively.

We use the F_1 score to calculate awareness score for a single instance:

$$a_{\mathcal{M}} = F_1(x_i, y_i, v_i) - F_1(x_i, y_i, \bar{v}_i) \quad (16)$$

Under this definition, the output of the evaluation performance measure should be higher in the presence of the congruent data than incongruent data, i.e., $F_1(x_i, y_i, v_i) > F_1(x_i, y_i, \bar{v}_i)$. If this is the case, on average, then the overall image awareness of a model $\Delta_{Awareness}$ is positive. This can only happen when model outputs are evaluated more favourably in the presence of the congruent image data than the incongruent image data.

To determine if a model passes the proposed evaluation, we conduct the statistical test using the pairs of values that are calculated in the process of computing the image awareness scores (Eq. 16)

Table 7 shows the evaluation results of product attribute prediction and value extraction. We find that, on both subtasks, the F_1 scores with incongruent images are much lower than that with the congruent images, and $\Delta_{Awareness}$ is significant positive. Moreover, we use $K = 8$ separate p values from each test based on Fisher's method, and get $\mathcal{X}^2$=6790.80, p <0.0001 in product attribute prediction and $\mathcal{X}^2$=780.80, p <0.0001 in value extraction, which proves that the incongruent image significantly degrades the model's performance. We can conclude that the visual information make substantial contribution to the attribute prediction and value extraction tasks.

	C	**I**	$\Delta_{Awareness}$
Value	87.48	$78.57_{0.23}$	$11.26_{0.18}$
Attribute	89.57	$86.64_{0.13}$	$3.2_{0.08}$

Table 7: F_1 scores in the **C**ongruent and **I**ncongruent settings, along with the Meteor-awareness results. Incongruent and $\Delta_{Awareness}$ scores are the mean and standard deviation of 8 permutations of product images in test dataset.

	Attribute			**Value**		
Models	**PI**	**QA**	$\Delta_{\downarrow}$	**PI**	**QA**	$\Delta_{\downarrow}$
JAVE	87.98	73.40	14.58	84.78	70.47	14.31
M-JAVE	90.69	77.71	12.98	87.17	76.17	11.00

Table 8: Experimental results (F_1 score $\%$) for domain adaptation. $\Delta_{\downarrow}$ denotes the F_1 score gap for the PI and QA domains.

4.4 Domain Adaptation

To verify the robustness of our models, we conduct an evaluation on the out-of-domain data. The source domain is our formal product information (PI) mentioned in Section 3. The target domain is the oral Question-Answering (QA), where the textual description consists of QA pairs about the product in the real e-commerce customer service dialogue, and the visual information is from the image of product mentioned in the dialogue. We directly apply the JAVE and M-JAVE models trained on PI to test on the QA testing set containing 900 manually annotated instances.

As shown in Table 8, on the QA testing set, M-JAVE outperforms JAVE with 4.31$\%$ and 5.70$\%$ F_1 scores on the attribute prediction and value extraction tasks, respectively. For the attribute prediction task, the gap between the results on the PI and QA testing reduces from 14.58$\%$ to 12.98$\%$ when using the visual information. Similarly, the gap reduces from 14.31$\%$ to 11.00$\%$ for the value extraction task. This demonstrates that visual product information makes our model more robust.

4.5 Low-Resource Evaluation

To further verify the robustness of our model, we evaluate our models trained with subsets of the whole training set in different proportions. For each proportion, we randomly sample the training data three times, and we report the mean and standard deviation in Table 9. It illustrates that visual product information brings considerable advantages on the robustness when few training instances are available.

% of data	100%	80%	60%	40%	20%
Attribute					
JAVE	87.98	$86.83_{0.31}$	$84.81_{0.64}$	$76.89_{2.81}$	$72.13_{3.64}$
M-JAVE	90.69	$88.48_{0.21}$	$86.14_{0.52}$	$81.23_{1.66}$	$78.70_{2.92}$
Value					
JAVE	84.78	$82.77_{0.45}$	$78.81_{0.82}$	$74.12_{2.42}$	$66.57_{4.24}$
M-JAVE	87.17	$86.61_{0.28}$	$83.88_{0.67}$	$79.67_{1.87}$	$74.63_{3.23}$

Table 9: Results (mean and standard deviation) with different sizes of of training data.

Figure 5: Heat maps for global (blocks above the text) and regional (images on the right) visual gates.

4.6 Visualization

To evaluate the global and regional visual gates qualitatively, we visualize these gates for different attribute values with the M-JAVE model. The results are shown in Figure 5. For the blocks above the text, the deeper color denotes the larger value for the global visual gate g_i^G, *i.e.*, more visual information is used for enhancing the semantic meaning of the text. We can find that the global visual gates are positively related to the relevance between the text and the image. For the product image on the right, the lighter color denotes the larger value for the regional visual gate g_k^R, *i.e.*, more visual information is drawn for extracting values. The results demonstrate that the regional visual gate successfully captures useful parts of the product image.

5 Related Work

Recent approaches related to the attribute value pair completion task can be classified as the following two categories.

1) Predicting integral attribute-value tags. Putthividhya and Hu (2011) and Zheng et al. (2018) introduce a set of entity tags for each attribute (*e.g.*, "*B-Material*" and "*I-Material*" for the attribute "*Material*"). Putthividhya and Hu (2011) adopt a NER system with bootstrapping to predict values, and Zheng et al. (2018) apply a Bi-LSTM-CRF model with the attention mechanism. It may be challenging to handle the massive amounts of attributes in the real world.

2) Predicting values for given attributes. Ghani et al. (2006) treat the task as a value classification task and create a specific text classifier for each given attribute. More (2016) and Xu et al. (2019) formulate the task as a special case of NER (Bikel et al., 1999; Collobert et al., 2011) task that predicts the values for each attribute. More (2016) combines CRF and structured perceptron with a curated normalization scheme to predict values, and Xu et al. (2019) regard attributes as queries and adopt BIO tags for any attributes, making it applicable for the large-scaled attribute system. However, our experimental results show that the model of Xu et al. (2019) may be insufficient to identify which attribute a value corresponds to.

In this paper, we propose a third category of method: **jointly predicting attributes and extracting values**. The attribute prediction module provides guidance and constraints for the value extraction module, which adapts our model to fit large-scaled attribute applications. Moreover, we explicitly model the relationship between attributes and values, which helps to establish the correspondence between them effectively.

6 Conclusion

We jointly tackle the tasks of e-commerce product attribute prediction and value extraction from multiple aspects towards the relationship between product attributes and values, and we prove that the models can benefit a lot from visual product information by the aid of global and regional visual gates. We collect a Multimodal E-commerce Product Attribute Value Extraction (MEPAVE) dataset[2]. The experimental results on this dataset show that the correlations between product attributes and values are valuable for this task, and visual information should be selectively used.

Abstract

Existing OIE (Open Information Extraction) algorithms are independent of each other such that there exist lots of redundant works; the featured strategies are not reusable and not adaptive to new tasks. This paper proposes a new pipeline to build OIE systems, where an Open-domain Information eXpression (OIX) task is proposed to provide a platform for all OIE strategies. The OIX is an OIE friendly expression of a sentence without information loss. The generation procedure of OIX contains shared works of OIE algorithms so that OIE strategies can be developed on the platform of OIX as inference operations focusing on more critical problems. Based on the same platform of OIX, the OIE strategies are reusable, and people can select a set of strategies to assemble their algorithm for a specific task so that the adaptability may be significantly increased. This paper focuses on the task of OIX and propose a solution – Open Information Annotation (OIA). OIA is a predicate-function-argument annotation for sentences. We label a data set of sentence-OIA pairs and propose a dependency-based rule system to generate OIA annotations from sentences. The evaluation results reveal that learning the OIA from a sentence is a challenge owing to the complexity of natural language sentences, and it is worthy of attracting more attention from the research community.

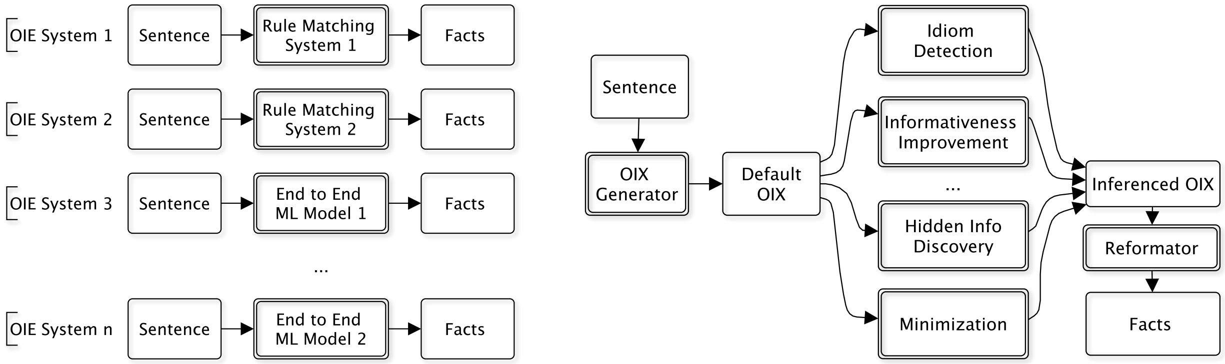
1 Introduction

In the past decades, various OIE (Open Information Extraction) systems (Banko et al., 2007; Yates et al., 2007; Wu and Weld, 2010; Etzioni et al., 2011; Fader et al., 2011; Mausam et al., 2012) have been developed to extract various types of facts. Earlier OIE systems extract verbal relations between entities, while more recent systems enlarge the types of relations. For example, RelNOUN (Pal and Mausam, 2016) extract nominal properties. Sun et al. (2018a; 2018b) can extract four types of facts: verbal, prepositional, nominal, and conceptional. OLLIE (Mausam et al., 2012) and ClauseIE (Corro and Gemulla, 2013) extract relations between clauses. In addition to extracting the fact tuples, NestIE (Bhutani et al., 2016) and StuffIE (Prasojo et al., 2018) extract nested facts. Furthermore, MinIE (Gashteovski et al., 2017) add factuality annotations to the facts.

Currently, existing OIE systems were typically developed from scratch, generally independent from each other. Each of them has their own concerned problem and builds its own pipeline from a sentence to the final set of facts (See Figure 1a). Generally, each OIE system is a complex composition of several extraction strategies (for rule-based systems) or data labeling strategies (for end-to-end supervised learning). It is rather straightforward for specific problems. However, this practice has several major drawbacks outlined as follows:

- *Redundant works*. Some common works are implemented again and again in different ways in each OIE system, such as converting simple sentences with clear *subj* and *obj* dependencies into a predicate-argument structure.
- *Strategies are not reusable*. During the years of OIE practice, several sub-problems are believed valuable, e.g., nested structure identification (Bhutani et al., 2016), informative predicate construction (Gashteovski et al., 2017), attribute annotation (Corro and Gemulla, 2013; Gashteovski et al., 2017), etc. Each sub-problem is worthy of being standardized and continually studied given a well defined objective and data sets so that the performance could be fairly evaluated and the progress can be continually made. However, it is not easy in the current methodology, since each pipeline's strategies are closely bonded to own implementation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2140–2150,
November 16–20, 2020.



(a) Traditional OIE systems.

(b) OIX based OIE system.

Figure 1: Methodologies to construct OIE systems

- *Unable to adapt*. Because of the above two factors, there is no platform to implement the shared requirement to provide unified data set, and the strategies are not reusable. Furthermore, each OIE system extracts the interested facts in the desired form at the time of development and omits the uninterested facts. Consequently, they are not adaptable to new requirements. If the interests or the requested form of facts change, one may need to write an entire new OIE pipeline.

As the OIE task has attracted more and more interest (Christensen et al., 2013, 2014; Fader et al., 2014; Mausam, 2016; Stanovsky et al., 2015; Khot et al., 2017), the above mentioned drawbacks have delayed the progress of OIE techniques. The key to conquering those obstacles is to provide a shared platform for all OIE algorithms, which express all the information in sentences in the form of OIE facts (that is, predicate-arguments tuples) without losing information. OIE strategies can focus on inferring new facts from existing ones without knowing the existence of the sentence. With this platform, the strategies are reusable and can be fairly compared. When confronting a specific task, one can select a set of strategies or develop new strategies and run the strategies on the platform to build a new OIE pipeline. In this manner, the adaptability is much improved. This new methodology of OIE is shown in Figure 1b.

We name the task of implementing such a platform as Open Information eXpression (OIX), where *eXpression* is used to distinguish from *Extraction* to emphasize that it focuses on expressing all the information in the sentence rather than extracting the interested part of the information. This methodology potentially results in a multi-task learning scenario where many agents (each one is interested in a part of information) compete with each other for words. This competition may result in more robust expressions than those who only extract part of the information. This paper focuses on investigating the OIX task requirements and finding a solution for this task.

In Section 2, we discuss the principle of design solution for OIX and propose a solution – the Open Information Annotation (OIA) – to fulfill those principles. The OIA of a sentence is a single-rooted directed-acyclic graph (DAG) with nodes representing phrases and edges connecting the predicate nodes to their argument nodes. We describe the detailed annotation strategies of OIA in Section 3. Based on the OIA, several featured strategies from existing OIE algorithms can be ported to work on the OIA. Section 4 discusses the possible implementation of those strategies on the OIA. We label a data set of OIA graphs, build a rule-based pipeline for automatically generating OIA graphs from sentences, and evaluate the pipeline's performance on the labeled data set. All these work are stated in Section 5. We discuss the connection from OIA to Universal Dependency, Abstract Meaning Representation (Banarescu et al., 2013), and SAOKE (Sun et al., 2018b) in Section 6. We conclude the paper in Section 7.

2 Open Information eXpression

2.1 Design Principles of the Expression Form

We consider the following factors in designing the expression form for the OIX task:

- **Information Lossless** As the OIX task is to provide a platform for following OIE strategies, the loss of any information is unacceptable. A simple constraint can guarantee this: any word in the sentence must appear in the target form of OIX.

- **Validity** It must implement the information structure of OIE tasks, that is, the predicate-argument structure. It builds a boundary for the OIE pipeline: after the OIX task, followed strategies all work on open-domain facts, without knowing the original sentences.
- **Capacity** The form should be able to express all kinds of information involved in the sentences, including 1) relation between entities; 2) the nested facts, that is, fact as an argument of another fact; 3) the relationships between facts, including the logical connections such as "if-else" and discourse relations such as "because", "although"; 4) information in the natural language other than declarative sentences, such as questions that ask to return one or a list of possible answers (Karttunen, 1977).
- **Atomicity** Since the form is a common expression of facts to serve different OIE strategies, we have no bias in the form of predicate and perform atomic expression so that followed strategies can assemble them according to their preference. For example (Gashteovski et al., 2017), for the sentence "Faust made a deal with the Devil", ClausIE produces (Faust, made, a deal with the Devil), while the MinIE extracts (Faust, made a deal with, the Devil). Instead, we would like a nested structure ((Faust, made, a deal), with, Devil) so that followed strategies can assemble the predicate according to the favor of either ClauseIE or MinIE. Notice that the atomicity does not means it is in word-level. We still need a phrase-level expression of facts, following the traditional OIE system's preference for *simple* phrase (detailed in later sections).

2.2 Information in Natural Languages

Natural languages talk about entities, the factual/logical relationship among them, and describe the status/attributes of them. When talking about entities, the human may talk about some explicit entity or refer a delegate of some unknown entities. When talking about relationships, the relationship may be among entities and can be among entities and relationships; that is, the relationship can be nested. So, from the logical view, we need the following components to express the information in languages:

- Constants: express entities, such as "the solar system", "the Baidu company"; or status of entities/events/relationships, such as "expensive", "hardly".
- Functions: $\mathbf{f}(arg_1, \cdots, arg_n) \rightarrow \{e\}$, express query of entities or delegation of entities, such as "the CEO of X", "when Y", where X and Y denote the arguments of the functions;
- Predicates: $\mathbf{p}(arg_1, \cdots, arg_n) \rightarrow \{0, 1\}$, express factual relationships and logical connections among entities, predicates, and functions, such as "X buy Y", "X says Y ", "Y, because Z".

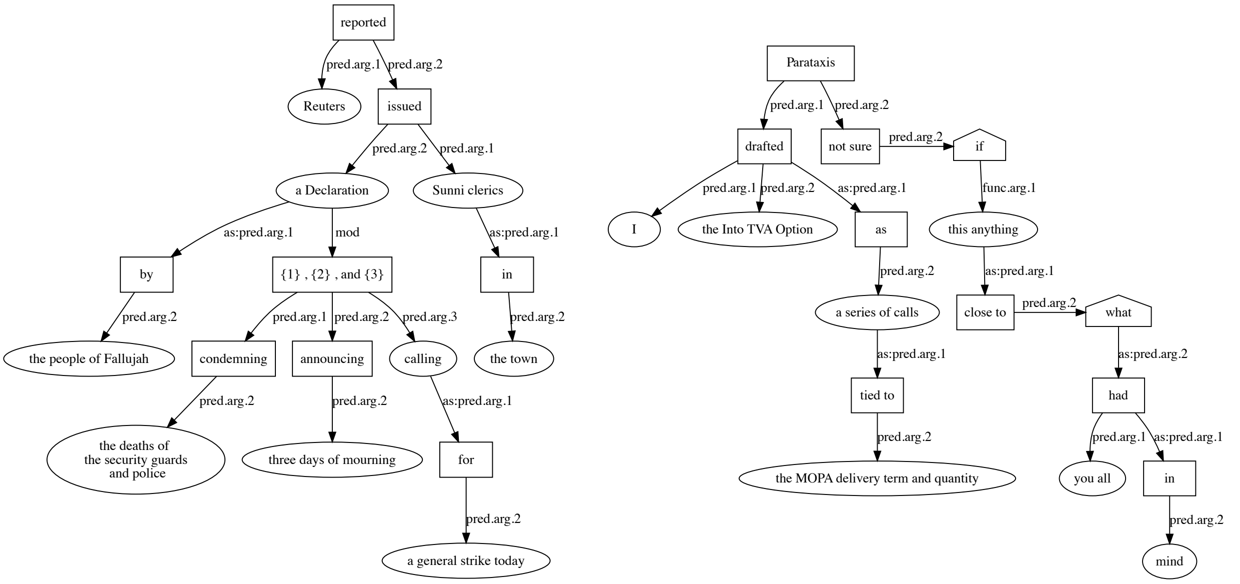
where arg_i could be a constant, predicate or function, and $\{e\}$ is some unknown set of entities returned by the function. With these components, the constants and the instantiated functions become terms, the instantiated factual predicates become atom formulas, the instantiated logical predicates become general formulas, and finally, a sentence can be expressed as a formula. Through this kind of expression, the gap between the language and the knowledge is narrowed. We propose Open Information Annotation to implement this methodology.

2.3 Open Information Annotation

Open Information Annotation (OIA) annotation of a sentence is a single-rooted directed-acyclic dependency graph (DAG), where nodes are predicates/functions/arguments and edges connect the predicates or functions to their arguments. OIA minimizes the information loss by requiring all the words (except the punctuation) in source sentences to appear in the graph. It is single-rooted, which meets the sentence's hierarchical semantic structure, and is for better visualization, understanding, and annotation. Figure 2 gives two sample sentences and their corresponding OIA annotations for intuitive understanding. We give a formal description of the OIA graph as follows:

Nodes. The OIA takes the simple phrases as the basic information units and build nodes based on these simple phrases. By *simple* phrase, we mean a fixed expression, or a phrase with a headword together with its auxiliary, determiner dependents, or adjacent *ADJ/ADV* modifiers. There are three types of nodes: constant, predicate, and function:

- Constant Nodes: simple nominal phrases, representing entities in a knowledge base, or simple description phrases, representing a description



(a) Case I – Reuters reported "Sunni clerics in the town issued a 'Declaration by the people of Fallujah' condemning the deaths of the security guards and police, announcing three days of mourning, and calling for a general strike today."

(b) Case II – I drafted the Into TVA Option as a series of calls tied to the MOPA delivery term and quantity - not sure if this anything close to what you all had in mind.

Figure 2: Two example cases of Open Information Annotations

for an event. They are visualized as the ellipse shapes;

- Function Nodes: the question phrases (what, where) since they are desired to return a set of entities in a knowledge base, or the "of" phrase that delegates an unknown entity. They are visualized as the house shapes;
- Predicate Nodes: predicate phrases, including the simple verbal phrase, simple prepositional phrase, simple conjunction phrases, simple modification phrases, etc. They are visualized as the box shapes;

The principles of OIX require that each word (except punctuation) in the sentences must belong to one and only one of the nodes. However, there is some information hidden in natural language that is not expressed by words. To honestly express the information, we introduce predefined functions and predicates, as shown in Table 1. Many predefined predicates are borrowed from the Universal Dependency (Nivre et al., 2020).

Edges. Edges in OIA are connecting each predicate node or function node to its argument, which can be any constant node, predicate node or function node. There are only two basic types of connecting edges: *pred.arg.*$\{n\}$ for predicates and *func.arg.*$\{n\}$ for functions, where n is the index of the argument.

Function	Meaning
Whether	whether-or-not function
2-ary Predicate	**Meaning**
Modification	modification
Reference	reference
Discourse	discourse element
Vocative	the dialogue participant
Appos	apposition
Reparandum	speech repair
***n*-ary Predicate**	**Meaning**
Parataxis	parataxis of *args*
List	*args* are elements of a list

Table 1: Predefined Functions and Predicates, where for 2-ary predicates, their meanings are "*arg1* has a {Meaning} *arg2*".

When a term is modified by a relative clause, the term is acting as an argument of the predicate expressed by the relative clause, but the predicate is used to modify the term. To express such relation, we reverse the edge and add a prefix *as:* to the argument edge, such as *as:pred.arg.1* or *as:func.arg.2*.

For those predefined predicates with two arguments, to reduce the graph's complexity, we al-

Edge	Meaning
$\mathbf{p} \xrightarrow{pred.arg.i} arg_i$	predicate to its i-th *arg*
$\mathbf{f} \xrightarrow{func.arg.i} arg_i$	function to its i-th *arg*
$arg_i \xrightarrow{as:+} \mathbf{p/f}$	i-th *arg* to its predicate/function
$arg_1 \xrightarrow{\mathbf{P}} arg_2$	$\mathbf{P}(arg_1, arg_2)$
$arg_1 \xrightarrow{as:\mathbf{P}} arg_2$	$is\_\mathbf{P}\_of(arg_1, arg_2)$

Table 2: Edges in OIA. "as:+" means add prefix "as:" to the previous listed predicates, and **P** denotes any predefined predicate with two arguments.

low the use of an edge connecting two arguments with the label of that predicates (lowercased) to express the relationship (just as the UD annotation). That is, the predicate *Appos(arg1, arg2)* would be expressed by an edge $arg1 \xrightarrow{appos} arg2$ in the OIA graph. The *as:* prefix applies these shortcut edges too, expressing the meaning of "*arg1* is the {Meaning} of *arg2*". We also give abbreviated names for most frequently used edges: *mod* for *modification*, and *ref* for *reference*.

3 Information Expression Using OIA

In this section, we show how to express information involved in various language phenomenons with our OIA. We can only brief the basic framework in the limited content of this paper. More details can be found on the online website for OIX [1].

3.1 Events

Eventive facts (Davidson and Harman, 2012; Kratzer and Heim, 1998) are facts about entities' actions or status, which is generally expressed by the *subj*, *obj* and **comp* dependencies. In OIA, the *pred.arg.1* always points to the subject of the event, and *pred.arg.2* to *pred.arg.N* refer to the (multiple) objects. A simple example is illustrated by Figure 3a. Events themselves can be arguments of predicates as well, as illustrated by Figure 3d.

3.2 Modification

Adjective/Adverbial Modification. Simple modifiers for nouns, verbs, and prepositions are directly merged into the corresponding phrase. For a complex or remote modifier, we use the predicate "Modification" with two arguments B and A (or an edge from B to A with label *mod*) to express the relation of A modifies B. The "today" in Figure 3a is an example.

Modification by Preposition. For preposition phrases such as "A in B" or "A for B", we take the prepositions as the predicates and A, B as the arguments. If A is an argument of another predicate, to preserve the single-root property, we reverse the edge from the preposition to A and add a *as:* prefix to the label, that is, a new edge from A to the preposition with the label *as:pred.arg.1*. Figure 3e is such an example.

Modification by Relative clause. When the relative clause B modifies an argument *a* of some other predicate/function, that is, B itself conveys a predicate/function with argument *a*, we reverse the related edge in B and add the *as:* prefix as we do for "Modification" by Preposition. Figure 3f illustrates this case. If B does not involve *a* as argument but an argument *b* referencing *a*, like "which", "who", we do the same thing to *b*, and add an edge from *a* to *b* with label *ref*.

3.3 Cross-Fact Relations

Cross-sentential Connectives. Sentential connectives are ignored in many OIE systems, but they are the "first-class citizen" in our scheme. Sentential connectives such as "therefore", "so", "if" and "because" can represent logical and temporal relations between sentences. We treat them as predicates and facts/propositions as arguments. An example is shown in Figure 3c.

Conjunction/Disjunction. The conjunction and disjunction are expressed by "and" and "or" among a list of parallel components. OIA annotation adds a connecting predicate node delegating the components such as "and" for two components and "{1} and {2} or {3}" for three components, and then link to the arguments with *pred.arg.*$\{n\}$. This is illustrated by Figure 3c. More complex situations like Figure 3e are detailed in the online document.

Adverbial Clause. We first build the OIA subgraph for the adverbial clause, and then connect the modified predicate to the root of the sub-graph with edge *mod*.

3.4 Questions and Wh-Clauses

We treat question phrases and wh-phrases as functions (Hamblin, 1976; Groenendijk and Stokhof, 1984; Groenendijk and Roelofsen, 2009) and as the root of the OIA graph/sub-graph for sen-

(e) The government of the people, by the people, for the people, shall not perish from the earth.

(f) He borrow the book she recommended.

Figure 3: Illustration of Information Expression in Open FPA Graph

tence/clauses. If the phrase ("what", "who", etc.) is an argument of the head predicate of the sentence/clause , the connecting edge is reversed and the *as:* prefix is added to the label; otherwise ("when", "where", etc.), we connect the phrase to the head predicate of the sentence/clause with the label *func.arg.1*. For polarity questions such as "Do you know Bob?", we introduce a predefined function "Whether" (see Table 1) to avoid the confusion caused by taking "Do" as the function phrase. See Figure 2b and Figure 3b.

3.5 Reference

In natural language sentences, words like "it, that, which" refer to an entity mentioned earlier. We express this knowledge by adding an edge *ref* from the entity to the reference word. Again, if this edge violates the single-root rule, the edge will be reversed as *as:ref*. Figure 3c shows the annotation for reference.

4 Inference Operations on OIA Graph

After the OIA graph is constructed, inference operations can be applied to generate a new graph. In this way, strategies from existing OIE algorithms can be ported to the OIA pipeline. We describe several possible operations as follows:

Constant Merging and Expansion. Noun phrases with conjunction/dis-conjunction and preposition involved (such as "the deaths of the security guards and police") may correspond to many nodes in the default OIA graph, which raise the costs of reading and annotation of the OIA graph. We can merge those nodes as one constant node to reduce the cost and expand it back when necessary. Figure 2 shows the merged versions of the OIA graphs.

Nested Facts. Nested fact extraction is a feature of NestIE, which is naturally supported by the OIA graph.

Idiom Discovery. Idioms like “in order to”, “as soon ... as”, “be proud of” have specific meanings and should be taken as one predicate. One can apply graph pattern mining on a set of OIA graphs and learn the pattern for idioms, or directly use the patterns discovered by previous OIE algorithms such as OLLIE or ClauseIE. Once an idiom is discovered and matched, we merge the relevant nodes to form one single predicate.

Informativeness Improvement. MinIE proposed this strategy to select informative expression of predicates, that is, in favor of (Faust, made a deal with, the Devil) instead of (Faust, made, a deal with the Devil). The informativeness measurement can be ported to OIA, and the target predicate can be obtained by merging relevant nodes.

Factuality. We can extract factuality annotations (negation, certainty/possibility) as in MinIE and add property edges to OIA linking the predicate node to the value node.

Condition and Attribution. The conditional relation considered in OLLIE is naturally supported by the OIA by taking the conditional word as the predicate. Attributions that mark facts by their contexts, such as “Some people say”, can be done by examining the nested structure in OIA.

Hidden Information in Nouns. OLLIE, RelNOUN, MinIE and Logician can extract relations hidden in noun phrases. We can apply these algorithms to extract the hidden facts and attach them to the OIA graph for future usage.

Minimization. The minimization strategies proposed by MinIE can be ported as a prune operation on the OIA graph to drop words useless to the current task.

5 Parsing Sentence into OIA Graph

This section introduces the automatic pipeline for parsing sentences in English into OIA graphs, which is illustrated in Figure 4. We first introduce each component of the pipeline, and then evaluate the proposed OIA parser’s performance.

5.1 Components of Pipeline

Universal Dependency Parser. The first step is to convert the sentence into Universal Dependency (UD) (Nivre et al., 2020) graph using a Universal Dependency Parser. Among various types of dependencies, we choose the Universal Dependency because 1) UD is designed cross-linguistically, which makes our pipeline potentially possible to port to languages other than English. 2) UD is one of the biggest data sets for dependency grammar. In this paper, we adopt the UD 2.0 standard as the target form of UD graphs and employed the neural network-based StanfordNLP toolkit [2] (Qi et al., 2018) to generate the Universal Dependency graphs for sentences.

Enhanced++ Universal Dependencies. The second step is to convert the original UD graph into an Enhanced++ UD graph. The Enhanced++ Universal Dependencies (Schuster and Manning, 2016) provide richer information about the relationships between the components in sentences, and some of them greatly help the construction of OIA graphs. Since there is no UD 2.x compatible Enhanced++ annotator available (while UD 1.x compatible version is available in the CoreNLP toolkit), we develop a UD 2.x compatible Enhanced++ annotator in Python by ourselves. Our Enhanced++ annotator’s accuracy on the set of changed edges of the UD English test data is 95.05%.

OIA Graph Annotator. The OIA Graph annotator works in three steps: 1) Simplifying the UD graph: Identify the simple phrases and merge the relevant word nodes in Enhanced++ UD graph into one node. Conjunction/dis-conjunction relationships are processed by adding an extra predicate node to the graph, connecting to all parallel components as arguments. Thirty-nine heuristic rules are developed to fulfill these procedures. 2) Mapping to the OIA graph: Map the dependencies in the simplified UD graph into the relationship between the OIA nodes, according to the conversion described in Section 3. In total, 37 heuristic rules are involved in this step. 3) Making the DAG: Select the root of the OIA graph (usually the predicate corresponding to the root of the UD graph or a connection word to that root) and then convert the graph to a DAG by reversing conflicting arcs and changing labels as described at Section 3.

5.2 Building the Pipeline and the Data Set

We used the Universal Dependencies project version 2.4 for English data set [3] as the source to build our pipeline. The data set contains about

---

[3] http://hdl.handle.net/11234/1-2988

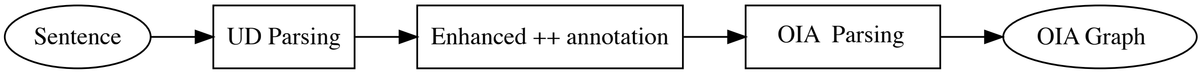

Figure 4: Pipeline to converting sentence into OIA graph

16,000 human-labeled pairs of the sentence and its Enhanced++ UD annotation, split into the train, develop, and test sets. With the existence of the ground-truth UD graph, we can investigate how the UD parser's accuracy influences the accuracy of the OIA pipeline.

We first implemented an initial version of the pipeline and then ran the pipeline over all the samples from the UD training set. All the samples that resulted in parsing errors like unexpected situations, disconnected components, missing words were collected and examined to improve our pipeline. The procedure continued until the pipeline could successfully run through almost all training samples. Then we labeled 100 samples from the development set of the UD data set and a small number of sentences from the UD training set. We tested and improved the pipeline on the labeled training data by examining the detailed correctness and evaluated the performance on the development data set. If there was a large gap between the development performance and train performance, we labeled more data until the gap tended to vanish. (The evaluation metrics are introduced in the next section.)

Finally, 500 sentences from the UD training set were labeled to obtain a converged pipeline. Furthermore, we labeled all (about 2,000) sentences from the UD testing set for performance evaluation. All the data were labeled by two annotators, with each labeling a half and then double-checking another half. We make all our labeled data public on the online website of OIX.

5.3 Evaluation

There are two configurations of OIA pipelines. One uses the ground-truth Enhanced++ UD annotation as input; the other uses the raw sentence as input and uses UD parser and our Enhanced++ annotator to generate the enhanced UD graph.

Evaluation on Generated OIA Graph. We measure how well the predicted OIA graphs match the ground truth OIA graph at three levels: Node Level, Edge Level, and Graph Level. The set of representations is collected at each level, and the precision, recall and F1 scores are evaluated. For node level, the representation is the node label; for edge level, the representation is a triplet <*starting node label*, *edge label*, *end node label*>; for graph level, the representation is the set of all edge triples. At all levels, we find the matched representations by exact match. The results of the pipeline with Enhanced++ input are shown in Table 3, and the results of the pipeline with raw sentence input are shown in Table 4.

Level	Precision	Recall	F1
Node	0.930	0.913	0.921
Edge	0.763	0.764	0.763
Graph	0.565	0.565	0.565

Table 3: Performance of our OIA converter given the ground-truth Enhance++ annotations.

Level	Precision	Recall	F1
Node	0.853	0.871	0.862
Edge	0.629	0.628	0.628
Graph	0.450	0.450	0.450

Table 4: Performance of the OIA pipeline given the raw sentences.

Evaluation on Facts Extracted from OIA. Extracting open-domain facts from an OIA graph is rather straightforward. First, we recover all the short-cut edges back into its original predicate form. Then, for each predicate node, we collect all its arguments and produce the OIE fact tuples. The sets of facts from predicted OIA graphs are compared to those from the ground-truth OIA graphs to compute the evaluation results. Exact match is used in evaluation and the precision, recall and F1 scores are computed as shown in Table 5.

Input	Precision	Recall	F1
UD Graph	0.696	0.708	0.702
Sentence	0.479	0.484	0.481

Table 5: Fact level performances of the OIA pipeline.

5.4 Error Analysis

From the above results, we can see that without the input of ground-truth Enhanced++ annotation, there are a roughly 10% increase in error for the OIA graph and even 20% for facts. The error in dependency parsing and Enhanced++ annotation is the major part of the error for the pipeline without ground-truth Enhanced++ annotation input.

We reviewed the error cases of predicted results with Enhanced++ annotation input and found several major sources of error: 1) the complexity of natural language sentences that our convert rules do not cover, especially in inversion sentences; 2) mistaken or incomplete annotations in Enhanced++ while a human can correctly annotate; 3) the ambiguity of human-labeled OIA samples since various inferences over the graph (see Section 4) are allowed while all preserve the validity.

A possible way to cope with the above errors is to formalize a standardized form of OIA graphs (see online website for details) and learn the mapping from sentence to the standard form in an end-to-end way. Recent advances in neural graph learning (You et al., 2018; Li et al., 2018; Sun and Li, 2019; Rahmani and Li, 2020) are suitable for generating the OIA graphs. Together with the recent advances on pre-trained language model (Devlin et al., 2019; Radford et al., 2019), the results are worth to be expected. These directions could be in the pipeline of our future work.

6 Discussion

Dependency Graph. One may wonder whether it is necessary to propose a new OIX or OIA learning task since the information in OIA can also be expressed by the dependency graph, especially Enhanced ++. However, the above experiments reveal that even with our very carefully written rule system, the error rate is still high. Due to the complexity of the natural language and the error in the dependency pipeline, it is very difficult to improve the rule-based pipeline. On the contrary, based on phrases with much fewer types of edge, the OIA is much simpler than the dependency graph, so end-to-end learning may avoid the error introduced by the dependency parser and obtain better results, which belongs to our future work. Defining the task and building a rule-based pipeline as the baseline is the first step to learn a good OIA annotator.

AMR. Abstract Meaning Representation (AMR) (Banarescu et al., 2013) is a symbolic representation of the sentence. Same as our OIA, information lossless is also a principle of AMR. AMR contains approximately 100 relations and selects symbolized concepts from PropBank (Palmer et al., 2005). It is also very abstract that sentences with the same meaning but in very different expressions will share the same AMR annotation. As a result, AMR is difficult to label (cost about 10 min to label a sample[4]) and is very difficult to learn. OIA can be viewed as an open-domain approximation of AMR and maybe a valuable step for AMR learning.

SAOKE. SAOKE(Symbol Aided Open Knowledge Expression) (Sun et al., 2018b) is our previous attempt to express various types of knowledge uniformly. It is designed following four requirements: *Completeness*, *Accurateness*, *Atomicity*, and *Compactness*, which are the predecessors of the principles of OIX. However, due to the limitation of the annotation form (a list of tuples), the expression capability of SAOKE is restricted, while the OIA greatly extends the expression capability. Several end-to-end learning strategies, such as dual learning (Sun et al., 2018a) and reinforcement learning (Sun et al., 2018a; Liu et al., 2020b,a) are developed to learn the SAOKE annotation, which can be ported to the learning of OIA graphs.

7 Conclusions and Future Work

This paper proposes a reusable and adaptive pipeline to construct OIE systems. As the core of the pipeline, the Open-domain Information eXpression (OIX) task is thoroughly studied, and an Open Information Annotation (OIA) is proposed as a solution to the OIX task. We discuss how to port the strategies of various existing OIE algorithms to the OIA graph. We label data for OIA annotation and build a rule-based baseline method to convert sentences into OIA graphs.

There are many potential directions for future work on OIA, including 1) more labeled data; 2) better learning algorithm; 3) becoming cross-lingual by adding support for more natural languages; 4) porting existing OIE strategies on OIA and evaluating the performance compared with the original ones.

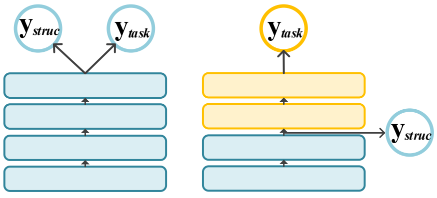
Abstract

We consider retrofitting structure-aware Transformer language model for facilitating end tasks by proposing to exploit syntactic distance to encode both the phrasal constituency and dependency connection into the language model. A middle-layer structural learning strategy is leveraged for structure integration, accomplished with main semantic task training under multi-task learning scheme. Experimental results show that the retrofitted structure-aware Transformer language model achieves improved perplexity, meanwhile inducing accurate syntactic phrases. By performing structure-aware fine-tuning, our model achieves significant improvements for both semantic- and syntactic-dependent tasks.

1 Introduction

Natural language models (LM) can generate fluent text and encode factual knowledge (Mikolov et al., 2013; Pennington et al., 2014; Merity et al., 2017). Recently, pre-trained contextualized language models have given remarkable improvements on various NLP tasks (Peters et al., 2018; Radford et al., 2018; Howard and Ruder, 2018; Yang et al., 2019; Devlin et al., 2019; Dai et al., 2019). Among such methods, the Transformer-based (Vaswani et al., 2017) BERT has become a most popular encoder for obtaining state-of-the-art NLP task performance. It has been shown (Conneau et al., 2018; Tenney et al., 2019) that besides rich semantic information, implicit language structure knowledge can be captured by a deep BERT (Vig and Belinkov, 2019; Jawahar et al., 2019; Goldberg, 2019). However, such structure features learnt via the vanilla Transformer LM are insufficient for those NLP tasks that heavily rely on syntactic or linguistic knowledge (Hao et al., 2019). Some effort devote to improved the ability of structure learning in Transformer LM by installing novel syntax-attention mechanisms (Ahmed et al., 2019; Wang et al., 2019). Nevertheless, several limitations can be observed.



(a) Full-layer (b) Middle-layer

Figure 1: Full-layer multi-task learning for structural training (left), and the middle-layer training for deep structure-aware Transformer LM (right).

First, according to the recent findings by probing tasks (Conneau et al., 2018; Tenney et al., 2019; Goldberg, 2019), the syntactic structure representations are best retained right at the middle layers (Vig and Belinkov, 2019; Jawahar et al., 2019). Nevertheless, existing tree Transformers employ traditional full-scale training over the whole deep Transformer architecture (as shown in Figure 1(a)), consequently weakening the upper-layer semantic learning that can be crucial for end tasks. Second, these tree Transformer methods encode either standalone constituency or dependency structure, while different tasks can depend on varying types of structural knowledge. The constituent and dependency representation for syntactic structure share underlying linguistic characteristics, while the former focuses on disclosing phrasal continuity and the latter aims at indicating dependency relations among elements. For example, semantic parsing tasks are more dependent on the dependency features (Rabinovich et al., 2017; Xia et al., 2019), while constituency information is much needed for sentiment classification (Socher et al., 2013).

In this paper, we aim to retrofit structure-aware

Transformer LM for facilitating end tasks. • On the one hand, we propose a structure learning module for Transformer LM, meanwhile exploiting syntactic distance as the measurement for encoding both the phrasal constituency and the dependency connection. • On the other hand, as illustrated in Figure 1, to better coordinate the structural learning and semantic learning, we employ a middle-layer structural training strategy to integrate syntactic structures to the main language modeling task under multi-task scheme, which encourages the induction of structural information to take place at most suitable layer. • Last but not least, we consider performing structure-aware fine-tuning with end-task training, allowing learned syntactic knowledge in accordance most with the end task needs.

We conduct experiments on language modeling and a wide range of NLP tasks. Results show that the structure-aware Transformer retrofitted via our proposed middle-layer training strategy achieves better language perplexity, meanwhile inducing high-quality syntactic phrases. Besides, the LM after structure-aware fine-tuning can give significantly improved performance for various end tasks, including semantic-dependent and syntactic-dependent tasks. We also find that supervised structured pre-training brings more benefits to syntactic-dependent tasks, while the unsupervised LM pre-training brings more benefits to semantic-dependent tasks. Further experimental results on unsupervised structure induction demonstrate that different NLP tasks rely on varying types of structure knowledge as well as distinct granularity of phrases, and our retrofitting method can help to induce structure phrases that are most adapted to the needs of end tasks.

2 Related Work

Contextual language modeling. Contextual language models pre-trained on a large-scale corpus have witnessed significant advances (Peters et al., 2018; Radford et al., 2018; Howard and Ruder, 2018; Yang et al., 2019; Devlin et al., 2019; Dai et al., 2019). In contrast to the traditional static and context-independent word embedding, contextual language models can strengthen word representations by dynamically encoding the contextual sentences for each word during pre-training. By further fine-tuning with end tasks, the contextualized word representation from language models can help to give the most task-related context-sensitive features (Peters et al., 2018). In this work, we follow the line of Transformer-based (Vaswani et al., 2017) LM (e.g., BERT), considering its prominence.

Structure induction. The idea of introducing tree structures into deep models for structure-aware language modeling has long been explored by supervised structure learning, which generally relies on annotated parse trees during training and maximizes the joint likelihood of sentence-tree pairs (Socher et al., 2010, 2013; Tai et al., 2015; Yazdani and Henderson, 2015; Dyer et al., 2016; Alvarez-Melis and Jaakkola, 2017; Aharoni and Goldberg, 2017; Eriguchi et al., 2017; Wang et al., 2018; Gū et al., 2018).

There has been much attention paid to unsupervised grammar induction task (Williams et al., 2017; Shen et al., 2018a,b; Kuncoro et al., 2018; Kim et al., 2019a; Luo et al., 2019; Drozdov et al., 2019; Kim et al., 2019b). For example, PRPN (Shen et al., 2018a) computes the syntactic distance of word pairs. On-LSTM (Shen et al., 2018b) allows hidden neurons to learn long-term or short-term information by a gate mechanism. URNNG (Kim et al., 2019b) applies amortized variational inference, encouraging the decoder to generate reasonable tree structures. DIORA (Drozdov et al., 2019) uses inside-outside dynamic programming to compose latent representations from all possible binary trees. PCFG (Kim et al., 2019a) achieves grammar induction by probabilistic context-free grammar. Unlike these recurrent network based structure-aware LM, our work focuses on structure learning for a deep Transformer LM.

Structure-aware Transformer language model. Some efforts have been paid for the Transformer-based pre-trained language models (e.g. BERT) by visualizing the attention (Vig and Belinkov, 2019; Kovaleva et al., 2019; Hao et al., 2019) or probing tasks (Jawahar et al., 2019; Goldberg, 2019). They find that the latent language structure knowledge is best retained at the middle-layer in BERT (Vig and Belinkov, 2019; Jawahar et al., 2019; Goldberg, 2019). Ahmed et al. (2019) employ a decomposable attention mechanism for recursively learn the tree structure for Transformer. Wang et al. (2019) integrate tree structures into Transformer via constituency-attention. However, these Transformer LMs suffer from the full-scale structural training and monotonous types of the structure, limiting the performance of structure LMs for end

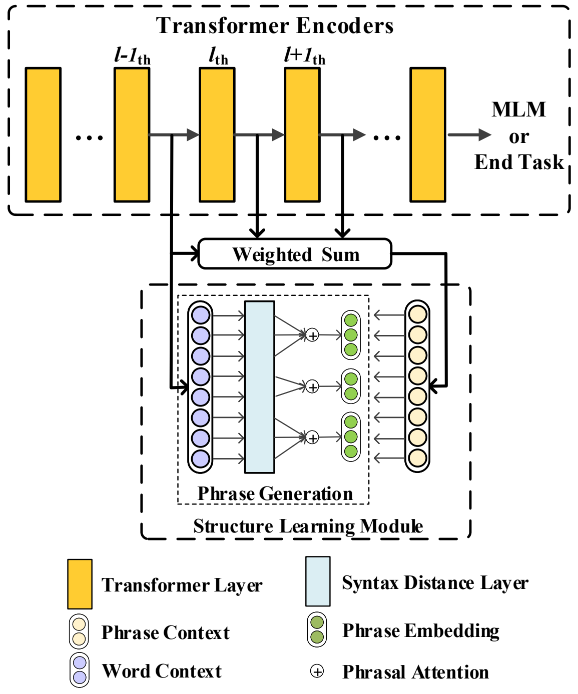

Figure 2: Overall framework of the retrofitted structure-aware Transformer language model.

tasks. Our work is partially inspired by Shen et al. (2018a) and Luo et al. (2019) on employing syntax distance measurements, while their works focus on the syntax learning by recurrent LMs.

3 Model

The proposed structure-aware Transformer language model mainly consists of two components: the Transformer encoders and structure learning module, which are illustrated in Figure 2.

3.1 Transformer Encoder

The language model is built based on N-layer Transformer blocks. One Transformer layer applies multi-head self-attention in combination with a feedforward network, layer normalization and residual connections. Specifically, the attention weights are computed in parallel via:

$$\begin{aligned} \boldsymbol{E} &= \text{softmax}(\frac{\boldsymbol{QK}^T}{\sqrt{d}})\boldsymbol{V} \\ &= \text{softmax}(\frac{(t\cdot\boldsymbol{x})\quad(t\cdot\boldsymbol{x})}{\sqrt{d}})(t\cdot\boldsymbol{x}) \end{aligned} \tag{1}$$

where Q (query), K (key) and V (value) in multi-head setting process the input $\boldsymbol{x} = \{x_1, \cdots, x_n\}$ t times.

Given an input sentence $\boldsymbol{x}$, the output contextual representation of the l-th layer Transformer block can be formulated as:

$$\begin{aligned} \{\boldsymbol{h}_1^l, \cdots, \boldsymbol{h}_n^l\} &= \text{Trm}(\{x_1, \cdots, x_n\}) \\ &= \eta(\Phi(\eta(\boldsymbol{E}^l)) + \boldsymbol{E}^l) \end{aligned} \tag{2}$$

where η is the layer normalization operation and Φ is a feedforward network. In this work, the output contextual representation $\boldsymbol{h}^l = \{\boldsymbol{h}_1^l, \cdots, \boldsymbol{h}_n^l\}$ of the middle layers can be used to learn the structure y_{struc}, and the one at the final layer will be used for language modeling or end task training y_{task}.

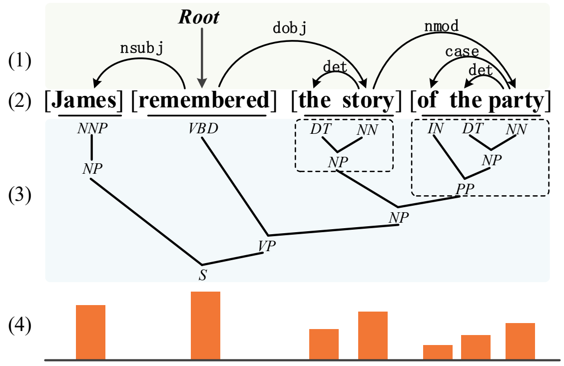

Figure 3: Simultaneously measuring dependency relations (1) and phrasal constituency (3) based on the example sentence (2) by employing syntax distance (4).

3.2 Unsupervised Syntax Learning Module

The structure learning module is responsible for unsupervisedly generating phrases, providing structure-aware language modeling to the host LM.

Syntactic context. We extract the context representations from Transformer middle layers for the next syntax learning. We optimize the structure-aware Transformer LM by forcing the structure knowledge injection focused at middle three layers: $(l-1)_{\text{th}}$, l_{th}, and $(l+1)_{\text{th}}$. Note that although we only make structural attending to the selected layers, structure learning can enhance lower layers via back-propagation.

Specifically, we take the first of the chosen three-layer as the word context $\boldsymbol{C}^{\Psi} = \boldsymbol{h}^{l-1}$. For the phrasal context $\boldsymbol{C}^{\Omega} = \{\boldsymbol{c}_1^{\Omega}, \cdots, \boldsymbol{c}_n^{\Omega}\}$, we make use of contextual representations from the three chosen layers by weighted sum:

$$\boldsymbol{C}^{\Omega} = \alpha_{l-1}\cdot\boldsymbol{h}^{l-1} + \alpha_l\cdot\boldsymbol{h}^l + \alpha_{l+1}\cdot\boldsymbol{h}^{l+1} \tag{3}$$

where α_{l-1}, α_l and α_{l+1} are sum-to-one trainable coefficients. Rich syntactic representations are expected to be captured in $\boldsymbol{C}^{\Omega}$ by LM.

Structure measuring. In this study, we reach the goal of measuring syntax by employing ***syntax distance***. The general concept of syntax distance d_i can be reckoned as a metric (i.e., distance) from a certain word x_i to the root node within the dependency tree (Shen et al., 2018a). For instance in Figure 3, the head word '*remembered*' x_i and its dependent word '*James*' x_j follow $d_i < d_j$. While in this work, to maintain both the dependency and phrasal constituents simultaneously, we add additional constraints on words and phrases. Given two words x_i and x_j ($0 \leq i < j \leq n$) in one phrase, we define $d_i < d_j$. This can be demonstrated by the word pair '*the*' and '*story*'. While if they are in different phrases[1], e.g., S_u and S_v, the corresponding inner-phrasal head words follow d_i (in S_u) $> d_j$ (in S_V), e.g., '*story*' and '*party*'.

In the structure learning module, we first compute the syntactic distances $\boldsymbol{d} = \{d_1, \cdots, d_n\}$ for each word based on the word context via a convolutional network:

$$\{d_1, \cdots, d_n\} = \Phi(\text{CNN}(\{\boldsymbol{c}_1^{\Psi}, \cdots, \boldsymbol{c}_n^{\Psi}\})) \quad (4)$$

where d_i is a scalar, and Φ is for linearization. With such syntactic distance, we expect both the dependency as well as constituency syntax can be well captured in LM.

Syntactic phrase generating. Considering the word x_i opening an induced phrase $S_m = [x_i, \cdots, x_{i+w}]$ in a sentence, where w is the phrase width, we need to decide the probability $p^*(x_j)$ that a word x_j (j=$i + w + 1$) (i.e., the first word outside phrase S_m) belongs to S_m:

$$p^*(x_j) = \prod_{k=i}^{i+w} \text{sigmoid}(d_j - d_k). \quad (5)$$

We set the initial width $w = 1$, if $p^*(x_j)$ is above the window threshold λ, x_j should be considered inside the phrase; otherwise, the phrase S_m should be closed and restart at x_j. We incrementally conduct such phrasal searching procedure to segment all the phrases in a sentence. Given an induced phrase $S_m = [x_i, \cdots, x_{i+w}]$, we obtain its embedding $\boldsymbol{s}_m$ via a phrasal attention:

$$u_i = \text{softmax}(d_i \cdot p^*(x_i)) \quad (6)$$

$$\boldsymbol{s}_m = \sum_{i}^{i+w} u_i \cdot \boldsymbol{c}_i^{\Psi} \quad (7)$$

4 Structure-aware Learning

Multi-task training for language modeling and structure induction. Different from traditional language models, a Transformer-based LM employs the masked language modeling (MLM), which can capture larger contexts. Likewise, we predict a masked word using the corresponding context representation at the top layer:

$$p^{\text{W}}(y_i|\boldsymbol{x}) = \text{softmax}(\boldsymbol{c_i}|\boldsymbol{x}) \quad (8)$$

$$\mathcal{L}_{\text{W}} = \sum_{i}^{k} \log p^{\text{W}}(y_i|\boldsymbol{x}) \quad (9)$$

On the other hand, the purpose on unsupervised syntactic induction is to encourage the model to induce $\boldsymbol{s}_m$ that is most likely entailed by the phrasal context $\boldsymbol{c}_i^{\Omega}$. The behind logic lies is that, if the initial Transformer LM can capture linguistic syntax knowledge, then after iterations of learning with the structure learning module, the induced structure can be greatly amplified and enhanced (Luo et al., 2019). We thus define the following probability:

$$p^{\text{G}}(\boldsymbol{s}_m|\boldsymbol{c}_i^{\Omega}) = \frac{1}{1 + \exp(-\boldsymbol{s}_m^T \cdot \boldsymbol{c}_i^{\Omega})} \quad (10)$$

Additionally, to enhance the syntax learning, we employ negative sampling:

$$\mathcal{L}_{\text{Neg}} = \frac{1}{n} \sum_{j}^{n} p^{\text{G}}(\hat{\boldsymbol{s}}_j^T|\boldsymbol{c}_i^{\Omega}) \quad (11)$$

where $\hat{s}$ is a randomly selected negative phrase. The final objective for structure learning is:

$$\mathcal{L}_{\text{G}} = \sum_{i}^{K} (\sum_{m}^{\text{M}} (1 - p^{\text{G}}(\boldsymbol{s}_m|\boldsymbol{c}_i^{\Omega})) + \mathcal{L}_{\text{Neg}}) \quad (12)$$

We employ multi-task learning for simultaneously training our LM for both word prediction and structure induction. Thus, the overall target is to minimize the following multi-task loss objective:

$$\mathcal{L}_{\text{pre}} = \mathcal{L}_{\text{W}} + \gamma^{\text{pre}} \cdot \mathcal{L}_{\text{G}} \quad (13)$$

where γ^{pre} is a regulating coefficient.

Supervised syntax injection. Our default structure-aware LM unsupervisedly induces syntax at the pre-training stage, as elaborated above. Alternatively, in Eq. (7), if we leverage the gold (or apriori) syntax distance information for phrases, we can achieve supervised structure injection.

---

[1] Note that we cannot explicitly define the granularity (width) of every phrases in constituency tree, while instead it will be decided by the structure learning module in heuristics.

Unsupervised structure fine-tuning. We aim to improve the learnt structural information for better facilitating the end tasks. Therefore, during the fine-tuning stage of end tasks, we consider further making the structure learning module trainable:

$$\mathcal{L}_{\text{fine}} = \mathcal{L}_{\text{task}} + \gamma^{\text{fine}} \cdot \mathcal{L}_{\text{G}} \tag{14}$$

where $\mathcal{L}_{\text{task}}$ refers to the loss function of the end task, and γ^{fine} is a regulating coefficient. Note that to achieve the best structural fine-tuning, the supervised structure injection is unnecessary, and we do not allow supervised structure aggregation at the fine-tuning stage.

Our approach is model-agnostic as we realize the syntax induction via a standalone structure learning module, which is disentangled from a host LM. Thus the method can be applied to various Transformer-based LM architectures.

5 Experiments

5.1 Experimental Setups

We employ the same architecture as BERT base model[2], which is a 12-layer Transformer with 12 attention heads and 768 dimensional hidden size. To enrich our experiments, we also consider the Google pre-trained weights as the initialization. We use Adam as our optimizer with an initial learning rate in [8e-6, 1e-5, 2e-5, 3e-5], and a L2 weight decay of 0.01. The batch size is selected in [16,24,32]. We set the initial values of coefficients α_{l-1}, α_l and α_{l+1} as 0.35, 0.4 and 0.25, respectively. The pre-training coefficient γ^{pre} is set as 0.5, and the fine-tuning one γ^{fine} as 0.23. These values give the best effects in our development experiments. Our implementation is based on the PyTroch library[3].

Besides, for supervised structure learning in our experiments, we use the state-of-the-art BiAffine dependency parser (Dozat and Manning, 2017) to parse sentences for all the relevant datasets, and use the Self-Attentive parser (Kitaev and Klein, 2018) to obtain the constituency structure. Being trained on the English Penn Treebank (PTB) corpus (Marcus et al., 1993), the dependency parser has 95.2% UAS and 93.4% LAS, and the constituency parser has 92.6% F1 score. With the auto-parsed annotations, we can calculate the syntax distances (substitute the ones in Eq. 4) and obtain the corresponding phrasal embeddings (in Eq. 7).

Figure 4: Development experiments on syntactic probing tasks at varying Transformer layer.

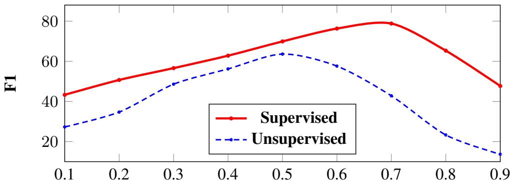

Figure 5: Constituency parsing under different λ.

5.2 Development Experiments

Structural learning layers. We first validate at which layer of depths the structural-aware Transformer LM can achieve the best performance when integrating our retrofitting method. We thus design probing experiments, in which we consider following two syntactic tasks. 1) **Constituency phrase parsing** seeks to generate grammar phrases based on the PTB dataset and evaluate whether induced constituent spans also exist in the gold Treebank dataset. 2) **Dependency alignment** aims to compute the proportion of Transformer attention connecting tokens in a dependency relation (Vig and Belinkov, 2019):

$$\text{Score} = \frac{\sum_{x \in X} \sum_{i=1}^{x} \sum_{j=1}^{x} \alpha_{i,j}(x) \cdot \text{dep}(x_i, x_j)}{\sum_{x \in X} \sum_{i=1}^{x} \sum_{j=1}^{x} \alpha_{i,j}(x)} \tag{15}$$

where $\alpha_{i,j}(x)$ is the attention weight, and $\text{dep}(x_i, x_j)$ is an indicator function (1 if x_i and x_j are in a dependency relation and 0 otherwise). The experiments are based on English Wikipedia, following Vig and Belinkov (2019).

As shown in Figure 4, both the results on unsupervised and supervised phrase parsing are the best at layer 6. Also the attention aligns with dependency relations most strongly in the middle layers (5-6), consistent with findings from previous work (Tenney et al., 2019; Vig and Belinkov, 2019). Both two probing tasks indicate that our proposed middle-layer structure training is practical. We thus inject the structure in the structure learning module at the 6-th layer ($l = 6$).

Table 2: Performance on constituency parsing and language modeling.

Phrase generation threshold. We introduce a hyper-parameter λ as a threshold to decide whether a word belong to a given phrase during the phrasal generation step. We explore the best λ value based on the same parsing tasks. As shown in Figure 5, with $\lambda = 0.5$ for unsupervised induction and $\lambda = 0.7$ for supervised induction, the induced phrasal quality is the highest. Therefore we set such λ values for all the remaining experiments.

5.3 Structure-aware Language Modeling

We evaluate the effectiveness of our proposed retrofitted structure-aware LM after pre-training. We first compare the performance on language modeling[4]. From the results shown in Table 2, our retrofitted Transformer yields better language perplexity in both unsupervised (37.0) or supervised (29.2) manner. This proves that our middle-layer structure training strategy can effectively relieve negative mutual influence of structure learning on semantic learning, while inducing high-quality of structural phrases. We can also conclude that language models with more successful structural knowledge can better help to encode effective intrinsic language patterns, which is consistent with the prior studies (Kim et al., 2019b; Wang et al., 2019; Drozdov et al., 2019).

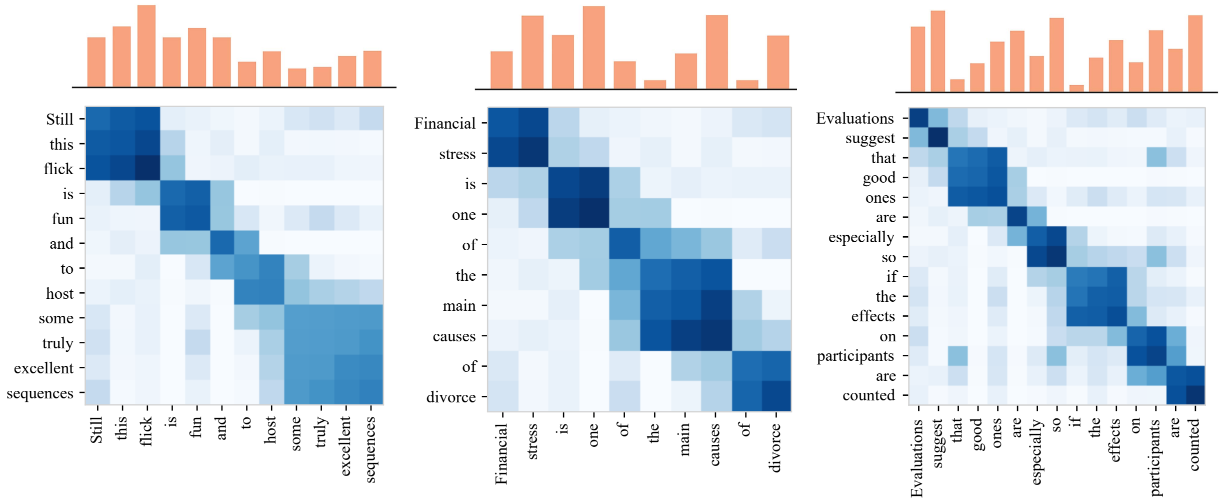
We also compare the constituency parsing with state-of-the-art structure-aware models, including **1) Recurrent-based models** described in §2: PRPN (Shen et al., 2018a), On-LSTM (Shen et al., 2018b), URNNG (Kim et al., 2019b), DIORA (Drozdov et al., 2019), PCFG (Kim et al., 2019a), and **2) Transformer based methods**: Tree+Trm (Wang et al., 2019), RvTrm (Ahmed et al., 2019), PI+TrmXL (Luo et al., 2019), and the BERT model initialized with rich weights. As shown in Table 2, all the structure-aware models can give good parsing results, compared with non-structured models. Our retrofitted Transformer LM gives the best performance (60.3% F1) in unsupervised induction. Combined with the supervised auto-labeled parses, it give the highest F1 score (68.8%).

5.4 Fine-tuning for End Tasks

We validate the effectiveness of our method for end tasks with structure-aware fine-tuning. All systems are first pre-trained for structure learning, and then fine-tuned with end task training. The evaluation is performed on eight tasks, involving

---

[4] Transformer can see its subsequent words bidirectionally, so we measure the perplexity on masked words. And we thus avoid directly comparing with the Recurrent-based LMs.



(a) SST

(b) Rel

(c) SRL

Figure 6: Visualization of attention heads (heatmap) and the corresponding syntax distances (bar chart).

syntactic tasks and semantic tasks. `TreeDepth` predicts the depth of the syntactic tree, `TopConst` tests the sequence of top level constituents in the syntax tree, and `Tense` detects the tense of the main-clause verb, while `SOMO` checks the sensitivity to random replacement of words, which are the standard probing tasks. We follow the same datasets and settings with previous work (Conneau et al., 2018; Jawahar et al., 2019).

Also we evaluate the semantic tasks including 1) `NER`, named entity recognition on CoNLL03 (Tjong Kim Sang and De Meulder, 2003), 2) `SST`, binary sentiment classification task on Standford sentiment treebank (Socher et al., 2013), 3) `Rel`, relation classification on Semeval10 (Hendrickx et al., 2010), and 4) `SRL`, semantic role labeling task on the CoNLL09 WSJ (Hajič et al., 2009). The performance is reported by the F1 score.

The results are summarized in Table 1. First, we find that structure-aware LMs bring improved performance for all the tasks, compared with the vanilla Transformer encoder. Second, the Transformer with our structural-aware fine-tuning achieves better results (70.74% on average) for all the end tasks, compared with the baseline tree Transformer LMs. This proves that our proposed middle-layer strategy best benefits the structural fine-tuning, compared with the full-layer structure training on baselines. Third, with supervised structure learning, significant improvements can be found across all tasks.

For the supervised setting, we replace the supervised syntax fusion in structure learning module with the auto-labeled syntactic dependency embedding and concatenate it with other input embeddings. The results are not as prominent as the supervised syntax fusion, which reflects the advantage of our proposed structure learning module. Besides, based on the task improvements from the retrofitted Transformer by our method, we can further infer that the supervised structure benefits more syntactic-dependent tasks, and the unsupervised structure benefits semantic-dependent tasks the most. Finally, the BERT model integrating with our method can give improved effects[5].

Table 3: Fine-grained parsing.

6 Analysis

6.1 Induced Phrase after Pre-training.

We take a further step, evaluating the fine-grained quality on phrasal structure induction after pre-training. Instead of checking whether the induced constituent spans are identical to the gold counterparts, we now consider measuring the deviation $PhrDev(\hat{y}, y) = \sqrt{\frac{1}{N}\sum_i[\Delta(\hat{y}_i, y_i) - \overline{\Delta}]^2}$,

---

[5] We note that the direct comparison with BERT model is not fair, because the large numbers of well pre-trained parameters can bring overwhelming advances.

where $\Delta(\hat{y}_i, y_i)$ is the phrasal editing distance between the induced phrase length and the gold length within a sentence. $\overline{\Delta}$ is the averaged editing distance. If all the predicted phrases are same with the ground truth, or all different from it, $PhrDev(\hat{y}, y) = 0$, which means that the phrases are induced with the maximum consistency, and vice versa. We make statistics for all the sentences in Table 3. Our method can unsupervisedly generate higher quality of structural phrases, while we can achieve the best injection of the constituency knowledge into LM by the supervised manner.

6.2 Fine-tuned Structures with End Tasks

Interpreting fine-tuned syntax. To interpret the fine-tuned structures, we empirically visualize the Transformer attention head from the chosen l-layer, and the syntax distances of the sentence. We exhibit three examples from `SST`, `Rel` and `SRL`, respectively, as shown in Figure 6. Overall, our method can help to induce clear structure of both dependency and constituency. While interestingly, different types of tasks rely on different granularity of phrase. Comparing the heat maps and syntax distances with each other, the induced phrasal constituency on `SST` are longer than that on `SRL`. This is because the sentiment classification task demands more phrasal composition features, while the SRL task requires more fine-grained phrases. In addition, we find that the syntax distances in `SRL` and `Rel` are higher in variance, compared with the ones on `SST`, Intuitively, the larger deviation of syntax distances in a sentence indicates the more demand to the interdependent information between elements, while the smaller deviation refers to phrasal constituency. This reveals that `SRL` and `Rel` rely more on the dependency syntax, while `SST` is more relevant to constituents, which is consistent with previous studies (Socher et al., 2013; Rabinovich et al., 2017; Xia et al., 2019; Fei et al., 2020).

Distributions of heterogeneous syntax for different tasks. Based on the above analysis, we further analyze the distributions of dependency and constituency structures after fine-tuning, in different tasks. Technically, we calculate the mean absolute differences of syntax distances between elements x_i and the sub-root node x_r in a sentence: $Diff = \frac{1}{N}\sum_i^N |d_i - d_r|$. We then linearly normalize them into [0,1] for all the sentences in the corpus of each task, and make statistics, as plotted in Figure 7. Intuitively, the larger the value is, the more interdependent to dependency syntax the task is, and otherwise, to constituency structure. Overall, distributions of dependency structures and phrasal constituents in fine-tuned LM vary among different tasks, verifying that different tasks depend on distinct types of structural knowledge. For example, `TreeDepth`, `Rel` and `SRL` are most supported by dependency structure, while `TopConst` and `SST` benefit from constituency the most. `SOMO` and `NER` can gain from both two types.

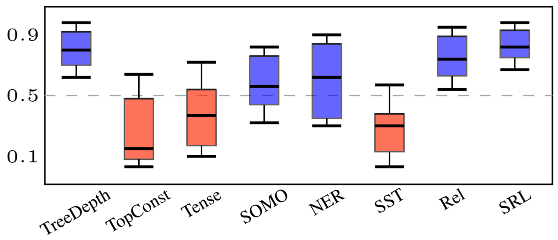

Figure 7: Distributions of dependency and constituency syntax in different tasks. Blue color indicates the predominance of dependency, while Red for constituency.

	SST		SRL	
	Ours+Trm	Tree+Trm	Ours+Trm	Tree+Trm
NP	0.48	0.45	0.37	0.53
VP	0.21	0.28	0.36	0.21
PP	0.08	0.14	0.17	0.06
ADJP	0.10	0.05	0.05	0.12
ADVP	0.07	0.02	0.03	0.02
Other	0.06	0.06	0.02	0.06
Avg.Len.	3.88	3.22	2.69	3.36

Table 4: Proportion of each type of induced phrase.

Phrase types. Finally, we explore the diversity of phrasal syntax required by two representative end tasks, `SST` and `SRL`. We first look into the statistical proportion for different types of induced phrases[6]. As shown in Table 4, our method tends to induce more task-relevant phrases, where the lengths of induced phrases are more variable to the task. Concretely, the fine-tuned structure-aware Transformer helps to generate more *NP* also with longer phrases for the `SST` task, and yield roughly equal numbers of *NP* and *VP* for `SRL` tasks with shorter phrases. This evidently gives rise to the better task performance. In contrast, the syntax phrases induced by the Tree+Trm model keep unvarying for `SST` (3.22) and `SRL` (3.36) tasks.

---

[6] Five main types are considered: noun phrase (*NP*), verb phrase (*VP*), prepositional phrase (*PP*), adjective phrase (*ADJP*) and adverb phrase (*ADVP*).

7 Conclusion

We presented a retrofitting method for structure-aware Transformer-based language model. We adopted the syntax distance to encode both the constituency and dependency structure. To relieve the conflict of structure learning and semantic learning in Transformer LM, we proposed a middle-layer structure learning strategy under a multi-tasks scheme. Results showed that structure-aware Transformer retrofitted via our proposed method achieved better language perplexity, inducing high-quality syntactic phrase. Furthermore, our LM after structure-aware fine-tuning gave significantly improved performance for both semantic-dependent and syntactic-dependent tasks, also yielding most task-related and interpretable syntactic structures.

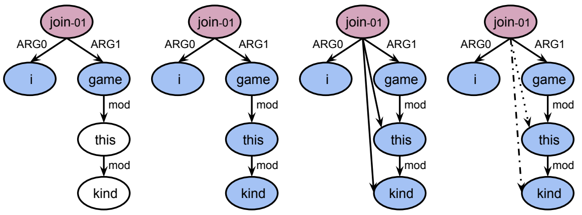
Abstract

AMR-to-text generation is used to transduce Abstract Meaning Representation structures (AMR) into text. A key challenge in this task is to efficiently learn effective graph representations. Previously, Graph Convolution Networks (GCNs) were used to encode input AMRs, however, vanilla GCNs are not able to capture non-local information and additionally, they follow a local (first-order) information aggregation scheme. To account for these issues, larger and deeper GCN models are required to capture more complex interactions. In this paper, we introduce a dynamic fusion mechanism, proposing Lightweight Dynamic Graph Convolutional Networks (LDGCNs) that capture richer non-local interactions by synthesizing higher order information from the input graphs. We further develop two novel parameter saving strategies based on the group graph convolutions and weight tied convolutions to reduce memory usage and model complexity. With the help of these strategies, we are able to train a model with fewer parameters while maintaining the model capacity. Experiments demonstrate that LDGCNs outperform state-of-the-art models on two benchmark datasets for AMR-to-text generation with significantly fewer parameters.

1 Introduction

Graph structures play a pivotal role in NLP because they are able to capture particularly rich structural information. For example, Figure 1 shows a directed, labeled Abstract Meaning Representation (AMR; Banarescu et al. 2013) graph, where each node denotes a semantic concept and each edge denotes a relation between such concepts. Within the realm of work on AMR, we focus in this paper on the problem of AMR-to-text generation, i.e. transducing AMR graphs into text that conveys the information in the AMR structure. A key challenge in this task is to efficiently learn useful representations of the AMR graphs. Early efforts (Pourdamghani et al., 2016; Konstas et al., 2017) neglect a significant part of the structural information in the input graph by linearizing it. Recently, Graph Neural Networks (GNNs) have been explored to better encode structural information for this task (Beck et al., 2018; Song et al., 2018; Damonte and Cohen, 2019; Ribeiro et al., 2019).



(a) Vanilla GCNs (b) LDGCNs (c) SANs (d) Structured SANs

Figure 1: The concept (*join-01*) in vanilla GCNs is that it only captures information from its immediate neighbors (first-order), while in LDGCNs it can integrate information from neighbors of different order (e.g., second-order and third-order). In SANs, the node collects information from all other nodes, while in structured SANs it is aware of its connected nodes in the original graph.

One type of such GNNs is Graph Convolutional Networks (GCNs; Kipf and Welling 2017). GCNs follow a local information aggregation scheme, iteratively updating the representations of nodes based on their immediate (first-order) neighbors. Intuitively, stacking more convolutional layers in GCNs helps capture more complex interactions (Xu et al., 2018; Guo et al., 2019b). However, prior efforts (Zhu et al., 2019; Cai and Lam, 2020; Wang et al., 2020) have shown that the locality property of existing GCNs precludes efficient non-local information propagation. Abu-El-Haija et al.

(2019) further proved that vanilla GCNs are unable to capture feature differences among neighbors from different orders no matter how many layers are stacked. Therefore, Self-Attention Networks (SANs; Vaswani et al. 2017) have been explored as an alternative to capture global dependencies. As shown in Figure 1 (c), SANs associate each node with other nodes such that we model interactions between any two nodes in the graph. Still, this approach ignores the structure of the original graph. Zhu et al. (2019) and Cai and Lam (2020) propose structured SANs that incorporate additional neural components to encode the structural information of the input graph.

Convolutional operations, however, are more computationally efficient than self-attention operations because the computation of attention weights scales quadratically while convolutions scale linearly with respect to the input length (Wu et al., 2019). Therefore, it is worthwhile to explore the possibility of models based on graph convolutions. One potential approach that has been considered is to incorporate information from higher order neighbors, which helps to facilitate non-local information aggregation for node classification (Abu-El-Haija et al., 2018, 2019; Morris et al., 2019). However, simple concatenation of different order representations may not be able to model complex interactions in semantics for text generation (Luan et al., 2019).

We propose to better integrate high-order information, by introducing a novel dynamic fusion mechanism and propose the Lightweight, Dynamic Graph Convolutional Networks (LDGCNs). As shown in Figure 1 (b), nodes in the LDGCN model are able to integrate information from first to third-order neighbors. With the help of the dynamic mechanism, LDGCNs can effectively synthesize information from different orders to model complex interactions in the AMR graph for text generation. Also, LDGCNs require no additional computational overhead, in contrast to vanilla GCN models. We further develop two novel weight sharing strategies based on the group graph convolutions and weight tied convolutions. These strategies allow the LDGCN model to reduce memory usage and model complexity.

Experiments on AMR-to-text generation show that LDGCNs outperform best reported GCNs and SANs trained on LDC2015E86 and LDC2017T10 with significantly fewer parameters. On the large-scale semi-supervised setting, our model is also consistently better than others, showing the effectiveness of the model on a large training set. We release our code and pretrained models at `https://github.com/yanzhang92/LDGCNs`.[1]

2 Background

Graph Convolutional Networks Our LDGCN model is closely related to GCNs (Kipf and Welling, 2017) which restrict filters to operate on a first-order neighborhood. Given an AMR graph $\mathcal{G}$ with n concepts (nodes), GCNs associate each concept v with a feature vector $\mathbf{h}_v \in \mathbb{R}^d$, where d is the feature dimension. $\mathcal{G}$ can be represented by concatenating features of all the concepts, i.e., $\mathbf{H}$=$[\mathbf{h}_{v_1}, ..., \mathbf{h}_{v_n}]$. Graph convolutions at l-th layer can be defined as:

$$\mathbf{H}_{l+1} = \phi(\mathbf{A}\mathbf{H}_l\mathbf{W}_l + \mathbf{b}_l), \tag{1}$$

where $\mathbf{H}_l$ is hidden representations of the l-th layer. $\mathbf{W}_l$ and $\mathbf{b}_l$ are trainable model parameters for the l-th layer, ϕ is an activation function. $\mathbf{A}$ is the adjacency matrix, $\mathbf{A}_{uv}$=1 if there exists a relation (edge) that goes from concept u to concept v.

Self-Attention Networks Unlike GCNs, SANs (Vaswani et al., 2017) capture global interactions by connecting each concept to all other concepts. Intuitively, the attention matrix can be treated as the adjacency matrix of a fully-connected graph. Formally, SANs take a sequence of representations of n nodes $\mathbf{H}$=$[\mathbf{h}_{v_1}, ..., \mathbf{h}_{v_n}]$ as the input. Attention score $\mathbf{A}_{uv}$ between the concept pair $(u$,$v)$ is:

$$\begin{aligned}\mathbf{A}_{uv} &= f(\mathbf{h}_u, \mathbf{h}_v)\\ &= \mathrm{softmax}(\frac{(\mathbf{h}_u\mathbf{W}^Q)(\mathbf{h}_v\mathbf{W}^K)^T}{\sqrt{d}})\end{aligned} \tag{2}$$

where $\mathbf{W}^Q$ and $\mathbf{W}^K$ are projection parameters. The adjacency matrix $\mathbf{A}$ in GCNs is given by the input AMR graph, while in SANs $\mathbf{A}$ is computed based on $\mathbf{H}$, which neglects the structural information of the input AMR. The number of operations required by graph convolutions scales is found linearly in the input length, whereas they are quadratic for SANs.

Structured SANs Zhu et al. (2019) and Cai and Lam (2020) extend SAN s by incorporating the relation $\mathbf{r}_{uv}$ between node u and node v in the

---

[1] Our implementation is based on MXNET (Chen et al., 2015) and the Sockeye toolkit (Felix et al., 2017).

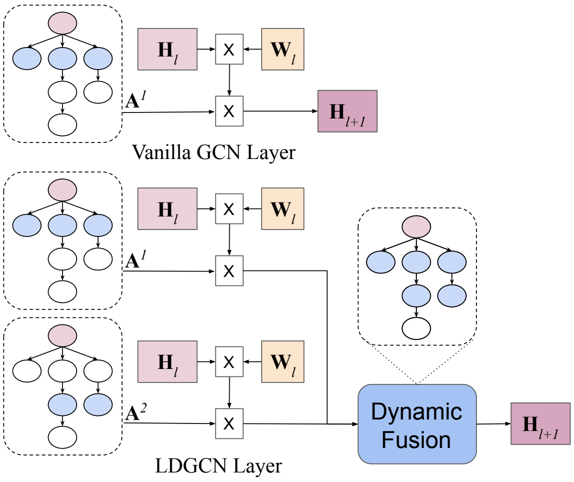

Figure 2: Comparison between vanilla GCNs and LDGCNs. $\mathbf{H}_l$ denotes the representation of l-th layer. $\mathbf{W}_l$ denotes the trainable weights and × denotes matrix multiplication. Vanilla GCNs take the 1st-order adjacency matrix $\mathbf{A}^1$ as the input, which only captures information from one-hop neighbors. LDGCNs take k number of k-order adjacency matrix $\mathbf{A}^k$ as inputs, $\mathbf{W}_l$ is shared for all $\mathbf{A}^k$. k is set to 2 here for simplification. A dynamic fusion mechanism is applied to integrate the information from 1- to k-hop neighbors.

original graph such that the model is aware of the input structure when computing attention scores:

$$\mathbf{A}_{uv} = g(\mathbf{h}_u, \mathbf{h}_v, \mathbf{r}_{uv}) \tag{3}$$

where $\mathbf{r}_{uv}$ is obtained based on the shortest relation path between the concept pair (u, v) in the graph. For example, the shortest relation path between (*join-01*, *this*) in Figure 1 (d) is [ARG1, mod]. Formally, the path between concept u and v is represented as s_{uv}=$[e(u, k_1), e(k_1, k_2), ..., e(k_m, v)]$, where e indicates the relation label between two concepts and $k_{1:m}$ are the relay nodes. We have $\mathbf{r}_{uv} = f(s_{uv})$ where f is a sequence encoder, and this can be performed with gated recurrent units (GRUs) or convolutional neural networks (CNNs).

3 Dynamic Fusion Mechanism

As discussed in Section 2, GCNs are generally more computationally efficient than structured SANs as their computation cost scales linearly and no additional relation encoders are required. However, the locality nature of GCNs precludes efficient non-local information propagation. To address this issue, we propose the dynamic fusion mechanism, which integrates higher order information for better non-local information aggregation. With the help of this mechanism, our model solely based on graph convolutions is able to outperform competitive structured SANs.

Inspired by Gated Linear Units (GLUs; Dauphin et al. 2016), which leverage gating mechanisms (Hochreiter and Schmidhuber, 1997) to dynamically control information flows in the convolutional neural networks, we propose dynamic fusion mechanism (DFM) to integrate information from different orders. DFM allows the model to automatically synthesize information from neighbors at varying degrees of hops away. Similar to GLUs, DFM retains non-linear capabilities of the layer while allowing the gradient to propagate through the linear unit without scaling. Based on this non-linear mixture procedure, DFM is able to control the information flows from a range of orders to specific nodes in the AMR graph. Formally, graph convolutions based on DFM are defined as:

$$\begin{aligned}\mathbf{H}_{l+1} =& (1 - \frac{1}{K-1}\sum_{1<k<K} \mathbf{G}_l^{(k)}) \odot \phi(\mathbf{A}\mathbf{H}_l\mathbf{W}_l + \mathbf{b}_l) \\ &+ \frac{1}{K-1}\sum_{1<k<K} \mathbf{G}_l^{(k)} \odot \phi(\mathbf{A}^k\mathbf{H}_l\mathbf{W}_l + \mathbf{b}_l).\end{aligned} \tag{4}$$

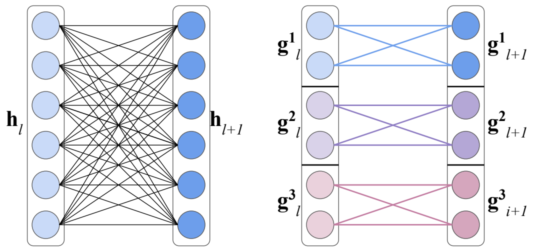
where $\mathbf{G}_l^{(k)}$ is a gating matrix conditioned on the k-th order adjacency matrix $\mathbf{A}^k$, namely:

$$\mathbf{G}_l^{(k)} = (1 - \lambda^k) \odot \sigma(\mathbf{A}^k\mathbf{H}_l\mathbf{W}_l + \mathbf{b}_l), \tag{5}$$

where $\odot$ denotes elementwise product, σ denotes the sigmoid function, $\lambda \in (0, 1)$ is a scalar, $K \geq 2$ is the highest order used for information aggregation, and $\mathbf{W}_l$ denotes trainable weights shared by different $\mathbf{A}^k$. Both λ and K are hyperparameters.

Computational Overhead In practice, there is no need to calculate or store $\mathbf{A}^k$. $\mathbf{A}^k\mathbf{H}_l$ is computed with right-to-left multiplication. Specifically, if k=3, we calculate $\mathbf{A}^3\mathbf{H}_l$ as $(\mathbf{A}(\mathbf{A}(\mathbf{A}\mathbf{H}_l)))$. Since we store $\mathbf{A}$ as a sparse matrix with m non-zero entries as vanilla GCNs, an efficient implementation of our layer takes $O(k_{max} \times m \times d)$ computational time, where k_{max} is the highest order used and d is the feature dimension of $\mathbf{H}_l$. Under the realistic assumptions of $k_{max} \ll m$ and $d \ll m$, running an l-layer model takes $O(lm)$ computational time. This matches the computational complexity of the vanilla GCNs. On the other hand, DFM does not require additional parameters as the weight matrix is shared over various orders.

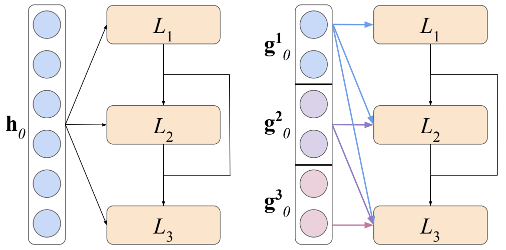
Deeper LDGCNs To further facilitate the non-local information aggregation, we stack several LDGCN layers. In order to stabilize the training, we introduce dense connections (Huang et al.,



Vanilla Graph Convolutions

Depthwise Graph Convolutions

Figure 3: Comparison between vanilla graph convolutions and depthwise graph convolutions. The input and output representation of the l-th layer $\mathbf{h}_l$ and $\mathbf{h}_{l+1}$ are partitioned into N=3 disjoint groups.



Densely Connected Graph Convolutions

Layerwise Graph Convolutions

Figure 4: Comparison between vanilla graph convolutions and layerwise graph convolutions. The input representation $\mathbf{h}_0$ is partitioned into M=3 disjoint groups.

2017; Guo et al., 2019b) into the LDGCN model. Mathematically, we define the input of the l-th layer $\hat{\mathbf{H}}_l$ as the concatenation of all node representations produced in layers $1, \cdots, l-1$:

$$\hat{\mathbf{H}}_l = [\mathbf{H}_0; \mathbf{H}_1; ...; \mathbf{H}_{l-1}]. \tag{6}$$

Accordingly, $\mathbf{H}_l$ in Eq. 4 is replaced by $\hat{\mathbf{H}}_l$.

$$\begin{aligned}\mathbf{H}_{l+1} =& (1 - \frac{1}{K-1} \sum_{1<k<K} \mathbf{G}_l^{(k)}) \odot \phi(\mathbf{A}\hat{\mathbf{H}}_l\mathbf{W}_l + \mathbf{b}_l) \\ &+ \frac{1}{K-1} \sum_{1<k<K} \mathbf{G}_l^{(k)} \odot \phi(\mathbf{A}^k\hat{\mathbf{H}}_l\mathbf{W}_l + \mathbf{b}_l).\end{aligned} \tag{7}$$

where $\mathbf{W}_l \in \mathbb{R}^{d_l \times d}$ and d_l=$d \times (l-1)$. The model size scales linearly as we increase the depth of the network.

4 Parameter Saving Strategies

Although we are able to train a very deep LDGCN model, the LDGCN model size increases sharply as we stack more layers, resulting in large model complexity. To maintain a better balance between parameter efficiency and model capacity, we develop two novel parameter saving strategies. We first reduce partial parameters in each layer based on group graph convolutions. Then we further share parameters across all layers based on weight tied convolutions. These strategies allow the LDGCN model to reduce memory usage and model complexity.

4.1 Group Graph Convolutions

Group convolutions have been used to build efficient networks for various computer vision tasks as they can better integrate feature maps (Xie et al., 2017; Li et al., 2019b) and have lower computational costs (Howard et al., 2017; Zhang et al., 2017) compared to vanilla convolutions. In order to reduce the model complexity in the deep LDGCN model, we extend group convolutions to GCNs by introducing group convolutions along two directions: depthwise and layerwise.

Depthwise Graph Convolutions: As discussed in Section 2, graph convolutions operate on the features of n nodes $\mathbf{H} \in \mathbb{R}^{n \times d}$. For simplicity, we assume n=1, the input and output representation of the l-th layer are $\mathbf{h}_l \in \mathbb{R}^{d_l}$ and $\mathbf{h}_{l+1} \in \mathbb{R}^{d_{l+1}}$, respectively. As shown in Figure 3, the size of the weight matrix $\mathbf{W}_l$ in a vanilla graph convolutions is $d_l \times d_{l+1}$. In depthwise graph convolutions, $\mathbf{h}_l$ is partitioned into N mutually exclusive groups $\{\mathbf{g}_l^1,...,\mathbf{g}_l^N\}$. The weight $\mathbf{W}_l$ of each layer is also partitioned into N mutually exclusive groups $\mathbf{W}_l^1$,...,$\mathbf{W}_l^N$. The dimension of each weight is $\frac{d_l}{N} \times \frac{d_{l+1}}{N}$. Finally, we obtain the output representation $\mathbf{h}_{l+1}$ by concatenating N groups of outputs $[\mathbf{g}_{l+1}^1;...;\mathbf{g}_{l+1}^N]$. Now the parameters of each layer can be reduced by a factor of N, to $\frac{d_l \times d_{l+1}}{N}$.

Layerwise Graph Convolutions: These group convolutions are built based on densely connected graph convolutions (Guo et al., 2019b). As shown in Figure 4, each layer takes the concatenation of outputs from all preceding layers as its input. For example, layer L_2 takes the concatenation of $[\mathbf{h}_0; \mathbf{h}_1]$ as its input. Guo et al. (2019b) further adopt a dimension shrinkage strategy. Assume $\mathbf{h}_0 \in \mathbb{R}^d$ and that the network has L layers. The dimension of output for each layer is set to $\frac{d}{L}$. Finally, we concatenate the output of L layers $[\mathbf{h}_1; ...; \mathbf{h}_L]$ to form the final representation $h_{final} \in \mathbb{R}^d$. Therefore, the size of weight matrix for l-th layer is $(d + \frac{d \times (l-1)}{L}) \times \frac{d}{L}$.

Notice that main computation cost originates in the computation of $\mathbf{h}_0$ as it has a large dimension and it is concatenated to the input of each layer. In layerwise graph convolutions however, we improve the parameter efficiency by dividing the input representation $\mathbf{h}_0$ into M groups $\{\mathbf{g}_0^1,...\mathbf{g}_0^M\}$, where M equals the total number of layers L. The first group $\mathbf{g}_0^1$ is fed to all L layers, and the second group $\mathbf{g}_0^2$ is fed to (L-1) layers, so on and so forth. Accordingly, the size of weight matrix for the l-th layer is $(\frac{d\times(2l-1)}{L}) \times \frac{d}{L}$.

Formally, we partition the input representations of n concept $\mathbf{H}_0 \in \mathbb{R}^{n\times d}$ to the first layer into M groups $\{\mathbf{G}_0^1, ..., \mathbf{G}_0^M\}$, where the size of each group is $n \times \frac{d}{M}$. Accordingly, we modify the input of the l-th layer $\hat{\mathbf{H}}_l$ in Eq. 6 as:

$$\hat{\mathbf{H}}_l = [\mathbf{G}_0^1; ...; \mathbf{G}_0^M; \mathbf{H}_1; ...; \mathbf{H}_{l-1}] \tag{8}$$

In practice, we combine these two convolutions together to further reduce the model size. For example, assume the size of the input is d=360 and the number of layers is L=6. The size of the weight matrix for the first layer (l=1) is $(d + \frac{d\times(l-1)}{L}) \times \frac{d}{L}$=360 × 60. Assume we set N=3 for depthwise graph convolutions and M=6 for layerwise graph convolutions. We first use layerwise graph convolutions by dividing the input into 6 groups, where each one has the size $\frac{d}{M}$=60. Then we feed the first group to the first layer. Next we use depthwise graph convolutions to further split the input into 3 groups. We now have 3 weight matrices for the first layer, each one with the size $\frac{d\times(2l-1)}{M} \times \frac{d}{M\times N}$= 20 × 20. With the increase of the feature dimension d and the number of layer L, more prominent parameter efficiency can be observed.

4.2 Weight Tied Convolutions

We further adopt a more aggressive strategy where parameters are shared across all layers. This further significantly reduces the size of the model. Theoretically, weight tied networks can be unrolled to any depth, typically with improved feature abstractions as depth increases (Bai et al., 2019a). Recently, weight tied SANs were explored to regularize the training and help with generalization (Dehghani et al., 2019; Lan et al., 2020). Mathematically, Eq. 1 can be rewritten as:

$$\mathbf{H}_{l+1} = \phi(\mathbf{A}\hat{\mathbf{H}}_l\mathbf{W} + \mathbf{b}), \tag{9}$$

where $\mathbf{W}$ and $\mathbf{b}$ are shared parameters for all convolutional layers. To stabilize training, a gating mechanism was introduced to graph neural networks in order to build graph recurrent networks (Li et al., 2016; Song et al., 2018), where parameters are shared across states (time steps). However, the graph convolutional structure is very deep (e.g., 36 layers). Instead, we adopt a jumping connection (Xu et al., 2018), which forms the final representation $\mathbf{H}_{final}$ based on the output of all layers. This connection mechanism can be considered deep supervision (Lee et al., 2015; Bai et al., 2019b) for training deep convolutional neural networks. Formally, the $\mathbf{H}_{final}$ of LDGCNs which have L layer is obtained by: $\mathbf{H}_{final} = \mathcal{F}(\hat{\mathbf{H}}_L, ..., \hat{\mathbf{H}}_1)$, where $\mathcal{F}$ is a linear transformation.

5 Experiments

5.1 Setup

We evaluate our model on the LDC2015E86 (AMR1.0), LDC2017T10 (AMR2.0) and LDC2020T02 (AMR3.0) datasets, which have 16,833, 36,521 and 55,635 instances for training, respectively. Both AMR1.0 and AMR2.0 have 1,368 instances for development, and 1,371 instances for testing. AMR3.0 has 1,722 instances for development and 1,898 instances for testing. Following Zhu et al. (2019), we use byte pair encodings (Sennrich et al., 2016) to deal with rare words.

Following Guo et al. (2019b), we stack 4 LDGCN blocks as the encoder of our model. Each block consists of two sub-blocks where the bottom one contains 6 layers and the top one contains 3 layers. The hidden dimension of LDGCN model is 480. Other model hyperparameters are set as λ=0.7, K=2 for dynamic fusion mechanism, N=2 for depthwise graph convolutions and M=6 and 3 for layerwise graph convolutions for the bottom and top sub-blocks, respectively. For the decoder, we employ the same attention-based LSTM as in previous work (Beck et al., 2018; Guo et al., 2019b; Damonte and Cohen, 2019). Following Wang et al. (2020), we use a transformer as the decoder for large-scale evaluation. For fair comparisons, we use the same optimization and regularization strategies as in Guo et al. (2019b). All hyperparameters are tuned on the development set[2].

For evaluation, we report BLEU scores (Papineni et al., 2002), CHRF++ (Popovic, 2017) scores and METEOR scores (Denkowski and Lavie, 2014) with additional human evaluation results.

5.2 Main Results

We consider two kinds of baseline models: 1) models based on Recurrent Neural Networks (Konstas et al., 2017; Cao and Clark, 2019) and Graph Neural Networks (GNNs) (Song et al., 2018; Beck et al., 2018; Damonte and Cohen, 2019; Guo et al., 2019b; Ribeiro et al., 2019). These models use an attention-based LSTM decoder. 2) models based on SANs (Zhu et al., 2019) and structured SANs (Cai and Lam, 2020; Zhu et al., 2019; Wang et al., 2020). Specifically, Zhu et al. (2019) leverage additional SANs to incorporate the relational encoding whereas Cai and Lam (2020) use GRUs. Additional results of ensemble models are also included. The results are reported in Table 1. Our model has two variants based on different parameter saving strategies, including LDGCN_WT (weight tied) and LDGCN_GC (group convolutions), and both of them use the dynamic fusion mechanism (DFM).

LDGCN v.s. Structured SANs. Compared to state-of-the-art structured SANs (GT_SAN), the performance of LDGCN_GC is 1.1 and 1.8 BLEU points higher on AMR1.0 and AMR2.0, respectively. Moreover, LDGCN_GC requires only about a quarter of the number of parameters (12.9M vs 49.0M, and 13.6M vs 54.0M). Our more lightweight variant LDGCN_WT achieves better BLEU scores than GT_SAN on AMR2.0 while using only 1/5 of their model parameters. However, LDGCN_WT obtains lower scores on AMR1.0 than GT_SAN. We hypothesize that weight tied convolutions require more data to train as we observe severe oscillations when training the model on the small AMR1.0 dataset. The oscillation is reduced when we train it on the larger AMR2.0 dataset and the semi-supervised dataset.

LDGCN v.s. Other GNNs. Both LDGCN models significantly outperform GNN-based models. For example, LDGCN_GC surpasses DCGCN by 5.1 points on AMR1.0 and surpasses DualGraph by 5.7 points on AMR2.0. Moreover, the single LDGCN model achieves consistently better results than previous ensemble GNN-based models in BLEU, CHRF++ and METEOR scores. In particular, on AMR2.0, LDGCN_WT obtains 1.5 BLEU points higher than the DCGCN ensemble model, while requiring only about 1/8 of the number of parameters. We also evaluate our model on the latest AMR3.0 dataset. Results are shown in Table 3. LDGCN_WT and LDGCN_GC consistently outperform GNN-based models including DCGCN and GGNNs on this larger dataset. These results suggest that LDGCN can learn better representation more efficiently.

Large-scale Evaluation. We further evaluate LDGCNs on a large-scale dataset. Following Wang et al. (2020), we first use the additional data to pretrain the model, then finetune it on the gold data. Evaluation results are reported in Table.2. Using 0.5M data, LDGCN_WT outperforms all models including structured SANs with 2M additional data. These results show that our model is more effective in terms of using a larger dataset. Interestingly, LDGCN_WT consistently outperforms LDGCN_GC under this setting. Unlike training the model on AMR1.0, training LDGCN_WT on the large-scale dataset has fewer oscillations, which confirms our hypothesis that sufficient data acts as a regularizer to stabilize the training process of weight tied models.

5.3 Development Experiments

We conduct an ablation study to demonstrate how dynamic fusion mechanism and parameter saving strategies are beneficial to the lightweight model with better performance based on development of experimental results on AMR1.0. Results are shown in Table 4. DeepGCN is the model with dense connections (Huang et al., 2017; Guo et al., 2019b). DeepGCN+GC+DF and DeepGCN+WT+DF are essentially LDGCN_GC and LDGCN_WT models in Section 5.2, respectively.

Dynamic Fusion Mechanism. The performance of DeepGCN+DF is 1.1 BLEU points higher than DeepGCN, which demonstrates that our dynamic fusion mechanism is beneficial for graph encoding when applied alone. Adding the group graph convolutions strategies gives a BLEU score of 30.3, which is only 0.1 points lower than DeepGCN+DF. This result shows that the representation learning ability of the dynamic fusion mechanism is robust against parameter sharing and reduction. We also observe that the mechanism helps to alleviate oscillation when training the weight tied model. DeepGCN+WT+DF achieves better results than DeepGCN+WT, which is hard to converge when training it on the small AMR1.0 dataset.

Model	#Parameters	BLEU
DeepGCN	19.9M	29.3
DeepGCN+DF	19.9M	30.4
DeepGCN+GC	12.9M	29.0
DeepGCN+GC+DF (LDGCN_GC)	12.9M	30.3
DeepGCN+WT	10.6M	27.4
DeepGCN+WT+DF (LDGCN_WT)	10.6M	28.3

Table 4: Comparisons between baselines. +DF denotes dynamic fusion mechanism. +WT and +GC refer to weight tied and group convolutions, respectively.

Model	Inference Speed
Transformer	1.00x
DeepGCN	1.21x
LDGCN_WT	1.22x
LDGCN_GC	1.17x

Table 5: Speed comparisons between baselines. For inference speed, the higher the better. Implementations are based on MXNet (Chen et al., 2015) and the Sockeye neural machine translation toolkit (Felix et al., 2017). Results on speed are based on beam size 10, batch size 30 on an NVIDIA RTX 1080 GPU.

Parameter Saving Strategy. Table 4 demonstrates that although the performance of DeepGCN+GC is only 0.3 BLEU points lower than that of DeepGCN, DeepGCN+GC only requires 65% of the number of parameters of DeepGCN. Furthermore, by introducing the dynamic fusion mechanism, the performance of DeepGCN+GC is improved greatly and is in fact on par with DeepGCN. Also, DeepGCN+GC+DF does not rely on any kind of self-attention layers, hence, its number of parameters is much smaller than that of graph transformers, i.e., DeepGCN+GC+DF only needs $1/4$ to $1/3$ the number of parameters of graph transformers, as shown in Table 1. On the other hand, DeepGCN+WT is more efficient than DeepGCN+GC. As shown in Table 2, with an increase in training data, more prominent parameter efficiency can be observed.

Time Cost Analysis. As shown in the Table 5, all three GCN-based models outperform the SAN-based model in terms of speed because the computation of attention weights scales quadratically while convolutions scale linearly with respect to the input graph size. LDGCN_GC is slightly slower

Model	Similarity	Readability
DualGraph (Ribeiro et al., 2019)	65.07	68.78
GT_SAN (Zhu et al., 2019)	69.63	72.23
DeepGCN	68.91	71.45
LDGCN_GC	**71.92**	**74.16**

Table 6: Human evaluation. We also perform significance tests by following (Ribeiro et al., 2019). Results are statistically significant with $p < 0.05$.

than the other two models, since it requires additional tensor split operations. We believe that state-of-the-art structured SANs are also strictly slower than vanilla SANs, as they require additional neural components, such as GRUs, to encode structural information in the AMR graph. In summary, our model not only has better parameter efficiency, but also lower time costs.

5.4 Human Evaluation

We further assess the quality of the generated sentences with human evaluation. Following Ribeiro et al. (2019), two evaluation criteria are used: (i) meaning similarity: how close in meaning the generated text is to the gold sentence; (ii) readability: how well the generated sentence reads. We randomly select 100 sentences generated by 4 models. 30 human subjects rate the sentences on a 0-100 rating scale. The evaluation is conducted separately and subjects were first given brief instructions explaining the criteria of assessment. For each sentence, we collect scores from 5 subjects and average them. Models are ranked according to the mean of sentence-level scores. Also, we apply a quality control step filtering subjects who do not score some faked and known sentences properly.

