Here $\times$ may denote any operator on V_2. The objective is to incorporate (inverse) selectional preference information from the context (r, w') in such a way as to identify the correct word sense of w. This suggests that the dimensions of $[\![w]\!]$ should be filtered so that only those compatible with the context remain. A more flexible approach than simple filtering, however, is to re-weight those dimensions with context information. This can be expressed by pointwise vector multiplication (in terms of the given basis of V_2). We therefore take $\times$ to be pointwise multiplication.

To contextualize (the vector of) a word w with multiple words $w_1, \ldots, w_n$ and corresponding relations $r_1, \ldots, r_n$, we compute the sum of the results of the pairwise contextualizations of the target vector with the vectors of the respective dependents:

$$[\![w_{r_1:w_1,\ldots,r_n:w_n}]\!] = \sum_{k=1}^{n} [\![w_{r_k:w_k}]\!]$$

4 Experiments: Ranking Paraphrases

In this section, we evaluate our model on a paraphrase ranking task. We consider sentences with an occurrence of some target word w and a list of paraphrase candidates $w_1, \ldots, w_k$ such that each of the w_i is a paraphrase of w for some sense of w. The task is to decide for each of the paraphrase candidates w_i how appropriate it is as a paraphrase of w in the given context. For instance, *buy*, *purchase* and *obtain* are all paraphrases of *acquire*, in the sense that they can be substituted for *acquire* in some contexts, but *purchase* and *buy* are not paraphrases of *acquire* in the first sentence of Table 1.

Sentence	Paraphrases
Teacher education students will *acquire* the knowledge and skills required to [...]	gain 4; amass 1; receive 1; obtain 1
Ontario Inc. will [...] *acquire* the remaining IXOS shares [...]	buy 3; purchase 1; gain 1; get 1; procure 2; obtain 1

Table 1: Two examples from the lexical substitution task data set

4.1 Resources

We use a vector model based on dependency trees obtained from parsing the English Gigaword corpus (LDC2003T05). The corpus consists of news from several newswire services, and contains over four million documents. We parse the corpus using the Stanford parser[1] (de Marneffe et al., 2006) and a non-lexicalized parser model, and extract over 1.4 billion dependency triples for about 3.9 million words (lemmas) from the parsed corpus.

To evaluate the performance of our model, we use various subsets of the SemEval 2007 lexical substitution task (McCarthy and Navigli, 2007) dataset. The complete dataset contains 10 instances for each of 200 target words—nouns, verbs, adjectives and adverbs—in different sentential contexts. Systems that participated in the task had to generate paraphrases for every instance, and were evaluated against a gold standard containing up to 10 possible paraphrases for each of the individual instances.

There are two natural subtasks in generating paraphrases: identifying paraphrase candidates and ranking them according to the context. We follow E&P and evaluate it only on the second subtask: we extract paraphrase candidates from the gold standard by pooling all annotated gold-standard paraphrases for all instances of a verb in all contexts, and use our model to rank these paraphrase candidates in specific contexts. Table 1 shows two instances of the target verb *acquire* together with its paraphrases in the gold standard as an example. The paraphrases are attached with weights, which correspond to the number of times they have been given by different annotators.

4.2 Evaluation metrics

To evaluate the performance of our method we use *generalized average precision* (Kishida, 2005), a variant of *average precision.*

Average precision (Buckley and Voorhees, 2000) is a measure commonly used to evaluate systems that return ranked lists of results. Generalized average precision (GAP) additionally rewards the correct order of positive cases w.r.t. their gold standard weight. We define average precision first:

$$AP = \frac{\Sigma_{i=1}^{n} x_i \, p_i}{R} \qquad p_i = \frac{\Sigma_{k=1}^{i} x_k}{i}$$

where x_i is a binary variable indicating whether the ith item as ranked by the model is in the gold standard or not, R is the size of the gold standard, and n is the number of paraphrase candidates to be ranked. If we take x_i to be the gold standard weight of the ith item or zero if it is not in the gold standard, we can define *generalized average precision* as follows:

$$GAP = \frac{\sum_{i=1}^{n} I(x_i) \, p_i}{\sum_{i=1}^{R} I(y_i)\bar{y}_i}$$

where $I(x_i) = 1$ if x_i is larger than zero, zero otherwise, and $\bar{y}_i$ is the average weight of the ideal ranked list $y_1, \ldots, y_i$ of gold standard paraphrases.

As a second scoring method, we use *precision out of ten* (P_{10}). The measure is less discriminative than GAP. We use it because we want to compare our model with E&P