As shown in Table 6, LDGCN_GC has better human rankings in terms of both meaning similarity and readability than the state-of-the art GNN-based (DualGraph) and SAN-based model (GT_SAN). DeepGCN without dynamic fusion mechanism obtains lower scores than GT_SAN, which further confirms that synthesizing higher order information helps in learning better graph representations.

5.5 Additional Analysis

To further reveal the source of performance gains, we perform additional analysis based on the characteristics of AMR graphs, i.e., graph size and graph reentrancy (Damonte and Cohen, 2019; Damonte et al., 2020). All experiments are conducted on the AMR2.0 test set and CHRF++ scores are reported.

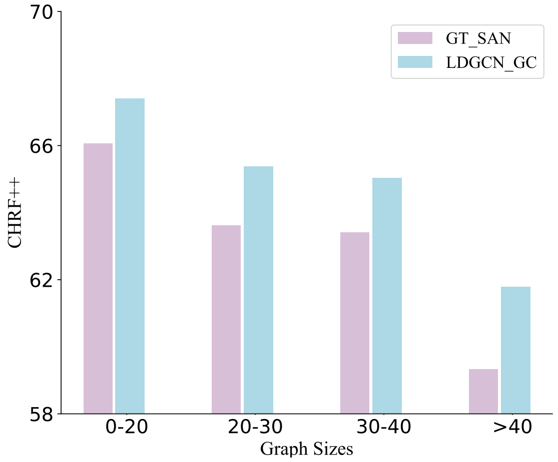

Figure 5: Performance against graph sizes.

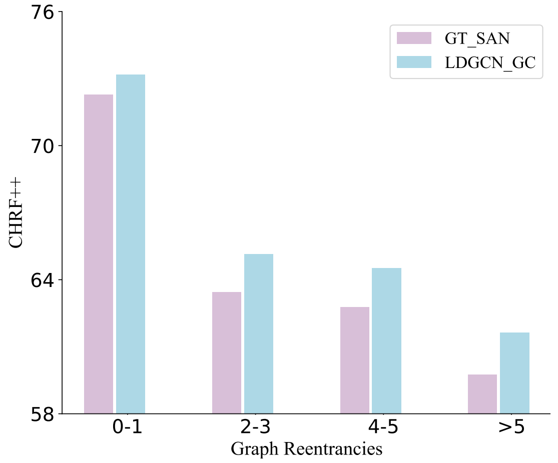

Figure 6: Performance against graph re-entrancies.

Graph Size. As shown in Figure 5, the size of AMR graphs is partitioned into four categories ((0, 20], (20, 30], (30, 40], > 40), Overall, LDGCN_GC outperforms the best-reported GT_SAN model across all graph sizes, and the performance gap becomes more profound with the increase of graph sizes. Although both models have sharp performance degradation for extremely large graphs (> 40), the performance of LDGCN_GC is more stable. Such a result suggests that our model can better deal with large graphs with more complicated structures.

Graph re-entrancies. Reentrancies describe the co-references and control structures in AMR graphs. A graph is considered more complex if it contains more re-entrancies. In Figure 6, we show how the LDGCN_GC and GT_SAN generalize to different scales of reentrancies. Again, LDGCN_GC consistently outperforms GT_SAN and the performance gap becomes noticeably wider when the number of re-entrancies increases. These results suggest that our model can better model the

LDGCN_GC: trust me . better to get these things as early as possible , rather than letting them even make worse .

Table 7: An example of AMR graph and generated sentences by different models.

complex dependencies in AMR graphs.

Case Study. Table 7 shows the generated sentence of an AMR graph from four models together with the gold reference. The phrase "trust me" is the beginning of the sentence. DualGraph fails to decode it. On the other hand, GT_SAN successfully generates the second half of the sentence, i.e., "rather than let them get even worse", but it fails to capture the meaning of word "early" in its output, which is a critical part. DeepGCN parses both "early" and "get even worse" in the results. However, the readability of the generated sentence is not satisfactory. Compared to baselines, LDGCN is able to produce the best result, which has a correct starting phrase and captures the semantic meaning of critical words such as "early" and "get even worse" while also attaining good readability.

6 Related Work

Graph convolutional networks (Kipf and Welling, 2017) have been widely used as the structural encoder in various NLP applications including question answering (De Cao et al., 2019; Lin et al., 2019), semantic parsing (Bogin et al., 2019a,b) and relation extraction (Guo et al., 2019a, 2020).

Early efforts for AMR-to-text generation mainly include grammar-based models (Flanigan et al., 2016; Song et al., 2017) and sequence-based models (Pourdamghani et al., 2016; Konstas et al., 2017; Cao and Clark, 2019), discarding crucial structural information when linearising the input AMR graph. To solve that, various GNNs including graph recurrent networks (Song et al., 2018; Ribeiro et al., 2019) and graph convolutional networks (Damonte and Cohen, 2019; Guo et al., 2019b) have been used to encode the AMR structure. Though GNNs are able to operate directly on graphs, the locality nature of them precludes efficient information propagation (Abu-El-Haija et al., 2018, 2019; Luan et al., 2019). Larger and deeper models are required to model the complex non-local interactions (Xu et al., 2018; Li et al., 2019a). More recently, SAN-based models (Zhu et al., 2019; Cai and Lam, 2020; Wang et al., 2020) outperform GNN-based models as they are able to capture global dependencies. Unlike previous models, our local, yet efficient model, based solely on graph convolutions, outperforms competitive structured SANs while using a significantly smaller model.

7 Conclusion

In this paper, we propose LDGCNs for AMR-to-text generation. Compared with existing GCNs and SANs, LDGCNs maintain a better balance between parameter efficiency and model capacity. LDGCNs outperform state-of-the-art models on AMR-to-text generation. In future work, we would like to investigate methods to stabilize the training of weight tied models and apply our model on other tasks in Natural Language Generation.

If Beam Search is the Answer, What was the Question?

Abstract

Quite surprisingly, exact maximum a posteriori (MAP) decoding of neural language generators frequently leads to low-quality results (Stahlberg and Byrne, 2019). Rather, most state-of-the-art results on language generation tasks are attained using beam search despite its overwhelmingly high search error rate. This implies that the MAP objective alone does not express the properties we desire in text, which merits the question: if beam search is the answer, what was the question? We frame beam search as the exact solution to a different decoding objective in order to gain insights into *why* high probability under a model alone may not indicate adequacy. We find that beam search enforces *uniform information density* in text, a property motivated by cognitive science. We suggest a set of decoding objectives that explicitly enforce this property and find that exact decoding with these objectives alleviates the problems encountered when decoding poorly calibrated language generation models. Additionally, we analyze the text produced using various decoding strategies and see that, in our neural machine translation experiments, the extent to which this property is adhered to strongly correlates with BLEU. Our code is publicly available at `https://github.com/rycolab/uid-decoding`.

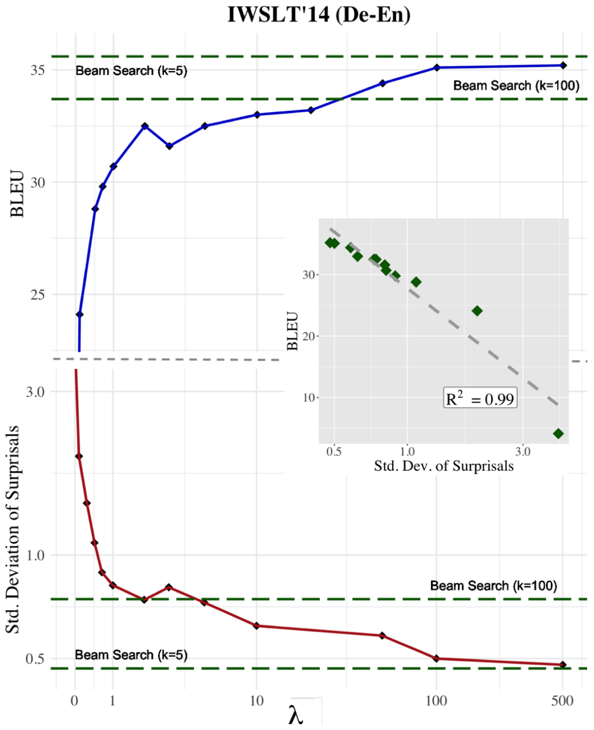

Figure 1: Average std. deviation σ of surprisals (per sentence) and corpus BLEU for translations generated using exact search over the MAP objective with a greedy regularizer (Eq. (11)) with varying degrees of λ. References for beam search ($k = 5$ and $k = 100$) are included. Sub-graph shows the explicit relationship between BLEU and σ. λ and σ axes are log-scaled.

1 Introduction

As a simple search heuristic, beam search has been used to decode models developed by the NLP community for decades. Indeed, it is noteworthy that beam search is one of the few NLP algorithms that has stood the test of time: It has remained a cornerstone of NLP systems since the 1970s (Reddy, 1977). As such, it became the natural choice for decoding neural probabilistic text generators—whose design makes evaluating the full search space impossible (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Vinyals and Le, 2015; Yin et al., 2016). While there is no formal guarantee that beam search will return—or even approximate—the highest-scoring candidate under a model, it has repeatedly proven its merit in practice (Serban et al., 2017; Edunov et al., 2018; Yang et al., 2019) and, thus, has largely been tolerated—even embraced—as NLP's go-to search heuristic. However, in the context of neural machine translation (NMT), a shocking empirical finding has emerged: Using beam search to decode sentences from neural text generators almost invariably leads to better text than using exact search (or beam search with a very large beam size). In fact, Stahlberg and Byrne (2019) report that exact search

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2173–2185,
November 16–20, 2020. ©2020 Association for Computational Linguistics

returns the empty string in $> 50\%$ of cases,[1] showing that the success of beam search does not stem from its ability to approximate exact decoding in practice, but rather due to a hidden inductive bias embedded in the algorithm. This inductive bias appears to be *paramount* for generating desirable text from neural probabilistic text generators. While several works explore this phenomenon (Murray and Chiang, 2018; Yang et al., 2018; Stahlberg and Byrne, 2019; Cohen and Beck, 2019), no one has yet hypothesized what beam search's hidden inductive bias may be. Our work fills this gap.

We analyze the **beam search blessing** by reverse engineering an objective that beam search returns the exact solution for. Specifically, we introduce a regularizer for the the standard (MAP) decoding objective for text generation models such that the exact solution to this regularized objective is equivalent to the solution found by beam search under the unmodified objective. Qualitative inspection reveals that our "beam search regularizer" has a clear connection to a theory in cognitive science—the **uniform information density** hypothesis (UID; Levy and Jaeger, 2007). The UID hypothesis states that—subject to the constraints of the grammar—humans prefer sentences that distribute information (in the sense of information theory) equally across the linguistic signal, e.g., a sentence. In other words, human-produced text, regardless of language, tends to have evenly distributed surprisal, formally defined in information theory as negative log-probability. This connection suggests beam search has an interpretation as exact decoding, but with a UID-promoting regularizer that encourages evenly distributed surprisal in generated text. This insight naturally leads to the development of several new regularizers that likewise enforce the UID property.

Empirically, we experiment with our novel regularizers in the decoding of NMT models. We first observe a close relationship between the standard deviation of surprisals—an operationalization of UID—and BLEU, which suggests that high-quality text does indeed exhibit the UID property. Additionally, we find that even with exact search, our regularized objective leads to performance similar to beam search on standard NMT benchmarks. Both of these observations are reflected in Fig. 1. Lastly, we see that our regularizers alleviate the text-quality degradation typically seen when decoding with larger beam sizes. We take all the above as evidence that our proposed explanation of beam search's inductive bias indeed elucidates *why* the algorithm performs so well as a search heuristic for language generation tasks.

2 Neural Probabilistic Text Generation

Probabilistic text generators define a probability distribution $p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$ over an output space of hypotheses $\mathcal{Y}$ (to be defined in Eq. (1)) conditioned on an input $\mathbf{x}$.[2] Modern generators are typically parameterized by a deep neural network—possibly recurrent—with a set of learned weights $\boldsymbol{\theta}$. In the case of text generation, the full set of possible hypotheses grows exponentially with the vocabulary size $|\mathcal{V}|$. We consider the set of complete hypotheses, i.e., valid outputs, as

$$\mathcal{Y} := \{\text{BOS} \circ \mathbf{v} \circ \text{EOS} \mid \mathbf{v} \in \mathcal{V}^*\} \tag{1}$$

where $\circ$ is string concatenation and $\mathcal{V}^*$ is the Kleene closure of $\mathcal{V}$. In words, valid hypotheses are text, e.g., sentences or phrases, padded with distinguished tokens, BOS and EOS. In this work, we consider models that are locally normalized, i.e., the model $p_{\boldsymbol{\theta}}$ is defined as the product of probability distributions:

$$p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x}) = \prod_{t=1}^{|\mathbf{y}|} p_{\boldsymbol{\theta}}(y_t \mid \mathbf{x}, \mathbf{y}_{<t}) \tag{2}$$

where each $p_{\boldsymbol{\theta}}(\cdot \mid \mathbf{x}, \mathbf{y}_{<t})$ is a distribution with support over $\bar{\mathcal{V}} := \mathcal{V} \cup \{\text{EOS}\}$ and $\mathbf{y}_{<1} = y_0 := \text{BOS}$.

The decoding objective for text generation aims to find the most-probable hypothesis among all candidate hypotheses, i.e. we aim to solve the following optimization problem:

$$\mathbf{y}^\star = \underset{\mathbf{y} \in \mathcal{Y}}{\operatorname{argmax}} \log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x}) \tag{3}$$

This is commonly known as maximum a posteriori (MAP) decoding since $p_{\boldsymbol{\theta}}$ is a probability model. While there exists a wealth of literature on decoding algorithms for statistical text generation models, e.g., phrase-based machine translation models, many of these methods cannot reasonably be used with neural models. Specifically, due to the non-Markovian structure of most neural text generators, dynamic-programming algorithms for searching

---

[1] This rate tends to decrease for larger models, although it is often still a considerable percentage.

[2] The input could be another sentence, a semantic structure or an image, to name a few examples.

over the exponentially large space are not efficient in this setting. Indeed, there are formal results that solving Eq. (3) with a recurrent neural network is NP-hard (Chen et al., 2018). Therefore decoding is performed almost exclusively with heuristic methods, such as beam search.

2.1 Beam Search

Beam search is a form of pruned breadth-first search where the breadth is limited to $k \in \mathbb{Z}_+$ (i.e., a maximum of k hypotheses) are expanded at each time step. We express beam search as the following recursion:

$$Y_0 = \{\text{BOS}\} \tag{4}$$

$$Y_t = \underset{\substack{Y' \subseteq \mathcal{B}_t, \\ |Y'|=k}}{\operatorname{argmax}} \log p_{\boldsymbol{\theta}}(Y' \mid \mathbf{x}) \tag{5}$$

where we define the candidate set at $t > 0$

$$\mathcal{B}_t = \Big\{ \mathbf{y}_{t\text{-}1} \circ y \mid y \in \bar{\mathcal{V}} \textbf{ and } \mathbf{y}_{t\text{-}1} \in Y_{t\text{-}1} \Big\} \tag{6}$$

For notational convenience, we define $\text{EOS} \circ \text{EOS} = \text{EOS}$. The above algorithm terminates after a fixed number of iterations[3] $n_{\max}$ and the set $Y_{n_{\max}}$ is returned. We overload $p_{\boldsymbol{\theta}}(\cdot \mid \mathbf{x})$ to take a set of hypotheses as an argument instead of just a single hypothesis. In this case, $p_{\boldsymbol{\theta}}(Y \mid \mathbf{x}) := \prod_{\mathbf{y} \in Y} p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$.[4] Using a similar schema, the argmax may also operate over a different objective, e.g., log-probabilities combined with various rewards or penaties, such as those discussed in §2.2.

Beam search has a long history in sequence transduction. For example, many of the decoding strategies used in statistical machine translation (SMT) systems were variants of beam search (Och et al., 1999; Koehn et al., 2003; Koehn, 2004). As language generation systems moved away from phrase-based statistical approaches and towards neural models, beam search remained the de-facto decoding algorithm (Sutskever et al., 2014; Vinyals and Le, 2015). However, it has been observed that when used as a decoding algorithm for neural text generation, beam search (for small beams) typically has a large percentage of search errors (Stahlberg and Byrne, 2019). Counterintuitively, it is widely known that increasing the beam size beyond 5 can hurt model performance in terms of downstream evaluation metrics (e.g., BLEU, ROUGE); while a number of prior works have referred to this phenomenon as a curse (Koehn and Knowles, 2017; Yang et al., 2018; Cohen and Beck, 2019), it should perhaps be seen as a *blessing*. Beam search typically generates well-formed and coherent text from probabilistic models, whose global optimum in many cases is the empty string, when they otherwise might fail to produce text at all. As we demonstrate in §4, this text also tends to be *human-like*. We will subsequently explore possible reasons as to why beam search leads to desirable text from models that are otherwise poorly calibrated, i.e., poor representations of the true distribution $p(\mathbf{y} \mid \mathbf{x})$ (Guo et al., 2017).

2.2 Alternative Decoding Objectives

When the MAP objective (Eq. (3)) is used for decoding neural text generators, the results are generally not satisfactory. Among other problems, the generated texts are often short and defaults to high-frequency words (Cho et al., 2014; Vinyals and Le, 2015; Shen et al., 2016). Methods such as length and coverage normalization (Jean et al., 2015; Tu et al., 2016; Murray and Chiang, 2018), which augment the MAP objective with an additive term or multiplicative factor, have been adopted to alleviate these issues. For example, two such forms of length[5] and coverage normalization use the following modified MAP objective respectively during decoding to produce higher-quality output:

$$\log p_{\boldsymbol{\theta}}(\mathbf{y} \,|\, \mathbf{x}) + \lambda |\mathbf{y}| \tag{7}$$

$$\log p_{\boldsymbol{\theta}}(\mathbf{y} \,|\, \mathbf{x}) + \lambda \sum_{i=1}^{|\mathbf{x}|} \log \min \left(1, \sum_{j=1}^{|\mathbf{y}|} \alpha_{ij} \right) \tag{8}$$

where $\lambda > 0$ is the (tunable) strength of the reward and α_{ij} is the attention weight (Bahdanau et al., 2015) from the j^{th} decoding step over the i^{th} input. Eq. (7) directly rewards longer outputs (He et al., 2016) while Eq. (8) aims to reward coverage of input words in a prediction using the attention mechanism of an encoder–decoder model as an oracle (Tu

---

[3] If all hypotheses in Y_t end in EOS for some $t < n_{\max}$, then we may terminate beam search early as it is then gauranteed that $Y_t = Y_{n_{\max}}$. We do not consider further early-stopping methods for beam search (Huang et al., 2017; Yang et al., 2018; Meister et al., 2020) as they generally should not affect the *quality* of the decoded set.

[4] There do exist objectives that take into account interactions between hypotheses in a set, e.g., diverse beam search (Vijayakumar et al., 2018), but we do not consider those here.

[5] The predominant form of length normalization divides (log) sequence probability by the length of the hypothesis rather than using an additive reward as in (He et al., 2016). We present results from the former in our experiments as we find it empirically leads to better performance.

et al., 2016). While such methods help obtain state-of-the-art results in neural MT (Wu et al., 2016; Gehring et al., 2017; Ng et al., 2019), we view them as a patch to the observed problems. The fact that text quality still degrades with increased beam sizes when these rewards are used (Koehn and Knowles, 2017; Ott et al., 2018a) suggests that they do not address the inherent issues with text generation systems. We subsequently hypothesize about the nature of these issues and provide a set of linguistically motivated regularizers—inspired by beam search—that appear to alleviate them.

3 Deriving Beam Search

We introduce a **regularized decoding** framework. The idea is simple; we seek to solve the *regularized* optimization problem to decode

$$\mathbf{y}^\star = \underset{\mathbf{y}\in\mathcal{Y}}{\operatorname{argmax}} \left(\log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x}) - \lambda \cdot \mathcal{R}(\mathbf{y}) \right) \tag{9}$$

for a strategically chosen $\mathcal{R}(\cdot)$. Clearly, for certain $\mathcal{R}(\cdot)$, we recover the decoding objectives discussed in §2.2. The question we ask in this work is the following: If we want to view beam search as an exact-decoding algorithm, which $\mathcal{R}(\cdot)$ should we choose to recover beam search?

We discovered an elegant answer rooted in information theory and cognitive science (the connections are discussed in-depth in §4). We first define the model's time-dependent surprisals, which are an information-theoretic concept that characterizes the amount of new information expressed at time t:

$$\begin{aligned} &u_0(\textsc{bos}) = 0 \\ &\quad u_t(y) = -\log p_{\boldsymbol{\theta}}(y \mid \mathbf{x}, \mathbf{y}_{<t}), \ \textbf{for } t \geq 1 \end{aligned} \tag{10}$$

Note that minimally surprising means maximally probable. For the special case of greedy decoding, where $k = 1$, the following choice of regularizer recovers beam search for sufficiently large λ:

$$\mathcal{R}_{\text{greedy}}(\mathbf{y}) = \sum_{t=1}^{|\mathbf{y}|} \left(u_t(y_t) - \min_{y' \in \mathcal{V}} u_t(y') \right)^2 \tag{11}$$

The intuition behind Eq. (11) is to encourage locally optimal decisions: Every local surprise u_t should be close to the minimally surprising choice. In the limiting case where locally optimal decisions are not just encouraged, but rather enforced, we recover greedy search.

Formally, we have the following theorem:

Theorem 3.1. *The argmax of* $\log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x}) - \lambda \cdot \mathcal{R}_{\text{greedy}}(\mathbf{y})$ *is exactly computed by greedy search in the limiting case as* $\lambda \to \infty$.

Proof. By induction. In App. A. ☐

Theorem 3.1 establishes that greedy search is the limiting case of a regularizer that seeks to encourage decisions to have high-probability *locally*. In contrast, the optimal MAP solution will generally not have this property. This is because a globally optimal MAP decoder may require a locally suboptimal decision for the sake of being able to make a **compensatory decision** later that leads to global optimality.[6]

We now consider the generalization of greedy search ($k = 1$) to full beam search ($k \geq 1$). Recall that beam search returns not just a single output, but rather a *set* of outputs. Thus, we must consider the set-decoding objective

$$Y^\star = \underset{\substack{Y\subseteq\mathcal{Y},\\ |Y|=k}}{\operatorname{argmax}} \left(\log p_{\boldsymbol{\theta}}(Y \mid \mathbf{x}) - \lambda \cdot \mathcal{R}(Y) \right) \tag{12}$$

where, as before, we have used our overloaded notation $p_{\boldsymbol{\theta}}(\cdot \mid \mathbf{x})$ to score sets of hypotheses. Similarly to $\mathcal{R}_{\text{greedy}}$, we formulate a greedy set-regularizer to recover beam search:

$$\begin{aligned} &\mathcal{R}_{\text{beam}}(Y) = \\ &\quad \sum_{t=1}^{n_{\max}} \left(u_t(Y_t) - \min_{\substack{Y'\subseteq\mathcal{B}_t,\\ |Y'|=k}} u_t(Y') \right)^2 \end{aligned} \tag{13}$$

where $Y_t = \{\mathbf{y}_{1:t} \mid \mathbf{y} \in Y\}$ corresponds to the set of hypotheses expanded by t steps.[7] Note that we additionally overload surprisal to operate on sets, $u_t(Y) = \sum_{y\in Y} u_t(y)$. We prove an analogous theorem to Theorem 3.1 for this regularizer.

Theorem 3.2. *The argmax of* $\log p_{\boldsymbol{\theta}}(Y \mid \mathbf{x}) - \lambda \cdot \mathcal{R}(Y)$ *is computed by beam search with beam size of* $k = |Y|$ *as* $\lambda \to \infty$.

Proof. The proof follows from the same argument as Theorem 3.1, albeit with sets instead of an individual hypothesis. ☐

---

[6] Indeed, we only have formal guarantees for greedy algorithms when local optimality translates into global optimality (Kleinberg and Tardos, 2005, Chapter 4).

[7] This includes both incomplete hypotheses of length t and complete hypotheses that have reached EOS at step $\leq t$.

Note that in the (predominant) case where we want to return a single candidate sentence as the output rather than an entire set—as would be generated by Eq. (12)—we can take the highest-probability sequence in the chosen set $Y^\star$ as our decoded output. The objective in Eq. (12) boils down to a subset selection problem which, given the size of $\mathcal{Y}$, is a computationally prohibitive optimization problem. Nonetheless, we can use it to analyze the properties enforced on generated text by beam search.

4 From Beam Search to UID

The theoretical crux of this paper hinges on a proposed relationship between beam search and the **uniform information density** hypothesis (Levy, 2005; Levy and Jaeger, 2007), a concept from cognitive science:

Hypothesis 4.1. *"Within the bounds defined by grammar, speakers prefer utterances that distribute information uniformly across the signal (information density). Where speakers have a choice between several variants to encode their message, they prefer the variant with more uniform information density (ceteris paribus)" (Jaeger, 2010).*

At its core, the theory seeks to explain various aspects of human language processing in terms of information theory; it is often applied to an area of psycholinguistics known as sentence processing where the UID hypothesis is used to explain experimental data (Hale, 2001). As the UID hypothesis concerns a cognitive process (virtually) independent of the language in use, the theory should hold across languages (Jaeger and Tily, 2011).

To see the hypothesis in action, consider the classic case of syntactic reduction from Levy and Jaeger (2007):

(1) How big is [$_{\text{NP}}$ the family$_{\text{i}}$ [$_{\text{RC}}$ (that) you cook for $\__{\text{i}}$]]?

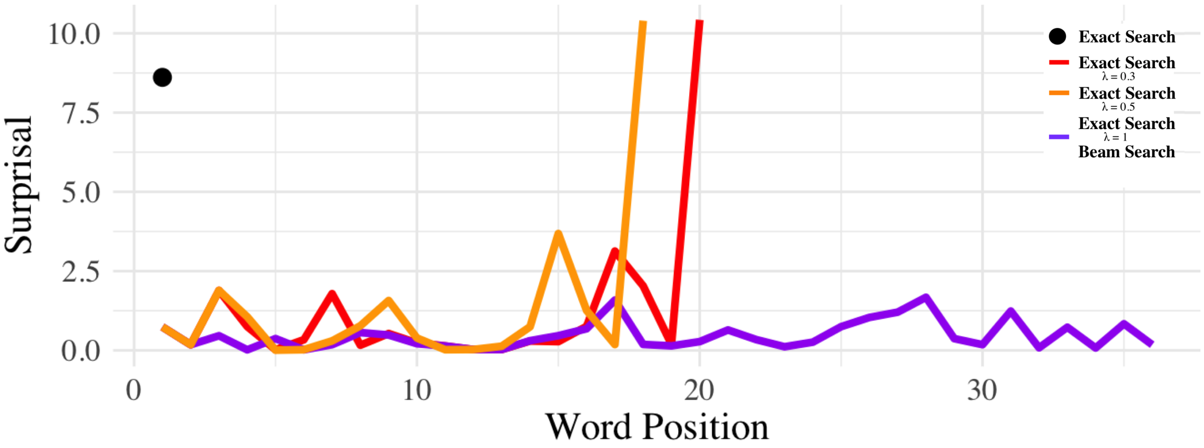
In the above example, the sentence does not require the relativizer *that* at the start of the relative clause (denoted by RC); it would also be syntactically correct without it. However, many would agree that the relativizer makes the text qualitatively better. The information-theoretic explanation of this perception is that without the relativizer, the first word of a relative clause conveys two pieces of information simultaneously: the onset of a relative clause and part of its internal contents. Including the relativizer spreads this information across two words, thereby distributing information across the sentence more uniformly and avoiding instances of high surprisal—which, from a psycholinguistic perspective, are displeasing. In short, the relativizer helps to ensure the UID property of the sentence.

Importantly, the preference suggested by the UID hypothesis is between possible utterances (i.e., outputs) where grammaticality and information content are held constant. Any violation of these assumptions presents confounding factors when measuring, or optimizing, the information density of the generated text. In our setting, there is reason to believe that grammaticallity and information content are approximately held constant while selecting between hypothesis. First, the high-probability outputs of neural generation models tend to be grammatical (Holtzman et al., 2020). Second, because decoding is conditioned on a specific input $\mathbf{x}$, the conditional probability model $p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$ is able to assign high-probability to outputs $\mathbf{y}$ that are plausible outputs (e.g., translations) of the given $\mathbf{x}$. Thus, even though the various $\mathbf{y}$ are not constrained to be sematically equivalent to one another, they tend to express similar information because they are at least relevant to the same $\mathbf{x}$. This is why our regularized optimization problem Eq. (9) combines an information-density regularizer with $\log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$: the term $\log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x})$ rewards grammaticallity and content relevance, whereas the information-density regularizer encourages the human preferences posited by the UID hypothesis. The parameter λ allows the preferences to be calibrated to perform well on downstream evaluation metrics, such as BLEU and ROUGE.

4.1 The UID Bias in Beam Search

It may not be immediately obvious how the UID hypothesis relates to beam search. After all, beam search narrows the scope of the search to only the lowest surprisal candidates at each time step, which does not clearly lead to a uniform distribution of surprisals in the final decoded sequences. The connection is best seen visually.

Fig. 2 shows the time-dependent surprisals u_t under the model of several candidate translations (German to English). Recall that we have $u_t(y) \in [0, \infty)$ and that the standard decoding objective explicitly minimizes the sum of surprisals, i.e., maximizes log-probability. Therefore, the only way the distribution of a solution can become distinctly non-uniform is when there are several high-surprisal



Exact:	“ ”
Exact (λ=0.3):	“people in modern secular world , who are interested in spiritual issues , in the issues of”
Exact (λ=0.5):	“people in modern, secular world who care about spiritual issues, on issues of”
Exact (λ=1):	“people in the modern secular world who are interested in spiritual issues, in issues of consciousness, in the higher, seelial problems, are quite often isolated.”
Beam (k=5):	“people in the modern secular world who are interested in spiritual issues, in issues of consciousness, in the higher, seelial problems, are quite often isolated.”
Reference:	“the people in the modern world, in the secular world, who are interested in matters of the spirit, in matters of the mind, in higher soul-like concerns, tend to be isolated individuals.”

Figure 2: Surprisals (according to $p_{\boldsymbol{\theta}}$) by time step of sequences generated with various decoding strategies. Values of λ indicate the greedy regularizer was used with the corresponding λ value. Note that beam search (k=5) and exact search ($\lambda = 1.0$) return the same prediction in this example, and thus, are represented by the same line.

decisions in the mix; we observe this in the orange and red curves. Intuitively, this corresponds to the notion of compensation discussed earlier: a globally optimal decoding scheme may select a high-surprisal step at some point in order to shorten the length of the path or to take a low-surprisal step later on. We observe an extreme example of this behavior above: Selecting the EOS character at the first step leads to a very non-uniform distribution, i.e., the degenerate distribution, which, violates our operationalization of UID described subsequently. In summary, we see that as λ is decreased, the decoded sentences obey the UID property less strictly. Indeed, setting $\lambda = 0$, i.e., exact inference of the MAP objective, results in the empty string.

A number of successful sampling methods (p-nucleus sampling (Holtzman et al., 2020) and top-k sampling (Fan et al., 2018)) enforce the UID property in generated text by the same logic as above. Both methods eliminate many of the high-surprisal choices at any given decoding step by narrowing the set of tokens that may be chosen.

4.2 Cognitive Motivation for Beam Search

The goal of this work is to expose a possible inductive bias of beam search. We now exhibit our primary hypothesis

Hypothesis 4.2. *Beam search is a cognitively motivated search heuristic for decoding language generation models. The success of beam search on such tasks is, in part, due to the fact that it inherently biases the search procedure towards text that humans prefer.*

The foundation of the argument for this hypothesis follows naturally from the previous sections: First, we demonstrated in §3 that beam search is an exact decoding algorithm for a certain regularized objective—to wit, the one in Eq. (9). Qualitatively, we related the behavior of the regularizer to the UID hypothesis from cognitive science. As a final step, we next provide operationalizations of UID—in the form of regularizers within our regularized decoding framework—through which we can empirically test the validity of this hypothesis.

5 Generalized UID Decoding

If beam search is trying to optimize for UID, can we beat it at its own game? This section develops a battery of possible sentence-level UID measures, which can be used as regularizers in our regularized decoding framework and compared experimentally on downstream evaluation metrics.

Variance Regularizer. We first consider the variance regularizer from Jain et al. (2018). In essence, UID concerns the distribution of information over the course (i.e., time steps) of a sentence. A natural measure for this is variance of the surprisals.

$$\mathcal{R}_{\mathrm{var}}(\mathbf{y}) = \frac{1}{|\mathbf{y}|}\sum_{t=1}^{|\mathbf{y}|}\Big(u_t(y_t) - \mu\Big)^2 \tag{14}$$

where $\mu = {}^1\!/_{|\mathbf{y}|}\sum_{t=1}^{|\mathbf{y}|} u_t(y_t)$. This regularizer, in contrast to Eq. (11), is a much more straightforward encoding of the UID: it directly operationalizes UID through variance.

Local Consistency. Next we consider a local consistency regularizer, also taken from Jain et al. (2018), that encourages adjacent surprisals to have similar magnitude:

$$\mathcal{R}_{\mathrm{local}}(\mathbf{y}) = \frac{1}{|\mathbf{y}|}\sum_{t=1}^{|\mathbf{y}|}\Big(u_t(y_t) - u_{t-1}(y_{t-1})\Big)^2 \tag{15}$$

Again, this is a straightforward encoding of the UID: if every surprisal is similar to its neighbor, it will be close to uniform. Note that both of the above regularizers are defined for all decoding steps $t > 0$ since we define $u_0(y_0) = 0$, $y_0 =$ BOS for all valid hypotheses.

Max Regularizer. We propose a UID-inspired regularizer of our own design that exploits the nature of MAP decoding, for which the overarching goal is to find a solution with low surprisal. In this setting, one strategy is to penalize decisions that move the distribution away from 0, the lowest possible surprisal. This suggests

$$\mathcal{R}_{\mathrm{max}}(\mathbf{y}) = \max_{t=1}^{|\mathbf{y}|} u_t(y_t) \tag{16}$$

would regularize for UID. Such a regularizer would also directly penalize extreme compensation during decoding (discussed in §3). It is worth noting that this regularizer has a connection to entropy regularization, which can be seen by looking at the formula for Rényi entropy.

Squared Regularizer. Finally, we consider a novel squared penalty, that, again, exploits the goal of MAP decoding. If we wish to keep everything uniform, we can try to push all surprisals close to 0, but this time with a squared penalty:

$$\mathcal{R}_{\mathrm{square}}(\mathbf{y}) = \sum_{t=1}^{|\mathbf{y}|} u_t(y_t)^2 \tag{17}$$

Experimentally, we expect to see the following: If encouraging decoded text to exhibit UID is helpful—and our logic in constructing regularizers is sound—all the regularizers (Eq. (14) to (17)) should lead to roughly the same performance under exact decoding and beam search with large beam widths. Such results would not only validate the connection between UID and high-quality text; comparable performance of optimal beam search[8] and exact search under our regularized objective would provide explicit evidence for our declarative explanation of the inductive bias in beam search.

6 Experiments

We explore how encouraging uniform information density in text generated by neural probabalistic text generators affects its downstream quality. To this end, we decode NMT models using the regularized objective (Eq. (9)) with our UID regularizers. We perform exact decoding for a range of λ and observe how text quality (quantified by BLEU (Papineni et al., 2002) using the SacreBLEU (Post, 2018) system) and the distribution of surprisal changes. We additionally evaluate our regularizers under the beam search decoding strategy to see if penalizing violations of UID alleviates the text-quality degradation typically seen with increased beam widths.

Experiments are performed using models trained on the IWSLT'14 De-En (Cettolo et al., 2012) and WMT'14 En-Fr (Bojar et al., 2014) datasets. For reproducibility, we use the model provided by fairseq (Ott et al., 2019) for the WMT'14 task;[9] we use the data pre-processing scripts and recommended hyperparameter settings provided by fairseq for training a model on the IWSLT'14 De-En dataset. We use the Newstest'14 dataset as the test set for the WMT'14 model. All model and data information can be found on the fairseq NMT repository. [10]

6.1 Exact Decoding

To perform exact decoding of neural probabilistic text generators, we build on the decoding framework of Stahlberg et al. (2017), albeit using Dijkstra's algorithm (Dijkstra, 1959) instead of depth-first search as we find it decreases decoding time. Note that Dijkstra's algorithm is guaranteed to find the global optimum when path cost is monotoni-

---

[8] By optimal beam search, we mean beam search using the beam width that empirically leads to the best results.

[9] This model uses a transformer architecture (Vaswani et al., 2017) and was trained as in Ott et al. (2018b).

[10] `https://github.com/pytorch/fairseq/tree/master/examples/translation`

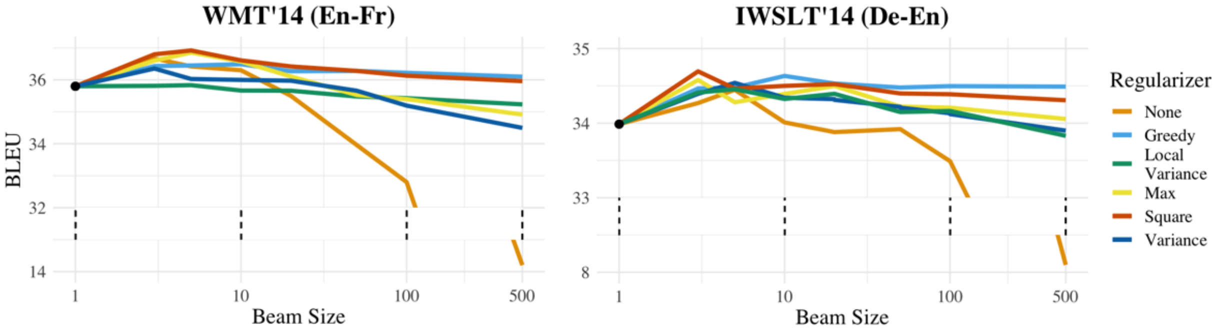


Figure 3: BLEU as a function of beam width for various regularizers. We choose λ for each regularizer by best performance on validation sets (see App. B). y-scales are broken to show minimum BLEU values. x-axis is log-scaled.

cally increasing, which is the case for hypotheses under the scoring scheme used by neural probabilistic text generators (see Meister et al. (2020) for more detailed discussion). While the variance and local consistency regularizers Eq. (14) and (15) break this monotonicity property, we can still guarantee optimality by using a stopping criterion similar to the one proposed by Yang et al. (2018). Explicitly, we check if the top-scoring complete hypothesis has a greater score than the maximum possible score of any hypothesis in the queue. All scores are bounded due to the maximum-length criterion. Additionally, we lower-bound each search by the score of the empty string to decrease the memory footprint, i.e., we stop considering hypotheses whose scores (or maximum possible score in the case of Eq. (14) and (15)) drop below that of the empty string at any time step.

Fig. 1 demonstrates how the addition of the greedy UID regularizer (Eq. (11)) to the regularized MAP objective (Eq. (9)) affects characteristics of the global optimum under the model as we vary λ. Notably, increasing the strength of the regularizer appears to alleviate the text quality degradation seen with exact search, leading to results that approach the BLEU of those generated using optimal beam search. Fig. 1 also shows a strong inverse relationship between BLEU and average standard deviation (per sentence) of surprisals. We take these observations as empirical validation of Hyp. 4.2.

6.2 Regularized Beam Search

We next look at how the regularized decoding objective affects text generated using beam search. As previously noted, text quality generally degrades with increased beam size when using the standard MAP objective; this phenomenon is demonstrated in Fig. 3. UID regularization appears to alleviate this problem. Notably, the greedy and squared regularizer aid performance for larger beam sizes more so than other regularizers, for which we still see a slight drop in performance for larger beam sizes. This drop is negligible compared to the one observed for unregularized beam search—a drop which is also frequently observed for length-normalized decoding (Koehn and Knowles, 2017). While intuitively, variance and local variance are the purest encodings of UID, they perform the poorest of the regularizers. Arguably, this may be due to the fact that they do not simultaneously (as the other regularizers do) penalize for high surprisal.

	$k=5$	$k=10$	$k=100$	$k=500$
No Regularization	36.42	36.30	32.83	14.66
Squared Regularizer	**36.92**	36.42	36.13	35.96
Greedy Regularizer	36.45	36.49	36.22	36.15
Combined Regularizers	36.69	**36.65**	**36.48**	**36.35**
Length Normalization	36.02	35.94	35.80	35.11

Table 1: BLEU scores on first 1000 samples of Newstest2014 for predictions generated with various decoding strategies. Best scores per beam size are bolded.

We additionally decode with a combination of the UID regularizers in tandem. We collectively tune the λ value for each of the regularizers on validation sets. We report performance in Tab. 1 and see that results outperform standard and length-normalized, i.e. score divided by sequence length, beam search with noticeable improvements for larger beams. Search details and parameter settings may be found in App. B. Notably, combining multiple UID regularizers does not lead to as great an increase in performance as one might expect, which hints that a single method for enforcing UID is sufficient for promoting quality in generated text.

7 Related Work

Neural probabilistic text generators are far from perfect; prior work has shown that they often generate text that is generic (Vinyals and Le, 2015; Li et al., 2016), unnatural (Holtzman et al., 2020), and sometimes even non-existent (Stahlberg and Byrne, 2019). In the context of the degenerate behavior of these models, the beam search curse—a specific phenomenon where using a larger beam size leads to worse performance—has been analyzed by a number of authors (Koehn and Knowles, 2017; Murray and Chiang, 2018; Yang et al., 2018; Stahlberg and Byrne, 2019; Jean et al., 2015; Tu et al., 2016; He et al., 2016; Cohen and Beck, 2019). Many of these authors attribute the performance drop (as search becomes better) to an inherent bias in neural sequence models to pefer shorter sentences. Other authors have ascribed fault to the model architectures, or how they are trained (Cho et al., 2014; Bengio et al., 2015; Sountsov and Sarawagi, 2016; Vinyals et al., 2017; Ott et al., 2018a; Kumar and Sarawagi, 2019). To remedy the problem, a large number of regularized decoding objectives and modified training techniques have been proposed. In contrast, this work analyzes the behavior of neural text generators from a different angle: We provide a plausible answer—inspired by psycholinguistic theory—as to *why* beam search (with small beams) leads to high-quality text, rather than another explanation of why exact search performs so badly.

8 Conclusion

We analyze beam search as a decoding strategy for text generation models by framing it as the solution to an exact decoding problem. We hypothesize that beam search has an inductive bias which can be linked to the promotion of uniform information density (UID), a theory from cognitive science regarding even distribution of information in linguistic signals. We observe a strong relationship between variance of surprisals (an operationalization of UID) and BLEU in our experiments with NMT models. With the aim of further exploring decoding strategies for neural text generators in the context of UID, we design a set of objectives to explicitly encourage uniform information density in text generated from neural probabalistic models and find that they alleviate the quality degradation typically seen with increased beam widths.

Acknowledgments

We would like to thank Ari Holtzman and Jason Eisner for useful feedback and discussion that helped improve this work.

A Theory

Proof. We prove Theorem 3.2 by induction. We denote the argmax of $\log p_{\boldsymbol{\theta}}(\mathbf{y} \mid \mathbf{x}) - \lambda \cdot \mathcal{R}_{\text{greedy}}(\mathbf{y})$ as $\mathbf{y}^{\mathcal{R}}$ and the solution found by greedy search as $\mathbf{y}^{\text{greedy}}$. We will show that $y_t^{\text{greedy}} = y_t^{\mathcal{R}}$ for all $0 \leq t \leq \max(|\mathbf{y}^{\mathcal{R}}|, |\mathbf{y}^{\text{greedy}}|)$. The theorem holds trivially for the base case of $t = 0$ because y_0 must be BOS for any valid hypothesis by definition of the hypothesis space (Eq. (1)). Now, by the inductive hypothesis, suppose $y_i^{\text{greedy}} = y_i^{\mathcal{R}}$ for all $i < t$. We will show that our regularized objective must choose the same word as greedy search at time-step t. In the limiting case of Eq. (11), the following function reflects the penalty to the distribution over tokens at position t:

$$\lim_{\lambda \to \infty} \left[\lambda \cdot \left(u_t(y_t) - \min_{y' \in \mathcal{V}} u_t(y') \right)^2 \right] = \begin{cases} 0 & \textbf{if } u_t(y_t) = \min_{y' \in \mathcal{V}} u_t(y') \\ \infty & \textbf{otherwise} \end{cases}$$

Since minimum surprisal implies maximum log-probability, the above function clearly returns either 0 or ∞ depending on whether the decoding choice at time-step t is greedy. Therefore the only choice that would not send the hypothesis score to $-\infty$ is the greedy choice, which implies any feasible solution to our objective must have $y_t^{\mathcal{R}} = y_t^{\text{greedy}}$. By the principle of induction, $y_t^{\text{greedy}} = y_t^{\mathcal{R}}$ for all $0 \leq t \leq |\mathbf{y}^{\mathcal{R}}| = |\mathbf{y}^{\text{greedy}}|$, which in turn implies $\mathbf{y}^{\text{greedy}} = \mathbf{y}^{\mathcal{R}}$. $\square$

B Parameters

For values in Fig. 3, we perform grid search over $\lambda \in [0.2, 0.5, 0.7, 1, 2, 3, 4, 6, 7, 8, 9, 10]$ and choose the λ with the best validation set performance. For combined UID regularization, we perform hyper-parameter search over the 5 strength parameters, each sampled uniformly from the following values: $[0, 0.2, 0.5, 0.7, 1, 2, 3, 4, 6, 7, 8, 9, 10]$. We run 50 trials on the validation set; $\lambda = 5$ and $\lambda = 2$ yield the best performance for the greedy and squared regularizers, respectively with all others λ set to 0.

Abstract

Latent structure models are a powerful tool for modeling language data: they can mitigate the error propagation and annotation bottleneck in pipeline systems, while simultaneously uncovering linguistic insights about the data. One challenge with end-to-end training of these models is the argmax operation, which has null gradient. In this paper, we focus on *surrogate gradients*, a popular strategy to deal with this problem. We explore latent structure learning through the angle of *pulling back* the downstream learning objective. In this paradigm, we discover a principled motivation for both the straight-through estimator (STE) as well as the recently-proposed SPIGOT—a variant of STE for structured models. Our perspective leads to new algorithms in the same family. We empirically compare the known and the novel pulled-back estimators against the popular alternatives, yielding new insight for practitioners and revealing intriguing failure cases.

1 Introduction

Natural language data is *rich in structure*, but most of the structure is not visible at the surface. Machine learning models tackling high-level language tasks would benefit from uncovering underlying structures such as trees, sequence tags, or segmentations. Traditionally, practitioners turn to *pipeline* approaches where an external, pretrained model is used to predict, *e.g.*, syntactic structure. The benefit of this approach is that the predicted tree is readily available for inspection, but the downside is that the errors can easily propagate throughout the pipeline and require further attention (Finkel et al., 2006; Sutton and McCallum, 2005; Toutanova, 2005). In contrast, deep neural architectures tend to eschew such preprocessing, and instead learn soft hidden representations, not easily amenable to visualization and analysis.

The best of both worlds would be to *model structure as a latent variable*, combining the transparency of the pipeline approach with the end-to-end unsupervised representation learning that makes deep models appealing. Moreover, large-capacity model tend to rediscover structure from scratch (Tenney et al., 2019), so structured latent variables may reduce the required capacity.

Learning with discrete, combinatorial latent variables is, however, challenging, due to the intersection of *large cardinality* and *null gradient* issues. For example, when learning a latent dependency tree, the latent parser must choose among an exponentially large set of possible trees; what's more, the parser may only learn from gradient information from the downstream task. If the highest-scoring tree is selected using an *argmax* operation, the gradients will be zero, preventing learning.

One strategy for dealing with the null gradient issue is to use a **surrogate gradient**, explicitly overriding the zero gradient from the chain rule, as if a different computation had been performed. The most commonly known example is the *straight-through estimator* (STE; Bengio et al., 2013), which pretends that the *argmax* node was instead an *identity* operator. Such methods lead to a fundamental mismatch between the objective and the learning algorithm. The effect of this mismatch is still insufficiently understood, and the design of successful new variants is therefore challenging. For example, the recently-proposed SPIGOT method (Peng et al., 2018) found it beneficial to use a projection as part of the surrogate gradient.

In this paper, we study surrogate gradient methods for deterministic learning with discrete structured latent variables. Our contributions are:

- We propose a novel motivation for surrogate gra-

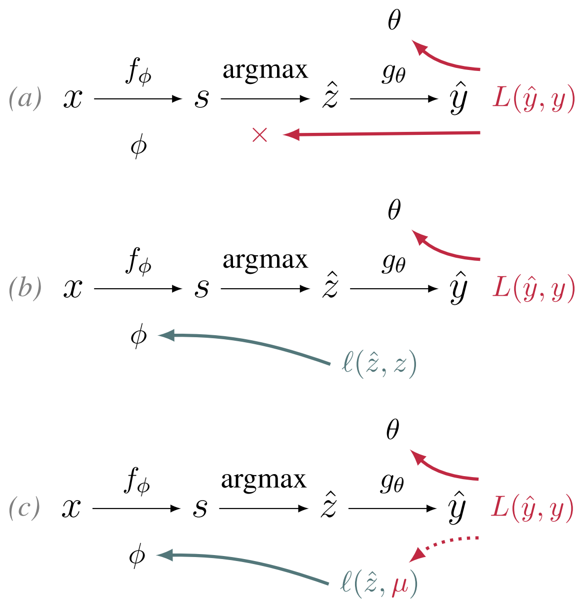

Figure 1: A model with a discrete latent variable z. Given an input x, we assign a score $s_z = [f(x)]_z$ to each choice, and pick the highest scoring one, $\hat{z}$, to predict $\hat{y} = g_\theta(\hat{z})$. For simplicity, here g_θ does not access x directly. (a). Since argmax has null gradients, the encoder parameters ϕ do not receive updates. (b). If ground truth supervision were available for the latent z, ϕ could be trained jointly with an auxiliary loss. (c). As such supervision is not available, we induce a best-guess label μ by pulling back the downstream loss. This strategy recovers the STE and SPIGOT estimators.

dient methods, based on optimizing a **pulled-back loss**, thereby inducing pseudo-supervision on the latent variable. This leads to new insight into both STE and SPIGOT.

- We show how our framework may be used to derive new surrogate gradient methods, by varying the loss function or the inner optimization algorithm used for inducing the pseudo-supervision.
- We experimentally validate our discoveries on a controllable experiment as well as on English-language sentiment analysis and natural language inference, comparing against stochastic and relaxed alternatives, yielding new insights, and identifying noteworthy failure cases.

While the discrete methods do not outperform the relaxed alternatives using the same building blocks, we hope that our interpretation and insights would trigger future latent structure research.

The code for the paper is available on `https://github.com/deep-spin/understanding-spigot`.

2 Related Work

Discrete latent variable learning is often tackled in **stochastic computation graphs**, by estimating the gradient of an expected loss. An established method is the score function estimator (SFE) (Glynn, 1990; Williams, 1992; Kleijnen and Rubinstein, 1996). SFE is widely used in NLP, for tasks including minimum risk training in NMT (Shen et al., 2016; Wu et al., 2018) and latent linguistic structure learning (Yogatama et al., 2017; Havrylov et al., 2019). In this paper, we focus on the alternative strategy of **surrogate gradients**, which allows learning in deterministic graphs with discrete, argmax-like nodes, rather than in stochastic graphs. Examples are the **straight-through estimator (STE)** (Hinton, 2012; Bengio et al., 2013) and the structured projection of intermediate gradients optimization technique (SPIGOT; Peng et al. 2018). Recent work focuses on studying and explaining STE. Yin et al. (2019) obtained a convergence result in shallow networks for the unstructured case. Cheng et al. (2018) show that STE can be interpreted as the simulation of the projected Wasserstein gradient flow. STE has also been studied in binary neural networks (Hubara et al., 2016) and in other applications (Tjandra et al., 2019). Other methods based on the surrogate gradients have been recently explored (Vlastelica et al., 2020; Meng et al., 2020).

A popular alternative is to **relax** an argmax into a continuous transform such as softmax or sparsemax (Martins and Astudillo, 2016), as seen for instance in soft attention mechanisms (Vaswani et al., 2017), or structured attention networks (Kim et al., 2017; Maillard et al., 2017; Liu and Lapata, 2018; Mensch and Blondel, 2018; Niculae et al., 2018a). In-between surrogate gradients and relaxation is **Gumbel softmax**, which uses the Gumbel-max reparametrization to sample from a categorical distribution, applying softmax either to relax the mapping or to induce surrogate gradients (Jang et al., 2017; Maddison et al., 2017). Gumbel-softmax has been successfully applied to latent linguistic structure as well (Choi et al., 2018; Maillard and Clark, 2018). For sampling from a structured variable is required, the **Perturb-and-MAP** technique (Papandreou and Yuille, 2011) has been successfully applied to sampling latent structures in NLP applications (Corro and Titov, 2019a,b).

3 Structured Prediction Preliminaries

We assume a general latent structure model involving input variables $x \in \mathcal{X}$, output variables $y \in \mathcal{Y}$, and latent discrete variables $z \in \mathcal{Z}$. We assume that $\mathcal{Z} \subseteq \{0,1\}^K$, where $K \le |\mathcal{Z}|$ (typically, $K \ll |\mathcal{Z}|$): *i.e.*, the latent discrete variable z can be represented as a K-th dimensional binary vector. This often results from a decomposition of a structure into parts: for example, z could be a dependency tree for a sentence of L words, represented as a vector of size $K = O(L^2)$, indexed by pairs of word indices (i, j), with $z_{ij} = 1$ if arc $i \to j$ belongs to the tree, and 0 otherwise. This allows us to define the **score** of a structure as the sum of the scores of its parts. Given a vector $s \in \mathbb{R}^K$, containing scores for all possible parts, we define

$$\operatorname{score}(z) := s^\top z. \tag{1}$$

Notation. We denote by e_k the one-hot vector with all zeros except in the k^{th} coordinate. We denote the simplex by $\triangle^{|\mathcal{Z}|} := \{p \in \mathbb{R}^{|\mathcal{Z}|} \mid p \ge 0, \sum_{z \in \mathcal{Z}} p(z) = 1\}$. Given a distribution $p \in \triangle^{|\mathcal{Z}|}$, the expectation of a function $h : \mathcal{Z} \to \mathbb{R}^D$ under p is $\mathbb{E}_{z \sim p}[h(z)] := \sum_{z \in \mathcal{Z}} p(z)h(z)$. We denote the convex hull of the (finite) set $\mathcal{Z} \subseteq \mathbb{R}^K$ by $\operatorname{conv}(\mathcal{Z}) := \{\mathbb{E}_{z \sim p}[z] \mid p \in \triangle^{|\mathcal{Z}|}\}$. The euclidean projection of s onto a set $\mathcal{D}$ is $\Pi_{\mathcal{D}}(s) := \operatorname{argmin}_{d \in \mathcal{D}} \|s - d\|_2$.

Background. In the context of structured prediction, the set $\mathcal{M} := \operatorname{conv}(\mathcal{Z})$ is known as the *marginal polytope*, since any point inside it can be interpreted as some marginal distribution over parts of the structure (arcs) under some distribution over structures. There are three relevant problems that may be formulated in a structured setting:

- Maximization (MAP inference): finds a highest scoring structure, $\texttt{MAP}(s) := \operatorname*{argmax}_{z \in \mathcal{Z}} s^\top z$.
- Marginal inference: finds the (unique) marginals induced by the scores s, corresponding to the Gibbs distribution where $p(z) \propto \exp\big(\operatorname{score}(z)\big)$. The solution maximizes the entropy-regularized objective

$$\texttt{Marg}(s) := \operatorname*{argmax}_{\mu \in \mathcal{M}} s^\top \mu + \tilde{H}(\mu), \tag{2}$$

where $\tilde{H}$ is the maximum entropy among all distributions over *structures* that achieve marginals μ (Wainwright and Jordan, 2008):

$$\tilde{H}(\mu) := \max_{\substack{p \in \triangle^{|\mathcal{Z}|} \\ \mathbb{E}_p[z] = \mu}} - \sum_{z \in \mathcal{Z}} p(z) \log p(z). \tag{3}$$

- SparseMAP: finds the (unique) *sparse* marginals induced by the scores s, given by a Euclidean projection onto $\mathcal{M}$: (Niculae et al., 2018a)

$$\begin{aligned} \texttt{SparseMAP}(s) &:= \Pi_{\mathcal{M}}(s) \\ &= \operatorname*{argmax}_{\mu \in \mathcal{M}} s^\top \mu - \frac{1}{2}\|\mu\|^2. \end{aligned} \tag{4}$$

Unstructured setting. As a check, we consider the encoding of a categorical variable with K distinct choices, encoding each choice as a one-hot vector e_k and setting $\mathcal{Z} = \{e_1, \ldots, e_K\}$. In this case, $\operatorname{conv}(\mathcal{Z}) = \triangle^K$. The optimization problems above then recover some well known transformations, as described in Table 1.

	unstructured	structured

interior points	p	μ
maximization	`argmax`	`MAP`
expectation	`softmax`	`Marg`
Euclidean projection	`sparsemax`	`SparseMAP`

Table 1: Building blocks for latent structure models.

4 Latent Structure Models

Throughout, we assume a classifier parametrized by ϕ and θ, which consists of three parts:

- An **encoder function** f_ϕ which, given an input $x \in \mathcal{X}$, outputs a vector of "scores" $s \in \mathbb{R}^K$, as $s = f_\phi(x)$;
- An **argmax node** which, given these scores, outputs the highest-scoring structure:

$$\hat{z}(s) := \operatorname*{argmax}_{z \in \mathcal{Z}} s^\top z = \texttt{MAP}(s)\,; \tag{5}$$

- A **decoder function** g_θ which, given $x \in \mathcal{X}$ and $z \in \mathcal{Z}$, makes a prediction $\hat{y} \in \mathcal{Y}$ as $\hat{y} = g_\theta(x, z)$. We will sometimes write $\hat{y}(z)$ to emphasize the dependency on z. For reasons that will be clear in the sequel, we must assume that the decoder also accepts *average structures*, *i.e.*, it can also output predictions $g_\theta(x, \mu)$ where $\mu \in \operatorname{conv}(\mathcal{Z})$ is a convex combination (weighted average) of structures.

Thus, given input $x \in \mathcal{X}$, this network predicts:

$$\hat{y} = g_\theta\left(x, \overbrace{\operatorname*{argmax}_{z \in \mathcal{Z}} f_\phi(x)^\top z}^{\hat{z}(s)}\right). \tag{6}$$

To train this network, we minimize a loss function $L(\hat{y}, y)$, where y denotes the target label; a common example is the negative log-likelihood loss.

The gradient *w.r.t.* the decoder parameters, $\nabla_\theta L(\hat{y}, y)$, is easy to compute using automatic differentiation on g_θ. The main challenge is to propagate gradient information **through the argmax node** into the encoder parameters. Indeed,

$$\nabla_\phi L(\hat{y}, y) = \frac{\partial f_\phi(x)}{\partial \phi} \underbrace{\frac{\partial \hat{z}(s)}{\partial s}}_{=0} \nabla_z L(\hat{y}(\hat{z}), y) = 0,$$

so no gradient will flow to the encoder. We list below the three main categories of approaches that tackle this issue.

Introducing stochasticity. Replace the argmax node by a stochastic node where z is modeled as a random variable Z parametrized by s (*e.g.*, using a Gibbs distribution). Then, instead of optimizing a deterministic loss $L(\hat{y}(\hat{z}), y)$, optimize the **expectation** of the loss under the predicted distribution:

$$\mathbb{E}_{Z \sim p(z;s)}[L(\hat{y}(Z), y)]. \tag{7}$$

The expectation ensures that the gradients are no longer null. This is sometimes referred to as *minimum risk training* (Smith and Eisner, 2006; Stoyanov et al., 2011), and typically optimized using the *score function estimator* (SFE; Glynn, 1990; Williams, 1992; Kleijnen and Rubinstein, 1996).

Relaxing the argmax. Keep the network deterministic, but relax the argmax node into a continuous function, for example replacing it with softmax or sparsemax (Martins and Astudillo, 2016). In the structured case, this gives rise to structured attention networks (Kim et al., 2017) and their SparseMAP variant (Niculae et al., 2018a). This corresponds to moving the expectation inside the loss, optimizing $L\big(\hat{y}(\underbrace{\mathbb{E}_{Z \sim p(z;s)}[Z]}_{\mu}), y\big)$.

Inventing a surrogate gradient. Keep the argmax node and perform the usual forward computation, but backpropagate a different, non-null gradient in the backward pass. This is the approach underlying straight-through estimators (Hinton, 2012; Bengio et al., 2013) and SPIGOT (Peng et al., 2018). This method introduces a mismatch between the measured objective and the optimization algorithm. In this work, we proposed a novel, principled justification for inducing surrogate gradients. In what follows, we assume that:

- We can compute the gradient

  $$\gamma(\mu) := \nabla_\mu L(\hat{y}(\mu), y), \tag{8}$$

  for any μ, usually by automatic differentiation;[1]
- We want to replace the null gradient $\nabla_s L(\hat{y}(\hat{z}), y)$ by a surrogate $\tilde{\nabla}_s L(\hat{y}(\hat{z}), y)$.

5 SPIGOT as the Approximate Optimization of a Pulled Back Loss

We next provide a novel interpretation of SPIGOT as the minimization of a "pulled back" loss. SPIGOT uses the surrogate gradient:

$$\begin{aligned}\tilde{\nabla}_s L(\hat{y}(\hat{z}), y) &= \hat{z} - \Pi_{\mathcal{M}}(\hat{z} - \eta\gamma) \\ &= \hat{z} - \texttt{SparseMAP}(\hat{z} - \eta\gamma),\end{aligned} \tag{9}$$

highlighting that SparseMAP (Niculae et al., 2018a) computes an Euclidean projection (Eq. 4).

5.1 Intermediate Latent Loss

To begin, consider a much simpler scenario: if we had supervision for the latent variable z (*e.g.*, if the true label z was revealed to us), we could define an **intermediate loss** $\ell(\hat{z}, z)$ which would induce nonzero updates to the encoder parameters. Of course, we do not have access to this z. Instead, we consider the following alternative:

Definition 1 (Pulled-back label)**.** A guess $\mu \in \mathcal{M} = \operatorname{conv}(\mathcal{Z})$ for what the unknown $z \in \mathcal{Z}$ should be, informed by the downstream loss.

Figure 1 provides the intuition of the pulled-back label and loss. We take a moment to justify picking $\mu \in \mathcal{M}$ rather than directly in $\mathcal{Z}$. In fact, if $K = |\mathcal{Z}|$ is small, we can enumerate all possible values of z and define the guess as the latent value minimizing the downstream loss, $\mu = \operatorname{argmin}_{z \in \mathcal{Z}} L(\hat{y}(z), y)$. This is sensible, but

---

[1] This gradient would not exist if the decoder g_θ were defined only at vertices $z \in \mathcal{Z}$ and not mean points $\mu \in \mathcal{M}$.

intractable in the structured case. Moreover, early on in the training process, while g_θ is untrained, the maximizing vertex carries little information. Thus, for robustness and tractability, we allow for some uncertainty by picking a convex combination $\mu \in \mathcal{M}$ so as to approximately minimize

$$\mu \approx \operatorname*{argmin}_{\mu \in \mathcal{M}} L(\hat{y}(\mu), y). \tag{10}$$

For most interesting predictive models $\hat{y}(\mu)$ (*e.g.*, deep networks), this optimization problem is nonconvex and lacks a closed form solution. One common strategy is the **projected gradient algorithm** (Goldstein, 1964; Levitin and Polyak, 1966), which, in addition to gradient descent, has one more step: projection of the updated point on the constraint set. It iteratively performs the following updates:

$$\mu^{(t+1)} = \Pi_{\mathcal{M}}\left(\mu^{(t)} - \eta_t \gamma(\mu^{(t)})\right), \tag{11}$$

where η_t is a step size and γ is as in Eq. 8. With a suitable choice of step sizes, the projected gradient algorithm converges to a local optimum of Eq. 10 (Bertsekas, 1999, Proposition 2.3.2). In the sequel, for simplicity we use constant η. If we initialize $\mu^{(0)} = \hat{z} = \operatorname{argmax}_{z \in \mathcal{Z}} s^\top z$, **a single iteration** of projected gradient yields the guess:

$$\mu^{(1)} = \Pi_{\mathcal{M}}\left(\hat{z} - \eta\gamma(\hat{z})\right). \tag{12}$$

Treating the induced μ as if it were the "ground truth" label of z, we may train the encoder $f_\phi(x)$ by **supervised learning**. With a **perceptron loss**,

$$\begin{aligned} \ell_{\text{Perc}}(\hat{z}(s), \mu) &= \max_{z \in \mathcal{Z}} s^\top z - s^\top \mu \\ &= s^\top \hat{z} - s^\top \mu, \end{aligned} \tag{13}$$

a single iteration yields the gradient:

$$\nabla_s \ell_{\text{Perc}}(\hat{z}, \mu^{(1)}) = \hat{z} - \mu^{(1)}, \tag{14}$$

which is precisely the SPIGOT gradient surrogate in Eq. 9. This leads to the following insight into how SPIGOT updates the encoder parameters:

> SPIGOT minimizes the **perceptron loss** between z and a pulled back target computed by **one projected gradient step** on $\min_{\mu \in \mathcal{M}} L(\hat{y}(\mu), y)$ starting at $\hat{z} = \texttt{MAP}(s)$.

This construction suggests possible alternatives, the first of which uncovers a well-known algorithm.

Relaxing the $\mathcal{M}$ constraint. The constraints in Eq. 10 make the optimization problem more complicated. We relax them and define $\mu \approx \operatorname{argmin}_{\mu \in \mathbb{R}^K} L(\hat{y}(\mu), y)$. This problem still requires iteration, but the projection step can now be avoided. One iteration of gradient descent yields $\mu^{(1)} = \hat{z} - \eta\gamma$. The perceptron update then recovers a novel derivation of **straight-through** with identity (STE-I), where the backward pass acts as if $\frac{\partial \hat{z}(s)}{\partial s} \overset{!}{=} \text{Id}$ (Bengio et al., 2013),

$$\nabla_s \ell_{\text{Perc}}(\hat{z}, \mu^{(1)}) = \hat{z} - (\hat{z} - \eta\gamma) = \eta\gamma. \tag{15}$$

This leads to the following insight into straight-through and its relationship to SPIGOT:

> Straight-through (STE-I) minimizes the **perceptron loss** between z and a pulled back target computed by **one gradient step** on $\min_{\mu \in \mathbb{R}^K} L(\hat{y}(\mu), y)$ starting at $\hat{z} = \texttt{MAP}(s)$.

From this intuition, we readily obtain new surrogate gradient methods, which we explore below.

6 New Surrogate Gradient Methods

Multiple gradient updates. Instead of a single projected gradient step, we could run multiple steps of Eq. 11. We would expect this to yield a better approximation of μ. This comes at a computational cost: each update involves running a forward and backward pass in the decoder g_θ with the current guess $\mu^{(t)}$, to obtain $\gamma(\mu^{(t)}) := \nabla_\mu L(\hat{y}(\mu^{(t)}), y)$.

Different initialization. The projected gradient update in Eq. 12 uses $\mu^{(0)} = \hat{z} = \operatorname{argmax}_{z \in \mathcal{Z}} s^\top z$ as the initial point. This is a sensible choice, if we believe the encoder prediction $\hat{z}$ is close enough to the optimal μ, and it is computationally convenient, because the forward pass uses $\hat{z}$, so $\gamma(\hat{z})$ is readily available in the backward pass, thus the first inner iteration comes for free. However, other initializations are possible, for example $\mu^{(0)} = \texttt{Marg}(s)$ or $\mu^{(0)} = 0$, at the cost of an extra computation of $\gamma(\mu^{(0)})$. In this work, we do not consider alternate initializations for their own sake; they are needed for the following two directions.

Different intermediate loss: SPIGOT-CE. For simplicity, consider the unstructured case where $\mathcal{M} = \triangle$, and use the initial guess $\mu^{(0)} =$

$\texttt{softmax}(s)$. Replacing ℓ_{Perc} by the cross-entropy loss $\ell_{\text{CE}}(\mu^{(0)}, \mu^{(1)}) = -\sum_{k=1}^{K} \mu_k \log \mu_k^{(0)}$ yields

$$\nabla_s \ell_{\text{CE}}(\mu^{(0)}, \mu^{(1)}) = \mu^{(0)} - \Pi_{\triangle}(\mu^{(0)} - \eta\gamma). \quad (16)$$

In the structured case, the corresponding loss is the CRF loss (Lafferty et al., 2001), which corresponds to the KL divergence between two distributions over structures. In this case, we initialize $\mu^{(0)} = \texttt{Marg}(s)$ and update

$$\nabla_s \ell_{\text{CE}}(\mu^{(0)}, \mu^{(1)}) = \mu^{(0)} - \Pi_{\mathcal{M}}(\mu^{(0)} - \eta\gamma). \quad (17)$$

Exponentiated gradient updates: SPIGOT-EG. In the unstructured case, optimization over $\mathcal{M} = \triangle$ can also be tackled via the exponentiated gradient (EG) algorithm (Kivinen and Warmuth, 1997), which minimizes Eq. 10 with the following multiplicative update:

$$\mu^{(t+1)} \propto \mu^{(t)} \odot \exp(-\eta_t \nabla_\mu L(\hat{y}(\mu^{(t)}), y)), \quad (18)$$

where $\odot$ is elementwise multiplication and thus each iterate $\mu^{(t)}$ is strictly positive, and normalized to be inside $\triangle$. EG cannot be initialized on the boundary of $\triangle$, so again we must take $\mu^{(0)} = \texttt{softmax}(s)$. A single iteration of EG yields:

$$\begin{aligned} \mu^{(1)} &\propto \mu^{(0)} \odot \exp(-\eta\gamma) \\ &= \texttt{softmax}(\log \mu^{(0)} - \eta\gamma) \\ &= \texttt{softmax}(s - \eta\gamma). \end{aligned} \quad (19)$$

It is natural to use the cross-entropy loss, giving

$$\nabla_s \ell_{\text{CE}}(\mu^{(0)}, \mu^{(1)}) = \mu^{(0)} - \texttt{softmax}(s - \eta\gamma), \quad (20)$$

i.e., the surrogate gradient is the difference between the softmax prediction and a "perturbed" softmax. To generalize to the structured case, we observe that both EG and projected gradient are instances of mirror descent under KL divergences (Beck and Teboulle, 2003). Unlike the unstructured case, we must iteratively keep track of both *perturbed scores* and *marginals*, since $\texttt{Marg}^{-1}$ is non-trivial. This leads to the following mirror descent algorithm:

$$\begin{aligned} s^{(0)} &= s, \quad \mu^{(0)} = \texttt{Marg}(s^{(0)}), \\ s^{(t+1)} &= s^{(t)} - \eta\gamma(\mu^{(t)}), \\ \mu^{(t+1)} &= \texttt{Marg}(s^{(t)}). \end{aligned} \quad (21)$$

With a single iteration and the CRF loss, we get

$$\nabla_s \ell_{\text{CE}} = \texttt{Marg}(s) - \texttt{Marg}(s - \eta\gamma). \quad (22)$$

Algorithm 1: Surrogate gradients pseudocode: common forward pass, specialized backward passes.

```
Parameters: step size $\eta$, n. iterations $k$

        $\mu^{(t)} \leftarrow$ Marg($s^{(t)}$)
    return $\mu^{(0)} - \mu^{(k)}$
```

Algorithm 1 sketches the implementation of the proposed surrogate gradients for the structured case. The forward pass is the same for all variants: given the scores s for the parts of the structure, it calculates the $\texttt{MAP}$ structure z. The surrogate gradients are implemented as custom backward passes. The function $\texttt{GradLoss}$ uses automatic differentiation to compute $\gamma(\mu)$ at the current guess μ; each call involves thus a forward and backward pass through g_θ. Due to convenient initialization, the first iteration of STE-I and SPIGOT come for free, since both $\mu^{(0)}$ and $\gamma(\mu^{(0)})$ are available as a byproduct when computing the forward and, respectively, backward pass through g_θ in order to update θ. For SPIGOT-CE and SPIGOT-EG, even with $k = 1$ we need a second call to the decoder, since $\mu^{(0)} \neq \hat{z}$, so an additional decoder call is necessary for obtaining the gradient of the loss with respect to $\mu^{(0)}$. The unstructured case is essentially identical, with $\texttt{Marg}$ replaced by $\texttt{softmax}$.

7 Experiments

Armed with a selection of surrogate gradient methods, we now proceed to an experimental comparison. For maximum control, we first study a synthetic unstructured experiment with known data generating process. This allows us to closely compare the various methods, and to identify basic failure cases. We then study the structured case of latent dependency trees for sentiment analysis and natural language inference in English. Full training details are described in Appendix A.

7.1 Categorical Latent Variables

For the unstructured case, we design a synthetic dataset from a mixture model $z \sim \text{Categorical}(1/K)$, $x \sim \text{Normal}(m_z, \sigma I)$, $y = \text{sign}(w_z^\top x + b_z)$, where m_z are randomly placed cluster centers, and w_z, b_z are parameters of a different ground truth linear model for each cluster. Given cluster labels, one could learn the optimal linear classifier separating the data in that cluster. Without knowing the cluster, a global linear model cannot fit the data well. This setup provides a test bed for discrete variable learning, since accurate clustering leads to a good fit. The architecture, following §4, is:

- **Encoder**: A linear mapping from the input to a K-dimensional score vector: $s = f_\phi(x) = W_f x + b_f$, where $\phi = (W_f, b_f) \in \mathbb{R}^{K \times \dim(\mathcal{X})} \times \mathbb{R}^K$ are parameters.
- **Latent mapping**: $\hat{z} = \rho(s)$, where ρ is argmax or a continuous relaxation such as `softmax` or `sparsemax`.
- **Decoder**: A bilinear transformation, combining the input x and the latent variable z:

$$\hat{y} = g_\theta(x, \hat{z}) = \hat{z}^\top W_g x + b_g,$$

where $\theta = (W_g, b_g) \in \mathbb{R}^{K \times \dim(\mathcal{X})} \times \mathbb{R}$ are model parameters. If $\hat{z} = e_k$, this *selects* the k^{th} linear model from the rows of W_g.

We evaluate two baselines: a linear model, and an *oracle* where $g_\theta(x, z)$ has access to the true z. In addition to the methods discussed in the previous section, we evaluate *softmax* and *sparsemax* end-to-end differentiable relaxations, and the STE-S variant which uses the `softmax` backward pass while doing `argmax` in the forward pass. We also compare *stochastic* methods, including score function estimators (with an optional moving average control variate), and the two Gumbel estimator variants (Jang et al., 2017; Maddison et al., 2017): Gumbel-Softmax with relaxed `softmax` in the forward pass, and the other using `argmax` in the style of STE (hence dubbed ST-Gumbel).

Results. We compare the discussed methods in Table 2. Knowledge of the data-generating process allows us to measure not only downstream accuracy, but also **clustering quality**, by comparing the model predictions with the known true z. We measure the latter via the V-measure (Rosenberg and Hirschberg, 2007), a clustering score independent of the cluster labels, *i.e.*, invariant to permuting the

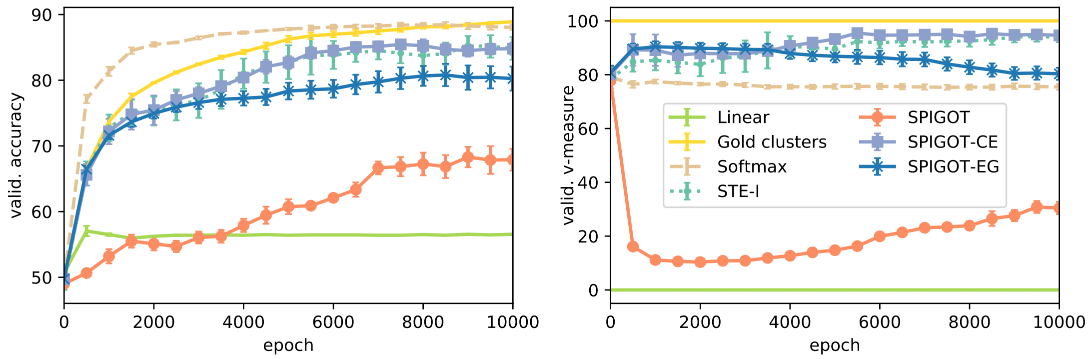

Figure 2: Learning curves on synthetic data with 10 clusters. Softmax learns the downstream task fast, but mixes the clusters, yielding poor V-measure. SPIGOT fails on both metrics; STE-I and the novel SPIGOT-CE work well.

labels (between 0 and 100, with 100 representing perfect cluster recovery). The linear and gold cluster oracle baselines confirm that cluster separation is needed for good performance. Stochastic models perform well across both criteria. Crucially, SFE requires variance reduction to performs well, but even a simple control variate will do.

Deterministic models may be preferable when likelihood assessment or sampling is not tractable. Among these, STE-I and SPIGOT-{CE,EG} are indistinguishable from the best models. Surprisingly, the vanilla SPIGOT fails, especially in cluster recovery. Finally, the relaxed deterministic models perform very well on accuracy and learn very fast (Figure 2), but appear to rely on mixing clusters, therefore they remarkably fail to recover cluster assignments.[2] This is in line with the structured results of Corro and Titov (2019b). Therefore, if latent structure recovery is less important than downstream accuracy, relaxations seem preferable.

Impact of multiple updates. One possible explanation for the failure of SPIGOT is that SPIGOT-CE and SPIGOT-EG perform more work per iteration, since they use a softmax initial guess and thus require a second pass through the decoder. We rule out this possibility in Figure 3: even when tuning the number of updates, SPIGOT does not substantially improve. We observe, however, that SPIGOT-CE improves slightly with more updates, outperforming STE-I. However, since each update step performs an additional decoder call, this also increases the training time.

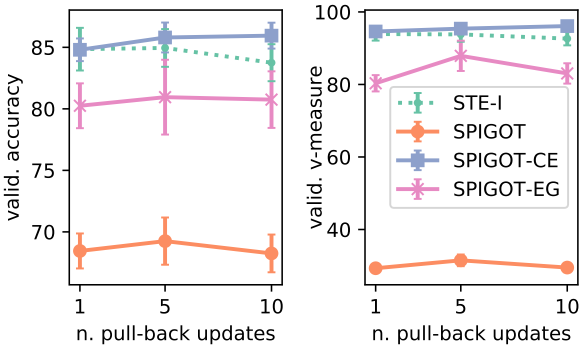

Figure 3: Impact of multiple gradient update steps for the pulled-back label, on the synthetic example with 10 clusters. For each point, the best step size η is chosen.

7.2 Structured Latent Variables

For learning structured latent variables, we study sentiment classification on the English language Stanford Sentiment Treebank (SST) (Socher et al., 2013), and Natural Language Inference on the SNLI dataset (Bowman et al., 2015).

7.2.1 Sentiment Classification

The model predicts a latent projective arc-factored dependency tree for the sentence, then uses the tree in predicting the downstream binary sentiment label. The model has the following components:

- **Encoder:** Computes a score for every possible dependency arc $i \to j$ between words i and j. Each word is represented by its embedding h_i,[3] then processed by an LSTM, yielding contextual vectors $\overleftrightarrow{h_i}$. Then, arc scores are computed as

$$s_{i\to j} = v^\top \tanh\left(W^\top[\overleftrightarrow{h_i};\overleftrightarrow{h_j}]+b\right). \tag{23}$$

---

[2] With relaxed methods, the V-measure is always calculated using the argmax, even though g_θ sees a continuous relaxation.

[3] Pretrained GloVe vectors (Pennington et al., 2014).

Table 3: SST and SNLI average accuracy and standard deviation over three runs, with latent dependency trees. Baselines are described in Section 7.2. We mark stochastic methods marked with *.

- **Latent parser:** We use the arc scores vector s to get a parse $\hat{z} = \rho(s)$ for the sentence, where $\rho(s)$ is the `argmax`, or combination of trees, such as `Marg` or `SparseMAP`.
- **Decoder:** Following Peng et al. (2018), we concatenate each $\overleftrightarrow{h_i}$ with its predicted head $\overleftrightarrow{h}_{\text{head}(i)}$. For relaxed methods, we average all possible heads, weighted by the corresponding marginal: $\overleftrightarrow{h}_{\text{head}(i)} := \sum_j \mu_{i\to j} \overleftrightarrow{h_j}$. The concatenation is passed through an affine layer, a `ReLU` activation, an attention mechanism, and the result is fed into a linear output layer.

For marginal inference, we use `pytorch-struct` (Rush, 2020). For the SparseMAP projection, we use the active set algorithm (Niculae et al., 2018a). The baseline we compare our models against is a BiLSTM, followed by feeding the sum of all hidden states to a two-layer ReLU-MLP.

Results. The results from the experiments with the different methods are shown in Table 3. As in the unstructured case, the relaxed models lead to strong downstream classifiers. Unlike the unstructured case, SPIGOT is a top performer here. The effect of tuning the number of gradient update steps is not as big as in the unstructured case and did not lead to significant improvement. This can be explained by a "moving target" intuition: since the decoder g_θ is far from optimal, more accurate μ do not overall help learning.

7.2.2 Natural Language Inference

We build on top of the decomposable attention model (DA; Parikh et al., 2016). Following the setup of Corro and Titov (2019b), we induce structure on the premise and the hypothesis. For computing the score of the arc from word i to j, we concatenate the representations of the two words, as in Eq. 23. In the *decoder*, after the latent parse tree is calculated, we concatenate each word with the average of its heads. We do this separately for the premise and the hypothesis. As baseline, we use the DA model with no intra-attention.

Results. The SNLI results are shown in Table 3. Here, the straight-through (argmax) methods are outperformed by the more stable relaxation-based methods. This can be attributed to the word-level alignment in the DA model, where soft dependency relations appear better suited than hard ones.

8 Conclusions

In this work, we provide a novel motivation for straight-through estimator (STE) and SPIGOT, based on pulling back the downstream loss. We derive promising new algorithms, and novel insight into existing ones. Unstructured controlled experiments suggest that our new algorithms, which use the cross-entropy loss instead of the perceptron loss, can be more stable than SPIGOT while accurately disentangling the latent variable. Differentiable relaxation models (using softmax and sparsemax) are the easiest to optimize to high downstream accuracy, but they fail to correctly identify the latent clusters. On structured NLP experiments, relaxations (SparseMAP and Marginals) tend to overall perform better and be more stable than straight-through variants in terms of classification accuracy. However, the lack of gold-truth latent structures makes it impossible to assess recovery performance. We hope that our insights, including some of our negative results, may encourage future research on learning with latent structures.

Acknowledgments

The authors are grateful to Caio Corro and the reviewers for their valuable suggestions. This work is built on the open-source scientific Python stack (Van Rossum and Drake, 2009; Harris et al., 2020; van der Walt et al., 2011; Virtanen et al., 2020; Behnel et al., 2011; Pedregosa et al., 2011; Paszke et al., 2019). This work was supported by the European Research Council (ERC StG DeepSPIN 758969), by the P2020 project MAIA (contract 045909), and by the Fundação para a Ciência e Tecnologia through contract UIDB/50008/2020.

A Training Details

We trained all models with AdamW optimizer (Kingma and Ba, 2014; Loshchilov and Hutter, 2018). The embeddings for the SST and SNLI experiments are initialized with Glove embeddings of size 300 (Pennington et al., 2014), available from `https://nlp.stanford.edu/projects/glove/`. The training details for all experiments are described in Table 4.

Computing Infrastructure Each experiment was run on a single GPU. The setup of the computers we used is as follows:

- GPU: Titan Xp - 12GB
  CPU: 16 x AMD Ryzen 1950X @ 3.40GHz - 128GB
- GPU: RTX 2080 Ti - 12GB
  CPU: 12 x AMD Ryzen 2920X @ 3.50GHz - 128GB

B Examples of Latent Trees

We performed a manual analysis of the trees output from the different models. We notice that, on the SST dataset, most latent trees produced by most models are flat. This agrees with related work (Williams et al., 2018; Niculae et al., 2018b). The notable exception is SPIGOT-CE, where the average tree depth on the test set is around 5 and trees seem more informative, suggesting benefits of the cross-entropy loss. Figures 4, 5, 6 show examples of the trees produced from different models.

Is the Best Better? Bayesian Statistical Model Comparison for Natural Language Processing

Abstract

Recent work raises concerns about the use of standard splits to compare natural language processing models. We propose a Bayesian statistical model comparison technique which uses k-fold cross-validation across multiple data sets to estimate the likelihood that one model will outperform the other, or that the two will produce practically equivalent results. We use this technique to rank six English part-of-speech taggers across two data sets and three evaluation metrics.

1 Introduction

Gorman and Bedrick (2019) raise concerns about standard procedures used to compare speech and language processing models. They evaluate the performance of six English part-of-speech taggers using multiple randomly-generated training-testing splits; in some cases, they fail to reproduce previously-published system rankings established using a single "standard" split. They argue that point estimates of performance derived from a single training-testing splits are insufficient to establish system rankings, even when null hypothesis significance testing is used for model comparison.

In this study, we propose a technique for system comparison based on Bayesian statistical analysis. Our approach, motivated in Section 2 and described in Section 3, allow us to infer the likelihood that one model will outperform the other, or even that both models' performance will be practically equivalent, something that is not possible with the frequentist statistical tests used by Gorman and Bedrick. Our approach can also be applied simultaneously across multiple data sets. As a proof of concept, in Sections 4–5 we apply the proposed method using the experimental setup of Gorman and Bedrick, and in Section 6, we use it to rank the six taggers, compare evaluation metrics, and interpret the results. Our failure to reproduce some of earlier reported results leads us to discuss the impact of repeating experiments, contrasting performance in multiple measures and the advantages of comparing likelihoods in Section 6. We also discuss the notion of *practical equivalence* for speech and language technology.

2 Prior work

Langley (1988) argues that machine learning should be viewed as an experimental science, and as such, machine learning technologies should be evaluated according to their performance on multiple held-out data sets. Dietterich (1998) proposes a framework for comparing two supervised classifiers using a null hypothesis tests to determine whether two classifiers have the same likelihood of predicting a correct result. This study introduces several methods, including a paired t-test for k-fold cross-validation results. However, he notes that the assumptions of normality and independence may not be satisfied in all cases. Nadeau and Bengio (2000) propose a correlation-based correction for the Dietterich t-test procedure which adjusts for the overlap between folds. Hull (1994) and Schütze et al. (1995) propose non-parametric tests for comparing models across multiple data sets; Salzberg (1997) proposes Bonferroni-corrected ANOVA analysis. Demšar (2006) reports that the Friedman non-parametric test with the Nemenyi correction makes fewer assumptions and has greater power than parametric tests. Other authors (e.g., Luengo et al., 2009; García et al., 2010; Derrac et al., 2011) further adapt the Friedman test for model comparison.

However, as Demšar (2006) notes, there still does not exist a non-parametric null hypothesis test designed for use with a repeated measure (i.e., k-fold) design across multiple data sets. As a result,

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2203–2212,
November 16–20, 2020.

there is no procedure that takes into consideration the variance in scores of a given data set, at least within the frequentist paradigm. Demšar (2008) and Benavoli et al. (2017) enumerate additional problems with null hypothesis significance testing (NHST) procedures for model comparison:

- NHST does not estimate probabilities for hypotheses; i.e., it does not tell us how likely two models are to perfrom equivalently,
- NHST p-values conflate effect size and sample size; i.e., with a sufficiently large sample, one can claim significance even if the effect size is trivial,
- NHST yields no information about the null hypothesis; i.e., one cannot draw further conclusions from a failure to reject the null hypothesis, and
- there is no principled way to select an appropriate α-level for NHST.

These issues lead Benavoli et al. to reject NHST-based model comparison in favor of a Bayesian approach. Bayesian hypothesis tests are defined by a likelihood function $p(d \mid \theta)$, a probability model of the data d conditioned on θ, a vector of parameters. The prior distribution for θ, $p(\theta)$ must also be defined. From these components, a posterior probability distribution $p(\theta \mid d)$ can then be calculated and queried (i.e., sampled from) to perform inference. Various techniques can be used to estimate θ; they are usually related to the differences in models' scores using some evaluation metric, and ultimately, to whether one method is likely to perform better or worse than the other. Thus, the posterior distribution can be used to perform model comparison. Benavoli et al. also introduce the notion of a *region of practical equivalence* (henceforth, ROPE), which allows Bayesian hypothesis testing to estimate the likelihood that two models' results will be functionally indistinguishable. ROPE defines an interval around a model's result - if another model's performance falls within this interval - they are deemed practically equivalent. For example, if one deems that a difference of 1 percentage point in accuracy between models denotes practical equivalence, a $[-0.01, 0.01]$ interval is used as ROPE. If one model performs at .941 accuracy and another at .949 - they will be deemed practically equivalent. This allows to protect the statistical procedure from artifacts and false alarms of significance. Readers are referred to the accessible tutorial by Benavoli et al. (2017) for further details.

Corani et al. (2017) generalize Bayesian model comparison to a repeated measures scenario in which there are multiple data sets with unequal score variances. They propose a hierarchical Bayesian model for estimating the likelihood of one model performing better, worse, or equivalently, to another. We now proceed to briefly describe and adapt this procedure to re-evaluate the findings of Gorman and Bedrick (2019).

3 Bayesian model comparison

Imagine a scenario where one wishes to compare the performance of two classifiers across q data sets. By performing m k-fold evaluations, the experimenter obtains a vector of $n = mk$ observations, i.e., differences in scores, between the two models: $\mathbf{x}_i = (x_{i,1}, \ldots, x_{i,n})$. The values in these vectors are a positive cross-correlation ϱ because cross-validation introduces overlap in training data. Let δ_i denote the mean difference score on the ith data set, and let δ_0 denote the average population-level difference. Corani et al. (2017) propose a hierarchical probabilistic model

$$\begin{aligned} \mathbf{x}_i &\sim \mathrm{MVN}(1\delta_i, \Sigma_i), \\ \delta_1 ... \delta_q &\sim t(\mu_0, \sigma_0, \nu), \\ \sigma_1 ... \sigma_q &\sim \mathrm{unif}(0, \bar{\sigma}) \end{aligned} \tag{1}$$

where MVN is a multivariate normal distribution over the vector of classifier differences with mean δ_i and a covariance matrix Σ_i with variance σ_i^2 along the diagonal and $\varrho\sigma_i^2$ on the off-diagonal. Data set variances are drawn from a Student distribution parameterized by the average population-level difference δ_0 and variance σ_0, with μ degrees of freedom. The prior distributions for δ_0, σ_0, and μ are defined so as to preserve the robustness of the model; these are motivated and described in more detail by Corani et al. (2017). Crucially, we model the differences obtained in individual runs using a multi-variate normal distribution oriented to the per-data set mean differences with a per-data set variance, and the mean differences using a unimodal distribution robust to outliers and non-normality. Per-data set variances are modeled by a uniform distribution.

After the model learns the parameter distributions from experimental data, we obtain a posterior probability distribution $p(\delta_0, \sigma_0, \mu \mid d)$. To infer whether one classifier is more likely to outperform another—or whether they are practically equivalent—we draw N_s samples from the posterior distribution. We use decision counters n_{left}, n_{rope}, and n_{right} to keep track of how many times the left model was more likely to outperform the right model, to be practically equivalent to the right model, and to be outperformed by the right model, respectively. For each sample of the parameters, we define the posterior of the mean difference accuracy on a new unseen data set δ_{next} as $t(\delta_0, \sigma_0, \mu)$. We obtain the outcome probabilities by integrating the distribution over the three intervals—e.g., we obtain the probability that the left model is better than the right by integrating from the left end of the distribution to the left edge of the ROPE interval, and so on—and then incrementing the decision counter for the region with the highest outcome probability. Finally, we compute likelihoods for the three scenarios by dividing the decision counts by the number of samples drawn: $P(left) = \frac{n_{left}}{N_s}$, $P(rope) = \frac{n_{rope}}{N_s}$, and $P(right) = \frac{n_{right}}{N_s}$.

Instead of significance, we thus estimate the likelihoods that one method is better than the other (or are practically equivalent). These estimates follow from observing the beliefs of a Bayesian model that models the probability of the methods' mean difference on unseen data sets, after sampling parameters from a meta-distribution which estimates the difference and variance over the population of data sets with μ degrees of freedom.

4 Materials and methods

To compare the results of our study with the ones obtained by Gorman and Bedrick (2019), we use the same models, data sets, and evaluation metrics.[1] That is, we compare implementations of the TnT (Brants, 2000), Collins (Collins, 2002), LAPOS (Tsuruoka et al., 2011), Stanford (Manning, 2011), NLP4J (Choi, 2016), and Flair (Akbik et al., 2018) part-of-speech taggers using the Wall St. Journal portions of the Penn Treebank (v. 3; Marcus et al., 1993) and OntoNotes (v. 5; Weischedel et al., 2011), two widely-used corpora of American English financial news. Summary statistics for this data are given in Table 1.

	# sentences	# tokens
Penn Treebank	49,208	1,173,766
OntoNotes	37,025	901,673

Table 1: Summary statistics for the two corpora.

We perform 20 randomized 10-fold cross validations, obtaining 200 measurements of each model's performance on each data set. In each run, 80% of the data is used for training, 10% for validation, and 10% for evaluation. We fit Bayesian models using the `baycomp` library[2] and draw 50,000 samples from the posterior.

Following Gorman and Bedrick, we use three evaluation metrics. Token accuracy is simply the number of test data tokens correctly tagged divided by the total number of tokens, and is the standard intrinsic evaluation metric used for this task. OOV accuracy is similar to token accuracy but is restricted to out-of-vocabulary tokens, i.e., those found in the test data but not in the training data. Finally, sentence accuracy is the number of test data sentences that contain no tagging errors, divided by the number of test sentences. Ground-truth data is provided by human annotators.[3]

5 Results

Posterior distributions of the hierarchical models are visualized in Figures 1–3 and summarized in Table 2. We define the ROPE to have the same size as the 95% confidence interval; this is roughly 2–3% for sentence and OOV accuracy, and 0.2% for token accuracy. Thus, two models are judged to be practically equivalent in sentence accuracy if they differ in performance on fewer than 98 sentences of the Penn Treebank or 75 sentences on the slightly smaller OntoNotes corpus. For token accuracy, they are practically equivalent if they differ on fewer than 210 PTB tokens or 162 OntoNotes tokens, respectively.

The hierarchical model estimates, for example, that TnT, the simplest tagger, would be outperformed in token accuracy by any of the other five taggers 80-90% of the time. However, there is a surprisingly high chance of practical equivalence in token accuracy between the Collins tagger, LAPOS, and the Stanford tagger; for instance,

Table 2: Token, sentence, and OOV accuracy ranking likelihoods.

the probability of practical equivalence of the latter two is 84%. This result is contrary to Gorman and Bedrick's replication of a standard split evaluation—they report that LAPOS is significantly better than the Collins tagger, and that the Stanford tagger is significantly better than LAPOS, according to two-tailed McNemar tests at $\alpha = .05$—but it is consistent with their subsequent failure to consistently reproduce this ranking using randomly-generated splits and Bonferroni-corrected McNemar tests. In contrast, NLP4J and Flair are quite likely to outperform the other taggers, and Flair has an 80% chance of outperforming NLP4J.

Similar results are obtained with sentence accuracy, a less-commonly used metric. TnT is once again quite likely to be outperformed by other models. Whereas LAPOS is quite likely to outperform the Collins tagger, there is an 82% probability that LAPOS and Stanford taggers will yield practically equivalent results. Both NLP4J and Flair are both quite likely to outperform earlier models, and Flair is most likely to outperform NLP4J.

There is a 55% chance of practical equivalence between TnT and the Collins tagger for OOV accuracy. This is somewhat surprising because the two models use rather different strategies for OOV inference: TnT estimates hidden Markov model emission probabilities for OOVs using a simple suffix-based heuristic (Brants, 2000, 225f.), whereas the Collins tagger, a discriminatively-trained model, uses sub-word features developed by Ratnaparkhi (1997) to handle rare or unseen words. Similarly, whereas NLP4J and Flair also use distinct OOV modeling strategies, we estimate that they have a 62% likelihood to achieve practical equivalence on this metric.

6 Discussion

Using the methods above, we obtain the following likelihood-based performance rankings:

- token accuracy: TnT $<$ Collins $\approx$ LAPOS $\approx$ Stanford $<$ NLP4J $<$ Flair,
- sentence accuracy: TnT $<$ Collins $<$ LAPOS $\approx$ Stanford $<$ NLP4J $<$ Flair, and
- OOV accuracy: TnT $\approx$ Collins $\approx$ LAPOS $<$ Stanford $\lessapprox$ NLP4J $\approx$ Flair.

We also find some divergences from the results reported by Gorman and Bedrick. For instance, they find that the Stanford tagger has significantly higher token accuracy than LAPOS on the Penn Treebank standard split. According to our model, the two taggers are most likely practically equivalent, a result which is consistent with their later finding that Stanford outperforms LAPOS on only 1 out of 20 Penn Treebank random splits. We also find out that while both taggers were practically equivalent in both token and sentence accuracy, Stanford is likely to outperform LAPOS in OOV words, which could have impacted the statistical significance in the original experiment, as the repetition of the k-fold procedure causes strong variation - of the vocabulary available at training and OOV token sets - between experimental runs.

We note that Bayesian comparison and the precise quantities it estimate may give insights into the particular strengths and weaknesses of the various models and evaluation metrics. For instance, we infer that whereas the Collins tagger improves upon TnT, and Flair improves upon NLP4J, in both token and sentence accuracy, these improvements are not likely to be due to differences in the models' handling of out-of-vocabulary words. This is because TnT and the Collins tagger, and NLP4J and Flair, are most likely practically equivalent in their tagging accuracy for OOV words.

In Bayesian approaches as we are thinking about probabilities of a method outperforming another method. As a result we can do what was not possible in the NHST approach taken by Gorman and Bedrick. We can order methods into at a partial ordering to gain an insight into which methods are more likely to perform better than others. We can do this based on the modeled likelihoods, but it would not be in a NHST framework, because there are currently no multiple comparison correction procedures that take into account the variance of repeated runs of a method on the same data set.

Gorman and Bedrick reported that LAPOS would be sure to outperform Collins on PTB (20 out of 20 times), but not on Ontonotes (7 out of 20 times) in token accuracy. We found out that that the most likely scenario, when the performance is modeled using a hierarchical model on evidence from both data sets jointly, that these difference are likely within practical equivalence.

We set the interval of practical equivalence of observed accuracies to match the 95% confidence intervals reported by Bedrick and Gorman, to maintain a capacity for comparing the two experimental approaches. However, we believe it is much more useful to have an interpretable and intuitively understandable definition of what practical equivalence means in the experiment. Instead of setting it based on statistical confidence intervals, we recommend selecting the ROPE to represent the scale of human annotator differences, or the error level that does not negatively impact a downstream task that depends on the prediction quality of evaluated methods.

7 Conclusions

We compare the performance of six part-of-speech taggers on two data sets using twenty repetitions of a ten-fold cross-validation procedure and statistical system comparison performed using hierarchical Bayesian models. By sampling from the posterior distribution of these models, we estimate the likelihood that a given tagger will be better than, worse than, or practically equivalent to other taggers on three different evaluation metrics. These estimates are valid insofar as the data sets used to estimate the Bayesian models comprise a representative sample of a coherent population of data sets. This method provides a principled way to perform statistical model comparison using *k*-fold cross-validation, a data-efficient evaluation technique. It also allows us to incorporate results obtained across multiple data sets and to make population-level inferences. We finally compare the results obtained with the proposed method to those computed using randomly generated splits and traditional NHST-based model comparison. The results provide new insights into the strengths and weaknesses of English part-of-speech tagging models, complementing other approaches to model comparison and interpretation.

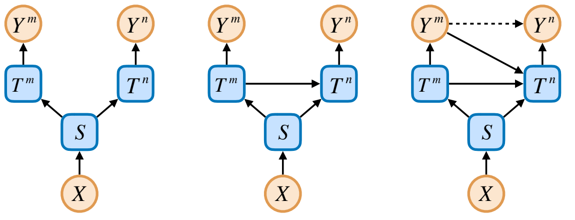
Abstract

Previous studies have shown that hierarchical multi-task learning (MTL) can utilize task dependencies by stacking encoders and outperform democratic MTL. However, stacking encoders only considers the dependencies of feature representations and ignores the label dependencies in logically dependent tasks. Furthermore, how to properly utilize the labels remains an issue due to the cascading errors between tasks. In this paper, we view logically dependent MTL from the perspective of causal inference and suggest a mediation assumption instead of the confounding assumption in conventional MTL models. We propose a model including two key mechanisms: label transfer (LT) for each task to utilize the labels of all its lower-level tasks, and Gumbel sampling (GS) to deal with cascading errors. In the field of causal inference, GS in our model is essentially a counterfactual reasoning process, trying to estimate the causal effect between tasks and utilize it to improve MTL. We conduct experiments on two English datasets and one Chinese dataset. Experiment results show that our model achieves state-of-the-art on six out of seven subtasks and improves predictions' consistency.

1 Introduction

Multi-task learning (MTL) has received increasing interest with the knowledge transfer potential among related tasks (Caruana, 1997; Ruder et al., 2017; Liu et al., 2019). Recently, hierarchical MTL models (Hashimoto et al., 2017; Sanh et al., 2018) were proposed for tasks with dependencies and achieved better performance than democratic ones. In their models, the encoders of different tasks were stacked. And the proposition is that complex tasks at top layers require deep processes to capture semantic richer features, and simple tasks at bottom layers require shallow processes.



(a) Democratic (b) Hierarchical (c) Logically Dependent

Figure 1: Three types of MTL schemes for two tasks t_m and t_n: (a) Democratic MTL shares an encoder S and owns task-specific encoders T^i ($i = m$ or n); (b) Hierarchical MTL stacks those task-specific encoders; (c) Logically dependent MTL further considers the label dependencies by re-utilizing low-level tasks' labels.

However, many hierarchical MTL models only consider the dependencies of feature representations and ignore the label dependencies. A direct comparison is shown in Figure 1. Let X denote a given input, and Y^m and Y^n denote the outputs of two tasks, respectively. The first two MTL schemes (Liu et al., 2017; Zheng et al., 2018; Sanh et al., 2018) substantially model the likelihood by $P(Y^m, Y^n|X)=P(Y^m|X)P(Y^n|X)$ while the third MTL scheme (Bekoulis et al., 2018; Luan et al., 2019) models it by: $P(Y^m, Y^n|X)=P(Y^m|X)P(Y^n|X, Y^m)$. From the causal perspective, the first two schemes assume that Y^m and Y^n are conditional independent, while the third scheme assumes that Y^m has a causal effect on Y^n. In this paper, we suggest that the causal effect is important for logically dependent tasks. And we propose a mechanism referred to label transfer (LT), which lets a task utilize the labels of all its lower-level tasks.

When utilizing discrete labels, there remains another issue. For example, the strategy in (Bek-

oulis et al., 2018) used gold labels of low-level tasks during training and used predicted ones during testing. Apparently, there was a train-test discrepancy which leads to cascading errors between tasks. And it was similar to the exposure bias problem in the field of text generation (Ranzato et al., 2016). Recently, two approaches have been investigated to overcome the problem, which are Gumbel Sampling (GS) (Kusner and Hernández-Lobato, 2016; Nie et al., 2019) and Reinforcement Learning (RL) (Yu et al., 2017; Guo et al., 2018). In this paper, we regard the logically dependent MTL as a task-level label generation problem. And we incorporate GS because it feeds the optimizer with low-variance gradients, improving stability and speed of training over RL. Specifically, our model samples a label from the predicted probability distribution for each task and feeds it to its higher-level tasks. And back-propagated gradients will penalize wrong predictions if the causal effect exists. From the perspective of causal inference, the sampling is a counterfactual reasoning process that can estimate the causal effect between different tasks' labels. And we hope a model properly cooperating causality will be more robust and transferable, as argued in (Schölkopf, 2019).

To verify the effectiveness of our model, we conduct experiments on two English and one Chinese MTL datasets. The results show that our model achieves state-of-the-art (SOTA) on 6 out of 7 subtasks and improves predictions' consistency. And we present the estimated causal effect for several cases, which is consistent with humans' prior knowledge. In conclusion, the contributions of this paper can be summarized as follows:

- We view MTL from the causal perspective and suggest a mediation assumption instead of the confounding assumption in conventional MTL models.
- We propose a novel MTL model with two key mechanisms: label transfer and Gumbel sampling, which better utilize task dependencies and alleviate cascading errors.
- The experiments are carried on both English and Chinese datasets and demonstrate our model's effectiveness and better consistency of predicted results for subtasks.

2 Related Work

In natural language processing (NLP), many studies focus on modeling task dependencies to improve MTL. A line of work proposed hierarchical MTL architectures by stacking the encoders of different tasks with simple tasks at lower layers and complex tasks at top layers (Sgaard and Goldberg, 2016; Hashimoto et al., 2017; Sanh et al., 2018). And Zhong et al. (2018) proposed a topological MTL architecture based on the topological hierarchy of tasks. Another line of work tried to re-encode the predictions of low-level tasks. Giannis et al. (2018) re-encoded the predicted labels with the highest probability of low-level tasks during testing, and encoded the gold labels during training. Luan et al. (2019) re-encoded the soft predictions during testing and also encoded the gold ones during training. Yang et al. (2019) proposed a bidirectional architecture producing initial probability distributions for different tasks and then refine the probability distributions by conditioning on each other during both training and testing.

Our work is also related to some studies for text generation. The democratic and hierarchical MTL schemes in Figure 1 are similar to the non-autoregressive language models like BERT (Devlin et al., 2019) which is possible to generate syntactically incorrect sentences (Ghazvininejad et al., 2019). The logically dependent MTL scheme is similar to the autoregressive language model but remains a train-test discrepancy. GS or RL learning have been investigated to deal with the discrepancy (Kusner and Hernández-Lobato, 2016; Yu et al., 2017; Guo et al., 2018; Nie et al., 2019).

3 Task Definition

To show that our method's high versatility, we investigate three different MTL scenarios: joint entity and relation extraction (JERE), aspect-based sentiment analysis (ABSA), and legal judgment prediction (LJP).

3.1 Joint Entity and Relation Extraction

JERE includes entity mention extraction (EMD) and relation extraction (RE) (Li and Ji, 2014).

Entity Mention Extraction. EMD can be formulated as a sequence labeling problem with a BILOU scheme (Sanh et al., 2018). Given a sequence of tokens $X = \{x_1, x_2, ..., x_n\}$, EMD assigns a categorical label to each token $Y^{(e)} =$

$\left\{y_1^{(e)}, y_2^{(e)}, ..., y_n^{(e)}\right\}, y_i^{(e)} \in \mathcal{C}_{(e)}$ where $\mathcal{C}_{(e)}$ denotes a predefined set of categories.

Relation Extraction. RE can be formulated as a multi-head selection problem (Bekoulis et al., 2018). For the given sentence X, RE will output a three-dimensional matrix $Y^{(r)} = \{y_{i,j,c}^{(r)}\}, i{\leq}n, j{\leq}n, c \in \mathcal{C}_{(r)}$ where $y_{i,j,k}^{(r)}$ denotes a binary value representing the existence of the cth relation between the ith and the jth tokens, and $\mathcal{C}_{(r)}$ denotes the set of categories. Consistent with (Bekoulis et al., 2018), we only consider relations between the last token of the head entity mentions. Redundant relations are therefore not classified.

3.2 Aspect Based Sentiment Analysis

The challenge of "SemEval-2014 Task 4" divides ABSA into four subtasks (Pontiki et al., 2014), and we consider two subtasks which are logically dependent.

Aspect Term Extraction. ATE can also be formulated as a sequence labeling problem with BILOU scheme (Li et al., 2019) or BIO scheme (Luo et al., 2019b; He et al., 2019). Similar to EMD, ATE assigns a categorical label to each token $Y^{(t)} = \left[y_1^{(t)}, y_2^{(t)}, ..., y_n^{(t)}\right], y_i^{(t)} \in \mathcal{C}_{(t)}$ where $\mathcal{C}_{(t)}$ denotes a predefined set of categories.

Aspect Category Detection. ACD is to detect the aspect categories for the given sentence X, which can be formulated as a multi-label classification problem. Let $\mathcal{C}_{(d)}$ denotes a predefined set of categories, we need to predict a label set $Y^{(d)} = \{y_c^{(d)}\}, c \in \mathcal{C}_{(d)}$ for the given sentence X where $y_c^{(d)}$ is a binary value representing existence of the cth category.

3.3 Legal Judgment Prediction

LJP aims to predict the judgment results of legal cases, such as relevant law articles and charges. In this paper, we consider three subtasks for Chinese LJP: **Relevant Article Prediction** (RAP), **Charge Prediction** (CP), and **Prison Term Prediction** (PTP). Following previous work (Zhong et al., 2018; Yang et al., 2019), we only consider those cases with single relevant article and single charge, and divide the prison term into non-overlapping intervals. Then each subtask can be formulated as a single-label classification problem. Specifically, for the given case X, LJP is to assign labels $y^{(a)} \in \mathcal{C}_{(a)}, y^{(c)} \in \mathcal{C}_{(c)}, y^{(p)} \in \mathcal{C}_{(p)}$ where $\mathcal{C}_{(a)}, \mathcal{C}_{(c)}$ and $\mathcal{C}_{(p)}$ are the sets of categories of RAP, CP, and PTP, respectively.

For the three MTL scenarios, the common point is that the subtasks in each are logically dependent. And we have prior knowledge of that the logical orders are EMD→RE, ATE→ACD, and RAP→CP→PTP respectively. And the first scenario is to investigate the knowledge transfer between two token-level tasks, and the second scenario is from a token-level to a sentence-level task. The third is among three sentence-level tasks.

4 Methodology

In this section, we first analyze MTL from the causal perspective in Subsection 4.1 and then introduce our models in the following subsections.

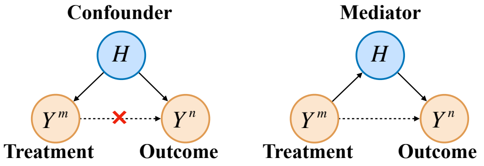

Figure 2: Two kinds of typical causal assumptions. Let H be the feature representation for X, and Y^m and Y^n be the outputs for two tasks t_m and t_n, respectively. The confounding assumption (the left sub-figure) considers Y^m and Y^n to be conditionally independent, while the mediation assumption (the right sub-figure) considers the logical dependency from Y^m to Y^n.

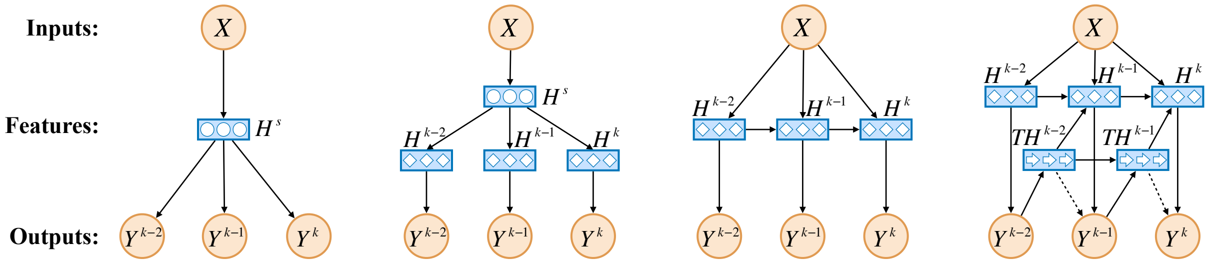
4.1 Basic Causal Assumptions

Let X, Y be two variables representing a sequence of text and the corresponding label, and H be the feature representations of X. The causal graph is therefore $X{\rightarrow}H{\rightarrow}Y$. Previous work suggests that MTL may help extract common useful features (Liu et al., 2017), which mainly enhance the process $X{\rightarrow}H$. When considering $H{\rightarrow}Y$, there are two possible causal assumptions for MTL: the confounding and mediation shown in Figure 2 where Y^m and Y^n are the outputs of task t_m and t_n respectively.

The confounding assumption is that Y^m and Y^n are conditionally independent and only determined by H. However, For logically dependent tasks, we suggest a mediation assumption that Y^m has a causal effect on Y^n. Specifically, the assumption includes two causal paths between Y^m and Y^n. One links Y^m to Y^n through the mediator H (the solid line), known as the indirect effect. The other links Y^m to Y^n directly (the dashed line), known as the direct effect.

It is worth noting that someone may argue that



(a) Fully-Shared MTL (b) Shared-Private MTL (c) Hierarchical MTL (d) Causal MTL (Ours)

Figure 3: The full causal graphs of four types of MTL models: (a) Fully-Shared MTL shares the feature representation H^s for all tasks; (b) Shared-Private MTL learns a task-specific representation H^k based on H^s for task t_k; (c) Hierarchical MTL stacks the encoders of different tasks; (d) Our model Causal MTL further incorporates the inter-task causality through the indirect causal path, $TH^{k-1} \to H^k \to Y^k$, and the direct causal path, $TH^{k-1} \to Y^k$.

Y^m and Y^n can have mutual causal effects on each other, but the causal graphs are acyclic in most cases. Moreover, recent work has demonstrated that the hierarchical order matters (Sanh et al., 2018).

4.2 Full Causal Graphs

We denote our model as causal multi-task learning (CMTL) and show the full causal graphs in Figure 3 when considering more than two tasks. We also compare with other three typical MTL models, including fully-shared multi-task learning (FSMTL), shared-private multi-task learning (SPMTL), hierarchical multi-task learning (HMTL). FSMTL shares the feature representation H^s for all tasks, and SPMTL learns a task-specific representation H^k based on H^s for task t_k. HMTL stacks the encoders of different tasks. Our model CMTL is derived from HMTL, but the main difference is that CMTL incorporates the inter-task causality through two paths. It first creates an intermediate variable TH^{k-1} conveying the label information of all tasks preceding t_k. Then the model involves the indirect causal effect by the path $TH^{k-1} \to H^k \to Y^k$. And it also involves the direct causal effect by the path $TH^{k-1} \to Y^k$.

4.3 Model Details

The architecture of our model is shown in Figure 4. Generally, the indirect causal effect is implemented by the solid lines connecting "Label Transfer" and "Encoders". And the direct causal effect is implemented by the dashed lines connecting "Label Transfer" and "Predictors".

Token Embedding. Firstly, given an input sentence, X with length n, a token embedding layer is used to map each token into a fixed-dimensional vector. When combining with BERT (Devlin et al., 2019), we will keep it fixed during training to save the cost of memory. And BERT will convert X to a sequence of WordPiece tokens with a length greater than n. To make it suitable for token-level tasks, we select the first WordPiece token embedding for each original token. Furthermore, we use the normalization of different layers, which is similar to ELMo (Peters et al., 2018) to utilize deep and shallow embeddings. The final token embeddings are denoted by $\boldsymbol{E} = \{\boldsymbol{e}_i\}_{1 \leq i \leq n}$.

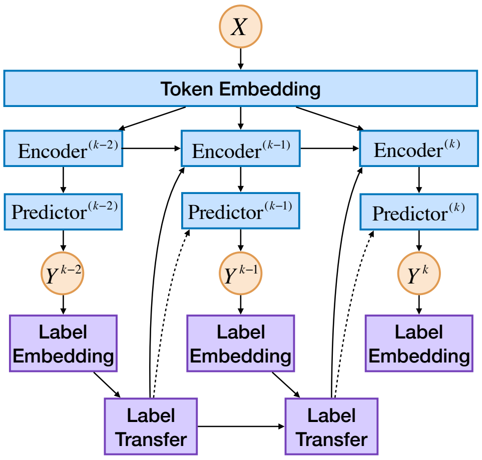


Figure 4: The architecture of CMTL. The indirect and direct causal paths are implemented by the solid lines connecting "Label Transfer" and "Encoders", and the dashed lines connecting "Label Transfer" and "Predictors", respectively.

Label Embedding. As shown in Figure 4, label embedding layers are used to encode the labels of tasks. We denote the gold label of task t_k as $Y^k = \{y_i^k\}, y_i^k \in \mathcal{C}_k$ where $\mathcal{C}_k$ is the set of categories. Let $1 \leq i \leq n$ when t_k is a token-level task, and let $i=0$ when t_k is a sentence-level task (Y^k contains only one element). Then our model encode Y^k to label embeddings $\boldsymbol{LE}^k = \{\boldsymbol{le}_i^k\}$. Specifically, our model convert y_i^k to a one-hot vector $\boldsymbol{y}_i^k$, and compute the label embedding by:

$$\boldsymbol{le}_i^k = \boldsymbol{W}^k \boldsymbol{y}_i^k \tag{1}$$

where $\boldsymbol{W}^k$ is the parameter matrix for task t_k with shape $d_l \times |\mathcal{C}_k|$ and d_l is the dimension of label embeddings. In this way, the labels of different tasks are mapped into the same latent space.

Label Transfer. After label embedding, for a task, we want our model to utilize the label information of all its preceding tasks instead of only the last one. This process is naturally suitable for recurrent neural networks (RNNs) in which the k-th element depends on its preceding $k-1$ elements. In our model, RNN-LSTM (Hochreiter and Schmidhuber, 1997) is adopted for LT which maintains transferred hidden states $\boldsymbol{TH}^k = \{\boldsymbol{th}_i^k\}$ for task t_k. And the computation of $\boldsymbol{th}_i^k$ can be expressed as:

$$\boldsymbol{th}_i^k = \overrightarrow{LSTM}^{(\mathrm{LT})}(\boldsymbol{le}_i^{k-1}, \boldsymbol{th}_i^{k-1}) \tag{2}$$

Similarly, we have $1 \le i \le n$ when t_k is a token-level task, and let $i=0$ when t_k is a sentence-level task. It means that Equation 2 can be used for token-level or sentence-level transfer.

Encoders. Then the transferred label will be fed to encoders. As shown in Figure 4, the inputs of Encoder$^{(k)}$ include three parts: the token embeddings, the transferred label, and the outputs of $(k-1)$th encoder. And the outputs $\boldsymbol{H}^k$ can be represented by:

$$\boldsymbol{H}^k = \mathrm{Encoder}^{(k)}\left(\boldsymbol{E}, \boldsymbol{TH}^{k-1}, \boldsymbol{H}^{k-1}\right) \tag{3}$$

Generally, the choice of encoder falls into three categories: RNN, CNN, and Transformer (Vaswani et al., 2017). And we mainly implement RNN and CNN in our model because the memory complexity of Transformer is $\mathrm{O}(n^2)$ (Kitaev et al., 2020), which is much higher for long text.

For the MTL scenarios JERE and ABSA, the encoders are based on bidirectional LSTM (BiLSTM). Equation 3 becomes:

$$\boldsymbol{H}^k = \mathrm{BiLSTM}^{(k)}\left(\boldsymbol{E} \oplus \boldsymbol{TH}^{k-1} \oplus \boldsymbol{H}^{k-1}\right) \tag{4}$$

where $\oplus$ denotes the concatenation operation along the last dimension. And $\boldsymbol{H}^k$ is the feature representation of X for task t_k with shape $n \times d_h$, and d_h is the size of hidden states.

For the MTL scenario LJP, the subtasks are all sentence-level classification tasks and we empirically find that involving CNN performs better than simply adopting BiLSTM (see Section 5.4). And we employ CNN encoders (Kim, 2014) followed with max pooling to generate initial sentence-level representations $\boldsymbol{h}_{init}^k$ and a shared LSTM layer to generate final representations $\boldsymbol{h}_0^k$ for task t_k:

$$\boldsymbol{h}_{init}^k = \mathrm{pool}\left(\mathrm{CNN}^{(k)}\left(\boldsymbol{E}\right)\right) \tag{5}$$

$$\boldsymbol{h}_0^k = \overrightarrow{LSTM}^{(\mathrm{s})}\left(\boldsymbol{h}_{init}^k \oplus \boldsymbol{th}_0^{k-1},\ \boldsymbol{h}_0^{k-1}\right) \tag{6}$$

where $\boldsymbol{th}_0^{k-1}$ denotes the sentence-level transferred label embedding.

Predictors. Then the predictors will process $\boldsymbol{H}^k$ (or $\boldsymbol{h}_0^k$) and $\boldsymbol{TH}^{k-1}$ (or $\boldsymbol{th}_0^{k-1}$) as follows:

$$\widehat{\boldsymbol{y}}_i^k = \mathrm{Predictor}^{(k)}\left(\boldsymbol{h}_i^k \oplus \boldsymbol{th}_i^{k-1}\right) \tag{7}$$

where $1 \le i \le n$ for JERE and ABSA, and $i=0$ for LJP. And $\widehat{\boldsymbol{y}}_i^k$ is the predicted probability distribution with shape for the categories in $\mathcal{C}_k$. The predictors are simply based on fully connected networks, and sequence labeling tasks do not involve conditional random field (CRF) (Lafferty et al., 2001). More details can be found in Appendix.

4.4 Gumbel Sampling

During the training stage, for task t_k, we can pre-train the network using the gold labels $Y^j = \{y_i^j\}_{j<k}$ of all the low-level tasks. However, the train-test discrepancy has not been tackled because the model uses predicted labels of low-level tasks during testing. To deal with the problem, we use GS to sample a label from the predicted probability distribution $\widehat{\boldsymbol{y}}_i^j$. Specifically, we assume that Predictor$^{(j)}$ involves a logit value $\boldsymbol{o}_i^j$ followed with a softmax function to produce the probability distribution $\widehat{\boldsymbol{y}}_i^j$.

$$\widehat{\boldsymbol{y}}_i^j = \mathrm{softmax}(\boldsymbol{o}_i^j) \tag{8}$$

Gumbel-softmax uses a re-parameter trick to approximate the multinomial sampling by:

$$\widetilde{\boldsymbol{y}}_i^j = \mathrm{softmax}((\boldsymbol{o}_i^j + \mathbf{g})/\tau) \tag{9}$$

where $\mathbf{g}$ samples from Gumbel$(0, 1)$ and τ is the temperature. When $\tau \to 0$, $\widetilde{\boldsymbol{y}}_i^j$ approximated to the one-hot vector of a sampled value from $\widehat{\boldsymbol{y}}_i^j$. During training, our model will replace gold labels by $\widetilde{\boldsymbol{y}}_i^j$. And then a low-level task will have certain probabilities to sample a counterfactual value, and get feedback from high-level tasks if the causal effect is actually existed.

4.5 Interpretation From a Causal Perspective

After training, we attempt to interpret our model from a causal perspective to inspect what matters for predictions. The key idea is causal effect estimation from observed data (Veitch et al., 2019), which is based on Pearl's theory with the intervening operation (Pearl, 2010). Considering two tasks t_m and t_n, we would estimate the causal effect of a label y_i^m of task t_m on a label y_j^n of task t_n. We first intervene y_i^m to get a random counterfactual value $\overline{y}_i^m \neq y_i^m$. Under the mediation assumption, the average causal effect is estimated by:

$$\begin{aligned}\Psi\left(y_i^m, y_j^n\right) &= \mathbb{E}\left[f\left(y_j^n | y_i^m, H^n(y_i^m)\right)\right] \\ &\quad - \mathbb{E}\left[f\left(y_j^n | \overline{y}_i^m, H^n(\overline{y}_i^m)\right)\right]\end{aligned} \tag{10}$$

where $\mathbb{E}(\cdot)$ stands for the expectation operation on the observed data, and $f(y_j^n | \overline{y}_i^m, H^n(\overline{y}_i^m)$ stands for the predicted probability of y_j^n given $\overline{y}_i^m$ and the corresponding features $H^n(\overline{y}_i^m)$ for task t_n.

Besides estimating the causal effect of labels, we also inspect the influence of the elements in X like n-grams. We can intervene the original sequence to get another text sequence $\overline{X}_{x_g}$ with an n-gram x_g masked out. Since n-grams may be quite sparse, only the individual causal effect is estimated:

$$\psi\left(x_g, y_j^n\right) = f^n\left(y_j^n | X\right) - f^n\left(y_j^n | \overline{X}_{x_g}\right) \tag{11}$$

where $f^n(\cdot)$ represents the prediction for task t^n given a text sequence.

Dataset	Train	Dev	Test	Type
JERE	351	80	80	Document
	7,273	1,765	1,535	Sentence
ABSA	2,587	457	800	Sentence
LJP	102,177	13,143	25,149	Document

Table 1: Statistics of three MTL datasets.

5 Experiments

5.1 Datasets

To verify the effectiveness of our model, we experiment on three datasets corresponding to three MTL scenarios. For JERE, we use the ACE05 corpus (Doddington et al., 2004), which covers 7 types of entities and 6 types of relations. We use the same data splits as previous work (Katiyar and Cardie, 2017; Sanh et al., 2018). For ABSA, we use restaurant domain reviews of SemEval-2014 task 4 (Pontiki et al., 2014). ATE is a simple BIO tagging task, and ACD is a multi-label classification task with 5 categories. Furthermore, we randomly hold-out 15% of the training data as the development set. For LJP, we use the CAIL (Chinese AI and Law Challenge) 2018 dataset. Following (Zhong et al., 2018; Yang et al., 2019), we only consider those cases with a single law article and single charge. Meanwhile, those infrequent law articles and charges (less than 100 in the train set) are not included. And we divide the terms into non-overlapping intervals, which is consistent with (Zhong et al., 2018). The number of categories for RAP, CP, and PTP is 94, 116, and 11, respectively. The statistics of the filtered datasets can be found in Table 1.

5.2 Baselines

The compared models include two single-task models which use **BiLSTM** and **CNN** (Kim, 2014) as encoders respectively, and three conventional multi-task models including **FSMTL** (Liu et al., 2017; Zheng et al., 2018), **SPMTL** (Liu et al., 2017; Zheng et al., 2018), and **HMTL** (Sanh et al., 2018). Besides these models, we also compare several SOTA models for each MTL scenario, which will be cited in the following subsections.

5.3 Evaluation and Settings

The evaluation metrics are micro Precision (P), Recall (R), and F_1 scores for each subtask in JERE and ABSA. For LJP, the evaluation metrics are accuracy (Acc.), macro P, macro R and macro F_1 scores which are consistent with (Zhong et al., 2018; Yang et al., 2019).

For all models, we use the Allennlp framework to build neural networks (Gardner et al., 2018). The hidden size of BiLSTM and label embeddings is 300. We also investigate each model with BERT-large-uncased (Devlin et al., 2019) or 300-dimensional Glove (Pennington et al., 2014) for JERE and ABSA. For LJP, since it is a Chinese dataset, we use THULAC (Maosong et al., 2016) for word segmentation. We randomly initialize the

word embeddings. For CNN-based models, we set the number of filters as 512 and the sliding window length as 2,3,4,5 (each window contains 128 filters). The temperature of GS τ is set to 0.05. The batch size is 32, and the learning rate is 5×10^{-4}. The maximum training epochs for JERE, ABSA, and LJP are 80, 20, and 10 respectively, and each model will stop training when F_1 scores reach the lowest on the development set in past 10 epochs (the patience is set to 10). Moreover, a special setting for LJP is that we pre-train our model for 5 epochs with gold labels and train the next 5 epochs with GS. For the other two MTL scenarios that have fewer categories of labels, pre-training is not involved. We report the averaged metrics after the training process is repeated 5 times.

5.4 Main Results

We first present the experiment results on two English datasets for JERE and ABSA, respectively, in Table 2. Regarding JERE, our model achieves a SOTA result on RE and beats the model proposed by (Luan et al., 2019), which uses an additional task (coreference resolution, CR) by 2.60 F_1 points. Among the models without CR, our model achieves the best results on both EMD and RE, improving F_1 scores by 1.93 and 2.97 points, respectively. Regarding ABSA, our model achieves new SOTA results on ATE and ACD, which increases F_1 scores by 2.62 and 0.39 points, respectively. Table 2 also shows the results of conventional MTL models, including FSMTL, SPMTL, and HMTL. Our model consistently outperforms them when using or not using BERT embeddings.

Then we present the experiment results on the Chinese dataset for LJP in Table 3. Note that "HMTL-CNN" is not merely replacing the BiLSTM encoders of "HMTL" by CNN, because we empirically find this way does not perform well. Therefore, we denote the ablated model of our model as "HMTL-CNN" which is consistent with the scenarios JERE and ABSA. It is also worth noting that the previous SOTA models for LJP are re-implemented by us because we get slightly different data splits after preprocessing the dataset. Moreover, they did not utilize the development set and only tested their models after training certain epochs. As a result, some models may greatly suffer from overfitting at the final epoch. In our experiments, as shown in Table 3, previous SOTA models perform best on PTP, and our model further improves the F_1 scores by 1.72 points over the best of them. Compared with other baseline models, our model performs best on all subtasks.

We also show the results of a toy experiment where our model uses gold labels of low-level tasks in Table 2 and 3. In the three MTL scenarios, using gold labels of low-level tasks leads to performance gains to high-level tasks. The results confirm the existence of label dependencies between tasks. It means that if humans rectify the predictions of low-level tasks, our model can utilize them to improve the predictions of high-level tasks. And conventional MTL models can not utilize this information because they assume the labels to be conditional independent.

Tasks	EMD	RE	ATE	ACD	RAP	CP	PTP
Metrics	F_1	F_1	F_1	F_1	F_1	F_1	F_1
CMTL	**87.91**	**65.80**	**87.93**	**91.00**	**84.93**	**85.69**	**37.35**
HMTL+LT	87.57	63.56	87.09	89.69	84.01	84.67	35.61
HMTL	87.07	61.33	87.29	88.49	84.54	84.63	35.27
CMTL (Indirect)	87.74	65.66	87.66	90.86	84.84	85.28	37.21
CMTL (Direct)	87.11	64.09	87.89	90.52	84.51	84.81	37.02

Table 4: Ablation analysis. The mechanisms GS and LT are eliminated from CMTL one after another, resulting in models "HMTL+LT" and "HMTL", respectively. Furthermore, only keeping the indirect or the direct causal path of LT results in models "CMTL (Indirect)" and "CMTL (Direct)", respectively.

5.5 Ablation Study

To analyze which mechanisms are driving the improvements, we present the results of an ablation study in Table 4. We first eliminate GS and LT from CMTL one after another, which results in models "HMTL+LT" and "HMTL". As shown, GS and LT are both influential, especially for high-level tasks. For example, eliminating GS leads to a drop of F_1 score by 2.24 points on RE, and eliminating the two mechanisms leads to a significant drop of 4.47 points. Moreover, we only keep the indirect and the direct causal path of CMTL, which results in models "CMTL (Indirect)" and "CMTL (Direct)" respectively. Both the two ablated models perform slightly worse than CMTL. Moreover, the indirect causal path is more important than the direct one for most subtasks.

Case 1 for JERE:
*Three people were killed and about 50 injured when another Briton, **Asif Muhammad Hanif**, 21, from **London**, detonated explosives strapped to his body.*

EMD: **B-PER, I-PER, L-PER —— U-LOC**
RE: HMTL: None (×) CMTL: GEN-AFF 133 (√)

Case 2 for LJP:
The defendant Jiang and others went to the residence of the victim Zhong. ... During this period, Jiang and others snatched 5,000 yuan of cash and bank card from Zhong's wallet, and forced Zhong to tell the bank card password. ... After succeeding, Jiang and others sent Zhong to Huangjiang Town and fled with the money.

	Relavant Article	Charge	Prison Term
HMTL	238 (√)	Kidnapping (×)	24-36 Months (×)
CMTL	238 (√)	Illegal Detention (√)	12-24 Months (√)

Article 238: *Those who **illegally detain** others or deprive others of their personal freedom shall be sentenced to fixed-term imprisonment, which is not more than three years.*

Figure 5: Example cases with the prediction results of HMTL and CMTL. The symbol √ denotes a correct prediction and × denotes a wrong prediction.

5.6 Case Study

Influence of Label Transfer. Generally, LT enables a high-level task to utilize all its lower-level tasks' predictions and, therefore, improves the consistency of the predicted results. To directly see the influence, we give some cases in Figure 5. For example, in Case 1, both HMTL and CMTL successfully recognize the entities, including "Asif Muhammad Hanif" and "London". Nevertheless, HMTL does not correctly predict their relationship "GEN-AFF" (citizens and the place they come from) while CMTL correctly predicts it. Another example is Case 2, which shows the translated document of a Chinese legal case. As shown, the relevant law is Article 238, which describes the crime of illegal detention. But the predicted charge of HMTL is kidnapping, which is a more serious crime. These inconsistent judgments are unacceptable to the judge or the public in practice.

	Illegal Detention	Illegal Trade of Drug-Making	Causing Traffic Accident	Dangerous Driving
Article 238	0.30	-	-	-
Article 350	-	0.90	-	-
Article 133	-	-	0.07	0.04

Table 5: The estimated causal effects of several law articles on certain charges in our model for LJP. The symbol "-" represents that the estimated effect is below 0.001.

Estimated Causal Effect. To show that the estimated causal effect (computed by Equation 10) in our model is consistent with humans' prior knowledge, we present some results in Table 5. As shown, *Article 238* has a causal effect on *Illegal Detention* with 0.30 points, and has no effect on other charges. This is consistent with legal knowledge (view *Article 238* in Figure 5). And *Article 350* has a causal effect on *Causing Traffic Accident* with 0.90 points that are quite high. The reason may be that *Article 350* has only 163 samples in the train set, while *Article 238* has 1,427 samples. The confidence of infrequent labels can be greatly improved by knowing the low-level gold labels. The third row shows the kind of one-to-many causal effect that *Article 133* has a causal effect on both *Causing Traffic Accident* and *Dangerous Driving*. But the effect is small, and the prediction should mainly count on the features extracted from the input text.

Case 3 for LJP:

被告人张某驾驶安全设施不合格的重型罐式半挂牵引车，与沿庞庄路由西向东行驶的被害人张某某驾驶的无牌二轮摩托车相撞，致被害人张某某受伤，经医院抢救无效死亡。被告人张某负事故主要责任。

The defendant, Zhang, was driving a heavy tank tractor with unqualified safety facilities, and collided with an unlicensed two-wheeled motorcycle driven by the victim Zhang,... The victim Zhang was injured and ***died after being rescued by the hospital*** **(N_1)**. *The defendant Zhang was* ***mainly responsible for the accident*** **(N_2)**.

Prediction: HMTL+LT: Article 233 (×) CMTL: Article 133 (√)

	Influential 4-grams	Article 133	Article 233
HMTL+LT	医院, 抢救, 无效, 死亡 (N_1)	-0.47	0.48
	负, 事故, 主要, 责任 (N_2)	0.45	-0.45
CMTL	医院, 抢救, 无效, 死亡 (N_1)	-0.02	0.02
	负, 事故, 主要, 责任 (N_2)	0.80	-0.79

Figure 6: The estimated causal effects of 4-grams. Article 133 is about dangerous driving, and Article 233 is about negligently causing one's death. Although the two law articles both describe one's death, Article 133 has priority in the event of traffic accidents.

Influence of Gumbel Sampling. GS enables a low-level task to get useful feedback from its higher-level tasks. To see the influence, we show another case for task RAP (the lowest-level task in LJP) in Figure 6. As shown, the gold label of the case is *Article 133*, which is about dangerous driving. Without GS, the model HMTL+LT predicts an incorrect result, *Article 233*, about negligently causing one's death. The two law articles both describe one's death, but *Article 133* has priority in the event of traffic accidents. Figure 6 shows the estimated causal effect of each 4-gram (computed by Equation 11). CMTL captures the priority of *Article 133* by understanding that the translated n-gram "mainly responsible for the accident" is more important (with a causal effect of 0.80 on *Article 133*) than the n-gram "died after being rescued by the hospital" (with a causal effect of -0.02).

6 Conclusion

In this paper, we investigated the MTL problem with logically dependent tasks. We first analyze MTL models from the perspective of causal inference and then propose a model CMTL to utilize task dependencies properly. The model achieves SOTA results on 6 out of 7 subtasks and improves the consistency of predicted results of different subtasks. In the future, we are interested in social science topics, such as modeling the causal effect between mental health and the suicide decisions reflected through social media, which may help predict and stop the final decisions.

A Details of Predictors and Loss Function

The subtasks in three MTL scenarios can be categorized into four types: sequence labeling, inter-token multi-label classification, multi-label text classification, and single-label text classification. Since the primary goal of our work is to investigate the task dependency, the architectures of predictors are based on simple fully-connected neural networks (FCNNs).

- If the task t_k is EMD or ATE which belongs to **sequence labeling**, given feature representations $\boldsymbol{H}^k{=}\{\boldsymbol{h}_i^k\}$, $1{\le}i{\le}n$, the prediction layer will make a token-level prediction as follows:

  $$\widehat{\boldsymbol{y}}_i^k = \mathrm{softmax}(\boldsymbol{W}_p^k \boldsymbol{h}_i^k + \boldsymbol{b}_p^k) \tag{12}$$

  where $\boldsymbol{W}_p^k$ and $\boldsymbol{b}_p^k$ are the trainable parameters of the FCNN. The loss is computed by cross-entropy:

  $$\mathcal{L}^k = -\sum_{i=1}^{n}\sum_{c=1}^{|\mathcal{C}_k|} y_{i,c}^k \log \widehat{y}_{i,c}^k \tag{13}$$

  where $y_{i,c}^k$ denotes the ground-truth value of the cth category for ith token, and $\mathcal{C}_k$ is the set of the categories.

- If task t_k is RE which belongs to **inter-token multi-label classification**, and the prediction process can be described by:

  $$\widehat{\boldsymbol{y}}_{i,j}^k = \sigma(\boldsymbol{V}_p^k f\left(\boldsymbol{U}_p^k \boldsymbol{h}_i^k + \boldsymbol{W}_p^k \boldsymbol{h}_j^k + \boldsymbol{b}_p^k\right)) \tag{14}$$

  where $\widehat{\boldsymbol{y}}_{i,j}^k$ denotes the predicted probability distribution of the relations between the ith and jth tokens. And $\boldsymbol{V}_p^k$, $\boldsymbol{U}_p^k$, $\boldsymbol{W}_p^k$ and $\boldsymbol{b}_p^k$ are the trainable parameters of the FCNN. The symbol $\sigma(\cdot)$ stands for the sigmoid function, and $f(\cdot)$ stands for the element-wise activation function ($relu$ in this paper). The loss $\mathcal{L}_{\mathrm{re}}$ is computed according to cross-entropy:

  $$\mathcal{L}^k = -\sum_{i=1}^{n}\sum_{j=1}^{n}\sum_{c=1}^{|\mathcal{C}_k|} y_{i,j,c}^k \log \widehat{y}_{i,j,c}^k \tag{15}$$

  where $y_{i,j,c}^k$ denotes the ground-truth value of the cth category for the relation between the ith and jth tokens. Note that we only consider relations between the last token of the head entity mentions. Redundant relations are therefore not classified.

- If task t_k is ACD which belongs to **multi-label text classification**, the prediction process is as follows:

$$\boldsymbol{h}_0^k = \text{pool}(\boldsymbol{H}^k) \tag{16}$$

where $\boldsymbol{h}_0^k$ represents the sentence-level feature representation obtained by the max-pooling function $\text{pool}(\cdot)$ over the tokens. And the predicted probability distribution is:

$$\widehat{\boldsymbol{y}}^k = \sigma(\boldsymbol{W}_p^k \boldsymbol{h}_0^k + \boldsymbol{b}_p^k) \tag{17}$$

Then the loss is computed by cross-entropy as follows:

$$\mathcal{L}^k = \sum_{c=1}^{|\mathcal{C}_k|} y_c^k \log \widehat{y}_c^k \tag{18}$$

- If task t_k is RAP, CP, or PTP which belongs to **single-label text classification**, the prediction process is as follows:

$$\widehat{\boldsymbol{y}}^k = \text{softmax}(\boldsymbol{W}_p^k \boldsymbol{h}_0^k + \boldsymbol{b}_p^k) \tag{19}$$

where the difference from multi-label text classification tasks is the use of $\text{softmax}(\cdot)$ instead of $\sigma(\cdot)$. And the loss is also computed by cross-entropy:

$$\mathcal{L}^k = \sum_{c=1}^{|\mathcal{C}_k|} y_c^k \log \widehat{y}_c^k \tag{20}$$

When considering multi-task learning, we denote the set of tasks by $\mathcal{T} = \{t_1, t_2, ..., t_k, ..., t_K\}$ and then sum up the losses of tasks by:

$$\mathcal{L}^{\text{MT}} = \sum_{k=1}^{K} \lambda^k \mathcal{L}^k \tag{21}$$

where λ^k is the hyper-parameter for each task t_k. We empirically set $\lambda^k = 1.0$ in this paper.

B Validation Performance During Training

We also show the validation performance of several models on the highest-level subtask for three MTL scenarios during training in Figure 7. As shown, the F_1 scores and losses on the development set of three models are presented, including CMTL and two ablated models, HMTL+LT and HMTL.

For RE, HMTL ran out of patience at about 35 epoch as it reached the lowest F_1 score in the past 10 epochs. And HMTL+LT and CMTL kept training for nearly 80 epochs. The best F_1 score of CMTL was slightly higher than that of HMTL+LT by 1.86 points, and the loss curve was more stable. Similarly, for ACD and PTP, the best F_1 scores of CMTL were consistently higher than the other two models, and the loss of CMTL was relatively stable. These results demonstrate that our model can better utilize the task dependencies and be more robust than the other two ablated models.

Moreover, an interesting result was that the validation loss of HMTL+LT grew faster than HMTL. The reason may be that the predicted labels of low-level tasks in HMTL+LT excessively influenced the decision of high-level tasks, leading to cascading errors. If an incorrectly predicted label of the low-level task is fed, the high-level task will have high confidence to make a wrong prediction, making the loss of HMTL+LT larger than HMTL. By adding Gumbel sampling, our model achieved the smallest loss on the development set, which indicated that Gumbel sampling properly considered the causal effect and alleviated the cascading errors.

Each model was trained on a Tesla P100 with a maximum memory of 16GB.

Abstract

We present an efficient method of utilizing pretrained language models, where we learn selective binary masks for pretrained weights in lieu of modifying them through finetuning. Extensive evaluations of masking BERT, RoBERTa, and DistilBERT on eleven diverse NLP tasks show that our masking scheme yields performance comparable to finetuning, yet has a much smaller memory footprint when several tasks need to be inferred. Intrinsic evaluations show that representations computed by our binary masked language models encode information necessary for solving downstream tasks. Analyzing the loss landscape, we show that masking and finetuning produce models that reside in minima that can be connected by a line segment with nearly constant test accuracy. This confirms that masking can be utilized as an efficient alternative to finetuning.

1 Introduction

Finetuning a large pretrained language model like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), and XLNet (Yang et al., 2019) often yields competitive or even state-of-the-art results on NLP benchmarks (Wang et al., 2018, 2019). Given an NLP task, standard finetuning stacks a linear layer on top of the pretrained language model and then updates all parameters using mini-batch SGD. Various aspects like brittleness (Dodge et al., 2020) and adaptiveness (Peters et al., 2019) of this two-stage transfer learning NLP paradigm (Dai and Le, 2015; Howard and Ruder, 2018) have been studied.

Despite the simplicity and impressive performance of finetuning, the prohibitively large number of parameters to be finetuned, e.g., 340 million in BERT-large, is a major obstacle to wider deployment of these models. The large memory footprint of finetuned models becomes more prominent when multiple tasks need to be solved – several copies of the millions of finetuned parameters have to be saved for inference.

Recent work (Gaier and Ha, 2019; Zhou et al., 2019) points out the potential of searching neural architectures within a fixed model, as an alternative to optimizing the model weights for downstream tasks. Inspired by these results, we present *masking*, a simple yet efficient scheme for utilizing pretrained language models. Instead of directly updating the pretrained parameters, we propose to *select* weights important to downstream NLP tasks while *discarding* irrelevant ones. The selection mechanism consists of a set of binary masks, one learned per downstream task through end-to-end training.

We show that masking, when being applied to pretrained language models like BERT, RoBERTa, and DistilBERT (Sanh et al., 2019), achieves performance comparable to finetuning in tasks like part-of-speech tagging, named-entity recognition, sequence classification, and reading comprehension. This is surprising in that a simple subselection mechanism that does not change any weights is competitive with a training regime – finetuning – that can change the value of every single weight. We conduct detailed analyses revealing important factors and possible reasons for the desirable performance of masking.

Masking is parameter-efficient: only a set of 1-bit binary masks needs to be saved per task after training, instead of all 32-bit float parameters in finetuning. This small memory footprint enables deploying pretrained language models for solving multiple tasks on edge devices. The compactness of masking also naturally allows parameter-efficient ensembles of pretrained language models.

Our **contributions**: (i) We introduce *masking*, a new scheme for utilizing pretrained language models by learning selective masks for pretrained weights, as an efficient alternative to finetuning.

[*] Equal contribution.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2226–2241,
November 16–20, 2020.

We show that masking is applicable to models like BERT/RoBERTa/DistilBERT, and produces performance on par with finetuning. (ii) We carry out extensive empirical analysis of masking, shedding light on factors critical for achieving good performance on eleven diverse NLP tasks. (iii) We study the binary masked language models' loss landscape and language representations, revealing potential reasons why masking has task performance comparable to finetuning.

2 Related Work

Two-stage NLP paradigm. Pretrained language models (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019b; Yang et al., 2019; Radford et al., 2019) advance NLP with contextualized representation of words. Finetuning a pretrained language model (Dai and Le, 2015; Howard and Ruder, 2018) often delivers competitive performance partly because pretraining leads to a better initialization across various downstream tasks than training from scratch (Hao et al., 2019). However, finetuning on individual NLP tasks is not parameter-efficient. Each finetuned model, typically consisting of hundreds of millions of floating point parameters, needs to be saved individually. Stickland and Murray (2019) use projected attention layers with multi-task learning to improve efficiency of finetuning BERT. Houlsby et al. (2019) insert adapter modules to BERT to improve memory efficiency. The inserted modules alter the forward pass of BERT, hence need to be carefully initialized to be close to identity.

We propose to directly pick parameters appropriate to a downstream task, by learning selective binary masks via end-to-end training. Keeping the pretrained parameters untouched, we solve several downstream NLP tasks with minimal overhead.

Binary networks and network pruning. Binary masks can be trained using the "straight-through estimator" (Bengio et al., 2013; Hinton, 2012). Hubara et al. (2016), Rastegari et al. (2016), Hubara et al. (2017), *inter alia*, apply this technique to train efficient binarized neural networks. We use this estimator to train selective masks for pretrained language model parameters.

Investigating the lottery ticket hypothesis (Frankle and Carbin, 2018) of network pruning (Han et al., 2015a; He et al., 2018; Liu et al., 2019c; Lee et al., 2019; Lin et al., 2020), Zhou et al. (2019) find that applying binary masks to a neural network is a form of training the network. Gaier and Ha (2019) propose to search neural architectures for reinforcement learning and image classification tasks, without any explicit weight training. This work inspires our masking scheme (which can be interpreted as implicit neural architecture search (Liu et al., 2019c)): applying the masks to a pretrained language model is similar to finetuning, yet is much more parameter-efficient.

Perhaps the closest work, Mallya et al. (2018) apply binary masks to CNNs and achieve good performance in computer vision. We learn selective binary masks for pretrained language models in NLP and shed light on factors important for obtaining good performance. Mallya et al. (2018) explicitly update weights in a task-specific classifier layer. In contrast, we show that end-to-end learning of selective masks, consistently for both the pretrained language model and a randomly initialized classifier layer, achieves good performance. Radiya-Dixit and Wang (2020) investigate finetuning of BERT by employing a number of techniques, including what they call sparsification, a method similar to masking. Their focus is analysis of finetuning BERT whereas our goal is to provide an efficient alternative to finetuning.

3 Method

3.1 Background on Transformer and finetuning

The encoder of the Transformer architecture (Vaswani et al., 2017) is ubiquitously used when pretraining large language models. We briefly review its architecture and then present our masking scheme. Taking BERT-base as an example, each one of the 12 transformer blocks consists of (i) four linear layers[1] $\mathbf{W}_K$, $\mathbf{W}_Q$, $\mathbf{W}_V$, and $\mathbf{W}_{AO}$ for computing and outputting the self attention among input wordpieces (Wu et al., 2016). (ii) two linear layers $\mathbf{W}_I$ and $\mathbf{W}_O$ feeding forward the word representations to the next transformer block.

More concretely, consider an input sentence $\mathbf{X} \in \mathbb{R}^{N \times d}$ where N is the maximum sentence length and d is the hidden dimension size. $\mathbf{W}_K$, $\mathbf{W}_Q$, and $\mathbf{W}_V$ are used to compute transformations of $\mathbf{X}$:

$$\mathbf{K} = \mathbf{X}\mathbf{W}_K, \mathbf{Q} = \mathbf{X}\mathbf{W}_Q, \mathbf{V} = \mathbf{X}\mathbf{W}_V,$$

---

[1] We omit the bias terms for brevity.

and the self attention of $\mathbf{X}$ is computed as:

$$\text{Attention}(\mathbf{K}, \mathbf{Q}, \mathbf{V}) = \text{softmax}(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}})\mathbf{V}.$$

The attention is then transformed by $\mathbf{W}_{AO}$, and subsequently fed forward by $\mathbf{W}_I$ and $\mathbf{W}_O$ to the next transformer block.

When finetuning on a downstream task like sequence classification, a linear classifier layer $\mathbf{W}_T$, projecting from the hidden dimension to the output dimension, is randomly initialized. Next, $\mathbf{W}_T$ is stacked on top of a pretrained linear layer $\mathbf{W}_P$ (the *pooler layer*). All parameters are then updated to minimize the task loss such as cross-entropy.

3.2 Learning the mask

Given a pretrained language model, we do not finetune, i.e., we do not update the pretrained parameters. Instead, we *select* a subset of the pretrained parameters that is critical to a downstream task while *discarding* irrelevant ones with binary masks. We associate each linear layer $\mathbf{W}^l \in \{\mathbf{W}^l_K, \mathbf{W}^l_Q, \mathbf{W}^l_V, \mathbf{W}^l_{AO}, \mathbf{W}^l_I, \mathbf{W}^l_O\}$ of the l-th transformer block with a real-valued matrix $\mathbf{M}^l$ that is randomly initialized from a uniform distribution and has the same size as $\mathbf{W}^l$. We then pass $\mathbf{M}^l$ through an element-wise thresholding function (Hubara et al., 2016; Mallya et al., 2018), i.e., a binarizer, to obtain a binary mask $\mathbf{M}^l_{\text{bin}}$ for $\mathbf{W}^l$:

$$(m^l_{\text{bin}})_{i,j} = \begin{cases} 1 & \text{if } m^l_{i,j} \geq \tau \\ 0 & \text{otherwise} \end{cases}, \qquad (1)$$

where $m^l_{i,j} \in \mathbf{M}^l$, i, j indicate the coordinates of the 2-D linear layer and τ is a global thresholding hyperparameter.

In each forward pass of training, the binary mask $\mathbf{M}^l_{\text{bin}}$ (derived from $\mathbf{M}^l$ via Eq. 1) selects weights in a pretrained linear layer $\mathbf{W}^l$ by Hadamard product:

$$\hat{\mathbf{W}}^l := \mathbf{W}^l \odot \mathbf{M}^l_{\text{bin}}.$$

In the corresponding backward pass of training, with the associated loss function $\mathcal{L}$, we cannot backpropagate through the binarizer, since Eq. 1 is a hard thresholding operation and the gradient with respect to $\mathbf{M}^l$ is zero almost everywhere. Similar to the treatment[2] in Bengio et al. (2013); Hubara et al. (2016); Lin et al. (2020), we use $\frac{\partial\mathcal{L}(\hat{\mathbf{W}}^l)}{\partial\mathbf{M}^l_{\text{bin}}}$ as a noisy estimator of $\frac{\partial\mathcal{L}(\hat{\mathbf{W}}^l)}{\partial\mathbf{M}^l}$ to update $\mathbf{M}^l$, i.e.:

$$\mathbf{M}^l \leftarrow \mathbf{M}^l - \eta\frac{\partial\mathcal{L}(\hat{\mathbf{W}}^l)}{\partial\mathbf{M}^l_{\text{bin}}}, \qquad (2)$$

where η refers to the step size. Hence, the whole structure can be trained end-to-end.

We learn a set of binary masks for an NLP task as follows. Recall that each linear layer $\mathbf{W}^l$ is associated with a $\mathbf{M}^l$ to obtain a masked linear layer $\hat{\mathbf{W}}^l$ through Eq. 1. We randomly initialize an additional linear layer with an associated $\mathbf{M}^l$ and stack it on top of the pretrained language model. We then update each $\mathbf{M}^l$ through Eq. 2 with the task objective during training.

After training, we pass each $\mathbf{M}^l$ through the binarizer to obtain $\mathbf{M}^l_{\text{bin}}$, which is then saved for future inference. Since $\mathbf{M}^l_{\text{bin}}$ is binary, it takes only $\approx 3\%$ of the memory compared to saving the 32-bit float parameters in a finetuned model. Also, we will show that many layers – in particular the embedding layer – do not have to be masked. This further reduces memory consumption of masking.

3.3 Configuration of masking

Our masking scheme is motivated by the observation: the pretrained weights form a good initialization (Hao et al., 2019), yet a few steps of adaptation are still needed to produce competitive performance for a specific task. However, not every pretrained parameter is necessary for achieving reasonable performance, as suggested by the field of neural network pruning (LeCun et al., 1990; Hassibi and Stork, 1993; Han et al., 2015b). We now investigate two configuration choices that affect how many parameters are "eligible" for masking.

Initial sparsity of $\mathbf{M}^l_{\text{bin}}$. As we randomly initialize our masks from uniform distributions, the sparsity of the binary mask $\mathbf{M}^l_{\text{bin}}$ in the mask initialization phase controls how many pretrained parameters in a layer $\mathbf{W}^l$ are assumed to be irrelevant to the downstream task. Different initial sparsity rates entail different optimization behaviors.

It is crucial to better understand how the initial sparsity of a mask impacts the training dynamics and final model performance, so as to generalize our masking scheme to broader domains and tasks. In §5.1, we investigate this aspect in detail. In practice, we fix τ in Eq. 1 while adjusting the uniform distribution to achieve a target initial sparsity.

---

[2] Bengio et al. (2013); Hubara et al. (2016) describe it as the "straight-through estimator", and Lin et al. (2020) provide convergence guarantee with error feedback interpretation.

Which layers to mask. Different layers of pretrained language models capture distinct aspects of a language during pretraining, e.g., Tenney et al. (2019) find that information on part-of-speech tagging, parsing, named-entity recognition, semantic roles, and coreference is encoded on progressively higher layers of BERT. It is hard to know a priori which types of NLP tasks have to be addressed in the future, making it non-trivial to decide layers to mask. We study this factor in §5.2.

We do not learn a mask for the lowest embedding layer, i.e., the uncontextualized wordpiece embeddings are completely "selected", for all tasks. The motivation is two-fold. (i) The embedding layer weights take up a large part, e.g., almost 21% (23m/109m) in BERT-base-uncased, of the total number of parameters. Not having to learn a selective mask for this layer reduces memory consumption. (ii) Pretraining has effectively encoded context-independent general meanings of words in the embedding layer (Zhao et al., 2020). Hence, learning a selective mask for this layer is unnecessary. Also, we do not learn masks for biases and layer normalization parameters as we did not observe a positive effect on performance.

4 Datasets and Setup

Datasets. We present results for masking BERT, RoBERTa, and DistilBERT in part-of-speech tagging, named-entity recognition, sequence classification, and reading comprehension.

We experiment with **part-of-speech tagging** (POS) on Penn Treebank (Marcus et al., 1993), using Collins (2002)'s train/dev/test split. For **named-entity recognition** (NER), we conduct experiments on the CoNLL-2003 NER shared task (Tjong Kim Sang and De Meulder, 2003).

For **sequence classification**, the following GLUE tasks (Wang et al., 2018) are evaluated: Stanford Sentiment Treebank (SST2) (Socher et al., 2013), Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005), Corpus of Linguistic Acceptability (CoLA) (Warstadt et al., 2019), Recognizing Textual Entailment (RTE) (Dagan et al., 2005), and Question Natural Language Inference (QNLI) (Rajpurkar et al., 2016).

In addition, we experiment on sequence classification datasets that have publicly available test sets: the 6-class question classification dataset TREC (Voorhees and Tice, 2000), the 4-class news classification dataset AG News (AG) (Zhang et al., 2015), and the binary Twitter sentiment classification task SemEval-2016 4B (SEM) (Nakov et al., 2016).

We experiment with **reading comprehension** on SWAG (Zellers et al., 2018) using the official data splits. We report Matthew's correlation coefficient (MCC) for CoLA, micro-F1 for NER, and accuracy for the other tasks.

Setup. Due to resource limitations and in the spirit of environmental responsibility (Strubell et al., 2019; Schwartz et al., 2019), we conduct our experiments on the base models: BERT-base-uncased, RoBERTa-base, and DistilBERT-base-uncased. Thus, the BERT/RoBERTa models we use have 12 transformer blocks (0–11 indexed) producing 768-dimension vectors; the DistilBERT model we use has the same dimension but contains 6 transformer blocks (0–5 indexed). We implement our models in PyTorch (Paszke et al., 2019) with the HuggingFace framework (Wolf et al., 2019).

Throughout all experiments, we limit the maximum length of a sentence (pair) to be 128 after wordpiece tokenization. Following Devlin et al. (2019), we use the Adam (Kingma and Ba, 2014) optimizer of which the learning rate is a hyperparameter while the other parameters remain default. We carefully tune the learning rate for each setup: the tuning procedure ensures that the best learning rate does not lie on the border of our search grid, otherwise we extend the grid accordingly. The initial grid is {1e-5, 3e-5, 5e-5, 7e-5, 9e-5}.

For sequence classification and reading comprehension, we use `[CLS]` as the representation of the sentence (pair). Following Devlin et al. (2019), we formulate NER as a tagging task and use a linear output layer, instead of a conditional random field layer. For POS and NER experiments, the representation of a tokenized word is its last wordpiece (Liu et al., 2019a; He and Choi, 2020). Note that a 128 maximum length of a sentence for POS and NER means that some word-tag annotations need to be excluded. Appendix §A shows our reproducibility checklist containing more implementation and preprocessing details.

5 Experiments

5.1 Initial sparsity of binary masks

We first investigate how initial sparsity percentage (i.e., fraction of zeros) of the binary mask $\mathbf{M}^{l}_{\text{bin}}$ influences performance of a binary masked language model on downstream tasks. We experiment on four tasks, with initial sparsities in {1%, 3%, 5%,

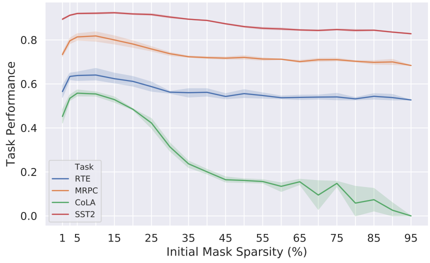

Figure 1: Dev set performance of masking BERT when selecting different amounts of pretrained parameters.

10%, 15%, 20%, . . . , 95%}. All other hyperparameters are controlled: learning rate is fixed to 5e-5; batch size is 32 for relatively small datasets (RTE, MRPC, and CoLA) and 128 for SST2. Each experiment is repeated four times with different random seeds {1, 2, 3, 4}. In this experiment, all transformer blocks, the pooler layer, and the classifier layer are masked.

Figure 1 shows that masking achieves decent performance without hyperparameter search. Specifically, (i) a large initial sparsity removing most pretrained parameters, e.g., 95%, leads to bad performance for the four tasks. This is due to the fact that the pretrained knowledge is largely discarded. (ii) Gradually decreasing the initial sparsity improves task performance. Generally, an initial sparsity in 3% $\sim$ 10% yields reasonable results across tasks. Large datasets like SST2 are less sensitive than small datasets like RTE. (iii) Selecting almost all pretrained parameters, e.g., 1% sparsity, hurts task performance. Recall that a pretrained model needs to be adapted to a downstream task; masking achieves adaptation by learning selective masks – preserving too many pretrained parameters in initialization impedes the optimization.

5.2 Layer-wise behaviors

Neural network layers present heterogeneous characteristics (Zhang et al., 2019) when being applied to tasks. For example, syntactic information is better represented at lower layers while semantic information is captured at higher layers in ELMo (Peters et al., 2018). As a result, simply masking all transformer blocks (as in §5.1) may not be ideal.

We investigate the task performance when applying the masks to different BERT layers. Figure 2 presents the optimal task performance when masking only a subset of BERT's transformer blocks on MRPC, CoLA, and RTE. Different amounts and indices of transformer blocks are masked: "bottom-up" and "top-down" indicate to mask the targeted amount of transformer blocks, either from bottom or top of BERT.

We can observe that (i) in most cases, top-down masking outperforms bottom-up masking when initial sparsity and the number of masked layers are fixed. Thus, it is reasonable to select all pretrained weights in lower layers, since they capture general information helpful and transferable to various tasks (Liu et al., 2019a; Howard and Ruder, 2018). (ii) For bottom-up masking, increasing the number of masked layers gradually improves performance. This observation illustrates dependencies between BERT layers and the learning dynamics of masking: provided with selected pretrained weights in lower layers, higher layers need to be given flexibility to select pretrained weights accordingly to achieve good task performance. (iii) In top-down masking, CoLA performance increases when masking a growing number of layers while MRPC and RTE are not sensitive. Recall that CoLA tests linguistic acceptability that typically requires both syntactic and semantic information[3]. All of BERT layers are involved in representing this information, hence allowing more layers to change should improve performance.

5.3 Comparing finetuning and masking

We have investigated two factors – initial sparsity (§5.1) and layer-wise behaviors (§5.2) – that are important in masking pretrained language models. Here, we compare the performance and memory consumption of masking and finetuning.

Based on observations in §5.1 and §5.2, we use 5% initial sparsity when applying masking to BERT, RoBERTa, and DistilBERT. We mask the transformer blocks 2–11 in BERT/RoBERTa and 2–5 in DistilBERT. $\mathbf{W}_P$ and $\mathbf{W}_T$ are always masked. Note that this global setup is surely suboptimal for some model-task combinations, but our goal is to illustrate the effectiveness and the generalization ability of masking. Hence, conducting extensive hyperparameter search is unnecessary.

For AG and QNLI, we use batch size 128. For the other tasks we use batch size 32. We search the optimal learning rate per task as described in §4,

---

[3] For example, to distinguish acceptable caused-motion constructions (e.g., "the professor talked us into a stupor") from inacceptable ones (e.g., "water talked it into red"), both syntactic and semantic information need to be considered (Goldberg, 1995).

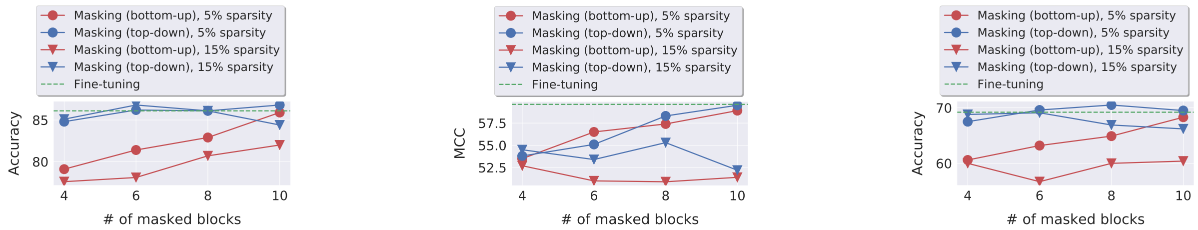

Figure 2: The impact of masking different transformer blocks of BERT for MRPC (left), CoLA (middle), and RTE (right). The number of masked blocks is shown on the x-axis; that number is either masked “bottom-up” or “top-down”. More precisely, a bottom-up setup (red) masking 4 blocks means we mask the transformer blocks $\{0, 1, 2, 3\}$; a top-down setup (blue) masking 4 blocks means we mask the transformer blocks $\{8, 9, 10, 11\}$. $\mathbf{W}_P$ and $\mathbf{W}_T$ are always masked.

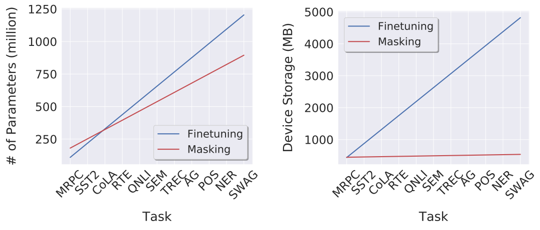
Table 1: Dev set task performances (%) of masking and finetuning. Each experiment is repeated four times with different random seeds and we report mean and standard deviation. Numbers below dataset name (second row) are the size of training set. For POS and NER, we report the number of sentences.

and they are shown in Appendix §A.4.

Performance comparison. Table 1 reports performance of masking and finetuning on the dev set for the eleven NLP tasks. We observe that applying masking to BERT/RoBERTa/DistilBERT yields performance comparable to finetuning. We observe a performance drop[4] on RoBERTa-RTE. RTE has the smallest dataset size (train: 2.5k; dev: 0.3k) among all tasks – this may contribute to the imperfect results and large variances.

Our BERT-NER results are slightly worse than Devlin et al. (2019). This may be due to the fact that “maximal document context” is used by Devlin et al. (2019) while we use sentence-level context of 128 maximum sequence length[5].

Rows “Single” in Table 2 compare performance of masking and finetuning BERT on the test set of SEM, TREC, AG, POS, and NER. The same setup and hyperparameter searching as Table 1 are used, the best hyperparameters are picked on the dev set. Results from Sun et al. (2019); Palogiannidi et al. (2016) are included as a reference. Sun et al. (2019) employ optimizations like layer-wise learning rate, producing slightly better performance than ours. Palogiannidi et al. (2016) is the best performing system on task SEM (Nakov et al., 2016). Again, masking yields results comparable to finetuning.



(a) Number of parameters. (b) Memory consumption.

Figure 3: The accumulated number of parameters and memory required by finetuning and masking to solve an increasing number of tasks.

Memory comparison. Having shown that task performance of masking and finetuning is comparable, we next demonstrate one key strength of masking: memory efficiency. We take BERT-base-uncased as our example. Figure 3 shows the accumulated number of parameters in million and memory in megabytes (MB) required when an increasing number of downstream tasks need to be solved using finetuning and masking. Masking re-

---

[4] Similar observations were made: DistilBERT has a 10% accuracy drop on RTE compared to BERT-base (Sanh et al., 2019); Sajjad et al. (2020) report unstableness on MRPC and RTE when applying their model reduction strategies.

Table 2: Error rate (%) on test set and model size comparison. Single: the averaged performance of four models with different random seeds. Ensem.: ensemble of the four models.

quires a small overhead when solving a single task but is much more efficient than finetuning when several tasks need to be inferred. Masking saves a single copy of a pretrained language model containing 32-bit float parameters for all the eleven tasks and a set of 1-bit binary masks for each task. In contrast, finetuning saves every finetuned model so the memory consumption grows linearly.

Masking naturally allows light ensembles of models. Rows "Ensem." in Table 2 compare ensembled results and model size. We consider the ensemble of predicted (i) labels; (ii) logits; (iii) probabilities. The best ensemble method is picked on dev and then evaluated on test. Masking only consumes 474MB of memory – much smaller than 1752MB required by finetuning – and achieves comparable performance. Thus, masking is also much more memory-efficient than finetuning in an ensemble setting.

6 Discussion

6.1 Intrinsic evaluations

§5 demonstrates that masking is an efficient alternative to finetuning. Now we analyze properties of the representations computed by binary masked language models with intrinsic evaluation.

One intriguing property of finetuning, i.e., stacking a classifier layer on top of a pretrained language model then update all parameters, is that a linear classifier layer suffices to conduct reasonably accurate classification. This observation implies that the configuration of data points, e.g., sentences with positive or negative sentiment in SST2, should be close to linearly separable in the hidden space. Like finetuning, masking also uses a linear classifier layer. Hence, we hypothesize that upper layers in binary masked language models, even without explicit weight updating, also create a hidden space in which data points are close to linearly separable.

Figure 4 uses t-SNE (Maaten and Hinton, 2008) to visualize the representation of `[CLS]` computed by the topmost transformer block in pretrained, finetuned, and masked BERT/RoBERTa, using the dev set examples of SST2. The pretrained models' representations (left) are clearly not separable since the model needs to be adapted to downstream tasks. The sentence representations computed by the finetuned (top right) and the binary masked (bottom right) encoder are almost linearly separable and consistent with the gold labels. Thus, a linear classifier is expected to yield reasonably good classification accuracy. This intrinsic evaluation illustrates that binary masked models extract good representations from the data for the downstream NLP task.

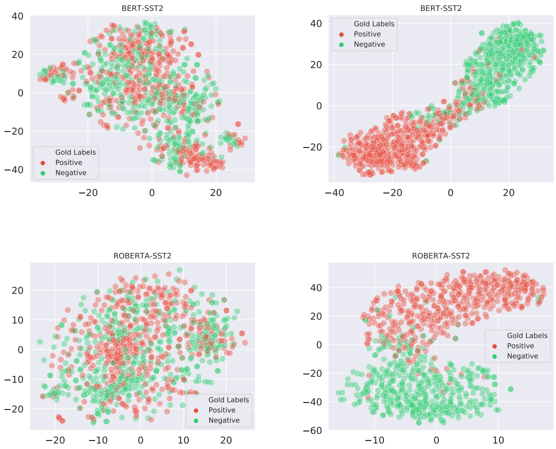

Figure 4: t-SNE visualization of the representation of `[CLS]` computed by the topmost transformer block in pretrained (left), finetuned (top right), and masked (bottom right) BERT/RoBERTa. We use `scikit-learn` (Pedregosa et al., 2011) and default t-SNE parameters.

(b) Finetuning

Table 3: Generalization on dev (%) of binary masked and finetuned BERT. Row: training dataset; Column: evaluating dataset. Numbers are improvements against the majority-vote baseline: 50.9 for SST2 and 74.4 for SEM. Results are averaged across four random seeds.

6.2 Properties of the binary masked models

Do binary masked models generalize? Figure 4 shows that a binary masked language model produces proper representations for the classifier layer and hence performs as well as a finetuned model. Here, we are interested in verifying that

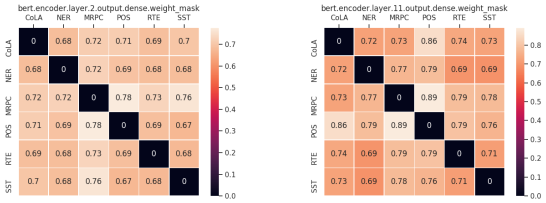

Figure 5: Scores s of two sets of masks, trained with two different tasks, of layer $\mathbf{W}_O$ in transformer blocks 2 (left) and 11 (right) in BERT. A large s means that the two masks are dissimilar.

the binary masked model does indeed solve downstream tasks by learning meaningful representations – instead of exploiting spurious correlations that generalize poorly (Niven and Kao, 2019; McCoy et al., 2019). To this end, we test if the binary masked mode is generalizable to other datasets of the same type of downstream task. We use the two sentiment classification datasets: SST2 and SEM. We simply evaluate the model masked or finetuned on SST2 against the dev set of SEM and vice versa. Table 3 reports the results against the majority-vote baseline. The finetuned and binary masked models of SEM generalize well on SST2, showing $\approx 20\%$ improvement against the majority-vote baseline.

On the other hand, we observe that the knowledge learned on SST2 does not generalize to SEM, for both finetuning and masking. We hypothesize that this is because the Twitter domain (SEM) is much more specific than movie reviews (SST2). For example, some Emojis or symbols like ":)" reflecting strong sentiment do not occur in SST2, resulting in unsuccessful generalization. To test our hypothesis, we take another movie review dataset IMDB (Maas et al., 2011), and directly apply the SST2-finetuned- and SST2-binary-masked- models on it. Masking and finetuning achieve accuracy 84.79% and 85.25%, which are comparable and both outperform the baseline 50%, demonstrating successful knowledge transfer.

Thus, finetuning and masking yield models with similar generalization ability. The binary masked models indeed create representations that contain valid information for downstream tasks.

Analyzing masks. We study the dissimilarity between masks learned by different BERT layers and downstream tasks. For the initial and trained binary masks $\mathbf{M}_{\text{bin}}^{t,init}$ and $\mathbf{M}_{\text{bin}}^{t,trained}$ of a layer trained on task $t \in \{t1, t2\}$. We compute:

$$s = \frac{\left\|\mathbf{M}_{\text{bin}}^{t1,trained} - \mathbf{M}_{\text{bin}}^{t2,trained}\right\|_1}{\left\|\mathbf{M}_{\text{bin}}^{t1,trained} - \mathbf{M}_{\text{bin}}^{t1,init}\right\|_1 + \left\|\mathbf{M}_{\text{bin}}^{t2,trained} - \mathbf{M}_{\text{bin}}^{t2,init}\right\|_1},$$

where $\|\mathbf{W}\|_1 = \sum_{i=1}^{m} \sum_{j=1}^{n} |w_{i,j}|$. Note that for the same random seed, $\mathbf{M}_{\text{bin}}^{t1,init}$ and $\mathbf{M}_{\text{bin}}^{t2,init}$ are the same. The dissimilarity s measures the difference between two masks as a fraction of all changes brought about by training. Figure 5 shows that, after training, the dissimilarities of masks of higher BERT layers are larger than those of lower BERT layers. Similar observations are made for finetuning: top layer weights in finetuned BERT are more task-specific (Kovaleva et al., 2019). The figure also shows that the learned masks for downstream tasks tend to be dissimilar to each other, even for similar tasks. For a given task, there exist different sets of masks (initialized with different random seeds) yielding similar performance. This observation is similar to the results of evaluating the lottery ticket hypothesis on BERT (Prasanna et al., 2020; Chen et al., 2020): a number of subnetworks exist in BERT achieving similar task performance.

6.3 Loss landscape

Training complex neural networks can be viewed as searching for good minima in the highly non-convex landscape defined by the loss function (Li et al., 2018). Good minima are typically depicted as points at the bottom of different locally convex valleys (Keskar et al., 2016; Draxler et al., 2018), achieving similar performance. In this section, we study the relationship between the two minima obtained by masking and finetuning.

Recent work analyzing the loss landscape suggests that the local minima in the loss landscape reached by standard training algorithms can be connected by a simple path (Garipov et al., 2018; Gotmare et al., 2018), e.g., a Bézier curve, with low task loss (or high task accuracy) along the path. We are interested in testing if the two minima found by finetuning and masking can be easily connected in the loss landscape. To start with, we verify the task performance of an interpolated model $\mathbf{W}(\gamma)$ on the line segment between a finetuned model $\mathbf{W}_0$ and a binary masked model $\mathbf{W}_1$:

$$\mathbf{W}(\gamma) = \mathbf{W}_0 + \gamma(\mathbf{W}_1 - \mathbf{W}_0), 0 \leq \gamma \leq 1 \,.$$

We conduct experiments on MRPC and SST2 with the best-performing BERT and RoBERTa

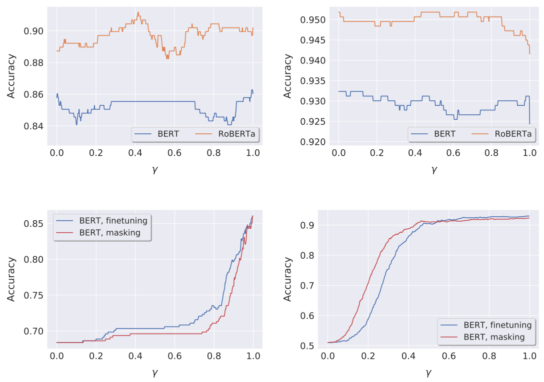

Figure 6: Mode connectivity results on MRPC (left) and SST2 (right). Top images: dev set accuracy of an interpolated model between the two minima found by finetuning ($\gamma = 0$) and masking ($\gamma = 1$). Bottom images: accuracy of an interpolated model between pretrained ($\gamma = 0$) and finetuned/masked ($\gamma = 1$) BERT.

models obtained in Table 1 (same seed and training epochs); Figure 6 (top) shows the results of mode connectivity, i.e., the evolution of the task accuracy along a line connecting the two candidate minima.

Surprisingly, the interpolated models on the line segment connecting a finetuned and a binary masked model form a high accuracy path, indicating the extremely well-connected loss landscape. Thus, masking finds minima on the same connected low-loss manifold as finetuning, confirming the effectiveness of our method. Also, we show in Figure 6 (bottom) for the line segment between the pretrained BERT and a finetuned/masked BERT, that mode connectivity is not solely due to an overparameterized pretrained language model. Bézier curves experiments show similar results, cf. Appendix §B.

7 Conclusion

We have presented masking, an efficient alternative to finetuning for utilizing pretrained language models like BERT/RoBERTa/DistilBERT. Instead of updating the pretrained parameters, we only train one set of binary masks per task to select critical parameters. Extensive experiments show that masking yields performance comparable to finetuning on a series of NLP tasks. Leaving the pretrained parameters unchanged, masking is much more memory efficient when several tasks need to be solved. Intrinsic evaluations show that binary masked models extract valid and generalizable representations for downstream tasks. Moreover, we demonstrate that the minima obtained by finetuning and masking can be easily connected by a line segment, confirming the effectiveness of applying masking to pretrained language models. Our code is available at: `https://github.com/ptlmasking/maskbert`.

Future work may explore the possibility of applying masking to the pretrained multilingual encoders like mBERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019). Also, the binary masks learned by our method have low sparsity such that inference speed is not improved. Developing methods improving both memory and inference efficiency without sacrificing task performance can open the possibility of widely deploying the powerful pretrained language models to more NLP applications.

A Reproducibility Checklist

A.1 Computing infrastructure

All experiments are conducted on following GPU models: Tesla V100, GeForce GTX 1080 Ti, and GeForce GTX 1080. We use per-GPU batch size 32. Thus, experiments comparing masking and finetuning on QNLI and AG take 4 GPUs and all the other tasks use a single GPU.

A.2 Number of parameters

In §5.3 we thoroughly compare the number of parameters and memory consumption of finetuning and masking. Numerical values are in Table 8.

A.3 Validation performance

The dev set performance of Table 2 is covered in Table 1. We report Matthew's correlation coefficient (MCC) for CoLA, micro-F1 for NER, and accuracy for the other tasks. We use the evaluation functions in `scikit-learn` (Pedregosa et al., 2011) and `seqeval` (`https://github.com/chakki-works/seqeval`).

A.4 Hyperparameter search

The only hyperparameter we searched is learning rate, for both masking and finetuning, according to the setup discussion in §4. The optimal values are in Table 4.

A.5 Datasets

For GLUE tasks, we use the official datasets from the benchmark `https://gluebenchmark.com/`. For TREC and AG, we download the datasets developed by Zhang et al. (2015), which are available at here. Note that this link is provided by Zhang et al. (2015) and also used by Sun et al. (2019). For SEM, we obtain the dataset from the official SemEval website: `http://alt.qcri.org/semeval2016/task4/`. For NER, we use the official dataset: `https://www.clips.uantwerpen.be/conll2003/ner/`. We obtain our POS dataset from the linguistic data consortium (LDC). We use the official dataset of SWAG (Zellers et al., 2018): `https://github.com/rowanz/swagaf/tree/master/data`.

For POS, sections 0-18 of WSJ are train, sections 19-21 are dev, and sections 22-24 are test (Collins, 2002). We use the official train/dev/test splits of all the other datasets.

To preprocess the datasets, we use the tokenizers provided by the `Transformers` package (Wolf et al., 2019) to convert the raw dataset to the formats required by BERT/RoBERTa/DistilBERT. Since wordpiece tokenization is used, there is no out-of-vocabulary words.

Since we use a maximum sequence length of 128, our preprocessing steps exclude some word-tag annotations in POS and NER. For POS, after wordpiece tokenization, we see 1 sentence in dev and 2 sentences in test have more than 126 (the `[CLS]` and `[SEP]` need to be considered) wordpieces. As a result, we exclude 5 annotated words in dev and 87 annotated words in test. Similarly, for NER (which is also formulated as a tagging task following Devlin et al. (2019)), we see 3 sentences in dev and 1 sentence in test have more than 126 wordpieces. As a result, we exclude 27 annotated words in dev and 8 annotated words in test.

The number of examples in dev and test per task is shown in following Table 5.

B More on Mode Connectivity

Following the mode connectivity framework proposed in Garipov et al. (2018), we parameterize the path joining two minima using a Bézier curve. Let $\mathbf{w}_0$ and $\mathbf{w}_{n+1}$ be the parameters of the models trained from finetuning and masking. Then, an n-bend Bézier curve connecting $\mathbf{w}_0$ and $\mathbf{w}_{n+1}$, with n trainable intermediate models $\theta = \{\mathbf{w}_1, \ldots, \mathbf{w}_n\}$, can be represented by $\phi_\theta(t)$, such that $\phi_\theta(0) = \mathbf{w}_0$ and $\phi_\theta(1) = \mathbf{w}_{n+1}$, and

$$\phi_\theta(t) = \sum_{i=0}^{n+1} \binom{n+1}{i} (1-t)^{n+1-i} t^i \mathbf{w}_i \, .$$

We train a 3-bend Bézier curve by minimizing the loss $\mathbb{E}_{t\sim U[0,1]} \mathcal{L}\left(\phi_\theta(t)\right)$, where $U[0,1]$ is the uniform distribution in the interval $[0,1]$. Monte Carlo method is used to estimate the gradient of this expectation-based function and gradient-based optimization is used for the minimization. The results are illustrated in Figure 7. Masking implicitly performs gradient descent, analogy to the weights update achieved by finetuning; the observations complement our arguments in the main text.

C More Empirical Results

Ensemble results of RoBERTa and DistilBERT. Following Table 6 shows the single and ensemble results of RoBERTa and DistilBERT on the test set of SEM, TREC, AG, POS, and NER.

		MRPC	SST2	CoLA	RTE	QNLI	POS	NER	SWAG	SEM	TREC	AG

Abstract

Document-level neural machine translation has yielded attractive improvements. However, majority of existing methods roughly use all context sentences in a fixed scope. They neglect the fact that different source sentences need different sizes of context. To address this problem, we propose an effective approach to select dynamic context so that the document-level translation model can utilize the more useful selected context sentences to produce better translations. Specifically, we introduce a selection module that is independent of the translation module to score each candidate context sentence. Then, we propose two strategies to explicitly select a variable number of context sentences and feed them into the translation module. We train the two modules end-to-end via reinforcement learning. A novel reward is proposed to encourage the selection and utilization of dynamic context sentences. Experiments demonstrate that our approach can select adaptive context sentences for different source sentences, and significantly improves the performance of document-level translation methods.

1 Introduction

Although neural machine translation (NMT) has achieved great progress in recent years (Cho et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Vaswani et al., 2017), when fed an entire document, standard NMT systems translate sentences in isolation without considering the cross-sentence dependencies. Consequently, document-level neural machine translation (DocNMT) methods are proposed to utilize source-side or target-side inter-sentence contextual information to improve translation quality over sentences in a document (Jean et al., 2017; Wang et al., 2017; Tiedemann and Scherrer, 2017; Tu et al., 2018; Kuang et al., 2018; Junczys-Dowmunt, 2019; Ma et al., 2020).

#	Test Context Settings	Model1	Model2
1	previous 2 sentences	<u>20.84</u>	20.94
2	previous 6 sentences	20.90	<u>21.15</u>
3	select 2 from previous 6	22.03	22.14
4	dynamic size from previous 6	22.90	22.74

Table 1: The BLEU (%) scores with different context settings. "Model1" and "Model2" are trained with previous 2 and 6 context sentences, respectively. Underlined results indicate that training and test context settings are consistent.

More recently, researchers of DocNMT mainly focus on exploring various attention-based networks to leverage the cross-sentence context efficiently, and evaluate the special discourse phenomena (Bawden et al., 2018; Müller et al., 2018; Voita et al., 2019b; Jwalapuram et al., 2019). However, there is still an issue that has received less attention: *which context sentences should be used when translating a source sentence?*

We conduct an experiment to verify an intuition: the translation of different source sentences requires different context. As shown in Table 1, we train two DocNMT models and test them using various context settings[1]. During the test, we obtain dynamic context sentences that achieve the best BLEU scores by traversing all the context combinations for each source sentence. Compared with the fixed size context (row 1 and 2), dynamic context (row 3 and 4) can significantly improve translation quality. Although row 2 uses more context, redundant information may hurt the results. Experiments indicate that only the limited context sentences are really useful, and they change with source sentences.

Majority of existing DocNMT models set the context size or scope to be fixed. They utilize all of

---

[1] We apply a typical DocNMT method (Zhang et al., 2018) to train models on Zh→En TED, and select 1,000 sentences to test. The BLEU of sentence-level baseline is 20.06.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2242–2254,
November 16–20, 2020. ©2020 Association for Computational Linguistics

the previous k context sentences (Voita et al., 2018; Zhang et al., 2018; Miculicich et al., 2018; Voita et al., 2019b; Yang et al., 2019; Xu et al., 2020), or the full context in the entire document (Maruf and Haffari, 2018; Tan et al., 2019; Xiong et al., 2019; Zheng et al., 2020). As a result, the inadequacy or redundancy of contextual information is almost inevitable. From this viewpoint, Maruf et al. (2019) propose a selective attention approach that uses the *sparsemax* function (Martins and Astudillo, 2016) instead of the softmax to normalize the attention weights. The sparsemax assigns the low probability in softmax to zero so that the model can focus on the sentences with high probability. However, the learning of attention weights lacks guidance, and they cannot handle the situation where the source sentences achieve the best translation results without relying on any context, which happens in about 39.4% of sentences in the experiment.

To address the problem, we propose an effective approach to select contextual sentences **dynamically** for each source sentence in the document-level translation. Specifically, we propose a *Context Scorer* to score each candidate context sentence according to the currently translated source sentence. Then, we utilize two selection strategies to select useful context sentences for the translation module. The size of selected context is variable for different sentences. A core challenge of our approach is that the selection process is non-differentiable. Therefore, we leverage the reinforcement learning (RL) method to train the selection and DocNMT modules together. We design a novel reward to encourage the model to be aware of different context sentences and select more appropriate context to improve translation quality.

In this paper, we make the following contributions:

- Our approach can measure the contribution of each context sentence to the source, and select dynamic context for the translation of different source sentences. Independent of the translation network, our approach is easily adaptable to existing DocNMT models.
- We bridge the training of context selection and context-aware translation via reinforcement learning. Experiments show that our approach can significantly improve the performance of DocNMT models with the selected dynamic context sentences.

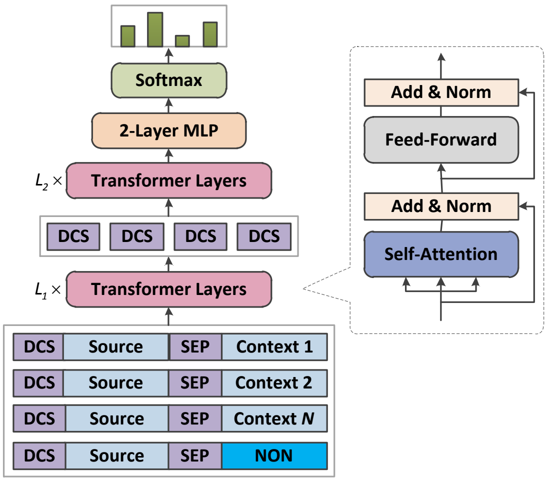

Figure 1: The architecture of context scorer. We add a special empty context sentence "NON" to help the decision of selection strategies. The details of Transformer layers are shown in the right dotted box.

2 Document-level Machine Translation

A standard DocNMT system generally translates a source sentence $X = \{x_1, \cdots, x_I\}$ to a target sentence $Y = \{y_1, \cdots, y_T\}$ with the aid of contextual information $\mathcal{Z}$ that is usually a subset of the candidate context set $\mathbb{Z}$. The model is trained to minimize the negative log-likelihood as:

$$\mathcal{L}_{mle} = -\sum_{t=1}^{T} \log P\left(y_t \mid y_{<t}, X, \mathcal{Z}; \theta\right) \qquad (1)$$

Different granularity (word or sentence) and different sources (source-side or target-side) of contextual information $\mathcal{Z}$ have been explored. Maruf et al. (2019) divide the candidate context set $\mathbb{Z}$ into two cases: *offline* where the context comes from the entire document, and *online* that only uses the past context. In this paper, we mainly focus on a general scenario, where DocNMT translates sentences with the online source-side context sentences.

3 Dynamic Context Selection

Our approach translates a source sentence X in the document in two steps. First, we select the appropriate context sentences for the translation of X via the selection module. Independent of DocNMT module, this step is conducted before the context encoding in DocNMT module. The core component is a *Context Scorer* that calculates the contribution of each context sentence $z \in \mathbb{Z}$ to the translation of X (sub-section 3.1). According to the context scores, we propose two strategies to choose the useful context sentences (sub-section 3.2). Second, we feed the selected context sentences into a DocNMT module to generate the translation.

To overcome the non-differentiable behavior of the context selection and the lack of direct supervision when training the context scorer, we connect the two steps through the reinforcement learning strategy. We propose an effective reward that is related to the translation quality to guide the dynamic selection of context sentences and the optimization of parameters in DocNMT model (sub-section 3.3).

3.1 Context Scorer

As Figure 1 shows, we obtain the representation of context sentences for scoring. Inspired by the popular pre-training language models such as GPT (Radford et al., 2018) and BERT (Devlin et al., 2019), we produce one instance by concatenating the source sentence with a context sentence, and adding a special symbol "$\langle DCS \rangle$" at the beginning and a separator token "$\langle SEP \rangle$" in between. The instance is fed into a stack of L_1 Transformer encoder layers. We believe the special symbol "$\langle DCS \rangle$" can encode the information of source-context sentence pairs well by the self-attention.

For a candidate context sentence $z \in \mathbb{Z}$, its hidden state of "$\langle DCS \rangle$" after L_1 layers is extracted as the input to L_2 Transformer encoder layers to model the dependencies among context sentences. We denote the hidden state after L_2 layers as $h_z \in \mathbb{R}^{d_1}$. After that, we adopt a two-layer linear scorer network to measure the score as follows:

$$Score_z = \sigma\left(W_2\left(W_1 h_z + b_1\right) + b_2\right) \tag{2}$$

where $W_1 \in \mathbb{R}^{d_1 \times d_2}$, and $W_2 \in \mathbb{R}^{d_2 \times 1}$. σ stands for the logistic sigmoid function.

Considering the sampling operation during training process, we normalize all scores of context sentences in candidate set $\mathbb{Z}$ as a probability distribution:

$$\mathcal{P}_{select} = \mathrm{softmax}\left(\left[Score_1; \cdots; Score_{|\mathbb{Z}|}\right]\right) \tag{3}$$

where $[\cdot;\cdot]$ concatenates elements into a vector.

3.2 Selection Strategies

According to the selection probability in $\mathcal{P}_{select}$, we can obtain useful context sentences for the translation task. To select context dynamically, we add a special empty sentence "$\langle NON \rangle$" into the candidate context set, which stands for the situation that translates a source sentence without any context. As a result, we select those context sentences whose probability is higher than "$\langle NON \rangle$". If the probability of "$\langle NON \rangle$" is the highest, context size is zero. We call this strategy as **probability-first**. The selected context sentences change dynamically with the change of source sentences, and the context size can range from 0 to $|\mathbb{Z}|$.

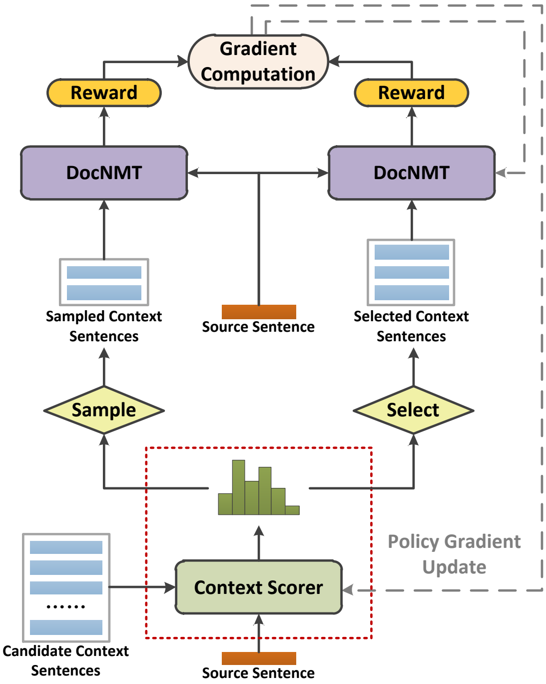

Figure 2: Reinforced training of the context selection and context-aware translation. The two DocNMT models share parameters.

In order to make a fair comparison with existing DocNMT models setting fixed context size, we also propose a **size-first** strategy that selects the certain number of context sentences with the highest probability except "$\langle NON \rangle$". Despite of the fixed size, the context is still dynamic because selected sentences can be anywhere and discontinuous in the document.

3.3 Model Learning

Our strategies perform a non-differentiable hard selection, and it is difficult to decide which context sentences are helpful for the translation. It makes the training quite intractable. Therefore, we apply the policy gradient method to train the selection module and the document-level translation module in an end-to-end fashion through a novel reward. The reward encourages the model to select more useful context to improve the generation probability of the ground truth translations. Figure 2 shows the reinforcement-guided training process.

3.3.1 Modules Initialization

It is well known that a fine initialization of network is important to optimize the parameters in reinforcement learning.

For DocNMT module that is usually trained in two stages (Tu et al., 2018; Zhang et al., 2018; Miculicich et al., 2018; Maruf et al., 2019), we load the parameters of standard sentence-level NMT model to initialize the network.

For the selection module, we simplify the initialization of context scorer as a binary classification task without considering the dependencies among context sentences. Its initialization contains two steps. First, we create pseudo labels for candidate context sentences. Each context sentence is labeled as `1` or `0`. The score in Eq. 2 is treated as the probability to predict label `1`. Specifically, pseudo labels are generated by an extra DocNMT model trained with a single random context sentence. We feed different candidate context sentences to the trained model to translate the same source sentence. Candidate context sentences with higher BLEU than "$\langle NON \rangle$" are labeled as `1`, while those with lower BLEU are labeled as `0`. Second, we train the context scorer to predict the pseudo labels. We share the parameters of embedding layer with initialized DocNMT model. The initial scorer is trained to minimize the cross-entropy loss.

3.3.2 Reward

Given that our goal of context selection is to improve translation quality, we propose a reward that can measure translation quality and is sensitive to the context changes [2].

For a decoding time t, we calculate the cost of generating ground truth target word y_t correctly as follows:

$$g_t = \log P_{\tilde{y}_t^{1st}} - \log P_{y_t} + \log P_{\tilde{y}_t^{1st}} \Big/ (P_{\tilde{y}_t^{1st}} - P_{\tilde{y}_t^{2nd}}) \quad (4)$$

where the first two items calculate the gap between the logarithmic probabilities of ground truth target word y_t and the best word $\tilde{y}_t^{1st}$ whose probability is the top one in the prediction probability distribution. And the last item is a regularization that indicates the difference of probabilities between $\tilde{y}_t^{1st}$ and the word $\tilde{y}_t^{2nd}$ with the second-highest probability. The bigger difference means the higher confidence on the prediction.

We obtain the average cost (whose value > 0) of generating the ground truth sentence $Y = \{y_1, \cdots, y_T\}$, and utilize a monotone decreasing function to get the final reward bounded in $0 \sim 1$ as follows:

$$r(g) = e^{-g} = e^{-\frac{1}{T}\sum_{t=1}^{T} g_t} \quad (5)$$

A high value of the reward means that it is easy to generate the ground truth. Therefore, the selected context sentences should be encouraged. Conversely, if a reward is low, generating the ground truth with the selected context would cost a lot, so the selection is discouraged.

3.3.3 Self-Critical Training

We train the whole model with the self-critical training method (Rennie et al., 2017; Bai et al., 2018). The goal of RL training is to minimize the negative expected reward. And in practice, the loss is usually approximated with a single sample u from the policy $\mathcal{P}$ as follows:

$$\mathcal{L}_{rl} = -\mathbb{E}_{u \sim \mathcal{P}}[r(u)] \approx -r(u), u \sim \mathcal{P} \quad (6)$$

The self-critical training introduces a baseline reward $r(u')$ to reduce the variance of the gradient, where u' is obtained by the inference algorithm at test time. The final gradient is estimated by:

$$\nabla \mathcal{L}_{rl} = (r(u) - r(u')) \nabla \log P(u) \quad (7)$$

Specifically, we denote the trainable parameters of the context scorer and DocNMT by ω and θ, respectively. For each source sentence X, we select a set of context sentences $\mathcal{Z}^*$ by our selection strategies in sub-section 3.2. Meanwhile, another set of context sentences $\hat{\mathcal{Z}}$ with the same size of $\mathcal{Z}^*$ is sampled according to $\mathcal{P}_{select}$ in equation 3. Two sets of context sentences are fed into the same DocNMT module to obtain the rewards $r(\mathcal{Z}^*)$ and $r(\hat{\mathcal{Z}})$, respectively. Therefore, referring to equation 7, the final gradient of the context scorer is calculated by:

$$\nabla_\omega \mathcal{L}(\omega) = (r(\hat{\mathcal{Z}}) - r(\mathcal{Z}^*)) \nabla_\omega \log P_\omega(\hat{\mathcal{Z}}) \quad (8)$$

where $P_\omega(\hat{\mathcal{Z}})$ is the probability of sampling $\hat{\mathcal{Z}}$ from $\mathcal{P}_{select}$. With the baseline reward $r(\mathcal{Z}^*)$ obtained by the current best policy (i.e., learned selection strategies), the method encourages model to explore more useful context (i.e., sampled context) that yields higher reward than the current best (i.e., selected context).

---

[2] In our preliminary experiment, we try BLEU as reward but it is not sensitive enough to distinguish different context. Also, decoding a sequence to calculate BLEU is time-consuming.

Datasets		Training	Dev	Test

	Europarl	1.67M	3.59K	5.14K

Table 2: Dataset statistics in the number of sentences.

For DocNMT module, we can combine the MLE objective (Eq. 1) and RL objective (Eq. 6) together to stabilize the training procedure (Wu et al., 2018) through a balance factor α as follows:

$$\mathcal{L}(\theta) = \alpha * \mathcal{L}_{mle}(Y \mid X, \hat{\mathcal{Z}}, \theta) + (1-\alpha) * \mathcal{L}_{rl}(\theta) \quad (9)$$

We introduce the RL objective into DocNMT module so that the model can make better use of the selected context. The final RL gradient of DocNMT is calculated by:

$$\nabla_\theta \mathcal{L}_{rl}(\theta) = (r(\hat{\mathcal{Z}}) - r(\mathcal{Z}^*)) \nabla_\theta \log P_\theta(\hat{Y} \mid X, \hat{\mathcal{Z}}) \quad (10)$$

where $\hat{Y}$ is a sequence generated by current DocNMT model with the sampled context $\hat{\mathcal{Z}}$.

4 Experiment

4.1 Datasets

We evaluate our approach on different domains of Chinese-English (Zh→En) and English-German (En→De) datasets. The corpora statistics are listed in Table 9. For TED Talks in IWSLT17[3], we use *dev-2010* as the development set, and *tst-2010∼2013* as the test set for both Zh→En and En→De language pairs. For News-Commentary v14[4], we use the *newstest2017* for development and *newstest2018* for testing. Europarl is a large scale corpus extracted from Europarl v7, and we use the same training, development and test sets as Maruf et al. (2019).

4.2 Models

We compare our approach with the following methods: **1) SENTNMT** (Vaswani et al., 2017) is a standard sentence-level Transformer model using the "base" version parameters. **2) TDNMT** (Zhang et al., 2018) introduces the contextual information by adding attention sub-layers at each encoder and decoder layer. We use 2 previous consecutive context sentences as they suggested. **3) HAN** (Miculicich et al., 2018) uses 3 previous sentences as context. We adopt the "HAN encoder + HAN decoder" strategy that adds a hierarchical network on the top of the last encoder and decoder layer to model sentence-level and word-level contextual information. **4) SAN** (Maruf et al., 2019) utilizes all context in the entire document by calculating the sentence-level and word-level weights. It focuses on relevant context sentences through the sparsemax function. We choose the model that integrates the online context into encoder with "sparse-soft H-Attention".

We implement our approach and baseline methods based on the toolkit THUMT (Zhang et al., 2017). The parameters are the "base" version of the original Transformer (Vaswani et al., 2017). The d_1 and d_2 in Eq. 2 are 512 and 256, respectively. We set the layers of $L_1 = 2$ and $L_2 = 2$. The effect of layer depth of context scorer and more implementation details are shown in the appendix.

5 Results and Analysis

5.1 Main Results

We use BLEU (Papineni et al., 2002) score to evaluate the translation quality. Considering the memory limitation and complex sampling space, we select dynamic context from previous six sentences. Table 10 shows the performance of models utilizing different context settings. We always keep the same setting for training and test.

Comparison with Fixed Context Methods. The performance of DocNMT models with fixed context is shown in row 2∼5. Row 2 and 3 follow the context settings in the published papers. It can be found that using more context sentences indiscriminately (row 4 and 5) does not bring significant BLEU improvement. Instead, it increases computational cost.

By contrast, our approach (row 10∼15) can significantly improve translation quality on all datasets. Let us take the TDNMT models on Zh→En TED for example. Row 11 applies the size-first strategy to select context sentences of the same size as original TDNMT model in row 3. The result achieves +0.70 BLEU improvement (20.09 vs. 19.39). Compared with row 5 that uses all context in previous six sentences, our approach can filter some redundant information and focus on fewer selected context sentences to gain +0.64 BLEU scores (20.09 vs. 19.45). On the other hand, even if the context is selected from previous two sentences (row 14), our model utilizing probability-

Table 3: Performance of models on BLEU (%) using different context settings. "full" means using all context in the scope. "random", "attend", and "select" stand for selecting sentences randomly, implicitly based on attention weights, and explicitly by our approaches, respectively. "dyn" stands for dynamic size. "DCS-SF" and "DCS-PF" mean dynamic context selection by size-first and probability-first strategies respectively. All results using "DCS" are statistically significantly (p-values < 0.05) better than corresponding original DocNMT models.

first strategy can still improve original TDNMT by +0.52 BLEU (19.91 vs. 19.39). It indicates that useless context sentences still exist in a small scope. Conclusions are similar for other models and datasets.

Comparison with Other Dynamic Methods. Row 6∼16 show the models trained and tested with dynamic context settings. Row 6 and 7 show a lower bound that randomly selects the fixed size context sentences. The results are similar to original models with the fixed size previous sentences (row 2 and 3). In contrast to the random selection, our approach (row 10 and 11) can select the same size of context sentences that are really helpful to generate better translations.

SAN (row 8) implicitly selects context from all previous sentences through sharpening the attention weights. It resets low attention weights to zero to filter out some sentences. For a fair comparison, we also implement SAN in a limited context scope (row 9). Even if the candidate set is limited to previous six sentences, the BLEU does not decrease significantly. Different from SAN, our approach explicitly selects context sentences via reinforced guide. As row 16 shows, when added into SAN (row 9), our approach can obtain +0.69 BLEU gains (20.18 vs. 19.49) on Zh→En TED by picking a more focused context candidate set for SAN. Furthermore, our approach can set the context size to be zero, but SAN cannot deal with this common cases that do not require any context.

#	Training		Balance RL Loss	BLEU
	Scorer	DocNMT		
1	×	×	–	29.04
2	✓	×	–	29.58
3	✓	✓	$\alpha = 1.00$	29.61
4	✓	✓	$\alpha = 0.75$	29.92
5	✓	✓	$\alpha = 0.50$	29.73
6	✓	✓	$\alpha = 0.25$	29.70
7	✓	✓	$\alpha = 0.00$	29.65

Table 4: Effect of training settings for DocNMT models. BLEU scores are measured based on TDNMT on the development set in En→De Europarl. ✓ means training the module while × means not. Row 1 stands for the original TDNMT model.

Comparison of Selection Strategies. We also compare the two selection strategies proposed in section 3.2. Results with probability-first strategy (row 13 and 15) are slightly better than size-first strategy (row 10 and 11). The size-first strategy has to contain some useless sentences because of the fixed size. By contrast, the probability-first strategy allows more flexible context selection of dynamic size. It can achieve +0.72 (20.26 vs. 19.54) and +0.95 (20.34 vs. 19.39) BLEU improvement on Zh→En TED when applied to HAN and TDNMT model, respectively.

5.2 Effect of DocNMT Training

Our proposed context selection module is independent of the translation module. Therefore, the con-

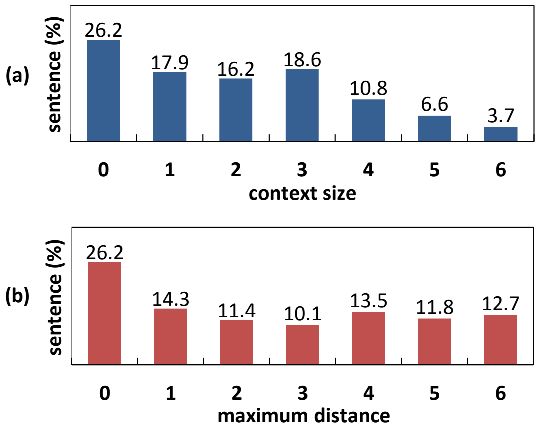

Figure 3: Distribution of dynamic context size and position. (a) shows the ratio of source sentences with different context sizes. (b) counts the maximum distance from the selected context sentences to their corresponding source sentences.

text scorer and DocNMT can be trained separately. As shown in Table 11, we discuss the impact of selected context on the training of DocNMT. In row 2, we only train the context scorer, and keep the original DocNMT model unchanged as a component to calculate rewards. The result shows that our selection module can effectively distinguish between useful and useless context sentences for translation, and achieves +0.54 BLEU gains on the En→De Europarl development set.

We also explore whether the selected context would be helpful for the DocNMT training. We set the balance factor α Eq. 9 to be [0, 0.25, 0.5, 0.75, 1.0] in our experiments. Row 3 shows the model setting $\alpha = 1.0$ that optimizes the standard MLE loss using the selected context sentences. Row 7 sets $\alpha = 0.0$ to fine-tune DocNMT with the RL loss. By contrast, DocNMT models guided by the combination of MLE and RL loss can be learned better. We think the RL loss may make the model more sensitive to the selected context sentences. When $\alpha = 0.75$, DocNMT can obtain the best BLEU score on development set, thus we use the setting in our experiments.

5.3 Distribution of Dynamic Context

Figure 3 shows the distribution of different context sizes and maximum distances in the test sets of Zh→En TED. Our approach selects context sentences whose size can range from zero to six. In Figure 3 (a), 78.9% of source sentences tend to select no more than three context sentences. 26.2% of sentences can be translated well without contextual information. The average context size over the test sets is 2.05 sentences. In Figure 3 (b), we show the maximum distances from the selected context sentences to the currently translated sentence. Except for the cases that need no context (distance 0), the distance distribution is relatively uniform. The total average distance is previous 2.57 sentences.

Precision	Recall	F1
68.46	51.78	58.96

Table 5: Results of empty context prediction on 500 sentences with human annotation as reference.

Model	Ctx-Empty	Ctx-Nonempty
SentNmt	19.75	20.04
TDNMT	20.49	20.72
+*DCS-PF*	21.51 (+1.02)	21.43 (+0.71)

Table 6: BLEU (%) scores on the context-empty and context-nonempty test sets. "+" stands for the improvement when compared with TDNMT.

5.4 Selection of Empty Context

Our approach has the ability to select empty context for translation, which other models such as SAN (Maruf et al., 2019) cannot do. To evaluate whether the selected empty context is reasonable, we annotate a special test set that contains 500 sentences selected randomly from Zh→En TED test sets. Each sentence is given its previous 6 sentences as context. Two annotators are instructed to mark context-empty sentences that can be translated well without any contextual information. The annotation details and statistics are shown in the appendix. The Cohen's Kappa value (Cohen, 1960) of annotation is 0.72. We gather sentences marked by both annotators as the final context-empty sentences (about 39.4% in 500 sentences). Therefore, the test set is divided into context-empty and context-nonempty subsets. Their sizes are 197 and 303, respectively.

Table 5 shows the performance of our approach (using "TDNMT+*DCS-PF*" model) for predicting empty context on the 500 annotated sentences. For the selection of empty context, our approach can achieve 58.96 F1-score.

Table 6 shows the BLEU scores on the context-empty and context-nonempty subsets. Through our context selection, the improvement of BLEU on context-empty set is higher than context-nonempty set. The analysis indicates that our approach is aware of context-empty sentences, and can select empty context to improve translation quality.

Model	deixis	lex.c.	ell.infl.	ell.VP
TDNMT+*DCS-PF*	60.9	85.1	52.4	81.0
	83.4	89.6	88.2	90.6
CADec+*DCS-PF*	67.0	90.5	50.8	84.4
	85.7	95.4	89.2	91.8

Table 7: Accuracy (%) of context selection on the discourse phenomena test sets. A model contains two rows: upper – exact match, lower – selected context contains the golden answer.

5.5 Analysis of Discourse Phenomena

In addition to the selection of empty context, we also want to examine whether our approach can select context sentences that are helpful to improve the translation of discourse phenomena.

Voita et al. (2019b) construct contrastive test sets for English-Russian to evaluate four types of discourse phenomena (i.e., deixis, lexical cohesion, inflection and VP ellipses). Each test instance consists of a positive and several negative translations with incorrect phenomena. Models are evaluated by the accuracy that is defined as the proportion of times the generation probability of positive translation is higher than negative ones. Meanwhile, each instance has three context sentences. Among them, there is one and only one context sentence that is decisive in resolving the phenomena. It has been marked. Therefore, we can evaluate the accuracy of context selection, taking the marked context sentences as the standard answer.

We use the same datasets as Voita et al. (2019b) to train models. Different from TDNMT (Zhang et al., 2018) that only uses source-side context, CADec (Voita et al., 2019b) is proposed to utilize both source-side and target-side context. Based on CADec, we try to extend our approach in a simple way to select the target-side context. When the context scorer selects a source-side context sentence, the corresponding sentence-level translation is directly selected as target-side context.

Table 7 shows the accuracy of context selection at four test sets. It can be found that our approach can select more than 85% standard context sentences for special phenomena, and achieve more than 80% exact match on lexical cohesion and VP ellipses sets.

The accuracy of discourse phenomena are shown in Table 8. TDNMT does not perform well because it only uses source-side context, which is unchanged in contrastive instances of test sets. Compared with original CADec, our approach can improve the performance of lexical cohesion. Although the simple way of selecting target-side context bears the risk of missing selection, the accuracy of some phenomena does not change significantly. Table 7 has shown that our approach can select useful target-side context in most cases. And the selection mechanism can make the model focus more on the useful context to resolve the discourse phenomena.

Model	deixis	lex.c.	ell.infl.	ell.VP
SENTNMT	50.0	45.9	53.0	28.4
TDNMT	50.0	46.0	56.4	48.0
CADec	81.6	58.1	72.2	80.0
+*DCS-PF*	79.2	62.0	71.8	80.8

6 Related Work

Standard neural machine translation methods usually focus on the sentence-level translation (Cho et al., 2014; Bahdanau et al., 2015; Zhang and Zong, 2015; Luong et al., 2015; Tu et al., 2016; Zhang and Zong, 2016; Vaswani et al., 2017; Wang et al., 2019; Zhou et al., 2019; Zhao et al., 2020). As a contrast, document-level neural machine translation methods mainly pay attention to how to utilize the cross-sentence context. Researchers propose various context-aware networks to utilize contextual information to improve the performance of DocNMT models on the translation quality (Jean et al., 2017; Tu et al., 2018; Kuang et al., 2018) or discourse phenomena (Bawden et al., 2018; Xiong et al., 2019; Voita et al., 2019b,a). However, most methods roughly leverage all context sentences in a fixed size that is tuned on development sets (Wang et al., 2017; Miculicich et al., 2018; Zhang et al., 2018; Yang et al., 2019; Voita et al., 2018; Xu et al., 2020) , or full context in the entire document (Maruf and Haffari, 2018; Tan et al., 2019; Kang and Zong, 2020; Zheng et al., 2020). They ignore the individualized needs for context when translating different source sentences.

Some works have noticed that not all context is useful (Jean and Cho, 2019; Kim et al., 2019). Kimura et al. (2019) explore the context selection in the single-encoder framework (Tiedemann and Scherrer, 2017), and select context sentences that yield highest forced back-translation probability. However, the method cannot optimize DocNMT model at training phase, and requires back-translation model at inference phrase. Maruf et al. (2019) sharpen the attention weights between the source and context sentences through the *sparse-*

max function, and implicitly select context with high attention weights. Nevertheless, the method lacks direct supervision over context selection, and it cannot cover the situation where context is not needed. Inspired by the extractive-abstractive summarization (Chen and Bansal, 2018), our approach is different from above DocNMT methods. Our approach can explicitly select dynamic size (that can be 0) of context sentences for the translation of different source sentences.

7 Conclusion and Future Work

We propose a dynamic selection method to choose variable sizes of context sentences for document-level translation. The candidate context sentences are scored and selected by two proposed strategies. We train the whole model via reinforcement learning, and design a novel reward to encourage the selection of useful context sentences. When applied to existing DocNMT models, our approach can improve translation quality significantly. In the future, we will select context sentences in larger candidate space, and explore more effective ways to extend our approach to select target-side context sentences.

A Experimental Setup

A.1 Parameters and Implementation

We implement all models based on the toolkit THUMT[5] with the parameters of the "base" version of Transformer (Vaswani et al., 2017). Specifically, we use 6 layers of encoder and decoder with 8 attention heads. The hidden size and feed-forward layer size are 512 and 2,048, respectively. For Zh→En, Chinese and English vocabulary sizes are 30K and 25K, respectively. For En→De, source-side and target-side share a vocabulary table. The vocabulary size is 30K. Chinese sentences are segmented into words by our in-house toolkit. English and German datasets are tokenized and truecased by the Moses toolkit[6]. Words are segmented by byte-pair encoding (Sennrich et al., 2016).

We introduce a context scorer that is independent of the DocNMT models, which allows our approach to be easily deployed on many baseline DocNMT systems. Compared with original DocNMT models, the amount of additional parameters depends on the number of Transformer encoder layers L_1 and L_2 in the context scorer.

		L_1		
		1	2	4
L_2	0	29.35	29.58	29.64
	1	29.60	29.72	29.77
	2	29.76	**29.92**	29.83

Table 9: BLEU (%) scores on En→De TED development set using different layers of context scorer.

In Table 9, we discuss the effect of layer depth of context scorer (defined in subsection 3.1). Experiments are conducted using "TDNMT+*DCS-PF*" model with the balance factor $\alpha = 0.75$. Our approach achieves the highest BLEU with a context scorer setting $L_1 = 2$ and $L_2 = 2$, which introduces 12.7M extra parameters to any original DocNMT models.

A.2 Training and Inference

For training, we use the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. We employ label smoothing with a value of 0.1 and dropout with a rate of 0.1. The batch size is 3,000 tokens. We employ 4 Titan Xp GPUs to train all models. Compared with original DocNMT (TDNMT), the training and testing speeds are slowed down by an order of 1.61 (mainly because of the generation of $\hat{Y}$ in Eq. 10) and 1.05, respectively.

We use *multi-bleu.perl*[7] to compute the BLEU score. The beam size is set to 4. The significance test is conducted by the script "bootstraphypothesis-difference-significance.pl" in Moses.

B Annotation and Statistics of Empty Context

In this section we describe the annotation process and statistics of the special test set constructed to evaluate the selection of empty context.

B.1 Annotation

We randomly select 500 sentences with previous 6 sentences as context from Chinese-English TED *tst-2010∼2013*. Each example to be annotated contains a source-reference sentence pair and six source-reference contextual sentence pairs. Two annotators proficient in both Chinese and English are instructed to annotate the sentences that can be translated well without any context. The process consists of three steps, and is carried out independently between two annotators.

Step1. Annotators are instructed to read a single source sentence X without any context, and translate it into Y' by themselves.

Step2. The reference Y of the sentence X is shown to annotators. Then, they are instructed to compare Y' with Y word-by-word to answer whether Y' is appropriate.

Step3. Annotators are instructed to read source-reference contxtual sentences, and compare Y' with Y word-by-word again. After that, they are asked to determain whether Y' needs to be modified better.

If a annotator insists that his translation Y' is appropriate at Step2 and needs no modification at Step3, the sentence X is annotated as "context-empty", which means it can be translated well with-

Abstract

Large-scale training datasets lie at the core of the recent success of neural machine translation (NMT) models. However, the complex patterns and potential noises in the large-scale data make training NMT models difficult. In this work, we explore to identify the inactive training examples which contribute less to the model performance, and show that the existence of inactive examples depends on the data distribution. We further introduce *data rejuvenation* to improve the training of NMT models on large-scale datasets by exploiting inactive examples. The proposed framework consists of three phases. First, we train an *identification model* on the original training data, and use it to distinguish inactive examples and active examples by their sentence-level output probabilities. Then, we train a *rejuvenation model* on the active examples, which is used to re-label the inactive examples with forward-translation. Finally, the rejuvenated examples and the active examples are combined to train the final NMT model. Experimental results on WMT14 English-German and English-French datasets show that the proposed *data rejuvenation* consistently and significantly improves performance for several strong NMT models. Extensive analyses reveal that our approach stabilizes and accelerates the training process of NMT models, resulting in final models with better generalization capability. [1]

1 Introduction

Neural machine translation (NMT) is a data-hungry approach, which requires a large amount of data to train a well-performing NMT model (Koehn and Knowles, 2017). However, the complex patterns and potential noises in the large-scale data make training NMT models difficult. To relieve this problem, several approaches have been proposed to better exploit the training data, such as curriculum learning (Platanios et al., 2019), data diversification (Nguyen et al., 2019), and data denoising (Wang et al., 2018).

In this paper, we explore an interesting alternative which is to reactivate the *inactive examples* in the training data for NMT models. By definition, inactive examples are the training examples that only marginally contribute to or even inversely harm the performance of NMT models. Concretely, we use sentence-level output probability (Kumar and Sarawagi, 2019) assigned by a trained NMT model to measure the activeness level of training examples, and regard the examples with the least probabilities as inactive examples (§3.1). Experimental results show that removing 10% most inactive examples can marginally improve translation performance. In addition, we observe a high overlapping ratio (e.g., around 80%) of the most inactive and active examples across random seeds, model capacity, and model architectures (§4.2). These results provide empirical support for our hypothesis of the existence of inactive examples in large-scale datasets, which is invariant to specific NMT models and depends on the data distribution itself.

We further propose *data rejuvenation* to rejuvenate the inactive examples to improve the performance of NMT models. Specifically, we train an NMT model on the active examples as the rejuvenation model to re-label the inactive examples, resulting in the rejuvenated examples (§3.2). The final NMT model is trained on the combination of the active examples and rejuvenated examples. Experimental results show that the data rejuvenation approach consistently and significantly improves performance on SOTA NMT models (e.g., LSTM (Domhan, 2018), TRANSFORMER (Vaswani et al., 2017), and DYNAMICCONV (Wu et al.,

November 16–20, 2020.

2019)) on the benchmark WMT14 English-German and English-French datasets (§4.4). Encouragingly, our approach is also complementary to existing data manipulation methods (e.g., data diversification (Nguyen et al., 2019) and data denoising (Wang et al., 2018)), and combining them can further improve performance.

Finally, we conduct extensive analyses to better understand the inactive examples and the proposed data rejuvenation approach. Quantitative analyses reveal that the inactive examples are more difficult to learn than active ones, and rejuvenation can reduce the learning difficulty (§5.1). The rejuvenated examples stabilize and accelerate the training process of NMT models (§5.2), resulting in final models with better generalization capability (§5.3).

Our contributions of this work are as follows:

- Our study demonstrates the existence of inactive examples in large-scale translation datasets, which mainly depends on the data distribution.
- We propose a general framework to rejuvenate the inactive examples to improve the training of NMT models.

2 Related Work

Data Manipulation. Our work is closely related to previous studies on manipulating training data for NMT models, which focuses on exploiting the original training data without augmenting additional data. For example, the data denoising approach (Wang et al., 2018) aims to identify and clean the noise training examples. Data diversification (Nguyen et al., 2019) tries to diversify the training data by applying forward-translation (Zhang and Zong, 2016) to the source side of the parallel data, or back-translation (Sennrich et al., 2016a) to the target side of parallel data in a reverse translation direction. Our approach is complementary to theirs, and using them together can further improve translation performance (Table 4). Another distantly related direction is to simplify the source sentences so that a black-box machine translation system can better translate them (Mehta et al., 2020), which is out of scope in this work.

Distinguishing Training Examples. Our work is also related to previous work on distinguishing training examples in machine learning. One stream is to re-weight training examples with different choices of preferred examples during the training stage. For example, self-paced learning (Kumar et al., 2010) prefers easy examples, hard example mining (Shrivastava et al., 2016) exploits hard examples, and active learning (Chang et al., 2017) emphasizes high variance examples. Another stream is to schedule the order of training examples according to their difficulty, e.g., curriculum learning which has been applied to the training of NMT models successfully (Kocmi and Bojar, 2017; Zhang et al., 2018; Platanios et al., 2019; Wang et al., 2019; Liu et al., 2020b). In contrast, we explore strategies to simplify the difficult (i.e., inactive) examples without changing the model architecture and model training strategy.

Inactive Examples in Computer Vision Dataset. Birodkar et al. (2019) reveals that data redundancy exists in large-scale image recognition datasets, e.g., CIFAR-10 (Krizhevsky et al., 2009) and ImageNet (Deng et al., 2009) datasets. They find that a subset can generalize on par with the full dataset and that at least 10% of training data are redundant in these large-scale image classification datasets. Our results confirm these findings on the large-scale NLP datasets. In addition, we propose to rejuvenate the inactive examples to further improve the model performance.

3 Methodology

Figure 1 shows the framework of the *data rejuvenation* approach, in which we introduce two models: an identification model and a rejuvenation model. The *identification model* distinguishes the inactive examples from the active ones. The *rejuvenation model*, which is trained on the active examples, rejuvenates the inactive examples. The rejuvenated examples and the active examples are combined to train the final NMT model.

There are many possible ways to implement the general idea of data rejuvenation. The aim of this paper is not to explore this whole space but simply to show that one fairly straightforward implementation works well and that data rejuvenation helps.

3.1 Identification Model

We describe a simple heuristic to implement the identification model by leveraging the output probabilities of NMT models. The training objective of the NMT model is to maximize the log-likelihood

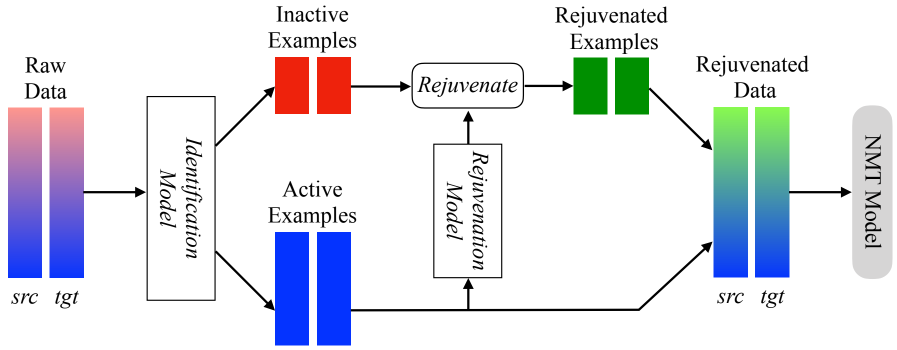

Figure 1: The framework of data rejuvenation. The inactive examples from the original training data are identified by the *identification model*, then rejuvenated by the *rejuvenation model*. The rejuvenated examples along with the active examples are used together to train the NMT model. Best view in color.

of the training data$\{[\mathbf{x}^n, \mathbf{y}^n]\}_{n=1}^{N}$:

$$L(\theta) = \sum_{n=1}^{N} \log P(\mathbf{y}^n|\mathbf{x}^n). \quad (1)$$

The trained NMT model assigns a sentence-level probability $P(\mathbf{y}|\mathbf{x})$ to each sentence pair $(\mathbf{x}, \mathbf{y})$, indicating the confidence of the model to generate the target sentence $\mathbf{y}$ from the source one $\mathbf{x}$ (Kumar and Sarawagi, 2019; Wang et al., 2020). Intuitively, if a training example has a low sentence-level probability, it is less likely to provide useful information for improving model performance, and thus is regarded as an inactive example.

Therefore, we adopt sentence-level probability $P(\mathbf{y}|\mathbf{x})$ as the metric to measure the activeness level of each training example:

$$I(\mathbf{y}|\mathbf{x}) = \prod_{t=1}^{T} p(y_t|\mathbf{x}, \mathbf{y}_{<t}), \quad (2)$$

where T is the number of target words in the training example. $I(\mathbf{y}|\mathbf{x})$ is normalized by the length of target sentence $\mathbf{y}$ to avoid length bias. We train an NMT model on the original training data and use it to score each training example. We treat a certain percent of training examples with the least sentence-level probabilities as inactive examples.

3.2 Rejuvenation Model

Inspired by recent successes on data augmentation for NMT, we adopt the widely-used back-translation (Sennrich et al., 2016a) and forward-translation (Zhang and Zong, 2016) approaches to implement the rejuvenation model. After the active examples are distinguished from the training data, we use them to train an NMT model in forward direction for forward-translation or/and reverse direction for back-translation. The trained model rejuvenates each inactive example by producing a synthetic-parallel example based on their source (for forward-translation) or target (for back-translation) side. Benefiting from the knowledge distillation based on active examples, the rejuvenated examples consist of simpler patterns than the original examples (Edunov et al., 2019), thus are more likely to be learned by NMT models.

4 Experiment

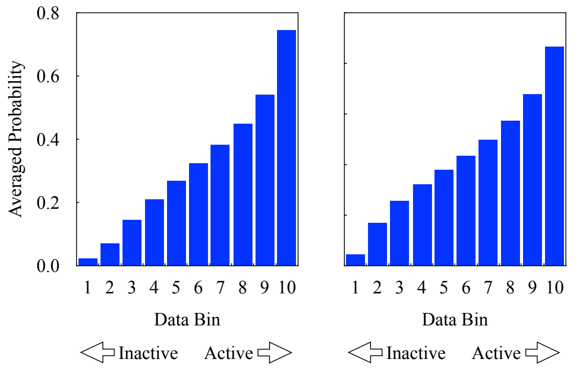
4.1 Experimental Setup

Data. We conducted experiments on the widely used WMT14 English⇒German (En⇒De) and English⇒French (En⇒Fr) datasets, which consist of about 4.5M and 35.5M sentence pairs, respectively. We applied BPE (Sennrich et al., 2016b) with 32K merge operations for both language pairs. The experimental results were reported in case-sensitive BLEU score (Papineni et al., 2002).

Model. We validated our approach on a couple of representative NMT architectures:

- LSTM (Domhan, 2018) that is implemented in the TRANSFORMER framework.
- TRANSFORMER (Vaswani et al., 2017) that is based solely on attention mechanisms.
- DYNAMICCONV (Wu et al., 2019) that is implemented with lightweight and dynamic convolutions, which can perform competitively to the best reported TRANSFORMER results.

We adopted the open-source toolkit Fairseq (Ott et al., 2019) to implement the above NMT models.



(a) En⇒De (b) En⇒Fr

Figure 2: Probability diagram on (a) En⇒De and (b) En⇒Fr datasets. Training examples in smaller bins (e.g., 1, 2) are regarded as inactive examples due to their lower probabilities.

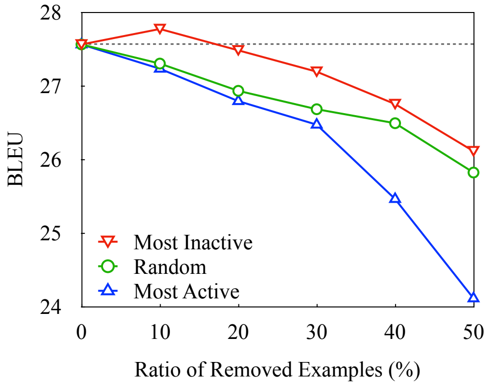


Figure 3: Translation performance of the NMT model trained on the training data with the most inactive examples removed. For comparison, results of the most active examples and randomly sampled examples are also presented.

We followed the settings in the original works to train the models. In brief, we trained the LSTM model for 100K steps with 32K (4096 × 8) tokens per batch. For TRANSFORMER, we trained 100K and 300K steps with 32K tokens per batch for the BASE and BIG models respectively. We trained the DYNAMICCONV model for 30K steps with 459K (3584 × 128) tokens per batch. We selected the model with the best perplexity on the validation set as the final model.

We first conducted ablation studies on the identification model (§4.2) and rejuvenation model (§4.3) on the WMT14 En⇒De dataset with TRANSFORMER-BASE. Then we reported the translation performance on different model architectures and language pairs, as well as the comparison with previous studies (§4.4).

4.2 Identification of Inactive Examples

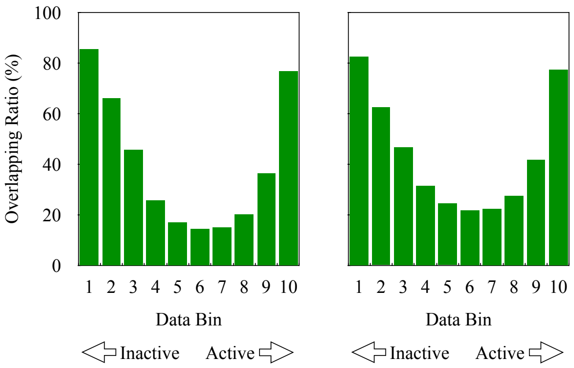
In this section, we investigated the reasonableness and consistency of the identified inactive examples.

Identified Inactive Examples. As aforementioned, we ranked the training examples according to the sentence-level output probability (i.e., confidence) assigned by a trained NMT model. We followed Wang et al. (2020) to partition the training examples into 10 equal bins (i.e., each bin contains 10% of training examples) according to the ranking of their probabilities and reported the averaged probability of each bin, as depicted in Figure 2. As seen, the examples in the 1^{st} data bin have much lower probabilities than the other ones, which we regard as inactive examples.

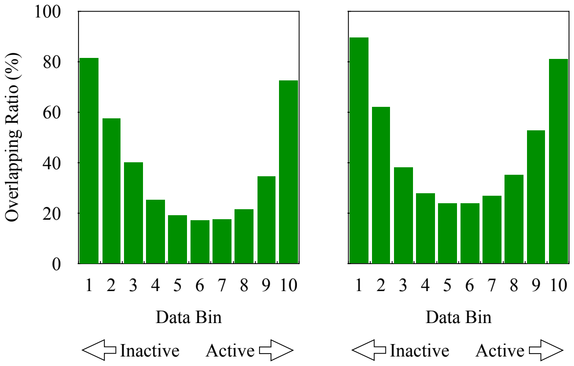
Reasonableness of Identified Inactive Examples. In this experiment, we evaluated the reasonableness of the identified inactive examples by measuring their contribution to the translation performance. Intuitively, a reasonable set of inactive examples can be removed from the training data without harming the translation performance, since they cannot provide useful information to the NMT models. Starting from this intuition, we removed a certain percentage of examples with the least probabilities (e.g., most inactive examples) from the training data, and evaluated the performance of the NMT model that is trained on the remaining data.

Figure 3 shows the contribution of the most inactive examples to translation performance. Generally, the performance drop grows up with the increased portion of examples being removed from the training data. The declining trend of the inactive examples is more gentle than the randomly selected examples, and that of the active examples is steepest. These results demonstrate the reasonableness of the identified examples. Encouragingly, the translation performance does not degrade when removing 10% of the most inactive examples, which is consistent with the finding of Birodkar et al. (2019) on the CV datasets.

Consistency of Identified Inactive Examples. Since our identification of inactive examples relies on a pre-trained NMT model, one doubt naturally arises: *are the identified inactive examples model-specific*? For example, different NMT models treat different portions of the training data as the inactive examples. To dispel the doubt, we identified some factors that can significantly af-



(a) En-De: Seed (b) En-De: Capacity



(c) En-De: Architecture (d) En-Fr: Architecture

Figure 4: Ratio of examples that are shared by different model variants: random seed (a), model capacity (b), model architecture on En⇒De (c) and En⇒Fr (d) datasets. A high overlapping ratio for most inactive examples (i.e., 1^{st} data bin) demonstrates that the identified inactive examples are not model-specific.

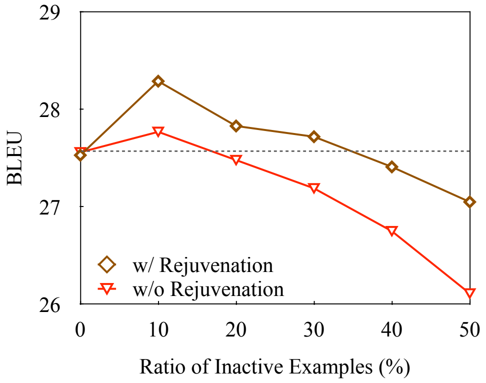


Figure 5: Effect of the ratio of examples labelled as inactive examples. We used forward-translation as the rejuvenation strategy and trained the final NMT model on the combination of rejuvenated examples and active examples from scratch.

Rejuvenation	**BLEU**	△
n/a	27.5	–
Forward Translation	**28.3**	+0.8
Back-Translation	27.5	+0.0
Both	27.8	+0.3

Table 1: Effect of different rejuvenation strategies.

fect the performance of NMT models: 1) *random seeds* for TRANSFORMER-BASE: "1", "12", "123", "1234", and "12345"; 2) *model capacity* for TRANSFORMER: TINY (3 × 256), BASE (6 × 512), and BIG (6 × 1024); and 3) *model architectures*: the aforementioned architectures in Section 4.1. For each data bin, we calculated the ratio of examples that are shared by different model variants (e.g., different random seeds). Generally, a high overlapping ratio denotes the identified examples are more agreed by different models, which suggests the examples are not model-specific.

Figure 4 depicts the results. As expected, there is always a high overlapping ratio (over 80%) for the most inactive examples (i.e., 1^{st} data bin) across model variants and language pairs. The high consistency of identified inactive examples demonstrates that *the proposed identification is invariant to specific models, and depends on the data distribution itself*. Another interesting finding is that the most active examples (i.e., 10^{th} data bin) also holds a high agreement by model variants. The overlapping ratios of all model variants (i.e., seeds, capacities, and architectures, 9 models in total) on the En⇒De dataset are 70.9%, and 62.5% for the most inactive and (most) active examples, respectively. This indicates that deep learning methods share a common ability to learn from the training examples.

4.3 Rejuvenation of Inactive Examples

In this section, we evaluated the impact of different components on the rejuvenation model.

Ratio of Examples Labelled as Inactive. After all examples were assigned a sentence-level probability by the identification model, we labelled $R\%$ of examples with the least probabilities as the inactive examples. We investigated the effect of different R on translation performance, as shown in Figure 5. Clearly, rejuvenating the inactive examples consistently outperforms its non-rejuvenated counterpart, demonstrating the necessity of the data rejuvenation. Concerning the rejuvenation model, the BLEU score decreases with the increase of R. This is intuitive, since examples with relative higher probabilities (e.g., beyond the 10% most inactive examples) can provide useful information

+ Rejuvenated Examples	27.3	-0.2

Table 2: Comparing data rejuvenation on identified inactive examples and forward translation on randomly sampling examples.

for NMT models, and rejuvenating them would inversely harm the translation performance. In the following experiments, we treat 10% examples with the least probabilities as inactive examples.

Effect of Rejuvenation Strategy. Table 1 lists the results of different rejuvenation strategies. Surprisingly, the back-translation strategy does not improve performance. One possible reason is that the inactive examples are identified by a forward-translation model (§3.1), indicating that these inactive examples are more difficult for NMT models to generate from the source side to the target side, rather than in the reverse direction. We conjecture that forward translation strategy may alleviate this problem by constructing a synthetic example, in which each source side is associated with a simpler target side. Combining both strategies cannot further improve translation performance. In the following experiments, we use forward translation as the default rejuvenation strategy.

Benefiting from Forward Translation or Data Rejuvenation? Some researchers may doubt: *does the improvement indeed come from data rejuvenation, or just from forward translation?* To dispel the doubt, we conducted the comparison experiment by randomly selecting 10% training examples as inactive examples and applying data rejuvenation with forward translation strategy. As shown in Table 2, removing 10% random examples inversely harms the translation performance, and rejuvenating them leads to a further decrease of performance. In contrast, the proposed data rejuvenation improves performance as expected. These results provide empirical support for our claim that the improvement comes from the proposed data rejuvenation rather than forward translation.

4.4 Main Results

Table 3 lists the results across model architectures and language pairs. Our Transformer models achieve better results than that reported in previous work (Vaswani et al., 2017), especially on the large-scale En⇒Fr dataset (e.g., more than 1.0 BLEU points). Ott et al. (2018) showed that models of larger capacity benefit from training with large batches. Analogous to DynamicConv, we trained another Transformer-Big model with

Model	BLEU	△

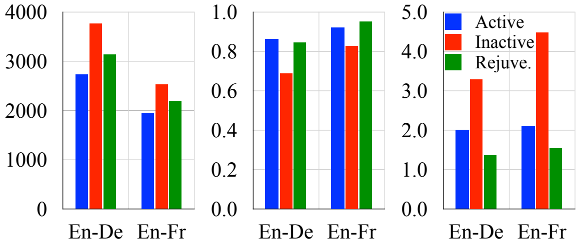
+ *Data Rejuvenation*	28.3	+0.8
+ Data Diversification-BT	26.9	-0.6
+ *Data Rejuvenation*	27.9	+0.4
+ Data Diversification-FT	28.1	+0.6
+ *Data Rejuvenation*	28.5	+1.0
+ Data Denoising	28.1	+0.6
+ *Data Rejuvenation*	28.6	+1.1

Table 4: Comparison with other data manipulation approaches. Results are reported on the En⇒De test set.



(a) Frequency Rank (b) Coverage (c) Uncertainty

Figure 6: Linguistic properties of different training examples: frequency rank (↑ more difficult), coverage (↓ more difficult), and uncertainty (↑ more difficult).

459K tokens per batch ("+ Large Batch" in Table 3) as a strong baseline. We tested statistical significance with paired bootstrap resampling (Koehn, 2004) using `compare-mt`[2] (Neubig et al., 2019).

Clearly, our data rejuvenation consistently and significantly improves translation performance in all cases, demonstrating the effectiveness and universality of the proposed data rejuvenation approach. It's worth noting that our approach achieves significant improvements without introducing any additional data and model modification. It makes the approach robustly applicable to most existing NMT systems.

Comparison with Previous Work. The proposed *data rejuvenation* approach belongs to the family of data manipulation. Accordingly, we compare it with several widely-used manipulation strategies: data diversification (Nguyen et al., 2019), and data denoising (Wang et al., 2018).

For data diversification, we used both forward-translation (FT, Zhang and Zong, 2016) and back-translation (BT, Sennrich et al., 2016a) strategies on the original training data, and no monolingual data is introduced. The final NMT model was trained on the combination of the original and the synthetic parallel data. Our approach is similar to "Data Diversification-FT" except that we only forward-translate the identified inactive examples (10% of the training data), while they forward-translate all the training examples.

For data denoising, we ranked the training data according to a noise metric, which requires a set of trusted examples. Following Wang et al. (2018), we used WMT newstest 2010-2011 as the trusted data, which consists of 5492 examples. The trained NMT model on the raw data was regarded as the noisy model, which was then fine-tuned on the trusted data to obtain the denoised model. For each sentence pair, a noise score is computed based on the noisy and denoised models, which is used for instance sampling during training.

Table 4 shows the comparison results on the WMT14 En⇒De test set. All approaches improve translation performance individually except for data diversification with back-translation. Our approach can obtain further improvement on top of these manipulation approaches, indicating that data rejuvenation is complementary to them.

In addition, we computed the overlapping ratio between the noisiest and most inactive examples (10% of the training data) identified by data denoising and data rejuvenation approaches, respectively. We found that there are only 32% of examples that are shared by the two approaches, indicating that the inactive examples are not necessarily noisy examples. In order to better understand the characteristics of inactive examples, we will give more detailed analyses on linguistic properties of the inactive examples in Section 5.1.

5 Analysis and Discussion

In this section, we performed an extensive study to understand inactive examples and data rejuvenation in terms of linguistic properties (§5.1), learning stability (§5.2) and generalization capacity (§5.3). We also investigated the strategy to speed up the pipeline of data rejuvenation (§5.4). Unless otherwise stated, all experiments were conducted on the En⇒De dataset with Transformer-Base.

5.1 Linguistics Properties

In this section, we investigated the linguistic properties of the identified inactive examples. We explored the following 3 types of properties: frequency rank, coverage, and uncertainty. Frequency rank measures the rarity of words, which is calcu-

---

(a) Training Loss (b) Validation BLEU

Figure 7: Learning curves on the En⇒De dataset.

Model	**Margin**	**GSNR**
TRANSFORMER-BASE	0.68	5.2e-3
+ *Data Rejuvenation*	0.71	8.5e-3

Table 5: Results of generalization capability on the En⇒De dataset. Larger Margin/GSNR values denote better generalization capability.

lated for the target words since the proposed data rejuvenation method modifies the target side of the training examples. Coverage measures the ratio of source words being aligned by any target words. Uncertainty measures the level of multi-modality of a parallel corpus (Zhou et al., 2019). These properties reflect the difficulty of training examples to be learned by NMT models.

Figure 6 depicts the results. As seen, the linguistic properties consistently suggest that inactive examples are more difficult than those active ones. By rejuvenation, the inactive examples are transformed into much simpler patterns such that NMT models are able to learn from them.

5.2 Learning Stability

In this section, we studied how data rejuvenation improved translation performance from the perspective of the optimization process, as shown in Figure 7. Concerning the training loss (Figure 7(a)), our approach converges faster and presents much less fluctuation than the baseline model during the whole training process. Correspondingly, the BLEU score on the validation set is significantly boosted (Figure 7(b)). These results suggest that data rejuvenation is able to accelerate and stabilize the training process.

Method	**TRANS.-BIG**		**DYN.CONV**	
	BLEU	Time	BLEU	Time
Standard	29.6	32h	29.7	31h
Rejuvenate	30.3	+65h	30.2	+62h
Rej.–Big	30.2	+33h	30.4	+32h

Table 6: Results of speeding up (“Rej.–Big”) on the WMT14 En⇒De dataset. “Time” denotes the time of the whole process using 4 NVIDIA Tesla V100 GPUs.

5.3 Generalization Capability

In this section, we investigated how data rejuvenation affected the generalization capability of NMT models with two measures, namely, Margin (Bartlett et al., 2017) and Gradient Signal-to-Noise Ratio (GSNR, Liu et al., 2020a). Table 5 lists the results, in which the GSNR values are at the same order of magnitude as that reported by Liu et al. (2020a). As seen, our approach achieves noticeably larger Margin and GSNR values, demonstrating that data rejuvenation improves the generalization capability of NMT models.

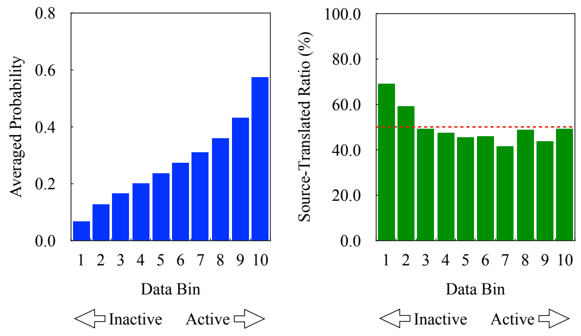
5.4 Speeding Up

The pipeline of data rejuvenation in Figure 1 is time-consuming: training the identification and rejuvenation models in sequence as well as the scoring and rejuvenating procedures make the time cost of data rejuvenation more than 3X that of the standard NMT system. To save the time cost, a promising strategy is to let the identification model take the responsibility of rejuvenation. Therefore, we used the TRANSFORMER-BIG model with the large batch configuration trained on the raw data to accomplish both identification and rejuvenation. The resulted data is used to train two final models, i.e., TRANSFORMER-BIG and DYNAMICCONV.

Figure 6 lists the results. With almost no decrease of translation performance, the time cost of data rejuvenation is reduced by about 33%. This makes the total time cost comparable with those data manipulation or augmentation techniques that require additional NMT systems, such as data diversification (Nguyen et al., 2019) and back-translation (Sennrich et al., 2016a). In addition, the superior performance of DYNAMICCONV (i.e., 30.4) further demonstrates the high agreement of inactive examples across architectures.

5.5 Analysis on Inactive Examples

Human Translations from Target to Source as Inactive Examples? Since forward translation



(a) Probability (b) Source-Translated Ratio

Figure 8: Probability and ratio of source-translated examples over the data bins of En⇒De test set.

performs better than back-translation for rejuvenation, one would wonder if the inactive examples correspond to human translations from target to source. For simplicity, we name such examples as source-translated whereas source-natural otherwise. The information of source-translated/natural examples is unavailable for training examples, but fortunately is provided for test sets[3]. We split the test examples of En⇒De into 10 data bins according to the sentence-level probability (see Eq. (2)) of the identification model (i.e., TRANSFORMER-BASE), and then calculate the ratio of source-translated examples in each bin. As seen in Figure 8, the ratios of source-translated examples in 1^{st} and 2^{nd} bins (i.e., 69% and 59%) significantly exceed that in the whole test set (i.e., 1500/3003), suggesting that human translations from target to source are more likely to be inactive examples.

Case Study. By inspecting the inactive examples, we find that the target sentences tend to be paraphrases of the source sentences rather than direct translations. We provide two cases in Table 7. In the first case, the target sentence does not translate "finished the destruction of the first" in the source sentence directly but rephrases it as "tat dann das seine und zerstörte den Rest", meaning "then did his and destroyed the rest" (that was not destroyed by The First World War). As for the second case, "denied by the latter" uses passive voice but its corresponding phrase in the target sentence is in active voice. These observations indicate that the inconsistent structure or expression between source and target sentences could make the examples difficult for NMT models to learn well.

	Side	Sentence
En⇒De	`X`	The Second World War finished the destruction of the first .
	`Y`	Der zweite Weltkrieg tat dann das seine und zerstörte den Rest . `=>En:` The Second World War then did his and destroyed the rest .
	`Y′`	Der Zweite Weltkrieg beendete die Zerstörung des ersten . `=>En:` The Second World War ended the destruction of the first .
En⇒Fr	`X`	Anything denied by the latter was effectively confirmed as true .
	`Y`	Tout ce que démentait cette agence se révélait dans la pratique bien réel . `=>En:` Everything that this agency denied turned out to be very real in practice .
	`Y′`	Toute chose niée par ce dernier a été effectivement confirmée comme vraie . `=>En:` Anything denied by the latter has actually been confirmed to be true .

Table 7: Inactive examples from the training sets of En⇒De and En⇒Fr. `X`, `Y` and `Y′` represent the source sentence, target sentence, and the rejuvenated target sentence, respectively. `Y` and `Y′` are also translated into English (`=>En:`) by Google Translate for reference. For either example, the underlined phrases correspond to the same content.

6 Conclusion

In this study, we propose data rejuvenation to exploit the inactive training examples for neural machine translation on large-scale datasets. The proposed data rejuvenation scheme is a general framework where one can freely define, for instance, the identification and rejuvenation models. Experimental results on different model architectures and language pairs demonstrate the effectiveness and universality of the data rejuvenation approach.

Future directions include exploring advanced identification and rejuvenation models that can better reflect the learning abilities of NMT models, as well as validating on other NLP tasks such as dialogue and summarization.

Acknowledgments

This work is partially supported by the National Key Research and Development Program of China (No. 2018AAA0100204) and the Research Grants Council of the Hong Kong Special Administrative Region, China (No. CUHK 14210717 of the General Research Fund). We sincerely thank Yongchang Hao for the help in implementing LSTM in the TRANSFORMER framework, Shuo Wang for the valuable advice on technical details, and the anonymous reviewers for their insightful suggestions on various aspects of this work.

A Appendix

A.1 Model Implementation

We adopt the default implementation of models in Fairseq[4] (Ott et al., 2019) except for LSTM.

LSTM. We follow Domhan (2018) to implement LSTM by replacing the self-attention (SAN) layers in TRANSFORMER-BASE with LSTM layers. Specifically, we use a bidirectional LSTM for each layer of the encoder, and a unidirectional LSTM for each layer of decoder. Each bidirectional LSTM layer is followed by a fully-connected layer with `ReLU` as the activation function.

Note that the training strategies of models with the proposed *data rejuvenation* are the same as that of the corresponding baseline models, without any modification of hyper-parameters.

A.2 Linguistics Properties

To understand the characteristics of inactive examples, we compare them with active examples and rejuvenated examples in terms of 3 linguistics properties: frequency rank, coverage, and uncertainty.

Frequency Rank. Frequency rank measures the rarity of words, which is calculated for the target words since our proposed data rejuvenation method modifies the target side of the training examples. In the target vocabulary, words are sorted in the descending order of their frequencies in the whole training data, and the frequency rank of a word is its position in the dictionary. Therefore, the higher the frequency rank is, the more rare the word is in the training data. We report the averaged frequency rank of each of the three subsets. The larger frequency rank of inactive examples indicates that they contain more rare words, which make them more difficult to be learned by NMT models than the active examples.

Coverage. Coverage measures the ratio of source words being aligned by any target words (Tu et al., 2016). Firstly, we train an alignment model on the training data by *fast-align*[5] (Dyer et al., 2013), and force-align the source and target sentences of each subset. Then, we calculate the coverage of each source sentence, and report the averaged coverage of each subset. The lower coverage of inactive examples indicates that they are not very well aligned as the active examples, which also make them more difficult for NMT models to learn.

Uncertainty. Uncertainty measures the level of multi-modality of a parallel corpus (Zhou et al., 2019). The uncertainty of a source sentence can reflect the number of its possible translations in the target side. We consider the corpus level uncertainty, which measures the complexity of each subset. Corpus level uncertainty is simplified as the sum of entropy of target words conditioned on the aligned source words denoted $H(y|x = x_t)$. Therefore, an alignment model is also required. To prevent uncertainty from being dominated by frequent words, we follow Zhou et al. (2019) to calculate uncertainty by averaging the entropy of target words conditioned on a source word denoted $\frac{1}{|\mathcal{V}_x|}\sum_{x\in\mathcal{V}_x} H(y|x)$. The larger uncertainty of inactive examples indicates that there are more possible translations for each source sentence of them. That is to say, inactive examples contain more complex patterns, which are more difficult to be learned by NMT models.

A.3 Generalization Capability

Margin. Margin (Bartlett et al., 2017) is a classic concept in support vector machine, measuring the geometric distance between the support vectors and the decision boundary. To apply margin for NMT models, we follow Li et al. (2019) to compute word-wise margin, which is defined as the probability of the correctly predicted word minus the maximum probability of other word types. We compute the word-wise margin over the training set and report the averaged value.

GSNR. The gradient signal to noise ratio (GSNR) metric (Liu et al., 2020a) is proposed

to positively correlate with generalization performance. The calculation of a parameter's GSNR is defined as the ratio between its gradient's squared mean and variance over the data distribution. For NMT models, we compute GSNR of each parameter and report the averaged value over all the parameters.

Compared with the baseline model trained on the raw data, the model trained with our *data rejuvenation* has larger Margin and GSNR, suggesting that *data rejuvenation* is able to improve the generalization capability of the final NMT models.

A.4 Validation Performance

In Table 8, we provide details of the main results, including the translation performance on both the validation and test sets. Generally, the models with our *data rejuvenation* outperform the baseline models on both validation and test sets.

A.5 More Ablation Studies

Reversed Models for Identification and Rejuvenation. Some researchers are curious whether the back-translation strategy will work if reversed NMT models are adopted for both identification and rejuvenation. To study this strategy, we trained a reversed translation model on the raw data as the identification model, and another reversed translation model on the identified active examples as the rejuvenation model. Finally, we trained a forward translation model on the rejuvenated training data. The final model marginally outperforms the baseline (27.7 v.s. 27.5) but significantly underperforms the forward translation method (27.7 v.s. 28.3).

Fine-tuning on Inactive Examples. We also tried a more straightforward strategy to re-use the inactive examples, i.e., to fine-tune the baseline NMT models on the inactive examples. We investigated this strategy on the En⇒De dataset with a pre-trained TRANSFORMER-BASE model. Experimental results show that the model diverges after fine-tuning on the inactive examples either individually or in combination with similar-sized active examples (the latter diverges slower), suggesting that fine-tuning on the inactive examples may not be a promising strategy.

A.6 Doubts on Main Results

Random Seeds. Some researchers may doubt if the improvement achieved by our approach comes from lucky random starts. To dispel this doubt, we conducted experiments on the En⇒De dataset using the TRANSFORMER-BASE model with three random seeds (i.e., 1, 12, and 123). Our approach consistently outperforms the baseline model in all cases (i.e., 27.5/28.3, 27.4/28.2, and 27.1/27.9), demonstrating the effectiveness of our approach.

Source Language. Some researchers may have questions about the language pairs used in the experiments that both language pairs have English as the source language, which could determine the rejuvenation strategy. To demonstrate the universality of our approach across language directions, we conducted an experiment on the WMT14 De-En translation task. The TRANSFORMER-BASE model achieved a BLEU score of 31.2, and the data rejuvenation approach improves performance by +0.6 BLEU point.

Pronoun-Targeted Fine-tuning for NMT with Hybrid Losses

Abstract

Popular Neural Machine Translation model training uses strategies like backtranslation to improve BLEU scores, requiring large amounts of additional data and training. We introduce a class of conditional generative-discriminative hybrid losses that we use to fine-tune a trained machine translation model. Through a combination of targeted fine-tuning objectives and intuitive re-use of the training data the model has failed to adequately learn from, we improve the model performance of both a sentence-level and a contextual model without using any additional data. We target the improvement of pronoun translations through our fine-tuning and evaluate our models on a pronoun benchmark testset. Our sentence-level model shows a 0.5 BLEU improvement on both the WMT14 and the IWSLT13 De-En testsets, while our contextual model achieves the best results, improving from 31.81 to 32 BLEU on WMT14 De-En testset, and from 32.10 to 33.13 on the IWSLT13 De-En testset, with corresponding improvements in pronoun translation. We further show the generalizability of our method by reproducing the improvements on two additional language pairs, Fr-En and Cs-En.[1]

1 Introduction

The advent of neural machine translation (NMT) (Bahdanau et al., 2015; Vaswani et al., 2017) brought about significant improvements that left the previously successful statistical machine translation models far behind. However, the availability of large corpora has been no small part of that success, with recent NMT models using millions of sentences for training. A lack of availability of such large parallel corpora across languages has given rise to methods utilizing large amounts of monolingual data, such as for backtranslation (Sennrich et al., 2016a), language modeling (Çaglar Gülçehre et al., 2017; Zheng et al., 2020), or for large-scale pre-training (Lewis et al., 2020).

Backtranslation (Sennrich et al., 2016a; Edunov et al., 2018) is a commonly used strategy to improve MT models in the absence of adequate parallel data for training. A target-to-source model is first trained using the available parallel data, which is then used to translate a large target-monolingual corpus into the source to create pseudo-parallel data for training a source-to-target MT model. This has been shown to result in improvements in the BLEU score, and has become a popular method for improving NMT models, with many recent works proposing strategies to further improve it (Hoa; Yang et al., 2019; Caswell et al., 2019). However, recent studies have suggested that there is a limit beyond which the addition of synthetic data hurts the performance of the model (Fadaee and Monz, 2018; Poncelas et al., 2018). Also, recent work (Edunov et al., 2020; Nguyen et al., 2020) point out that back-translation suffers from the *translationese effect*, where back-translation only improves the performance when the source sentences are translationese but does not offer any improvement when the sentences are natural text.

Automatic post-editing (APE) is another common strategy that is used to improve translations. APE models are commonly monolingual, and typically take the output from some MT model as input, which they then modify. In the absence of adequate human post-edited data to train data-hungry neural models, Voita et al. (2019) and Freitag et al. (2019) both use round-trip translation data to train their post-editing models. In round-trip translations, target monolingual data is translated using a target-to-source model to the source text, and then back to the target using another source-to-target

model. This round-trip translated text is considered an approximation of poor quality MT output, which can be used in combination with the original target reference text to train the post-editing model. Voita et al. (2019) train a model to make corrections in context, using groups of 4 sentences as input, and show improvements in BLEU as well as translations of discourse phenomena.

NMT models typically fail on rare words that may not be adequately seen during training, such as named entities, or on words whose interpretation depends on the context such as discourse phenomena (Koehn and Knowles, 2017; Sennrich, 2018). For the latter, NMT models tend to prefer a more typical alternative to a relatively rare but correct one (*e.g.,* French "*Il*" is often wrongly translated to the more common "*it*" than "*he*"). However, these seemingly trivial errors can erode translation to the extent that they can be easily distinguishable from human-translated texts (Läubli et al., 2018).

There could be several reasons for why NMT models make such mistakes; our hypothesis is that since almost all NMT models are trained with a conditional language model objective, it is clear that this objective alone is proving inadequate to capture all of the information available in the text. We therefore propose a class of conditional generative-discriminative hybrid losses that explicitly teach models what to generate and what not to generate. Using these specialized losses, we aim to improve the learning power of the MT model.

Specifically, in this work, we target the improvement of pronoun translation by focusing our fine-tuning efforts through our proposed objectives and also through the fine-tuning data. We aim to leverage the training data we already have by extracting a subset of targeted fine-tuning data from the training corpus that the model has failed to learn correctly from. We use the newly proposed training objectives in combination with the targeted data to help the model fully reach its learning potential on the training corpus. We attempt to improve both general translation quality and the pronoun translation without compromising on either, and to do this without any elaborate model architecture.

Our main contributions are as follows:

- A class of Conditional Generative-Discriminative Hybrid losses that improve the learning potential of the model (§2).
- Effective fine-tuning strategy that uses the training data itself to improve MT (§3).
- Improvements in BLEU over WMT14 and IWSLT13 De-En testsets, and in pronoun translations over a pronoun challenge testset (§4.5, §5.3).
- Demonstration of generalizability through additional fine-tuning experiments on Fr-En and Cs-En (§5.4).

2 Targeted Finetuning Objectives

Before introducing our proposed Conditional Generative-Discriminative hybrid losses for fine-tuning NMT models on a targeted dataset, we first describe the Conditional Language Modeling (CLM) objective used to train NMT models.

2.1 Conditional Language Modeling

NMT models are generally trained with the CLM generative loss that relies on an auto-regressive factorization to perform density estimation and generation of target texts. For a source-target sentence pair (x, y), a CLM predicts a conditional probability distribution $P_\theta(y_{1:n}|x)$, where n is the number of tokens in the target text. The auto-regressive factorization for a CLM is given by

$$P_\theta(y_{1:n}|x) = \prod_{t=1}^{n} P_\theta(y_t|y_{<t}, \boldsymbol{c}) \tag{1}$$

where $\boldsymbol{c}$ is a context vector that summarizes the relevant input (*e.g.,* attended vector over source text and the current decoder state). The CLM training objective for NMT can be written as:

$$\mathcal{L}_g = -\frac{1}{n}\sum_{t=1}^{n} \log P_\theta(y_t|y_{<t}, \boldsymbol{c}) \tag{2}$$

Generating from CLM trained NMT models requires iteratively sampling from $P_\theta(y_t|y_{<t}, \boldsymbol{c})$, and then feeding y_t back into the model as input.

2.2 Generative-Discriminative Hybrid Loss

While CLM has been the de-facto loss to train NMT models, models trained with CLM make mistakes that can erode translation quality, making them easily distinguishable from human translation. For example, state-of-the-art NMT models are not very good at handling rare words like named entities. They have also been criticized for not being sensitive to discourse-level aspects such as pronouns, lexical consistency, and discourse connectives (Sennrich, 2018; Jwalapuram et al., 2020).

We introduce a generative-discriminative hybrid method for fine-tuning NMT models, with the motivation of generating tokens that are more strongly in one class vs. another. We consider that the reference tokens come from a positive class, whereas the model generated tokens come from a negative class. We propose two variants of our hybrid training – (*i*) log-likelihood and (*ii*) max-margin.

Log-likelihood training. Let $z \in \{0,1\}$ represent the class for a training instance (x, y). We can consider a generative classifier as follows.

$$P_\theta(z=k|x,y) = \frac{P(z=k)P_\theta(y|x,z=k)}{\sum_{k'=0}^{1} P(z=k')P_\theta(y|x,z=k')} \quad (3)$$

Assuming an equal prior class probability, *i.e.,* $P(z = 1) = P(z = 0)$ and by replacing $P_\theta(y|x, z = k)$ with Equation (1), we can write:

$$P_\theta(z=k|x,y) = \frac{\prod_{t=1}^{n} P_\theta(y_t|y_{<t}, \boldsymbol{c}, k)}{\sum_{k'} \prod_{t=1}^{n} P_\theta(y_t|y_{<t}, \boldsymbol{c}, k')} \quad (4)$$

Since our objective is to maximize the probability of the reference tokens, we minimize the following negative log-likelihood loss:

$$\mathcal{L}_{nll} = -\log P_\theta(z=1|x,y) \quad (5)$$

If y^+ is the reference (positive) translation and y^- is the model (negative) output, it is easy to show that the above loss is equivalent to

$$\mathcal{L}_{nll} = -\frac{1}{n}\sum_{t=1}^{n} \log \frac{\exp(\hat{y}_t^+/\tau)}{\left(\exp(\hat{y}_t^+/\tau) + \exp(\hat{y}_t^-/\tau)\right)} \quad (6)$$

where τ is the temperature parameter of the softmax,[2] and $\hat{y}_t^+$ and $\hat{y}_t^-$ are the final-layer logits (pre-softmax activations) corresponding to the reference token y_t^+ and model generated token y_t^-, respectively. The logit for the model generated token is computed by just taking the max over all the logits. We use $\tau = 0.5$ for our experiments.

Max-margin training. Following Collobert et al. (2011), we also propose a pairwise ranking loss that maximizes the distance between positive and negative samples. Formally,

$$\mathcal{L}_{mm} = \frac{1}{n}\sum_{t=1}^{n} \max\{0, \mu - \hat{y}_t^+ + \hat{y}_t^-\} \quad (7)$$

where μ is the margin; we use $\mu = 0.3$.

Note that the additional losses can be applied to all the tokens in the sequence, or restricted to some tokens. We demonstrate this in our experiments by applying the loss on all tokens and selectively applying the loss only on pronouns. Both of the discriminative losses essentially promote the probability of the positive (*i.e.,* correct) sample. However, the intuition behind using the additional loss over the standard loss is that the fine-tuning here focuses on improving the positive sample over the negative sample that the model has learnt to produce, rather than over the entire probability distribution over the full vocabulary.

We average these losses at both the sentence and the batch-level to add it to the existing CLM loss. The overall loss for training is

$$\mathcal{L}_{gd} = \lambda\mathcal{L}_g + (1-\lambda)\mathcal{L}_d \quad (8)$$

where λ is a weighting hyperparameter, and the discriminative loss $\mathcal{L}_d$ is either $\mathcal{L}_{mm}$ (Eq. 7) or $\mathcal{L}_{nll}$ (Eq. 6). In our training, the discriminative loss $\mathcal{L}_d$ is aimed at correcting the mistakes, whereas the generative loss $\mathcal{L}_g$ is needed to preserve the translation adequacy and fluency. In our experiments, we simply set $\lambda = 0.5$.

3 Fine-tuning Data & MT Baselines

3.1 Pronoun-Targeted Fine-tuning Data

We create a subset of the training corpus in order to find training data that has not been fully learnt from; particularly, we focus our fine-tuning experiments on pronoun translation. Pronouns are an important discourse phenomenon that provide references to entities that have previously occurred in a text. Mistranslations can lead to loss of grammaticality or inference of the wrong antecedent, resulting in a misunderstanding of the text (Guillou, 2012).

Consider a parallel corpus $\mathcal{D} = (\mathcal{S}, \mathcal{R})$, where $\mathcal{S}$ is the source and $\mathcal{R}$ is the target/reference text. Assuming that the baseline NMT models (§3.2) are trained until convergence using this data, for our targeted fine-tuning of pronoun translations, we derive a subset of the training corpus $\mathcal{D}$ as follows:

1. Translate $\mathcal{D}$ using a baseline model $\mathcal{M}$ to obtain source to target translations $\mathcal{T}_\mathcal{M}$.
2. Align $\mathcal{T}_\mathcal{M}$ with reference $\mathcal{R}$ using *efmaral* (Östling and Tiedemann, 2016).
3. Find pronoun translations in $\mathcal{T}_\mathcal{M}$ that do not match reference $\mathcal{R}$. To exclude equivalent but non-identical translations, we use the list provided by Jwalapuram et al. (2019)[3].

---

[2] For the sake of simplicity, we omit τ in Eq. 3 - 4

[3] https://github.com/ntunlp/eval-anaphora

4. For each sentence with a mistranslated pronoun, extract the source sentences from $\mathcal{S}$.

5. The corresponding source and reference sentences form the pronoun-targeted fine-tuning subset, referred to as $\mathcal{D}_{\text{prn}} = (\mathcal{S}', \mathcal{T}')$.

3.2 Baseline MT Models

Typically, MT models are trained at the sentence level, taking one sentence as input and producing one sentence as output. Most MT systems at the sentence-level do not have access to adequate context that may be required for the translation of pronouns (Sennrich, 2018). Since it is our aim to improve pronoun translation, we train both a sentence-level model and a simple concatenation-based contextual model as our baselines:

SEN2SEN: A standard 6-layer base Transformer model (Vaswani et al., 2017) trained to translate each sentence independently.

CONCAT: A standard 6-layer base Transformer trained to translate a sentence given one previous sentence as context (Tiedemann and Scherrer, 2017). The input to the model is the previous sentence and the current sentence combined with a special separator character. Jwalapuram et al. (2020) show that this simple context model performs comparably or better than other elaborate contextual models like Voita et al. (2018), Zhang et al. (2018), and Miculicich et al. (2018).

Both the baseline models are trained for 100,000 steps. Other parameter details are in the Appendix.

4 Experiments

We conduct our fine-tuning experiments on the German-English (De-En) translation task. We describe our baseline training and fine-tuning corpus (§4.1), our experiments and results on fine-tuning using only the targeted subset data (§4.4), and fine-tuning using both the targeted subset data and the hybrid training losses (§4.5).

4.1 MT Training Data

Baseline training corpus. We use a De-En training dataset consisting of about 2.5 million sentence pairs, taken from the News Commentary, IWSLT (Cettolo et al., 2012) and Europarl (Tiedemann, 2012) corpora.[4] Sentences are encoded through Byte-Pair Encoding (BPE) (Sennrich et al., 2016b) with 40,000 operations, which results in a shared vocabulary of 40,224 tokens. We will refer to our baseline dataset as $\mathcal{D}$.

		WMT14	Pronoun Testset			
Model	**Train**	**BLEU**	**BLEU**	**P**	**R**	**F1**
SEN2SEN	$\mathcal{D}$	31.64	35.56	77.92	66.01	69.55
CONCAT	$\mathcal{D}$	**31.81**	**36.16**	**80.39**	**68.49**	**72.03**

Table 1: Baseline BLEU results on the WMT14 De-En testset and the BLEU (for translation), **P**recision, **R**ecall and **F1** scores (for pronoun translations) on the pronoun testset from Jwalapuram et al. (2019).

Pronoun targeted fine-tuning data. As described in §3.1, we derive the pronoun-targeted fine-tuning subset $\mathcal{D}_{\text{prn}}$ from the baseline training corpus $\mathcal{D}$ based on the translation errors of the baseline models. This results in a pronoun-targeted subset of 294,535 pairs for the SEN2SEN model and 285,783 pairs for the CONCAT model.

Random subset. We randomly extract a subset of 300,000 sentence pairs from $\mathcal{D}$, which approximately matches the size of the pronoun-targeted subset. We will refer to this dataset as $\mathcal{D}_{\text{rand}}$.

4.2 Pronoun Translation Evaluation

Testset. We run the models on the pronoun challenge testset provided by Jwalapuram et al. (2019), which is extracted from WMT testsets based on submission errors. For De-En, the testset has 2245 sentences, taken from WMT17-WMT19.

Evaluation. We report the macro-averaged F1 scores of the pronoun translation based on a simplified version of AutoPRF (Hardmeier and Federico, 2010). For each sentence in the testset, the counts of the pronouns in the system translation are clipped based on the pronouns in the reference translation; these counts are then used to compute the precision, recall and F1 scores.

4.3 Baseline Results

We first report the BLEU scores on the WMT14 De-En testset, and the BLEU, precision, recall, and F1 scores on the pronoun testset from Jwalapuram et al. (2019) in Table 1. The SEN2SEN model results in a BLEU of **31.64**, while the CONCAT model results in a slightly higher performance at **31.81** BLEU. More importantly, there is an improvement in the pronoun translations, with the F1 increasing from 69.55 for the SEN2SEN model to 72.03

---

[4] We exclude the UN corpus as our analysis showed that it does not have a high incidence of pronouns.

for the CONCAT model. To confirm that the context provides useful information rather than acting simply as a regularizer, we also run an experiment with the CONCAT model using a random sentence as context instead of the previous sentence. This model achieves a BLEU of 31.65 and a pronoun F1 of 69.65 - both lower than the baseline, confirming that the extended context from the previous sentence does provide helpful information.

4.4 Fine-tuning on Pronoun-Targeted Data

For the first set of fine-tuning experiments, we only fine-tune on the pronoun targeted subset $\mathcal{D}_{\text{prn}}$ for the SEN2SEN model. This helps us assess the training schedule so that we can achieve a balance between preserving the information from the full data and gaining targeted information from the subset.

Setup. Given a trained baseline model, we train additional epochs on the targeted subset $\mathcal{D}_{\text{prn}}$. Apart from training only on the subset data, we also try training on a shuffled dataset consisting of the training + targeted subset data (which essentially doubles the error-prone subset compared to the baseline training data), alternating the training between the subset and the full data ($\mathcal{D} + \mathcal{D}_{\text{prn}}$), and the subset and full data upsampled by 2 (*i.e.,* $2\mathcal{D} + \mathcal{D}_{\text{prn}}$).

To ensure that the results we see are from the fine-tuning and not simply from increased training, we train the original baseline model on the full data $\mathcal{D}$ for additional epochs, equivalent to the number of fine-tuning epochs.

Results. We see from the results in Table 2 that although the pronoun F1 improves, the BLEU scores drop when the model is fine-tuned only with the subset data $\mathcal{D}_{\text{prn}}$. Shuffling a mix of the full training data with the subset data leads to a smaller drop in BLEU and a gain in pronoun F1. However, alternating the training on the full corpus and the subset ($\mathcal{D} + \mathcal{D}_{\text{prn}}$) stabilizes the BLEU score, and upsampling the primary dataset ($2\mathcal{D} + \mathcal{D}_{\text{prn}}$) results in a smaller drop in BLEU, while gaining more significantly in pronoun F1 over the baseline. A similar trend is also observed for the CONCAT model. Further upsampling does not lead to a significant improvement in results, so all subsequent experiments upsample the primary dataset by 2.

Increased training of the baseline also results in a drop in BLEU scores. However, the pronoun F1 is also lower, which is not the case for the fine-tuning results, indicating that fine-tuning rather than increased training is the source of the improvements.

Fine-tuning	**WMT14**	**Pronoun Testset**			
data for SEN2SEN	**BLEU**	**BLEU**	**P**	**R**	**F1**
$\mathcal{D}$ (baseline)	31.64	35.56	77.92	66.01	69.55

$2\mathcal{D} + \mathcal{D}_{\text{prn}}$	31.31	36.12	81.20	69.35	72.84

Table 2: Subset data: fine-tuning results on the WMT14 De-En with precision, recall and F1 scores on the pronoun testset. $\mathcal{D}$ represents the full training corpus; $2\mathcal{D}$ is the full training corpus upsampled by 2, while $\mathcal{D}_{\text{prn}}$ represents the pronoun targeted subset.

4.5 Effect of Additional Losses

We conduct experiments using both targeted data and proposed hybrid losses.

Setup. In accordance with our settings to alternate training between the upsampled full dataset and the subset data ($2\mathcal{D} + \mathcal{D}_{\text{prn}}$), we also alternate the additional loss such that it is only applied to the targeted subset. That is, in every alternate epoch, the model is trained on the upsampled full dataset ($2\mathcal{D}$) with the standard CLM translation loss $\mathcal{L}_g$ (Eq. 2), and then trained on the targeted subset $\mathcal{D}_{\text{prn}}$ with the proposed hybrid loss $\mathcal{L}_{gd}$ (Eq. 8).

Each fine-tuning model is trained for 9 additional epochs, such that the first and the last epoch use the targeted subset data and loss. This is effectively about 4 cycles of fine-tuning on ($2\mathcal{D}+\mathcal{D}_{\text{prn}}$); further training does not lead to improved loss.

Apart from applying the additional loss on all tokens in the subset data, we also experiment with applying the additional loss only on the pronoun tokens, *i.e.,* the loss is only applied to those tokens which have a pronoun as the target translation.

To further assess the contribution of the targeted subset data, we conduct experiments by replacing it with a random subset $\mathcal{D}_{\text{rand}}$. We also conduct fine-tuning experiments by applying the additional loss on the full training dataset $\mathcal{D}$ while training the baseline model for additional epochs.

Max-margin loss results. Results for fine-tuning with the max-margin loss are shown in Table 7a. We see that there is an improvement in BLEU from 31.64 to **32.14**. From the difference in improvement of the results from fine-tuning over

(b) Fine-tuning results using **log-likehihood** loss

Table 3: Targeted fine-tuning loss: fine-tuning results on the WMT14 De-En testset with F1 scores on the pronoun testset. Fine-tuning results on $2\mathcal{D} + \mathcal{D}_{\text{prn}}$ refer to alternated training with pronoun-targeted fine-tuning data and the upsampled full training data. Fine-tuning on $2\mathcal{D} + \mathcal{D}_{\text{rand}}$ is the same setting with the targeted data replaced with a random subset. Fine-tuning on $\mathcal{D}$ refers to additional training with the hybrid losses applied on the full dataset. * indicates statistically significant difference from the baseline ($p \leq 0.05$ for F1; $>80\%$ confidence for BLEU).

$\mathcal{D}_{\text{rand}}$ and $\mathcal{D}$, it is apparent that this increase is a consequence of both the targeted data and the targeted loss. There is also a corresponding increase in pronoun F1 from 69.55 to 69.77.

More importantly, we see that the Concat model drops slightly in BLEU to 31.75 with respect to the baseline, but the pronoun translation F1 improves from 72.03 to **72.88**. When the loss is applied only on pronouns, the Sen2Sen model has a smaller BLEU increase to 31.81, but a larger pronoun F1 increase to 70.37. The Concat model benefits the most from having both pronoun-targeted fine-tuning data and loss; both the BLEU score and the pronoun F1 improve.

Log-likelihood loss results. Results for fine-tuning with the log-likelihood loss are shown in Table 7b. The overall increase in BLEU with the log-likelihood loss is lower for Sen2Sen compared to the max-margin loss, but the improvements in pronoun F1 are higher. With respect to the results on fine-tuning over $\mathcal{D}_{\text{rand}}$ and $\mathcal{D}$, improvement in BLEU score here does not result in a corresponding improvement in pronoun translation, further confirming the contribution of the targeted data. Once again, the Concat model outperforms the rest by gaining in both BLEU and pronoun F1.

Both losses perform comparably - while the Sen2Sen model achieves a higher increase in BLEU with the max-margin loss, gains in pronoun translation are higher with the log-likelihood loss. For the Concat model, both losses provide similar BLEU improvements, but the max-margin loss leads to higher gains in pronoun F1.

5 Additional Experiments and Analysis

5.1 Qualitative Analysis of Results

We performed a qualitative analysis to see the effect of our fine-tuning. Some examples of improvements in translation resulting from our fine-tuning are shown in Table 4 (see Appendix for more).

The results of the targeted fine-tuning show that both the targeted data and the additional loss play a role in improving the translations. Another important conclusion that can be drawn is that there is no correlation between the BLEU score and the pronoun translation quality; in this case we have shown that it is possible to target the improvement of pronoun translations.

However, for the Sen2Sen model in particular, we see that there are improvements in BLEU that do not correspondingly improve pronoun translations, which can be surprising given that the fine-tuning data is targeted towards pronouns. It can be surmised from the improvements in the Concat model that the Sen2Sen model fails to improve in pronoun translation because it simply lacks the additional information that the context provides, which can be important for translating discourse phenomena like pronouns (Sennrich, 2018). See Table 4 for examples from the pronoun testset.

Another anomaly is that in some cases, the pronoun translation results are better when the loss is applied to all tokens rather than only to pronouns. A similar phenomenon may be the cause here - improved translation of the rest of the sentence may result in better contextual information, that in turn leads to better pronoun translations. This under-

Description	**Examples**
	WMT14 Testset
Source	14 stunden kämpften die ärzte um das überleben des opfers , jedoch vergeblich .
Reference	for 14 hours, doctors battled to save the life of the victim , ultimately in vain .
Baseline	14 hours of doctors fought for the victim's survival , but in vain .
Our best model	the doctors fought 14 hours for the survival of the victim , but in vain .
Source	der handel am nasdaq options market wurde am freitagnachmittag deutscher zeit unterbrochen .
Reference	trading at the nasdaq options market was interrupted on friday afternoon , german time .
Baseline	trade at nasdaq options market was cut off on the german friday afternoon .
Our best model	trade in nasdaq options market was suspended on friday afternoon in germany .
	Pronoun Testset
Context	... die die amerikanische flamme in die umnachtete welt bringe : lady liberty geht voran .
Source	sie soll die fackel der freiheit von den vereinigten staaten in den rest der welt tragen .
Context	... taking the american flame out to the benighted world : **lady liberty** is stepping forward .
Reference	she is meant to be carrying the torch of liberty from the united states to the rest of the world .
Baseline	it is meant to carry the torch of freedom from the united states to the rest of the world .
Our best model	she is supposed to carry the torch of freedom from the united states to the rest of the world .
Context	versteinerte reste der haut bedecken noch immer die holprigen panzerplatten , die den schädel des tieres tragen .
Source	sein rechter vorderfuß liegt an seiner seite , seine fünf finger sind nach oben gespreizt .
Context	fossilized remnants of skin still cover the bumpy armor plates dotting the **animal's** skull .

Backtranslation*	**32.57**	**38.54**	80.61	67.14	71.37
Best fine-tuned Sen2Sen	32.14	36.16	78.83	66.15	69.77
Best fine-tuned Concat	32.00	36.57	**80.89**	**68.66**	**72.39**

Table 5: Comparison with backtranslation and the DocRepair post-editing model. * indicates models use extra monolingual data. BLEU scores reported on the WMT14 De-En testset, with **P**recision/**R**ecall/**F1** on the pronoun testset. For DocRepair, the input is the output from our baseline Sen2Sen De-En model.

scores the importance of using context rather than trying to improve pronoun translations in isolation.

The general improvements in BLEU result from the fact that the targeted data is a subset that the model has failed to learn adequately from. Thus, our method of obtaining targeted data seemingly results in a subset that is generally poorly translated by the original baseline model, so training on this data results in an improved BLEU score. This also explains the disparity in results with the fine-tuning on the random ($\mathcal{D}_{\text{rand}}$) and the full ($\mathcal{D}$) datasets.

5.2 Comparison with Related Work

Backtranslation. We train a target-source En-De model with the same training data ($\mathcal{D}$, consisting of 2.5M pairs of parallel data) and settings as the baseline Sen2Sen model. This achieves a BLEU score of **27.4** on the WMT14 En-De testset. We use this model to translate about 76M sentences of NewsCrawl, a monolingual English corpus, to German. Using this pseudo-parallel corpus in addition to the original training corpus (≈ 78M pairs), we train a Sen2Sen source-target De-En backtranslation model. This model is trained for 500K steps. The results are shown in Table 5. Although backtranslation achieves highest BLEU score at 32.57, our fine-tuned Concat model achieves the highest F1 for pronoun translation at 72.39, without having been trained on any extra monolingual data. This is further proof that it may be insufficient to simply improve the BLEU scores at a sentence-level. Performing fine-tuning on a Concat backtranslation model may be interesting to consider; we leave this for future work.[5]

Automatic post-editing. We train a contextual, monolingual automatic post-editing model proposed by Voita et al. (2019) for English. To capture MT errors, the model is trained with round-trip-translated texts as inputs with reference texts as the intended outputs. We use default settings and similar data sizes as proposed in their paper. We use 2.5M sentences from parallel data $\mathcal{D}$ and monolingual English sentences from NewsCrawl to make up ≈ 30M sentences. Using the En-De model described above and our baseline De-En model, we translate this data to German and then back to English to obtain round-trip translations. We use this

---

[5] A caveat here is that this would require training alternately on a targeted subset and an upsampled backtranslation dataset according to our training schedule. Considering the size of the backtranslation dataset, it would require massive amounts of additional training.

data to train their model[6] for around 750K steps as recommended by the authors.

We use the outputs of our baseline SEN2SEN De-En model on the WMT14 testset and the pronoun challenge testset as input to the model.[7] The results are shown in Table 5. We see that automatic post-editing does not lead to an improvement in BLEU[8] or pronoun translation in this case.

Our analysis of round-trip-translations suggests that this is possibly because they do not contain enough errors. Experiments conducted on the WMT14 En-De testset show that if it is translated using our En-De model (BLEU:27.40) to German and then translated using our De-En model (BLEU:31.64) back to English, the resulting text has a BLEU of 44.44, which is significantly higher. It is a well-known phenomenon that MT models perform substantially better on *translationese* (Graham et al., 2019), which refers to text that is unnatural by virtue of being translated. This means that it is not very likely to resemble typical MT output or capture the same errors (Poncelas et al., 2018); twice-translated texts therefore contain considerably fewer errors that can be learnt from.

5.3 Results on the IWSLT13 Testset

We evaluate our fine-tuned models on the IWSLT13 De-En testset (Table 6). We also evaluate the pronoun translation for this testset. The backtranslation model fails to generalize, and performs worse than the baseline. It can be seen that our fine-tuned models improve over the baseline performance on this testset as well; the best SEN2SEN model improves from 31.64 to 32.16, while the best CONCAT model improves from 32.10 to 33.13, with corresponding improvements in pronoun F1. CONCAT continues to be the best performing model, showing significant improvements for both fine-tuning losses.

	SEN2SEN		CONCAT	
Model	**BLEU**	**Prn. F1**	**BLEU**	**Prn. F1**
Baseline	31.64	60.47	32.10	62.01

Table 6: BLEU score and **Pron**oun translation **F1** results of the baselines and the fine-tuned models on the IWSLT13 De-En testset.

5.4 Generalizability to Other Languages

Finally, we test the generalizability of our fine-tuning method by running experiments for French-English and Czech-English. We use the same training dataset sources as for German-English (*i.e.,* News Commentary, IWSLT (Cettolo et al., 2012) and Europarl (Tiedemann, 2012)). This results in 2.53M sentences of training data and 500K sentences of fine-tuning data for Fr-En, and 992K sentences of training data and 100K sentences of fine-tuning data for Cs-En. We report the baseline BLEU results on the WMT14 testsets and the pronoun translation results on the corresponding testsets from Jwalapuram et al. (2019) containing 1478 (Fr-En) and 1686 (Cs-En) sentences. We see from Table 7 that our fine-tuning approach shows similar trends in improving BLEU and pronoun translation results for both Fr-En and Cs-En.

5.5 Discussion

Our objective is to propose a novel fine-tuning method that leverages “unlearned” data using additional loss. To this end, we proposed two different losses. We do not mean to advocate for any particular loss; in our experiments we happened to get comparable results, which may not conclusively point to one loss as being better. A different loss may perform better in other tasks.

Although we focused on pronoun translations, our fine-tuning method is generic and can be used to correct other kinds of errors in machine translations, like named entities or other rare words. Our proposed losses can be adapted to other directed generation tasks; *e.g.,* to improve coherence/factual correctness in abstractive summarization, or for controlled text generation. Our fine-tuning approach also opens up new ways to address training issues that originate from datasets; *e.g.,* it could potentially be used to correct biases (such as gender) or used to improve system robustness.

---

[6] Taken from https://github.com/lena-voita/good-translation-wrong-in-context.

[7] For the pronoun testset, we were only able to provide groups of 3 sentences as input instead of 4 which the original model uses, since the testset only provides two previous sentences as context. We add dummy text as the first sentence to make it a 4-sentence group input.

[8] Note that we calculate the BLEU scores for each sentence separately as is standard, unlike in groups of 4 as the original paper. This is to more accurately compare against the results from the rest of our experiments.

6 Related Work

Our idea of conditional generative-discriminative training is related to the idea of discriminative training of generative models. Previously, this idea was proposed for Markov models. Collins (2002) trained a Hidden Markov Model (HMM) discriminatively for sequence tagging with structured perceptron algorithm. Yakhnenko et al. (2005) used a similar idea for sequence classification. In deep learning, the well-known generative adversarial networks (GANs) (Goodfellow et al., 2014) are an example where a generator is trained with the help of a discriminator. To the best of our knowledge, ours is the first work to explore this idea with conditional language models for guiding the model on what to generate and what not to generate.

A few fine-tuning methods are related to our work. Abdulmumin et al. (2019) pre-train an MT model on synthetic backtranslated data and fine-tune it on authentic parallel data, and show that it can improve 0.7 BLEU over backtranslation on English-Vietnamese. Fadaee and Monz (2018) use various sampling strategies to improve the results of backtranslation by targeting difficult-to-predict words based on prediction loss. Our strategy is similar in that we also try to target words that the model has trouble with, but we do not use additional data.

A number of methods have been proposed for adapting a trained MT model to another domain by fine-tuning. A common strategy is to simply perform additional training on the new domain dataset (Luong and Manning, 2015) or use a mix of in-domain and out-domain data for fine-tuning without loss of generalization (Chu et al., 2017) or upweight out-of-domain data (Wang et al., 2017).

There has been some work on targeted improvement of translations, specifically for named-entities. Ugawa et al. (2018) adapt MT network architecture to encode named entity features and tags while Li et al. (2018) perform domain adaptation in addition to feature encoding. With respect to discourse phenomena, Stojanovski and Fraser (2019) propose a curriculum learning based approach, where a context-aware model is trained on randomly sampled oracle data containing gold-standard pronouns. In our work, we focus on the baseline model's failings and try to increase its learning capacity by proposing additional losses.

Most recent work on improving pronoun translations has involved building more complex architectures that incorporate contextual information (Voita et al., 2018; Wong et al., 2020). In contrast, we present a more generalized approach.

7 Conclusions and Future Work

We have proposed a class of conditional generative-discriminative losses to increase the learning potential of NMT models, showing that it is possible to leverage "unlearned" training data to further improve an MT model, by strategically filtering the data and applying additional targeted losses.

We demonstrated the effectiveness of our methods on different languages and testsets, also reporting improved pronoun translations. Although we focus on pronoun translations, our fine-tuning method is generic and can be used to correct other kinds of errors in machine translations, like named entities or other rare words. In future work, we will explore other such applications of our proposed methods.

Learning Adaptive Segmentation Policy for Simultaneous Translation

Abstract

Balancing accuracy and latency is a great challenge for simultaneous translation. To achieve high accuracy, the model usually needs to wait for more streaming text before translation, which results in increased latency. However, keeping low latency would probably hurt accuracy. Therefore, it is essential to segment the ASR output into appropriate units for translation. Inspired by human interpreters, we propose a novel adaptive segmentation policy for simultaneous translation. The policy learns to segment the source text by considering possible translations produced by the translation model, maintaining consistency between the segmentation and translation. Experimental results on Chinese-English and German-English translation show that our method achieves a better accuracy-latency trade-off over recently proposed state-of-the-art methods.

1 Introduction

In recent years, simultaneous translation has attracted increasing interest both in research and industry community. It aims at a real-time translation that demands high translation quality and an as-short-as-possible delay between speech and translation output.

A typical simultaneous translation system consists of an auto-speech-recognition (ASR) system that transcribes the source speech into source streaming text, and a machine translation (MT) system that performs the translation from the source into the target text. However, there is a gap between the output of ASR and the input of MT. The MT system takes sentences as input, while the streaming ASR output has no segmentation boundaries. Therefore, exploring a *policy* to split ASR output into appropriate segments becomes a vital issue for simultaneous translation. If translation starts before adequate source content is delivered, the translation quality degrades. However, waiting for too much source text increases latency.

The *policies* of recent work generally falls into two classes:

- **Fixed Policies** are hard policies that follow a pre-defined schedule independent of the context. They segment the source text based on a fixed length (Ma et al., 2019; Dalvi et al., 2018). For example, the wait-k method (Ma et al., 2019) first reads k source words, and then generates one target word immediately after each subsequent word is received. Policies of this type are simple and easy to implement. However, they do not consider contextual information and usually result in a drop in translation accuracy.

- **Adaptive Policies** learn to do segmentation according to dynamic contextual information. They either use a specific model to chunk the streaming source text (Sridhar et al., 2013; Oda et al., 2014; Cho and Esipova, 2016; Gu et al., 2017; Zheng et al., 2019a, 2020) or jointly learn segmentation and translation in an end-to-end framework (Arivazhagan et al., 2019; Zheng et al., 2019b; Ma et al., 2020). The adaptive methods are more flexible than the fixed ones and achieve state-of-the-art.

In this paper, we propose a novel adaptive segmentation policy for simultaneous translation. Our method is motivated by two widely used strategies in simultaneous interpretation:

- Meaningful Unit (MU) Chunking. While listening to speakers, interpreters usually preemptively group the streaming words into units with clear and definite meaning, referred to as meaningful units that can be directly translated without waiting for more words.

Source with MU:	上午	10	点	||	我	去了	趟	||	公园
Simul. Interpretation:			At 10 a.m.	||			I went to	||	the park.

Table 1: A comparison of Chinese-English text translation and simultaneous interpretation. A text translator translates the full sentence after reading all the source words and produces a translation with a long-distance reordering by moving the initial part (as underlined) of the source sentence to the end of the target side. But when doing simultaneous interpreting, an interpreter starts to translate as soon as he or she judges that the current received streaming text constitutes an MU ("||") and translate them monotonically.

- Interpreters are often obliged to keep close to the source speech and render the translation of MUs in order, i.e., perform translation monotonically while making the translation grammatically tolerable.

See Table 1 for illustration. Unlike text translator, a simultaneous interpreter dynamically segments the source text into 3 MUs and translates them monotonically.

In our approach, we model the *policy* as an MU segmentation model, which dynamically splits the streaming text into meaning units. Once a meaning unit is detected [1], it is fed to the MT model to generate translation. The MU segmentation is implemented by a classification model under the pre-training & fine-tuning framework (Devlin et al., 2018; Sun et al., 2019). As there are no standard training corpora to train the MU segmentation classifier, we propose a novel translation-prefix based method to generate training data. Basically, the method detects whether the translation of a sequence of words is a prefix of the full sentence's translation. If so, the sequence is considered as an MU. This makes the segmentation model consistent with the translation model. We further propose a refined method to extract fine-grained MUs to reduce latency.

Experimental results on NIST Chinese-English and WMT 2015 German-English datasets show that our method outperforms the previous state-of-the-art methods in balancing translation accuracy and latency. The contributions of this paper can be summarized as follows:

- Inspired by human interpreters, we propose a novel adaptive segmentation policy that splits the ASR output into meaning units for simultaneous translation. The meaning units ensure the MT model to produce high-quality translation with low latency.
- We propose a novel prefix-attention method to extract fine-grained MUs by training a neural machine translation (NMT) model that generates monotonic translations.
- Our method is simple yet effective. It can be easily integrated into a practical simultaneous translation system.

2 Adaptive Segmentation Policy

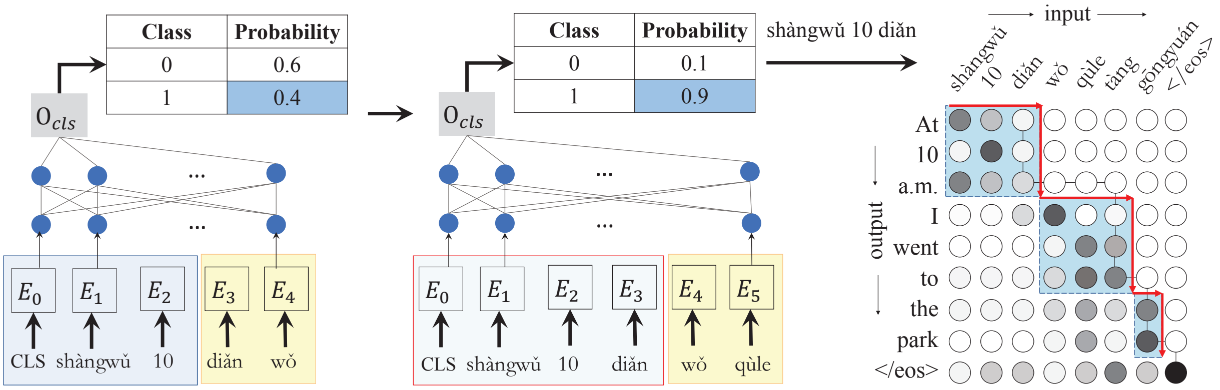
Our idea is inspired by human interpreters who start translating as soon as they recognize an MU. In this paper, we aim to split the streaming text into MUs to get a trade-off between translation quality and latency. See Figure 1 for illustration. We model the MU segmentation as a classification problem and train a classifier, which receives a streaming text from ASR output and detects whether it constitutes an MU (Figure 1 (a) and (b)). Once an MU is detected, it is sent to the MT model to produce translation (Figure 1 (c)). Meanwhile, the MU segmentation model keeps receiving source words.

To build an MU segmentation model, there are three key issues:

1. What is an MU? Though it is a widely adopted concept in simultaneous interpretation, it has no precise definition. We will discuss it in Section 2.1.
2. How to construct a training corpus for the MU segmentation model? We propose two methods to extract MUs from the training corpus automatically. In the basic method, we propose a generation framework (Section 2.2). To further generate fine-grained MU, we then propose a refined method (Section 2.3).

---

[1] In this paper, we use segmentation and detection interchangeably.



(a). Detect whether "shàngwǔ 10" is an MU (b). Detect whether "shàngwǔ 10 diǎn" is an MU (c). Monotonic translation

Figure 1: Illustration of our simultaneous translation system. The MU segmentation model receives streaming ASR output and detects whether the streaming source text forms a meaning unit. (a). Detect whether the sequence in the left rectangle constitutes an MU, with the reference of two future words in the right rectangle. The output probability of **class 1** (predicts the sequence as an MU) is lower than threshold δ (e.g. $\delta = 0.7$). (b). The model reads more source words and the probability of **class 1** is greater than δ now. (c). As soon as an MU is detected, it is sent to the translation model to generate translation. Once an MU is translated, the translation will not be changed by the incoming source text. We thus use a force decoding to ensure the monotonic translation.

3. How to train the MU segmentation model? We train the classifier under a pre-training & fine-tuning framework (Section 2.4).

Finally, the MU segmentation model is integrated into a cascaded simultaneous translation system. It receives ASR output and produces MUs as MT input.

2.1 MU Definition

As mentioned, an MU in simultaneous interpretation refers to a group of streaming words with definite or clear meaning. However, it is not easy to give it a precise definition. Even human interpreters cannot determine the exact boundary of MUs during interpreting.

Before we describe our definition, we first try to list the properties of an ideal MU:

1. An MU should be short to reduce latency.
2. The translation of an MU should not be changed (or affected) by the incoming source words. [2] This requires that an MU should contain enough information to produce a translation.

Accordingly, we define an MU as *the minimum segment whose translation will not be changed by subsequent text.*

Formally, we can take a pre-trained MT system M_{nmt} to extract MUs. Given a streaming source sequence $\mathbf{x} = \{x_1, x_2, ...x_T\}$, we want to find a list of MU segments $\mathbf{S_{MU}} = \{S_1, S_2, ...S_K\}$ i.e., to split $\mathbf{x}$ into K MUs, satisfying the above properties that each partial translation $M_{nmt}(S_k)$ will not change by the incoming words. And our goal is to find a segmentation $\mathbf{S_{MU}}$ with appropriate granularity.

2.2 Basic Method for Constructing Training Data

We propose a simple method to generate MUs for a source sentence $\mathbf{x} = \{x_1, x_2, ...x_T\}$. The main idea is that, for a prefix $\mathbf{x}_{\leq t} = \{x_1, x_2, ...x_t\}$ $(1 \leq t \leq T)$, if its translation $\mathbf{y}^t = M_{nmt}(\mathbf{x}_{\leq t})$ is also a prefix of the full sentence translation $\tilde{\mathbf{y}} = M_{nmt}(\mathbf{x})$, we take x_t as a boundary of MU. The reason is that, in this case, the translation of $\mathbf{x}_{\leq t}$ is not affected by more source words, indicating that the information of the current source sequence is sufficient to generate an accurate partial translation. To keep the MU as short as possible, we incrementally input the source text word-by-word to an MT model and detect whether the translation $\mathbf{y}^t$ of current source sequence is a prefix of the full-sentence translation $\tilde{\mathbf{y}}$. If the answer is true, then we segment the current source sequence as an MU. Otherwise, the model continues reading more source words.

Note that once an MU is detected, its translation

---

[2] Once an MU is detected, the simultaneous translation system should output its translation immediately, and the translation cannot be modified. Rewriting the generated MU translation in a practical system will hurt user experience.

Algorithm 1: Extract MUs

```
Input: $\mathbf{x} = x_1, ..., x_T$      ▷ streaming input
Output: $\mathbf{S_{MU}}$      ▷ list of MU segmentation
1 $k = 0$      ▷ position of last MU boundary
2 $\widetilde{\mathbf{y}} = M_{nmt}(src= \mathbf{x}, tgt_{force} = None\ )$
                        ▷ full sentence decoding
3 while Reading $x_t$ do
4     $\mathbf{y}^t = M_{nmt}(src= \mathbf{x}_{\leq t}\ , tgt_{force}= \mathbf{y}^k)$
5     if $y^t$ is a prefix of $\widetilde{\mathbf{y}}$ then
6         $\mathbf{S_{MU}} = \mathbf{S_{MU}} \cup \{x_{k+1}, ..., x_t\}$
7         $k = t$
8 return $\mathbf{S_{MU}}$
```

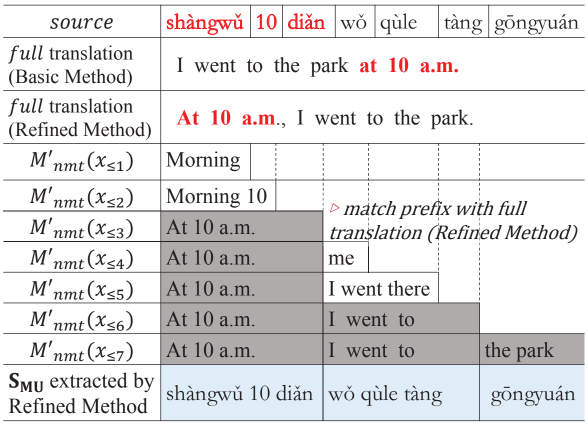
is fixed. To keep consistency, when detecting a new MU, we first force decode the translation of previous MUs and then decode the new sequence. The whole process is described in Algorithm 1. The algorithm reads source sequence word-by-word (Line 3), and generates translation by force decoding using the history translation of previous detected MUs, denoting as tgt_{force}(Line 4). The sequence is detected as an MU if its translation is a prefix of the full-sentence translation (Line 5).

The above algorithm is simple, however, there are two main problems. First, the constraint that $\mathbf{y}^t$ is a prefix of $\widetilde{\mathbf{y}}$ (Line 5) is too strict. To alleviate this problem, we expand the full-sentence translation $\widetilde{\mathbf{y}}$ to a set of candidates through beam search [3].

The second problem is that the translation model M_{nmt} is trained on sentence pairs used for text translation rather than simultaneous translation. There are often long-distance reorderings in the training corpus, which have been learned by the translation model and prevent the basic method from extracting fine-grained MUs. See Figure 2 for illustration, the initial part of the *source* is translated to a sequence at the end of the target (in bold) in the basic method. This makes all the translation of **x** prefixes fail to match the *full translation*, resulting in only one MU could be extracted, as the whole sentence itself. For this problem, we propose a **refined method** to train an NMT model M'_{nmt} with fewer reorderings.

2.3 Refined Method for Constructing Training Data

The process of the **refined method** is described as below:



source	shàngwǔ	10	diǎn	wǒ	qùle	tàng	gōngyuán
full translation (Basic Method)	I went to the park **at 10 a.m.**						
full translation (Refined Method)	**At 10 a.m.**, I went to the park.						
$M'_{nmt}(x_{\leq 1})$	Morning						
$M'_{nmt}(x_{\leq 2})$	Morning 10						
$M'_{nmt}(x_{\leq 3})$	At 10 a.m.						
$M'_{nmt}(x_{\leq 4})$	At 10 a.m.			me

$M'_{nmt}(x_{\leq 6})$	At 10 a.m.			I went to			
$M'_{nmt}(x_{\leq 7})$	At 10 a.m.			I went to			the park
$\mathbf{S_{MU}}$ extracted by Refined Method	shàngwǔ 10 diǎn			wǒ qùle tàng			gōngyuán

▷ *match prefix with full translation (Refined Method)*

Figure 2: A running example of extracting MUs. Using the **refined method**, we obtain three MUs according to the matching of partial translation and full translation. While due to the long-distance reordering of full translation in the **basic method**, we cannot extract short MUs. The gray blocks denotes the tgt_{force} parts.

1. Use standard sentence aligned parallel corpus to pre-train an NMT model M_{nmt};
2. Generate monotonic translation for each source sentence in the corpus using M_{nmt} with *prefix-attention*. [4]
3. Use the generated training data to train a monotonic translation model M'_{nmt} by fine-tuning on M_{nmt}.
4. Use M'_{nmt} to extract MUs on the training corpus according to Algorithm 1.

Prefix-attention. To generate monotonic translation, we propose a method that each target word y_j is generated by a prefix source sequence rather than by the full source sentence. Formally, given a source sentence **x**=$\{x_1, x_2, ..., x_T\}$, we define $g(j)$ as a monotonic non-decreasing function that denotes the current source position the encoder observed from the beginning. At decoding step j, only a prefix source sequence $x_{\leq g(j)} = \{x_1, x_2, ..., x_{g(j)}\}$ can be used to generate y_j, where $0 < g(j) \leq T$.

The key issue is how to carefully choose $g(j)$ for each target word y_j. Our main idea is that, to generate target word y_j, we expect the model to

---

[3] In this paper, we keep top $N = 10$ results as candidates

[4] From the translation results produced by M_{nmt} with prefix attention, we filter out two kinds of low-quality sentences: 1) Remove those sentences whose word orders are identical with their counterparts in corresponding full sentence translations. 2) Remove the translation whose score is lower than full-sentence translation.

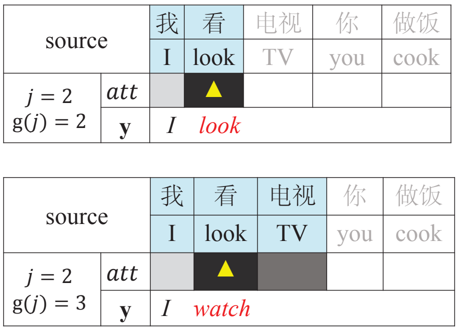

Figure 3: A Chinese-English example for our prefix attention. In the upper case, the model fails to produce correct translation because of a lack of future contextual information. By expanding the source prefix (lower case), the model produces correct translation. *att* is the encoder-decoder attention, and the triangle indicates the location of maximum attention for the current decoding step.

Algorithm 2: Prefix-attention Decoding

```
   Input: x = $x_1, ..., x_T$          ▷ streaming input
   Output: y                         ▷ monotonic translation
1  $j = 1$                               ▷ decoding step
2  $g(j) = 1$                            ▷ initialize $g$
3  while Decoding step $j$ do
4      $a_j = \arg\max_{t \in [1, g(j)]} \alpha_{jt}$
                  ▷ the position with max attention
5      if $1 \leq a_j < g(j)$ then
6          $p(y_j | \mathbf{x}) = p(y_j | \mathbf{x}_{\leq g(j)}, \mathbf{y}_{<j}; M_{nmt})$
7          $j \leftarrow j + 1$                      ▷ next step
8          $g(j) = g(j-1)$           ▷ non-decreasing
9      else
10         $g(j) += 1$ ▷ expand $g(j)$ by 1 word
11 return y
```

observe limited but adequate contextual information to produce correct translation. See Figure 3 for illustration where the full-sentence translation should be "*I watch TV, you cook*". For the upper case of Figure 3, the current decoding step is $j = 2$, and $g(j) = 2$, meaning that the NMT model uses prefix $x_{\leq 2}$ to generate y_2. However, in this case, the model makes an error to generate y_2. Without observing more context, the model is difficult to make a decision whether y_2 should be "*look*" or "*watch*" or "*see*", etc. For the lower case, the model expands the source prefix by one more source word and produces correct translation.

This raises a question of how do we know whether a source prefix is sufficient or not for producing a target word? Let's take a look at the encoder-decoder attention. To generate a target word y_j, the NMT model computes probabilities between each source word x_t ($1 \leq t \leq g(j)$) and y_j via encoder-decoder attention α_{jt}. The higher the attention weight is, the greater contribution the corresponding source words make in decoding. Therefore, we can find the source words that contribute the most by locating the highest attention weight. For example, in Figure 3, the source word x_2 contributes the most for y_2. When the source word with maximum attention appears at the end of a prefix span, the model takes a risk that it cannot observe future context for translation. In this case, we should expand the span to reduce the risk.

Algorithm 2 shows the whole process of prefix-attention decoding. Initially, we set $g(j) = 1$ for $j = 1$. For each decoding step j, the algorithm first locates the maximum attention to a_j (Line 4), according to the following equation:

$$a_j = \arg \max_{t \in [1, g(j)]} (\alpha_{jt}) \tag{1}$$

where,

$$\alpha_{jt} = \frac{\exp(e_{jt})}{\sum_{t'=1}^{g(j)} \exp(e_{jt'})} \tag{2}$$

If $1 \leq a_j < g(j)$, it means that the model can observe both history and future source context to generate y_j. Otherwise, the model faces the risk of lacking future context. In this case, we expand $g(j)$ by one more word.

2.4 The MU Segmentation Model

Our MU segmentation model is illustrated in Figure 1 (a) & (b). Given a streaming source sequence $x = \{x_1, x_2, ...\}$, the model aims to detect whether a prefix of x constitutes an MU on-the-fly. The model takes two inputs: the source sequence $c_t = \{x_{\leq t}\}$ and future words $f_t = \{x_{t+1}, ..., x_{t+m}\}$, and outputs the probability of predicted label l_t, denoting the context c_t being an MU (class 1) or not (class 0). m is a hyper-parameter as the number of future words. Larger m means to wait for more future words at inference time. In this paper, we set $m = 2$. c_t is considered as an MU if $p(l_t = 1 | c_t, f_t; \theta_{model})$ is larger than a threshold δ.

In the training stage, we first extract the MUs in the training corpus according to the basic method (Section 2.3) or refined method (Section 2.2). Then we generate the training data for the MU detection model. For each sentence $x = \{x_1, x_2, ..., x_N\}$ in

t	c_t	$f_t(m=2)$	l_t
1	shàngwǔ	10 diǎn	0
2	shàngwǔ 10	diǎn wǒ	0
3	shàngwǔ 10 diǎn	wǒ qùle	1
4	shàngwǔ 10 diǎn wǒ	qùle tàng	0
5	shàngwǔ 10 diǎn wǒ qùle	tàng gōngyuán	0
6	shàngwǔ 10 diǎn wǒ qùle tàng	gōngyuán	1
	...		

Table 2: The training samples for the MU detection model generated according to the MU segmentation result in Figure 2.

the training corpus, we generate N samples. Each sample is a triple $<c_t, f_t, l_t>$ for $t = \{1, 2, ..., N\}$. If x_t is a boundary of MU, we set l_t to 1; otherwise 0. Take the extracted MUs in Figure 2 as example, we generate training samples as illustrated in Table 2. Note that for t larger than $N - m$, we only use the remaining words in the sentence as future words, which is less than m. Our training follows the pre-training and fine-tuning framework (Devlin et al., 2018; Sun et al., 2019).

3 Experiments

We carry out experiments on two translation tasks: the NIST Chinese-English (Zh-En) translation task (2M sentences), and the WMT 2015 German-English (De-En) translation task (4.5M sentences).we use BLEU (Papineni et al., 2002) score to evaluate translation quality, and Average Lagging [5] (Ma et al., 2019) to measure latency.

3.1 Data Preprocess

We use an open-source Chinese Tokenizer [6] to preprocess Chinese and apply Moses Tokenizer [7] to preprocess English and German. For Zh-En, we validate on NIST newstest 2006 and report results on newstest 2002, 2003, 2004, 2005, and 2008. We use SententcePiece [8] to implement byte-pair encoding (BPE) (Sennrich et al., 2016) for both Chinese and English by setting the vocabulary size to 20K and 18K, respectively. For De-En, we validate on newstest 2013 and then report results on newstest 2015. We utilize a joint vocabulary, with a vocabulary size of 32K. Notably, translation quality in all experiments is measured using detokenized, cased BLEU.

3.2 Model Settings

We compare our methods with previous state-of-the-art methods:

- *wait-k* (Ma et al., 2019): first waiting for k words, then emiting one token after reading each word.
- *chunk*: extracting the training segments by segmenting the source sentence into minimally sized chunks such that crossing and one-to-many links between source and target words in an optimal GIZA++ alignment occur only within individual chunks. We borrow this idea of training samples generation from Rangarajan Sridhar et al. (2013).
- *MILk* (Arivazhagan et al., 2019): using hard attention to schedule the policy and train the policy together with the NMT model in an end-to-end framework. It uses a weight λ in the loss function to balance translation quality and latency. [9]
- *MU*: our proposed **basic method** of translating after detecting a meaning unit.
- *MU++*: our proposed **refined method** to detect fine-grained meaning units.

The training of segmentation models for *chunk*, *MU* and *MU++* are based on the classification task of BERT [10] and ERNIE [11], with the pre-trained language model of German and Chinese, respectively. We use the base model and take the learning rate of $2e^{-5}$ at the fine-tuning stage.

Our translation models are trained on big Transformer (Vaswani et al., 2017). All the approaches share the same machine translation corpus except *MU++*, which is trained on the augmented training corpus generated by *prefix-attention* (Section 2.3).

3.3 Overall Results

3.3.1 Chinese-English Translation

Figure 4 shows the translation quality and latency on Chinese-English translation tasks. We have the following observations:

- Our methods, both *MU* and *MU++*, outperform *wait-k* and *chunk* method in terms of translation quality and latency.

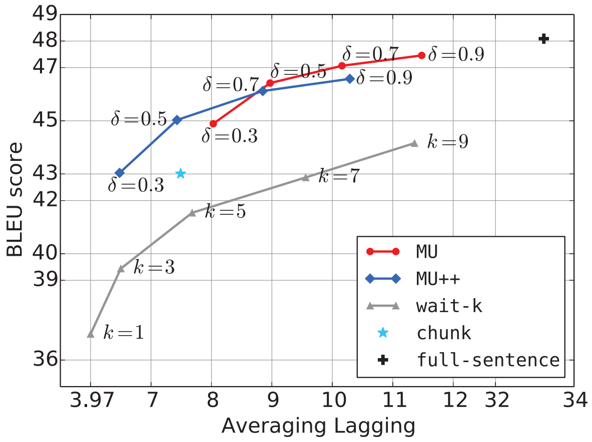

Figure 4: Quality-latency results on the NIST dataset. We report the averaged results on NIST02, NIST03, NIST04, NIST05, and NIST08. Note that each method has its own performance on full-sentence translation, which is denoted as "+" with the same color with the corresponding method. δ is the threshold of the MU detection model (Section 2.4).

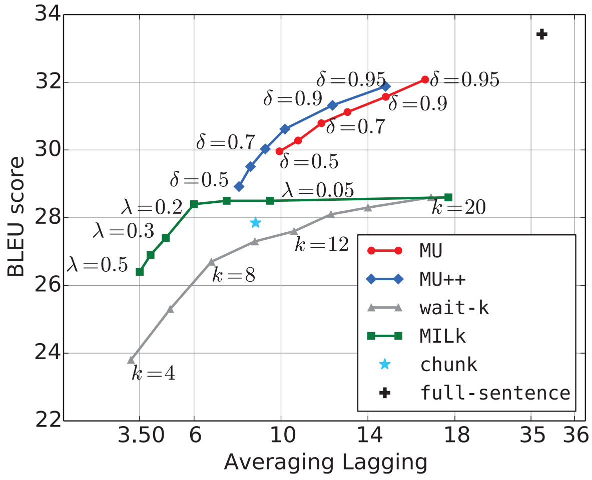

Figure 5: Quality-latency results on the WMT15 German-English dataset.

- With the increase of δ (the threshold for MU detection, in Section 2.4), the quality is improved while the latency is also increased. In practice, δ can be tuned to obtain a trade-off between quality and latency according to real requirement.

- Compared to *MU*, *MU++* significantly reduces latency while causing a drop in quality. A possible reason is that the references in the test set are produced via text translation and contain many long-distance reorderings. But *MU++* is designed to produce translation with less reordering. We'll further analyze this issue in Section 3.4.

3.3.2 German-English Translation

Figure 5 shows the De-En translation results. When the average lagging is larger than 8, our model's translation quality outperforms the other models. Note that low latency in other models performance causes a large decrease in BLEU scores.

For the joint learning method, *MILk*, its full-sentence performance is limited by the RNN architecture, which is inferior to the Transformer. Furthermore, its full-sentence translation model uses a bidirectional encoder, while the streaming model uses unidirectional encoders, resulting in the performance gap in its full-sentence model and streaming model. Both models in our approaches, on the contrary, use the bidirectional encoder, thus avoiding such gaps.

It's interesting to find that the trend of *MU* and *MU++* is different from that of the Zh-En experiment. According to Figure 4, *MU++* is inferior to *MU*, achieving low latency while impairing the translation quality. But in De-En translation, *MU++* performs better than *MU*. We analyze this in the next section.

3.4 Test on Reference with Simulated Simultaneous Interpretation

We randomly select 200 sentences in Zh-En and De-En, respectively, from the corresponding test set and ask human translators to translate them in the way that they do simultaneous interpretation. For example in Figure 6 ("*Simul-Ref*"), "*next week*" appears at the initial position of the target sentence, keeping the order of the "*Source*". We also list the translation process of the comparing methods.

Using the re-translated text as references, we evaluate both *MU* and *MU++* with flexible latency ($\delta = 0.3, 0.5, 0.7, 0.9$) on the test sets. The performance on the new Zh-En test set is depicted in Figure 7. *MU++* presents shorter latency as well as more promising quality on this dataset compared to *MU*. Another finding is the quality of *MU* degrades even with a larger δ. We attribute this to the inconsistency between reference and translation of *MU*, because longer MU may further cause long-distance reordering. This also explains that the superiority of *MU* to *MU++* in the original test set is due to the distribution inconsistency.

The performance of De-En is illustrated in 8, in which the performance of the two methods is in line with that on the original test set: *MU++* performs slightly better than *MU*. The reason is that in

Source:	jǐngfāng 警方 police	xiàzhoū 下周 next week	jiāng 将 will	duì 对 for	bù fèn 部分 part	shè àn 涉案 involved	rén yuán 人员 people	tí qǐ gōng sù 提起 公诉 indict
Text-Ref:	Police will indict some of the people involved in the case next week .							
Simul-Ref:	Next week, police will indict some of the people involved in the case.							
chunk		Police next week						will prosecute part of the suspects.
Wait-3:				Police to		part	of	the people involved will be charged next week.
MU	The police							will bring lawsuits against some of the suspects next week.
MU++		Next week, the police	will					bring lawsuits against some of the suspects.

Figure 6: A Chinese-English example in the test set with the original text translation reference ("*Text-Ref*") and the simultaneous interpretation reference ("*Simul-Ref*"). Both *chunk* and *wait-3* generates incorrect translation. But *MU* and *MU++* translates accurately. Furthermore, *MU++* avoids long-distance reordering by keeping "xiàzhoū (next week)" in order with the source sentence, and thus reduces latency.

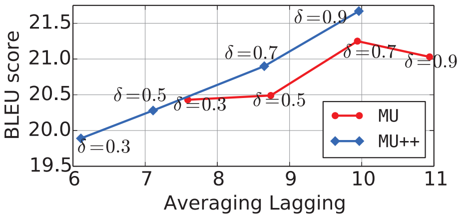

Figure 7: Performance of Zh-En on 200 sentences with simultaneous interpretation reference (*Simul-Ref*).

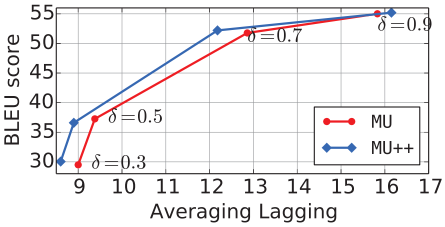

Figure 8: Performance of De-En on 200 sentences with simultaneous interpretation reference (*Simul-Ref*).

German, there are a lot of "SOV" structures, while English is an "SVO" language. In this case, both *MU* and *MU++* should wait until a verb at the end of a sentence before generating an accurate translation. Thus the performance of *MU* and *MU++* is similar.

We further ask human translators to evaluate the quality of *MU* and *MU++*. They rated each translation in **Bad**, **OK** and **Good** based on the translations' adequacy, correctness and fluency:

- **Bad** indicates the translation is unacceptable and incorrect or inadequate.
- **OK** denotes the translation is comprehensible and adequate, but with minor errors such as incorrect function words and less fluent phrases.
- **Good** means a translation is correct and contains no obvious errors.

	Method	**Bad**	**OK**	**Good**	**Acceptablity**
Zh-En	*MU*	28.5%	49%	22.5%	71.5%
	MU++	30.0%	46.5%	23.5%	70.0%
De-En	*MU*	23.5%	54.5%	22.0%	76.5%
	MU++	22.0%	57.0%	21.0%	78.0%

Table 3: The human evaluation of the Zh-En and De-En translation on 200 sentences with $\delta = 0.7$.

We evaluate the performance of *MU* and *MU++* at $delta = 0.7$, which is the point of achieving relatively high translation quality with limited latency. The evaluated performance of the 200 sentences in Zh-En and De-En is reported in Table 3. We define the overall acceptability as a percentage of the sum of **OK** and **Good** cases. It is obvious that the acceptability of *MU* and *MU++* shows a consistent trend with their BLEU in Figure 7 and Figure 8 that *MU++* performs slightly worse in Zh-En but the opposite in De-En. However in both language pairs, *MU++* achieves a lower latency.

4 Related Work

Recent simultaneous translation work focuses on exploring a policy to decide whether to wait for another source word or generate a target word. Rangarajan Sridhar et al. (2013) investigated a variety of policies depending on lexical cues. Oda et al. (2014) proposed to optimize a segmentation model with the target of achieving better translation quality. However, their performance is limited largely by weak features such as N-gram and POS. Some research learns the policy depending on reinforcement learning, with the goal of good translation quality and low latency (Grissom II et al., 2014; Satija and Pineau, 2016; Gu et al., 2017; Alinejad et al., 2018). But reinforcement learning is notorious for its unstable training process. Cho and Esipova (2016) proposed a heuristic measure to determine the policy at inference time, without using a deep model. Ma et al. (2019) and Dalvi et al. (2018) applied fixed policy independent of contextual information, which inevitably need to guess the future context in translation (Zheng et al., 2019a). Some work applied advanced attention mechanisms that replace the softmax attention with a stepwise Bernoulli selection probability (Raffel et al., 2017). Arivazhagan et al. (2019) proposed infinite lookback to integrate the hard monotonic attention with soft attention. Ma et al. (2020) proposed multi-head monotonic attention and obtained further improvements. However, the autoregressive training process makes its exploration inefficient.

5 Conclusions

In this paper, we propose a novel adaptive segmentation policy for simultaneous translation. Motivated by human interpreters, the model constantly reads streaming text and dynamically segments it into meaning units. We first generate training data for MU via a translation-prefix based method, keeping consistency between the segmentation model and the translation model. Further, we propose a refined-method to extract fine-grained MUs to reduce latency. Experimental results on both Chinese-English and German-English show that our model outperforms the previous state-of-the-art. The method obtains a good trade-off between translation accuracy and latency and can be easily implemented into a practical simultaneous translation system.

Abstract

The recent emergence of multilingual pre-training language model (mPLM) has enabled breakthroughs on various downstream cross-lingual transfer (CLT) tasks. However, mPLM-based methods usually involve two problems: (1) simply fine-tuning may not adapt general-purpose multilingual representations to be task-aware on low-resource languages; (2) ignore how cross-lingual adaptation happens for downstream tasks. To address the issues, we propose a meta graph learning (MGL) method. Unlike prior works that transfer from scratch, MGL can learn to cross-lingual transfer by extracting meta-knowledge from historical CLT experiences (tasks), making mPLM insensitive to low-resource languages. Besides, for each CLT task, MGL formulates its transfer process as information propagation over a dynamic graph, where the geometric structure can automatically capture intrinsic language relationships to guide cross-lingual transfer explicitly. Empirically, extensive experiments on both public and real-world datasets demonstrate the effectiveness of the MGL method.

1 Introduction

The diversity of human languages is a critical challenge for natural language processing. To alleviate the cost in annotating data for each task in each language, cross-lingual transfer (CLT) (Yarowsky et al., 2001), aiming to leverage knowledge from source languages that are sufficiently labeled to improve the learning in a target language with little supervision, has become a promising direction.

To bridge the gaps between languages, numerous CLT algorithms have emerged, ranging from early translation-based methods (Prettenhofer and Stein, 2010), cross-lingual word representation learning (Conneau et al., 2018a), to powerful mPLM (Devlin et al., 2019; Lample and Conneau, 2019), from which the versatile multilingual representations derived suffice it to become a mainstream approach for various downstream CLT tasks. However, existing mPLM-based methods focus on designing costly model pre-training while ignoring equally crucial downstream adaptation. With simply fine-tuning on the downstream labeled data for CLT tasks, mPLM often underperforms on low-resource target languages, especially for the languages distant from the source ones since the generalization ability of mPLM highly relies on lexical overlap across languages (Huang et al., 2019). On the other hand, existing adaptation approaches for mPLM behave as a black box without explicitly identifying intrinsic language relations.

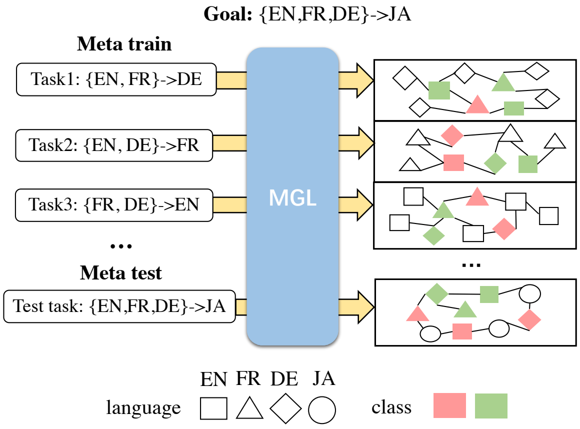

Figure 1: The meta learning process of the MGL.

To address the issues, we propose meta graph learning (MGL), a meta learning framework to learn how to cross-lingual transfer for mPLM. Specifically, MGL models each CLT process as heterogeneous information propagation over a dynamic graph, which captures latent language correlations and makes the downstream CLT adaptation more interpretable. However, solely learning the

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2290–2301,
November 16–20, 2020.

dynamic graph structures may be insufficient since the graph-based metric space usually favors high-resource languages over low-resource ones.

Meta learning, a.k.a learning to learn, (Finn et al., 2017; Snell et al., 2017), addresses the few-shot problems, by extracting common meta-knowledge from previous tasks (**Meta-train**) that can be rapidly adapted to new tasks with a few examples (**Meta-test**). Inspired by it, MGL takes advantage of historical CLT experiences to quickly adapt the dynamic graphs to our target CLT task. This enables MGL to meta-learn a graph-based cross-lingual metric space that is invariant across languages. For example, suppose we transfer from *English* (**EN**), *French* (**FR**) and *German* (**DE**) to *Japanese* (**JA**), i.e., {**EN**, **FR**, **DE**}→**JA**. We construct previous CLT experiences by *leave-one-out* among source languages: for each source CLT task, we leave one out of source languages as a *pseudo-target language* in turn and use the remaining ones as the *pseudo-source languages*. As such, we expect the MGL can borrow knowledge from source CLT pairs: {**FR**, **DE**}→**EN**, {**EN**, **DE**}→**FR**, {**EN**, **FR**}→**DE** to improve the transfer effectiveness in the target CLT pair {**EN**, **FR**, **DE**}→**JA**, which is illustrated in Figure 1.

Recently, some efforts have been initiated on meta learning for low-resource NLP tasks that straightforwardly views each dataset with its objective as a task (Dou et al., 2019). However, this strategy can only make meta-leaner learn knowledge from each language separately. And meanwhile, most existing meta-learners lack the ability to handle tasks lying in different distributions, especially tasks for heterogeneous languages. On the contrary, MGL resorts to learning how to adapt across languages from each CLT task. Empirically, extensive experiments on both the public multilingual Amazon review dataset (Prettenhofer and Stein, 2010) and the real-world industrial multilingual search relevance dataset (Ahuja et al., 2020) demonstrate the effectiveness of the MGL method.

Overall, our contributions can be summarized as follows: (1) A novel MGL method is proposed to *learn to cross-lingual transfer* (L2CLT) for task-aware adaptation of mPLM by leveraging previous CLT experiences; (2) The MGL automatically captures intrinsic correlations between languages, which improves the interpretability of the downstream adaptation process; (3) Extensive experiments verify the effectiveness of the MGL.

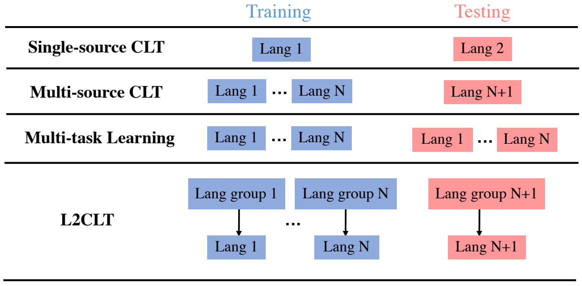

Figure 2: Differences between our work and other existing methods. "Lang" refers to the language.

2 Related Work

2.1 Cross-lingual Transfer

Most CLT studies focus on transferring from a single source language (Wan, 2009; Prettenhofer and Stein, 2010; Zhou et al., 2016b,a; Xu and Yang, 2017; Chen et al., 2018). However, single-source CLT methods would incur the risk of negative transfer when there exists a large language shift. Alternately, multi-source CLT (McDonald et al., 2011; Xu and Wan, 2017; Chen et al., 2019), transferring from multiple source languages, has been proved to increase the stability of the transfer. Another research efforts made on cross-lingual word representation learning (Zou et al., 2013; Mikolov et al., 2013; Conneau et al., 2018a; Chen and Cardie, 2018; Artetxe et al., 2018) and mPLM (Devlin et al., 2019; Lample and Conneau, 2019; Yang et al., 2019; Eisenschlos et al., 2019; Chidambaram et al., 2019), which exploit unsupervised learning on large-scale multilingual corpus to learn versatile multilingual contextualized embeddings.

2.2 Meta Learning

There are mainly three categories of meta learning: (1) Black-box amortized methods (Andrychowicz et al., 2016; Ravi and Larochelle, 2017; Mishra et al., 2017) design neural meta-learners (black-box) to infer the parameters of the base learner; (2) Gradient-based methods (Finn et al., 2017; Nichol et al., 2018; Yao et al., 2019, 2020) learn a good initialization of parameters, which can be adapted to new tasks by a few steps of gradient descent; (3) Metric-based methods (Vinyals et al., 2016; Snell et al., 2017; Garcia and Bruna, 2018; Ying et al., 2018; Sung et al., 2018; Oreshkin et al., 2018; Liu et al., 2019b) learn a task-invariant distance metric. Our work is built upon the third category to learn a cross-lingual metric space rapidly adapted to the low-resource language. Recently, some efforts have been initiated on meta learning for low-resource NLP applications, such as few-shot text classification classification (Sun et al., 2019; Gao et al., 2019; Geng et al., 2019; Bao et al., 2020), natural language understanding (Dou et al., 2019), and medical prediction (Zhang et al., 2019). Very few works have explored meta learning for CLT problems like machine translation (Gu et al., 2018) and cross-lingual named entity recognition (Wu et al., 2019). However, these methods simply combine the MAML (Finn et al., 2017) or its variants for gradient optimization without considering latent relations between languages. Overall, the differences between our MGL paradigm and existing methods are illustrated in Figure 2.

3 Problem Definition

Cross-lingual Transfer Suppose that there are T high-resource (***Source***) languages $\{\ell_i^s\}_{i=1}^T$. Each source language ℓ_i^s has sufficient labeled data $D_{\ell_i^s} = \{\mathbf{x}_{\ell_i^s}^j, y_{\ell_i^s}^j\}_{j=1}^{|\ell_i^s|}$, where $|\ell_i^s|$ is the number of labeled data for the i-th source language ℓ_i^s. Besides, only a few labeled data $D_{\ell^t} = \{\mathbf{x}_{\ell^t}^j, y_{\ell^t}^j\}_{j=1}^{|\ell^t|}$ are available in a low-resource (***Target***) language ℓ^t, i.e., $|\ell^t| \ll |\ell_i^s|, \forall i \in [1, T]$. All languages share the same label space, i.e., the label set $\mathcal{Y}$. Our goal aims to leverage knowledge from high-resource languages $\{\ell_i^s\}_{i=1}^T$ to help the learning in the low-resource language ℓ^t, i.e., $\{\ell_i^s\}_{i=1}^T \rightarrow \ell^t$.

4 Methodology

Our framework is a language-agnostic task-aware model for CLT. On the one hand, we use the mPLM as the base encoder to calculate language-agnostic representations. On the other hand, we propose a meta graph learning (MGL) method to further guide the versatile multilingual representations to be task-aware for downstream CLT tasks.

4.1 Language-Agnostic Backbone

We employ a multilingual BERT (**mBERT**) (Devlin et al., 2019) as the language-agnostic encoder, which harnesses self-supervised learning with shared word piece tokens as the anchor across languages to produce weakly aligned multilingual representations. Our framework is quite general and can be easily compatible with any other mPLMs, e.g., XLM (Lample and Conneau, 2019), mUnicoder (Yang et al., 2019), etc. With the aid of mBERT as the standard encoder, we can demonstrate that the primary efforts come from the design of the task-aware MGL approach.

4.2 Task-aware Adaptation

In this section, we introduce some existing downstream adaptation approaches for CLT tasks.

Common approaches With the power of mPLM, some simple adaptation approaches can yield superior results for downstream CLT tasks, including **Target-Only**: It fine-tunes a mPLM with only the target low-resource language, which is usually regarded as a lower bound for reference; **Fine-tune**: It first trains a mPLM on the source languages and then fine-tunes the model on the target language; **Mix** (Liu et al., 2018): it ignores language characteristics and simply combines the labeled data from all languages to fine-tune a mPLM; **Multi-task** (Liu et al., 2019a): It consists of a shared mPLM encoder with language-specific discriminative layers for multi-task learning.

Meta approaches There are some efforts on gradient-based meta learning with BERT for low-resource NLU tasks (Dou et al., 2019), including second-order optimization-based **MAML** (Finn et al., 2017) with its first-order variants **FOMAML** and **Reptile** (Nichol et al., 2018). They view each dataset as one task, which may not be able to handle the language heterogeneity. Here, we compare with Reptile that is much faster when deployed to the heavy mPLM and has proved to achieve the best results as observed in (Dou et al., 2019).

4.3 Meta Graph Learning (MGL)

Here, we introduce the MGL that involves: (1) learning to CLT from historical CLT experiences; (2) learning correlations between languages.

4.3.1 Learn to Cross-lingual Transfer

The MGL is optimized over CLT tasks to achieve the L2CLT paradigm. The mechanism aims to learn knowledge from various source CLT pairs (**Meta-train**) to improve the transfer learning effectiveness for a target CLT pair (**Meta-test**).

Meta-train: we simulate the source CLT pairs by *leave-one-out* strategy among source languages $\{\ell_i^s\}_{i=1}^T$. That is, we leave one language out from the T source languages in turn as the *pseudo-target language* ℓ^{tst}, using the remaining languages as the *pseudo-source languages* to constitute a source CLT pair $p^s : \{\ell_i^s\}_{i=1}^T \backslash \ell^{\text{tst}} \rightarrow \ell^{\text{tst}}$. In total, we can obtain T source CLT pairs $\{p_o^s\}_{o=1}^T$. **Meta-test**: we directly use $\{\ell_i^s\}_{i=1}^T \rightarrow \ell^t$ as the target CLT pair

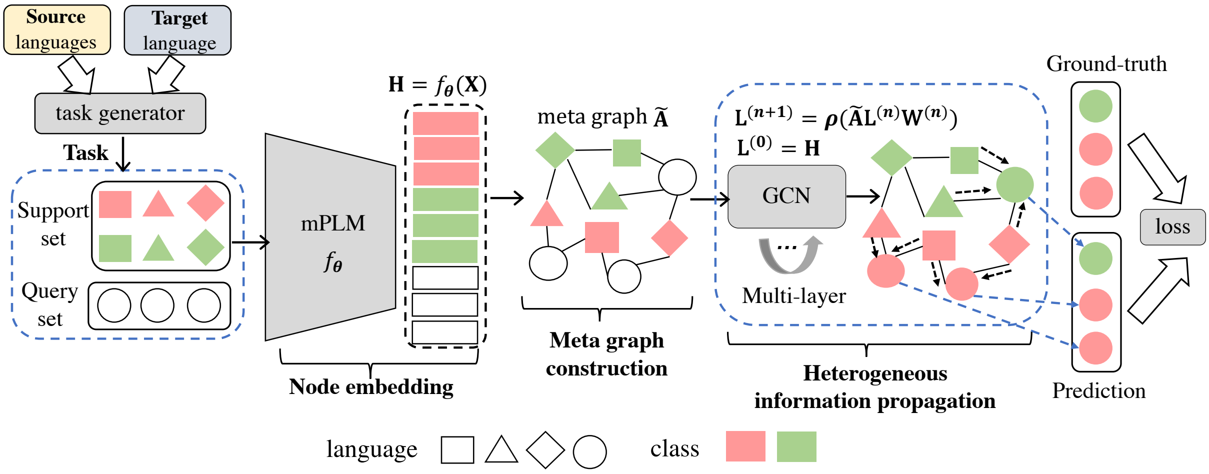

Figure 3: The framework of the proposed Meta Graph Learning (MGL) method.

p^t since the ultimate goal is to improve the learning in the low-resource language ℓ^t.

We follow the effective episodic training strategy (Vinyals et al., 2016) for training a meta-learner. In each episode, we are given a CLT pair p: $\{\ell_i^{\text{trn}}\}_{i=1}^{M} \rightarrow \ell^{\text{tst}}$, where $\{\ell_i^{\text{trn}}\}_{i=1}^{M}$ denotes M source languages ($M = T - 1$ for Meta-train and $M = T$ for Meta-test) and the ℓ^{tst} is the target language. We then use the label set $\mathcal{Y}$ to randomly sample a *support set* $\mathcal{S}$ and a *query set* $\mathcal{Q}$ from the CLT pair p. The support set $\mathcal{S}$ includes $|\mathcal{Y}|$ different classes and each class contains M source languages, each of which consists of N randomly sampled instances, i.e., $\mathcal{S} = \{\mathbf{x}_j^{\mathcal{S}}, y_j^{\mathcal{S}}\}_{j=1}^{|\mathcal{Y}| \times M \times N}$.While the query set $\mathcal{Q} = \{\mathbf{x}_j^{\mathcal{Q}}, y_j^{\mathcal{Q}}\}_{j=1}^{R}$ includes R different examples of the target language from the same $|\mathcal{Y}|$ classes. $\mathcal{S}$ in each episode serves as the labeled training set on which the model is trained to minimize the loss of its predictions for $\mathcal{Q}$. In the following, we introduce how to organize $\mathcal{S}$ and $\mathcal{Q}$ into a dynamic meta graph and propagate knowledge over it for CLT as illustrated in Figure 3.

4.3.2 Node Embedding

Given a support set $\mathcal{S}$ and a query set $\mathcal{Q}$ of a sampled CLT task, we regard each instance as a node and employ the mPLM, i.e., mBERT, to extract the feature representation of each instance $\mathbf{x}_j \in \mathcal{S} \cup \mathcal{Q}$. Formally, let $\mathbf{h}_j = f_{\boldsymbol{\theta}}(\mathbf{x}_j; \boldsymbol{\theta}) \in \mathbb{R}^{dim_h}$ denote the output representation, where $\boldsymbol{\theta}$ indicates the parameters of the encoder. Then we stack all $\mathbf{h}_j$ to obtain the node embedding matrix $\mathbf{H} = \{\mathbf{h}_j\}_{j=1}^{|\mathcal{S}|+|\mathcal{Q}|}$.

4.3.3 Meta Graph Construction

To capture intrinsic correlations between languages, we propose a meta graph construction module to build their manifold structure. A *meta graph* $G = \{V, E\}$ is dynamically learned using the sampled $\mathcal{S} \cup \mathcal{Q}$ in each episode, where V ($|V| = |\mathcal{S}| + |\mathcal{Q}|$) and E denote the sets of nodes and edges, respectively. Thus, each meta graph corresponds to a sampled task's geometric formulation from the given CLT pair in meta learning. In the meta graph G, each instance is regarded as a node. The weights $\mathbf{A} \in \mathbb{R}^{|V| \times |V|}$ of the edges are based on the similarity between their node embeddings.

It is critical to build an appropriate neighborhood graph, where the manifold structure affects the transferability among different languages. Inspired by manifold learning (Chung and Graham, 1997; Zhou et al., 2004), we choose the commonly used Radial Basis Function (RBF) $A_{jj'} = \exp(-\frac{d(\mathbf{x}_j, \mathbf{x}_{j'})}{2\sigma^2})$ to compute the similarity, where d is a distance metric function, i.e., the squared Euclidean distance, and σ is a length-scale parameter. The graph structure behaves differently with respect to various σ. To avoid carefully tuning σ, we propose to instance-wisely learn the scale parameter such that it can be tailored to different language compositions. Specifically, we feed the embedding of each instance $\mathbf{x}_j \in \mathcal{S} \cup \mathcal{Q}$ into a fully-connected layer as

$$\sigma_j = \text{sigmoid}(\mathbf{W}_{\sigma} f_{\boldsymbol{\theta}}(\mathbf{x}_j) + \mathbf{b}_{\sigma}), \qquad (1)$$

where σ_j is an instance-wise length-scale parameter, $\mathbf{W}_{\sigma}$ and $\mathbf{b}_{\sigma}$ are the weight matrix and bias. Then, the adjacency weight matrix $\mathbf{A}$ based on the learnable metric function is calculated as

$$A_{jj'} = \exp(-\frac{1}{2} d(\frac{f_{\boldsymbol{\theta}}(\mathbf{x}_j)}{\sigma_j}, \frac{f_{\boldsymbol{\theta}}(\mathbf{x}_{j'})}{\sigma_{j'}})). \qquad (2)$$

We only keep the top K values in each row of $\mathbf{A}$ to retain K nearest neighbors, which makes the episodic training more efficient.

4.3.4 Heterogeneous Information Propagation

After that, we apply a graph convolutional network (GCN) (Kipf and Welling, 2016) on the meta graphs to produce more abstract node embeddings based on properties of their neighborhoods. Here, we only use the simple GCN to propagate heterogeneous information from the support set $\mathcal{S}$ (source languages) to the query set $\mathcal{Q}$ (target language). The generality of MGL makes it be easily adapt to other graph neural networks, e.g., GAT (Veličković et al., 2017). For GCN, it can capture first-order information about immediate neighbors with one-layer of graph convolution. When multiple GCN layers are stacked, higher-order neighbor information can be aggregated layer-wisely. Based on the last n-th layer, the node embeddings $\mathbf{L}^{(n+1)} \in \mathbb{R}^{|V| \times dim_{n+1}}$ at the $(n+1)$-th layer can be obtained as

$$\mathbf{L}^{(n+1)} = \rho(\tilde{\mathbf{A}}\mathbf{L}^{(n)}\mathbf{W}^{(n)}), \tag{3}$$

where $\mathbf{W}^{(n)}$ is the parameter of the layer and ρ is the LeakyRelu (Maas et al., 2013) activation function. We use the embedding matrix $\mathbf{H}$ as the initial node representations, i.e., $\mathbf{L}^{(0)} = \mathbf{H}$. $\tilde{\mathbf{A}}$ is the normalized symmetric adjacency matrix,

$$\tilde{\mathbf{A}} = \mathbf{D}^{-\frac{1}{2}}\mathbf{A}\mathbf{D}^{-\frac{1}{2}}, \tag{4}$$

where $\mathbf{D}$ is a diagonal degree matrix with D_{jj} to be the sum of the j-th row of $\mathbf{A}$. Stacking proper GCN layers can exploit latent propagation patterns over heterogeneous languages and meanwhile avoid extra noises. Empirically, we consider a two-layer GCN, which can capture the second-order relationships between nodes such that more underlying knowledge from source languages can be aggregated to help the prediction of the target language (e.g., $\ell_1 \rightarrow \ell_3 \rightarrow \ell_2$, where ℓ_1 and ℓ_2 are distant languages while ℓ_3 similar to both can serve as anchors for transitive transfer.) A two-layer GCN is as:

$$\begin{aligned} \mathbf{L}^{(1)} &= \rho(\tilde{\mathbf{A}}\mathbf{H}\mathbf{W}^{(0)}) \\ \mathbf{z} &= \mathrm{Softmax}(\tilde{\mathbf{A}}\mathbf{L}^{(1)}\mathbf{W}^{(1)}), \end{aligned} \tag{5}$$

where $\mathbf{z} \in \mathbb{R}^{|V| \times |\mathcal{Y}|}$ is the probabilistic scores over the label set $\mathcal{Y}$. We let $\mathbf{z}^{\mathcal{Q}} \in \mathbb{R}^{|\mathcal{Q}| \times |\mathcal{Y}|}$ denote the last $|\mathcal{Q}|$ row of the $\mathbf{z}$ to be the query set score, where $\mathbf{z}_j^{\mathcal{Q}} = \mathbf{p}(\mathbf{y}_j^{\mathcal{Q}} | \mathbf{x}_j^{\mathcal{Q}}, \mathcal{S})$ denotes the predicted scores for j-th query instance $\mathbf{x}_j^{\mathcal{Q}}$.

4.3.5 Episodic Training

We follow the episodic training as described in Section 4.3.1 to optimize the MGL meta learner. In each episode, the training objective is to minimize the classification loss between the ground-truth labels and the predictions of the query set (target language) with the aid of the support set (source languages) for the given CLT pair:

$$\mathcal{J} = \sum_{j=1}^{|\mathcal{Q}|} \mathcal{L}(\mathbf{z}_j^{\mathcal{Q}}, \mathbf{y}_j^{\mathcal{Q}}), \tag{6}$$

where $\mathcal{L}$ is the cross-entropy loss and $\mathbf{y}_j^{\mathcal{Q}}$ is the one-hot label of the j-th query instance. All the parameters are jointly updated by the gradient descent method in an end-to-end manner during the episodic training. Through learning to CLT, meta graphs can learn a cross-lingual metric space invariant for downstream languages without suffering from overfitting to the low-resource one.

5 Experiment

In this section, we present an extensive set of experiments across two datasets. The first experiment is on a public multilingual Amazon review dataset (Prettenhofer and Stein, 2010). In addition, we conduct experiments on a real-world industrial multilingual search relevance dataset (Ahuja et al., 2020) used for E-commerce product search.

5.1 Cross-lingual Sentiment Classification

Dataset The aim of the task is binary sentiment classification, where each review document is classified into positive or negative sentiment. We use the multilingual Amazon review dataset (Prettenhofer and Stein, 2010), which has four languages: English (**EN**), German (**DE**), French (**FR**) and Japanese (**JA**) on three domains: *Books*, *DVD* and *Music*. For statistics, the sizes of the training, validation, and testing data are 1600, 400 and 2000, respectively, for each language of all the domains.

Setting We treat each domain as separate experiments and consider FR, JA, DE as the target language (Here, we do not consider EN since it is usually high-resource) while the remaining three being source languages, which results in 9 total cross-lingual experiments. In the low-resource setting, we only use ***10%*** labeled training data for the target language, i.e., *160 labeled data*. The evaluation metric is Accuracy. All experiments are

repeated 5 times, and we report the average results.

Baselines In addition to mBERT-based baselines mentioned in Section 4.2, we also compare with the state-of-the-art CLT baselines:

- **MT-BOW** uses machine translation to translate the bag of words of a target language into the source language.
- **CL-SCL** (Prettenhofer and Stein, 2010) learns a shared cross-lingual feature space with cross-lingual structural correspondence learning.
- **CL-RL** (Xiao and Guo, 2013) learns cross-lingual representation learning, where part of the word vector is shared among languages.
- **BWE** (Upadhyay et al., 2018) bridges the language gap with Bilingual Word Embedding and weight sharing. We use the unsupervised MUSE (Conneau et al., 2018a) BWE.
- **MAN-MoE** (Chen et al., 2019) exploits both language-invariant and language-specific features with multinomial adversarial training and mixture-of-experts, respectively.

Results Based on the results in Table 1, we can summarize the following observations:

- The MGL achieves the best results on most transfer pairs, significantly outperforming the best baseline Reptile by 1.84% accuracy on average. Our model exceeds the translation-based methods MT-BOW, CL-SCL, and CL-RL by 5.36%, 4.81% and 5.25% accuracy on average, respectively. Without additional translation resources, the embedding-based method BWE shows significant performance degradation. Though MAN-MoE attempts to fully identify both invariant and specific language features, it can only achieve competitive results with translation-based methods. This proves that language correspondences play a critical role in minimizing language gaps. However, obtaining general-purpose alignment usually relies on off-the-shelf translators, e.g., *Google Translate*, making them inflexible and unscalable to the big data.
- Our method achieves 2.40%, 2.96%, and 2.10% average accuracy gains over mBERT with common adaption approaches, i.e., Mix, Multi-task, and Fine-tune, respectively. These methods ignore task-aware adaptation for low-resource target languages and perform poorly for the adaptation between distant languages. On the contrary, our method can effectively alleviate the language gaps by meta-learning previous CLT knowledge.
- Though combining the strengths of both mBERT and meta learning, Reptile can only achieve marginal improvements over common adaptation methods since language heterogeneity hinders the effectiveness of this gradient-based meta learner to adapt across different languages. Differently, our model can alleviate the issue by learning meta graphs over languages to reduce the gaps between them.

5.2 Cross-lingual Relevance Classification

Dataset The task aims to determine the binary relevance label (relevant or irrelevant) of a pair of user search query and product title. We use a large-scale multilingual search relevance dataset (Ahuja

et al., 2020), which arises from 5 languages: French (**FR**), Spanish (**ES**), Italian (**IT**), English (**EN**) and German (**DE**). The human-annotated query-product pairs are sampled from the search results from each of the above country-specific services of an E-commerce search engine. The annotators return a binary label that indicates the relevance of the product item to the query.

Setting We use the same setting as described in Section 5.1. Considering the imbalance of the dataset, we use Precision (P), Recall (R), and F1 score as the evaluation metrics.

Baselines Additionally, we compare with the start-of-the-art baseline **LAPS** (Ahuja et al., 2020), which relies on external task-specific cross-lingual parallel data (Ahuja et al., 2020), i.e., product-to-product and query-to-query correspondences among all 5 languages.

Results Based on the results in Table 2, we can summarize the following observations:

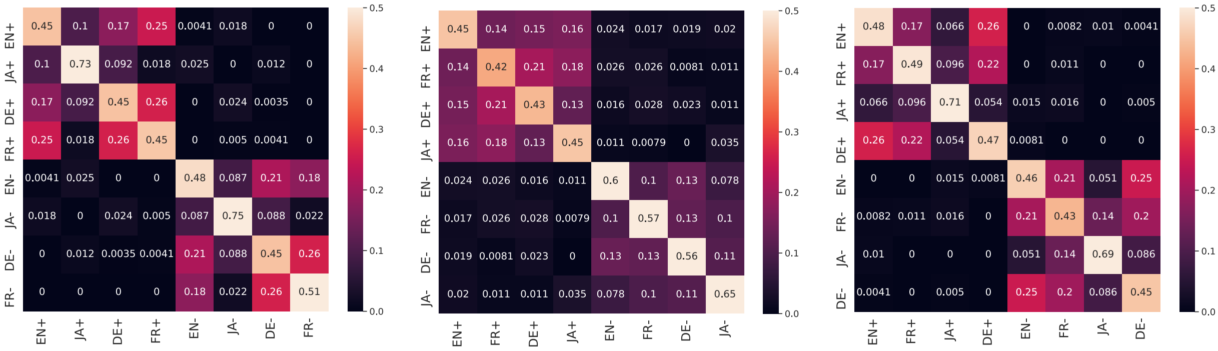
- For the imbalanced industrial dataset with more noises, the MGL method consistently achieves the best results for all pairs, significantly exceeding the best baseline Reptile by 1.23% F1 score on average. The efficacy of the LAPS comes from task-specific parallel data, which is usually difficult to obtain in practice. Without any aid of task-specific resources, our MGL method can still achieve a large gain of 4.61% average F1 score by adapting general mPLM with task-aware meta-knowledge for CLT tasks.
- Compared with mBERT-based methods, we can also obtain consistent observations as on the Amazon dataset. Even with the power of mBERT, common adaptation approaches still cannot handle the low-resource target language. Reptile cannot compete against our MGL method due to its meta-knowledge learned from each separate language.

5.3 Ablation Study

To verify the efficacy of each component, we compare MGL with its ablation variants in Table 3.

No Meta v.s. **Meta** For MGL w/o Meta, we directly learn the dynamic graphs with GCN for cross-lingual transfer without any meta process, i.e., no Meta-train stage. MGL exceeds MGL w/o Meta by 2.84% accuracy on average. This proves that simply adding a GCN cannot work well. Without leveraging historical CLT experiences, the dynamic graphs cannot learn a robust cross-lingual metric space that facilitates knowledge propagation to the target low-resource language.

No L2CLT v.s. **L2CLT** For MGL w/o L2CLT, we treat each language as one task like Reptile and change to sample the support set and query set from the same language for each task. As such, this MGL variant solely uses the dynamic graphs to meta-learn knowledge from each language. MGL can outperform MGL w/o L2CLT by 1.46% accuracy on average, especially obtaining more gains for distant language **JA**. The reason is that



(a) **EN+JA+DE→FR** (b) **EN+FR+DE→JA** (c) **EN+FR+JA→DE**

Figure 4: Visualization of meta graphs for different pairs of the *Music* domain on the multilingual Amazon review dataset. $+$ and $-$ denote positive and negative classes, respectively. Brighter colors denote higher correlations.

previous CLT experiences can benefit MGL to transfer across heterogeneous languages in a new target one. For example, for the hard {**EN, FR, DE**}→**JA**, MGL will learn the transfer skill from the comparatively distant source CLT pair: Germanic languages[1] {**EN, DE**} to Romance languages[1] **FR** for Meta-train, and then leverage the skill to rapidly adapt the meta graphs to transfer from {**EN, FR, DE**} to **JA** for Meta-test.

No σ v.s. σ For MGL w/o σ, we remove the scale factor σ in Eq. 2 that controls the learnability of the metric function. MGL outperforms MGL w/o σ by 0.77% average accuracy. This demonstrates that an learnable metric distance function can be more adaptive to measure intrinsic relations among different languages and improve the transferability of the meta graphs.

The number of GCN layers MGL consists of a multi-layer GCN to progressively propagate information across languages over the meta graphs. Multiple GCN layers are necessary to distill more latent propagation patterns. As we can see, increasing the number of GCN layers from 1 to 2 (default) shows significant improvements. However, when further increasing the number of layers to 3 and 4, the performances will be degraded. A possible reason is that more layers may bring in more noises from higher-order neighborhoods in the meta graphs, causing negative transfer.

5.4 Visualization of Meta Graph

To demonstrate that the MGL can automatically capture latent correlations among languages, we perform visualization of the meta graphs on the Amazon review dataset. We visualize the meta graph, i.e., the dynamic normalized symmetric adjacency matrix $\tilde{\mathbf{A}}$ as defined in Eq. 4. For each pair, we only randomly sample one instance for each class of each language, which constitutes a meta graph $\tilde{\mathbf{A}} \in \mathbb{R}^{8\times 8}$ on the Meta-test stage. And we set the number of the neighborhoods for the K-nearest graph to be 2. To be more convincing, we calculate the averaged meta graph obtained by averaging the accumulated meta graphs over a random sampling of 100 times.

First, as shown in Figure 4-(a), we transfer from {**EN, JA, DE**} to **FR**, our model can capture stronger connections from **FR** to {**EN, DE**} than **FR** to **JA**. This is reasonable since {**EN, DE, FR**} all belong to Indo-European languages[1], which are very dissimilar to **JA**. Second, when transferring from {**EN, FR, JA**} to **DE** as shown in Figure 4-(c), **DE** behaves more correlative to **EN** than to **FR**. The possible reason may be that **EN** and **DE** are both Germanic languages, while **FR** belongs to Romance languages[1]. Finally, in Figure 4-(b), when there exists a large gap between the source and target languages, all source languages {**EN, FR, DE**} have weak correlations with **JA**, and thus the results on the target language **JA** (77.73%) are usually worse than the target language **FR** (84.07%) or **DE** (82.18%) on average. This proves that our model can automatically exploit language relations with learnable graph structures to make task-aware adaptation more interpretable.

5.5 Target Labeled Proportion

We vary the labeled proportion of the target language's training set and compare MGL with Reptile, Mix, Multi-task, and Fine-tune based on

---

[1] `https://simple.wikipedia.org/wiki/Language_family`

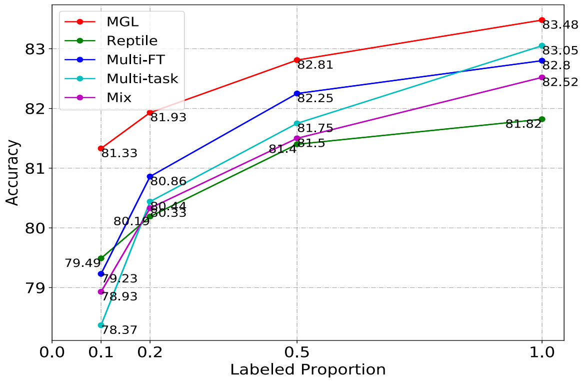


Figure 5: Averaged results w.r.t proportions of the target training data on the Amazon review dataset.

mBERT. We use averaged accuracy on the multilingual Amazon review dataset and change the labeled proportion from 0.1, 0.2, 0.5 to 1.0. As shown in Figure 5, the gap between the MGL and common adaptation methods grows as the training size shrinks, verifying that the MGL is more robust to the drop in the labeled size for the target language. Reptile shows marginal improvements over common adaptation methods and performs worse as the training size grows. This demonstrates that roughly incorporating existing meta learning algorithms into the CLT problem may not work well.

6 Implementation details

Encoder We use the *bert-base-multilingual-cased*[2] model pre-trained on 104 languages as the encoder, which has 12 layers, 768-d hidden size, 12 heads and 110M total parameters. The mBERT is jointly optimized with other parameters during both the Meta-train and Meta-test stages.

Training & Validation & Testing set For each cross-lingual transfer experiment, during the Meta-train stage, its training set is the combination of the training data of the source languages. Meanwhile, it employs the combination of validation data of the source languages as the validation set. As for the Meta-test stage, the training set is the combination of the training data of all languages. The validation data and testing data of the target language will be used for the validation and final evaluation, respectively.

Initialization & Training For all the experiments, the model is optimized by the Adam algorithm (Kingma and Ba, 2014) for training. The weight matrices are initialized with a uniform distribution $U(-0.01, 0.01)$. Gradients with the ℓ_2 norm larger than 40 are normalized to be 40. To alleviate overfitting, we apply the dropout on the node representations of the first GCN layer with the dropout rate 0.5. We also perform early stopping on the validation set during both the Meta-train and Meta-test stages.

Hyper-parameter	Dataset	
	Amazon Review	Search Relevance
dim_0, dim_1	768, 768	768, 768

learning rate	10^{-5}	10^{-5}

Table 4: Settings of hyper-parameters.

Hyperparameter For the multilingual Amazon review dataset, we use the same hyper-parameters, which are manually tuned on 10% randomly held-out training data of the source languages in **EN+FR+DE→JA** on the *Book* domain, for all cross-lingual transfer experiments. As for the multilingual search relevance dataset, the hyper-parameters are manually tuned on 10% randomly held-out training data of the source languages in **ES+IT+EN+DE→FR** and fixed to be used in all cross-lingual experiments. The detailed hyperparameters for the two datasets are listed in Table 4.

7 Conclusion and Future Works

In this paper, we propose a novel MGL method for task-aware CLT adaptation of mPLM by leveraging historical CLT experiences. Extensive evaluations on both the public benchmark and large-scale industrial dataset quantitively and qualitatively demonstrate the effectiveness of the MGL. In the future, the proposed MGL method can potentially applied to more cross-lingual natural language understanding (XLU) tasks (Conneau et al., 2018b; Wang et al., 2019; Lewis et al., 2019; Karthikeyan et al., 2020), and be generalized to learn to learn for domain adaptation (Blitzer et al., 2007), representation learning (Shen et al., 2018), multi-task learning (Shen et al., 2019) problems, etc.

UDapter: Language Adaptation for Truly Universal Dependency Parsing

Ahmet Üstün **Arianna Bisazza** **Gosse Bouma** **Gertjan van Noord**

Abstract

Recent advances in multilingual dependency parsing have brought the idea of a truly universal parser closer to reality. However, cross-language interference and restrained model capacity remain major obstacles. To address this, we propose a novel multilingual task adaptation approach based on *contextual parameter generation* and *adapter modules*. This approach enables to learn adapters via language embeddings while sharing model parameters across languages. It also allows for an easy but effective integration of existing *linguistic typology features* into the parsing network. The resulting parser, UDapter, outperforms strong monolingual and multilingual baselines on the majority of *both* high-resource and low-resource (zero-shot) languages, showing the success of the proposed adaptation approach. Our in-depth analyses show that soft parameter sharing via typological features is key to this success.[1]

1 Introduction

Monolingual training of a dependency parser has been successful when relatively large treebanks are available (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2017). However, for many languages, treebanks are either too small or unavailable. Therefore, multilingual models leveraging Universal Dependency annotations (Nivre et al., 2018) have drawn serious attention (Zhang and Barzilay, 2015; Ammar et al., 2016; de Lhoneux et al., 2018; Kondratyuk and Straka, 2019). Multilingual approaches learn generalizations across languages and share information between them, making it possible to parse a target language without supervision in that language. Moreover, multilingual models can be faster to train and easier to maintain than a large set of monolingual models.

However, scaling a multilingual model over a high number of languages can lead to sub-optimal results, especially if the training languages are typologically diverse. Often, multilingual neural models have been found to outperform their monolingual counterparts on low- and zero-resource languages due to positive transfer effects, but underperform for high-resource languages (Johnson et al., 2017; Arivazhagan et al., 2019; Conneau et al., 2020), a problem also known as "the curse of multilinguality". Generally speaking, a multilingual model without language-specific supervision is likely to suffer from over-generalization and perform poorly on high-resource languages due to limited capacity compared to the monolingual baselines, as verified by our experiments on parsing.

In this paper, we strike a good balance between maximum sharing and language-specific capacity in multilingual dependency parsing. Inspired by recently introduced parameter sharing techniques (Platanios et al., 2018; Houlsby et al., 2019), we propose a new multilingual parser, UDapter, that learns to modify its language-specific parameters including the adapter modules, as a function of language embeddings. This allows the model to share parameters across languages, ensuring generalization and transfer ability, but also enables language-specific parameterization in a single multilingual model. Furthermore, we propose not to learn language embeddings from scratch, but to leverage a mix of linguistically curated and predicted typological features as obtained from the URIEL language typology database (Littell et al., 2017) which supports 3718 languages including all languages represented in UD. While the importance of typological features for cross-lingual parsing is known for both non-neural (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015) and neural approaches (Ammar et al., 2016; Scholivet et al., 2019), we are the first to use them

---

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2302–2315,
November 16–20, 2020.

effectively as direct input to a neural parser, without manual selection, over a large number of languages in the context of zero-shot parsing where gold POS labels are not given at test time. In our model, typological features are crucial, leading to a substantial LAS increase on zero-shot languages and no loss on high-resource languages when compared to the language embeddings learned from scratch.

We train and test our model on the 13 syntactically diverse high-resource languages that were used by Kulmizev et al. (2019), and also evaluate it on 30 genuinely low-resource languages. Results show that UDapter significantly outperforms state-of-the-art monolingual (Straka, 2018) and multilingual (Kondratyuk and Straka, 2019) parsers on most high-resource languages and achieves overall promising improvements on zero-shot languages.

Contributions We conduct several experiments on a large set of languages and perform thorough analyses of our model. Accordingly, we make the following contributions: 1) We apply the idea of adapter tuning (Rebuffi et al., 2018; Houlsby et al., 2019) to the task of universal dependency parsing. 2) We combine adapters with the idea of contextual parameter generation (Platanios et al., 2018), leading to a novel language adaptation approach with state-of-the art UD parsing results. 3) We provide a simple but effective method for conditioning the language adaptation on existing typological language features, which we show is crucial for zero-shot performance.

2 Previous Work

This section presents the background of our approach.

Multilingual Neural Networks Early models in multilingual neural machine translation (NMT) designed dedicated architectures (Dong et al., 2015; Firat et al., 2016) whilst subsequent models, from Johnson et al. (2017) onward, added a simple language identifier to the models with the same architecture as their monolingual counterparts. More recently, multilingual NMT models have focused on maximizing transfer accuracy for low-resource language pairs, while preserving high-resource language accuracy (Platanios et al., 2018; Neubig and Hu, 2018; Aharoni et al., 2019; Arivazhagan et al., 2019), known as the (positive) transfer - (negative) interference trade-off. Another line of work builds massively multilingual pre-trained language models to produce contextual representation to be used in downstream tasks (Devlin et al., 2019; Conneau et al., 2020). As the leading model, multilingual BERT (mBERT)[2] (Devlin et al., 2019) which is a deep self-attention network, was trained without language-specific signals on the 104 languages with the largest Wikipedias. It uses a shared vocabulary of 110K WordPieces (Wu et al., 2016), and has been shown to facilitate cross-lingual transfer in several applications (Pires et al., 2019; Wu and Dredze, 2019). Concurrently to our work, Pfeiffer et al. (2020) have proposed to combine language and task adapters, small bottleneck layers (Rebuffi et al., 2018; Houlsby et al., 2019), to address the capacity issue which limits multilingual pre-trained models for cross-lingual transfer.

Cross-Lingual Dependency Parsing The availability of consistent dependency treebanks in many languages (McDonald et al., 2013; Nivre et al., 2018) has provided an opportunity for the study of cross-lingual parsing. Early studies trained a delexicalized parser (Zeman and Resnik, 2008; McDonald et al., 2013) on one or more source languages by using either gold or predicted POS labels (Tiedemann, 2015) and applied it to target languages. Building on this, later work used additional features such as typological language properties (Naseem et al., 2012), syntactic embeddings (Duong et al., 2015), and cross-lingual word clusters (Täckström et al., 2012). Among lexicalized approaches, Vilares et al. (2016) learns a bilingual parser on a corpora obtained by merging harmonized treebanks. Ammar et al. (2016) trains a multilingual parser using multilingual word embeddings, token-level language information, language typology features and fine-grained POS tags. More recently, based on mBERT (Devlin et al., 2019), zero-shot transfer in dependency parsing was investigated (Wu and Dredze, 2019; Tran and Bisazza, 2019). Finally Kondratyuk and Straka (2019) trained a multilingual parser on the concatenation of all available UD treebanks.

Language Embeddings and Typology Conditioning a multilingual model on the input language is studied in NMT (Ha et al., 2016; Johnson et al., 2017), syntactic parsing (Ammar et al., 2016) and language modeling (Östling and Tiedemann, 2017). The goal is to embed language information in real-

---

[2] `https://github.com/google-research/bert/blob/master/multilingual.md`

valued vectors in order to enrich internal representations with input language for multilingual models. In dependency parsing, several previous studies (Naseem et al., 2012; Täckström et al., 2013; Zhang and Barzilay, 2015; Ammar et al., 2016; Scholivet et al., 2019) have suggested that typological features are useful for the selective sharing of transfer information. Results, however, are mixed and often limited to a handful of manually selected features (Fisch et al., 2019; Ponti et al., 2019). As the most similar work to ours, Ammar et al. (2016) uses typological features to learn language embeddings as part of training, by augmenting each input token and parsing action representation. Unfortunately though, this technique is found to underperform the simple use of randomly initialized language embeddings ('language IDs'). Authors also reported that language embeddings hurt the performance of the parser in zero-shot experiments (Ammar et al., 2016, *footnote 30*). Our work instead demonstrates that typological features can be very effective if used with the right adaptation strategy in both supervised and zero-shot settings. Finally, Lin et al. (2019) use typological features, along with properties of the training data, to choose optimal transfer languages for various tasks, including UD parsing, in a hard manner. By contrast, we focus on a *soft* parameter sharing approach to maximize generalizations within a single universal model.

3 Proposed Model

In this section, we present our truly universal dependency parser, UDapter. UDapter consists of a biaffine attention layer stacked on top of the pretrained Transformer encoder (mBERT). This is similar to (Wu and Dredze, 2019; Kondratyuk and Straka, 2019), except that our mBERT layers are interleaved with special adapter layers inspired by Houlsby et al. (2019). While mBERT weights are frozen, biaffine attention and adapter layer weights are generated by a contextual parameter generator (Platanios et al., 2018) that takes a language embedding as input and is updated while training on the treebanks.

Note that the proposed adaptation approach is not restricted to dependency parsing and is in principle applicable to a range of multilingual NLP tasks. We will now describe the components of our model.

3.1 Biaffine Attention Parser

The top layer of UDapter is a graph-based biaffine attention parser proposed by Dozat and Manning (2017). In this model, an encoder generates an internal representation $\mathbf{r}_i$ for each word; the decoder takes $\mathbf{r}_i$ and passes it through separate feedforward layers (MLP), and finally uses deep biaffine attention to score arcs connecting a head and a tail:

$$\mathbf{h}_i^{(\text{head})} = \texttt{MLP}^{(\text{head})}(\mathbf{r}_i) \quad (1)$$

$$\mathbf{h}_i^{(\text{tail})} = \texttt{MLP}^{(\text{tail})}(\mathbf{r}_i) \quad (2)$$

$$\mathbf{s}^{(\text{arc})} = \texttt{Biaffine}(\mathbf{H}^{(\text{head})}, \mathbf{H}^{(\text{tail})}) \quad (3)$$

Similarly, label scores are calculated by using a biaffine classifier over two separate feedforward layers. Finally, the Chu-Liu/Edmonds algorithm (Chu, 1965; Edmonds, 1967) is used to find the highest scoring valid dependency tree.

3.2 Transformer Encoder with Adapters

To obtain contextualized word representations, UDapter uses mBERT. For a token i in sentence S, BERT builds an input representation $\mathbf{w}_i$ composed by summing a WordPiece embedding x_i (Wu et al., 2016) and a position embedding f_i. Each $\mathbf{w}_i \in S$ is then passed to a stacked self-attention layers (SA) to generate the final encoder representation $\mathbf{r}_i$:

$$\mathbf{w}_i = \mathrm{x}_i + \mathrm{f}_i \quad (4)$$

$$\mathbf{r}_i = \texttt{SA}\,(\mathbf{w}_i\,;\Theta^{(\text{ad})}) \quad (5)$$

where $\Theta^{(\text{ad})}$ denotes the adapter modules. During training, instead of fine-tuning the whole encoder network together with the task-specific top layer, we use adapter modules (Rebuffi et al., 2018; Stickland and Murray, 2019; Houlsby et al., 2019), or simply *adapters*, to capture both task-specific and language-specific information. Adapters are small modules added between layers of a pre-trained network. In adapter tuning, the weights of the original network are kept frozen, whilst the adapters are trained for a downstream task. Tuning with adapters was mainly suggested for parameter efficiency but they also act as an information module for the task or the language to be adapted (Pfeiffer et al., 2020). In this way, the original network serves as a memory for the language(s). In UDapter, following Houlsby et al. (2019), two bottleneck adapters with two feedforward projections and a GELU nonlinearity (Hendrycks and Gimpel, 2016) are inserted into each transformer layer as shown in

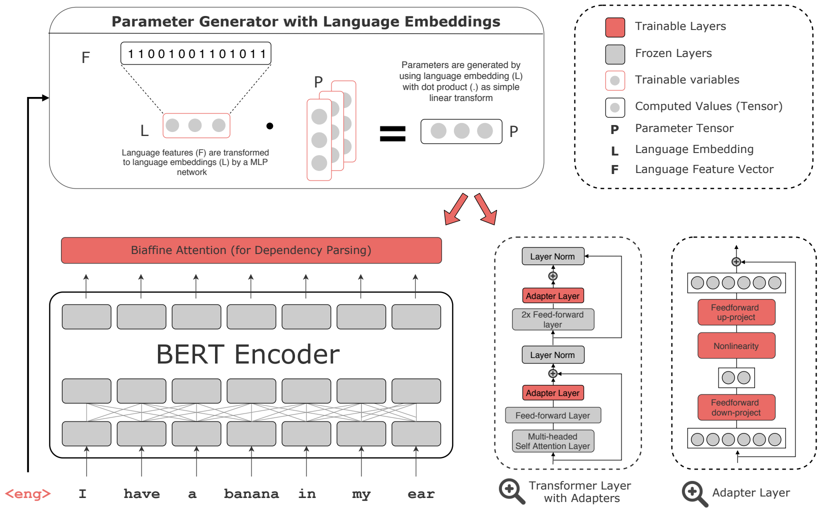

Figure 1: UDapter architecture with contextual parameter generator (CPG) and adapter layers. CPG takes languages embeddings projected from typological features as input and generates parameters of adapter layers and biaffine attention.

Figure 1. We apply adapter tuning for two reasons: 1) Each adapter module consists of only few parameters and allows to use contextual parameter generation (CPG; see § 3.3) with a reasonable number of trainable parameters.[3] 2) Adapters enable task-specific as well as language-specific adaptation via CPG since it keeps backbone multilingual representations as memory for all languages in pre-training, which is important for multilingual transfer.

3.3 Contextual Parameter Generator

To control the amount of sharing across languages, we generate trainable parameters of the model using a contextual parameter generator (CPG) function inspired by Platanios et al. (2018). CPG enables UDapter to retain high multilingual quality without losing performance on a single language, during multi-language training. We define CPG as a function of language embeddings. Since we only train adapters and the biaffine attention (i.e. adapter tuning), the parameter generator is formalized as $\{\theta^{(ad)}, \theta^{(bf)}\} \triangleq g^{(m)}(\mathbf{l}_e)$ where $g^{(m)}$ denotes the parameter generator with language embedding $\mathbf{l}_e$, and $\theta^{(ad)}$ and $\theta^{(bf)}$ denote the parameters of adapters and biaffine attention respectively. We implement CPG as a simple linear transform of a language embedding, similar to Platanios et al. (2018), so that weights of adapters in the encoder and biaffine attention are generated by the dot product of language embeddings:

$$g^{(m)}(\mathbf{l}_e) = (\mathbf{W}^{(\mathrm{ad})}, \mathbf{W}^{(\mathrm{bf})}) \cdot \mathbf{l}_e \tag{6}$$

where $\mathbf{l}_e \in \mathbb{R}^{\mathrm{M}}$, $\mathbf{W}^{(\mathrm{ad})} \in \mathbb{R}^{\mathbf{P}^{(\mathrm{ad})} \times \mathrm{M}}$, $\mathbf{W}^{(\mathrm{bf})} \in \mathbb{R}^{\mathbf{P}^{(\mathrm{bf})} \times \mathrm{M}}$, M is the language embedding size, $\mathbf{P}^{(\mathrm{ad})}$ and $\mathbf{P}^{(\mathrm{bf})}$ are the number of parameters for adapters and biaffine attention respectively.[4] An important advantage of CPG is the easy integration of existing task or language features.

3.4 Typology-Based Language Embeddings

Soft sharing via CPG enables our model to modify its parsing decisions depending on a language embedding. While this allows UDapter to perform well on the languages in training, even if they are typologically diverse, information sharing is still a problem for languages not seen during training (zero-shot learning) as a language embedding is not available. Inspired by Naseem et al. (2012) and Ammar et al. (2016), we address this problem by defining language embeddings as a function of a large set of language typological features, including syntactic and phonological features. We use a multi-layer perceptron $\mathtt{MLP}^{(\mathrm{lang})}$ with two feed-forward layers and a $\mathtt{ReLU}$ nonlinear activation to compute a language embedding $\mathbf{l}_e$:

$$\mathbf{l}_e = \mathtt{MLP}^{(\mathrm{lang})}(\mathbf{l}_t) \tag{7}$$

where $\mathbf{l}_t$ is a typological feature vector for a language consisting of **all** 103 syntactic, 28 phonological and 158 phonetic inventory features from the URIEL language typology database (Littell et al., 2017). URIEL is a collection of binary features

---

[3] Due to CPG, the number of adapter parameters is multiplied by language embedding size, resulting in a larger model compared to the baseline (more details in Appendix A.1).

[4] Platanios et al. (2018) also suggest to apply *parameter grouping*. We have not tried that yet, but one may learn separate low-rank projections of language embeddings for the adapter parameters group and the biaffine parameters group.

Table 2: Labelled attachment scores (LAS) on a subset of 30 low-resource languages. Languages with '*' are not included in mBERT training corpus. (Results for all low-resource languages, together with the chosen proxy, are given in Appendix A.2.)

extracted from multiple typological and phylogenetic databases such as WALS (World Atlas of Language Structures) (Dryer and Haspelmath, 2013), PHOIBLE (Moran and McCloy, 2019), Ethnologue (Lewis et al., 2015) and Glottolog (Hammarström et al., 2020). As many feature values are not available for each language, we use the values predicted by Littell et al. (2017) using a k-nearest neighbors approach based on average of genetic, geographical and feature distances between languages.

4 Experiments

Data and Training Details For our training languages, we follow Kulmizev et al. (2019), who selected from UD 2.3 (Nivre et al., 2018) 13 treebanks "from different language families, with different morphological complexity, scripts, character set sizes, training sizes, domains, and with good annotation quality" (see codes in Table 1).[5] During training, a language identifier is added to each sentence, and gold word segmentation is provided. We test our models on the training languages (*high-resource* set), and on 30 languages that have no or very little training data (*low-resource* set) in a zero-shot setup, i.e, without any training data.[6] The detailed treebank list is provided in Appendix A.3. For evaluation, the official CoNLL 2018 Shared Task script[7] is used to obtain LAS scores on the test set of each treebank.

For the encoder, we use *BERT-multilingual-cased* together with its WordPiece tokenizer. Since dependency annotations are between words, we pass the BERT output corresponding to the first wordpiece per word to the biaffine parser. We apply the same hyper-parameter settings as Kondratyuk and Straka (2019). Additionally, we use 256 and 32 for adapter size and language embedding size respectively. In our approach, pre-trained BERT weights are frozen, and only adapters and biaffine attention are trained, thus we use the same learning rate for the whole network by applying an inverse square root learning rate decay with linear warm-up (Howard and Ruder, 2018). Appendix A.1 gives the hyper-parameter details.

Baselines We compare UDapter to the current state of the art in UD parsing: [1] UUparser+BERT (Kulmizev et al., 2019), a graph-based BLSTM

---

[5] To reduce training time we cap the very large Russian Syntagrus treebank (48K sentences) to a random 15K sample.

[6] For this reason, the terms 'zero-shot' and 'low-resource' are used interchangeably in this paper.

[7] `https://universaldependencies.org/conll18/evaluation.html`

parser (de Lhoneux et al., 2017; Smith et al., 2018) using mBERT embeddings as additional features. [2] UDpipe (Straka, 2018), a monolingually trained multi-task parser that uses pretrained word embeddings and character representations. [3] UDify (Kondratyuk and Straka, 2019), the mBERT-based multi-task UD parser on which our UDapter is based, but originally trained on *all* language treebanks from UD. UDPipe scores are taken from Kondratyuk and Straka (2019).

To enable a direct comparison, we also re-train UDify on our set of 13 high-resource languages both monolingually (one treebank at a time; *mono-udify*) and multilingually (on the concatenation of languages; *multi-udify*). Finally, we evaluate two variants of our model: 1) Adapter-only has only task-specific adapter modules and no language-specific adaptation, i.e. no contextual parameter generator; and 2) UDapter-proxy is trained without typology features: a separate language embedding is learnt from scratch for each in-training language, and for low-resource languages we use one from the same language family, if available, as proxy representation.

Importantly, all baselines are either trained for a single language, or multilingually without any language-specific adaptation. By comparing UDapter to these parsers, we highlight its unique character that enables language specific parameterization by typological features within a multilingual framework for both supervised and zero-shot learning setup.

4.1 Results

Overall, UDapter outperforms the monolingual and multilingual baselines on both high-resource and zero-shot languages. Below, we elaborate on the detailed results.

High-resource Languages Labelled Attachement Scores (LAS) on the *high-resource* set are given in Table 1. UDapter consistently outperforms both our monolingual and multilingual baselines in all languages, and beats the previous work, setting a new state of the art, in 9 out of 13 languages. Statistical significance testing[8] applied between UDapter and *multi/mono-udify* confirms that UDapter's performance is significantly better than the baselines in 11 out of 13 languages (all except *en* and *it*).

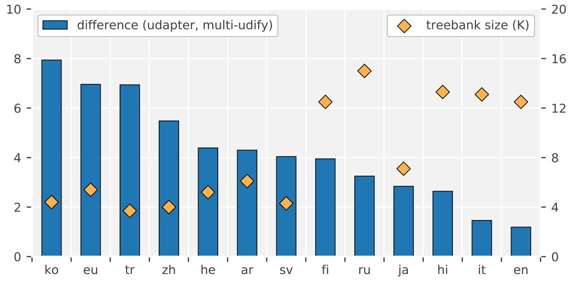

Figure 2: Difference in LAS between UDapter and multi-udify in the high-resource setting. Diamonds indicate the amount of sentences in the corresponding treebank.

Among directly comparable baselines, *multi-udify* gives the worst performance in the typologically diverse high-resource setting. This multilingual model is clearly worse than its monolingually trained counterparts *mono-udify*: 83.0 *vs* 86.0. This result resounds with previous findings in multilingual NMT (Arivazhagan et al., 2019) and highlights the importance of language adaptation even when using high-quality sentence representations like those produced by mBERT.

To understand the relevance of adapters, we also evaluate a model which has almost the same architecture as multi-udify except for the adapter modules and the tuning choice (frozen mBERT weights). Interestingly, this adapter-only model considerably outperforms multi-udify (85.0 *vs* 83.0), indicating that adapter modules are also effective in multilingual scenarios.

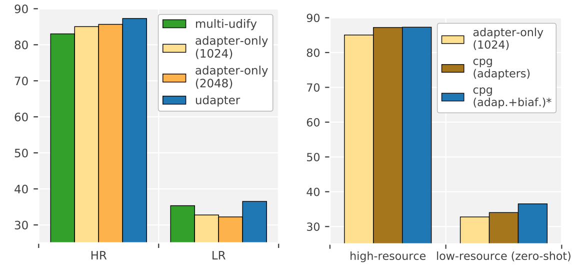
Finally, UDapter achieves the overall best results, with consistent gains over both *multi-udify* and *adapter-only*, showing the importance of linguistically informed adaptation even for in-training languages.

Low-Resource Languages Average LAS on the 30 low-resource languages are shown in column *lr-avg* of Table 1. Overall, UDapter slightly outperforms the multi-udify baseline (36.5 *vs* 36.3), which shows the benefits of our approach on both in-training and zero-shot languages. For a closer look, Table 2 provides individual results for the 18 representative languages in our low-resource set. Here we find a mixed picture: UDapter outperforms multi-udify on 13 out of 18 languages[9]. Achieving improvements in the zero-shot parsing

---

[8] We used *paired bootstrap resampling* to check whether the difference between two models is significant ($p < 0.05$) by using Udapi (Popel et al., 2017).

[9] LAS scores for all 30 languages are given in Appendix A.2. By significance testing, UDapter is *significantly* better than multi-udify on 16/30 low-resource languages, which is shown in Table 4



(a) (b)

Figure 3: Impact of different UDapter components on parsing performance (LAS): (a) adapters and adapter layer size, (b) application of contextual parameter generation to different portions of the network. In (b) the model named 'cpg (adap.+biaf.)' coincides with the full UDapter.

setup is very difficult, thus we believe this result is an important step towards overcoming the problem of positive/negative transfer trade-off.

Indeed, UDapter-proxy results show that choosing a *proxy* language embedding from the same language family underperforms UDapter, apart from not being available for many languages. This indicates the importance of typological features in our approach (see § 5.2 for further analysis).

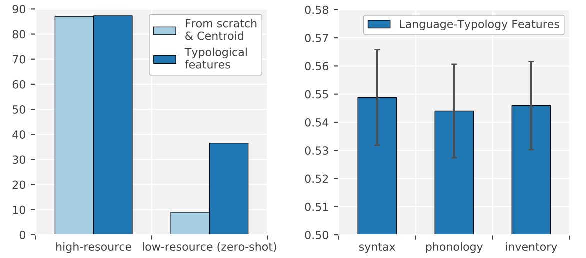
5 Analysis

In this section, we further analyse UDapter to understand its impact on different languages, and the importance of its various components.

5.1 Which languages improve most?

Figure 2 presents the LAS gain of UDapter over the multi-udify baseline for each high-resource language along with the respective treebank training size. To summarize, the gains are higher for languages with less training data. This suggests that in UDapter, useful knowledge is shared among in-training languages, which benefits low resource languages without hurting high resource ones.

For zero-shot languages, the difference between the two models is small compared to high-resource languages (+1.2 LAS). While it is harder to find a trend here, we notice that UDapter is typically beneficial for the languages *not* present in the mBERT training corpus: it outperforms multi-udify in 13 out of 22 (non-mBERT) languages. This suggests that typological feature-based adaptation leads to improved sentence representations when the pre-trained encoder has not been exposed to a language.



(a) (b)

Figure 4: (a) Impact of language typology features on parsing performance (LAS). (b) Average of normalized feature weights obtained from linear projection layer of the language embedding network.

5.2 How much gain from typology?

UDapter learns language embeddings from syntactic, phonological and phonetic inventory features. A natural alternative to this choice is to learn language embeddings from scratch. For a comparison, we train a model where, for each in-training language, a separate language embedding (of the same size: 32) is initialized randomly and learned end-to-end. For the zero-shot languages we use the average, or centroid, of all in-training language embeddings. As shown in Figure 4a, on the high-resource set, the models with and without typological features achieve very similar average LAS (87.3 and 87.1 respectively). On zero-shot languages, however, the use of centroid embedding performs very poorly: 9.0 *vs* 36.5 average LAS score over 30 languages. As already discussed in § 4.1 (Table 2), using a proxy language embedding belonging to the same family as the test language, when available, also clearly underperforms UDapter.

These results confirm our expectation that a model can learn reliable language embeddings for in-training languages, however typological signals are required to obtain a robust parsing quality on zero-shot languages.

5.3 How does UDapter represent languages?

We start by analyzing the projection weights assigned to different typological features by the first layer of the language embedding network (see eq. 7). Figure 4b shows the averages of normalized syntactic, phonological and phonetic inventory feature weights. Although dependency parsing is a syntactic task, the network does not only utilize syntactic features, as also observed by Lin et al. (2019), but exploits all available typological features to learn its representations.

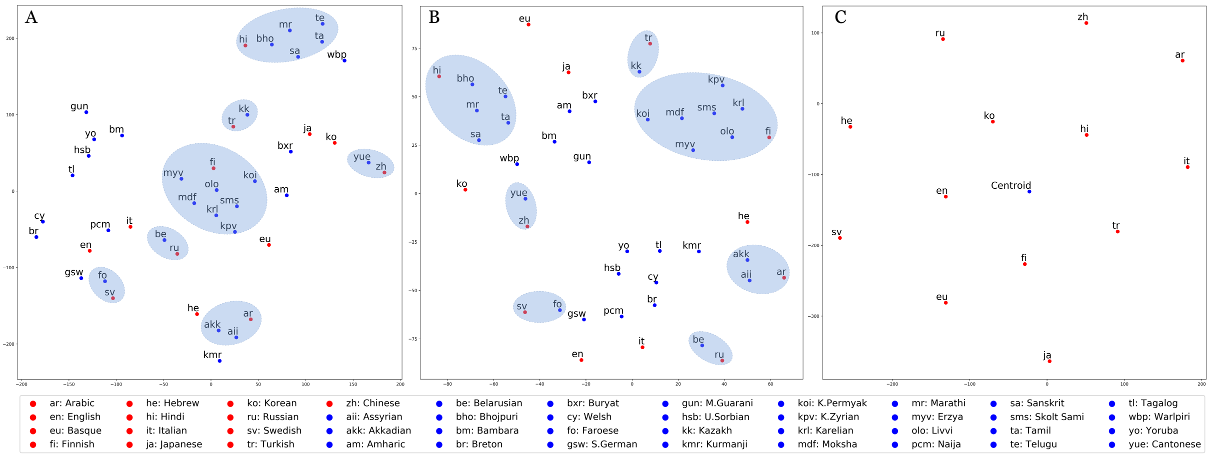


Figure 5: Vector spaces for (A) language-typology feature vectors taken from URIEL, (B) language embeddings learned from typological features by UDapter, and (C) language embeddings learned without typological features. High- and low-resource languages are indicated by red and blue dots respectively. Highlighted clusters in A and B denote sets of genetically related languages.

Next, we plot the language representations learned in UDapter by using t-SNE (van der Maaten and Hinton, 2008), which is similar to the analysis carried out by Ponti et al. (2019, figure 8) using the language vectors learned by Malaviya et al. (2017). Figure 5 illustrates 2D vector spaces generated for the typological feature vectors $\mathbf{l}_t$ (**A**) and the language embeddings $\mathbf{l}_e$ learned by UDapter with or without typological features (**B** and **C** respectively). The benefits of using typological features can be understood by comparing **A** and **B**: During training, UDapter learns to project URIEL features to language embeddings in a way that is optimal for in-training language parsing quality. This leads to a different placement of the high-resource languages (red points) in the space, where many linguistic similarities are preserved (e.g. Hebrew and Arabic; European languages except Basque) but others are overruled (Japanese drifting away from Korean). Looking at the low-resource languages (blue points) we find that typologically similar languages tend to have similar embeddings to the closest high-resource language in both **A** and **B**. In fact, most groupings of genetically related languages, such as the Indian languages (*hi*-cluster) or the Uralic ones (*fi*-cluster) are largely preserved across these two spaces.

Comparing **B** and **C** where language embeddings are learned from scratch, the absence of typological features leads to a seemingly random space with no linguistic similarities (e.g. Arabic far away from Hebrew, Korean closer to English than to Japanese, etc.) and, therefore, no principled way to represent additional languages.

Taken together with the parsing results of § 4.1, these plots suggest that UDapter embeddings strike a good balance between a linguistically motivated representation space and one solely optimized for in-training language accuracy.

5.4 Is CPG really essential?

In section 4.1 we observed that adapter tuning alone (that is, without CPG) improved the multilingual baseline in the high-resource languages, but worsened it considerably in the zero-shot setup. By contrast, the addition of CPG with typological features led to the best results over all languages. But could we have obtained similar results by simply increasing the adapter size? For instance, in multilingual MT, increasing overall model capacity of an already very large and deep architecture can be a powerful alternative to more sophisticated parameter sharing approaches (Arivazhagan et al., 2019). To answer this question we train another adapter-only model with doubled size (2048 instead of the 1024 used in the main experiments).

As seen in 3a, increase in model size brings a slight gain to the high-resource languages, but actually leads to a small loss in the zero-shot setup. This shows that adapters enlarge the per-language capacity for in-training languages, but at the same time they hurt generalization and zero-shot transfer. By contrast, UDapter including CPG which increases the model size by language embeddings (see Appendix A.1 for details), outperforms both adapter-only models, confirming once more the importance of this component.

For our last analysis (Fig. 3b), we study soft parameter sharing via CPG on different portions of the network, namely: only on the adapter modules 'cpg (adapters)' *versus* on both adapters and biaffine attention 'cpg (adap.+biaf.)' corresponding to the full UDapter. Results show that most of the gain in the high-resource languages is obtained by only applying CPG on the multilingual encoder. On the other hand, for the low-resource languages, typological feature based parameter sharing is most important in the biaffine attention layer. We leave further investigation of this result to future work.

6 Conclusion

We have presented UDapter, a multilingual dependency parsing model that learns to adapt language-specific parameters on the basis of adapter modules (Rebuffi et al., 2018; Houlsby et al., 2019) and the contextual parameter generation (CPG) method (Platanios et al., 2018) which is in principle applicable to a range of multilingual NLP tasks. While adapters provide a more general task-level adaptation, CPG enables language-specific adaptation, defined as a function of language embeddings projected from linguistically curated typological features. In this way, the model retains high per-language performance in the training data and achieves better zero-shot transfer.

UDapter, trained on a concatenation of typologically diverse languages (Kulmizev et al., 2019), outperforms strong monolingual *and* multilingual baselines on the majority of *both* high-resource and low-resource (zero-shot) languages, which reflects its strong balance between per-language capacity and maximum sharing. Finally, the analyses we performed on the underlying characteristics of our model show that typological features are crucial for zero-shot languages.

Table 3: Hyper-parameter setting

A Appendix

A.1 Experimental Details

Implementation UDapter's implementation is based on UDify (Kondratyuk and Straka, 2019). We use the same hyper-parameters setting optimized in UDify without applying a new hyper-parameter search. Together with the additional *adapter size* and *language embedding size* that are picked manually by parsing accuracy, hyper-parameters are given in Table 3. Note that, to give a fair chance to the adapter-only baseline (see §4), we used 1024 as adapter size unlike that of the final UDapter (256). For fair comparison, mono-udify and multi-udify are re-trained on the concatenation of 13 high-resource languages for only dependency parsing. Besides, we did not use a layer attention for both our model and the baselines.

Training Time and Model size Comparing to UDify, UDapter has a similar training time. An epoch over the full training set takes approximately 27 and 30 minutes in UDify and UDapter respectively on a Tesla V100 GPU. In terms of number of *trainable* parameters, UDify has 191M total number of parameters whereas UDapter uses 550M parameters in total, 302M for adapters (32x9.4M) and 248M for biaffine attention (32x7.8M), since the parameter generator network (CPG) multiplies the tensors with language embedding size (32). Note that for multilingual training, UDapter's parameter cost depends only on language embedding size regardless of number of languages, therefore it highly scalable with an increasing number of languages for larger experiments. Finally, monolingual UDify models are trained separately so the total number of parameters for 13 languages is 2.5B (13x191M).

Abstract

Conditional random fields (CRF) for label decoding has become ubiquitous in sequence labeling tasks. However, the local label dependencies and inefficient Viterbi decoding have always been a problem to be solved. In this work, we introduce a novel two-stage label decoding framework to model long-term label dependencies, while being much more computationally efficient. A base model first predicts draft labels, and then a novel two-stream self-attention model makes refinements on these draft predictions based on long-range label dependencies, which can achieve parallel decoding for a faster prediction. In addition, in order to mitigate the side effects of incorrect draft labels, Bayesian neural networks are used to indicate the labels with a high probability of being wrong, which can greatly assist in preventing error propagation. The experimental results on three sequence labeling benchmarks demonstrated that the proposed method not only outperformed the CRF-based methods but also greatly accelerated the inference process.

1 Introduction

Linguistic sequence labeling is one of the fundamental tasks in natural language processing. It has the goal of predicting a linguistic label for each word, including part-of-speech (POS) tagging, text chunking, and named entity recognition (NER). Benefiting from representation learning, neural network-based approaches can achieve state-of-the-art performance without massive handcrafted feature engineering (Ma and Hovy, 2016; Lample et al., 2016; Strubell et al., 2017; Peters et al., 2018; Devlin et al., 2019).

Although the use of representation learning to obtain better text representation is very successful, creating better models for label dependencies has always been the focus of sequence labeling tasks (Collobert et al., 2011; Ye and Ling, 2018; Zhang et al., 2018). Among them, the CRF layer integrated with neural encoders to capture label transition patterns (Zhou and Xu, 2015; Ma and Hovy, 2016) has become ubiquitous in sequence labeling tasks. However, CRF only captures the neighboring label dependencies and must rely on inefficient Viterbi decoding. Many of the recent methods try to introduce label embeddings to manage longer ranges of dependencies, such as two-stage label refinement (Krishnan and Manning, 2006; Cui and Zhang, 2019) and seq2seq (Vaswani et al., 2016; Zhang et al., 2018) frameworks. In particular, Cui and Zhang (2019) introduced a hierarchically-refined representation of marginal label distributions, which predicts a sequence of draft labels in advance and then uses the word-label interactions to refine them.

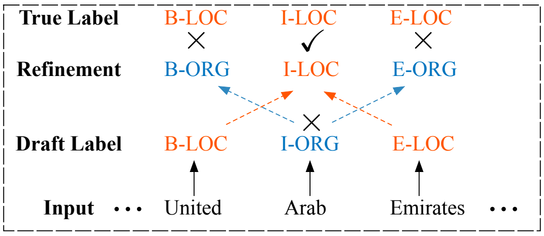

Figure 1: Schematic of label refinement framework (Cui and Zhang, 2019). The goal is refining the label of "Arab" using contextual labels and words, while the refinement of other correct labels may be negatively impacted by incorrect draft labels.

Although these methods can model longer label dependencies, they are vulnerable to error propagation: if a label is mistakenly predicted during inference, the error will be propagated and the other labels conditioned on this one will be impacted (Bengio et al., 2015). As shown in Figure 1, the label attention network (LAN) (Cui and

Draft	Uncertainty	Refinement	#Tokens
✔	0.018	✔ → ✘	**39**
✘	**0.524**	✘ → ✔	54

Table 1: Results of LAN with uncertainty estimation evaluated on CoNLL2003 test dataset. ✔ refers to the correct prediction, and ✘ refers to the wrong prediction. We use Bayesian neural networks (Kendall and Gal, 2017) to estimate the uncertainty. We can see that the uncertainty value of incorrect prediction is 29 times larger than that of correct predictions, which can effectively indicate the incorrect predictions.

Zhang, 2019) would negatively impact the correct predictions in the refinement stage. There are 39 correct tokens that have been incorrectly modified (Table 1). Hence, the model should selectively correct the labels with high probabilities of being incorrect, not all of them. Fortunately, we find that uncertainty values estimated by Bayesian neural networks (Kendall and Gal, 2017) can effectively indicate the labels that have a high probability of being incorrect. As shown in Table 1[1], the average uncertainty value of incorrect prediction is 29 times larger than that of correct predictions for the draft labels. Hence, we can easily set an uncertainty threshold to only refine the potentially incorrect labels and prevent side effects on the correct labels.

In this work, we propose a novel two-stage Uncertainty-Aware label refinement Network (UANet). At the first stage, the Bayesian neural networks take a sentence as input and yield all of the draft labels together with corresponding uncertainties. At the second stage, a two-stream self-attention model performs attention over label embeddings to explicitly model the label dependencies, as well as context vectors to model the context representations. All of these features are fused to refine the potentially incorrect draft labels. The above label refinement operations can be processed in parallel, which can avoid the use of Viterbi decoding of the CRF for a faster prediction. Experimental results on three sequence labeling benchmarks demonstrated that the proposed method not only outperformed the CRF-based methods but also significantly accelerated the inference process.

The main contributions of this paper can be summarized as follows: 1) we propose the use of Bayesian neural networks to estimate the uncertainty of predictions and indicate the potentially incorrect labels that should be refined; 2) we propose a novel two-stream self-attention refining framework to better model different ranges of label dependencies and word-label interactions; 3) the proposed parallel decoding process can greatly speed up the inference process; and 4) the experimental results across three sequence labeling datasets indicate that the proposed method outperforms the other label decoding methods.

2 Related Work and Background

2.1 Sequence Labeling

Traditional sequence labeling models use statistical approaches such as Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (Passos et al., 2014; Cuong et al., 2014; Luo et al., 2015) with handcrafted features and task-specific resources. With advances in deep learning, neural models could achieve competitive performances without massive handcrafted feature engineering (Chiu and Nichols, 2016; Santos and Zadrozny, 2014). In recent years, modeling label dependencies has been the other focus of sequence labeling tasks, such as using a CRF layer integrated with neural encoders to capture label transition patterns (Zhou and Xu, 2015; Ma and Hovy, 2016), and introducing label embeddings to manage longer ranges of dependencies (Vaswani et al., 2016; Zhang et al., 2018; Cui and Zhang, 2019). Our work is an extension of label embedding methods, which applies label dependencies and word-label interactions to only refine the labels with high probabilities of being incorrect. The probability of making a mistake is estimated using Bayesian neural networks, which will be described in the next subsection.

2.2 Bayesian Neural Networks

The predictive probabilities obtained by the softmax output are often erroneously interpreted as model confidence. However, a model can be uncertain in its predictions even with a high softmax output (Gal and Ghahramani, 2016a). Gal and Ghahramani (2016a) gives results showing that simply using predictive probabilities to estimate the uncertainty results in extrapolations with unjustified high confidence for points far from the training data. They verified that modeling a distribution over the parameters through Bayesian NNs can effectively reflect the uncertainty, and

---

[1] We slightly modified the code using Bayesian neural networks.

Bernoulli Dropout is exactly one example of a regularization technique corresponding to an approximate variational distribution. Some typical examples of using Bernoulli distribution to estimate uncertainty are Bayesian CNN (Gal and Ghahramani, 2015) and variational RNN (Gal and Ghahramani, 2016b).

Given the dataset $\mathcal{D}$ with training inputs $\mathbf{X} = \{\mathbf{x}_1, \ldots, \mathbf{x}_n\}$ and their corresponding outputs $\mathbf{Y} = \{\mathbf{y}_1, \ldots, \mathbf{y}_n\}$, Bayesian inference looks for the posterior distribution of the parameters given the dataset $p(\mathbf{W}|\mathcal{D})$. This makes it possible to predict an output for a new input point $\mathbf{x}^*$ by marginalizing over all of the possible parameters, as follows:

$$p(\mathbf{y}^*|\mathbf{x}^*, \mathcal{D}) = \int p(\mathbf{y}^*|\mathbf{W}, \mathbf{x}^*) p(\mathbf{W}|\mathcal{D}) \mathrm{d}\mathbf{W}. \tag{1}$$

Bayesian inference is intractable for many models because of the complex nonlinear structures and high dimension of the model parameters. Recent advances in variational inference introduced new techniques into the field. Among these, Monte Carlo Dropout (Gal and Ghahramani, 2016a) requires minimum modification to the original model. It is possible to use the variational inference approach to find an approximation $q_\theta^*(\mathbf{W})$ to the true posterior $p(\mathbf{W}|\mathcal{D})$ parameterized by a different set of weights θ, where the Kullback-Leibler (KL) divergence of the two distributions is minimized. The integral can be approximated as follows:

$$p(\mathbf{y}^*|\mathbf{x}^*, \mathcal{D}) \approx \sum_{j=1}^{T} p(\mathbf{y}^*|\mathbf{W}_j, \mathbf{x}^*) q_\theta^*(\mathbf{W}_j). \tag{2}$$

In contrast to non-Bayesian networks, at test time, Dropouts are also activated. As a result, model uncertainty can be approximately evaluated by summarizing the variance of the model outputs from multiple forward passes.

3 Uncertainty-Aware Label Refinement

In this work, we propose a novel sequence labeling framework, which incorporates Bayesian neural networks to estimate the epistemic uncertainty of the draft labels. The uncertain labels that have a high probability of being wrong can be refined by a two-stream self-attention model using long-term label dependencies and word-label interactions. The proposed model is shown in Figure 2.

3.1 Variational LSTM for Uncertainty Estimation

Long short-term memory (LSTM) stands at the forefront of many recent developments in sequence labeling tasks. To facilitate comparison with LSTM-based models, variational LSTMs (Gal and Ghahramani, 2016b) as special Bayesian neural networks are used to encode sentences and determine the labels with a high probability of being wrong. Obviously, the uncertainty estimation methods can also be easily applied to other sequence labeling models, like the CNN and Transformer.

Word Representation Following Santos and Zadrozny (2014) and Lample et al. (2016), we use character information to enhance the word representation. Given a word sequence $S = \{w_1, w_2, \ldots, w_n\}$, the product of the one-hot encoded vector with an embedding matrix then gives a word embedding: $\mathbf{w}_i = \mathbf{e}^w(w_i)$, where $\mathbf{e}^w$ denotes a word embedding lookup table. Each word is made up of a sequence of characters $c_1, c_2, \ldots, c_l$. We adopt CNNs for character encoding and $\mathbf{x}_i^c$ denotes the output of character-level encoding. Then a word is represented by concatenating its word embedding and its character-level encoding: $\mathbf{x}_i = [\mathbf{w}_i; \mathbf{x}_i^c]$. All the word representations make up an embedding matrix $\mathbf{E} \in \mathbb{R}^{V \times D}$, where D is the embedding dimensionality of $\mathbf{x}$ and V is the number of words in the vocabulary.

Variational LSTM A common practice of Dropout technique on LSTM is that the technique should be used with the inputs and outputs of the LSTM alone. In contrast, the variational LSTM additionally applies Dropout on recurrent connections by repeating the same mask at each time step. Hence, the variational LSTM can model the uncertainty more accurately.

As shown in Figure 2, we use the same Dropout vectors $\mathbf{z}_x$ and $\mathbf{z}_h$ on four gates: "input", "forget", "output", and "input modulation" as follows:

$$\begin{aligned}
\begin{bmatrix} \mathbf{g}_i \\ \mathbf{i}_i \\ \mathbf{f}_i \\ \mathbf{o}_i \end{bmatrix} &= \left(\begin{bmatrix} \mathbf{W}^g \\ \mathbf{W}^i \\ \mathbf{W}^f \\ \mathbf{W}^o \end{bmatrix} \bullet \begin{bmatrix} \mathbf{x}_i' \odot \mathbf{z}_x \\ \mathbf{h}_{i-1} \odot \mathbf{z}_h \end{bmatrix} + \begin{bmatrix} \mathbf{b}^g \\ \mathbf{b}^i \\ \mathbf{b}^f \\ \mathbf{b}^o \end{bmatrix} \right) \\
\mathbf{c}_i &= \phi(\mathbf{g}_i) \odot \sigma(\mathbf{i}_i) + \mathbf{c}_{i-1} \odot \sigma(\mathbf{f}_i) \\
\mathbf{h}_i &= \sigma(\mathbf{o}_i) \odot \phi\left(\mathbf{c}_i\right),
\end{aligned} \tag{3}$$

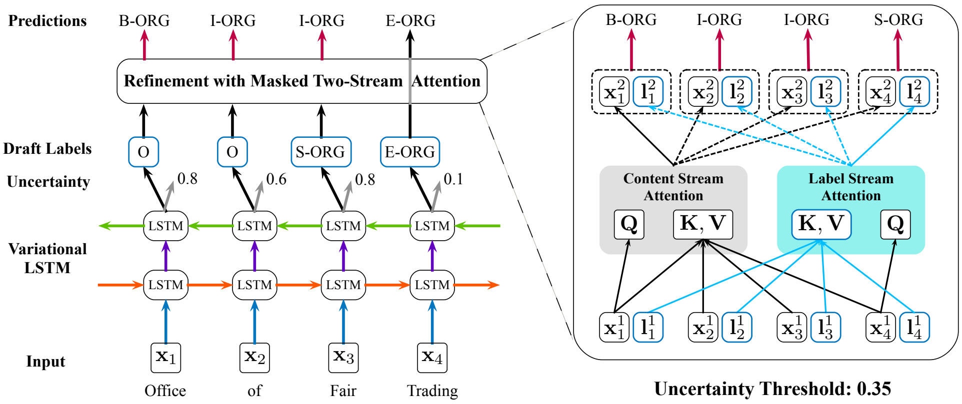

Figure 2: Graphical illustration of architecture and inference process for the proposed UANet. The variational LSTM outputs draft labels and model uncertainties simultaneously. The refinement only works on draft labels with threshold greater than 0.35.

where ϕ denotes the `tanh` function, and σ is the `sigmoid` function. $\odot$ and $\bullet$ represent the Hadamard product and matrix product, respectively. We assume that t is one of $\{g, i, f, o\}$. Then, $\theta = \{\mathbf{E}, \mathbf{W}^t\}$ and the Dropout rate r are the parameters of the variational LSTM.

Draft Labels and Uncertainty Estimation Assuming that we have completed the training and obtained the optimized approximated posterior $q^*_\theta(\mathbf{W})$ (the optimizing method is shown in § 3.3), at inference time, we can predict an output for a new input point by performing Monte Carlo integration in Eq.2 as follows:

$$\mathbf{p}_i(y = c|S, \mathcal{D}) \approx \frac{1}{M}\sum_{j=1}^{M} \mathtt{Softmax}(\mathbf{h}_i|\mathbf{W}_j) \quad (4)$$

with M sampled masked model weights $\mathbf{W}_j \sim q^*_\theta(\mathbf{W})$, where $q^*_\theta(\mathbf{W})$ is the Dropout distribution. In order to make the model with multiple sampling the same speed as the standard LSTM, we repeat the same input M times to form a batch and run in parallel on the GPU. Hence, M samples can be done concurrently in the forward passes, resulting in constant running time identical to that of standard Dropout (Gal and Ghahramani, 2016a), which is verified in Table 6.

Similar to classic sequence labeling models, the model applies $y^*_i = \mathrm{argmax}(\mathbf{p}_i)$ to obtain the draft label. Then the uncertainty of this probability vector $\mathbf{p}_i$ can be summarized using the entropy of the probability vector:

$$u_i = H(\mathbf{p}_i) = -\sum_{c=1}^{C} p_c \log p_c. \quad (5)$$

In this way, we can obtain the draft labels $Y^* = \{y^*_1, y^*_2, \ldots, y^*_n\}$ coupled with the corresponding epistemic uncertainties $U = \{u_1, u_2, \ldots, u_n\}$ for each input sentence. We find when the epistemic uncertainty u_i is larger than some threshold value Γ, then the draft label y^*_i has a high probability of being wrong. Hence, we utilize a novel two-stream self-attention model to refine those uncertain labels using long-term label dependencies and word-label interactions.

3.2 Two-Stream Self-Attention for Label Refinement

Given the draft labels and corresponding epistemic uncertainties, we seek the help of label dependencies and word-label interactions to refine the uncertain labels. In order to refine the draft labels in parallel, we use the Transformer (Vaswani et al., 2017) incorporating relative position encoding (Dai et al., 2019) to model the words and draft labels.

In the standard Transformer, the attention score incorporating absolute position encoding between query q_i and key vector k_j can be decomposed as

$$\begin{aligned}\mathbf{A}^{abs}_{i,j} &= \mathbf{E}^\top_{x_i}\mathbf{W}^\top_q\mathbf{W}_k\mathbf{E}_{x_j} + \mathbf{E}^\top_{x_i}\mathbf{W}^\top_q\mathbf{W}_k\mathbf{U}_j \\ &+ \mathbf{U}^\top_i\mathbf{W}^\top_q\mathbf{W}_k\mathbf{E}_{x_j} + \mathbf{U}^\top_i\mathbf{W}^\top_q\mathbf{W}_k\mathbf{U}_j,\end{aligned} \quad (6)$$

where $\mathbf{U} \in \mathbb{R}^{L_{max}\times d}$ provides a set of positional encodings. The ith row $\mathbf{U}_i$ corresponds to the ith absolute position and L_{max} prescribes the maximum possible length to be modeled.

The relative position between labels is very important for modeling the label dependencies. Inspired by Dai et al. (2019), we modify the Eq.6 using the relative position encoding to model words and corresponding labels simultaneously, but offer a different derivation, arriving at a new form of two-stream relative positional encodings. We not only provide a word-to-word interactions but also provide a word-to-label interactions correspondence to its counterpart. The relative position encodings are reparameterized as follows:

$$
\begin{aligned}
\mathbf{A}^{x2x}_{i,j} &= \mathbf{E}_{x_i}^{\top}\mathbf{W}_{qx}^{\top}\mathbf{W}_{kx}\mathbf{E}_{x_j} + \mathbf{E}_{x_i}^{\top}\mathbf{W}_{qx}^{\top}\mathbf{W}_{kR}\mathbf{R}_{i-j} \\
&\quad + \mathbf{u}_x^{\top}\mathbf{W}_{kx}\mathbf{E}_{x_j} + \mathbf{v}_x^{\top}\mathbf{W}_{kR}\mathbf{R}_{i-j} \\
\mathbf{A}^{x2l}_{i,m} &= \mathbf{E}_{x_i}^{\top}\mathbf{W}_{ql}^{\top}\mathbf{W}_{kl}\mathbf{E}_{y^*_m} + \mathbf{E}_{x_i}^{\top}\mathbf{W}_{ql}^{\top}\mathbf{W}_{kR}\mathbf{R}_{i-m} \\
&\quad + \mathbf{u}_l^{\top}\mathbf{W}_{kl}\mathbf{E}_{y^*_m} + \mathbf{v}_l^{\top}\mathbf{W}_{kR}\mathbf{R}_{i-m},
\end{aligned}
\tag{7}
$$

where $\mathbf{A}^{x2x}_{i,j}$ and $\mathbf{A}^{x2l}_{i,m}$ denotes the attention from the ith word (x_i) to the jth word (x_j) and the ith word (x_i) to the mth label (y^*_m), respectively. $\mathbf{R}_{i-j}$ is the encoding of relative distance between position i and j, and $\mathbf{R}$ is the sinusoid matrix like Dai et al. (2019). $\varphi = \{\mathbf{W}, \mathbf{u}, \text{and } \mathbf{v}\}$ are learnable parameters.

Equipping the transformer with our proposed relative positional encoding, we finally arrive at the two-stream self-attention architecture. We summarize the computational procedure for one layer with a single attention head here:

$$
\begin{aligned}
\mathbf{V}_x &= \mathbf{E}_x\mathbf{W}_x, \mathbf{a}_x = \texttt{Softmax}(\mathbf{A}^{x2x})\mathbf{V}_x \\
\mathbf{V}_l &= \mathbf{E}_{y^*}\mathbf{W}_l, \mathbf{a}_l = \texttt{Softmax}(\mathbf{A}^{x2l})\mathbf{V}_l \\
\mathbf{o}_x &= \texttt{LayerNorm}(\texttt{Linear}(\mathbf{a}_x) + \mathbf{E}_x) \\
\mathbf{o}_l &= \texttt{LayerNorm}(\texttt{Linear}(\mathbf{a}_l) + \mathbf{E}_{y^*}) \\
\mathbf{H}_x &= \texttt{FeedForward}(\mathbf{o}_x) \\
\mathbf{H}_l &= \texttt{FeedForward}(\mathbf{o}_l).
\end{aligned}
\tag{8}
$$

3.3 Training and Decoding

There are two networks to be optimized: one is variational LSTM for draft labels and uncertainty estimation, the other is two-stream self-attention model for label refinement. Our ultimate training goal is to minimize the total loss function on the two models: $\mathcal{L}_{total} = \mathcal{L}_1(\theta, r) + \mathcal{L}_2(\varphi)$.

The variational LSTM performs approximate variational inference. We use a simple Bernoulli distribution (Dropout) $q^*_\theta(\mathbf{W})$ in a tractable family to minimize the KL divergence to the true model posterior $p(\mathbf{W}|\mathcal{D})$. The minimization objective is given by (Jordan et al., 1999):

$$
\mathcal{L}_1(\theta, r) = -\frac{1}{N}\sum_{i=1}^{N}\log p(y_i|\mathbf{W}_j) + \frac{1-r}{2N} \parallel \theta \parallel^2,
\tag{9}
$$

where N is the number of data points, and r is the Dropout probability to sample $\mathbf{W}_j \sim q^*_\theta(\mathbf{W})$.

For the two-stream self-attention model, we use the concatenation of $\mathbf{H}_x$ and $\mathbf{H}_l$ for the final prediction $\hat{y}_i = f(\mathbf{H}_x, \mathbf{H}_l|\mathbf{E}_x, \mathbf{E}_{y^*_m})$. In particular, we can optimize the model using cross entropy loss as:

$$
\mathcal{L}_2(\varphi) = -\sum_{i=1}^{N} y_i \log \hat{y}_i,
\tag{10}
$$

where y_i is the one-hot vector of the label corresponding to w_i. When training is complete, we can obtain the draft labels $Y^* = \{y^*_1, y^*_2, \ldots, y^*_n\}$ and corresponding uncertainties $U = \{u_1, u_2, \ldots, u_n\}$ from variational LSTM, and refined labels $\hat{Y} = \{\hat{y}_1, \hat{y}_2, \ldots, \hat{y}_n\}$ from two-stream self-attention model. To avoid the correct labels being incorrectly modified, we set an uncertainty threshold Γ to distinguish which labels should be used, i.e., we use refined labels when $u_i > \Gamma$ and vice versa (as an example, given $u_1 > \Gamma$, $u_2 \leq \Gamma$, and $u_n > \Gamma$, decoding labels will become $\{\hat{y}_1, y^*_2, \ldots, \hat{y}_n\}$).

4 Experimental Setup

In this section, we describe the datasets across different sequence labeling tasks, including two English NER datasets and one POS tagging dataset. We also detail the baseline models for comparison. Finally, we clarify the hyperparameters configuration of our uncertainty-aware refinement network.

4.1 Datasets

We conduct experiments on three sequence labeling datasets. The statistics are listed in Table 2.

CoNLL2003. The shared task of CoNLL2003 dataset (Tjong Kim Sang and De Meulder, 2003) for named entity recognition is collected from Reuters Corpus. The dataset divide name entities into four different types: persons, locations, organizations, and miscellaneous entities. We use the BIOES tag scheme instead of standard BIO2, which is the same as Ma and Hovy (2016).

OntoNotes 5.0. English NER dataset OntoNotes 5.0 (Weischedel et al., 2013) is a large corpus consists of various genres, such as newswire, broadcast, and telephone speech. Named entities are labeled in eleven types and values are specifically divided into seven types, like DATE, TIME, ORDINAL.

WSJ. Wall Street Journal portion of Penn Treebank (Marcus et al., 1993), which contains 45 types of part-of-speech tags. We adopts standard splits following previous works (Collins, 2002; Manning,

Dataset	#Train	#Dev	#Test	class
CoNLL2003	204,567	51,578	46,666	17
OntoNotes	1,088,503	147,724	152,728	73
WSJ	912,344	131,768	129,654	45

Table 2: Statistics of CoNLL2003, OntoNotes and WSJ datasets, where # represents the number of tokens in datasets. The class number of NER datasets is counted under BIOES tag scheme.

2011), selecting section 0-18 for training, section 19-21 for validation and section 22-24 for test.

4.2 Compared Methods

In this work, we mainly focus on improving decoding efficiency and enhancing label dependencies. Thus, we make comparisons with the classic methods that have different decoding layers, such as Softmax, CRF, and LAN frameworks. We also compare some recent competitive methods, such as Transformer, IntNet (Xin et al., 2018), and BERT (Devlin et al., 2019).

BiLSTM-Softmax. This baseline uses bidirectional LSTM to represent a sequence. The BiLSTM concatenates the forward hidden state $\overrightarrow{\mathbf{h}}_i$ and backward hidden state $\overleftarrow{\mathbf{h}}_i$ to form an integral representation $\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i]$. Finally, sentence representation $\mathbf{H} = \{\mathbf{h}_i, \cdots, \mathbf{h}_n\}$ is fed to softmax layer for predicting.

BiLSTM-CRF. A CRF layer is used on top of the hidden vectors $\mathbf{H}$ (Ma and Hovy, 2016). The CRF can model bigram interactions between two successive labels (Lample et al., 2016) instead of making independent labeling decisions for each output. In the decoding time, the Viterbi algorithm is used to find the highest scored label sequence over an input word sequence.

BiLSTM-Seq2seq. To model longer label dependencies, Zhang et al. (2018) predicts a sequence of labels as a sequence to sequence problem.

BiLSTM-LAN. The label attention network (LAN) (Cui and Zhang, 2019) introduces label embedding, and uses consecutive attention layers on the label embeddings to refine the draft labels. It achieves the state-of-the-art results on several sequence labeling tasks.

Rel-Transformer. This baseline model adopts self-attention mechanism with relative position representations (Vaswani et al., 2017; Dai et al., 2019).

4.3 Hyper-parameter Settings

Following (Ma and Hovy, 2016), we use the same 100-dimensional GloVe embeddings[2] as initialization. We use 1-layer variational LSTM with a hidden size of 400 to create draft labels. The vanilla dropout after the embedding layer and the variational dropout is set to 0.5 and 0.25, respectively. We use 2 layers of multi-head transformer for WSJ and CoNLL2003 and 3 for OntoNotes dataset to refine the label. The number of heads is chosen from $\{5, 7, 9\}$, and the dimension of each head is chosen from $\{80, 120, 160\}$ via grid search. We use SGD as the optimizer for variational LSTM and Adam (Kingma and Ba, 2014) for transformer. Learning rates are set to 0.015 for SGD on CoNLL2003 and Ontonotes datasets and 0.2 on WSJ dataset. The learning rates for Adam are set to 0.0001 for all datasets. F1 score and accuracy are used for NER and POS tagging, respectively. All experiments are implemented in NCRF++ (Yang and Zhang, 2018) and conducted using a GeForce GTX 1080Ti with 11GB memory. More details are shown in our codes[3].

5 Results and Analysis

In this section, we present the experimental results of the proposed and baseline models. We show that the proposed method not only achieves better performance but also has a significant speed advantage. Since our contribution is mainly focused on the label decoding layer, the proposed model can also be combined with the latest pre-trained model to further improve performance.

5.1 Main Results

Table 3 reports model performances on CoNLL2003, OntoNotes, and WSJ dataset, which shows that the proposed method not only can achieve state-of-the-art results on NER task but also is effective on other sequence labeling tasks, like POS tagging. The previous methods leverage rich handcrafted features (Huang et al., 2015; Chiu and Nichols, 2016), CRF decoding (Strubell et al., 2017), and longer range label dependencies (Zhang et al., 2018; Cui and Zhang, 2019). Compared with these methods, our UANet model gives better results. Benefitting from the strong capability of modeling long-term label dependencies, the UANet outperforms models with the CRF inference layer by a large margin. Moreover, different from the seq2seq and LAN models that also leverage label dependencies, our UANet model integrates model uncertainty into the refinement stage to avoid side effects on correct draft labels. As a result, it outperforms LAN and seq2seq models on all of the three datasets.

5.2 Ablation Study

To study the contribution of each component in BiLSTM-UANet, we conducted ablation experiments on the three datasets and display the results in Table 4. The results show that the model's performance is degraded if the draft label information is removed, indicating that label dependencies are useful in the refinement. We also find that both the variational LSTM and two-stream self-attention play an important role in label refinement. Even though we replace any component with the CRF layer, the performance will be seriously hurt.

We also give our model more complex character representations (IntNet) or use the pretrained model (BERT) to replace the Glove embeddings. We fine-tune the BERT for each task. The results are shown in Table 5. We find that the contribution of our model and more complex word representations may be orthogonal, i.e., whether or not the UANet uses the IntNet and BERT, our methods have similar improvements, because of better modeling label dependencies.

5.3 Efficient Advantage

Table 6 shows a comparison of inference speeds. BiLSTM-UANet processes 1,630, 1,262, and 1,192 sentences per second on the CoNLL2003, OntoNotes, and WSJ development data, respectively, outperforming BiLSTM-CRF by 13.7%, 32.8% and 48.8%, respectively. We can see that for the dataset with a longer average length, the speed of inference will be more advantageous. Because the model calculates uncertainties through parallel sampling the same input multiple times, the inference time of the BiLSTM-UANet ($M = 8$)

only slightly increases.

To further investigate the influence of the different sentence lengths, we analyze the inference speed of the UANet and CRF on the CoNLL2003 development set, which is split into five parts according to sentence length. We ruled out the influence of the text encoder and only counted the time of label decoding. The left subfigure in Figure 3 shows the decoding speed on the different sentence lengths. The results reveal that as the sentence length increases, the speed of the UANet is relatively stable, while the speed of the CRF decreases substantially. Due to the UANet's parallelism, when processing the sentence longer than 30, the UANet is nearly 3 times faster than the CRF. In addition, we exhibit the F1 score of the sentences with different lengths in right subfigure. It is worth noting that the UANet outperforms the CRF by a large margin when the length of the sentence is greater than 15, verifying the UANet's superiority in long-term label dependencies.

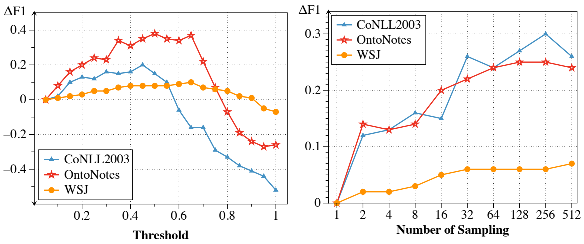

Figure 4: F1 variation under different uncertainty thresholds and numbers of sampling in variational LSTM, respectively. The results are evaluated on the development sets. ΔF1 represents the F1 scores at different steps minus the initial results.

5.4 Discussion

Uncertainty Threshold. In order to investigate the influence of uncertainty threshold Γ, we evaluate the performance with different uncertainty thresholds on three datasets, as shown in Figure 4. $\Gamma = 0$ represents that the model uses all of the refined labels as final predictions. As the threshold gets larger, the performance of UANet can improve by reducing the negative effects on correct draft labels. However, when Γ is too large, the model mainly uses draft labels as final predictions, resulting in performance degradation, which verifies our motivation that a reasonable uncertainty threshold can avoid side effects on correct draft labels.

Number of Sampling. We also investigate the influence of the number of sampling in the variational LSTM as shown in Figure 4. The results meet our expectation that a larger number of sampling can lead to better performance because a larger number of sampling can make the model better approximate the posterior $p(\mathbf{W}|\mathcal{D})$.

Case Study. Table 7 shows two cases from CoNLL2003 NER dataset. The first case reflects the necessity of modeling higher-order dependencies in the NER task. UANet can learn the label consistency of two phrases near the word `and`. Moreover, seq2seq decoding model (Zhang et al., 2018) refines the labels in a left-to-right way and can't refine the previous labels in this case. The second case shows the effectiveness of the uncertainty threshold in mitigating the side effect of incorrect refinement. In this case, the refinement model is affected by the incorrect label of `Yangon` (E-LOC) when predicting the word `University`. Since the uncertainty value of `University` is lower than the threshold, our model can get the correct results.

6 Conclusions

In this work, we introduce a novel sequence labeling framework that incorporates Bayesian neural networks to estimate model uncertainty. We find that the model uncertainty can effectively indicate the labels with a high probability of being wrong. The proposed method can selectively refine the uncertain labels to avoid the side effects of the refinement on correct labels. In addition, the proposed model can capture different ranges of label dependencies and word-label interactions in parallel, which can avoid the use of Viterbi decoding of the CRF for a faster prediction. Experimental results across three sequence labeling datasets demonstrated that the proposed method significantly outperforms the previous methods.

Abstract

Building an effective adversarial attacker and elaborating on countermeasures for adversarial attacks for natural language processing (NLP) have attracted a lot of research in recent years. However, most of the existing approaches focus on classification problems. In this paper, we investigate attacks and defenses for structured prediction tasks in NLP. Besides the difficulty of perturbing discrete words and the sentence fluency problem faced by attackers in any NLP tasks, there is a specific challenge to attackers of structured prediction models: the structured output of structured prediction models is sensitive to small perturbations in the input. To address these problems, we propose a novel and unified framework that learns to attack a structured prediction model using a sequence-to-sequence model with feedbacks from multiple reference models of the same structured prediction task. Based on the proposed attack, we further reinforce the victim model with adversarial training, making its prediction more robust and accurate. We evaluate the proposed framework in dependency parsing and part-of-speech tagging. Automatic and human evaluations show that our proposed framework succeeds in both attacking state-of-the-art structured prediction models and boosting them with adversarial training.

1 Introduction

Adversarial examples, which contain perturbations to the input of a model that elicit large changes in the output, have been shown to be an effective way of assessing the robustness of models in natural language processing (NLP) (Jia and Liang, 2017; Belinkov and Bisk, 2018; Hosseini et al., 2017; Samanta and Mehta, 2017; Alzantot et al., 2018; Ebrahimi et al., 2018; Michel et al., 2019; Wang et al., 2019). Adversarial training, in which models are trained on adversarial examples, has also been shown to improve the accuracy and robustness of NLP models (Goodfellow et al., 2015; Tramèr et al., 2017; Yasunaga et al., 2018). So far, most existing methods of generating adversarial examples only work for classification tasks (Jia and Liang, 2017; Wang et al., 2019) and are not designed for structured prediction tasks. However, since many structured prediction tasks such as part-of-speech (POS) tagging and dependency parsing are essential building blocks of many AI systems, it is important to study adversarial attack (generating adversarial examples) and defense (adversarial training) of structured prediction models.

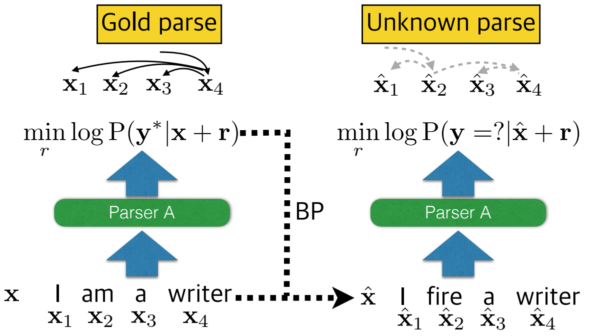

Figure 1: An example showing the challenges in attacking a dependency parser using gradient-based methods. A small perturbation to the sentence x changes one word from “am” to “fires”. This change makes the perturbed example *I fires a writer* ungrammatical. Even if the perturbed example is “I fire a writer” that meets the rules of grammar, the true output structure is still different from the input sentence “I am a writer”. More importantly, this true parse is unknown to the attacker, which hinders the next update step.

There are multiple challenges that have to be addressed in building an efficient and effective attacker for structured prediction models in NLP. Zhang et al. (2019a) pointed out two major prob-

November 16–20, 2020.

lems encountered by attackers of NLP tasks. First, since words are discrete, making small disturbances to words in the gradient direction is difficult. Secondly, there is no guarantee that the generated adversarial examples are fluent. In addition to these two problems, there is a unique challenge faced by attackers of structured prediction tasks. While small perturbations to images or even texts typically do not change their classification labels, small perturbations to sentences in structured prediction may very likely change the true output structures. In other words, many structured prediction tasks are very sensitive to small perturbations in the input sentence. Consequently, almost all the existing attacking methods are not directly applicable to structured prediction. To illustrate this challenge, we take adversarial attack of dependency parsing as an example (Figure 1). We use the fast gradient sign method (FGSM) (Goodfellow et al., 2015) as the attack method, which is a classic gradient-based attacker that perturbs the input by minimizing the likelihood of the true output. When applied to NLP tasks (Miyato et al., 2017), FGSM perturbs the embeddings of the words in the input sentence and then replaces individual words based on the new embeddings. However, there is no guarantee that the new sentence has the same parse tree as the original sentence. Once the true output parse tree becomes unknown, subsequent updates become impossible in FGSM, resulting in perturbation that might be insufficiently adversarial. In Figure 1, after just one step of perturbation, the sentence indeed has a different parse tree that is unknown to the attacker.

To address the aforementioned problems, we propose to attack structured prediction models with sequence-to-sequence (seq2seq) sentence generators. Before attack, the seq2seq generator is trained by reinforcement learning based on a novelty designed reward function that evaluates the output of the victim structured prediction model against an ensemble of multiple reference models of the same structured prediction task. During attack, the seq2seq generator is simply applied to input sentences to produce adversarial examples. Our framework has the following features.

- Our proposed attacker is a black-box attacker that does not need to know the internal details of the target model (such as the model structure, the hyper-parameters, the training strategy, the training dataset, and gradients over each layer). This ensures that our framework (including attack and defense) can be applied to almost any structured prediction models.
- In contrast to previous black-box attackers, our attacker is an *online* attacker. Once the seq2seq sentence generator is trained, it can generate adversarial examples directly from original sentences during attacks without any optimization procedure and also without the need to access the victim model. This significantly increases the efficiency of the attack.
- Most existing methods perform word or character level manipulations and hence cannot change the sentence length. We use a seq2seq generator to modify the whole sentence without this limitation.
- Our generator can utilize some recent pretrained language models (e.g., BERT (Devlin et al., 2019), GPT-2 (Radford et al., 2019)) to improve quality of adversarial examples.

We evaluate our framework on the dependency parsing task and the POS tagging task. Both automatic and human evaluations show that our method outperforms previous approaches in attacking state-of-the-art structured prediction models as well as boosting these models with adversarial training for better accuracy and robustness. The code and the trained model can be found at `https://github.com/WinnieHAN/structure_adv`.

2 Background

2.1 Structured Prediction

Structured prediction in NLP aims to predict output variables that are mutually dependent or constrained given an input sentence. We represent the training data with N samples as $\mathcal{D} = \{\mathbf{x}^{(j)}, \mathbf{y}^{(j)} : j = 1, ..., N\}$, where $\mathbf{x}^{(j)}$ is the j-th sentence and $\mathbf{y}^{(j)}$ is the corresponding structure. The set of all $\mathbf{x}^{(j)}$ is $\mathcal{X}$. For each $\mathbf{x}$ with length n, it can be written as a sequence of tokens $\{\mathbf{x}_i : i = 1, ..., n\}$. We also define $\mathbf{v}$ to represent the concatenation of all the word vectors in sentence $\mathbf{x}$.

A structured prediction model predicts the output $\mathbf{y}$ given an input sentence $\mathbf{x}$ by maximizing the log conditional probability:

$$\arg\max_{\mathbf{y} \in \mathcal{T}} \log P(\mathbf{y}|\mathbf{x}; \Theta)$$

where $\mathcal{T}$ is the set of all possible outputs and Θ is the set of parameters.

We train the model by minimizing the following loss:

$$\mathcal{L}(\Theta) = -\frac{1}{N} \sum_{(\mathbf{x}^{(j)},\mathbf{y}^{(j)}) \in \mathcal{D}} \log P(\mathbf{y}^{(j)}|\mathbf{x}^{(j)};\Theta)$$

2.2 Word-level Adversarial Attack

Goodfellow et al. (2015) proposed the fast gradient sign method (FGSM) in the image processing field, which uses the direction of the gradient to update image pixels and generate adversarial examples. Then Miyato et al. (2017) applied this approach to add perturbations in the word embedding space, though their approach cannot generate adversarial text examples. In order to solve the mapping problem from a modified word vector to a word, word level manipulation is used to replace original words (Papernot et al., 2016). In addition to the replacement manipulation, Samanta and Mehta (2017) introduced two new modification strategies: removal and addition.

2.3 Word-level Adversarial Attack for Structured Prediction

The gradient of the negative log likelihood with respect to the input in a structured prediction model can be leveraged to find adversarial examples. The original input sentence $\mathbf{x}$ is manipulated by adding or subtracting a small adversarial perturbation $\mathbf{r}$ to the vector $\mathbf{v}$. Adding $\mathbf{r}$ in the direction of the gradient means that the sentence is modified to decrease the log likelihood so that the model is less likely to predict the correct output. We use $\hat{\mathbf{x}}$ to represent $\mathbf{x}$ with perturbation.

The following formula describes the adversarial example:

$$\hat{\mathbf{x}} = search(\mathbf{x}, \mathbf{r}) = search(\mathbf{v}, \mathbf{r})$$

where we use $\mathbf{v}$ to represent the concatenation of all the word vectors in sentence $\mathbf{x}$. *search* is a searching approach to find an adversarial example $\hat{\mathbf{x}}$ according to perturbed vector $\mathbf{v} + \mathbf{r}$ and $\mathbf{r}$ is calculated by maximizing the loss function as follows.

$$\mathbf{r} = \arg \max_{\mathbf{r}, ||\mathbf{r}|| \leq \epsilon} \{-\log P(\mathbf{y}|\mathbf{x} + \mathbf{r}; \Theta)\}$$

where ϵ is a hyper-parameter to control the scale of the perturbation.

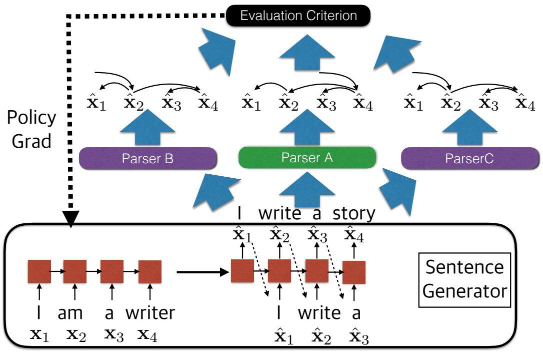

Figure 2: Our framework illustrated on the dependency parsing task. It consists of three parts: a seq2seq generator, an evaluation module (including the reference Parser B, the reference Parser C and the evaluation criteria), and the victim model A.

It is intractable to exactly solve the problem, so an approximate approach is proposed to compute $\mathbf{r}$ as follows:

$$\mathbf{r} = \frac{\epsilon \mathbf{g}}{||\mathbf{g}||}$$
$$\mathbf{g} = sign(\nabla_{\mathbf{v}} \log P(\mathbf{y}|\mathbf{v}; \Theta))$$

To generate natural and legible adversarial sentences, we search in the word embedding space and replace the original word with a word that is closest to the perturbed word vector. However, as discussed in section 1, this approach can only generate perturbed examples using one perturbation step for structured prediction. Moreover, this model cannot guarantee quality (e.g., fluency) of the generating sentences.

3 Sentence-level Adversarial Attack and Defense

We aim to mislead a structured prediction model by generating adversarial examples $\hat{\mathbf{x}}$ from the original examples $\mathbf{x}$ using a seq2seq generator. We train the generator using reinforcement learning following Williams (1992). The reward function for reinforcement learning evaluates whether the generated sentence could induce an incorrect output from the victim model, and the evaluation is facilitated by two reference models. In addition, the reward function also evaluates the quality of the generated sentence. Figure 2 illustrates the overall architecture of our proposed model, which mainly consists of three parts: a generator, an evaluation module, and the victim model. We use dependency parsing as our example structured prediction task and name the victim parser as parser A and the reference parsers as Parsers B and C.

In contrast to the word-level attackers described in section 2.3, our proposed method aims to do sentence-level attacks that are capable of generating a sentence of a different length and structure instead of merely making local word changes.

3.1 Evaluation Criterion for Structured Outputs

Since the structured output is very sensitive to perturbation of the input, the parse of the original sentence $\mathbf{x}$ cannot be treated as the ground truth of the generated adversarial sentence $\hat{\mathbf{x}}$. Without knowing the new ground truth, we would not know if the adversarial sentence can indeed mislead parser A to produce an incorrect prediction. Thus we make use of two reference parsers B and C to evaluate the prediction of parser A and help guide the generation of truly adversarial examples. Intuitively, if B and C produce the same parse tree, then it is more likely to be correct and can be used as ground-truth to evaluate parser A.

Given a generated sentence $\hat{\mathbf{x}}$, if the predicted parse tree $\mathbf{y}^A_{\hat{\mathbf{x}}}$ from parser A is greatly different from the predicted trees $\mathbf{y}^B_{\hat{\mathbf{x}}}$ and $\mathbf{y}^C_{\hat{\mathbf{x}}}$ from parsers B and C, while $\mathbf{y}^B_{\hat{\mathbf{x}}}$ and $\mathbf{y}^C_{\hat{\mathbf{x}}}$ agree with each other, then we think $\hat{\mathbf{x}}$ is a good adversarial example of parser A. The criterion is defined as follows:

$$s_p(\hat{\mathbf{x}}) = -f(\mathbf{y}^A_{\hat{\mathbf{x}}}, \mathbf{y}^B_{\hat{\mathbf{x}}}) - f(\mathbf{y}^A_{\hat{\mathbf{x}}}, \mathbf{y}^C_{\hat{\mathbf{x}}}) + f(\mathbf{y}^B_{\hat{\mathbf{x}}}, \mathbf{y}^C_{\hat{\mathbf{x}}}) \tag{1}$$

where $f(\mathbf{y}, \mathbf{y}^*)$ is a symmetric function that evaluates the difference between two parse trees $\mathbf{y}$ and $\mathbf{y}^*$. A higher value of $s_p(\hat{\mathbf{x}})$ means $\hat{\mathbf{x}}$ is more adversarial.

The primary criterion for selecting parsers B and C is their parsing accuracy. As we defined in Equation 1, the consensus prediction of parsers B and C is regarded as ground truth, no matter whether the prediction is actually right or wrong. Thus parsers B and C should have high accuracy and also different inductive biases so that they are unlikely to make the same mistake. In addition, B and C should not be too similar to parser A, because otherwise the first two terms in Equation 1 would become hard to optimize.

3.2 Evaluation Criteria for Sentence Quality

We consider two aspects of the sentence quality as follows:

- Fluency: Inspired by Holtzman et al. (2018); Xu et al. (2018); Pang et al. (2020), we use perplexity on GPT-2 (Radford et al., 2019), a large Transformer language model trained on massive texts, to evaluate the fluency of the generated sentences. We use the negative perplexity as a reward in the learning process.

$$s_f(\hat{\mathbf{x}}) = -PPL(\hat{\mathbf{x}})$$

- Meaning Preservation: Adversarial examples that differ too much from the original sentences are less effective in attacks because humans can easily identify them. We use BERTScore (Zhang et al., 2019b) as another reward in learning to evaluate the similarity between two sentences at the meaning level. We choose to use BERTScore because it correlates better with human judgments than traditional measures such as BLEU (Papineni et al., 2002).

$$s_m(\mathbf{x}, \hat{\mathbf{x}}) = BERTScore(\mathbf{x}, \hat{\mathbf{x}})$$

By maximizing these criteria, we hope to make the adversarial examples look more like human generated sentences and not differ too much from the original sentences in meaning.

3.3 Sentence Generator

We propose to use a seq2seq model (Wang et al., 2016) as the adversarial sentence generator, which has been widely used in machine translation, dialogue and many other areas. The seq2seq model specifies $P(\hat{\mathbf{x}}|\mathbf{x}; \Theta)$, the conditional probability of generating an adversarial sentence $\hat{\mathbf{x}}$ given an input sentence $\mathbf{x}$. We train the model by reinforcement learning guided by our aforementioned criteria. The objective function is the expected reward based on the sentences from the training corpus $\mathcal{X}$,

$$J(\Theta) = \sum_{\mathbf{x} \in \mathcal{X}} E_{\hat{\mathbf{x}} \sim P(\hat{\mathbf{x}}|\mathbf{x};\Theta)} s(\mathbf{x}, \hat{\mathbf{x}})$$

The reward $s(\mathbf{x}, \hat{\mathbf{x}})$ is composed of three parts.

$$s(\mathbf{x}, \hat{\mathbf{x}}) = \alpha s_p(\hat{\mathbf{x}}) + \beta s_f(\hat{\mathbf{x}}) + \gamma s_m(\mathbf{x}, \hat{\mathbf{x}}) \tag{2}$$

where α, β, γ are tunable hyper-parameters that control the balance between the three parts. We optimize the objective function with the REINFORCE algorithm (Williams, 1992).

To further encourage meaning preservation between $\mathbf{x}$ and $\hat{\mathbf{x}}$, we also pretrain the seq2seq model as a denoising auto-encoder before reinforcement learning. Specifically, during pretraining we add noise to the hidden states of encoder and train the decoder to recover the input sentence. We employ the masking noise method that masks each word of the input sentence by a fixed probability and trains the denoising autoencoder to fill in these "blanks" (Vincent et al., 2008).

3.4 Defense against Adversarial Attack

Following Goodfellow et al. (2015), we use adversarial training to withstand attacks. More specifically, we enhance the victim model by injecting adversarial examples into the training data and retraining the model with the mixed data.

4 Experiments on Dependency Parsing

We first perform experiments on dependency parsing, a well-known structured prediction task.

4.1 Data

Our model does not need labeled data for training but we need a victim parser and two reference parsers in our experiments. We learn these parsers on an English dataset: Penn Treebank 3.0 (PTB, Marcus et al. (1994)). We also use the same data for training and evaluating our model.

4.2 Parser Selection

We choose the Deep Biaffine parser (Dozat and Manning (2017)), one of the state-of-the-art graph-based parsers, as the victim parser A. For the reference parsers, we choose two other well-known dependency parsers:

- **Parser B**: StackPTR from Ma et al. (2018)
- **Parser C**: BiST from Kiperwasser and Goldberg (2016)

The three parsers are trained with PTB. All the hyper-parameters of these parsers are the same as reported in their papers.

4.3 Evaluation Metrics

Our goal is to generate fluent sentences that are mispredicted by the victim model. Thus, we evaluate the adversarial examples produced by our model from 2 aspects: generation fluency and attacking efficiency (6 metrics).

Generation Fluency We use the perplexity on GPT-2 to evaluate the fluency of the generated sentences.

Attacking efficiency We evaluate the attacking success rates at the token level and sentence level. The token level attacking success rate is the percentage of words in the generated adversarial examples that are assigned the wrong head without considering the labels of the dependence type. It is also known as unlabeled attachment score (UAS). Sentence-level attacking success rate is the percentage of mispredicted sentences in the generated adversarial examples. Due the lack of golden parse trees of generated sentences, here we leverage the parses predicted by Parsers B and C as ground truth. The token level and sentence level each has three metrics: predictions of B as ground truth, predictions of C as ground truth, and consensus predictions of B and C as ground truth (discarding the sentences on which they disagree).

Human evaluation We conduct human evaluation of the fluency and attacking efficiency. All the volunteers have a background of linguistic study and are proficient in English. We further train the volunteers with the annotated English PTB treebank. From the adversarial examples generated by our method, we randomly sample 50 examples. During labeling, we ask two of them to label the sentences and the third skilled volunteers to double-check the evaluation results. For fluency, we ask them to rate the fluency of a sentence by an integer from 1 to 5. 5 indicates a sentence is fluent and has no grammatical errors. 1 indicates a sentence is full of grammatical errors and meaningless. For attacking efficiency, we ask them to manually annotate erroneous dependency edges and calculate the error rate in the same way as in automatic evaluation. The predictions of the Parsers B and C are given for reference.

4.4 Experimental Setup

We take the word-level approach in section 2.3 as our baseline, which uses a one-step update. Intuitively, this approach maintains the length of sentences and perturbs sentences by word-level replacement.

For our seq2seq generator, we use an attention-based three layers of BiLSTM with hidden vector dimension 1024. First, we pretrain the seq2seq generator for 3 epochs with unlabeled sentences from the PTB training set. The objective function for pretraining is negative conditional log likelihood. Then we train the seq2seq generator using reinforcement learning with hyper-parameter $\alpha = 1$,

	Generation Fluency (Perplexity ↓)	**Token level Attacking Success Rate**			**Sentence level Attacking Success Rate**		
		Parser B	*Parser C*	*Parsers B&C*	*Parser B*	*Parser C*	*Parsers B&C*
Origin	**156.02**	3.2	3.6	4.6	34.2	35.3	40.7
Baseline	217.02	3.8	4.2	6.5	55.6	57.5	71.7
Ours	174.16	**13.9**	**19.2**	**24.1**	**87.4**	**86.5**	**89.0**

Table 1: Experimental results on dependency parsing based on automatic evaluation. "Origin" shows the results of original sentences in the PTB test set. Lower perplexity is better.

	Generation Fluency ↑	**Attacking Success Rate**	
		Token	*Sentence*
Baseline	3.21	10.8	64
Ours	**3.84**	**18.3**	**72**

Table 2: Experimental results on dependency parsing based on human evaluation. Higher is better.

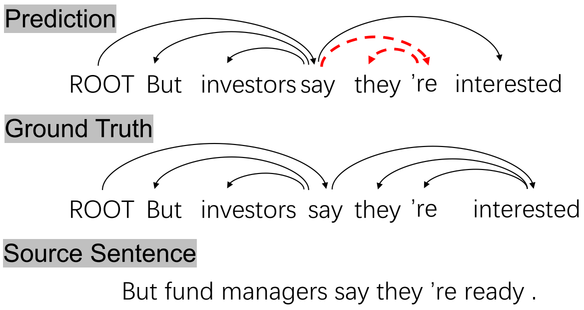

Figure 3: Case study of an adversarial example for dependency parsing task. The mispredicted dependencies of victim parser A are highlighted by dotted lines.

$\beta = 0.001$, $\gamma = 100$. Adam (Kingma and Ba, 2014) is used to optimize the parameters with the learning rate is $2e$-5. The minibatch size during reinforcement learning is 16. A detailed description of hyper-parameter settings can be found in Appendix A.

4.5 Experimental Results

Table 1 shows the automatic evaluation results. The attacking success rate improvement of our method over the baseline reflects the effectiveness of our reinforcement learning strategy. Particularly, our method improves the token level and sentence level attacking success rate 17.5% and 17.3% on Parsers B&C, respectively. It can also be seen that our proposed method maintains good fluency while making successful attacks. Human evaluation shown in Table 2 is consistent with automatic evaluation: our proposed method is significantly better than the baseline model at both generation fluency and attacking success rate. For better comparison, we ask volunteers to label the fluency score of the original sentences in PTB and obtain 4.64. We show an adversarial example in Figure 3.

	BLLIP-ABC	95.46
	Ours	**95.63**

Table 3: Adversarial Training on different datasets for dependency parsing. *Adv Train*: adversarial training.

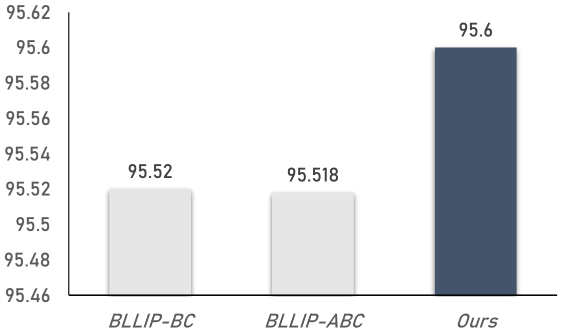

Figure 4: Average results of five time retrain using different datasets.

4.6 Adversarial Training

We then conduct experiments on adversarial training and summarize the results in Table 3. We add 2000 adversarial examples to the original training data and retrain the Biaffine parser[1]. We use the predicted parser Tree from Parsers B and C as the ground truth for these adversarial examples. If the parse trees from Parsers B and C are not the same, we drop the sentence. In addition to *W/O Adv Train* (result without adversarial training) and *Baseline* (retraining with adversarial examples produced by the word-level approach), we also experiment with the following two baseline methods of collecting 2000 additional training samples the BLLIP

---

[1] The candidate sentences are generated by the seq2seq generator using sentences in the training dataset as input. Then we drop the sentences that do **not** meet the criterion: reference parsers B and C predict the same parse trees that are different from the predictions of parser A (namely, the victim parser). Finally, we select the first 2000 sentences from the remaining 2044 sentences as the adversarial examples.

	Generation Fluency (Perplexity ↓)	**Token level Attacking Success Rate**			**Sentence level Attacking Success Rate**		
		Tagger B	*Tagger C*	*Tagger B&C*	*Tagger B*	*Tagger C*	*Tagger B&C*
Origin	156.02	1.9	2.1	3.2	30.6	35.5	45.7
Baseline	354.24	3.8	4.2	6.5	55.6	57.5	71.6
Ours	**142.59**	**9.2**	**7.3**	**14.5**	**78.1**	**73.3**	**89.0**

Table 4: Experimental results on POS tagging based on automatic evaluation. "Origin" shows the results of the original sentences. Lower perplexity is better.

	Generation Fluency ↑	**Attacking Success Rate**	
		Token	*Sentence*
Baseline	**3.98**	1.8	16
Ours	3.88	**8.1**	**52**

Table 5: Experimental results on POS tagging based on human evaluation. Higher means better.

dataset[2]:

- *BLLIP-BC*: Sampling sentences on which Parsers B and C predict the same parse trees.

- *BLLIP-ABC*: Sampling sentences on which Parsers B and C predict the same parse trees that are different from the predictions of Parser A.

We use the predicted parse trees from Parsers B and C as the ground truth for these two kinds of baselines. It can be seen that adversarial training, with adversarial examples leads to the largest performance gain over the "no adversarial training" baseline.

Although Table 3 shows that fine-tuning the victim parser A on our adversarial samples achieves better performance, the improvement is small. To investigate whether the improvement is significant or not, we retrain the parser A for five times with different random seeds. We also rerun the *BLLIP-BC* and *BLLIP-ABC* baselines (including the sampling step) for five times with different random seeds. The learning rate is $5e$-4. After training for 50 epochs, the average results are shown in Figure 4. It shows that our method outperforms the two baselines. We also perform Student's t-test:

- *BLLIP-BC* and *Ours*: t-value is -2.77 and p-value is 0.024.

- *BLLIP-ABC* and *Ours*: t-value is -3.39 and p-value is 0.010.

Both p-values are less than 0.05. That means the advantage of our method is statistically significant.

We also perform human evaluation on the retrained parser. The token level attacking success rate drops 1.3 points from 18.3 to 17.0, and the sentence level attacking success rate reduces from 72 to 70. We perform significance tests on the attacking success rate. The p-value is calculated by using the one-tailed sign test with bootstrap resampling on 50 samples following Chollampatt, Wang, and Ng (2019). We compare the attacking success rate with and without retraining. The p-values (5.42e-20 at the token level and 3.39e-21 at the sentence level) show that the improvement is significant.

5 Experiments on POS Tagging

5.1 Experimental Setup

In this section, we apply our method to the part-of-speech tagging task using the tagger from Ma and Hovy (2016) as the victim model. For the reference taggers, we choose two state-of-the-art taggers: Stanford POS tagger from Toutanova et al. (2003) and Senna tagger from Collobert et al. (2011). All the hyper-parameters of the three taggers are the same as reported in their papers. We conduct the experiments on the PTB dataset.

Similar to dependency parsing, the word level approach in section 2.3 is the baseline. For the adversarial example generator, we use the same structure and pretrain strategy as Section 4.4, except that the dimension of hidden state is set to 512. We train the sentence generator using reinforcement learning with hyper-parameter $\alpha = 1$, $\beta = 0.001$, $\gamma = 30$. Adam(Kingma and Ba, 2014) is used to optimize the parameters with learning rate $5e$-4. The minibatch size during reinforcement learning is 64. A detailed description of hyper-parameter settings can be found in Appendix B. We employ the same set of evaluation metrics as in section 4.3.

5.2 Experimental Results

We perform automatic evaluation over all the samples generated from the test dataset. As shown in

---

[2] Brown Laboratory for Linguistic Information Processing (BLLIP) 1987-89 WSJ Corpus Release 1. We choose the BLLIP corpus because it is collected from the same news article source as the WSJ corpus.

Prediction	NNP	NNS	VBD	VBG	.
Ground Truth	CC	NNS	VBD	VBG	.
Generated Sentence	But	stocks	went	falling	.
Original Sentence	Stocks kept falling .				
Prediction	NNP	NN	VBD	.	
Ground Truth	DT	NN	VBD	.	
Generated Sentence	The	market	went	.	
Original Sentence	Market crumbled .				

Figure 5: Case study of an adversarial example for POS tagging task. The mispredicted POS tags of victim tagger A are highlighted with underlines.

Table 4, attacking success rate and fluency of our proposed method are both above those of the baseline, which indicates the effectiveness of our proposed method. Particularly, our method improves the token level and sentence level attacking success rate 8.0% and 17.3%, respectively.

Similar to the dependency parsing task, Table 5 shows the result of human evaluation of 50 samples. According to human evaluation, the fluency of sentences generated by the two methods is similar, but the attacking success rate of our method is significantly higher than the baseline. Two example are shown in Figure 5.

We also conduct experiments on adversarial training with 1000 additional samples produced by our method. After retraining, the accuracy of Tagger A improves 0.13 point from 97.55 to 97.68 on PTB the test set. Similar to dependency parsing, we perform t-test to measure the statistical significance of the advantage of our method in POS tagging. The resulting p-value is 0.027.

6 Analysis

6.1 Selecting Reference Model

We mention in the Section 3.1 that the victim model and the two reference model should differ from each other as much as possible. In our previous experiments in Section 4 , we use three different types of parsers as the victim parser (Deep Biaffine) and reference parsers (StackPtr and BiST). Here we investigate the impact of making them similar. First, we make the two reference parsers similar to the victim parser, by training two Deep Biaffine parsers with different random seeds. We call this AllSame. Second, we make the two reference parsers similar to each other but different from the victim parser, by training two StackPtr parsers with different random seeds. We call this EvalSame.

Table 7 shows that AllSame tends to generate fluent sentences but the sentences are less adversarial. This can be explained by the fact that the similarity between the parsers make the first term of Equation 2 very small and the reward function is dominated by the two sentence quality terms. EvalSame can be seen to produce slightly higher token level attacking success rate but significantly lower generation fluency. Compared with AllSame and EvalSame, our standard method of using two different parsers as the reference models can reach a better attacking success rate, while keeping the sentences relatively fluent.

6.2 Applicability Analysis

We repeat our experiment of dependency parsing following the setup of Table 1 except for the choice of the victim parser and reference parsers. We use StackPTR as the victim model while the Deep Biaffine parser and BiST as Parser B and Parser C. Table 6 shows the automatic evaluation results. The results show similar trends to those in Table 1, suggesting that our approach is effective to different choices of the victim parser and reference parsers.

7 Related Work

Attack Design on Un-structured Prediction Model Following the success in the image processing area (Goodfellow et al., 2015), the idea of adding continuous perturbations to inputs has been applied to tasks in NLP (Sato et al., 2018; Gong et al., 2018). In order to solve the mapping problem from the modified word vector to the word, Papernot et al. (2016) built a special dictionary to select words to replace the original words. In addition to replacement manipulation, Samanta and Mehta (2017) introduced three modification strategies: removal and addition. Michel et al. (2019) leveraged atomic character-level operation. Some attack strategies to generate adversarial examples have been proposed in the sentence level setting. Zhao et al. (2018) searched adversarial examples in the continuous vector space and then used generative adversarial networks (Goodfellow et al., 2014) to map the fixed-length vectors to data instances. However, these attackers are only designed for classification tasks or generation tasks and can not be easily applied to structured prediction systems.

Attack Design on Structured Prediction Model There is also some prior work on attacking structured prediction models. Cisse et al. (2017) proposed to attack structured prediction models in the

image processing field, such as those for pose estimation and semantic segmentation. In a separate line of work, Zügner and Günnemann (2019) proposed to attack graph neural network for node classification.

8 Conclusion

Building an effective adversarial attacker for structured prediction models is challenging. The biggest challenge is the sensitivity of the output to small perturbations in the input in structured prediction. In this paper, we propose a novel framework to attack structured prediction models in NLP. Our framework consists of a structured-output evaluation criterion based on reference models and a seq2seq sentence generator. We propose to utilize reinforcement learning to train the sentence generator based on the evaluation criterion. Our attack experiments on dependency parsing and POS tagging show that our proposed framework can produce high-quality sentences that can effectively attack current state-of-the-art models. Our defense experiments show that adversarial training using the adversarial samples generated by our model can be used to improve the original model. We believe that our framework is general and can be applied to many other structured prediction tasks in NLP, such as neural machine translation, semantic parsing and so on.

C Hyper-Parameter Search

The criterion used to select all the hyper-parameters is the performance on the development data. We mainly tune the hyper-parameters of the text generator. For example, we choose the dimension of the hidden layer from 20 values in the range of 32 to 2048.

Position-Aware Tagging for Aspect Sentiment Triplet Extraction

Abstract

Aspect Sentiment Triplet Extraction (ASTE) is the task of extracting the triplets of target entities, their associated sentiment, and opinion spans explaining the reason for the sentiment. Existing research efforts mostly solve this problem using pipeline approaches, which break the triplet extraction process into several stages. Our observation is that the three elements within a triplet are highly related to each other, and this motivates us to build a joint model to extract such triplets using a sequence tagging approach. However, how to effectively design a tagging approach to extract the triplets that can capture the rich interactions among the elements is a challenging research question. In this work, we propose the first end-to-end model with a novel *position-aware* tagging scheme that is capable of jointly extracting the triplets. Our experimental results on several existing datasets show that jointly capturing elements in the triplet using our approach leads to improved performance over the existing approaches. We also conducted extensive experiments to investigate the model effectiveness and robustness[1].

1 Introduction

Designing effective algorithms that are capable of automatically performing sentiment analysis and opinion mining is a challenging and important task in the field of natural language processing (Pang and Lee, 2008; Liu, 2010; Ortigosa et al., 2014; Smailović et al., 2013; Li and Wu, 2010). Recently, Aspect-based Sentiment Analysis (Pontiki et al., 2014) or Targeted Sentiment Analysis (Mitchell et al., 2013) which focuses on extracting target phrases as well as the sentiment associated with each target, has been receiving much attention. In this work, we focus on a relatively new task – Aspect Sentiment Triplet Extraction (ASTE) proposed by Peng et al. (2019). Such a task is required to extract not only the targets and the sentiment mentioned above, but also the corresponding opinion spans expressing the sentiment for each target. Such three elements: a target, its sentiment and the corresponding opinion span, form a triplet to be extracted. Figure 1 presents an example sentence containing two targets in solid boxes. Each target is associated with a sentiment, where we use + to denote the positive polarity, 0 for neutral, and − for negative. Two opinion spans in dashed boxes are connected to their targets by arcs. Such opinion spans are important, since they largely explain the sentiment polarities for the corresponding targets (Qiu et al., 2011; Yang and Cardie, 2012).

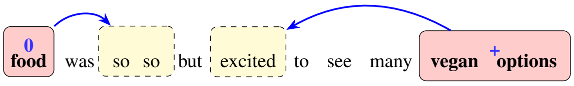

Figure 1: ASTE with targets in bold in solid squares, their associated sentiment on top, and opinion spans in dashed boxes. The arc indicates connection between a target and the corresponding opinion span.

This ASTE problem was basically untouched before, and the only existing work that we are aware of (Peng et al., 2019) employs a 2-stage pipeline approach. At the first stage, they employ a unified tagging scheme which fuses the target tag based on the $BIOES$[2] tagging scheme, and sentiment tag together. Under such a unified tagging scheme, they proposed methods based on Long Short-Term Memory networks (LSTM) (Hochreiter and Schmidhuber, 1997), Conditional Random

---

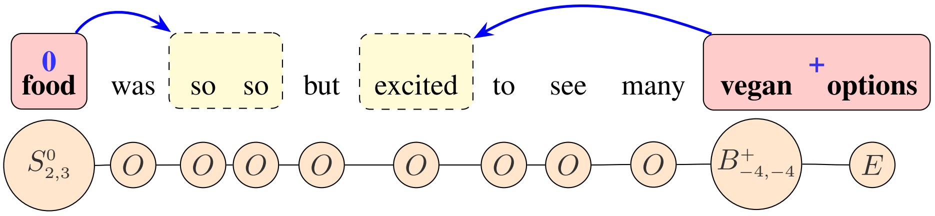

Figure 2: The position-aware tagging scheme for the example instance.

Fields (CRF) (Lafferty et al., 2001) and Graph Convolutional Networks (GCN) (Kipf and Welling, 2017) to perform sequence labeling to extract targets with sentiment as well as opinion spans. At the second stage, they use a classifier based on Multi-Layer Perceptron (MLP) to pair each target (containing a sentiment label) with the corresponding opinion span to obtain all the valid triplets.

One important observation is that the three elements in a triplet are highly related to each other. Specifically, sentiment polarity is largely determined by an opinion span as well as the target and its context, and an opinion span also depends on the target phrase in terms of wording (e.g., an opinion span *"fresh"* usually describes food targets instead of service). Such an observation implies that jointly capturing the rich interaction among three elements in a triplet might be a more effective approach. However, the $BIOES$ tagging scheme on which the existing approaches based comes with a severe limitation for this task: such a tagging scheme without encoding any positional information fails to specify the connection between a target and its opinion span as well as the rich interactions among the three elements due to the limited expressiveness. Specifically, $BIOES$ uses the tag B or S to represent the beginning of a target. For example, in the example sentence in Figure 1, *"vegan"* should be labeled with B, but the tagging scheme does not contain any information to specify the position of its corresponding opinion *"excited"*. Using such a tagging scheme inevitably leads to an additional step to connect each target with an opinion span as the second stage in the pipeline approach. The skip-chain sequence models (Sutton and McCallum, 2004; Galley, 2006) are able to capture interactions between given input tokens which can be far away from each other. However, they are not suitable for the ASTE task where the positions of targets and opinion spans are not explicitly provided but need to be learned.

Motivated by the above observations, we present a novel approach that is capable of predicting the triplets jointly for ASTE. Specifically, we make the following contributions in this work:

- We present a novel position-aware tagging scheme that is capable of specifying the structural information for a triplet – the connection among the three elements by enriching the label semantics with more expressiveness, to address the above limitation.
- We propose a novel approach, **JET**, to Jointly Extract the Triplets based on our novel position-aware tagging scheme. Such an approach is capable of better capturing interactions among elements in a triplet by computing factorized features for the structural information in the ASTE task.
- Through extensive experiments, the results show that our joint approach **JET** outperforms baselines significantly.

2 Our Approach

Our objective is to design a model **JET** to extract the triplet of Target, Target Sentiment, and Opinion Span jointly. We first introduce the new position-aware tagging scheme, followed by the model architecture. We next present our simple LSTM-based neural architecture for learning feature representations, followed by our method to calculate factorized feature scores based on such feature representations for better capturing the interactions among elements in a triplet. Finally, we also discuss a variant of our model.

2.1 Position-Aware Tagging Scheme

To address the limitations mentioned above, we propose our position-aware tagging scheme by enriching expressiveness to incorporate position information for a target and the corresponding opinion span. Specifically, we extend the tag B and tag S in the $BIOES$ tagging scheme to new tags respectively:

$$B^{\epsilon}_{j,k}, S^{\epsilon}_{j,k}$$

where $B^{\epsilon}_{j,k}$ with the sub-tag[3] B still denotes the beginning of a target, and $S^{\epsilon}_{j,k}$ with the sub-tag S denotes a single-word target. Note that $\epsilon \in \{+, 0, -\}$ denotes the sentiment polarity for the target, and j, k indicate the position information which are the distances between the two ends of an opinion span and the starting position of a target respectively. Here, we use the term "*offset*" to denote such position information for convenience. We keep the other tags I, E, O as is. In a word, we use sub-tags $BIOES$ for encoding targets, ϵ for sentiment, and offsets for opinion spans under the new position-aware tagging scheme for the structural information.

For the example in Figure 1, under the proposed tagging scheme, the tagging result is given in Figure 2. The single-word target *"food"* is tagged with $S^{0}_{2,3}$, implying the sentiment polarity for this target is neutral (0). Furthermore, the positive offsets $2, 3$ indicate that its opinion span is on the right and has distances of 2 and 3 measured at the left and right ends respectively, (i.e., *"so so"*). The second target is *"vegan options"* with its first word tagged with $B^{+}_{-4,-4}$ and the last word tagged with E, implying the sentiment polarity is positive $(+)$. Furthermore, the negative offsets $-4, -4$ indicate that the opinion span *"excited"* appears on the left of the target, and has distances of 4 and 4 measured at the left and right ends respectively, (i.e., *"vegan"*).

Our proposed position-aware tagging scheme has the following theoretical property:

Theorem 2.1. *There is a one-to-one correspondence between a tag sequence and a combination of aspect sentiment triplets within the sentence as long as the targets do not overlap with one another, and each has one corresponding opinion span.*[4]

Proof. For a given triplet, we can use the following process to construct the tag sequence. First note that the sub-tags of our proposed tags $B^{\epsilon}_{j,k}, I, O, E, S^{\epsilon}_{j,k}$, are B, I, O, E, S. The standard $BIOES$ tagset is capable of extracting all possible targets when they do not overlap with one another. Next, for each specified target, the position information j, k that specifies the position of its corresponding opinion span can be attached to the B (or S) tag, resulting in $B_{j,k}$ (or $S_{j,k}$). Note that the opinion span can be any span within the sentence when j, k are not constrained. Finally, we assign each extracted target its sentiment polarity ϵ by attaching it to the tag B (or S), resulting in $B^{\epsilon}_{j,k}$ (or $S^{\epsilon}_{j,k}$). This construction process is unique for each combination of triplets. Similarly, given a tag sequence, we can reverse the above process to recover the combination of triplets. $\square$

We would like to highlight that our proposed position-aware tagging scheme is capable of handling some special cases where the previous approach is unable to. For example, in the sentence *"The salad is cheap with fresh salmon"*, there are two triplets, (*"salad"*, *"cheap with fresh salmon"*, positive)[5] and (*"salmon"*, *"fresh"*, positive). The previous approach such as (Peng et al., 2019), which was based on a different tagging scheme, will not be able to handle such a case where the two opinion spans overlap with one another.

2.2 Our JET Model

We design our novel **JET** model with CRF (Lafferty et al., 2001) and Semi-Markov CRF (Sarawagi and Cohen, 2004) based on our position-aware tagging scheme. Such a model is capable of encoding and factorizing both token-level features for targets and segment-level features for opinion spans.

Given a sentence $\mathbf{x}$ with length n, we aim to produce the desired output sequence $\mathbf{y}$ based on the position-aware tagging scheme. The probability of $\mathbf{y}$ is defined as:

$$p(\mathbf{y}|\mathbf{x}) = \frac{\exp\left(s(\mathbf{x}, \mathbf{y})\right)}{\sum_{\mathbf{y}' \in \mathbf{Y}_{\mathbf{x},M}} \exp(s(\mathbf{x}, \mathbf{y}'))} \quad (1)$$

where $s(\mathbf{x}, \mathbf{y})$ is a score function defined over the sentence $\mathbf{x}$ and the output structure $\mathbf{y}$, and $\mathbf{Y}_{\mathbf{x},M}$ represents all the possible sequences under our position-aware tagging scheme with the offset constraint M, indicating the maximum absolute value of an offset. The score $s(\mathbf{x}, \mathbf{y})$ is defined as:

$$s(\mathbf{x}, \mathbf{y}) = \sum_{i=0}^{n} \psi_{\bar{\mathbf{y}}_i, \bar{\mathbf{y}}_{i+1}} + \sum_{i=1}^{n} \Phi_{\mathbf{y}_i}(\mathbf{x}, i) \quad (2)$$

where $\bar{\mathbf{y}}_i \in \{B, I, O, E, S\}$ returns the sub-tag of $\mathbf{y}_i$, $\psi_{\bar{\mathbf{y}}_i, \bar{\mathbf{y}}_{i+1}}$ represents the transition score: the weight of a "transition feature" – a feature defined over two adjacent sub-tags $\bar{\mathbf{y}}_i$ and $\bar{\mathbf{y}}_{i+1}$, and $\Phi_{\mathbf{y}_i}(\mathbf{x}, i)$ represents the factorized feature score with tag $\mathbf{y}_i$ at position i. In our model, the calculation of transition score $\psi_{\bar{\mathbf{y}}_i, \bar{\mathbf{y}}_{i+1}}$ is similar to the one

---

[3] We define the sub-tags of $B^{\epsilon}_{j,k}$, $S^{\epsilon}_{j,k}$ as B and S respectively, and the sub-tags of I, O, E as themselves.

[4] See the supplementary material for detailed statistics on how often this condition is satisfied.

[5] We use the format (target, opinion spans, sentiment).

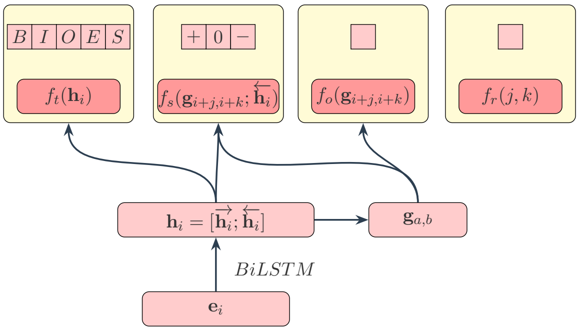

Figure 3: Neural Module for Feature Score

in CRF[6]. For the factorized feature score $\Phi_{\mathbf{y}_i}(\mathbf{x}, i)$, we will explain computation details based on a simple LSTM-based neural network in the following two subsections. Such a factorized feature score is able to encode both token-level features as in standard CRF, segment-level features as in Semi-Markov CRF as well as the interaction among a target, its sentiment and an opinion span in a triplet.

2.2.1 Neural Module

We deploy a simple LSTM-based neural architecture for learning features. Given an input token sequence $\mathbf{x} = \{x_1, x_2, \cdots, x_n\}$ of length n, we first obtain the embedding sequence $\{\mathbf{e}_1, \mathbf{e}_2, \cdots, \mathbf{e}_n\}$. As illustrated in Figure 3, we then apply a bi-directional LSTM on the embedding sequence and obtain the hidden state $\mathbf{h}_i$ for each position i, which could be represented as:

$$\mathbf{h}_i = [\overrightarrow{\mathbf{h}}_i; \overleftarrow{\mathbf{h}}_i] \tag{3}$$

where $\overrightarrow{\mathbf{h}}_i$ and $\overleftarrow{\mathbf{h}}_i$ are the hidden states of the forward and backward LSTMs respectively.

Motivated by (Wang and Chang, 2016; Stern et al., 2017), we calculate the segment representation $\mathbf{g}_{a,b}$ for an opinion span with boundaries of a and b (both inclusive) as follows:

$$\mathbf{g}_{a,b} = [\overrightarrow{\mathbf{h}}_b - \overrightarrow{\mathbf{h}}_{a-1}; \overleftarrow{\mathbf{h}}_a - \overleftarrow{\mathbf{h}}_{b+1}] \tag{4}$$

where $\overrightarrow{\mathbf{h}}_0 = \mathbf{0}$, $\overleftarrow{\mathbf{h}}_{n+1} = \mathbf{0}$ and $1 \leq a \leq b \leq n$.

2.2.2 Factorized Feature Score

We explain how to compute the factorized feature scores (the second part of Equation 2) for the position-aware tagging scheme based on the neural architecture described above. Such factorized feature scores involve 4 types of scores, as illustrated in the solid boxes appearing in Figure 3 (top).

Basically, we calculate the factorized feature score for the tag $\mathbf{y}_i$ as follows:

$$\Phi_{\mathbf{y}_i}(\mathbf{x}, i) = f_t(\mathbf{h}_i)_{\bar{\mathbf{y}}_i} \tag{5}$$

where the linear layer f_t is used to calculate the score for local context for targets. Such a linear layer takes the hidden state $\mathbf{h}_i$ as the input and returns a vector of length 5, with each value in the vector indicating the score of the corresponding sub-tag among $BIOES$. The subscript $\bar{\mathbf{y}}_i$ indicates the index of such a sub-tag.

When $\mathbf{y}_i \in \{B^{\epsilon}_{j,k}, S^{\epsilon}_{j,k}\}$, we need to calculate 3 additional factorized feature scores for capturing structural information by adding them to the basic score as follows:

$$\Phi_{\mathbf{y}_i}(\mathbf{x}, i) \mathrel{+}= \tag{6}$$
$$f_s([\mathbf{g}_{i+j,i+k}; \overleftarrow{\mathbf{h}}_i])_{\epsilon} + f_o(\mathbf{g}_{i+j,i+k}) + f_r(j,k)$$

Note that the subscript of the variable $\mathbf{g}$ is represented as $i+j, i+k$ which are the absolute positions since j, k are the offsets. We explain such 3 additional factorized scores appearing in Equation 6.

- $f_s([\mathbf{g}_{i+j,i+k}; \overleftarrow{\mathbf{h}}_i])_{\epsilon}$ calculates the score for the sentiment. A linear layer f_s takes the concatenation of the segment representation $\mathbf{g}_{i+j,i+k}$ for an opinion span and the local context $\overleftarrow{\mathbf{h}}_i$ for a target, since we believe that the sentiment is mainly determined by the opinion span as well as the target phrase itself. Note that we only use the backward hidden state $\overleftarrow{\mathbf{h}}_i$ here, because the end position of a target is not available in the tag and the target phrase appears on the right of this position i. The linear layer f_s returns a vector of length 3, with each value representing the score of a certain polarity of $+, 0, -$. The subscript ϵ indicates the index of such a polarity.
- $f_o(\mathbf{g}_{i+j,i+k})$ is used to calculate a score for an opinion span. A linear layer f_o takes the segment representation $\mathbf{g}_{i+j,i+k}$ of an opinion span and returns one number representing the score of an opinion span.
- $f_r(j,k)$ is used to calculate a score for offsets, since we believe the offset is an important feature. A linear layer f_r returns one number representing the score of offsets j, k which again are the distances between a target and two ends of the opinion span. Here, we introduce the offset embedding $\mathbf{w_r}$ randomly initialized for encoding different offsets. Specifically, we

---

[6] We calculate the transition parameters among five sub-tags $BIOES$ for targets.

calculate the score as follows[7]:

$$f_r(j,k) = W_r \mathbf{w_r}[\min{(j,k)}] + b_r \qquad (7)$$

where W_r and b_r are learnable parameters.

2.3 One Target for Multiple Opinion Spans

The approach **JET** described above allows multiple targets to point to the same opinion span. One potential issue is that such an approach is not able to handle the case where one target is associated with multiple opinion spans. To remedy such an issue, we could swap a target and an opinion span to arrive at a new model as a model variant, since they are both text spans which are characterized by their boundaries. Specifically, in such a model variant, we still use the extended tags $B^{\epsilon}_{j,k}$ and $S^{\epsilon}_{j,k}$, where we use sub-tags $BIOES$ to encode an opinion span, the offsets j,k for the target and ϵ for the sentiment polarity. We use a similar procedure for the feature score calculation.

To differentiate with our first model, we name our first model as **JET**^{t} and such a model variant as **JET**^{o}. The superscripts t and o indicate the use of the sub-tags B and S to encode a target and an opinion span respectively. Figure 4 presents the gold tagging sequence of **JET**^{o}.

2.4 Training and Inference

The loss function $\mathcal{L}$ for the training data D is defined as:

$$\mathcal{L} = -\sum_{(\mathbf{x},\mathbf{y})\in D} \log p(\mathbf{y}|\mathbf{x}). \qquad (8)$$

The overall model is analogous to that of a neural CRF (Peng et al., 2009; Do et al., 2010; Lample et al., 2016); hence the inference and decoding follow standard marginal and MAP inference[8] procedures. For example, the prediction of $\mathbf{y}$ follows the Viterbi-like MAP inference procedure during decoding. Notice that the number of labels at each position under the position-aware tagging scheme is $O(M^2)$, since we need to compute segment representation for text spans of lengths within M. Hence, the time complexity for inference is $O(nM^2)$. When $M \ll n$ (empirically, we found n can be up to 80 in our datasets, and we set $M \in [2,6]$), this complexity is better than the existing work with complexity $O(n^2)$ (Peng et al., 2019).

3 Experiments

3.1 Data

We refine the dataset previously created by Peng et al. (2019)[9]. We call our refined dataset ASTE-Data-V2, and the original version as ASTE-Data-V1[10]. Note that ASTE-Data-V1 does not contain cases where one opinion span is associated with multiple targets. For example, there are two targets, "*service*" and "*atmosphere*", in the sentence "*Best service and atmosphere*". The opinion span "*Best*" is associated with such two targets, resulting in two triplets. However, we found that not all such triplets are explicitly annotated in ASTE-Data-V1. We refine the dataset with these additional missing triplets in our dataset ASTE-Data-V2[11].

Table 1 presents the detailed statistics for 4 datasets.[12] `14Rest`, `15Rest`, `16Rest` are the datasets of restaurant domain and `14Lap` is of laptop domain. Such datasets were all created based on the datasets originally released by SemEval (Pontiki et al., 2014, 2015, 2016).

---

[7] We use $\min{(j,k)}$ since we care the offset between the starting positions of an opinion span and a target.

[8] See the supplementary materials for detailed algorithm.

[9] `https://github.com/xuuuluuu/SemEval-Triplet-data`

[10] We also report the results on ASTE-Data-V1 in the supplementary material.

[11] We also remove triplets with sentiment originally labeled as "conflict" by SemEval.

[12] See the supplementary material for more statistics.

3.2 Baselines

Our **JET** approaches are compared with the following baselines using pipeline.

- **RINANTE+** (Peng et al., 2019) modifies **RINANTE** (Dai and Song, 2019) which is designed based on LSTM-CRF (Lample et al., 2016), to co-extract targets with sentiment, and opinion spans. Such an approach also fuses mined rules as weak supervision to capture dependency relations of words in a sentence at the first stage. At the second stage, it generates all the possible triplets and applies a classifier based on MLP on such triplets to determine if each triplet is valid or not.
- **CMLA+** (Peng et al., 2019) modifies **CMLA** (Wang et al., 2017) which leverages attention mechanism to capture dependencies among words, to co-extract targets with sentiment, and opinion spans at the first stage. At the second stage, it uses the same method to obtain all the valid triplets as **RINANTE+**.
- **Li-unified-R** (Peng et al., 2019) modifies the model (Li et al., 2019) to extract targets with sentiment, as well as opinion spans respectively based on a customized multi-layer LSTM neural architecture. At the second stage, it uses the same method to obtain all the valid triplets as **RINANTE+**.
- Peng et al. (2019) proposed an approach motivated by **Li-unified-R** to co-extract targets with sentiment, and opinion spans simultaneously. Such an approach also fuses GCN to capture dependency information to facilitate the co-extraction. At the second stage, it uses the same method to obtain all the valid triplets as **RINANTE+**.

3.3 Experimental Setup

Following the previous work (Peng et al., 2019), we use pre-trained 300d GloVe (Pennington et al., 2014) to initialize the word embeddings. We use 100 as the embedding size of $\mathbf{w_r}$ (offset embedding). We use the bi-directional LSTM with the hidden size 300. For experiments with contextualised representation, we adopt the pre-trained language model BERT (Devlin et al., 2019). Specifically, we use bert-as-service (Xiao, 2018) to generate the contextualized word embedding without fine-tuning. We use the representation from the last layer of the uncased version of BERT base model for our experiments.

Before training, we discard any instance from the training data that contains triplets with offset larger than M. We train our model for a maximal of 20 epochs using Adam (Kingma and Ba, 2014) as the optimizer with batch size 1 and dropout rate 0.5[13]. We select the best model parameters based on the best F_1 score on the development data and apply it to the test data for evaluation.

Following the previous works, we report the *precision* ($P.$), *recall* ($R.$) and F_1 scores for the correct triplets. Note that a correct triplet requires the boundary[14] of the target, the boundary of the opinion span, and the target sentiment polarity to be all

---

[13] See the supplementary materials for experimental details. We use a different dropout rate 0.7 on the dataset `14Lap` based on preliminary results since the domain is different from the other 3 datasets.

[14] We define a boundary as the beginning and ending positions of a text span.

correct at the same time.

3.4 Main Results

Table 2 presents the main results, where all the baselines as well as our models with different maximum offsets M are listed. In general, our joint models **JET**^{t} and **JET**^{o}, which are selected based on the best F_1 score on the dev set, are able to outperform the most competitive baseline of Peng et al. (2019) on the 4 datasets `14Rest`, `15Rest`, `16Rest`, and `14Lap`. Specifically, the best models selected from **JET**^{t} and **JET**^{o} outperform Peng et al. (2019) significantly[15] on `14Rest` and `16Rest` datasets with $p < 10^{-5}$ respectively. Such results imply that our joint models **JET**^{t} and **JET**^{o} are more capable of capturing interactions among the elements in triplets than those pipeline approaches. In addition, we observe a general trend from the results that the F_1 score increases as M increases on the 4 datasets when $M \leq 5$. We observe that the performance of **JET**^{t} and **JET**^{o} on the dev set of `14Lap` drops when $M = 6$.

For the dataset `14Rest`, **JET**$^o(M = 6)$ achieves the best results on F_1 scores among all the **JET**^{o} models. Such a **JET**$^o(M = 6)$ model outperforms the strongest baseline Peng et al. (2019) by nearly 7 F_1 points. **JET**$^t(M = 6)$ also achieves a good performance with 56.58 in terms of F_1 score. Comparing results of our models to baselines, the reason why ours have better F_1 scores is that our models **JET**$^t(M \geq 4)$ and **JET**$^o(M \geq 4)$ both achieve improvements of more than 15 precision points, while we maintain acceptable recall scores. Similar patterns of results on the datasets `14Lap`, `15Rest` and `16Rest` are observed, except that **JET**$^t(M = 5)$ and **JET**$^o(M = 5)$ achieves the best F_1 score on the dev set of `14Lap`. Furthermore, we discover that the performance of both **JET**^{o} and **JET**^{t} on `14Rest` and `16Rest` datasets is better than on`14Lap` and `15Rest` datasets. Such a behavior can be explained by the large distribution differences of positive, neutral and negative sentiment between the train and test set of the `14Rest` and `16Rest` datasets, shown in Table 1.

Furthermore, we also conduct additional experiments on our proposed model with the contextualized word representation BERT. Both **JET**^{t} $(M = 6)_{\text{+ BERT}}$ and **JET**^{o} $(M = 6)_{\text{+ BERT}}$ achieve new state-of-the-art performance on the four datasets.

4 Analysis

4.1 Robustness Analysis

We analyze the model robustness by assessing the performance on targets, opinion spans and offsets of different lengths for two models **JET**$^t(M = 6)_{\text{+ BERT}}$ and **JET**$^o(M = 6)_{\text{+ BERT}}$ on the four datasets. Figure 5 shows the results on the `14Rest` dataset[16]. As we can see, **JET**$^o(M = 6)_{\text{+ BERT}}$ is able to better extract triplets with targets of lengths ≤ 3 than **JET**$^t(M = 6)_{\text{+ BERT}}$. Furthermore, **JET**$^o(M = 6)_{\text{+ BERT}}$ achieves a better F_1 score for triplets whose opinion spans are of length 1 and 4. However, **JET**$^o(M = 6)_{\text{+ BERT}}$ performs comparably to **JET**$^t(M = 6)_{\text{+ BERT}}$ for triplets whose opinion spans are of length 2 and 3. In addition, **JET**$^o(M = 6)_{\text{+ BERT}}$ is able to outperform **JET**$^t(M = 6)_{\text{+ BERT}}$ with offset of length 4 and above. We also observe that the performance drops when the lengths of targets, opinion spans and offsets are longer. This confirms that modeling the boundaries are harder when their lengths are longer. Similar patterns of results are observed on `14Lap`, `15Rest`, and `16Rest`[17].

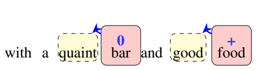
We also investigate the robustness on different evaluation methods, as presented in Figure 6. T

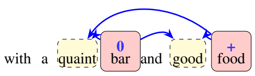
---

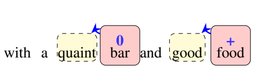
[15] We have conducted significance test using the bootstrap resampling method (Koehn, 2004).

[16] See the supplementary material for the statistics of accumulative percentage of different lengths for targets, opinion spans and offsets.

[17] See the supplementary material for results on the other 3 datasets.

Gold	Peng et al. (2019)	**JET**^{t}	**JET**^{o}
						






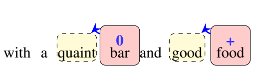


Table 3: Qualitative Analysis

(Target), O (Opinion Span) and S (Sentiment) are the elements to be evaluated. The subscript p on the right of an element in the legend denotes "partially correct". We define two boundaries to be partially correct if such two boundaries overlap. (T, O, S) is the evaluation method used for our main results. (T_p, O, S) requires the boundary of targets to be partially correct, and the boundary of opinion spans as well as the sentiment to be exactly correct. (T, O_p, S) requires the boundary of opinion spans to be partially correct, and the boundary of targets as well as the sentiment to be exactly correct. The results based on (T, O_p, S) yield higher improvements in terms of F_1 points than results based on (T_p, O, S), compared with (T, O, S) for **JET**$^t(M = 6)_{\text{+ BERT}}$ except on `15Rest`. The results based on (T_p, O, S) yield higher F_1 improvements than results based on (T, O_p, S), compared with (T, O, S) for **JET**$^o(M = 6)_{\text{+ BERT}}$ except on `15Rest`. Such a comparison shows the boundaries of opinion spans or target spans may be better captured when the sub-tags $BIOES$ are used to model the opinion or target explicitly.

4.2 Qualitative Analysis

To help us better understand the differences among these models, we present two example sentences selected from the test data as well as predictions by Peng et al. (2019), **JET**^{t} and **JET**^{o} in Table 3 [18]. As we can see, there exist 2 triplets in the gold data in the first example. Peng et al. (2019) predicts an incorrect opinion span *"hot ready"* in the second triplet. **JET**^{t} only predicts 1 triplet due to the model's limitation (**JET**^{t} is not able to handle the case of one target connecting to multiple opinion spans). **JET**^{o} is able to predict 2 triplets correctly. In the second example, the gold data contains two triplets. Peng et al. (2019) is able to correctly predict all the targets and opinion spans. However, it incorrectly connects each target to both two opinion spans. Our joint models **JET**^{t} and **JET**^{o} are both able to make the correct prediction.

Model	`14Rest` **JET**^{t}	`14Rest` **JET**^{o}	`14Lap` **JET**^{t}	`14Lap` **JET**^{o}
$M = 6_{\text{+ BERT}}$	58.41	62.40	47.86	51.04
+char embedding	59.13	62.23	47.71	51.38
−offset features	55.36	61.24	44.16	49.58
−opinion span features	57.93	62.04	47.66	50.48
	`15Rest`		`16Rest`	
	JET^t	**JET**^{o}	**JET**^{t}	**JET**^{o}
$M = 6_{\text{+ BERT}}$	52.66	57.53	57.85	63.83
+char embedding	51.28	56.84	57.11	63.95
−offset features	48.74	53.68	52.83	61.72
−opinion span features	51.37	56.92	57.16	62.71

Table 4: Ablation Study (F_1)

4.3 Ablation Study

We also conduct an ablation study for **JET**$^t(M = 6)_{\text{+ BERT}}$ and **JET**$^o(M = 6)_{\text{+ BERT}}$ on dev set of the 4 datasets, presented in Table 4. "+char embedding" denotes concatenating character embedding into word representation. The results show that concatenating character embedding mostly has no much positive impact on the performance, which we believe is due to data sparsity. "−offset features" denotes removing $f_r(j, k)$ in the feature score calculation, Equation 6. F_1 scores drop more on the **JET**$^t(M = 6)_{\text{+ BERT}}$, this further confirms that modeling the opinion span is more difficult than target. "−opinion features" denotes removing $f_o(\mathbf{g}_{i+j,i+k})$ in the feature score calculation in Equation 6. F_1 scores drop consistently, implying the importance of such features for opinion spans.

4.4 Ensemble Analysis

As mentioned earlier, **JET**^{o} is proposed to overcome the limitation of **JET**^{t}, and vice versa. We believe that such two models complement each other. Hence, we propose two ensemble models **JET**$^{o \rightarrow t}$ and **JET**$^{t \rightarrow o}$ to properly merge the results produced by **JET**^{t} and **JET**^{o}. **JET**$^{o \rightarrow t}$ merges results of **JET**^{o} towards **JET**^{t} by adding distinct triplets from **JET**^{o} to **JET**^{t}, and analogously for **JET**$^{t \rightarrow o}$. We discuss how we build the ensemble models based on the two models **JET**^{t} and **JET**^{o} (with BERT, $M = 6$). First we call two triplets are *overlap* with one another if two targets overlap *and* any of their opinions overlap with one another. The ensemble model **JET**$^{o \rightarrow t}$ merges results from **JET**^{o} towards **JET**^{t}. Specifically, within the same

---

Dataset	Model	$P.$	$R.$	F_1
`14Rest`	**JET**^{t}	63.44	54.12	58.41
	JET^{o}	70.56	55.94	62.40
	JET$^{o\rightarrow t}$	61.28	63.38	62.31
	JET$^{t\rightarrow o}$	61.10	63.98	**62.51**
`14Lap`	**JET**^{t}	53.53	43.28	47.86
	JET^{o}	55.39	47.33	51.04
	JET$^{o\rightarrow t}$	48.68	51.01	49.82
	JET$^{t\rightarrow o}$	49.57	53.22	**51.33**
`15Rest`	**JET**^{t}	68.20	42.89	52.66
	JET^{o}	64.45	51.96	57.53
	JET$^{o\rightarrow t}$	61.41	53.81	57.36
	JET$^{t\rightarrow o}$	61.75	55.26	**58.32**
`16Rest`	**JET**^{t}	65.28	51.95	57.85
	JET^{o}	70.42	58.37	**63.83**
	JET$^{o\rightarrow t}$	61.94	62.06	62.00
	JET$^{t\rightarrow o}$	62.50	63.23	62.86

Table 5: Results for Ensemble. We use the models **JET**^{t} and **JET**^{o} (with BERT, $M = 6$) as base models for building two ensemble models on 4 datasets.

instance, if a triplet produced by **JET**^{o} does not overlap with any triplet produced by **JET**^{t}, we augment the prediction space with such an additional triplet. After going through each triplet produced by **JET**^{o}, we regard the expanded predictions as the output of the ensemble model **JET**$^{o\rightarrow t}$. Similarly, we merge the result from **JET**^{t} towards **JET**^{o} to obtain the result for the ensemble model **JET**$^{t\rightarrow o}$.

We report results for ensemble models **JET**$^{o\rightarrow t}$ and **JET**$^{t\rightarrow o}$ presented in Table 5. As we can see, on `14Rest`, `14Lap` and `15Rest`, the ensemble model **JET**$^{t\rightarrow o}$ is able to achieve better F_1 score than **JET**^{t} and **JET**^{o}. However, such a simple ensemble approach appears to be less effective on `16Rest`. It is worth highlighting that the ensemble models have significant improvements in terms of recall score. Note that the recall score reflects the number of gold triplets extracted. Such improvement confirms our earlier hypothesis that the two models largely complement each other.

5 Related Work

ASTE is highly related to another research topic – Aspect Based Sentiment Analysis (ABSA) (Pontiki et al., 2014, 2016). Such a research topic focuses on identifying aspect categories, recognizing aspect targets as well as the associated sentiment. There exist a few tasks derived from ABSA. Target extraction (Chernyshevich, 2014; San Vicente et al., 2015; Yin et al., 2016; Lample et al., 2016; Li et al., 2018b; Ma et al., 2019) is a task that focuses on recognizing all the targets which are either aspect terms or named entities. Such a task is mostly regarded as a sequence labeling problem solvable by CRF-based methods. Aspect sentiment analysis or targeted sentiment analysis is another popular task. Such a task either refers to predicting sentiment polarity for a given target (Dong et al., 2014; Chen et al., 2017; Xue and Li, 2018; Wang and Lu, 2018; Wang et al., 2018; Li et al., 2018a; Peng et al., 2018; Xu et al., 2020) or joint extraction of targets as well as sentiment associated with each target (Mitchell et al., 2013; Zhang et al., 2015; Li and Lu, 2017; Ma et al., 2018; Li and Lu, 2019; Li et al., 2019). The former mostly relies on different neural networks such as self-attention (Liu and Zhang, 2017) or memory networks (Tang et al., 2016) to generate an opinion representation for a given target for further classification. The latter mostly regards the task as a sequence labeling problem by applying CRF-based approaches. Another related task – target and opinion span co-extraction (Qiu et al., 2011; Liu et al., 2013, 2014, 2015; Wang et al., 2017; Xu et al., 2018; Dai and Song, 2019) is also often regarded as a sequence labeling problem.

6 Conclusion

In this work, we propose a novel position-aware tagging scheme by enriching label expressiveness to address a limitation associated with existing works. Such a tagging scheme is able to specify the connection among three elements – a target, the target sentiment as well as an opinion span in an aspect sentiment triplet for the ASTE task. Based on the position-aware tagging scheme, we propose a novel approach **JET** that is capable of jointly extracting the aspect sentiment triplets. We also design factorized feature representations so as to effectively capture the interaction. We conduct extensive experiments and results show that our models outperform strong baselines significantly with detailed analysis. Future work includes finding applications of our novel tagging scheme in other tasks involving extracting triplets as well as extending our approach to support other tasks within sentiment analysis.

Abstract

Simultaneous machine translation (SiMT) aims to translate a continuous input text stream into another language with the lowest latency and highest quality possible. The translation thus has to start with an incomplete source text, which is read progressively, creating the need for anticipation. In this paper, we seek to understand whether the addition of visual information can compensate for the missing source context. To this end, we analyse the impact of different multimodal approaches and visual features on state-of-the-art SiMT frameworks. Our results show that visual context is helpful and that visually-grounded models based on explicit object region information are much better than commonly used global features, reaching up to 3 BLEU points improvement under low latency scenarios. Our qualitative analysis illustrates cases where only the multimodal systems are able to translate correctly from English into gender-marked languages, as well as deal with differences in word order, such as adjective-noun placement between English and French.

1 Introduction

Simultaneous machine translation (SiMT) aims to reproduce human interpretation, where an interpreter translates spoken utterances as they are produced. The interpreter has to dynamically find the balance between how much context is needed to generate the translation reliably, and how long the listener has to wait for the translation. In contrast to *consecutive* machine translation where source sentences are available in their entirety before translation, the challenge in SiMT is thus the design of a strategy to find a good trade-off between the quality of the translation and the latency incurred in producing it. Previous work has considered *rule-based strategies* that rely on waiting until some constraint is satisfied, which includes approaches based on syntactic constraints (Bub et al., 1997; Ryu et al., 2006), segment/chunk/alignment information (Bangalore et al., 2012) heuristic-based conditions during decoding (Cho and Esipova, 2016) or deterministic policies with pre-determined latency constraints (Ma et al., 2019). An alternative line of research focuses on *learning* the decision policy: Gu et al. (2017) and Alinejad et al. (2018) frame SiMT as learning to generate `READ`/`WRITE` actions and employ reinforcement learning (RL) to formulate the problem as a policy agent interacting with its environment (i.e. a pre-trained MT model). Recent work has also explored supervised learning of the policy, by using oracle action sequences predicted by a pre-trained MT using confidence-based heuristics (Zheng et al., 2019) or external word aligners (Arthur et al., 2020) (details in §2).

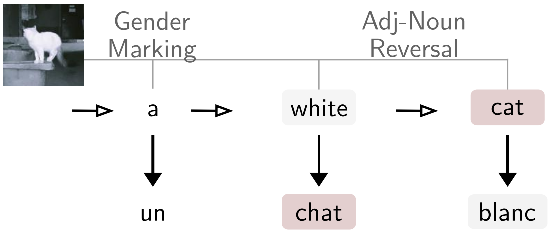

Figure 1: An illustration of a 1-word latency system that makes use of visual grounding to resolve the gender of the article 'un' and to predict the noun 'chat' after reading its qualifier 'white'. —▷ and —▶ denote `READ` and `WRITE`, respectively.

Thus far, all prior research has focused on unimodal interpretation[1]. In this paper, we explore SiMT for multimodal machine translation (MMT) (Specia et al., 2016), where in addition to

---

[1] We note that Imankulova et al. (2020) also attempted to explore multimodality in SiMT. However, their paper overestimates the impact of visual cues, and in personal correspondence with the authors about the mismatch in the findings, they discovered critical bugs in their implementation.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2350–2361,
November 16–20, 2020. ©2020 Association for Computational Linguistics

the source sentence, we have access to visual information in the form of an image. We believe that having access to a complementary context should help the models anticipate the missing context (Figure 1) by grounding their decisions about 'when' and 'what' to translate. To test our hypothesis, we explore heuristic-based decoding and fixed-latency wait-k policy[2], and investigate the effectiveness of different visual representations (§3). Based on experiments on the Multi30k dataset (Elliott et al., 2016) (§4), we provide quantitative and qualitative analyses for English→German and English→French (§5).

Our **contributions** highlight that: (i) visual context offers up to 3 BLEU points improvement for low-latency wait-k policies, and consistently lowers the latency for *wait-if-diff* (Cho and Esipova, 2016) decoding, (ii) explicit object region features are more expressive than commonly used global visual features, (iii) training wait-k MMTs offers remarkably better grounding capabilities than decoding-only wait-k for linguistic phenomena such as gender resolution and adjective-noun ordering, and (iv) with twice the runtime speed of decoder-based visual attention, the encoder-based grounding is promising for application scenarios.

2 Related Work

2.1 Multimodal Machine Translation (MMT)

MMT aims to improve the quality of automatic translation using auxiliary sources of information (Sulubacak et al., 2020). The most typical framework explored in previous work makes use of the images when translating their descriptions between languages, with the hypothesis that visual grounding could provide contextual cues to resolve linguistic phenomena such as word-sense disambiguation or gender marking.

Existing work often rely on the use of visual features extracted from state-of-the-art CNN models pre-trained on large-scale visual tasks. The methods can be grouped into two branches depending on the feature type used: (i) multimodal attention (Calixto et al., 2016; Caglayan et al., 2016; Libovický and Helcl, 2017; Delbrouck and Dupont, 2017) which implements a soft attention (Bahdanau et al., 2014) over *spatial* feature maps, and (ii) multimodal interaction between a *pooled* visual feature vector and linguistic representations (Calixto and Liu, 2017; Caglayan et al., 2017a; Elliott and Kádár, 2017; Grönroos et al., 2018).

2.2 Simultaneous Neural MT

Simultaneous NMT was first explored by Cho and Esipova (2016) in a greedy decoding framework where heuristic waiting criteria are used to decide whether the model should read more source words or emit a target word. Gu et al. (2017) instead utilised a pre-trained NMT model in conjunction with a reinforcement learning agent whose goal is to learn a `READ/WRITE` policy by maximising quality and minimising latency. Alinejad et al. (2018) further extended the latter approach by adding a `PREDICT` action whose purpose is to anticipate the next source word.

A common property of the above approaches is their reliance on *consecutive* NMT models pretrained on full-sentences. Dalvi et al. (2018) pointed out a potential mismatch between the training and decoding regimens of such approaches and proposed fine-tuning the models using chunked data or prefix pairs. Ma et al. (2019) proposed an end-to-end, fixed-latency framework called 'wait-k' which allows *prefix-to-prefix* training using a deterministic policy: the agent starts by reading a specified number of source tokens (k), followed by alternating `WRITE` and `READ` actions. Arivazhagan et al. (2019) extended the wait-k framework using an advanced attention mechanism and optimising a differential latency metric (DAL). Recently, Arivazhagan et al. (2020) explored a radically different approach which enriches full-sentence training with prefix pairs (Niehues et al., 2018) and allows *re-translation* of previously committed target tokens to increase the translation quality.

Another line of research focuses on learning adaptive policies in a supervised way by using oracle `READ/WRITE` actions generated with heuristic or alignment-based approaches. Zheng et al. (2019) extracted action sequences from a pre-trained NMT model with a confidence-based heuristic and used them to train a separate policy network while Arthur et al. (2020) explored jointly training the translation model and the policy with oracle sequences obtained from a word alignment model.

---

[2] During our initial experiments we also explored the RL-based SiMT policy (Gu et al., 2017) but could not find good hyper-parameter settings, especially settings which were stable across two language pairs. Therefore, we did not proceed with RL for multimodal SiMT.

3 Methods

In this section, we first describe the underlying NMT architectures and baseline simultaneous MT approaches, to then introduce the proposed multimodal extensions to SiMT.

3.1 Baseline NMT

Our *consecutive* baseline consists of a 2-layer GRU (Cho et al., 2014) encoder and a 2-layer Conditional GRU decoder (Sennrich et al., 2017) with attention (Bahdanau et al., 2014). The encoder is **unidirectional** as source sentences would be progressively read[3]. Given a source sequence of embeddings $X{=}\{x_1, \ldots, x_S\}$ and a target sequence of embeddings $Y{=}\{y_1, \ldots, y_T\}$, the encoder first computes the sequence of hidden states $H{=}\{h_1, \ldots, h_S\}$. At a given timestep t of decoding, the output layer estimates the probability of the next target word y_t as follows:

$$\begin{aligned} d_t &= \text{GRU}(y_{t-1}, d'_{t-1}) \\ c_t &= \text{Attention}(H, \text{query} \leftarrow d_t) \qquad (1) \\ d'_t &= \text{GRU}'(c_t, d_t) \\ o_t &= \tanh(\mathbf{W_c} c_t + \mathbf{W_d} d'_t + \mathbf{W_y} y_{t-1}) \\ l_t &= \mathbf{W_o}(\mathbf{W_b} o_t + b_b) + b_o \\ P(y_t|X, Y_{<t}) &= \text{softmax}(l_t) \end{aligned}$$

For a single training sample, we then maximise the joint likelihood of source and target sentences:

$$\text{L}(X, Y) = \sum_{t=1}^{T} \log \left(P \left(y_t | X_{\leq g(t)}, Y_{<t} \right) \right) \qquad (2)$$

Following the formulation of Ma et al. (2019), $g(t)$ in equation 2 is a function which returns the number of source tokens encoded so far when predicting the target token y_t. In the case of consecutive NMT, since all source tokens are observed before the decoder runs, $g(t)$ is equal to the length of the source sentence i.e. $g(t) = |X|$.

3.2 Incorporating the visual modality

We consider a setting where the visual context is static and is available in its entirety at encoding time. This is a realistic setting in many applications, for example, the simultaneous translation of news, where images (or video frames) are shown before the whole source stream is available. We consider the following ways of integrating visual information.

Object classification (OC) features are *global* image information extracted from convolutional feature maps, which are believed to capture spatial cues. These *spatial* features are extracted from the final convolution layer of a ResNet-50 CNN (He et al., 2016) trained on ImageNet (Deng et al., 2009) for object classification. An image is represented by a feature tensor $V \in \mathbb{R}^{8 \times 8 \times 2048}$.

Object detection (OD) features are explicit object information where *local* regions in an image detected as objects are encoded by *pooled* feature vectors. These features are generated by the "bottom-up-top-down (BUTD)" (Anderson et al., 2018) extractor[4] which is a Faster R-CNN/ResNet-101 object detector (with 1600 object labels) trained on the Visual Genome dataset (Krishna et al., 2017). For a given image, the detector provides 36 object region proposals and extracts a pooled feature vector from each. An image is thus represented by a feature tensor $V \in \mathbb{R}^{36 \times 2048}$. We hypothesise that explicit object information can result in better referential grounding by using conceptually meaningful units rather than global features.

3.3 Multimodal architectures

Decoder attention (DEC-OC/OD). A standard way of integrating visual modality into NMT is to apply a secondary attention at each decoding timestep (Calixto et al., 2016; Caglayan et al., 2016). We follow this approach to construct an MMT baseline. Specifically, equation 1 is extended so that the decoder attends to both the source hidden states H (eq. 3) and the visual features V (eq. 4), and they are added together to form the *multimodal* context vector c_t (eq. 5):

$$c_t^{\mathbf{T}} = \text{Attention}^{\mathbf{T}}(H, \text{query}{=}d_t) \qquad (3)$$

$$c_t^{\mathbf{V}} = \text{Attention}^{\mathbf{V}}(V, \text{query}{=}d_t) \qquad (4)$$

$$c_t = c_t^{\mathbf{T}} + c_t^{\mathbf{V}} \qquad (5)$$

Multimodal encoder (ENC-OD). Instead of integrating the visual modality into the decoder, we propose to ground the source sentence representation within the encoder similar to Delbrouck and Dupont (2017). We hypothesise that early visual integration could be more appropriate for SiMT to fill in the missing context. Our approach differs from Delbrouck and Dupont (2017) in the use of *scaled-dot* attention (Vaswani et al., 2017) and **object detection (OD)** features. The attention layer

---

[3] Although it is possible to encode the growing prefixes bidirectionally, it would incur a quadratic complexity.

[4] https://hub.docker.com/r/airsplay/bottom-up-attention

receives unidirectional hidden states H (for source states that were encoded/read so far) as the *query* and the visual features V as *keys* and *values*, i.e. it computes a mixture M of region features based on the cross-modal relevance. The final representation that will be used as input to the equation 1 is defined as $\text{LAYERNORM}(M+H)$ (Ba et al., 2016).

Regardless of the multimodal approach taken, all visual features are first linearly projected into the dimension of textual representations H. To make modality representations compatible in terms of magnitude statistics, we apply layer normalisation (Ba et al., 2016) on textual representations H and the previously projected visual representations V. A dropout (Srivastava et al., 2014) of $p = 0.5$ follows the layer normalisation.

3.4 Simultaneous MT approaches

This section summarises the SiMT approaches explored in this work: (i) the *heuristic-based* decoding approach **wait-if-diff** (Cho and Esipova, 2016), (ii) the wait-k policy (Ma et al., 2019), and (iii) the reinforcement learning (RL) policy (Gu et al., 2017). The first approach offers a heuristically guided latency while the second one fixes it to an arbitrary value. The third one learns a stochastic policy to find the desired quality-latency trade-off. But before going into full details of methods, we now introduce the common metrics used to measure the latency of a given SiMT model.

3.4.1 Latency metrics

Average proportion (AP) is the very first metric used for latency measurement in the literature (Cho and Esipova, 2016). AP computes a normalised score between 0 and 1, which is the average number of source tokens required to commit a translation:

$$\text{AP}(X,Y) = \frac{1}{|X||Y|}\sum_{t=1}^{|Y|} g(t)$$

AP produces different scores for 2 samples when the underlying latency is actually the same but the source and target sentence lengths differ. To remedy this, Ma et al. (2019) propose **Average Lagging** (AL) which estimates the number of tokens the "writer" is lagging behind the "reader", as a function of the number of input tokens read. τ denotes the timestep where the entire source sentence has been read, as the authors state that the subsequent timesteps do not incur further delay:

$$\text{AL}(X,Y) = \frac{1}{\tau}\sum_{t=1}^{\tau} g(t) - \frac{t-1}{\gamma} \quad (\gamma = \tfrac{|Y|}{|X|})$$

Finally, **Consecutive Wait** (CW) (Gu et al., 2017) measures how many source tokens are consecutively read between committing two translations:

$$C_0 = 0$$
$$C_t = \begin{cases} C_{t-1}+1 & \text{if action is } \texttt{READ} \\ 0 & \text{if action is } \texttt{WRITE} \end{cases}$$

3.4.2 Wait-k training

Ma et al. (2019) propose a simple deterministic policy which relies on training and decoding an NMT model in a *prefix-to-prefix* fashion. Specifically, a wait-k model starts by reading k source tokens and writes the first target token. The model then reads and writes one token at a time to complete the translation process. This implies that the attention layer will now attend to a **partial textual representation** $H_{\leq g(t)}$ instead of H, with $g(t)$ redefined as $\min(k+t-1, |X|)$ (eq. 1 and 2).

Decoding-only mode. A wait-k model is denoted as "trained" if it is both trained and decoded using the algorithm above. It is also possible to take a pre-trained consecutive NMT or MMT model, and apply wait-k algorithm at decoding time i.e. during *greedy search*.

3.4.3 Wait-if decoding

Cho and Esipova (2016) propose two decoding algorithms which can be directly applied on a pre-trained *consecutive* NMT model, similar to the consecutive wait-k decoding. These algorithms have two hyper-parameters, namely the number of initial source tokens to read (k) before starting the translation and the number of further tokens to read (δ) if the algorithm decides to wait for more context. We specifically use the **wait-if-diff (WID)** variant, which reads more tokens if the current most likely target word **changes** when doing so. We intentionally left out the **wait-if-worse (WIW)** approach as it exhibits very high latency.

3.4.4 Reinforcement learning

Gu et al. (2017) frame SiMT as a sequence of `READ` or `WRITE` actions and aim to learn a reinforcement learning (RL) strategy with a reward function taking into account both quality and latency. Following standard RL, the framework is composed of

	Sents	En→De T/S	En→De OOV	En→Fr T/S	En→Fr OOV
TRAIN	29K	0.96	–	1.10	–
VAL	1014	0.98	30.4%	1.09	19.0%
2016	1000	0.94	28.6%	1.09	18.1%
2017	1000	0.97	37.1%	1.14	21.3%
COCO	461	0.99	38.2%	1.10	21.1%

Table 1: Multi30k statistics: T/S and OOV are the average target-to-source sentence length ratio and the % of sentence pairs with at least 1 unknown token.

an environment and an agent. The environment is a pre-trained NMT system which is not *updated* during RL training. The agent is a GRU that parameterises a stochastic policy which decides on the action a_t by receiving as input the observation o_t. The observation o_t is defined as $[c_t; d_t; y_t]$, i.e. the concatenation of vectors coming from the environment. At each step, the agent receives a reward $r_t = r_t^Q + r_t^D$ where r_t^Q is the quality reward (the difference of smoothed BLEU scores for partial hypotheses produced from one step to another) and r_t^D is the latency reward formulated as:

$$r_t^D = \alpha\,[\mathrm{sgn}(C_t - C^*) + 1] + \beta\lfloor D_t - D^*\rfloor_+$$

where C_t denotes the CW metric introduced here to avoid long consecutive waits and D_t refers to AP (see § 3.4.1 for metrics). D^* and C^* are hyperparameters that determine the expected/target values for AP and CW, respectively. The optimal quality-latency trade-off is achieved by balancing the two reward terms.

4 Experimental Setup

4.1 Dataset

We use the Multi30k dataset (Elliott et al., 2016)[5] which has been the primary corpus for MMT research across the three shared tasks of the "Conference on Machine Translation (WMT)" (Specia et al., 2016; Elliott et al., 2017; Barrault et al., 2018). Multi30k extends the Flickr30k image captioning dataset (Young et al., 2014) to provide caption translations in German, French and Czech. In this work, we focus on the English→German and English→French (Elliott et al., 2017) language directions (Table 1). We use flickr2016 (**2016**), flickr2017 (**2017**) and coco2017 (**COCO**) for model evaluation. The latter test set is explicitly designed (Elliott et al., 2017) to contain at least one ambiguous word per sentence, which makes it appealing for MMT experiments.

Preprocessing. We use Moses scripts (Koehn et al., 2007) to lowercase, punctuation-normalise and tokenise the sentences with *hyphen splitting*. We then create word vocabularies on the *training* subset of the dataset. We did not use subword segmentation to avoid its potential side effects on SiMT and to be able to analyse the grounding capability of the models better. The resulting English, French and German vocabularies contain 9.8K, 11K and 18K tokens, respectively.

4.2 Reproducibility

Hyperparameters. The dimensions of embeddings and GRU hidden states are set to 200 and 320, respectively. The decoder's input and output embeddings are shared (Press and Wolf, 2017). We use ADAM (Kingma and Ba, 2014) as the optimiser and set the learning rate and mini-batch size to 0.0004 and 64, respectively. A weight decay of $1e{-}5$ is applied for regularisation. We clip the gradients if the norm of the full parameter vector exceeds 1 (Pascanu et al., 2013). For the **RL baseline**, we closely follow (Gu et al., 2017)[6]. The agent is implemented by a 320-dimensional GRU followed by a softmax layer and the baseline network – used for variance reduction of policy gradient – is similar to the agent except with a scalar output layer. We use ADAM as the optimiser and set the learning rate and mini-batch size to 0.0004 and 6, respectively. For each sentence pair in a batch, ten trajectories are sampled. For inference, greedy sampling is used to pick action sequences. We set the hyperparameters $C^*{=}2$, $D^*{=}0.3$, $\alpha{=}0.025$ and $\beta{=}-1$. To encourage exploration, the negative entropy policy term is weighed empirically with 0.1 and 0.3 for En→Fr and En→De directions, respectively.

Training. We use `nmtpytorch` (Caglayan et al., 2017b) with PyTorch (Paszke et al., 2019) v1.4 for our experiments[7]. We train each model for a maximum of 50 epochs and early stop the training if validation BLEU (Papineni et al., 2002) does not improve for 10 epochs. We also halve the learning rate if no improvement is obtained for two epochs. On a single NVIDIA RTX2080-Ti GPU, it takes around 35 minutes for the *unimodal* and *multimodal encoder* variants to complete train-

ing whereas the *decoder attention* variant requires around twice that time. The number of learnable parameters is between 6.9M and 9.4M depending on the language pair and the type of multimodality. For the **RL baseline**, we choose the model that maximises the quality-to-latency ratio (BLEU/AL) on the validation set with patience set to ten epochs. The number of learnable parameters is around 6M.

4.3 Evaluation

To mitigate variance in results due to different initialisations, we repeat each experiment **three** times, with random seeds. Following previous work, we decode translations with *greedy search*, using the checkpoint that achieved the lowest perplexity. We report **average** BLEU scores across three runs using sacreBLEU (Post, 2018), which is also used for computing sentence-level scores for the oracle experiments.

5 Results

5.1 Consecutive baselines

We first present the impact of the visual integration approaches on *consecutive* NMT performance (Table 2). We observe that the decoder-attention using object detection features (DEC-OD) performs better than other variants. We also see that the improvements on flickr2017 (⇑ 0.5) and coco2017 (⇑ 1.03) test sets are higher than flickr2016 (⇑ 0.1) on average. A possible explanation is that flickr2017 and coco2017 are more distant from the training set distribution (higher OOV count, see Table 1) and thus there is more room for improvement with the visual cues. In summary, unlike previous conclusions in MMT where improvements were not found to be substantial (Grönroos et al., 2018; Caglayan et al., 2019), we observe that the benefit of the visual modality is more pronounced here. We believe that this is due to (i) the encoder being now *unidirectional* different from state-of-the-art NMT, (ii) the modality representations being passed through layer normalisation (Ba et al., 2016), and (iii) the representational power of OD features.

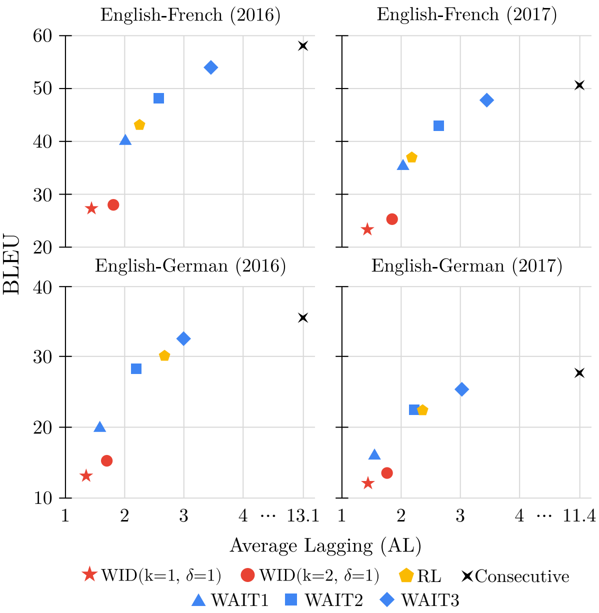

Figure 2: AL vs BLEU comparison across unimodal SiMT approaches: wait-k systems are "trained".

5.2 Unimodal SiMT baselines

We now compare **unimodal** SiMT approaches to get an initial understanding of how they perform on Multi30k. Figure 2 contrasts AL and BLEU for three trained wait-k systems, wait-if-diff (WID) decoding with $k \in \{1, 2\}$ and δ=1, reinforcement learning (RL) and the consecutive NMT. These configurations are chosen particularly to satisfy a low-latency regimen. The results suggest that wait-k models offer good translation quality for fixed latency. The RL based policy, however, is not able to surpass wait-k models. Finally, WID decoding exhibits the worst performance, according to BLEU. Given the difficulty in finding stable hyper-parameters for the RL models, we leave the integration of RL to MMT for future work and explore wait-k, and WID approaches in what follows.

5.3 Wait-k training for MMT

We present results with trained wait-k MMTs with $k \in \{1, 2, 3, 5, 7\}$. Figure 3 plots a summary of the gains obtained by three MMT variants with respect to the unimodal wait-k. We observe that as k increases, the gains due to the visual modality decrease globally, in line with the findings of Caglayan et al. (2019). This phenomenon is more visible for German, which exhibits 1 BLEU point

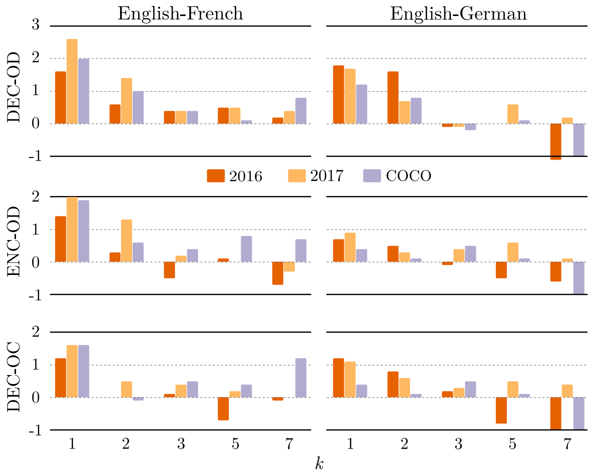

Figure 3: BLEU comparison of trained wait-k MMT systems: the vertical axes of each subplot represent the improvement with respect to the unimodal wait-k.

Table 3: Examples showing the effectiveness of DEC-OD MMT (wait-1) for gender marking (top) and adjective noun placement (bottom). underlined and **bold** represent wrong and correct word choices, respectively.

drop consistently across all models and two test sets at k=7. We hypothesise that this instability is probably due to the interplay of several factors for German, including the high OOV rates & rich morphology and source sentences being slightly longer than target on average. The latter is a major issue for trained wait-k systems since the source sentences may not have been fully observed during training,[8] preventing the decoder to learn about source `<EOS>` markers. For French, the results are much more encouraging as the improvements are larger and still observed with larger k values.

From a multimodal perspective, like with the consecutive models, the DEC-OD system has the best performance: it is beneficial for all values of k in French, and it shows the largest gains in German for $k \in \{1, 2\}$. From a runtime perspective, encoder-based attention benefits heavily from batched matrix operations and runs almost at the same speed as a unimodal NMT, thus encouraging us to focus more on that in the future.

Qualitative examples. Table 3 shows some examples regarding the impact of the visual modality for the wait-1 policy. In the first example, the image assists in predicting the correct article **eine** (feminine ‘a’) instead of **ein** (masculine ‘a’) in German. Upon inspecting the attention over object regions, we observe that the region that obtained the highest probability (p=0.2) when predicting **eine** is labelled with ‘woman’ by the object detector. In the second example, we observe a biased anticipation case where the NMT system had to emit a wrong translation **chien** (‘dog’) before seeing the noun ‘bird’. However, the multimodal model successfully leveraged the visual context for anticipation and correctly handled the adjective-noun placement phenomenon. Once again, the attention distribution confirms that when generating the first two words – **un** and **oiseau** (‘bird’), the model correctly attends to the object regions corresponding to ‘bird’ (with p=0.22 and p=0.14 respectively).

5.4 Trained vs. decoding-only SiMT

We are now interested in how trained wait-k MMTs compare to decoding-only wait-k and wait-if-diff (WID) heuristic under low latency. Figure 4 summarises latency vs. quality trade-off across all languages and test sets. First of all, the translation **quality** of the heuristic WID approach consistently improves with visual information with its latency slightly increasing across the board. Second, the translation **quality** of both trained and decoding-only wait-k policies improve with multimodality.

Interestingly, although Ma et al. (2019) show that trained wait-k models are substantially better than decoding-only ones for a news translation task, here we observe quite the opposite: in almost all cases there exists a shift between these approaches which favours the decoding-only approach for small k values. Zheng et al. (2019) observed a similar phenomenon for their wait-1 and wait-2 textual SiMT models. To investigate further, we compute an adaptive low-latency wait-k **oracle** for $k \in \{1, 2, 3\}$. Specifically, for a given model, we first select a representative hypothesis across the three runs using median[9] sentence-level BLEU. We then pick the hypothesis with best BLEU (and

---

[8] Ma et al. (2019) proposed optional “catchup” logic for this, but we did not apply it here for the sake of simplicity.

[9] We use median across the three runs of the same model as a way to smooth out variance related to random initialisations.

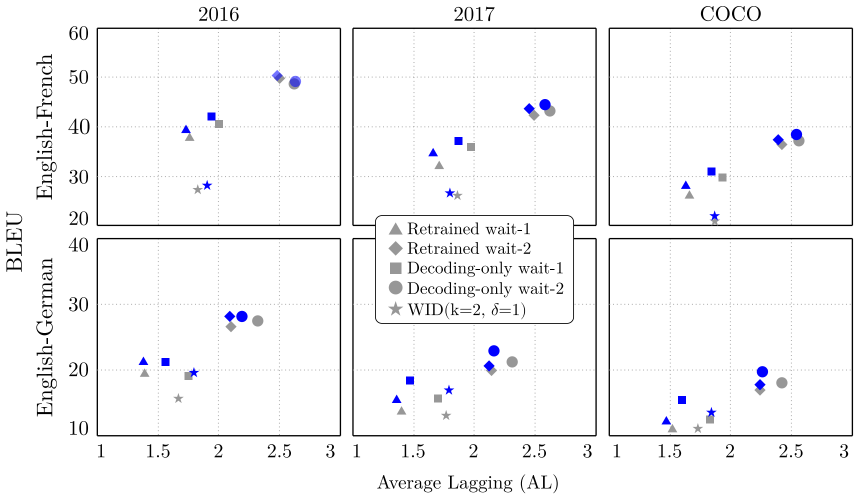

Figure 4: Comparison of trained vs. decoding-only SiMT approaches: light and dark colors denote unimodal and multimodal (DEC-OD) systems, respectively.

Algorithm 1: Multi-run oracle algorithm

```
output : Oracle BLEU → CorpusBLEU($O$)

$O$ : Final oracle list of $N$ translations
$O \leftarrow []$
for $n$ in $1 \dots N$ do
    $C \leftarrow []$
    for $k$ in $\{1, 2, 3, 5, 7\}$ do
        $R \leftarrow$ wait-$k$ hypotheses for input $n$
        $B \leftarrow$ [BLEU $(R[i])\ \forall i \in \{1, 2, 3\}$]
        $m \leftarrow$ Index of run with median BLEU
        HYP $\leftarrow R[m]$; BLEU $\leftarrow B[m]$
        $C$.append({HYP, BLEU, k})
    end
    $h \leftarrow$ Best HYP from $C$ (lowest $k$ if tie)
    $O$.append($h$)
end
```

lowest k in case of a tie) across all wait-k systems of that model, as the oracle translation. Once the hypotheses are collected, we compute corpus-level BLEU and AL (Algorithm 1).

Table 4 suggests that when we let the oracle choose between different k values, trained wait-k systems are almost always better than decoding-only counterparts. Moreover, this boost in quality is accompanied by slight latency improvements over unimodal NMT across the board. Therefore, we conjecture that the shifts between decoding-only and trained wait-k systems may be due to several factors coming into play such as the length discrepancy issue (§5.3) or the low resourced nature of Multi30k which prevents it from benefiting from prefix-to-prefix training for small k values.

	2016	2017	COCO

Gender resolution accuracy. Motivated by the qualitative examples in §5.3, we further investigate how accurate English→French MMT variants are at choosing the correct indefinite article **une** when translating sentences beginning with 'a woman'. Table 5 shows that the unimodal NMT has no way of anticipating the context to resolve this kind of gender ambiguity, and therefore always picks the masculine version of the article. This is a clear example of models reflecting biases in the training data. In fact, 69.4% of all training instances starting with an indefinite article in French, have the masculine realisation of the article (**un**) instead of its feminine counterpart (**une**). The results also make it clear that decoding-only wait-k systems are not as successful as their trained counterparts when it comes to incorporating the visual modality, and the explicit object information is more expressive

wait-1	DECODING ONLY	TRAINED

than global object features. At $k = 2$ however, all systems reach 100% accuracy eventually.

6 Conclusion

We present the first thorough investigation of the utility of visual context for the task of simultaneous machine translation. Our experiments reveal that integrating visual context lowers the latency for heuristic policies while retaining the quality of the translations. Under low-latency wait-k policies, the visual cues are highly impactful with quality improvements of almost 3 BLEU points compared to unimodal baselines. From a multimodal perspective, we introduce effective ways of integrating visual features and show that explicit object region information consistently outperforms commonly used global features. Our qualitative analysis illustrates that the models are capable of resolving linguistic particularities, including gender marking and word order handling by exploiting the associated visual cues.

We hope that future research continues this line of work, especially by finding novel ways to devise adaptive policies – such as reinforcement learning models with the visual modality. We believe that our work can also benefit research in multimodal speech translation (Niehues et al., 2019) where the audio stream is accompanied by a video stream.

Acknowledgments

We would like to thank Aizhan Imankulova for being very responsive to our questions regarding their results in Imankulova et al. (2020), and Kyunghyun Cho for answering a question related to wait-if decoding (Cho and Esipova, 2016).

Abstract

In order to simulate human language capacity, natural language processing systems must be able to reason about the dynamics of everyday situations, including their possible causes and effects. Moreover, they should be able to generalise the acquired world knowledge to new languages, modulo cultural differences. Advances in machine reasoning and cross-lingual transfer depend on the availability of challenging evaluation benchmarks. Motivated by both demands, we introduce Cross-lingual Choice of Plausible Alternatives (**XCOPA**), a typologically diverse multilingual dataset for causal commonsense reasoning in 11 languages, which includes resource-poor languages like Eastern Apurímac Quechua and Haitian Creole. We evaluate a range of state-of-the-art models on this novel dataset, revealing that the performance of current methods based on multilingual pretraining and zero-shot fine-tuning falls short compared to translation-based transfer. Finally, we propose strategies to adapt multilingual models to out-of-sample resource-lean languages where only a small corpus or a bilingual dictionary is available, and report substantial improvements over the random baseline. The XCOPA dataset is freely available at `github.com/cambridgeltl/xcopa`.

1 Introduction

Commonsense reasoning is a critical component of any natural language understanding system (Davis and Marcus, 2015). Contrary to textual entailment, commonsense reasoning must bridge between premises and possible hypotheses with *world knowledge* that is not explicit in text (Singer et al., 1992). Such world knowledge encompasses, among other aspects: temporal and spatial relations, causality, laws of nature, social conventions, politeness, emotional responses, and multiple modalities. Ultimately, it shapes the individuals' expectations about typical situations (Shoham, 1990).[1]

A seminal work on the quantitative evaluation of commonsense reasoning is the Choice Of Plausible Alternatives dataset (COPA; Roemmele et al., 2011), which focuses on cause–effect relationships. In recent years, more datasets have been dedicated to other facets of world knowledge (Sakaguchi et al., 2020; Bisk et al., 2020; Bhagavatula et al., 2020; Rashkin et al., 2018; Sap et al., 2019, *inter alia*). Unfortunately, the extensive efforts related to this thread of research have so far been limited only to the English language.[2] Such a narrow scope not only curbs the development of natural language understanding tools in other languages (Bender, 2011; Ponti et al., 2019a), but also exacerbates the Anglocentric bias in modeling commonsense reasoning. In fact, the expectations about typical situations do vary across cultures (Thomas, 1983).

Datasets that cover multiple languages for other natural understanding tasks, such as language inference (Conneau et al., 2018), question answering (Lewis et al., 2020; Artetxe et al., 2020a; Clark et al., 2020), and paraphrase identification (Yang et al., 2019b) have received increasing attention. In fact, the requirement to generalise to new languages encourages the development of more versatile language understanding models, which can be ported across different grammars and lexica. These efforts have recently culminated in the integration of several multilingual tasks into the XTREME evaluation suite (Hu et al., 2020). However, a compre-

---

[*] Equal contribution.

[1] Moreover, there are often multiple legitimate chains of sentences that can be invoked in between premises and hypotheses. In short, commonsense reasoning does not just involve understanding what is possible, but also ranking what is most *plausible*.

[2] The only exception is direct translation of the 272 paired English Winograd Schema Challenge instances to Japanese (Shibata et al., 2015), French (Amsili and Seminck, 2017), and Portuguese (Melo et al., 2020).

Table 1: Examples of forward (Result [R]) and backward (Cause [C]) reasoning from the XCOPA validation sets.

hensive multilingual benchmark for commonsense reasoning in particular is still missing.

In order to address this gap, we develop a novel dataset, **XCOPA** (see examples in Table 1), by carefully translating and re-annotating the validation and test sets of English COPA into 11 target languages. A key design choice is the selection of a typologically diverse sample of languages. In particular, we privilege variety over the abundance in *digital* texts. Since resource-rich languages tend to belong to a few families and areas, samples inspired by this criterion are highly biased and not indicative of true models' performance (Gerz et al., 2018; Ponti et al., 2019a; Joshi et al., 2020; Lauscher et al., 2020). Following this guiding principle, we select 11 languages from 11 distinct families, and 5 geographical macro-areas (Africa, Eurasia, Papunesia, North America, and South America).

We leverage XCOPA to benchmark a series of state-of-the-art pretrained multilingual models, including XLM-R (Conneau et al., 2020), MBERT (Devlin et al., 2019), and multilingual USE (Yang et al., 2019a). Two XCOPA languages (i.e., Southern Quechua and Haitian Creole) are out-of-sample for the pretrained models: this naturally raises the question of how to adapt the pretrained models to such unseen languages. In particular, we investigate the resource-lean scenarios where either some monolingual data or a bilingual dictionary with English (or both) are available for the target language.

In summary, we offer the following contributions. **1)** We create the first large-scale multilingual evaluation set for commonsense reasoning, spanning 11 languages, and discuss the challenges in accounting for world knowledge across different cultures and languages. **2)** We propose quantitative metrics to measure the internal variety of a language sample, which can guide the design of any multilingual dataset in the future. **3)** We benchmark pretrained state-of-the-art models in cross-lingual transfer of commonsense knowledge, and **4)** investigate how to (post-hoc) improve transfer for languages unseen at pretraining time.

In order to rise to the challenge of this dataset, models must be able not only to combine textual evidence with world knowledge – which makes commonsense reasoning challenging *per se* (Talmor et al., 2019; Rajani et al., 2019), but they must also transfer the acquired causal reasoning abilities across languages. The results we obtain on XCOPA thus indicate the limitations of current state-of-the-art multilingual models in cross-lingual transfer settings for complex reasoning tasks.

2 Annotation Design

Design Objectives. The principal objectives in devising XCOPA were: **1)** to create a *genuinely* typologically diverse multilingual dataset, aligned across target languages to make performance scores comparable, and **2)** to ensure high quality, naturalness and idiomacity of each monolingual dataset. While the commonly used translation approach addresses the former objective, it is prone to compromise the latter goal, bending the target language to the structural and lexical properties of the source language: the resulting evaluation benchmarks thus fail to measure system performance adequately (Koppel and Ordan, 2011; Volansky et al., 2015; Artetxe et al., 2020a; Freitag et al., 2020).

To avoid these pitfalls, we: (i) entrusted the translation task to a single (carefully selected) translator per target language,[3] and (ii) offered enough leeway for necessary target-language adjustments (e.g., substitutions with culture-specific concepts and multi-word paraphrases, wherever the original text eluded direct translation). Detailed translation guidelines are available in the Appendix.

Language Sampling. Multilingual evaluation benchmarks assess the *expected performance* of a model across languages. However, should such languages be sampled according to the distribution of digital texts or rather based on the distribution over the languages spoken around the world? The

---

[3] Crowd-sourcing offers faster annotation at a lower cost – however, in our trial experiments, chasing low annotation times and costs resulted in low translation quality. In our experiment, the average wage was £15 per hour, for a (self-paced) total time per language between 12 and 20 hours.

	Range	XCOPA	TyDiQA	XNLI	XQUAD	MLQA	PAWS-X
Typology	[0, 1]	0.41	0.41	0.39	0.36	0.32	0.31
Family	[0, 1]	1	0.9	0.5	0.6	0.66	0.66
Geography	[0, ln 6]	1.67	0.92	0.37	0	0	0

Table 2: Indices of typological, genealogical, and areal diversity for the language samples of a set of NLU datasets.

former strategy is unreliable, as languages rich in resources tend to belong to the same families and areas, which facilitates knowledge transfer and hence leads to an overestimation of the expected performance (Gerz et al., 2018; Ponti et al., 2019a).

Moreover, rather than samples that account for independent and identically distributed draws from the 'true' language distribution (known as *probability* sampling), we opt for a *uniform* distribution of linguistic phenomena, which encourages the inclusion of outliers (known as *variety* sampling; Rijkhoff et al., 1993; Dryer, 1989). Thus, the performance on XCOPA also reflects the *robustness* of a model, i.e., its resilience to linguistic features that are unlikely to be observed in the training data.

Inspired by Rijkhoff et al. (1993) and Miestamo (2004), we propose a series of simple and interpretable metrics that quantify diversity of a language sample independent of its size: **1)** a *typology* index based on 103 typological features of each language from URIEL (Littell et al., 2017), originally sourced from the World Atlas of Language Structures (WALS; Dryer and Haspelmath, 2013). Each feature is binary and indicates the presence or absence of an attribute in a language. We estimate the entropy of the distribution of values in a sample. Afterwards, we average across all 103 feature-specific entropies. Intuitively, if all values are equally represented, the entropy is high. If all languages have identical features, the entropy is 0; **2)** The *family* index is simply the number of distinct families divided by the sample size. **3)** The *geography* index is the entropy of the distribution over macro-areas in a sample.[4]

The sample of languages for XCOPA aims at maximising these indices. In particular, XCOPA includes Estonian (ET), Haitian Creole (HT), Indonesian (ID), Italian (IT), Eastern Apurímac Quechua (QU), Kiswahili (SW), Tamil (TA), Thai (TH), Turkish (TR), Vietnamese (VI), and Mandarin Chinese (ZH). These languages belong to distinct families, respectively: Uralic, Creole, Austronesian, Indo-European, Yuman–Cochimí, Niger-Congo, Dravidian, Kra-Dai, Turkic, Austroasiatic, and Sino-Tibetan. Moreover, HT and QU are spoken in North and South America, respectively, which are both underrepresented macro-areas. We report the 3 metrics in Table 2 and compare them to samples from other standard multilingual NLU datasets. XCOPA offers the most diverse sample in terms of typology (on a par with TyDiQA), family, and geography.

Final Dataset. As Table 1 shows, each (X)COPA instance corresponds to a premise, a question ("*What was the* CAUSE?" or "*What happened as a* RESULT?"), and two alternatives. The task is framed as binary classification where the machine has to predict the more plausible choice. For each target language, XCOPA comprises 100 annotated data instances in the validation set and 500 instances as the test set, which are translations from the respective English COPA validation and test set. Our translators performed labeling prior to translation, deciding on the correct alternative for the English premise and preserving the correctness of the same alternative in translation. We measure inter-translator agreement using the Fleiss' κ statistic (Fleiss, 1971): the obtained score of 0.921 for validation and 0.911 for test data reveal very high agreement (i.e., Landis and Koch (1977) define $\kappa \geq 0.81$ as almost perfect agreement).

From the 11 sets of annotation labels we obtain the majority labels (i.e., 6+ translators agree). We observe perfect agreement between our majority labels and the English COPA labels for development data. We then compute the percentage of annotated labels which agree with the majority label for each language individually, reported in Table 3, and find very high agreement across 11 languages. The small discrepancies in label choices in our work stem not only from the actual semantic ambiguity of the original English question, but also reflect the translators' different cultural frames of reference and patterns of association. On average, 2.1% of labels in the validation set and 2.4% of labels in the test set do not match the majority label.[5]

---

[4] Six macro-areas, as defined by WALS (Dryer and Haspelmath, 2013), are: Africa, Australia, Eurasia, North America, Papunesia, and South America. Whenever a language spans multiple macro-areas, we select that of the standard variety.

[5] In order to accurately represent ambiguity of the small number of disagreement labels, in the final datasets we explic-

	ET	HT	ID	IT	QU	SW	TA	TH	TR	VI	ZH
val	97.0	97.0	99.0	98.0	98.0	99.0	100.0	99.0	97.0	97.0	96.0
test	98.2	96.4	100.0	97.0	94.8	99.0	98.6	98.2	96.4	98.4	96.6

Table 3: Percentage of annotated labels in each language agreeing with the majority label. Note that the majority label is highly reliable, as we observed a 100% agreement with the development set labels in the original COPA.

3 Qualitative Analysis

As highlighted in §2, our guidelines anticipated that the adopted translation approach may entail language-specific challenges, e.g., the lack of equivalent concepts or the grammatical expression of tense and aspect. We now analyse the main design challenges and the adopted solutions.

Cultural Context. The scenarios included in English COPA were authored by American English speakers with a particular cultural background. It is therefore inevitable that some concepts, intended as commonplace, sound unusual or even completely foreign in the target language. Examples include: (i) concrete referents with no language-specific term available (e.g., *bowling ball*, *hamburger*, *lottery*); (ii) systems of social norms absent in the target culture, e.g., traffic regulations (e.g., *parallel parking*, *parking meter*); (iii) social, political, and cultural institutions and related terminology (e.g., e.g., *mortgage*, *lobbyist*, *gavel*); (iv) idiomatic expressions (e.g., *put the caller on hold*).

In such cases, the translators were advised to resort (in the following order of preference) to (i) paraphrasing; (ii) substitutions with similar concepts, e.g., 'faucet' is replaced with 'pipe' in Tamil (குழாய், *kul̲āy*) and Haitian Creole (*tiyo*); or (iii) phonetically transcribed loan words, e.g., in Tamil: பௌலிங் பந்து (*pauliṅ pantu*, 'bowling ball'), சோப்பு (*cōppu*, 'soap').

Grammatical Tense. The temporal contiguity between two events and their duration is crucial in establishing their causal relationship (Bohnemeyer et al., 2011). A number of languages in our sample (i.e., TH, VI, ID, ZH) do not have the grammatical category of tense and express temporality by means of aspect, mood or lexical items and expressions referring to time (e.g., adverbs), or rely entirely on pragmatic context to provide sufficient information for the interpretation of the utterance. Even if aspectual viewpoint markers exist, they are optional, e.g., the perfective marker 了 (*le*) in ZH. To ensure naturalness of the translated sentences and faithfully represent the properties of the so-called tenseless languages, we favoured the unmarked variants, with the temporal relations established by the situational context. For example, compare: (a) 我想节约能源。, *Wǒ xiǎng jiéyuē néngyuán.*, 'I want(ed) to conserve energy.' (no perfective marker), and (b) 学生拼错了这个词。, *Xuéshēng pīn cuò**le** zhège cí.*, 'The student misspelled the word.' (with completed action marker).

Label Discrepancies. The analysis of inter-translator agreement in §2 revealed a small number of COPA scenarios with discrepancies in annotations across languages. To better understand the source of such disagreements, we identified all the validation set instances on which one or more translators diverged from the majority label.[6] We identified two cases where the translator's experience and cultural frame of reference played a role (as attested in translator feedback), which required, for instance, understanding of the procedures and structure of U.S. court trials (e.g., *The judge pounded the gavel.* CAUSE: (a) *The courtroom broke into uproar.* (b) *The jury announced its verdict.*).

Most disagreement cases (87.5%), however, seem to be culturally independent and concern genuinely ambiguous cases (e.g. *The detective revealed an anomaly in the case.* RESULT: (a) *He finalized his theory.* (b) *He scrapped his theory.*). To verify this in a monolingual setting, we conducted a follow-up experiment where 4 Italian native speakers labeled the translated validation and test instances. The Fleiss' κ agreement scores were 0.926 (validation) and 0.917 (test). This corroborates our decision to override a single translator's label with the majority label without altering the translation.

4 Experiments and Results

XCOPA is a multiple–choice classification task: given a premise and a prompt (CAUSE or RESULT), the goal is to select the more plausible of the two answer choices (see Table 1). We now benchmark

---

itly tag the corresponding questions with an apposite marker.

[6] Overall, there were 10 validation set questions with 1 translator out of 11 in disagreement, 5 questions with 2, and 1 question with 3.

a series of state-of-the-art models on XCOPA to provide baseline scores for future research, as well as to expose the challenging nature of the dataset. In §4.1, we list the main axes of comparison of our baselines and outline the general neural architecture for multiple-choice classification that we employ in all experiments. In §4.2, we discuss the results. Afterwards in §4.3, in order to prove that solving this task requires relying on true causal reasoning rather than spurious correlations, we test the best-performing model on 'adversarial' variants where either the premise or the prompt are hidden (Niven and Kao, 2019). Finally, in §4.4 we explore several strategies to adapt massively multilingual models to new languages not observed during pretraining, such as Quechua and Haitian Creole.

4.1 Baselines

We evaluate baselines in several combinations of experimental setups based on: **1)** different methods for cross-lingual transfer, either based on model transfer or machine translation; **2)** different multilingual pretrained encoders; **3)** different sources of training and validation data.

Cross-lingual Transfer Methods. We consider two high-level methods for cross-lingual transfer (Tiedemann, 2015; Ponti et al., 2019a): **1)** *multilingual model transfer* (MuMoTr), whereby a Transformer-based encoder is pretrained on multiple languages in an unsupervised fashion, and subsequently trained on English annotated data for multiple-choice classification, therefore enabling zero-shot generalisation to the other languages. **2)** *translate test* (TrTe), whereby target test data[7] are translated into English via Google Translate. This includes all languages except for QU, for which the service is not available.

Multilingual Encoders. For model transfer, we evaluate the following state-of-the-art pretrained multilingual encoders: **1)** multilingual BERT (MBERT) (Devlin et al., 2019) and XLM-on-RoBERTa (Conneau et al., 2020), both the Base (XLM-R) and Large (XLM-R-L) variants, in the standard *fine-tuning regime* (i.e., their parameters are fine-tuned together with the task classifier's parameters), and **2)** multilingual Universal Sentence Encoder (USE) (Yang et al., 2019a) in the *feature-based regime* (i.e., its parameters are fixed during the task classifier's training). Both MBERT and XLM-R include all XCOPA languages in their pretraining data spanning ∼100 languages, except Haitian Creole and Quechua. Multilingual USE was trained on 16 languages, covering IT, TH, TR, and ZH from the XCOPA language sample.

Data Sources. The only direct in-domain data available for training is the original English COPA training set covering 400 instances. Due to data scarcity, we probe the usefulness of an intermediate training stage (Phang et al., 2018; Glavaš and Vulić, 2020) on larger multiple–choice English commonsense reasoning datasets, such as SOCIALIQA (SIQA; Sap et al., 2019), before finetuning the model on COPA. The SIQA dataset is in a distant domain (commonsense reasoning about social interactions) with open-format prompts and three answer choices. However, it comes with a much larger training set, consisting of 33K instances. Therefore, it can provide useful learning signal also for causal commonsense reasoning in XCOPA. Moreover, we consider two different model selection regimes for hyper-parameter tuning and early stopping, namely (i) using the EN COPA validation set or (ii) target language XCOPA validation set. Table 4 lists all experimental setups.

Neural Architecture. As multiple–choice selection tasks differ in the number of choices (e.g., there are 2 possible answers in COPA, whereas there are 3 in SIQA), a classifier with a fixed number of classes is not a good fit for this scenario. We thus follow Sap et al. (2019) and couple the (pretrained) encoder with a feed-forward net which produces a single scalar score for each possible answer. The scores for individual choices are then concatenated and passed to the softmax function.

As an input to the encoder, we couple each of the answer choices with the concatenation of the premise and the prompt. We feed this as a "sentence pair" input to MBERT and XLM-R, or as a single "sentence" to USE.[8]

Let c_i be the i-th answer choice of an instance of multiple-choice dataset (i.e., $i \in \{1, 2\}$ in XCOPA and $i \in \{1, 2, 3\}$ in SIQA) and let $\mathbf{x}_i \in \mathbb{R}^H$ (with H as the vector size of the encoder)[9] be the en-

---

[7] As shown by Conneau et al. (2018), translating the test data from the target language to English is more cost-effective than translating English training data into the target language.

[8] For MBERT and XLM-R, we insert the standard special tokens. For example, for the last example from Table 1 and Choice 1, the input for MBERT would be as follows: "*[CLS] My eyes became red and puffy. What was the cause? [SEP] I was sobbing. [SEP]*".

[9] For MBERT Base and XLM-R Base, $H = 768$; for XLM-R Large, $H = 1,024$; for multilingual USE Large, $H = 512$.

	Train dataset		Valid dataset

SI+CO-TLV	✓	✓		✓

Table 4: Different experimental setups for data sources. CO=COPA; SI=SIQA; ZS=Zero-Shot; TLV=Target Language Validation (Set).

coding of its corresponding input consisting of the premise, prompt and the answer itself, as explained above.[10] The predicted score $\hat{y}_i$ for the answer c_i is then obtained with the following feed-forward net: $\hat{y}_i = \mathbf{W}_o \tanh(\mathbf{W}_h \mathbf{x}_i + \mathbf{b}_h)$, with $\mathbf{W}_h \in \mathbb{R}^{H \times H}$, $\mathbf{b}_h \in \mathbb{R}^{H}$ and $\mathbf{W}_o \in \mathbb{R}^{1 \times H}$ as parameters. We obtain the score $\hat{y}_i$ for each answer c_i and concatenate them into a prediction vector to which we apply softmax normalisation: $\hat{\mathbf{y}} = \mathrm{softmax}([\hat{y}_1, \dots, \hat{y}_N])$, where N is the number of answers in the multiple-choice classification dataset. We minimise the cross-entropy loss function via stochastic gradient descent.

4.2 Results and Discussion

We first present the results for model transfer based on multilingual pretrained encoders. Table 5 shows the aggregate accuracy of MBERT, XLM-Rs and USE over 11 XCOPA languages for each of the previously described training setups from Table 4. We first compare our cross-lingual average XCOPA results in the best setup with the English COPA performance of the monolingual English BERT (Base) reported by Sap et al. (2019), namely 63 accuracy in COPA-only fine-tuning (+7%) and 80 after sequential SIQA + COPA fine-tuning (+17%). This contributes to recent suspicions (Cao et al., 2020; Hu et al., 2020) that massively multilingual pretrained transformers do not offer a completely satisfactory solution for language transfer.

Setup	**Model**	All	MBERT ∩ XCOPA	USE ∩ XCOPA
CO-ZS	XLM-R	55.6	56.9	55.4
	XLM-R-L	52.4	52.5	52.1
	MBERT	54.1	54.4	55.7
	USE	54.7	56.0	58.1
CO-TLV	XLM-R	55.1	56.4	55.2
	XLM-R-L	51.6	51.7	52.1
	MBERT	54.2	54.5	55.8
	USE	54.8	55.4	59.0
SI-ZS	XLM-R	60.1	62.3	62.9
	XLM-R-L	68.4	72.1	72.9
	MBERT	54.7	55.6	56.4
	USE	55.0	56.4	60.1

	XLM-R-L	**69.1**	**72.8**	**74.6**
	MBERT	54.4	54.8	54.2
	USE	54.3	55.2	59.1

Table 5: Summary of XCOPA results. **All**: average over all 11 XCOPA languages; **MBERT ∩ XCOPA**: average over 9 XCOPA languages (without HT and QU) included in MBERT and XLM-R pretraining; **USE ∩ XCOPA**: average over 4 XCOPA languages (IT, TH, TR, and ZH), included in the USE pretraining.

Multilingual Encoders. XLM-R (both Base and Large) outperforms MBERT and USE in all setups, but the gains are pronounced only where the models were first fine-tuned on SIQA (SI-ZS, SI+CO-ZS, and SI+CO-TLV). USE outperforms MBERT often, which is especially surprising in the few-shot learning setup of COPA-only, as it contradicts the received wisdom that a larger amount of trainable parameters guarantees higher sample efficiency (Kaplan et al., 2020). What is more, USE in some setups even surpasses MBERT for some of the languages (e.g., ID, TA, SW) on which MBERT was pretrained and USE was not (cf. the scores in the MBERT ∩ XCOPA column). We speculate that this is due to a combination of two effects: (1) the infamous "curse of multilinguality" (Conneau et al., 2020) is much more pronounced for MBERT (which is pretrained on 104 languages) than for USE, pretrained on only 16 languages; and (2) there are subword-level similarities between XCOPA target languages and the 16 languages used in USE pretraining.

Unsurprisingly, XLM-R Large substantially outperforms its Base counterpart in all setups with SIQA training. Due to almost 3 times more parameters (355M vs. 125M), XLM-R-L stores more language-specific information during pretraining. The large parameter space, however, also causes XLM-R-L to under-perform XLM-R in COPA-only setups (CO-ZS and CO-TLV), with the small COPA fine-tuning dataset.

---

[10] For MBERT and XLM-R $\mathbf{x}_i$ is the transformed representation of the sequence start token. For USE, $\mathbf{x}_i$ is the average of contextualised vectors of all tokens.

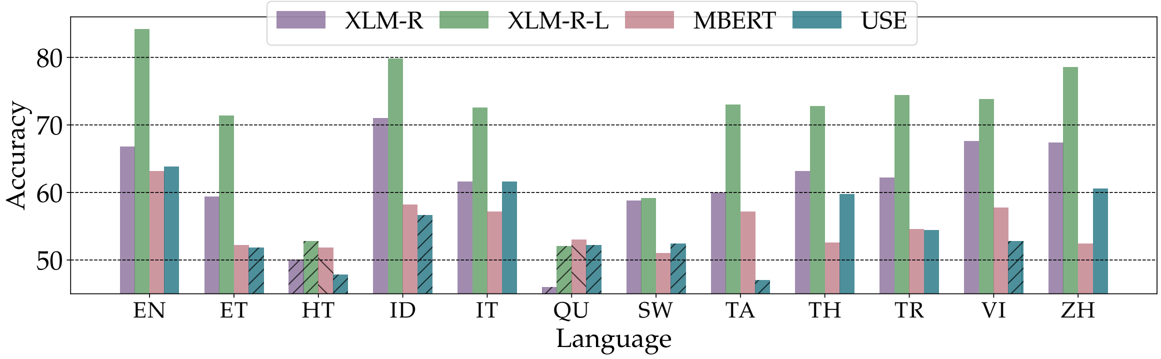

Figure 1: Per-language XCOPA results for XLM-R, MBERT, and USE in the SIQA + COPA-TLV setup. Striped bars correspond to language-model pairs where the language was not included in model pretraining.

Data Sources. Training models only on SIQA yields performance that is comparable (and for MBERT and USE often better) to performance we obtain with additional COPA training (setups SI + CO-ZS and SI + CO-TLV). While this is in part due to the limited size of the COPA training set, it confirms the assumption that SIQA and COPA are compatible tasks. We also note that only slight gains are achieved by hyper-parameter tuning on the target language validation set (TLV).

Per-Language Performance. In Figure 1, we report the language-specific performances for the best setup, SIQA + COPA-TLV, while we provide detailed results for all other setups in the Appendix. As expected, all models fluctuate around random-level accuracy on the two out-of-sample languages, HT and QU. Surprisingly, we also observe that for some languages (ID, VI, ZH) performance of transfer from English is slightly higher than the actual performance in English, without transfer. Moreover, the scores are often better for languages typologically distant from English than for closer ones (e.g., TH, VI, ZH vs. IT). We speculate that this is due to the fact that languages such as ZH and TH are better represented in the pretrained models due to their unique scripts, which are shared with few other languages and therefore prevent lexical interferences.

Cross-Lingual Transfer Methods. Finally, in Table 6 (bottom) we compare the best setup for multilingual model transfer (XLM-R-L encoder with SIQA + COPA-TLV) with the method based on machine translation of the test set into English. In particular, for machine translation we consider both the massively multilingual (XLM-R-L) and the monolingual (RoBERTa Large, R-L) versions of the best encoder found in previous experiments.[11] No clear pattern emerges as the same model, XLM-R-L, is superior in 5 languages under the translation-based setup, and in 4 languages for the multilingual model transfer setup. A boost in accuracy, however, is especially evident for SW, with a gain of 13.8 points (+25%). On the other hand, the translation-based setup largely outpaces multilingual model transfer when paired with a monolingual encoder, R-L. This baseline surpasses the others in all languages except for TH. This brings us to the conclusion that it is not the cross-lingual transfer method in itself, but rather the avoidance of the 'curse of multilinguality,' that makes translation-based cross-lingual transfer superior.

4.3 Adversarial Variants

After detecting an effective baseline, we 'stress test' its robustness to prove that true causal reasoning is needed to solve our task. Recently, Niven and Kao (2019) demonstrated that state-of-the-art pretrained encoders tend to rely on spurious correlations in natural language understanding datasets. Inspired by their work, we create two 'adversarial' variants of XCOPA (and SIQA) where part of the input is masked. In the first variant (NoP), we hide premises; in the second (NoQ), we hide prompts.

The results of the best configuration for multilingual model transfer are reported in Table 6 (top). Clearly, without premises the performance is not much better than chance (accuracy of 50.0). Without prompts (CAUSE and EFFECT for XCOPA), performance is higher but still lags behind the original variant with full inputs. Hence, we may conclude that solving this task requires causal reasoning over all components of the event dynamics.

---

[11] As a caveat, note that these results are not perfectly comparable as Google Translate was trained on different (possibly more abundant) data, in addition to parallel texts.

Setup	Variant	Model	EN	ET	HT	ID	IT	SW	TA	TH	TR	VI	ZH
MuMoTr	NoP	XLM-R-L	63.0	56.2	-	62.4	56.6	56.0	60.2	60.6	58.8	60.2	63.2
MuMoTr	NoQ	XLM-R-L	76.2	63.8	-	73.4	72.8	59.0	64.4	70.2	69.2	69.8	70.8
MuMoTr	Full	XLM-R-L	84.2	71.4	-	79.8	72.6	59.2	73.0	**72.8**	74.4	73.8	78.6
TrTe	Full	XLM-R-L	84.2	76.8	70.0	79.6	74.6	74.0	74.0	71.4	72.8	77.8	78.4
TrTe	Full	R-L	**88.4**	**81.0**	**73.8**	**82.2**	**77.8**	**74.2**	**79.6**	71.4	**79.6**	**81.0**	**86.0**

Table 6: Detailed per-language XCOPA results of the best cross-lingual transfer setups (bottom). Performance with two adversarial variants of the dataset where premises and prompts are hidden, respectively (top).

4.4 Adaptation to Unseen Languages

Even massively multilingual encoders like MBERT and XLM-R, pretrained on corpora of over 100 languages, cover only a fraction of the world's 7,000+ languages. In fact, the majority of the world languages suffer from data paucity (Kornai, 2013): we thus explore several resource-lean approaches for extending encoders post-hoc to support transfer to languages not observed during pretraining, such as QU and HT in XCOPA.

Adaptation Strategies. We use XLM-R, the best-performing among the "base size" multilingual encoders on XCOPA, and probe several strategies for adapting it to the two unseen XCOPA target languages. In all strategies, we simply continue training the XLM-R model via the masked language modeling (MLM) objective on different combinations of data (Pfeiffer et al., 2020), in particular:

1) T. Sentences in the target language. We create the monolingual corpora for HT and QU by concatenating their respective Wikipedia dumps with their respective text from the JW300 corpus (Agić and Vulić, 2019). In total, the training size is 5,710,426 tokens for HT, and 2,263,134 tokens for QU.

2) S. Sentences in English (EN). This could prevent (catastrophic) forgetting of the source language while fine-tuning, which presumably may occur with T only. We create the English corpus of comparable size to HT and QU corpora by randomly sampling 200K sentences from EN Wikipedia.

3) D. A bilingual EN–HT and EN–QU dictionary. The dictionaries were extracted from PanLex (Kamholz et al., 2014): we retain the 5k most reliable word translation pairs according to the available PanLex confidence scores. We create a synthetic corpus from the dictionary (termed *D-corpus* henceforth) by concatenating each translation pair from the dictionary into a quasi-sentence.

4) T-REP. T data with all occurrences of target language terms from the 5K dictionary replaced with their English translations.

Setup	Model	HT	QU
CO-ZS	XLM-R	49.4	50.7
	+T	**53.8**	49.8
	+S+T	52.8	54.0
	+D	52.2	51.2
	+S+T+D	53.6	52.0
	+T-REP	49.6	**55.0**
SI-ZS	XLM-R	49.2	51.0
	+T	56.2	**57.9**
	+S+T	55.2	55.0
	+D	55.4	57.4
	+S+T+D	56.4	53.5
	+T-REP	**58.6**	57.7
SI+CO-ZS	XLM-R	51.4	51.2
	+T	57.8	54.0
	+S+T	55.8	55.2
	+D	57.8	**57.9**
	+S+T+D	55.4	54.0
	+T-REP	**58.4**	54.4

Table 7: XCOPA accuracy scores of different transfer variants that adapt to out-of-sample languages.

We select 5k target language sentences as the development corpus and use it for early stopping the MLM training (with perplexity as a metric).

Results and Discussion. The performance of the five adaptation variants with XLM-R on HT and QU in the zero-shot XCOPA evaluation setups is reported in Table 7. When using sufficiently large fine-tuning datasets (SI-ZS and SI+CO-ZS setups) all adaptation methods yield substantial improvements over the XLM-R Base model. The improvements are less consistent in the COPA-ZS setup. However, we attribute this to the limited size of the English COPA training set (which contains mere 400 instances) used for fine-tuning rather than to the ineffectiveness of the proposed adaptation strategies. A comparison between XLM-R+T and XLM-R+S+T suggests that additional MLM pretraining on a moderately sized target language corpus does not lead to catastrophic forgetting of the source language information.

The results of the light-weight post-hoc XLM-R adaptations for HT and QU are encouraging,[12] as

---

[12] Note that the unseen languages, however, must rely on

they bypass retraining the encoder from scratch while achieving downstream results almost comparable with seen languages. Also, the results in Table 7 suggest that leveraging additional knowledge from a general bilingual dictionary can lead to further benefits: e.g., note the results of XLM-R+T-REP in SIQA-ZS and SIQA+COPA-ZS transfer setups, as well as XLM-R+D. Building on this proof-of-concept experiment, further adaptation strategies for zero-shot learning may be explored in the future, such as conditioning parameters on typological features (Ponti et al., 2019b).

5 Related Work

Evaluation of Commonsense Reasoning. Besides COPA, another important early dataset that instigated computational modeling of commonsense reasoning is the Winograd Schema Challenge (WSC; Levesque et al., 2012; Morgenstern and Ortiz, 2015). WSC consists in a pronoun coreference resolution task with paired instances, and has been recently expanded into the WinoGrande dataset (Sakaguchi et al., 2020) through crowd-sourcing.

Several recent evaluation sets target particular aspects of commonsense, e.g., abductive reasoning (Bhagavatula et al., 2020),[13] intents and reactions to events (Rashkin et al., 2018), social (Sap et al., 2019) and physical (Bisk et al., 2020) interactions, or visual commonsense (Zellers et al., 2019a). Others, e.g., CommonsenseQA (Talmor et al., 2019), SWAG (Zellers et al., 2018), and HellaSWAG (Zellers et al., 2019b) are cast as open-ended multiple-choice problems where the most sensible option is chosen. Another line of evaluation involves commonsense-enabled reading comprehension and question answering (Ostermann et al., 2018; Zhang et al., 2018; Huang et al., 2019).

Multilingual Evaluation of Natural Language Understanding. While the above commonsense reasoning datasets are limited to English, several multilingual datasets for other natural language understanding tasks are available, e.g., lexical semantic similarity (Multi-SimLex; Vulić et al., 2020), document classification (MLDoc; Schwenk and Li, 2018), sentiment analysis (Barnes et al., 2018), and natural language inference (XNLI; Conneau et al., 2018). Other recent multilingual sets target the QA task based on reading comprehension: MLQA (Lewis et al., 2020) in 7 languages, XQuAD (Artetxe et al., 2020b) in 10; and TyDiQA (Clark et al., 2020) in 11 typologically diverse languages. Further, PAWS-X (Yang et al., 2019b) evaluates paraphrase identification in 6 languages. A standard and pragmatic approach to multilingual dataset creation is translation from an existing (English) dataset, e.g., Multi-SimLex from the extended English SimLex-999 (Hill et al., 2015), XNLI from MultiNLI (Williams et al., 2018), XQuAD from SQuAD (Rajpurkar et al., 2016), and PAWS-X from PAWS (Zhang et al., 2019). TyDiQA, however, was built independently in each language. Finally, a large number of tasks has been recently integrated into unified multilingual evaluation suites, XTREME (Hu et al., 2020) and XGLUE (Liang et al., 2020).

6 Conclusion and Future Work

We presented the Cross-lingual Choice of Plausible Alternatives (XCOPA), a multilingual evaluation benchmark for causal commonsense reasoning. All XCOPA instances are aligned across 11 languages, which enables cross-lingual comparisons. The language selection was informed by variety sampling, in order to maximise diversity in terms of typological features, geographical macro-area, and language family. This allows us to test the robustness of machine learning models for an array of rare phenomena displayed by the chosen languages.

We also ran a series of cross-lingual transfer experiments, evaluating state-of-the-art transfer methods based on multilingual pretraining and fine-tuning on English. We observed that, although these methods perform better than chance, they still lag significantly behind the monolingual setting where test data are translated into English, due to the 'curse of multilinguality.' In addition, we verified that spurious correlations are insufficient to solve this new task by creating 'adversarial' variants of the dataset, where premises or prompts are masked, thus showing that robust causal reasoning is indeed required to solve XCOPA. Finally, we investigated resource-lean adaptation of pretrained multilingual models to out-of-sample languages, exploiting only small monolingual corpora and/or bilingual dictionaries, reporting notable gains.

We hope that this new challenging evaluation set will foster further research in multilingual commonsense reasoning and cross-lingual transfer.

---

seen scripts (e.g., both HT and QU are written in Latin script).

[13] Abductive reasoning is inference to the most plausible explanation of incomplete observations (Peirce, 1960).

A Detailed Translation Guidelines

Translation of the English COPA validation and test set instances into each of the 11 languages was carried out by a single translator per language, meeting the following eligibility criteria: (i) a native speaker of the target language, (ii) fluent in English, (iii) with minimum undergraduate education level. Each translator was presented with translation guidelines and a spreadsheet accessible online, containing one English premise-hypothesis triple per line, followed by an empty line where target translations were entered. The task consisted in (a) identifying the correct alternative for the English premise and (b) translating the premise and both alternatives into the target language, preserving the causal relations present in the original (see §3 for discussion of ambiguous and problematic cases). Each translator worked independently (using any external resources, such as English-target language dictionaries, if needed) and completed the task in its entirety, producing 100 validation and 500 test instance translations, and a label for each. To ensure the output preserves the lexical, temporal, and causal relations present in the original triples, the guidelines instructed to:

i. maintain the original correspondence relations between lexical items, i.e., if the same English word appeared both in the premise and in the alternative choices (Premise: *The friends decided to share the hamburger.*; A1: *They cut the hamburger in half.*; A2: *They ordered fries with the hamburger.*), it was mapped into the same target-language equivalent in all three translated sentences;

ii. ensure that the original chronology and temporal extension of events is preserved through appropriate choice of verbal tense and aspect in the target language, e.g., maintaining the distinction between perfective and imperfective aspect (Premise: *My eyes became red and puffy.* [PERF], A1: *I was sobbing.* [IMPERF], A2: *I was laughing.* [IMPERF]; See also §3 and Appendix B for discussion of the challenges posed by tenseless languages);

iii. in case of English words with no exact translations in the target language or referring to concepts absent from the target language culture (e.g., *peach*), the following solutions were to be adopted, in order of preference: (1) using a common loanword from another language, provided it is understood by the general population of target-language speakers; (2) using a periphrasis to describe the same concept (e.g., *a juicy fruit*); (3) substituting the original concept with a similar one that is more familiar to the target language speaker community (e.g., *santol*), provided that it can play a similar role in the causal relations captured by the original premise–prompt–answers triple.

The translators were encouraged to split the workload into multiple sessions with breaks in between. Additionally, translators were encouraged to provide feedback, commenting on translation challenges and solutions, which we discuss in §3.

B Why is Grammatical Tense Problematic for XCOPA?

The scenarios included in COPA refer to events that took place in the past and are formulated in what can be described as a narrative register: one of the sources from which question topics were drawn was a corpus of personal stories published online (Gordon and Swanson, 2009). This is grammatically rendered exclusively by means of past simple (preterite) or past continuous (imperfect) verb forms. Temporal anteriority of a hypothesis sentence with respect to the premise is not grammatically marked (e.g., with a past perfect verb form) and can only be deduced based on the prompt ("*What was the* CAUSE *of this?*"). The preterite-imperfect contrast used in English to distinguish background states (imperfective) from the main event (perfective) (e.g., *I was expecting company.* IMPERF VS. *I tidied up my house.* PERF) is not universally applicable and different languages employ different discourse grounding strategies (Hopper, 1979), which has interesting implications for the multilingual extension of COPA to XCOPA.

In the languages with grammatical tense, different strategies are employed to capture the perfective–imperfective distinction, which is prominent in COPA. For example, in Haitian Creole, the simple past marker *te* is used to indicate a bounded event in the past, while the continuous aspect is signaled with an *ap* marker. Italian additionally distinguishes between two perfective past tenses, expressed by means of a simple and compound past (*vidi* - *ho visto*, 'I saw'). The opposition is between completed actions whose effects are detached from the present and those with persisting effects on the present. Both contrast with the im-

perfect, which emphasises the event's extension or repetition in time. Given that the opposition is a matter of the speaker's perspective on events and partially based on deixis (remote versus proximate past), the translator opted for the most natural choice given a specific context/situation.

C Hyper-Parameter Search

For MBERT and XLM-R we searched the following hyper-parameter grid in both SIQA and COPA training: learning rate $\in \{5 \cdot 10^{-6}, 10^{-5}, 3 \cdot 10^{-5}\}$, dropout rate (applied to the output layer of the transformer and the hidden layer of the feed-forward scoring net) $\in \{0, 0.1\}$, and batch size $\in \{4, 8\}$. For USE, we searched over different values for the learning rate, $\{10^{-3}, 10^{-4}, 10^{-5}\}$. We evaluate the performance on the respective development set every 500 updates for SIQA and every 10 updates for COPA and stop the training if there is no improvement after 10 consecutive evaluations. In all setups, we optimise the parameters with the Adam algorithm (Kingma and Ba, 2015) with $\epsilon = 10^{-8}$, no weight decay, and no warm-up. We clip the norms of gradients in single updates to 1.

D Full Results (Per Language)

Table 8 contains the detailed per-language results of multilingual model transfer for all XCOPA languages and all five of our evaluation setups (CO-ZS, CO-TLV, SI-ZS, SI+CO-ZS, SI+CO-TLV).

E Code and Dependencies

Our code is built on top of the HuggingFace Transformers framework[14] and USE[15] and is available at `github.com/cambridgeltl/xcopa`. Table 9 details the pretrained models that we exploited in this work. Besides these, our code relies only on standard Python's scientific computing libraries (e.g., `numpy`).

Abstract

Performance in cross-lingual NLP tasks is impacted by the (dis)similarity of languages at hand: e.g., previous work has suggested there is a connection between the expected success of bilingual lexicon induction (BLI) and the assumption of (approximate) isomorphism between monolingual embedding spaces. In this work we present a large-scale study focused on the correlations between monolingual embedding space similarity and task performance, covering thousands of language pairs and four different tasks: BLI, parsing, POS tagging and MT. We hypothesize that statistics of the spectrum of each monolingual embedding space indicate how well they can be aligned. We then introduce several isomorphism measures between two embedding spaces, based on the relevant statistics of their individual spectra. We empirically show that **1)** language similarity scores derived from such spectral isomorphism measures are strongly associated with performance observed in different cross-lingual tasks, and **2)** our spectral-based measures consistently outperform previous standard isomorphism measures, while being computationally more tractable and easier to interpret. Finally, our measures capture complementary information to typologically driven language distance measures, and the combination of measures from the two families yields even higher task performance correlations.

1 Introduction

The effectiveness of joint multilingual modeling and cross-lingual transfer in cross-lingual NLP is critically impacted by the actual languages in consideration (Bender, 2011; Ponti et al., 2019). *Characterizing, measuring, and understanding this cross-language variation* is often the first step towards the development of more robust multilingually applicable NLP technology (O'Horan et al., 2016; Bjerva et al., 2019; Ponti et al., 2019). For instance, selecting suitable source languages is a prerequisite for successful cross-lingual transfer of dependency parsers or POS taggers (Naseem et al., 2012; Ponti et al., 2018; de Lhoneux et al., 2018). In another example, with all other factors kept similar (e.g., training data size, domain similarity), the quality of machine translation also depends heavily on the properties and language proximity of the actual language pair (Kudugunta et al., 2019).

In this work, we contribute to this research endeavor by proposing a suite of spectral-based measures that capture the degree of isomorphism (Søgaard et al., 2018) between the monolingual embedding spaces of two languages. Our main hypothesis is that the potential to align two embedding spaces and learn transfer functions can be estimated through the differences between the monolingual embeddings' spectra. We therefore discuss representative statistics of the spectrum of an embedding space (i.e., the set of the singular values of the embedding matrix), such as its condition number or its sorted list of singular values. We then derive measures for the isomorphism between two embedding spaces based on these statistics.

To validate our hypothesis, we perform an extensive empirical evaluation with a range of cross-lingual NLP tasks. This analysis reveals that our proposed spectrum-based isomorphism measures better correlate and explain greater variance than previous isomorphism measures (Søgaard et al., 2018; Patra et al., 2019). In addition, our measures also outperform standard approaches based on linguistic information (Littell et al., 2017),

The first part of our empirical analysis targets bilingual lexicon induction (BLI), a cross-lingual task that received plenty of attention, in particular as a case study to investigate the impact of cross-language variation on task performance (Søgaard et al., 2018; Artetxe et al., 2018). Its popularity stems from its simple task formulation and reduced

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2377–2390,
November 16–20, 2020.

resource requirements, which makes it widely applicable across a large number of language pairs (Ruder et al., 2019b).

Prior work has empirically verified that for some language pairs BLI performs remarkably well, and for others rather poorly (Søgaard et al., 2018; Vulić et al., 2019). It attempted to explain this variance in performance by grounding it in the differences between the monolingual embedding spaces themselves. These studies introduced the notion of *approximate isomorphism*, and argued that it is easier to learn a mapping function (Mikolov et al., 2013; Ruder et al., 2019b) between language pairs whose embeddings are approximately isomorphic, than between languages pairs without this property (Barone, 2016; Søgaard et al., 2018). Subsequently, novel methods to quantify the degree of isomorphism were proposed, and were shown to significantly correlate with BLI scores (Zhang et al., 2017; Søgaard et al., 2018; Patra et al., 2019).

In this work, we report much higher correlations with BLI scores than existing isomorphism measures, across a variety of state-of-the-art BLI approaches. While previous work was limited only to coarse-grained analysis with a small number of language pairs (i.e., < 10), our study is the first large-scale analysis that is focused on the relationship between quantifiable isomorphism and BLI performance. Our analysis covers hundreds of diverse language pairs, focusing on typologically, geographically and phylogenetically distant pairs as well as on similar languages.

We further show that our findings generalize beyond BLI, to cross-lingual transfer in dependency parsing and POS tagging, and we also demonstrate strong correlations with machine translation (MT) performance. Finally, our spectral-based measures can be combined with typologically driven language distance measures to achieve further correlation improvements. This indicates the complementary nature of the implicit knowledge coded in continuous semantic spaces (and captured by our spectral measures) and the discrete linguistic information from typological databases (captured by the typologically driven measures).

2 Quantifying Isomorphism with Spectral Statistics

Following the distributional hypothesis (Harris, 1954; Firth, 1957), word embedding models learn the meaning of words according to their co-occurrence patterns. Hence, the word embedding space of a language whose words are used in diverse contexts is intuitively expected to encode richer information and greater variance than the word embedding space of a language with more restricting word usage patterns. The difference between two monolingual embedding spaces may also result from other reasons, such as the difference between the training corpora on which the embedding induction algorithm is trained, and the degree to which this algorithm accounts for the linguistic properties of each of the languages.

While the exact combination of factors that govern the difference between the embedding spaces of different languages is hard to figure, this difference is likely to be indicative of the quality of cross-lingual transfer. This is particularly true when the embedding spaces are used by cross-lingual transfer algorithms. Our core hypothesis is that the difference between two monolingual spaces can be quantified by spectral statistics of the two spaces.

2.1 Spectrum Statistics

Given a d-dimensional embedding matrix $\mathbf{X}$, we perform Singular Value Decomposition (SVD) and obtain a diagonal matrix $\mathbf{\Sigma}$ whose main diagonal comprises of d singular values, $\sigma_1, \sigma_2, \ldots, \sigma_d$, sorted in a descending order.[1] Our aim is to quantify the difference between two embedding spaces by comparing statistics of their singular values. We next describe such statistics and in §2.2 use them to measure the isomorphism between the spaces.

Condition Number. In numerical analysis, a function's condition number measures the extent of change of the function's output value conditioned on a small change in the input (Blum, 2014). Consider the case of $\varphi : \mathbf{X} \rightarrow \mathbf{Y}$, where $\mathbf{X}$ and $\mathbf{Y}$ are two embedding spaces mapped via φ. The condition number, $\kappa(\mathbf{X})$, represents the degree to which small perturbations in the input $\mathbf{X}$ are amplified in the output $\varphi(X)$. Following Higham et al. (2015), we compute the condition number of an input matrix $\mathbf{X}$ with d singular values as the ratio between its first (largest) and last (smallest) singular values:

$$\kappa(\mathbf{X}) = \frac{\sigma_1}{\sigma_d} \tag{1}$$

Why is it a relevant statistic? A smaller condition number denotes a more "stable" matrix that is less

---

[1] $\mathbf{X}$ is mean-centered, column means have been subtracted and are equal to zero.

sensitive to perturbations. Consequently, learning a transfer function φ from one embedding space to another is more robust to noise when dealing with spaces with smaller $\kappa(\mathbf{X})$. We thus expect that embedding matrices with high condition numbers might impede the learning of good transfer functions in cross-lingual NLP: A function learnt on an embedding space that is sensitive to small perturbations may not generalize well.

Are small singular values reliable? Small singular values are associated with noise, or with the least important information, and many noise reduction techniques remove them (Ford, 2015). If the smallest singular value indeed captures noise, this might affect the condition number (Eq. (1)). It is thus crucial to distinguish between "small but significant" and "small and insignificant" singular values. This is what we do below.

Effective Rank. Given sorted singular values, how can we determine the last effective singular value? For a matrix with d singular values $\sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_d \geq 0$, the ϵ-numerical rank can be defined as: $r_\epsilon = \min\{r : \sigma_r \geq \epsilon\}$, which means that singular values below a certain threshold are removed. However, this formulation introduces a dependency on the hyper-parameter ϵ. To avoid this, Roy and Vetterli (2007) proposed an alternative method that considers the full spectrum of singular values before computing the so-called *effective rank* of the input matrix $\mathbf{X}$:

$$erank(\mathbf{X}) = \left\lfloor e^{H(\Sigma)} \right\rfloor \tag{2}$$

where $H(\Sigma)$ is the entropy of the matrix $\mathbf{X}$'s normalized singular value distribution $\bar{\sigma}_i = \frac{\sigma_i}{\sum_{i=1}^{d} \sigma_i}$, computed as $H(\Sigma) = -\sum_{i=1}^{d} \bar{\sigma}_i \log \bar{\sigma}_i$. $erank(\mathbf{X})$, rounded to the smaller integer, yields the index of the last singular value that is considered significant, and is interpreted as the effective dimensionality, or rank, of the matrix $\mathbf{X}$. If d is the dimensionality of the embedding space $\mathbf{X}$, and we assume that the number of word vectors in $\mathbf{X}$ is typically much larger than d, it then holds that (see Roy and Vetterli (2007)):

$$1 \leq erank(\mathbf{X}) \leq rank(\mathbf{X}) \leq d \tag{3}$$

The dimensionality of an embedding space is intuitively assumed to be equal to the dimensionality of its constituent vectors: the matrix rank. Effective rank undermines this assumption: with effective rank matrices of the same 'initial dimensionality' can have very different 'true dimensionalities' (Yin and Shen, 2018). Effective rank is used for various problems outside NLP, such as source localization for acoustic (Tourbabin and Rafaely, 2015) and seismic (Leeuwenburgh and Arts, 2014) waves, video compression (Bhaskaranand and Gibson, 2010), and for the evaluation of implicit regularization in neural matrix factorization (Arora et al., 2019). We propose to use it to inform and improve the estimation of the condition number.

Effective Condition Number. We replace σ_d in Eq. (1) with the singular value at the position of $\mathbf{X}$'s effective rank (see Eq. (2)), and compute the *effective condition number* κ_{ecn} as follows:

$$\kappa_{ecn}(\mathbf{X}) = \frac{\sigma_1}{\sigma_{erank(\mathbf{X})}} \tag{4}$$

In §5 we empirically validate the quality of the effective condition number in comparison to the standard condition number.

Having defined spectral statistics of an embedding space, we move to define means of comparing two spaces using these statistics.

2.2 Spectral-Based Isomorphism Measures

The statistics described in §2.1 capture properties of a single embedding space, but it is not straightforward how to employ them in order to quantify the similarity between two distinct embedding spaces. In what follows, we introduce isomorphism measures based on the spectral statistics.

Let us assume two embedding matrices $\mathbf{X}_1$ and $\mathbf{X}_2$, with their condition numbers, $\kappa(\mathbf{X_1})$ and $\kappa(\mathbf{X_2})$. We combine the two numbers using the harmonic mean function (HM) to derive an isomorphism measure between two embedding spaces, COND-HM$(\mathbf{X}_1, \mathbf{X}_2)$:

$$\text{COND-HM}(\mathbf{X}_1, \mathbf{X}_2) = \frac{2 \cdot \kappa(\mathbf{X_1})\kappa(\mathbf{X_2})}{\kappa(\mathbf{X_1}) + \kappa(\mathbf{X_2})} \tag{5}$$

We similarly define the ECOND-HM measure over $\kappa_{ecn}(\mathbf{X_1})$ and $\kappa_{ecn}(\mathbf{X_2})$.

Why harmonic mean? The higher the (effective) condition number of an embedding space, the higher its sensitivity to perturbations (i.e., the performance of transfer functions will be low). We view the condition number as a constraining factor on transferability, but what is the right way to evaluate the 'transferability potential' of two spaces via their condition numbers? There are multiple ways to combine two condition numbers, but we have empirically validated (§5) that HM is a robust choice that outperforms some other possibilities (e.g., the arithmetic mean). We hypothesize this is because HM treats large discrepancies between two numbers in a manner that leans towards the smaller one (unlike e.g. arithmetic mean). Two noisy and two stable embedding spaces would have high and low HMs, respectively, but a noisy embedding space and a stable one would have an HM that leans towards the stable one.[2] Our results suggest that embedding spaces with small condition numbers can often tolerate noisy mappings from embedding spaces with high condition numbers, which might result from the improved stability of the former spaces.

Singular Value Gap. In addition to COND-HM and ECOND-HM, we introduce another measure that empirically quantifies the divergence between the full spectral information of two embedding spaces. This measure quantifies the gap between the singular values obtained from the matrices $\mathbf{X}_1$ and $\mathbf{X}_2$ sorted in descending order. We define the measure of Singular Value Gap (SVG) between two d-dimensional spaces $\mathbf{X}_1$ and $\mathbf{X}_2$, as the squared Euclidean distance between the corresponding sorted singular values after log transform:

$$SVG(\mathbf{X}_1, \mathbf{X}_2) = \sum_{i=1}^{d} (\log \sigma_i^1 - \log \sigma_i^2)^2 \quad (6)$$

where σ_i^1 and σ_i^2, $i = 1, \ldots, d$ are the sorted singular values characterizing the two embedding matrices $\mathbf{X}_1$ and $\mathbf{X}_2$. The intuition here is that two embedding spaces with similar singular values at the same index will be more isomorphic and therefore easier to align into a shared space, and enable more effective cross-lingual transfer.

In summary, this section has presented methods that estimate the degree of isomorphism between any given pair of embedding spaces, which may differ in their language, training corpus, embedding induction algorithm or in other factors. While the focus of our empirical analysis (§4, §5) is cross-language learning and transfer, we note that the scope of our methods may be wider, and that they have not been developed only with cross-lingual learning in mind.

3 Related Work and Baselines

We now provide an overview of prior research that focused on two relevant themes: **1)** measuring approximate isomorphism between two embedding spaces, and **2)** more generally, quantifying the (dis)similarity between languages, going beyond isomorphism measures. The discussed approaches will also be used as the main baselines later in §5.

Measuring Approximate Isomorphism. We focus on two standard isomorphism measures from prior work which are most similar to our work, and use them as our main baselines. The first measure, termed **Isospectrality (IS)** (Søgaard et al., 2018), is based on spectral analysis as well, but of the Laplacian eigenvalues of the nearest neighborhood graphs that originate from the initial embedding spaces $\mathbf{X}_1$ and $\mathbf{X}_2$ (for further technical details see Appendix A). Søgaard et al. (2018) argue that these eigenvalues are compact representations of the graph Laplacian, and that their comparison reveals the degree of (approximate) isomorphism. Although similar in spirit to our approach, constructing nearest neighborhood graphs (and then analyzing their eigenvalues) removes useful information on the interaction between all vectors from the initial space, which our spectral method retains.

The second measure is the **Gromov-Hausdorff distance (GH)** introduced by Patra et al. (2019). It measures the maximum distance of a set of points to the nearest point in another set, or in other words the worst case distance between two metric spaces $\mathcal{X}$ and $\mathcal{Y}$ (for further technical details see again Appendix A). Patra et al. (2019) propose this distance to test how well two language embedding spaces can be aligned under an isometric transformation.

While both IS and GH were reported to have strong correlations with BLI performance in prior work, they have not been evaluated in large-scale experiments before. In fact, the correlations were computed on a very small number of language pairs (IS: 8 pairs, GH: 10 pairs). Further, both measures do not scale well computationally. Therefore, for computational tractability, the scores are computed only on the sub-matrices spanning the sub-spaces of the most frequent subsets from the full embedding spaces (IS: 10k words, GH: 5k words). In this work, we provide full-fledged empirical analyses of the two measures on a much larger number of pairs from diverse languages, and compare them against the spectral-based measures introduced in §2. The fact that the proposed spectral-based meth-

---

[2] Constraining factors are usually handled by taking the minimum (or maximum) values; however, this approach would impede the validity of our correlation analysis (see later §4) as it would artificially decrease the variance in only one variable (the language with the lowest measure will be systematically chosen). We refer the reader to Appendix C for an analysis.

ods are grounded in linear algebra theory (cf. §2.1) also arguably provides a more intuitive understanding of their theoretical underpinning than what is currently offered in the relevant prior work.

Measuring Language Similarity. At the same time, distances between language pairs can also be captured through (dis)similarities in their *discrete* linguistic properties, such as overlap in syntactic features, or proximity along the phylogenetic language tree. The properties are typically handcrafted, and are extracted from available typological databases such as the World Atlas of Languages (WALS) (Dryer and Haspelmath, 2013) or URIEL (Littell et al., 2017), among others (O'Horan et al., 2016; Ponti et al., 2019). Such distances were found useful in guiding and informing cross-lingual transfer tasks (Cotterell and Heigold, 2017; Agić, 2017; Lin et al., 2019; Ponti et al., 2019).

In particular, we compare against three precomputed measures of language distance based on the URIEL typological database (Littell et al., 2017). **Phylogenetic distance (PHY)** is derived from the hypothesized phylogenetic tree of language descent. **Typological distance (TYP)** is computed based on the overlap in syntactic features of languages from the WALS database (Dryer and Haspelmath, 2013). **Geographic distance (GEO)** is obtained from the locations where languages are spoken; see the work of Littell et al. (2017) for more details.

We use these isomorphism measures and linguistic measures as language distance measures. We simply compute language distance between two languages L_1 and L_2 as $LDist(L_1, L_2) = D(\mathbf{X}_1, \mathbf{X}_2)$, where $D = \{$SVG, COND-HM, ECOND-HM, GH, IS, PHY, TYP, GEO$\}$. Later in §5 we show that "proxy" language distances originating from the proposed spectral-based isomorphism measures (see §2.2) correlate better with cross-lingual transfer scores across several tasks, than these language distances which are based on discrete linguistic properties. We verify that implicit knowledge coded in continuous embedding spaces and linguistic knowledge explicitly coded in external databases often complement each other.

4 Experimental Setup

The conducted empirical analyses can be divided into two major parts. First, we run large-scale BLI analyses across several hundred language pairs from dozens of languages, comparing the correlation of spectral-based isomorphism measures (§2.2) and all baselines (§3) with performance of a wide spectrum of state-of-the-art BLI methods. Second, we run further correlation analyses with performances in cross-lingual downstream tasks: dependency parsing, POS tagging, and MT. We first provide the details of the experiments that are shared between the two parts, and then provide further specifics of each experimental part.

Monolingual Word Embeddings. For all isomorphism measures (SVG, COND-HM, ECOND-HM, GH and IS) and languages in our analyses we use publicly available 300-dim monolingual fastText word embeddings pretrained on Wikipedia with exactly the same default settings (see Bojanowski et al. (2017)), length-normalized and trimmed to the 200k most frequent words.[3]

Isomorphism Measures: Technical Details. For our spectral-based measures, we compute a full SVD decomposition (i.e., no dimensionality reduction) of the embedding space. We compute SVG scores for BLI based on the first 40 singular values, which we empirically found to produce slightly better results;[4] for the other tasks we use all singular values. For IS and GH, we replicate the experimental setup from prior work: we compute the IS score over the top 10k most frequent words in each monolingual space, while the GH score is computed over the top 5k words from each monolingual space.[5]

4.1 Bilingual Lexicon Induction

We conduct correlation analyses of the results from previous studies that report BLI scores for a large number of language pairs. On top of that, we complement the existing results from previous research with new results obtained with state-of-the-art BLI methods, applied to additional language pairs.

BLI Setups and Scores. Vulić et al. (2019) ran BLI experiments on 210 language pairs, spanning 15 diverse languages. Their training and test dictionaries (5k and 2k translation pairs) are derived from **PanLex** (Baldwin et al., 2010; Kamholz et al., 2014). We complement the original 210 pairs with additional 210 language pairs of 15 closely related (European) languages using dictionaries extracted from PanLex following the procedure of Vulić et al. (2019). With the additional language set, the aim is

---

[3] fasttext.cc/docs/en/pretrained-vectors.html

[4] The average gains were around 10%; we note that running SVG with the full set of singular values also outperforms the baseline measures.

[5] `github.com/joelmoniz/BLISS`

to probe if isomorphism measures can also capture more subtle and smaller language differences.[6]

We also analyze the BLI results of 108 language pairs from **MUSE** (Conneau et al., 2018). This dataset systematically covers English, with 88 translation pairs that involve English as either the source or target language. Finally, we analyze the available BLI results of Glavaš et al. (2019) (referred to as **GTrans**) that are based on dictionaries obtained from Google Translate and include 28 language pairs spanning 8 different languages. For the full list of language pairs involved in previous BLI studies, we refer the reader to prior work (Conneau et al., 2018; Glavaš et al., 2019; Vulić et al., 2019).

BLI Methods in Comparison. The scores in each BLI setup were computed by several state-of-the-art BLI methods based on cross-lingual word embeddings, briefly described here. **1)** SUP is the standard supervised method (Artetxe et al., 2016; Smith et al., 2017) that learns a mapping between two embedding spaces based on a training dictionary by solving the orthogonal Procrustes problem (Schönemann, 1966). **2)** SUP+ is another standard supervised method that additionally applies a variety of pre-processing and post-processing steps (e.g., whitening, dewhitening, symmetric reweighting) before and after learning the mapping matrix, see (Artetxe et al., 2018). **3)** UNSUP is a fully unsupervised method based on the "similarity of monolingual similarities" heuristic to extract the seed dictionary from monolingual data. It then uses an iterative self-learning procedure to improve on the initial noisy dictionary (Artetxe et al., 2018). For more technical details on the fully unsupervised model, we refer the reader to prior work (Ruder et al., 2019a; Vulić et al., 2019).[7]

In sum, our analyses are conducted in three BLI setups (PanLex, MUSE, GTrans) and examine three types of state-of-the-art mapping-based methods, both supervised and unsupervised (SUP, SUP+, UNSUP). Altogether, these span 556 language pairs, and cover both related and distant languages.[8] Following prior work (Glavaš et al., 2019), our BLI evaluation measure is Mean Reciprocal Rank (MRR). We note that identical findings emerge from running the correlation analyses based on Precision@1 scores in lieu of MRR.

4.2 Downstream Tasks

Following the large-scale nature of our BLI analyses, we run similar correlation analyses on several downstream tasks that comprise a large number of (both similar and distant) language pairs.[9] We rely on results from a recent study of Lin et al. (2019) that focused on cross-lingual transfer performance in MT, dependency parsing, and POS tagging.[10]

Machine Translation. Lin et al. (2019) report BLEU scores when translating 54 source L_1 languages into English as the target language. We report correlations between the different language distance measures and these 54 BLEU scores.

Dependency Parsing. We base our analysis on the cross-lingual zero-shot parser transfer results of Lin et al. (2019): The standard biaffine dependency parser (Dozat and Manning, 2017; Dozat et al., 2017) is trained on the training portions of Universal Dependencies (UD) treebanks from 31 languages (Nivre et al., 2018), and is then used to parse the test treebank of each language, now used as the target language. We report correlations between the language distance measures and the Labeled Attachment Scores (LAS) for all combinations of 31 languages, resulting in 930 pairs.

POS Tagging. We use POS tagging accuracy scores reported by Lin et al. (2019). These scores span 26 low-resource target languages and 60 source languages which measure the utility of each source language to each of the 26 target languages in POS tagging. We use a sample of 840 language pairs for the correlation analysis, as 16 low-resource target languages and 49 source languages have readily available pretrained fastText vectors.

---

[6] The initial set of Vulić et al. (2019) comprises Bulgarian, Catalan, Esperanto, Estonian, Basque, Finnish, Hebrew, Hungarian, Indonesian, Georgian, Korean, Lithuanian, Norwegian, Thai, Turkish. The additional 210 language pairs are only composed of Germanic, Romance and Slavic languages. For a full list of the languages see Table 4 in the appendix.

[7] The SUP+ and UNSUP methods are based on the VecMap framework (`github.com/artetxem/vecmap`) which showed very competitive and robust BLI performance across a wide range of language pairs in recent comparative analyses (Glavaš et al., 2019; Vulić et al., 2019; Doval et al., 2019).

[8] We report all results for each BLI method, dictionary and language pairs in the supplementary material (and also here `https://tinyurl.com/skn5cf7`). We also report scores with another method, RCSLS (Joulin et al., 2018), benchmarked in the GTrans BLI setup (see Table 1).

[9] For the full list of languages that were analyzed throughout all our experiments see Table 4 in the appendix.

[10] For full details regarding the models used to compute the scores for each downstream task, we refer the interested reader to the work of Lin et al. (2019) and the accompanying repository: `https://github.com/neulab/langrank`. We note that scores for each language pair in each task have been produced with the same task architectures.

4.3 Correlation Analyses and Statistical Tests

All scores from isomorphism measures and BLI scores were log-transformed[11] prior to any correlation computation. We report Pearson's correlation coefficients in all tasks. This allows us to investigate which of the different individual measures is most important to predict task performance.

Regression Analyses. The individual (i.e., single-variable) analyses are not sufficient to account for the complex interdependencies between the distance measures themselves, and how they interact with task performance when combined. Therefore, we also use standard linear stepwise regression model (Hocking, 1976; Draper and Smith, 1998):

$$\mathbf{Y} = \beta_0 + \beta_1 x_1 + \ldots + \beta_n x_n + \epsilon. \qquad (7)$$

Here, task performance $\mathbf{Y}$ is predicted using a set of regressors, $x_1, \ldots, x_n$ (i.e., SVG, COND-HM, ECOND-HM, GH, IS, PHY, TYP, GEO), that are added to the model incrementally only if their marginal addition to predicting $\mathbf{Y}$ is statistically significant ($p < .01$). This method is useful for finding variables (i.e., in our case distance measures) with *maximal* and *unique* contribution to the explanation of $\mathbf{Y}$, when the variables themselves are strongly cross-correlated, as in our case.

This model is able to: (a) discern which variables overlap in their information; (b) detect variables that complement each other; and (c) evaluate their joint contribution in predicting task performance. We compute the regression model's score for all statistically significant variables, and report its square-root, $\hat{r}$.

Importantly, $\hat{r}$ is *not* a one-number description of a language, but rather an illustrative quantification of the joint contribution of several *different* distance measures to the explanation of $\mathbf{Y}$. Its goal is to investigate potential gains achieved through the combination of several distance measures, as opposed to using a single-best measure. The distance measures that are found statistically significant in the regression analyses are marked by superscripts over $\hat{r}$ (see later in Tables 1 and 2).

5 Analyses and Results

The results are summarized in Tables 1 and 2. The first main finding is that our proposed spectral-based isomorphism measures are strongly correlated with performance across all tasks and settings.[12] In fact, they show the strongest individual correlations with task performance among all isomorphism measures and linguistic distances alike. The only exception is the MT task, where our measures fall short of TYP (see Table 2), although we mark that they still hold a strong advantage over the baseline GH and IS isomorphism measures that do not seem to capture any useful language similarity properties needed for the MT task.

ECOND-HM systematically outperforms COND-HM on 2 of 3 BLI datasets and 2 of 3 downstream tasks, validating our assumption that discarding the smallest singular values reduces noise. Additionally, SVG shows greater stability across tasks and datasets than ECOND-HM. A general finding across all tasks is that our spectral measures are the most robust isomorphism measures: they substantially outperform the widely used baselines GH and IS.

As stepwise regression discerns between overlapping and complementing variables (see §4.3), another finding indicates that our spectral measures are complemented by linguistically driven language distances. Indeed, their combination achieves very high correlation scores. The results demonstrate this across all tasks and settings (see bottom rows of the tables). For instance, when combining spectral measures with the linguistic distances, the regression model reaches outstanding correlation scores up to $r = .91$ on PanLex BLI (Table 1); with 420 language pairs, PanLex is the most comprehensive BLI dataset in our study. In addition, GH and IS are not chosen as significant regressors in the stepwise regression model, which indicates that they capture less information than our spectral methods.[13] Overall, the regression results support the notion that conceptually different distances (i.e., isomorphism-based versus measures based on linguistic properties) capture different properties of similarities between languages, which has a synergistic effect when they are combined.

Concerning individual tasks, we note that our spectral-based measures outperform the baselines

---

[11] This is an order-preserving transformation which is often used when the data distribution is skewed (as was the case with our BLI and isomorphism scores).

[12] The negative correlations between SVG and ECOND-HM scores and task performance have a clean interpretation: they are distance/dissimilarity measures, so high scores of those measures indicate less similar languages.

[13] This does not imply GH or IS do not capture information that is complementary to discrete linguistic information, only that the implicit knowledge captured by GH or IS cannot match that of our spectral-based methods, and their combination with linguistic distances obtained from external knowledge sources.

regardless of the underlying BLI method. Further, SVG is the most informative distance measure in parsing experiments, and all linguistic distances fall behind isomorphism measures. Combining linguistic distances with SVG increases the already high correlation from 0.79 to 0.87 (Table 2, second column). For the POS tagging task, SVG and GH are on par, and the combination with IS and TYP increase their correlation from 0.52 to 0.59 (Table 2, third column). This is the only analysis where baseline methods are found significant.

Additional results and analyses are provided in Appendix B. They further demonstrate that our measures also indicate transfer quality of different target languages for a given source language, and transfer quality of source languages for a given target language, for the tasks discussed in this paper.

6 Further Discussion and Conclusion

This work introduces two spectral-based measures, SVG and ECOND-HM, that excel in predicting performance on a variety of cross-lingual tasks. Both measures leverage information from singular values in different ways: ECOND-HM uses the ratio between two singular values, and is grounded in linear algebra and numerical analysis (Blum, 2014; Roy and Vetterli, 2007), while SVG directly utilizes the full range of singular values. We suspect that the use of the full range of singular values is what makes SVG more robust across different tasks and datasets, compared to ECOND-HM that shows greater variance, as observed in our results above.

While the spectral methods are computed solely on word vectors from Wikipedia, the results in the downstream tasks are computed with different sets of embeddings (e.g., multilingual embeddings for dependency parsing), or the embeddings are learnt during training (for POS tagging and MT). We believe that this discrepancy does not constitute a shortcoming of our analyses, but rather the opposite: spectral-based methods maintain their high correlations in the downstream tasks as well, and this supports the notion that these measures might indeed capture deeper linguistic information than mere similarities between embedding spaces.

Our use of effective rank in improving the condition number (via effective condition number) is also inspired by recent work that aimed to automatically detect true dimensionality of embedding spaces. However, previous work has taken an empirical approach by simply tuning embedding dimensionality to evaluation tasks at hand (Wang, 2019; Raunak et al., 2019; Carrington et al., 2019). Our intention, on the other hand, is to extract the true embedding dimensionality directly from the embedding space. Another recent study (Yin and Shen, 2018) employed perturbation analysis to study the robustness of embedding spaces to noise in monolingual settings, and established that it is also related to effective dimensionality of the embedding space. All these inspired us to replace the standard matrix rank with effective rank when computing the condition number, and to introduce the statistic of effective condition number in §2.1.

Our study is also the first to compare language distance measures that are based on discrete linguistic information (Littell et al., 2017) with measures of isomorphism (i.e., our spectral-based measures, IS, GH), which can also be used as proxy language distance measures. Our findings, suggesting that it is possible to effectively combine these two types of language distance measures, call for further research that will advance our understanding of: 1) what knowledge is captured in monolingual and cross-lingual embedding spaces (Gerz et al., 2018; Pires et al., 2019; Artetxe et al., 2020); 2) how that knowledge complements or overlaps with linguistic knowledge compiled into lexical-semantic and typological databases (Dryer and Haspelmath, 2013; Wichmann et al., 2018; Ponti et al., 2019); and 3) how to use the combined knowledge for more effective transfer in cross-lingual NLP applications (Ponti et al., 2018; Eisenschlos et al., 2019).

The differences in embedding spaces of different languages do not only depend on linguistic properties of the languages in consideration, but also on other factors such as the chosen training algorithm, underlying training domain, or training data size and quality (Søgaard et al., 2018; Arora et al., 2019; Vulić et al., 2020). In future research we also plan an in-depth study of these factors and their relation to our spectral analysis.

We believe that the main insights from this study will inform and guide different cross-lingual transfer learning methods and scenarios in future work. These might range from choosing source languages for transfer in low-data regimes, over monolingual word vector induction guided by the spectral statistics, even to more effective hyperparameter search.

A IS and GH

Isospectrality (IS) After length-normalizing the vectors, Søgaard et al. (2018) compute the nearest neighbor graphs using a subset of the top N most frequent words in each space, and then calculate the Laplacian matrices LP_1 and LP_2 of each graph. For LP_1, the smallest k_1 is then sought such that the sum of its k_1 largest eigenvalues $\sum_{i=1}^{k_1} \lambda_{1i}$ is at least 90% of the sum of all its eigenvalues. The same procedure is used to find k_2. They then define $k = \min(k_1, k_2)$. The final IS measure Δ is then the sum of the squared differences of the k largest Laplacian eigenvalues: $\Delta = \sum_{i=1}^{k}(\lambda_{1i} - \lambda_{2i})^2$. The lower Δ, the *more* similar are the graphs and, consequently, the more isomorphic are the two embedding spaces.

Gromov-Hausdorff Distance (GH) It measures the worst case distance between two metric spaces $\mathcal{X}$ and $\mathcal{Y}$ with a distance function m as:

$$\mathcal{H}(\mathcal{X}, \mathcal{Y}) = \max\{\sup_{x \in \mathcal{X}} \inf_{y \in \mathcal{Y}} m(x, y), \sup_{y \in \mathcal{Y}} \inf_{x \in \mathcal{X}} m(x, y)\} \tag{8}$$

It computes the distance between the nearest neighbors that are farthest apart. The Gromov-Hausdorff distance then minimizes this distance over all isometric transforms $\mathcal{X}$ and $\mathcal{Y}$:

$$\mathcal{GH}(\mathcal{X}, \mathcal{Y}) = \inf_{f,g} \mathcal{H}(f(\mathcal{X}), g(\mathcal{Y})) \tag{9}$$

Computing $\mathcal{GH}$ directly is computationally intractable in practice, but it can be tractably approximated by computing the Bottleneck distance between the metric spaces (Chazal et al., 2009).

B Source and Target Selection Analysis

In addition to the correlation analyses in the main text that aggregate all language pairs, some tasks and datasets also support analyses where one language is fixed as a target language (i.e., *source-language selection analysis*), or as a source language (i.e., *target-language selection analysis*). Such analyses could inform us on how to choose the right transfer language. That is, given a target language one would like to transfer to, which is the best source language to transfer from, and vice versa. These analyses are conducted for the following tasks with sufficient language pairs: BLI with PanLex, parsing, and POS tagging.

For these analyses we report average correlation: across target languages in the source-language selection analysis, or across the source languages in the target-language selection analysis. We provide the percentage of times each compared measure scored the highest for a particular task and setting.

Stepwise regression analysis is not suitable for the selection analysis due to the limited number of language pairs in each language selection setup (e.g., PanLex offers 14 language pairs for each source- or target- language selection analysis). These conditions impede the statistical significance power of the tests which stepwise regression requires. We therefore opt for a standard multiple linear regression model instead; the regressors include the isomorphism measure with the highest individual correlation combined with the linguistic measures. Similarly to the stepwise analysis, we report the unified correlation coefficient, $\hat{r}$.

We observe that the same findings reported for the aggregated correlation analyses (Tables 1 and 2 in the main text) also hold for the language selection analyses (Table 3 below). This indicates that our spectral measures have an applicative value as they can facilitate better cross-language transfer.

We also observe interesting patterns in the selection analyses for the POS tagging task in Table 3: While the results in the target-language selection analysis largely follow the main-text results, the same does not hold for source-language selection (Table 3, POS Target and Source columns). We speculate that this is in fact an artefact of the experimental design of Lin et al. (2019). Their set of target languages deliberately comprises only truly low-resource languages, and such languages are expected to have lower-quality embedding spaces. Transferring to such languages is bound to fail with most source languages regardless of the actual source-target language similarity. The difficulty of this setting is reflected in the actual scores: average accuracy scores for the best source-target combination is 0.55 in the source-language selection analysis, and 0.92 for target-language selection.

C Single and Combined Analysis

We show (Figure 1) a single experimental condition (SUP method in the PanLex BLI dataset, leftmost column in Table 1 in the main text) to illustrate the data distribution and the correlation for spectral-based measures (e.g., ECOND-HM), and their improvement once this measure is combined with linguistic measures through regression analysis.

Bridging Linguistic Typology and Multilingual Machine Translation with Multi-View Language Representations

Arturo Oncevay **Barry Haddow** **Alexandra Birch**
School of Informatics, University of Edinburgh, Scotland
{a.oncevay,a.birch}@ed.ac.uk,bhaddow@inf.ed.ac.uk

Abstract

Sparse language vectors from linguistic typology databases and learned embeddings from tasks like multilingual machine translation have been investigated in isolation, without analysing how they could benefit from each other's language characterisation. We propose to fuse both views using singular vector canonical correlation analysis and study what kind of information is induced from each source. By inferring typological features and language phylogenies, we observe that our representations embed typology and strengthen correlations with language relationships. We then take advantage of our multi-view language vector space for multilingual machine translation, where we achieve competitive overall translation accuracy in tasks that require information about language similarities, such as language clustering and ranking candidates for multilingual transfer. With our method, which is also released as a tool, we can easily project and assess new languages without expensive retraining of massive multilingual or ranking models, which are major disadvantages of related approaches.

1 Introduction

Recent surveys consider linguistic typology as a potential source of knowledge to support multilingual natural language processing (NLP) tasks (O'Horan et al., 2016; Ponti et al., 2019). Linguistic typology studies language variation in terms of their functional processes (Comrie, 1989). Several typological knowledge bases (KB) have been crafted, from where we can extract categorical language features (Littell et al., 2017). Nevertheless, their sparsity and reduced coverage present a challenge for an end-to-end integration into NLP algorithms. For example, the World Atlas of Language Structure (WALS; Dryer and Haspelmath, 2013) encodes 143 features for 2,679 languages, but their mean coverage per language is barely around 14%.

Dense and data-driven language representations have emerged in response. They are computed from multilingual settings of language modelling (Östling and Tiedemann, 2017) and neural machine translation (NMT) (Malaviya et al., 2017). However, the language diversity in the corpus-based representations is limited. The language coverage could be broadened with other knowledge, such as that encoded in WALS, to distinguish even more language properties. Therefore, to obtain the best of both views (KB and task-learned) with minimal information loss, we project a shared space of discrete and continuous features using a variant of canonical correlation analysis (Raghu et al., 2017).

For our study, we fuse language-level embeddings from multilingual machine translation with syntactic features of WALS. We inspect how much typological knowledge is present by predicting features for new languages. Then, we infer language phylogenies and inspect whether specific relationships are induced from the task-learned vectors.

Furthermore, to demonstrate that our approach has practical benefits in NLP, we apply our language vectors in multilingual NMT with language clustering (Tan et al., 2019) and adapt the ranking of related languages for multilingual transfer (Lin et al., 2019). As a side outcome, we identify that there is an ideal setting to encode language relationships in language embeddings from NMT. Finally, we are releasing a simple tool to allow everyone to fuse their own representations for clustering, ranking and more.

2 Multi-view language representations

Our primary goal is to fuse parallel representations of the same language in one shared space, and **canonical correlation analysis** (CCA) allows us to find a projection of two views for a given set of

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2391–2406,
November 16–20, 2020.

data. With CCA, we look for linear combinations that maximise the correlation of the two sources in each coordinate iteratively (Hardoon et al., 2004). After training, we can apply the transformation learned on a new sample from any view to obtain a CCA-based language representation.[1]

CCA considers all dimensions of the two views as equally important. However, our sources are potentially redundant: KB features are mostly one-hot-encoded, whereas task-learned ones inherit the high dimensionality of the embedding layer. Moreover, few samples and sparsity could make the convergence harder. For the redundancy issue, **singular value decomposition** (SVD) is an appealing alternative. With SVD, we factorise the source data matrix to compute the principal components and singular values. Furthermore, to deal with sparsity, we adopt a truncated SVD approximation, which is also known as latent semantic analysis in the context of linear dimensionality reduction for term-count matrices (Dumais, 2004).

The two-step transformation of SVD followed by CCA is called **singular vector canonical correlation analysis** (SVCCA; Raghu et al., 2017) in the context of understanding the representation learning throughout neural network layers. That being said, we use SVCCA to get language representations and not to inspect a neural architecture.[2]

3 Methodology and research questions

To embed linguistic typology knowledge in dense representations for a broad set of languages, we employ SVCCA (§2) with the following sources:

KB view. We employ the language vectors from the URIEL and lang2vec database (Littell et al., 2017). Precisely, we work with the k-NN vectors of the Syntax feature class (U_S; 103 feats.), that are composed of binary features encoded from WALS (Dryer and Haspelmath, 2013).

(NMT) Learned view. Firstly, we exploit the NMT-learned embeddings from the Bible (L_B; 512 dim.) (Malaviya et al., 2017). Up to 731 entries are available in lang2vec that intersects with U_S. They were trained in a many-to-English NMT model with a pseudo-token identifying the source language at the beginning of every input sentence.

Secondly, we take the many-to-English language embeddings learned for the language clustering task on multilingual NMT (L_W; 256 dim.) (Tan et al., 2019), where they use 23 languages of the WIT^3 corpus (Cettolo et al., 2012).

One main difference for the latter is the use of factors in the architecture, meaning that the embedding of every input token was concatenated with the embedded pseudo-token that identifies the source language. The second difference is the neural architecture used to extract the embeddings: the former use a recurrent neural network, whereas the latter a small transformer model (Vaswani et al., 2017).

Finally, we train a new set of embeddings (L_T) that we extracted from the 53 languages of the TED corpus (many-to-English) processed by Qi et al. (2018), using the approach of Tan et al. (2019).[3]

What knowledge do we represent? Each source embeds specialised knowledge to assess language relatedness. The KB vectors can measure typological similarity, whereas task-learned embeddings correlates with other kinds of language relationships (e.g. genetic) (Bjerva et al., 2019b). To analyse whether each kind of knowledge is induced with SVCCA, we assess the tasks of typological feature prediction (§4) and reconstruction of a language phylogeny (§5).

What is the benefit for multilingual NMT (and NLP)? Language-level representations can evaluate the distance between languages in a vector space. We then can assess their applicability on multilingual NMT tasks that require guidance from language relationships. Therefore, language clustering and ranking related partner languages for (multilingual) transfer are our study cases (§6).

4 Prediction of typological features

An example of a typological feature is a word order specification, like whether the adjective is predominately placed before or after the noun (features #24 and #25 of U_S). Our task consists in predicting syntactic features (U_S) leaving one-language and

---

[1] With language representations, we refer to an annotated or unsupervised characterisation of a language itself (e.g. Spanish or English), and not to word or sentence-level representations, as it is used in the recent NLP literature.

[2] As the SVD step performs a dimensionality reduction while preserving the most explained variance as possible, we can consider two additional parameters: a threshold value in the [0.5,1.0] range with 0.05 incremental steps, for the explained variance ratio of each view. With a value equal to 1, we bypass SVD and compute CCA only. We then tuned all our following experiments (see Appendix C for details).

[3] We prefer to use factored embeddings over initial pseudo-tokens as we identified that there is a difference for encoding information about language similarity (see §7).

Table 1: Avg. accuracy (↑) of typological feature prediction per NMT-learned and SVCCA(U_S,L_*) setting.

one-language-family out to control phylogenetic relationships (Bjerva et al., 2019a). Previous work has shown that task-learned embeddings are potential candidates to predict features of a linguistic typology KB (Malaviya et al., 2017), and our goal is to evaluate whether SVCCA can enhance the NMT-learned language embeddings with typological knowledge from their KB parallel view.

Experimental setup. We use a Logistic Regression classifier per U_S feature, which is trained with the NMT-learned or SVCCA representations in both one-language-out and one-language-family-out settings. For prediction, we use the original embedding or its SVCCA projection as inputs.

Results. In Table 1, we observe that SVCCA outperformed their NMT-learned counterparts for L_W and L_T, where the performance is significantly better for the one-language-out setting. In the case of L_B (with 731 entries), we notice that the overall performance drops, and the SVCCA transformation cannot improve it. We argue that a potential reason for the accuracy dropping is the method used to extract the NMT-learned embeddings (initial pseudo-token instead of factors: §7), which could diminishes the information embedded about each language, and consequently, impacts the SVCCA projection.[4] In conclusion, we notice that specific typological knowledge is usually hard to learn in an unsupervised way, and fusing them with KB vectors using SVCCA is feasible for inducing information of linguistics typology in some scenarios.

5 Language phylogeny analysis

According to Bjerva et al. (2019b), there is a positive correlation between the language distances in a phylogenetic tree and a pairwise distance-matrix of task-learned representations. Our goal therefore is to investigate whether fusing linguistic typology with SVCCA can preserve or enhance the embedded relationship information. For that reason, we examine how well a language phylogeny can be reconstructed from language representations (§5.1), and also study the correlation (Appendix B).

5.1 Inference of a phylogenetic tree

Experimental design. Based on previous work (Rabinovich et al., 2017), we take a tree of 17 Indo-European languages (Serva and Petroni, 2008) as a Gold Standard (GS), which is shown in Figure 1a.[5] We also use agglomerative clustering with variance minimisation (Ward Jr, 1963) as linkage, but we employ cosine similarity as Bjerva et al. (2019b).

We also consider a concatenation (⊕) of the KB and NMT-learned views as a baseline.

It is essential to highlight that none of the NMT-learned and ⊕ vectors have all the 17 language entries of the GS. Therefore, we can already see one of the significant advantages of the SVCCA vectors, as we are able to represent "unknown" languages using one of the views. The NMT-learned views lack English, since they were extracted from the source side of a many-to-English system, but we were able to project the KB English vectors into the shared space.[6] In addition, we project other four languages (Swedish, Danish, Latvian, Lithuanian) to complete the L_W embeddings of Tan et al. (2019) and Latvian to complete our own L_T set.

Evaluation metric. We differ from previous studies and use a tree edit distance metric, which is defined as the minimum cost of transforming one tree into another by inserting, deleting or modifying (the label of) a node. Specifically, we used the All Path Tree Edit Distance algorithm (APTED; Pawlik and Augsten, 2015, 2016), a novel one for the task. We chose an edit-distance method as it is more transparent for assessing what is the degree of impact for a single change of linkage in the GS.

As we need to compare inferred pruned trees with different number of nodes, we propose a normalised version given by: $\mathrm{nAPTED} = \mathrm{APTED}/(|\mathrm{GS}| + |\tau|)$, where τ is the inferred

---

[4] In other words, for SVCCA, it is difficult to deal with the noise provided in the learned embeddings. In Figures 6a and 6b of the Appendix, we observe noisy agglomerations in the dendrograms (obtained by clustering different language representations), which is preserved after the fusing with the KB vectors through SVCCA as we can see in Fig. 6c)

[5] We do not generalise the analysis for more languages, as the inferred tree of Serva and Petroni (2008) is only an approximation by lexicostatistic methods (see Appendix B).

[6] This is illustrative only, as we could obtain an English vector from many-to-many multilingual NMT models or language models. However, the artificial case generalises as a benefit for projecting new languages with SVCCA. For instance, lang2vec contains 2,989 and 287 unique entries in the KB and NMT-learned views, respectively.

	KB-view		
U_S (Syntax)	30 – 0.45		
	NMT-learned	$U_S \oplus L_*$	SVCCA(U_S,L_*)
L_B (Bible)	35 – 0.54	27 – 0.42	23 – 0.34
L_W (WIT-23)	35 – 0.62	23 – 0.41	27 – 0.48
L_T (TED-53)	15 – 0.26	18 – 0.29	**10 – 0.15**

Table 2: APTED and nAPTED scores (↓) between the GS and inferred trees from all scenarios. APTED ranges from 0 (no difference) and the size of the tree at most. NMT-learned and concatenation (⊕) can only reconstruct pruned trees of 16 (L_B), 12 (L_W) and 15 (L_T) languages.

tree, and $|.|$ indicates the number of nodes. The denominator then is the maximum cost possible of deleting all nodes of τ and inserting each GS node.

Results. Table 2 shows the results for all settings, where the single-view scores are meagre in most of the cases. For instance, the U_S inferred tree (Fig.1c) requires 30 edits to match the GS. The exception is L_T (Fig.1d), which requires half the edits, although it is incomplete.

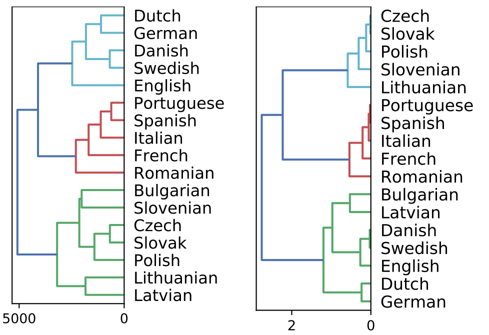
We observe that the best absolute and normalised scores are obtained by fusing U_S and L_T with SVCCA (Fig.1b). English is projected in the Germanic branch, although Latvian is separated from the Balto-Slavic group. The latter case is similar for Bulgarian, which is misplaced in the original L_T tree as well. Nevertheless, we only require ten editions to equate the GS (where 66 is the maximum cost possible), confirming that our approach is a robust alternative for completing language entries and inferring a language phylogeny.[7]

In conclusion, we observe that using typological knowledge with SVCCA enhances the language relationship encoded in the NMT-learned embeddings. In Appendix B, we further discuss what kind of relationship we are representing in the NMT-learned embeddings and SVCCA, and study their correlation.

6 Application in multilingual NMT

With multilingual NMT, we can translate several language-pairs using a single model. Low-resource languages usually benefit through multilingual transfer, which resembles a simultaneous training of the parent(s) and child models. Therefore, we want to take advantage of a language-level vector space for relating similar languages and enhancing multilingual transfer within multilingual NMT. For that reason, we first address the language clustering task proposed by Tan et al. (2019), and afterwards, the language ranking model of Lin et al. (2019).

(a) Gold Standard (b) SVCCA(U_S,L_T)



(c) U_S: Syntax (d) L_T: TED-53

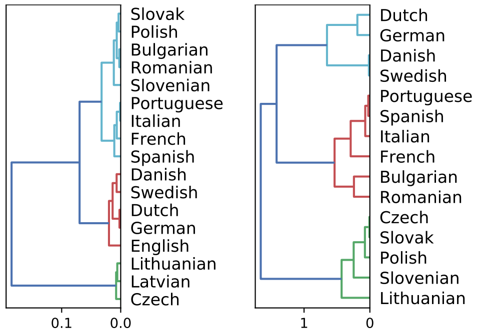


Figure 1: Gold Standard phylogeny (a) and reconstructed trees (b-d). L_T is smaller.

Language clustering. The main idea is to obtain smaller multilingual NMT models as an intermediate point between maintaining many pairwise systems and a single massive multilingual model. With limited resources, it is challenging to support the first scenario, whereas the advantages for the massive setting are also very appealing (e.g. simplified training process, translation improvement for low-resource languages or zero-shot translation (Johnson et al., 2017)). Therefore, to address the task, Tan et al. (2019) trained a factored multilingual NMT model of 23 languages from Cettolo et al. (2012), where the language embedding is concatenated in every input token. Then, they performed hierarchical clustering with the representations, and selected a number of clusters guided by the Elbow method. Finally, they compared the systems against individual, massive and language family-based cluster models.

In a practical multilingual NMT system, it is not only necessary to choose the right clustering, the

---

[7] In further analysis, we confirmed that the inferred tree with only 12 languages of SVCCA (without projection of extra entries) is comparable or better against the rest of the baselines.

ability to easily add new languages is also important. With this in mind, we apply our multi-view representations to compute a set of clusters, and we also address the question: do we need to train the massive model again if we want to add one or more new languages to our setting?

Language ranking. The original goal of LANGRANK is to choose a parent language to perform transfer learning in different tasks, NMT included. To achieve this, Lin et al. (2019) trained a model based on the performance of several hundred pairwise MT systems using the dataset of Qi et al. (2018). For the input features, they considered linguistically-informed vectors from lang2vec (Littell et al., 2017) and corpus-based statistics, such as word/sub-word overlapping and the ratio of the token-types or the data size between the target child and potential candidates, where the latter features were some of the most relevant.

Considering the transfer capabilities within multilingual NMT and the possibility to obtain a ranked list of candidates from LANGRANK, we propose an adapted task of choosing k-related languages for multilingual transfer. We then use our multi-view representations to rank related languages from the vector space, as they embed information about typological and lexical relationships. This is similar to the features that Lin et al. (2019) consider, but without training a ranking model fed with scores from pairwise MT systems.

6.1 Experimental setup

We focus on the many-to-one (English) multilingual NMT setting to simplify the evaluation in both tasks. However, similar experiments could be performed in a one-to-many direction.

Dataset. We use the dataset processed and tokenised by Qi et al. (2018) of 53 languages (TED-53), from where we learned our L_T embeddings. We opted for TED-53 to better evaluate the extensibility of clusters and because it is also used to train the LANGRANK model. The list of languages, set sizes and other details are included in Appendix A. Before preprocessing the text, we drop any sentences from the training sets which overlap with any of the test sets. Since we are building many-to-English multilingual systems, this is important, as any such overlap will bias the results.

Model and training. Similar to Tan et al. (2019), we train small transformer models (Vaswani et al., 2017). We jointly learn 90k shared sub-words with the byte pair encoding (Sennrich et al., 2016) algorithm built in SentencePiece (Kudo and Richardson, 2018). We also oversample all the training data of the less-resourced languages in each cluster, and shuffle them proportionally in all batches.

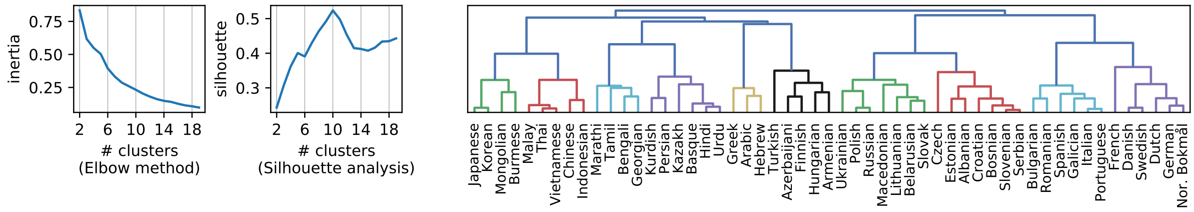
We use Nematus (Sennrich et al., 2017) only to extract the factored language embeddings from the TED-53 corpus (L_T). Besides, given the large number of experiments, we also choose the efficient Marian NMT (Junczys-Dowmunt et al., 2018) toolkit for training the rest of systems. With Marian NMT, we only use the basic pseudo-token setting for identifying the source language, as we did not need to retrieve new language embeddings after training. Besides, we allow the Marian NMT framework to automatically determine the mini-batch size given the sentence-length and available memory (mini-batch-fit parameter).

We train our models with up to four NVIDIA P100 GPUs using Adam optimiser (Kingma and Ba, 2014) with default parameters ($\beta_1 = 0.9, \beta_2 = 0.98, \varepsilon = 10^{-9}$) and early stopping at 5 validation steps for the cross-entropy metric. Finally, the sacreBLEU version string (Post, 2018) is as follows: BLEU+case.mixed+numrefs.1+smooth.exp +tok.13a+version.1.3.7.

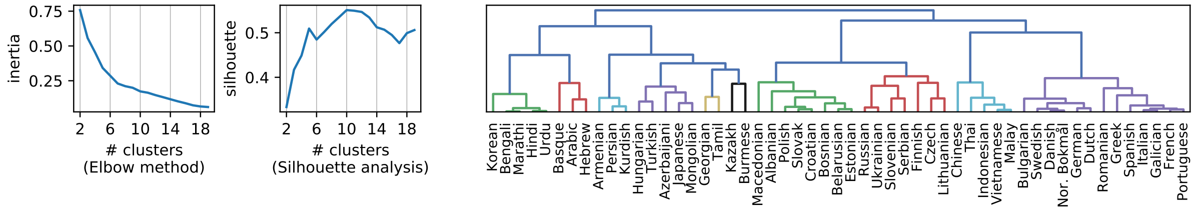
Clustering settings. We first list the baselines and our approaches, with the number of clusters/models between brackets:

1. Individual [53]: Pairwise model per language.
2. Massive [1]: A single model for all languages.
3. Language families [20]: Based on historical linguistics. We divide the 33 Indo-European languages into 7 branches. Moreover, 11 groups only have one language.
4. KB [3]: U_S (Syntax) tends to agglomerate large clusters (with 4-13-33 languages), behaving similar to a massive model (Fig. 2c).
5. Learned [11]: We train a set of 53 factored embeddings (L_T) similar to Tan et al. (2019) (Fig. 2d).
6. Concatenation [18]: $U_S \oplus L_T$.
7. SVCCA-53 [10]: Multi-view representation with SVCCA composing both U_S and L_T vectors (Fig. 2a).
8. SVCCA-23 [10]: Similar to the previous setting, but we use the set of 23 language embeddings L_W instead (Tan et al., 2019), and project the 30 complementary languages with SVCCA(U_S,L_W) (Fig. 2b).

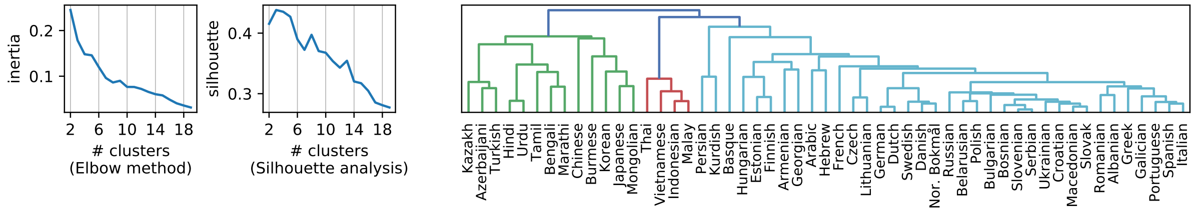
(a) SVCCA-53(U_S, L_T): SVCCA representations of Syntax and TED-53



(b) SVCCA-23(U_S, L_W): SVCCA representations of Syntax and WIT-23



(c) U_S: Syntax



(d) L_T: NMT-learned from TED-53 (using factors)

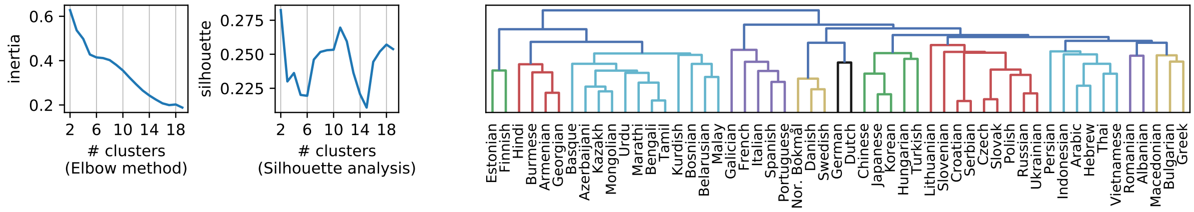


Figure 2: (a) Clustering of TED-53 using the SVCCA-53 representations. At the left, we include the Elbow and Silhouette criteria to define the number of clusters. For the former, it is not clear what is the value to choose, whereas for the later we automatically select the highest peak at ten clusters. (b-d) Elbow method, silhouette analysis and dendrograms for SVCCA-23(U_S,L_W) with 30 additionally projected languages, U_S and L_T.

With the last setting, we are interrogating whether SVCCA is a useful method for rapidly increasing the number of languages without retraining massive models given new entries that require their NMT-learned embeddings for clustering.

Similar to Tan et al. (2019), we use hierarchical agglomeration with average linkage and cosine similarity. However, we choose a different criterion for choosing the optimal number of clusters.

Selection of number of clusters. The Elbow criterion has been suggested for this purpose (Tan et al., 2019); however, as we can see in Figure 2, it might be ambiguous. Thus, we propose using a heuristic called Silhouette (Rousseeuw, 1987), which returns a score in the [-1,1] range. A sample cluster with a silhouette close to 1 indicates that it is cohesive and well-separated. With the average silhouette of all samples, we vary the number of clusters, and look for the peak value above two.

Ranking settings. We focus on five low-resource languages from TED-53: Bosnian (bos, Indo-European/Balto-Slavic), Galician (glg, Indo-European/Italic), Malay (zlm, Austronesian), Estonian (est, Uralic) and Georgian (kat, Kartvelian). They have between 5k and 13k translated sentences with English, and we chose them as they achieved the most significant improvement from the individual to the massive setting. We then identified the top-3 related languages using LANGRANK, which give us a multilingual training set of around 500 thousand sentences for each case. Given that LANGRANK usually prefers to choose candidates with larger data size (Lin et al., 2019), for a fair comparison, we use SVCCA and cosine similarity to choose the k closest languages that can agglomerate a similar amount of parallel sentences.

6.2 Language clustering results

We first briefly discuss the composition of clusters obtained by SVCCA. Then, we analyse the results grouped by training size bins. We complement the analysis by family groups in Appendix D.

Cluster composition: In Figure 2, we observe that SVCCA-53 (Fig. 2a) has adopted ten clusters with a proportionally distributed number of languages (the smallest one is Greek-Arabic-Hebrew, and the largest one has seven entries). Moreover, the languages are usually grouped by phylogenetic or geographical criteria. These agglomeration trends are adopted from both the KB (Fig. 2c) and NMT-learned (Fig. 2d) sources.

From a more detailed inspection, there are entries that do not correspond to their respective family branches, although the single-view sources might induce the bias. For instance, the L_T phylogenetic tree (Fig. 1d) "misplaced" Bulgarian within Italic languages. Nevertheless, the unexpected agglomerations rely on the features encoded in the KB or the NMT learning process, and we expect they can uncover surprising clusters to avoid isolating languages without close relatives (e.g. Basque, or even Japanese as the only Japonic member in the set). Another benefit is noticeable in the SVCCA-23 clusters (Fig. 2b), which have resemblances with the SVCCA-53 agglomeration despite using only 23 languages to compute the shared space.

Training size bins: We manually define the upper bounds of the bins as [10,75,175,215] thousands of training sentences, which results in groups composed by [14,14,13,12] languages. Figure 3 shows the box plots of BLEU from where we can analyse each distribution (mean, variance).

Throughout all the bins, we observe that both SVCCA-53 and SVCCA-23 accomplish a comparable accuracy with the best setting in each group. In other words, their clusters provide stable performance for both low or high-resource languages.

In the first bin of the smallest corpora, the Massive baseline and the large clusters of U_S barely surpass the SVCCA schemes. Nevertheless, SVCCA contributes a notable advantage if we want to train a multilingual NMT model for a specific low-resource language, and we do not have the resources for training a massive system. We further analyse this scenario in §6.3.

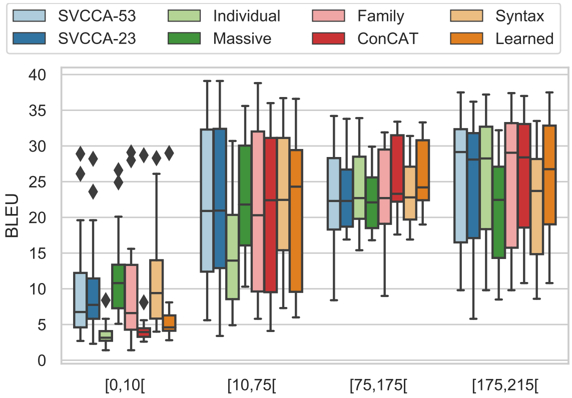

Figure 3: Box plots of BLEU scores per training-size bins. Each bin is represented by the range of minimum and maximum training size. Outliers are shown as diamonds.

In the rightmost bin, for the highest resource languages, the Massive and U_S performed worse than SVCCA. Furthermore, we show a competitive accuracy for the Individual and Family approaches. The former's clusters have steady performance across most of the bins as well. Nevertheless, they double the number of clusters that we have in both SVCCA settings, and with more than half of the "clusters" having only one language.

Other approaches, like using the NMT-learned embeddings (L_T) as Tan et al. (2019) or the concatenation baseline, obtain similar translation results in the last three bins. However, we need to obtain the NMT-learned embeddings first in order to fulfil those methods (from a 53-languages massive model). Using SVCCA and a pre-trained smaller set of language embeddings is enough for projecting new representations, as we present with our SVCCA-23 approach.

6.3 Language ranking results

After discussing overall translation accuracy for all the languages, we now focus on five specific low-resource cases and how multilingual transfer enhance their performance. Table 3 shows the BLEU scores of the translation into English for the smaller multilingual models that group each child language with their candidates ranked by LANGRANK and our SVCCA-53 representations.

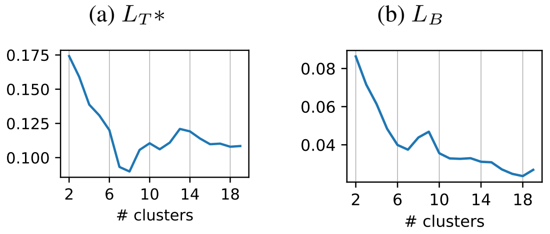
We also include the results of the individual and massive MT systems. Even when the latter baseline provides a significant improvement over the former, we observe that many of the smaller multilingual models outperform the translation accuracy of the massive system. The result suggests that the amount of data is not the most important confound for supporting multilingual transfer in a low-resource language, which is aligned with the literature (Wang and Neubig, 2019).

Comparing the two ranking approaches, we observe that SVCCA approximates the performance of LANGRANK in most of the cases. We note that LANGRANK prefers related languages with large datasets, as it only requires three candidates to group around half a million training samples, whereas SVCCA suggests to include from three to ten languages to reach a similar amount of parallel sentences. However, increasing the number of languages could impact the multilingual transfer negatively (see the case of Georgian or *kat*), as it is analogous to adding different "out-of-domain" samples. To alleviate this, we could bypass candidate languages that do not possess a specific amount of training samples.

We argue that our representations still provides a robust alternative to determine which languages are suitable for multilingual transfer learning. The notable advantage is that we do not need to pretrain MT systems from a specific dataset, and we can easily extend the coverage of languages without re-training the ranking model to consider new language entries[8].

L	Ind.	Mas.	LANGRANK	SVCCA-53
bos	4.2	26.6	28.8 (434)	28.2 [5]
glg	8.4	24.9	27.7 (443)	28.4 [3]
zlm	4.1	20.1	21.2 (463)	21.0 [4]
est	5.8	13.5	13.5 (533)	12.1 [6]
kat	5.8	14.3	13.3 (499)	10.5 [10]

Table 3: BLEU scores (L→English) for Individual, Massive and ranking approaches. LANGRANK shows the accumulated training size (in thousands) for the top-3 candidates, whereas with SVCCA we approximate the amount of data and include the number of languages between brackets.



(a) L_T*

(b) L_B

Figure 4: Silhouette analysis for the L_T* embeddings trained using an initial pseudo-token (left) and the L_B Bible vectors (right). Both cases present a downtrend curve with scores below 0.2. The hierarchies of L_T* and L_B are shown in Figures 6b and 6a (in the Appendix), respectively.

7 Factors over initial pseudo-tokens

We additionally argue that the configuration used to compute the language embeddings impacts what relationship they can learn. For the analysis, we extract an alternative set of 53 language embeddings (L_T*) but using the initial pseudo-token setting instead of factors. Then, we perform a silhouette analysis to identify whether we can build cohesive and well-separated clusters of languages.

Figure 4 shows the silhouette analysis for the aforementioned embeddings (L_T*) together with the Bible embeddings (L_B) that were trained with the same configuration. We observe that the silhouette score never exceeds 0.2, and the curve keeps degrading when we examine a higher number of clusters, which contrast the trend shown in Figure 2. The pattern proves that the vectors are not suitable for clustering (the hierarchies are shown in Figure 6 in the Appendix), and they might only encode enough information to perform a classification task in the multilingual NMT training and inference. For that reason, we consider it essential to use language embeddings from factors for extracting language relationships.

8 Related work

For language-level representations, URIEL and lang2vec (Littell et al., 2017) allow a straightforward extraction of typological binary features from different KBs. Murawaki (2015, 2017, 2018) exploits them to build latent language representations with independent binary variables. Language features are encoded from data-driven tasks as well, such as NMT (Malaviya et al., 2017) or language modelling (Tsvetkov et al., 2016; Östling and Tiedemann, 2017; Bjerva and Augenstein, 2018b)

---

[8] However, we do not answer what multilingual NMT really transfers to the low-resource languages. We left that question for further research, together with optimising the k number of languages or the amount of data per each language.

with complementary linguistic-related target tasks (Bjerva and Augenstein, 2018a).

Our approach is most similar to Bjerva et al. (2019a), as they build a generative model from typological features and use language embeddings, extracted from factored language modelling at character-level, as a prior of the model to extend the language coverage. However, our method primarily differs as it is mainly based in linear algebra, encodes information from both sources since the beginning, and can deal with a small number of shared entries (e.g. 23 from L_W) to compute robust representations.

There has been very little work on adopting typology knowledge for NMT. There is not a deep integration of the topics (Ponti et al., 2019), but one shallow and prominent case is the ranking method (Lin et al., 2019) that we analysed in §6.

Finally, CCA and its variants have been previously used to derive embeddings at word-level (Faruqui and Dyer, 2014; Dhillon et al., 2015; Osborne et al., 2016). Kudugunta et al. (2019) also used SVCCA but to inspect sentence-level representations, where they uncover relevant insights about language similarity that are aligned with our results in §5. However, as far as we know, this is the first time a CCA-based method has been used to compute language-level representations.

9 Takeaways and practical tool

We summarise our key findings as follows:

- SVCCA can fuse linguistic typology KB entries with NMT-learned embeddings without diminishing the originally encoded typological and genetic similarity of languages.
- Our method is a robust alternative for identifying clusters and choosing related languages for multilingual transfer in NMT. The advantage is notable when it is not feasible to pre-train a ranking model or learn embeddings from a massive multilingual system. Assessing new languages is an important ability, given that most of them do not have even enough monolingual corpora to learn embeddings from multilingual language modelling (Joshi et al., 2020).
- Factored language embeddings encode more information to agglomerate related languages than the initial pseudo-token setting.

Furthermore, we make our code available as an open-source tool[9], together with our L_T factored-embeddings, to compute multi-view language representations using SVCCA. We enable the option to use other language vectors from lang2vec (Phonology or Phonetic Inventory) as the KB-source, and to upload new task-learned embeddings from different settings, such as one-to-many or many-to-many NMT, and also multilingual language modelling. Besides, given a list of languages to assess, our method will project new language representations when they are only available in the KB-view. Finally, we include the tasks of language clustering and ranking candidates, which could benefit multilingual NLP studies that involve massive datasets of hundreds of languages.

10 Conclusion

We compute multi-view language representations with SVCCA using two sources: KB and NMT-learned vectors. With a typological feature prediction task and the inference of phylogenetic trees, we showed that the knowledge and language relationship encoded in both sources is preserved in the combined representation. Moreover, our approach offers important advantages because we can evaluate projected languages with entries in only one of the views and can easily extend the language coverage. The benefits are noticeable in multilingual NMT tasks, like language clustering and ranking related languages for multilingual transfer. We plan to study how to deeply incorporate our typologically-enriched embeddings in multilingual NMT, where there are promising avenues in parameter selection (Sachan and Neubig, 2018) and generation (Platanios et al., 2018).

A Languages and individual BLEU scores

We work with 53 languages pre-processed by (Qi et al., 2018), from where we mapped the ISO 639-1 codes to the ISO 693-2 standard. However, we need to manually correct the mapping of some codes to identify the correct language vector in the URIEL (Littell et al., 2017) library:

- *zh* (*zho* , Chinese macro-language) mapped to *cmn* (Mandarin Chinese).
- *fa* (*fas* , Persian inclusive code for 11 dialects) mapped to *pes* (Western/Iranian Persian).
- *ar* (*ara* , Arabic) mapped to *arb* (Standard Arabic).

We disregard working with artificial languages like Esperanto (eo) or variants like Brazilian Portuguese (pt-br) and Canadian French (fr-ca).

Table 4 presents the list of all the languages with the following details: ISO 693-2 code, language family, size of the training set in thousands of sentences (with their respective training size bin) and the individual BLEU score obtained per clustering approach and other baselines.

B Correlation of SVCCA with genetic similarity

Bjerva et al. (2019b) argued that raw language embeddings from language modelling correlates with *genetic* and structural similarity[10]. For the former,

---

[10] We note that Bjerva et al. (2019b) used monolingual texts translated from different languages to investigate what kind

Table 4: List of languages with their BLEU scores per clustering approach (IE=Indo-European).

they correlated a distance matrix with pairwise-leaf-distances of the GS. However, Serva and Petroni (2008) originally inferred the phylogeny by comparing the translated Swadesh list of 200-words (Dyen et al., 1992) with Levenshtein (edit) distance. The list is a crafted set of concepts for comparative linguistics (e.g. I, eye, sleep), and it is usually processed by lexicostatistics methods to study language relationship through time. Therefore, we prefer to argue that corpus-based embeddings could partially encode **lexical** similarity of languages.

We perform a Spearman correlation between

---

of genetic information is preserved. Concerning structural similarity, they computed a distance matrix using syntax-dependency-tags counts per language from annotated treebanks. We leave this analysis for further work.

the cophenetic matrix[11] of the GS and the pairwise cosine-distance matrices of U_S, L_T and SVCCA(U_S,L_T), where we obtain correlation coefficients of 0.48, 0.68 and 0.80, respectively (p-values$<$0.001). Our conclusion is that typological knowledge strengthen the representation of lexical similarity within NMT-learned embeddings.

C SVD explained variance selection

To compute SVCCA, we transform each source space using SVD, where we can choose to preserve a number of dimensions that represents an accumulated explained variance of the original dataset. For that reason, we perform a parameter sweep between 0.5 and 1.0 using 0.05 incremental steps. For a fair comparison, we also transform the single spaces (KB or Learned) with SVD and look for the optimal threshold.

Prediction of typological features. We selected a 0.5 threshold for the NMT-learned vectors of L_B and L_W, and 0.7 for L_T. In case of the SVCCA representation, L_T uses [0.75,0.70], whereas L_B and L_W employ [0.95,0.50] values. The parameter values are for both one-language-out and one-family-out settings. We can argue that there is redundancy in the NMT-learned embeddings, as the prediction of typological features with Logistic Regression always prefers a dimensionality-reduced version instead of the original data (threshold at 1.0).

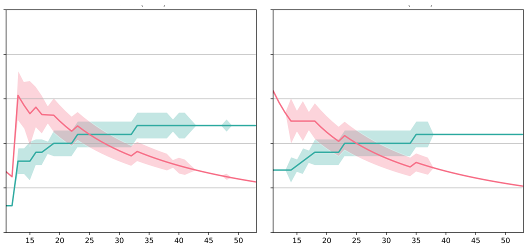
Language phylogeny inference. In Table 5, we report the optimal value for the SVD explained variance ratio in each single and multi-view (concatenation and SVCCA) setting.

Language clustering (and ranking). We cannot perform an exhaustive analysis for the threshold of the explained variance ratio per view. As our main goal is to increase the coverage of languages steadily, we must determine what configuration allows a stable growth of the hierarchy.

We thereupon take inspiration from bootstrap clustering (Nerbonne et al., 2008), and increase the number of language entries from few entries (e.g. 10) to 53 by resample bootstrapping using each of the source vectors: U_S, L_T and L_W. Afterwards, we search for the threshold value that preserves a stable number of clusters given the peak silhouette value. Our heuristic looks for the least variability throughout the incremental bootstrapping (Fig. 5).

	Single	$U_S \oplus L_*$	SVCCA(U_S,L_*)
U_S (Syntax)	30 / 0.45 (0.5)		
L_B (Bible)	35 / 0.54 (0.9)	27 / 0.42 (0.70,0.55)	23 / 0.34 (0.70,0.75)
L_W (WIT-23)	35 / 0.62 (0.8)	23 / 0.41 (0.75,0.95)	27 / 0.48 (0.50,0.95)
L_T (TED-53)	15 / 0.26 (0.6)	18 / 0.29 (0.70,0.55)	**10 / 0.15** (1.00,0.55)

Table 5: Similar to Table 2, but including the optimal values for the SVD explained variance in each setting.



(a) Syntax: U_S (0.65)

(b) TED-53: L_T (0.6)

Figure 5: Analysis of the number of clusters (blue) and the ratio of number of clusters per total languages (red) given the chosen thresholds of explained variance ratio. We show the confidence interval computed from the bootstrapping, and we observe that the number of clusters is stable since 42 and 38 languages for U_S and L_T vectors, respectively.

We found that 0.65 is the most stable value for U_S, whereas 0.60 is the best one for both L_T and L_W, so we thereupon fix SVCCA-53 and SVCCA-23 to [0.65,0.6]. We also apply the chosen thresholds on the concatenation baseline for a fair comparison. In the single-view cases, the transformations with the tuned variance ratio do not overcome any non-optimised counterparts.

D Language clustering results by language families

Following a guide for evaluating multilingual benchmarks (Anastasopoulos, 2019), we also group the scores by language families. Table 6 includes the overall weighted average per number of languages in each family branch. We observe that most of the approaches have obtained clusters with similar overall translation accuracy. The individual models are the only ones that significantly underperform. The poor performance is transferred to the Family baseline, as most of the groups contains only one language given the low language diversity of the dataset.

The U_S vectors obtain the highest overall accuracy, mostly from their few large clusters (see Fig. 2c). Meanwhile, SVCCA-53 achieves the second-best overall result, by a minimal margin, and with 3 to 7 languages per cluster, which are usually faster

---

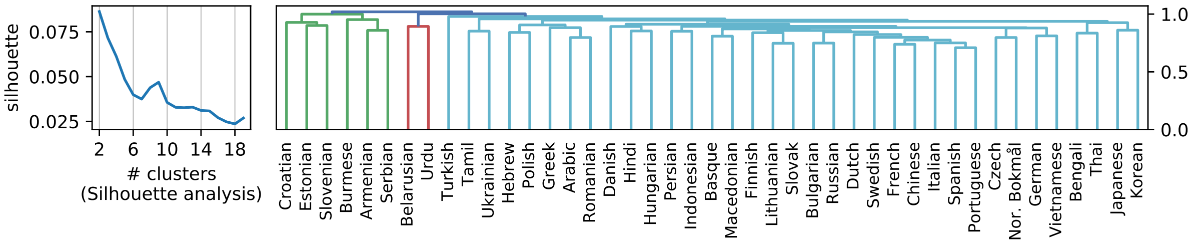
Table 6: BLEU score average per language family (IE=Indo-European). Every method includes the weighted BLEU average per number of languages (#L) and the number of clusters/models. Bold and italic represent first and second best results per family. Δ for SVCCA indicates the difference with respect to the highest score.

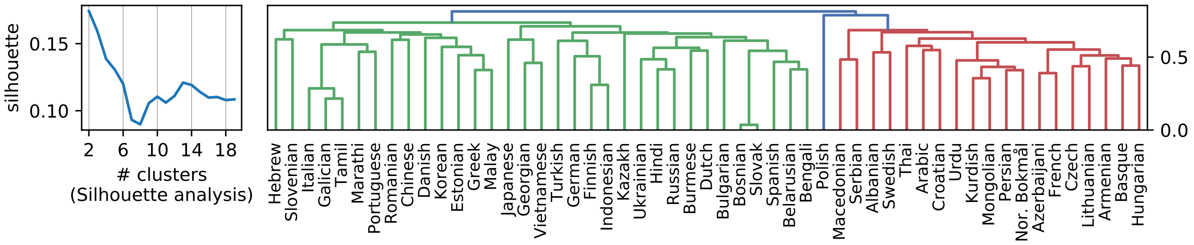
to converge. Besides, the massive model, the L_T embeddings and the concatenation baseline present a competitive achievement as well. However, the first requires more resources to train until convergence, whereas the last two need the 53 pre-trained embeddings from a previous massive system.

In contrast, SVCCA-23 is a faster alternative if we want to target specific new languages (see Fig. 2b). We only require a small group of language embeddings (e.g. L_W of 23 entries) and project the rest with SVCCA and a set KB-vectors as a side view. For instance, if we need to deploy a translation model for Basque or Thai, we could reach a comparable or better accuracy to a massive model with the SVCCA-23 chosen clusters of only 3 (Arabic, Hebrew) or 5 (Chinese, Indonesian, Vietnamese, Malay) languages, respectively.

(a) L_B: NMT-learned from Bible



(b) L_T*: NMT-learned from TED-53 but with initial pseudo-tokens



(c) SVCCA-53*(U_S,L_T*): SVCCA representations of Syntax and TED-53 but with initial pseudo-tokens

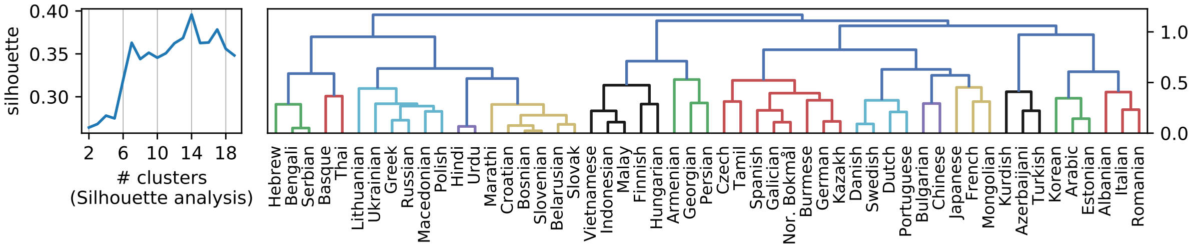


Figure 6: Silhouette analysis and dendrograms for clustering the 53 languages of TED-53 using different language representations. In (a) and (b), we note that the silhouette score is below 0.2 (1 is best), and the hierarchies do not define natural groups for the languages, as they are usually very separated from each other. In (c), we note that SVCCA is affected by the noisy agglomeration of the original NMT-learned embeddings with initial pseudo-tokens.

AnswerFact: Fact Checking in Product Question Answering*

Abstract

Product-related question answering platforms nowadays are widely employed in many E-commerce sites, providing a convenient way for potential customers to address their concerns during online shopping. However, the misinformation in the answers on those platforms poses unprecedented challenges for users to obtain reliable and truthful product information, which may even cause a commercial loss in E-commerce business. To tackle this issue, we investigate to predict the veracity of answers in this paper and introduce AnswerFact, a large scale fact checking dataset from product question answering forums. Each answer is accompanied by its veracity label and associated evidence sentences, providing a valuable testbed for evidence-based fact checking tasks in QA settings. We further propose a novel neural model with tailored evidence ranking components to handle the concerned answer veracity prediction problem. Extensive experiments are conducted with our proposed model and various existing fact checking methods, showing that our method outperforms all baselines on this task.

1 Introduction

The ability to ask questions during online shopping is found to be a key factor for customers to make purchase decisions (Smith and Anderson, 2016). To this end, product-related community question answering (PQA) platforms have emerged in many E-commerce sites such as *Amazon* and *Taobao*, allowing users to pose their concerns as questions and receive answers from fellow users to obtain useful product information. However, similar to other community question answering (CQA) platforms, the user-provided answers on PQA platforms vary significantly on their qualities (Zhang et al., 2020b), and more seriously, their veracity due to the lack of systematic quality control (Mihaylova et al., 2018). Those untruthful answers may attribute to multiple factors such as misunderstandings of the question, improper expressions during writing, and even intentionally malicious attacks from the competitors (Carmel et al., 2018). Therefore, automatically verifying the answer veracity is becoming a demanding need, which can offer a more reliable online shopping environment, for example, by triggering a double-check on the detected doubtful answers.

Question: Is this egg coker automatic shut off?
Answer (Claim): Yes there's an automatic shut-off when the cooking cycle is finished. (`Verdict` : `FALSE`)
Evidence:
s_1: A buzzer sounds to let you know the eggs are done, I wish it would just shut off instead.
s_2: When the alarm sounds you need to turn it off and open it.
s_3: I would have liked the cooker to turn off automatically but instead a bell rings until you turn if off.
s_4: Also, by the time the timer goes off, the hot pan has a burning smell.
s_5: And it turns off itself after the bell rings.
...

Table 1: An example instance in AnswerFact, where the answer is the claim to be verified. The relevant product information are provided as evidence sentences.

Fact checking aiming at verifying the truthfulness of a given claim (Thorne and Vlachos, 2018; Sharma et al., 2019) can be a promising direction to tackle the concerned problem. However, the claim on which existing fact checking methods mainly focus is usually a standalone text snippet such as news (Wang, 2017; Popat et al., 2018; Ma et al., 2019) or twitter posts (Derczynski et al., 2017; Wei et al., 2019). To predict the veracity of an answer in the QA settings, one can notice that it is insufficient to consider the answer alone since the question text

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2407–2417,
November 16–20, 2020.

also carries important semantic information for the prediction. Thus, we need to appropriately leverage the question text into the verification process.

In the context of CQA problems, most existing studies focus on measuring the semantic relevance of a candidate answer to the given question (Tay et al., 2017; Yang et al., 2019b) or ranking available answers for a given question (Zhang et al., 2020a). However, the notion of veracity poses a more rigorous requirement of an answer where it needs to be factually correct. For example, the given answer in Table 1 will be labeled as positive from the perspective of the typical CQA task (Nakov et al., 2017) since it is topically relevant to the question. But its verdict is indeed false which can be verified from the product description. Recently, a new shared task, namely SemEval-2019 Task 8 (Mihaylova et al., 2019) investigates the fact checking problem in question answering scenario, requiring a system to classify the veracity of answers in a web forum. However, only QA pairs are given in this task, making it less practical since most of the predictions require extra knowledge from external sources. Moreover, with only hundreds of QA pairs provided, such limited number of samples precludes its use to develop powerful machine learning based fact checking models.

To tackle the aforementioned issues, we introduce a large scale fact checking dataset called AnswerFact for investigating the answer veracity in product question answering forums. An instance of the dataset is shown in Table 1. It consists of 60,864 answer claims, each with its veracity label derived from the community votes. Moreover, the relevant product information from product descriptions and user reviews are retrieved as evidence sentences providing the external knowledge for judging the answer veracity. Compared with existing works (Thorne et al., 2018a; Mihaylova et al., 2018), AnswerFact exhibits some unique characteristics: Firstly, different from a typical single text claim, a sentence pair (i.e., QA pair) is given in AnswerFact, indicating that the rich interaction information between the question and answer text needs to be explored and utilized. Secondly, since part of the evidence sentences come from user reviews written by ordinary users, the potential unreliability of some evidence sentences needs to be investigated and the consistency among evidence needs to be verified to uncover the common judgement towards the answer for the prediction.

We further propose AVER, an **A**nswer **V**eracity prediction model with tailored **E**vidence **R**anking modules to predict the answer veracity in PQA forums. AVER first utilizes the information from both the question and answer text to rank the evidence sentences with different gating mechanisms. An agreement-matching strategy is then employed to model the self-coherence of the evidence sentences for obtaining reliable combined evidence embeddings to verify the answer verdict. To summarize, our main contributions are as follows:

- We study the fact checking problem in product question answering. To our best knowledge, this is the first work to investigate the truthfulness of answers in E-commerce QA platforms.
- We introduce AnswerFact, a large dataset consisting of 60,864 answer claims across five product domains. Each claim comes with its veracity label and associated evidence sentences.
- We propose a novel neural model with tailored evidence ranking module to tackle the answer veracity prediction problem, which shows to outperforms all established baselines.

2 Related Work

2.1 Community Question Answering

Existing methods in community question answering (CQA) mainly focus on the answer selection task (Nakov et al., 2017; Tay et al., 2017; Yang et al., 2019b; Deng et al., 2020), where an answer is considered to be positive if it is semantically relevant to the question regardless of its veracity. Some studies further measure the quality of answers, trying to predict the answer helpfulness in PQA platforms (Zhang et al., 2020b) or ranking all available answers for a given question (Zhang et al., 2020a). One closely related work in the CQA context is a recent attempt of investigating the fact checking task in QA settings (Mihaylova et al., 2018), which was later adopted as the SemEval-2019 Task 8 (Mihaylova et al., 2019). Its goal is to classify an answer in the Qatar forum[1] into true, false or non-factual. However, only QA pairs are given in this shared task to predict the answer veracity, making it less practical due to the lack of evidence sources. Moreover, the small number of training data consisting only 495 QA pairs restricts the possibility of trying some powerful machine learning models such as deep neural networks.

---

[1] `http://www.qatarliving.com`

As pointed out in Mihaylova et al. (2019), verifying the verdict of answers in CQA requires using rich world knowledge. However, gathering relevant information as evidence can be difficult due to the open-domain nature of those questions. Compared with general CQA forums, PQA provides product-specific forums, making the evidence collection process more realistic and controllable. Also, as will be described in Section 3, the high proportion of factual type QA pairs also makes it suitable for studying the fact checking problem on PQA.

2.2 Fact Checking Datasets & Methods

Automatically predicting the veracity of claims has been extensively studied in recent years and various fact checking datasets have been released (Thorne et al., 2018a; Sharma et al., 2019; Augenstein et al., 2019). Typically, the data are collected from news checking websites such as Politifact and Snopes, where the evidence is either not given (Rashkin et al., 2017; Pérez-Rosas et al., 2018) or provided as an external URL link containing machine-unreadable format ranging from statistical tables to PDF reports (Wang, 2017). One recent trend is that evidence-based fact checking has gained more attention where datasets with well-formatted claims and evidence are adopted (Thorne et al., 2018a; Popat et al., 2018; Chen et al., 2020).

Fact checking methods are mostly tailored to specific types of datasets. Methods involving small datasets often use hand-crafted features to represent the claim (Mihaylova et al., 2018). These features are then fed into a SVM or MLP classifier to make the prediction (Baly et al., 2018). Deep learning based methods are also proposed given the existence of large datasets. The claim and evidence representations can be learned with neural networks such as recurrent neural networks (RNNs) (Rashkin et al., 2017) or convolutional neural networks (CNNs) (Wang, 2017).

However, none of these work conducts fact checking problem in QA settings with associated well-formatted evidence sentences.

3 AnswerFact Dataset Construction

We build our dataset upon a large QA collection (Wan and McAuley, 2016) crawled from *Amazon*. Five product domains with the largest number of QA pairs are selected, namely, *Electronics*, *Home and Kitchen*, *Sports and Outdoors*, *Health and Personal Care*, and *Cell Phones and Accessories*, constituting around 2.7 million QA pairs in total.

Labels	**Community Votes**
TRUE	$n_{up} = n_{total}$
PARTTRUE	$n_{down} < n_{up} < n_{total}$
UNSURE	$n_{down} = n_{up}$
PARTFALSE	$n_{up} < n_{down} < n_{total}$
FALSE	$n_{down} = n_{total}$

Table 2: Veracity labels from community votes. n_{up}, n_{down}, n_{total} refers to the number of upvotes, downvotes and total votes of the answer respectively.

3.1 Factual QA Pairs Filtering

The raw data collection contains various questions spanning from questions asking for product details to personal user experience. Since it can be difficult to verify the truthfulness of answers to subjective questions given the diversity of user experience, we focus on factual QA pairs to investigate the answer veracity. We begin by manually labeling the factual types of two thousand randomly sampled questions, judging whether the answer will vary from user to user. For example, questions asking for product attributes are judged as FACTUAL since the answers are objective facts. Questions looking for personal experience are treated as NONFACTUAL since their answers depend on users' own experience and vary from person to person. Each question is labeled by two annotators and the disagreements are settled by discussions. From the annotation, we found that factual questions are actually the dominant type in PQA forums where around 71% of the annotated questions are factual ones.

Following the strategy in Syed et al. (2019) which ranked first for predicting the question type in SemEval-2019 Task 8, we applied the Universal Sentence representation (Cer et al., 2018) to encode question texts. While we found that the SVM classifier performs slightly better than the XGBoost (Chen and Guestrin, 2016) used in their work, achieving average 0.85 accuracy and 0.90 F1 score under the 5-fold cross validation. We then trained the SVM classifier on the whole 2k annotated questions for predicting the type of all questions. Note that since we can sacrifice some recall for the sake of precision to ensure that the questions we want are all factual ones, we discarded questions whose predicted scores are close to decision boundary. Finally, to measure the performance of such auto-filtering, we randomly sample 150 ques-

	Electronics	Home	Sports	Health	Phones	Total
# Answers per Label						
TRUE	13,054	10,592	4,539	6,879	2,467	37,531
PARTTRUE	1,737	1,297	581	1,035	336	4,986
UNSURE	3,116	2,228	1,134	1,782	738	8,998
PARTFALSE	822	683	308	564	151	2,528
FALSE	2,491	1,797	897	1211	415	6,821
# Answers	21,220	16,597	7,459	11,481	4,107	**60,864**
# Questions	11,554	8,210	3,918	5,816	2,245	**31,743**

Table 3: Summary statistics of the AnswerFact dataset

tions with their predicted types and annotate their question types again. The results showed that the precision score reached 0.99 on this set.

3.2 Veracity Labels from Community Votes

To obtain the veracity label of each answer, an intuitive way is to manually digest relevant product information to make the annotation. However, since the annotators may not be familiar with the concerned product, their annotations might be influenced by the surface level of the answer such as its writing style instead of its actual correctness. Such labeling process can also be time-consuming and difficult to collect large amounts of data. On the other hand, we observe that the community votes of each answer can be a valuable numerical indicator reflecting its veracity. Specifically, in PQA forums, each answer can receive upvotes and downvotes from the former buyers. For factual type QA pairs, such community votes reflect users' stance towards the statement claimed in the answer, indicating the overall veracity judgement given by the entire community. It is not surprising that some answers may not have any vote in practice. But those answers with votes can provide precious labeled data for our investigation in PQA forums.

To ensure the quality of labels, we first filter out answers with total votes (including upvotes and downvotes) less than 2. Then following typical settings in fact checking datasets (Vlachos and Riedel, 2014; Wang, 2017; Augenstein et al., 2019), we consider the problem as a multi-class classification task and divide answers into five types according to their community votes as shown in Table 2. The rationality is that fully objective truth is often elusive and ill-defined as pointed out in Popat et al. (2018). For example, an answer may contain partially true information for the question. Thus, such veracity label partition can also be interpreted as measuring the answer credibility or reliability in multiple scales.

3.3 Evidence Retrieval

We then use the question text to retrieve relevant product information as evidence for providing external information when predicting the answer veracity. In E-commerce scenario, product descriptions from the manufacture and user reviews from the former buyers contain rich product information, which can be treated as the candidate information pool for the retrieval process. Similar with Thorne et al. (2018a), we rank the evidence sentences by TF-IDF similarity to the question text. To further improve the accuracy of the retrieved evidence, we only use the TF-IDF similarity as an initial filtering step, then the pre-trained BERT (Devlin et al., 2019) is utilized as the sentence encoder to encode the filtered evidence sentences and question text. The k nearest evidence sentences using cosine similarity with the encoded question are kept as the evidence for veracity verification. The statistics of the entire dataset is reported in Table 3.

4 Answer Veracity Prediction

Problem Definition. Given an answer $\boldsymbol{a}$ to its corresponding question $\boldsymbol{q}$, our aim is to predict the answer veracity which falls into one of the predefined veracity type, with the help of k relevant evidence sentences $\boldsymbol{s}_1, \boldsymbol{s}_2, \ldots, \boldsymbol{s}_k$.

In this section, we describe our proposed model AVER for the Answer Veracity prediction task with tailored Evidence Ranking module. An overview of AVER is shown in Figure 1.

4.1 Attention-based Input Encoding

For each word in the given text sequences, which is either a question, an answer or an evidence sentence, we use an embedding matrix to map it into a vector representation. To capture the temporal

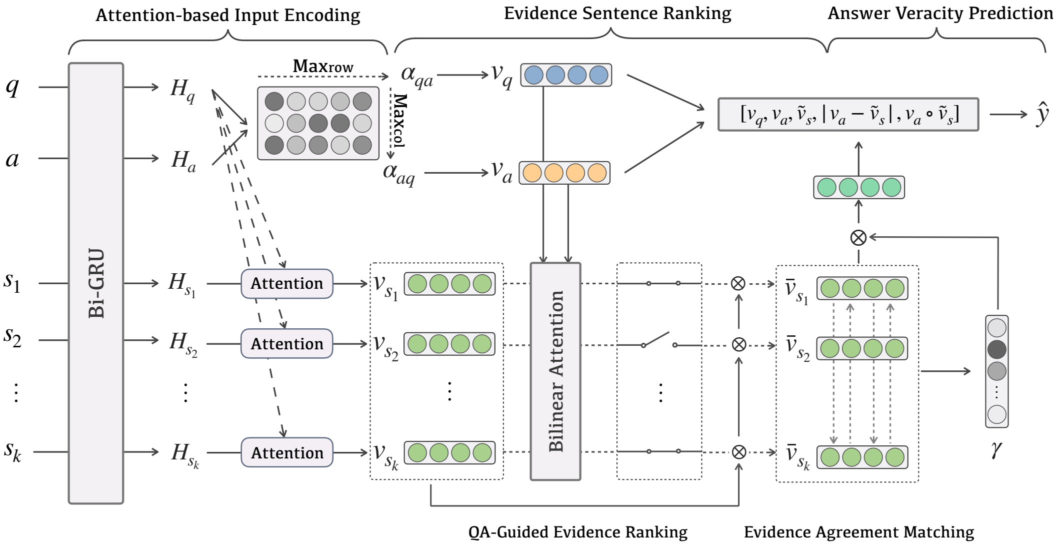

Figure 1: The architecture of our proposed AVER model

interactions between words, we employ a bidirectional GRU to transform the word embedding w_t to the context-aware representation h_t:

$$h_t^* = \text{Bi-GRU}(h_{t-1}^*, w_t), \quad * \in [q, a, s_i] \tag{1}$$

where $h_t^* \in \mathbb{R}^{d_h}$ is the hidden state at the t-th time step for the corresponding text sequence, d_h is the dimension of the hidden state. We denote the whole sequence as $H_* = [h_1^*, h_2^*, \ldots, h_l^*] \in \mathbb{R}^{l_* \times d_h}$ where l is the corresponding sequence length.

For predicting the answer veracity, one can note that rich semantic information is implicitly contained in the question text, indicating the importance of capturing the interrelations between the QA pair when encoding them. We thus employ a dual attention mechanism to encode the question and answer text with attention from each other:

$$S = H_q \cdot H_a^T \in \mathbb{R}^{l_q \times l_a} \tag{2}$$

where each item S_{ij} in the alignment matrix S denotes the alignment score between the i-th word in H_q and the j-th word in H_a. Next we can compute the dual attention weight for the question and answer respectively as follows:

$$\alpha_{qa} = \text{softmax}(\max_{\text{row}}(S)) \tag{3}$$

$$\alpha_{aq} = \text{softmax}(\max_{\text{row}}(S^T)) \tag{4}$$

$$v_q = H_q^T \cdot \alpha_{qa}, \quad v_a = H_a^T \cdot \alpha_{aq} \tag{5}$$

where $\max_{\text{row}}()$ denotes row-wise max-pooling operation. We can then obtain the encoded question embedding v_q and answer embedding v_a as the weighted sum of the context-aware representations of each word in the corresponding sequence.

Since the evidence sentences, either reviews or product descriptions are not written specifically for answering the question, we utilize the question text to highlight the important units in the evidence sentences during their encoding process. Therefore, we can obtain the encoded vector representation v_{s_i} for the i-th evidence sentence as follows:

$$T = H_{s_i} W_1 H_q^T \in \mathbb{R}^{l_{s_i} \times l_q} \tag{6}$$

$$v_{s_i} = H_{s_i}^T \cdot \text{softmax}(\max_{\text{row}}(T)) \tag{7}$$

where $W_1 \in \mathbb{R}^{d_h \times d_h}$ is a trainable weight matrix of the bilinear attention module to incorporate the different writing styles between q and s_i. We denote the encoded representations for all evidence sentences as $v_s = [v_{s_1}, v_{s_2}, \ldots, v_{s_k}] \in \mathbb{R}^{k \times d_h}$.

4.2 Evidence Sentence Ranking

One characteristic of our problem setting is that not all evidence sentences are equally useful and reliable. For example, some user reviews can be misleading and even conflicting with other evidences, requiring the model to take such imperfectness of the evidence sentences into consideration. To this end, we design an evidence sentence ranking module to capture the importance of each sentence.

4.2.1 QA-guided Evidence Ranking

We first use the question and answer to measure the usefulness of each evidence sentence:

$$\beta = f(v_s W_2 v_q + v_s W_3 v_a) \tag{8}$$

where $\beta \in \mathbb{R}^k$ denotes the weights for each evidence sentence, W_2 and W_3 are trainable parameters. The function $f()$ acts as a gate, which can be $sigmoid()$ or $softmax()$ function, corresponding to two different gating strategies:

Hard Gate. When the $sigmoid()$ function is applied element-wise for each sentence, the network will tend to assign weights closing to 0 or 1 to each evidence sentence. Thus such process will be similar as an evidence selection process, where only the useful evidence sentences will be "activated" to play the role in verifying the claim.

Soft Gate. The $softmax()$ function on the other hand will normalize the score for each evidence sentence. Thus, more important evidence can have larger weight and attach more importance in the subsequent prediction process.

After obtaining a score for each sentence, we then apply an element-wise product to obtain a new representation for each evidence sentence s_i:

$$\bar{v}_s = \beta \otimes v_s \in \mathbb{R}^{k \times d_h} \tag{9}$$

4.2.2 Evidence Agreement Matching

One remaining issue is that not all evidence sentences are always reliable. For example, s_5 in Table 1 contains opposite opinions with other evidence sentences and can mislead the veracity prediction process. To tackle this issue, we conduct an agreement matching process among the evidences to cross-check their internal coherence:

$$\gamma = \text{softmax}(w_4^T \tanh(W_5 \cdot \bar{v}_s^T)) \tag{10}$$

where $w_4 \in \mathbb{R}^{d_a}$ and $W_5 \in \mathbb{R}^{d_a \times d_h}$ are trainable parameters, $\gamma \in \mathbb{R}^k$ denotes the coherence weight for each evidence sentence. As discussed in Lin et al. (2017), such vector representation usually focuses on one specific aspect among the sentences. To capture multiple factual aspects involved in the verification process, we extend Equation 10 to a multi-view agreement matching as follows:

$$\Gamma = W_4 \cdot \tanh(W_5 \cdot \bar{v}_s^T) \tag{11}$$

$$\gamma' = \text{softmax}(\max_{\text{col}}(\Gamma)) \in \mathbb{R}^k \tag{12}$$

where $W_4 \in \mathbb{R}^{n_a \times d_a}$ and $W_5 \in \mathbb{R}^{d_a \times d_h}$ are trainable parameters, Γ is the multi-view agreement matching matrix. We then conduct a max-pooling on such matrix and take the softmax operation on the resulting vector to obtain the weight vector γ'.

Then a combined evidence embedding denoting the most related evidence information from all evidence sentences can be calculated as follows:

$$\tilde{v}_s = \sum\nolimits_{i=1}^{k} \bar{v}_{s_i} \cdot \gamma'_i \tag{13}$$

Note that the evidence embedding $\bar{v}_s$ is obtained by scaling with the importance weights of each evidence sentence if the soft gate is utilized. Thus we will substitute $\bar{v}_s$ by v_s in Equation 13 if the soft gate is utilized, which is also empirically better on our held-out validation set.

4.3 Answer Veracity Prediction

After obtaining the combined evidence embedding $\tilde{v}_s$, we utilize it to verify the answer claim. Following (Mou et al., 2016; Yang et al., 2019a) for strengthening the inference relations between the evidence and answer claim, we integrate the answer claim embedding v_a, evidence embedding $\tilde{v}_s$, their absolute difference $|v_a - \tilde{v}_s|$, and the element-wise product $v_a \otimes \tilde{v}_s$ into a prediction vector. Moreover, since the question text also implicitly contains useful semantic information, we also concatenate the question embedding v_q to the prediction vector. It is then fed to a MLP layer to make the prediction:

$$\hat{y} = \text{MLP}\left([v_q, v_a, \tilde{v}_s, |v_a - \tilde{v}_s|; v_a \otimes \tilde{v}_s]\right) \tag{14}$$

The entire model can then be trained end-to-end by computing the cross-entropy loss between the prediction $\hat{y}$ and the ground-truth label y.

5 Experiments

5.1 Experimental Setup

Dataset As introduced in Section 3, AnswerFact has 60,864 QA pairs in total [2]. We randomly split them into a training set and a test set with the ratio being 90:10. In addition, we set aside 10% data from the training set as the validation set to tune hyper-parameters during training.

Following previous work (Rashkin et al., 2017; Ma et al., 2019), we conduct experiments in two label settings, one considering all five classes introduced in Table 2, another merging the middle three classes, i.e., PARTTRUE, UNSURE and PARTFALSE as the class MIXED similarly with Ma et al. (2019). Such different label granularities can provide us a more practical and comprehensive understanding of our concerned task.

---

[2] The dataset can be found at `https://isakzhang.github.io/`.

Model	3-CLASS					5-CLASS

Table 4: Performance of various methods for answer veracity predictions on AnswerFact dataset. F_{TRUE}, F_{MIXED} and F_{FALSE} denotes the F1 scores for TRUE, MIXED and FALSE class respectively.

Experimental Details We utilize the pre-trained 300D GloVe word vectors (Pennington et al., 2014) to initialize the embedding matrix and fine-tune it during training. k in Section 3 is set to 5. The hidden dimension of the Bi-GRU is set to be 256 with dropout of 0.4. For the evidence agreement matching module, we perform a grid search over n_a and d_a with the following hyperparameters where the final setting is underlined: $n_a = [2, \underline{3}, 4]$ and $d_a = [64, \underline{128}, 256]$. ReLU is used as the activation function in the MLP layer. We assemble batches of answers with similar length together with the batch size being 64. We use the Adam optimiser with learning rate of 0.0005 and train all models on two Tesla K80 GPUs. To avoid overfitting, we conduct early stopping on the validation set with a patience being 5 and add a L2 regularization with the weight of 0.002.

Evaluation Metrics We use macro and micro averaged F1 score, as well as class-specific F1 score as the evaluation metrics.

5.2 Baseline Models

We compare our proposed model with the following baseline and state-of-the-art models: 1) **CNN-claim** and 2) **LSTM-claim**: Two claim-focused fact checking models based on CNN (Rashkin et al., 2017) and LSTM (Rashkin et al., 2017) for obtaining claim representations respectively. Both of them exploit the claim text solely without considering any external evidence. 3) **DeClarE** (Popat et al., 2018): An evidence-aware neural fact checking model of textual claims. It utilizes a word-level attention for highlighting important units in evidence sentences. 4) **NSMN** (Nie et al., 2019): A pipeline-based system which ranked first in the FEVER shared task (Thorne et al., 2018b). We use its claim verification module for our task. 5) **MultiFC** (Augenstein et al., 2019): An evidence-based fact checking model which jointly rank evidence pages and conduct veracity predictions. Since the answer itself often does not contain enough information for the veracity prediction as discussed before, we concatenate the question and answer text as the "claim" for these fact checking models facilitating a more fair comparison.

For our proposed model, we report its performance with no gate mechanism involved ("**AVER-w/o gate**"), with hard gate ("**AVER-hard gate**") and soft gate ("**AVER-soft gate**") respectively as introduced in Section 4.2.1.

5.3 Veracity Prediction Results

Table 4 shows the results of different methods for predicting the answer veracity on the AnswerFact dataset with two label settings. It can be observed that models considering evidence information (e.g., MultiFC and AVER model) consistently achieve better results than those relying on claim text only (e.g., CNN-claim model). An exception is the DeClarE model which only obtains similar performance with the CNN-claim method. We conjecture that DeClarE treats each claim-evidence pair as one training instance without considering the relations between evidence sentences. Thus the model can be misled by conflicting evidence sentences and makes random predictions. This further indicates the necessity of selecting and ranking the evidence sentences by their importance for the prediction.

For our proposed model, we can find that AVER without any gate can already achieve better results

	3-CLASS	5-CLASS
QA (claim) only	0.507	0.253
+ avg evidence embed	0.514	0.313
+ fc evidence ranking	0.511	0.264
+ hard evidence ranking	0.526	0.326
+ soft evidence ranking	0.534	0.330

Table 5: Comparison of different evidence ranking strategies, Macro-F1 scores are reported.

	3-CLASS		5-CLASS	
	Mac	Mic	Mac	Mic
AVER-soft gate	**0.534**	**0.673**	**0.330**	**0.665**
- w/o QA-guided	0.516	0.661	0.305	0.657
- w/o agree-match	0.514	0.659	0.298	0.656
- w/o multi-view	0.522	0.669	0.315	0.656

Table 6: Ablation studies on AVER. Mac/Mic refer to Macro/Micro F1 scores respectively.

than most baseline models, showing the effectiveness of the agreement matching mechanism among evidence sentences for cross-checking their coherence. With the guide from question and answer information, the model with either soft or hard gate mechanism consistently outperforms all baseline methods on two label settings. This result suggests that the attention information from the QA pair is very important for ranking the evidence sentences and highlighting those more helpful sentences for assisting the prediction. Moreover, we can notice that the model with soft gate obtains better results than the model with hard gate in general, suggesting that measuring the importance of each evidence sentence with a soft weight is better than aggressively determining whether to "select" an evidence sentence or not in the hard gate mechanism for our concerned problem.

5.4 Analysis and Discussion

In this section, we conduct detailed analysis on our proposed evidence ranking module, which plays an important role for finding out more helpful and reliable evidence sentences for the subsequent veracity prediction.

Impact of Evidence Ranking Strategies

To investigate the effectiveness of our proposed evidence ranking strategy, we substitute it with two possible alternatives and present the results in Table 5. Specifically, we first report the results with QA pair only ("QA only") as a base model. Then we use the average sentence embedding $\frac{1}{k}\sum_{i=1}^{k} v_{s_i}$ to replace $\tilde{v}_s$ in Eq.13 to examine what if we do not consider the relations among the evidence sentences ("avg evidence embed"). We also create another model by utilizing a fully-connected layer to capture the relation of each evidence sentence with the answer and then concatenate these predictions to make the final judgement ("fc evidence ranking") as proposed in Augenstein et al. (2019).

We can see that our proposed model is superior than both alternatives since it carefully ranks the evidence sentences with both information from QA pair and agreement matching. It can be noticed that the model with fully connected evidence ranking performs even worse than averaging the evidence embeddings. This is likely due to the fact that it would be difficult for the model to implicitly learn the relations for each claim-evidence pair given only the veracity label. We alleviate this issue by conducting an agreement matching among the sentences first and then calculating a combined evidence embeddings to assist the prediction.

Ablation Study

We perform ablation studies by discarding some important components of AVER to investigate their effectiveness. For two evidence ranking modules, we discard QA-guided evidence ranking by directly replacing $\bar{v}_s$ in Eq.11 with v_s so as to neglect the QA information ("w/o QA-guided"). Then we create another variant by using the weight vector β in Eq.8 for calculating the combined evidence embedding in Eq.13 resulting in leaving out the evidence agreement matching component ("w/o agree-match"). As shown in Table 6, both modules contribute to the final veracity prediction performance in either label setting, indicating the importance of treating each evidence sentence differently for predicting the answer veracity. Moreover, we also replace the multi-view agreement matching with the single-view matching operation in Eq.10 ("w/o multi-view"), which leads to an inferior performance. This result indicates that cross-checking the coherence among the evidence from multiple perspectives can better measure the importance of each sentence, thus helping the final prediction.

Case Study

We present a sample case in Table 7 which is correctly predicted as false by AVER. The evidence

Question: Does this case fit the S4 with the inductive charging back? It is slightly thicker than the original back.
Answer: No, it will not is only for the S2.
Verdict: `FALSE`

s_1: Love these cases...they fit the Galaxy S4 so well, they even accommodate the wireless charger back plate.
s_2: It fits the s4 perfect, the cut outs are perfect and its not bulky.
s_3: I had a very similar case for my Galaxy S2, so I bought this one hoping it would hold up as well as the first.
s_4: I wish it was available in more colors for the Galaxy S4.
s_5: The case didn't work with extended battery and cover.

Table 7: A sample case of the prediction where the evidence sentences are ranked by their attention weights.

sentences are also shown, ranked by their weight γ_i' in Eq.12. We can observe that the top ranked evidences are highly topically relevant to the QA pair and coherent to other evidence sentences. Moreover, they contain essential information that can be directly used to infer the verdict of the answer. In contrast, the lower ranked sentences contain less relevant information which should play less important role during the prediction. This example indicates that different importance and usefulness of each evidence sentence need to be taken into consideration when predicting the answer verdict.

6 Conclusions

In this paper, we investigate the fact checking problem in product question answering forums, aiming to predict the answer veracity so as to provide more reliable online shopping environment. To this end, we introduce AnswerFact, an evidence-based fact checking datasets in QA settings. Further, we propose AVER model to predict answer veracity via tailored evidence ranking module. Extensive experiments show that our proposed method outperforms various established baselines.

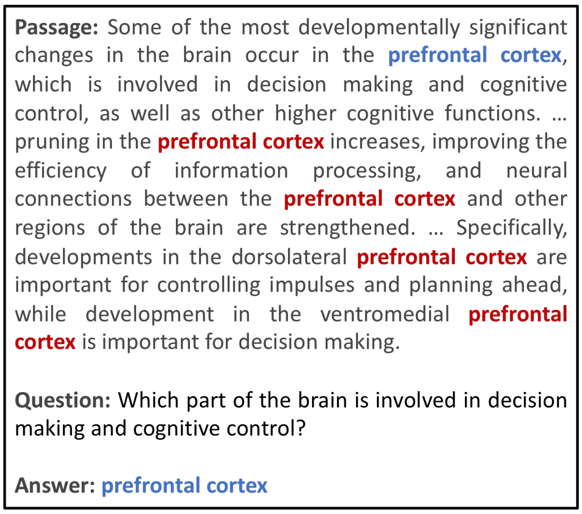
Abstract

Extractive QA models have shown very promising performance in predicting the correct answer to a question for a given passage. However, they sometimes result in predicting the correct answer text but in a context irrelevant to the given question. This discrepancy becomes especially important as the number of occurrences of the answer text in a passage increases. To resolve this issue, we propose **BLANC** (**BL**ock **A**ttentio**N** for **C**ontext prediction) based on two main ideas: context prediction as an auxiliary task in multi-task learning manner, and a block attention method that learns the context prediction task. With experiments on reading comprehension, we show that BLANC outperforms the state-of-the-art QA models, and the performance gap increases as the number of answer text occurrences increases. We also conduct an experiment of training the models using SQuAD and predicting the supporting facts on HotpotQA and show that BLANC outperforms all baseline models in this zero-shot setting.

1 Introduction

Question answering tasks require a high level of reading comprehension ability, which in turn requires a high level of general language understanding. This is why the question answering (QA) tasks are often used to evaluate language models designed to be used in various language understanding tasks. Recent advances in contextual language models brought on by attention (Hermann et al., 2015; Chen et al., 2016; Seo et al., 2017; Tay et al., 2018) and transformers (Vaswani et al., 2017) have led to significant improvements in QA, and these improvements show that better modeling of contextual meanings of words plays a key role in QA.

While these models are designed to select answer-spans in the relevant contexts from given passages, they sometimes result in predicting the correct answer text but in contexts that are irrelevant to the given questions. Figure 1 shows an example passage where the correct answer text appears multiple times. In this example, the only answer-span in the context relevant to the given question is the first occurrence of the “prefrontal cortex” (in blue), and all remaining occurrences of the answer text (in red) show incorrect predictions. Figure 2 shows quantitatively, the discrepancy between predicting the correct answer text versus predicting the correct answer-span. Using BERT (Devlin et al., 2019) trained on curated NaturalQuestions (Fisch et al., 2019), we show the results of extractive QA task using exact match (EM) and Span-EM. EM only looks for the text to match the ground truth answer, whereas Span-EM additionally requires the span to be the same as the ground truth answer-span. Figure 2 shows that BERT finds the correct answer text more than it finds the correct answer-spans, and this proportion



Passage: Some of the most developmentally significant changes in the brain occur in the **prefrontal cortex**, which is involved in decision making and cognitive control, as well as other higher cognitive functions. … pruning in the **prefrontal cortex** increases, improving the efficiency of information processing, and neural connections between the **prefrontal cortex** and other regions of the brain are strengthened. … Specifically, developments in the dorsolateral **prefrontal cortex** are important for controlling impulses and planning ahead, while development in the ventromedial **prefrontal cortex** is important for decision making.

Question: Which part of the brain is involved in decision making and cognitive control?

Answer: **prefrontal cortex**

Figure 1: Example passage, question, and answer triple. This passage has multiple spans that are matched with the answer text. The first occurrence of “prefrontal cortex” is the only answer-span within the context of the question.

Proceedings of the 2020 Conference on Empirical Methods in Natural Language Processing, pages 2418–2428,
November 16–20, 2020. ©2020 Association for Computational Linguistics

of wrong predictions increases as the number of occurrences of answer text in a passage increases.

Tackling this problem is very important in more realistic datasets such as NaturalQuestions (Kwiatkowski et al., 2019), where the majority of questions have more than one occurrence of the answer text in the passage. This is in contrast with the SQuAD dataset, where most questions have a single occurrence of the answer. These details of the SQuAD (Rajpurkar et al., 2016), NewsQA, and NaturalQuestions datasets (Fisch et al., 2019) are shown in Figure 3.

To address this issue, we define context prediction as an auxiliary task and propose a block attention method, which we call **BLANC** (**BL**ock **A**ttentio**N** for **C**ontext prediction) that explicitly forces the QA model to predict the context. We design the context prediction task to predict soft-labels which are generated from given answer-spans. The block attention method effectively calculates the probability of each word in a passage being included in the context with negligible extra parameters and inference time. We provide the implementation of BLANC publicly available [1].

Adding context prediction and block attention enhances BLANC to correctly identify context related to a given question. We conduct two types of experiments to verify the context differentiation performance of BLANC: extractive QA task, and zero-shot supporting facts prediction. In the extractive QA task, we show that BLANC significantly increases the overall reading comprehension performance, and we verify the performance gain increases as the number of answer texts in a passage increases. We verify BLANC's context-aware performance in terms of generalizability in the zero-shot supporting facts prediction task. We train BLANC and baseline models on SQuAD1.1. and perform zero-shot supporting facts (supporting sentences in passages) prediction experiment on HotpotQA dataset (Yang et al., 2018). The results show that the context prediction performance that the model has learned from one dataset is generalizable to predicting the context of an answer to a question in another dataset.

Contributions in this paper are as follows:

- We show the importance of correctly identifying the answer-span to improving the model performance on extractive QA.

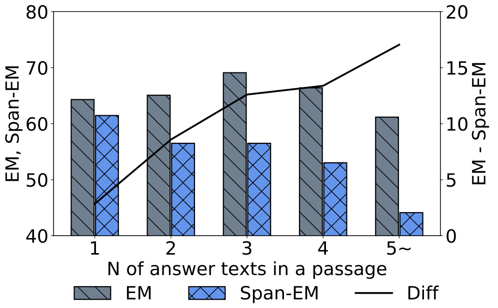


Figure 2: EM (text-matching) and Span-EM (span matching) of BERT on the groups divided by the number of answer text occurrences in a passage. Note: The difference for $N = 1$ results from post-processing steps (removing articles) in EM evaluation.

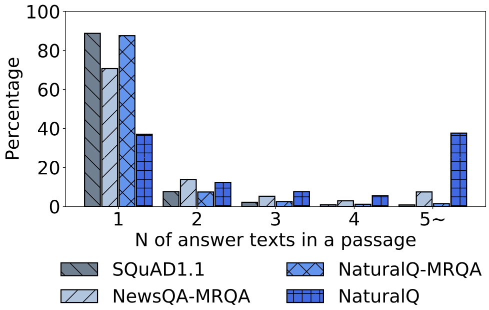

Figure 3: Proportions of questions with various numbers of the answer text in a passage. SQuAD has only a few examples for ($n \geq 5$), while NaturalQuestions has a large proportion.

- We show that context prediction task plays a key role in the QA domain.
- We propose a new model BLANC that resolves the discrepancy between answer text prediction and answer-span prediction.

2 Related Work

Evidence in the form of documents, paragraphs, and sentences, has been shown to be necessary and effective in predicting the answers in open-domain QA (Chen et al., 2017; Wang et al., 2018; Das et al., 2018; Lee et al., 2019) and multi-hop QA (Yang et al., 2018; Min et al., 2019b; Asai et al., 2020). One problem of identifying evidence in answering questions is the expensive cost in labeling the evidence. Self-labeling with simple heuristics can be a solution to this problem, as shown in Choi et al. (2017); Li et al. (2018). Self-training is another solution, as presented in Niu et al. (2020). In this paper, we propose self-generating soft-labeling method to indicate support words of answer texts, and train BLANC with the soft-labels.

---

[1] `https://github.com/yeonsw/BLANC`

Related but different from our work, Swayamdipta et al. (2018) and Min et al. (2019a) predict the answer-span when only the answer texts are provided and the ground truth answer-spans are not. Swayamdipta et al. (2018) designs a model that benefits from aggregating information from multiple mentions of the answer text in predicting the final answer. Min et al. (2019a) approach the problem of the lack of ground truth answer-spans with latent modeling of candidate spans. Both of these papers tackle the problem of identifying the correct answer among multiple mentions of the answer text in datasets without annotations of the correct answer-spans. Our work solves a different problem from the above-mentioned papers in that the golden answer-spans are provided.

3 Model

We propose BLANC based on two novel ideas: soft-labeling method for the context prediction and a block attention method that predicts the soft-labels. Two important functionalities of BLANC are 1) calculating the probability that a word in a passage belongs to the context, which is in latent, and 2) enabling the probability to reflect spatial locality between adjacent words. We provide an overall illustration of BLANC in Figure 4.

3.1 Notations

In this section, we define the notations and the terms used in our study. We denote a word at index i in a passage with w_i. We define the context of a given question as a segment of words in a passage and denote with $\mathcal{C}$. In our circumstance, the context is latent. We denote the start and end indices of a context with s_c and e_c. Training a block attention model to predict the context requires the labeling process for the latent context, and we define two probabilities for that, $p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C})$ and $p(\mathrm{w}_i \in \mathcal{C})$. $p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C})$ represents the self-generated soft-label that we assume as ground truth of the context, and $p(\mathrm{w}_i \in \mathcal{C})$ is a block attention model's prediction. We denote the start and end indices of a labeled answer-span with s_a and e_a.

3.2 Soft-labeling for latent context $\mathcal{C}$

We assume words near an answer-span are likely to be included in the context of a given question. From our assumption, we define the probability of words belong to the context, $p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C})$, which is used as a soft-label for the auxiliary context prediction task. To achieve this, we hypothesize the words in an answer-span are included in the context and make the probability of adjacent words decrease with a specific ratio as the distance between answer-span and a word increases. The soft-label for the latent context is as follows:

$$p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C}) = \begin{cases} 1.0 & \text{if } i \in [s_a, e_a] \\ q^{|i-s_a|} & \text{if } i < s_a \\ q^{|i-e_a|} & \text{if } i > e_a, \end{cases} \quad (1)$$

where $0 \leq q \leq 1$, and q is a hyper-parameter for the decreasing ratio as the distance from a given answer-span. For computational efficiency, we apply (1) to words bounded by certain window-size only, which is a hyper-parameter, on both sides of an answer-span. This results in assigning $p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C})$ to 0 for the words outside the segment bounded by the window-size.

3.3 Block Attention

Block attention model calculates $p(\mathrm{w}_i \in \mathcal{C})$ to predict the soft-label, $p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C})$, and localizes the correct index of an answer-span with $p(\mathrm{w}_i \in \mathcal{C})$. We embed spatial locality of $p(\mathrm{w}_i \in \mathcal{C})$ to block attention model with the following steps: 1) predicting the start and end indices of context, $p(i = s_c)$ and $p(i = e_c)$, and 2) calculating $p(\mathrm{w}_i \in \mathcal{C})$ with cumulative distribution of $p(i = s_c)$ and $p(i = e_c)$. In the first step, at predicting the start and end indices, all encoder models that produce vector representation of words in a passage are compatible with the block attention model. In this paper, we apply the same structure of the answer-span classification layer used in the transformer model (Devlin et al., 2019) to our context words prediction layer.

$$\boldsymbol{H} = \text{Encoder}(\text{Passage}, \text{Question}) \quad (2)$$

Here, we denote $\boldsymbol{H}$ as output vectors of transformer encoder and $\boldsymbol{H}_j$ as output vector of w_j. From $\boldsymbol{H}$, we predict the start and end indices of the context:

$$\begin{aligned} p(i = s_c) &= \frac{\exp(\boldsymbol{W_c}\boldsymbol{H}_i + b_s^c)}{\sum_j \exp(\boldsymbol{W_c}\boldsymbol{H}_j + b_s^c)}, \\ p(i = e_c) &= \frac{\exp(\boldsymbol{V_c}\boldsymbol{H}_i + b_e^c)}{\sum_j \exp(\boldsymbol{V_c}\boldsymbol{H}_j + b_e^c)}, \end{aligned} \quad (3)$$

where $\boldsymbol{W_c}$, $\boldsymbol{V_c}$, b_s^c, and b_e^c represent weight and bias parameters for context prediction layer. We calculate $p(\mathrm{w}_i \in \mathcal{C})$ as multiplication of the probability

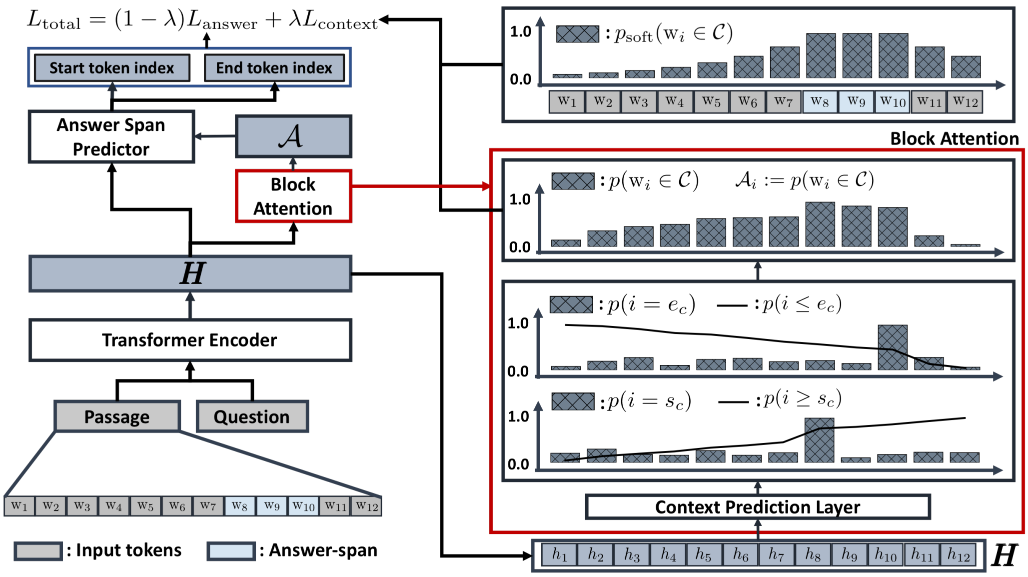

Figure 4: Schematic visualization of BLANC. Block attention model takes contextual vector representations from transformer encoder and predicts context words of an answer, $p(\text{w}_i \in \mathcal{C})$. We define loss function for context words with the prediction, $p(\text{w}_i \in \mathcal{C})$ and the self-generated soft-label $p_{\text{soft}}(\text{w}_i \in \mathcal{C})$ defined in (1). Answer-span predictor takes $p(\text{w}_i \in \mathcal{C}$ and $\boldsymbol{H}$ to predict an answer-span. We optimize our model in manner of multi-task learning of two tasks: answer-span prediction and context words prediction.

of the word w_i which appears after s_c and that of the word w_i which appears before e_c.

$$p(\text{w}_i \in \mathcal{C}) = p(i \geq s_c) \times p(i \leq e_c). \quad (4)$$

Here, we assume the independence between s_c and e_c for computational conciseness. The cumulative distributions of $p(i \geq s_c)$ and $p(i \leq e_c)$ are calculated with the following equations:

$$\begin{aligned} p(i \geq s_c) &= \sum_{j \leq i} p(j = s_c) \\ p(i \leq e_c) &= \sum_{j \geq i} p(j = e_c). \end{aligned} \quad (5)$$

We explicitly force the block attention model to learn context words of a given question by minimizing the cross-entropy of the two probabilities, $p(\text{w}_i \in \mathcal{C})$ and $p_{\text{soft}}(\text{w}_i \in \mathcal{C})$. The loss function for the latent context is defined by the following equation:

$$\begin{aligned} L_{\text{context}} = &- \sum_{1 \leq i \leq l} p_{\text{soft}}(\text{w}_i \in \mathcal{C}) \log p(\text{w}_i \in \mathcal{C}) \\ &- \sum_{1 \leq i \leq l} p_{\text{soft}}(\text{w}_i \notin \mathcal{C}) \log p(\text{w}_i \notin \mathcal{C}), \end{aligned} \quad (6)$$

where l is the length of a passage. By averaging L_{context} across all train examples, we get the final context loss function.

3.4 Answer-span Prediction

BLANC predicts answer-span with the context probability, $p(\text{w}_i \in \mathcal{C})$. We use the same answer-span prediction layer as BERT, but we multiply $p(\text{w}_i \in \mathcal{C})$ to the output of the encoder, $\boldsymbol{H}$ to give attention at indices of answer-span within the context, $\mathcal{C}$.

$$\begin{aligned} p(i = s_a) &= \frac{\exp(\mathcal{A}_i \boldsymbol{W_a} \boldsymbol{H}_i + b_s^a)}{\sum_j \exp(\mathcal{A}_j \boldsymbol{W_a} \boldsymbol{H}_j + b_s^a)}, \\ p(i = e_a) &= \frac{\exp(\mathcal{A}_i \boldsymbol{V_a} \boldsymbol{H}_i + b_e^a)}{\sum_j \exp(\mathcal{A}_j \boldsymbol{V_a} \boldsymbol{H}_j + b_e^a)}, \end{aligned} \quad (7)$$

where $\boldsymbol{W_a}$, $\boldsymbol{V_a}$, b_s^a, and b_e^a represent weight and bias parameters for answer-span prediction layer, and $\mathcal{A}_i = p(\text{w}_i \in \text{context})$. The loss function for answer-span prediction is defined by the following equation:

$$\begin{aligned} L_{\text{answer}} = -\frac{1}{2}\{ &\sum_{1 \leq i \leq l} \mathbb{1}(i = s_a) \log p(i = s_a) \\ &+ \sum_{1 \leq i \leq l} \mathbb{1}(i = e_a) \log p(i = e_a)\}. \end{aligned} \quad (8)$$

$\mathbb{1}(\text{condition})$ represents an indicator function that returns 1 if the condition is true and returns 0 otherwise. By averaging L_{answer} across all train examples, we get the final answer-span loss function. We define our final loss function as the weighted sum of the two loss functions:

$$L_{\text{total}} = (1-\lambda)L_{\text{answer}} + \lambda L_{\text{context}}, \tag{9}$$

where λ is a hyper-parameter moderating the ratio of two loss functions.

3.5 Property of Block Attention

$p_{\text{soft}}(\mathrm{w}_i \in \mathcal{C})$ defined at (1) can be represented by the probability distributions calculated by block attention model, $p(\mathrm{w}_i \in \mathcal{C})$. We provide detailed proof in Appendix A.1.

4 Experimental Setup

We validate the efficacy of BLANC on two types of tasks: extractive QA and zero-shot supporting fact prediction. In the extractive QA, we evaluate the overall reading comprehension performance with three QA datasets, and we further analyze the ability of BLANC to discern relevant contexts on passages with multiple answer texts. In zero-shot supporting facts prediction, we train QA models on SQuAD (Rajpurkar et al., 2016) and predict supporting facts (supporting sentences) of answers in HotpotQA (Yang et al., 2018). Due to our experimental computing resource limitation, we compare BLANC to baseline models trained in slightly modified hyperparameter settings instead of the results from their original papers.

4.1 Datasets

SQuAD: SQuAD1.1 (Rajpurkar et al., 2016) is a large reading comprehension dataset for QA. Since the test set for SQuAD1.1 (Rajpurkar et al., 2016) is not publicly available, and their benchmark does not provide an evaluation on the span-based metric, we split train data (90%/10%) into new train/dev dataset and use development dataset as test dataset.

NewsQA & NaturalQ: NewsQA (Trischler et al., 2017) consists of answer-spans to questions generated in a way that reflects realistic information seeking processes in the news domain. NaturalQuestions (Kwiatkowski et al., 2019) is a QA benchmark in a real-world scenario with Google search queries for naturally-occurring questions and passages from Wikipedia for annotating answer-spans. Due to computational limits, we use the curated versions of NewsQA and NaturalQ provided by Fisch et al. (2019). The curated datasets contain train and development set only, so we use the development set as the test set and build new train and dev sets from the train set (90%/10%).

HotpotQA: HotpotQA (Yang et al., 2018) aims to measure complex reasoning performance of QA models and requires finding relevant sentences from the given passages. HotpotQA consists of passages, questions, answer, and corresponding supporting facts (sentences) for each answer. We use the development set in HotpotQA.

4.2 Evaluation Metrics

F1 and EM are evaluation metrics widely used in existing QA models (Rajpurkar et al., 2016). These two metrics measure the number of overlapping tokens between the predicted answers and the ground truth answers. Token matching evaluation treats as correct even answers in unrelated contexts, thus being insufficient to evaluate the context prediction performance. As the alternatives, we propose span-EM and span-F1. We modify the metric proposed in Kwiatkowski et al. (2019) to be suitable for our experiment setting.

Span-F1 and Span-EM: Span-F1 and span-EM are defined with overlapping indices between the predicted span and the ground truth span:

$$\begin{aligned}
\text{Span-P} &= |[s_p, e_p] \cap [s_g, e_g]| / |[s_p, e_p]| \\
\text{Span-R} &= |[s_p, e_p] \cap [s_g, e_g]| / |[s_g, e_g]| \\
\text{Span-F1} &= 2 \times \frac{\text{Span-P} \times \text{Span-R}}{\text{Span-P} + \text{Span-R}} \\
\text{Span-EM} &= \mathbb{1}(s_p = s_g \wedge e_p = e_g)
\end{aligned}$$

Here, s_p / e_p represent the start/end indices of a predicted answer-span in a passage and s_g / e_g denote the start/end indices of the ground truth answer-span in a passage. Span-EM measures exactly matched predicted spans, and Span-F1 quantifies the degree of overlap between the predicted answer-span and the ground truth span.

4.3 Baselines

BERT, RoBERTa, and ALBERT: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and ALBERT (Lan et al., 2019) are language models built upon the transformer encoder. They use the same model structure, except for the bigger vocabulary size of RoBERTa. Due to the computational limitation, we use 12-layer base models for BERT, and RoBERTa and 24-layer large model for ALBERT.

SpanBERT: SpanBERT (Joshi et al., 2020) has the same model structure and the same parameter

		#Param	Span-F1	Span-EM	F1	EM
NaturalQA	BERT	108M	72.92 ± 0.36	60.63 ± 0.39	76.39 ± 0.26	64.48 ± 0.28
	ALBERT	17M	72.66 ± 0.48	60.31 ± 0.49	75.89 ± 0.36	63.81 ± 0.37

	BLANC$_{\text{large}}$	333M	$\mathbf{66.48 \pm 0.20}$	$\mathbf{52.39 \pm 0.08}$	$\mathbf{72.36 \pm 0.01}$	$\mathbf{57.40 \pm 0.21}$

Table 1: Reading comprehension performance of baseline models and BLANC. We conduct experiments on three QA datasets: NaturalQ, SQuAD1.1, and NewsQA. For all evaluation metrics, we report mean and standard deviation of three separate trials. The results show that BLANC outperforms baseline models.

size as BERT. SpanBERT uses span-oriented pretraining for span representation. Since the block attention is stacked on SpanBERT, and to provide detailed results of effectiveness of BLANC, we use both 12-layer SpanBERT-base and 24-layer SpanBERT-large.

4.4 Hyper-parameter Settings

We conduct experiments on limited hyper-parameter settings (e.g. max_len, batch size), as we were limited by computational resources. We use the same hyperparameter settings across all baseline models and BLANC. We set the training batch size to 8, learning-rate to $2 \times e^{-5}$, the number of train epochs to 3, the max sequence length of transformer encoder to 384, warm-up proportion to 10%, and we use the various optimizers used in the respective original papers. We set λ to 0.8, which is the optimal value as we show in Figure 6, for all experiments except the large model experiment on SQuAD1.1. We set $\lambda = 0.2$ in the large model experiment on SQuAD1.1. We use different q, the decreasing ratio in (1), and different window-size for each dataset to reflect the average length of passages of each QA datasets. We set $q = 0.7$ and window-size to 2 on SQuAD which contains relatively short passages, and $q = 0.99$ and window-size to 3 on the other two QA datasets where most passages are longer than SQuAD. q and window-size are optimized empirically.

	Span-F1	Span-EM
RoBERTa	65.99 ± 0.92	60.12 ± 0.86
SpanBERT	63.47 ± 0.72	57.63 ± 0.79
BLANC	$\mathbf{67.07 \pm 0.36}$	$\mathbf{61.43 \pm 0.38}$

5 Results & Discussion

We now present the results for the experiments described in the previous section. We describe the overall reading comprehension performance, highlighting the increased gain for passages with multiple mentions of the answer text. We show that

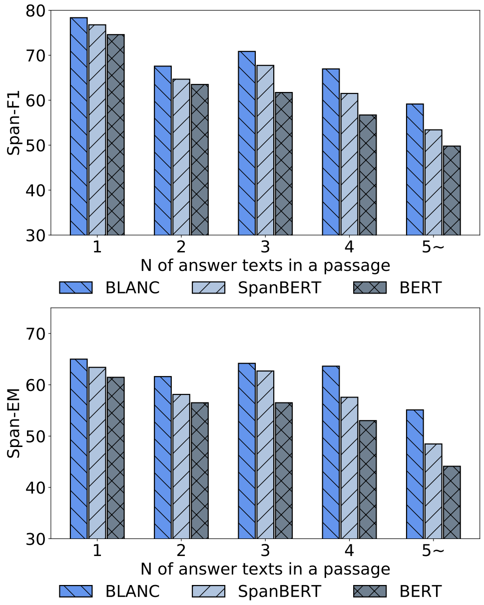

Figure 5: Span-F1 and Span-EM of baseline models and BLANC trained on NaturalQ. We categorize NaturalQ dataset into five groups by number answer texts appeared in a passage: $n = 1, 2, 3, 4$, and $n \geq 5$. BLANC outperforms baseline models on every groups and the performance gap increases as the number of answer texts in a passage increases.

BLANC outperforms other models for zero-shot supporting fact prediction. We also demonstrate the importance of the context prediction loss and the negligible extra parameter and inference time.

5.1 Reading Comprehension

We verify the reading comprehension performance of BLANC with four evaluation metrics (F1, EM, Span-F1, and Span-EM) on three QA datasets: SQuAD, NaturalQ, and NewsQA. We show the results in Table 1 which shows BLANC consistently outperforms all comparison models including RoBERTa and SpanBERT.

We focus on the evaluation metric Span-EM which measures the exact match of the answer-span, and we further highlight the performance gain of BLANC over the most recent SpanBERT model, both base and large. On NaturalQ, BLANC outperforms SpanBERT by 1.86, whereas the performance difference between SpanBERT and RoBERTa is 0.12. On NewsQA, BLANC outperforms by 2.56, whereas the difference between SpanBERT and RoBRTa is 0.61. This pattern holds for the large models as well.

We now compare the performance gain between the datasets. Recall that we showed in Figure 3 the proportion of multi-mentioned answer is smallest in SQuAD, medium for NaturalQ-MRQA, and largest in NewsQA-MRQA. Reading comprehension results show the performance gap of BLANC and SpanBERT increases in the same order, verifying the effectiveness of BLANC on the realistic multi-mentioned datasets.

	Accuracy
BERT	33.34 ± 0.82
ALBERT$_{\text{large}}$	35.62 ± 1.17
RoBERTa	37.93 ± 0.80
SpanBERT	34.79 ± 0.40
BLANC	**39.80 ± 1.18**

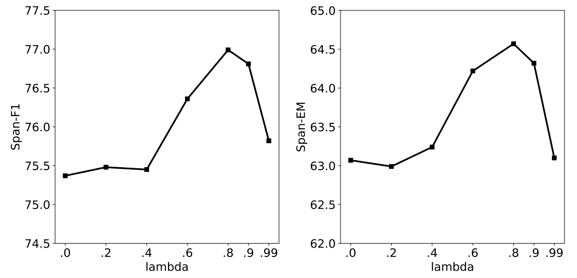
Table 3: Performance on zero-shot supporting fact (supporting sentence) prediction by models trained with SQuAD1.1. BLANC outperforms all other models.

5.2 Performance on Passages with Multi-mentioned Answers

In Section 5.1, we show Span-EM and EM of BLANC and baselines on the entire datasets. However, the context discerning performance is only observed on passages with multiple mentions of the answer text. We investigate the context-aware performance (distinguishing relevant context and irrelevant context) of BLANC by categorizing NaturalQ dataset by the number of occurrences of the answer text in a passage. We subdivide the dataset into five groups: $n = 1, 2, 3, 4$ and $n \geq 5$, where n is the number of occurrences of the answer text in a passage. Figure 5 presents Span-F1 and Span-EM on those subsets of the data. BLANC outperforms SpanBERT and BERT across all subsets, and we show that the performance gain increases as n increases. In Table 2, we explicitly show reading comprehension performance of BLANC on the question-answer pairs of passages with $n \geq 2$ from NaturalQ, and we confirm that block attention method increases context-aware performance of SpanBERT by 3.6 with Span-F1, and by 3.8 with Span-EM, which are larger improvements than the increments on the data including $n = 1$ shown in Table 1.

5.3 Supporting Facts Prediction

We present the results of the zero-shot supporting facts prediction task on HotpotQA dataset (Yang et al., 2018) in Table 3. HotpotQA has ten passages and two supporting facts (sentences) for each question-answer pair. Since HotpotQA has a different data format than the extractive QA datasets, we curate HotpotQA with the following steps. We con-



(a) Span-F1 (b) Span-EM

Figure 6: Analysis on λ for context word prediction for NaturalQ. We adjust λ, weight of (L_{context}), from 0.0 to 0.99 and report Span-F1 and Span-EM. Increasing λ improves answer-span prediction until $\lambda = 0.8$ and then decreases. This decrease is expected as the weight for (L_{answer}) becomes too small.

	Train	Inf
BERT	1.00x	1.00x
ALBERT$_{\text{large}}$	1.42x	1.89x
RoBERTa	1.01x	1.02x
SpanBERT	1.00x	1.00x
BLANC	1.04x	1.00x

Table 4: Training and inference time of each model measured on the same number of QA pairs.

catenate the ten passages to make one passage. Two supporting facts exist in the passage. By removing each one of them, we build two passages and each of passage contains one supporting fact. We repeat this process for all examples in HotpotQA. As a result, the curated dataset contains triples of one question, one supporting fact, and one passage. We report the accuracy of models by checking if the supporting fact includes the predicted span. We train baseline models and BLANC on SQuAD1.1 and test on the curated development set of HotpotQA dataset. Table 3 shows that BLANC captures sentence relevant to the given question better than other baseline models in zero-shot setting. This result shows that BLANC is capable of applying what it has learned from one dataset to predicting the context of an answer to a question in another dataset.

5.4 Analysis on λ

We verify the relationship between reading comprehension performance and context word prediction task by conducting reading comprehension experiment with $\lambda = [0.2, 0.4, 0.6, 0.8, 0.9, 0.99]$. The hyperparameter λ represents weight of L_{context} in the total loss function L_{total}. Figure 6 shows that the performance increases as λ increases until it reaches 0.8 and decreases after $\lambda = 0.8$. Leveraging the context word prediction task increases reading comprehension performance, and we show efficacy of BLANC. As λ increases, the weight on L_{answer} decreases, so we expect to see a decrease in performance as λ becomes too large.

5.5 Space and Time Complexity

The additional parameters of block attention model come from Eq. (3) in Section 3.3. The number of parameters is $(768 + 1) * 2 = 1538$ when the hidden dimension size of the transformer encoder is 768, and 1538 is negligible considering the total number of parameters in BERT-base (108M). The exact numbers of parameters of baseline models are presented in Table 1. Table 4 shows relative training and inference time of baseline models and BLANC. We measure each model's train time on the same number of train steps and the inference time on the same number of passage-question pairs. Since we use the 24-layer ALBERT-large model which has twice as many layers as other models, ALBERT requires the longest training/inference time, despite its much smaller model size. BLANC requires 4% extra training time which includes the time to generate the soft-labels in (1) and the time to calculate the context word distribution in (4). For inference, BLANC requires negligible additional time on SpanBERT.

6 Conclusion

In this paper, we showed the importance of predicting an answer with the correct context of a given question. We proposed BLANC with two novel ideas: context word prediction task and a block attention method that identifies an answer within the context of a given question. The context words prediction task labels latent context words with the labeled answer-span and is used in a multi-task learning manner. Block attention models the latent context words with negligible extra parameters and training/inference time. We showed that BLANC increases reading comprehension performance, and we verify that the performance gain increases for complex examples (i.e., when the answer occurs two or more times in the passage). Also, we showed the generalizability of BLANC and its context-aware performance with the zero-shot supporting fact prediction task on the HotpotQA dataset.
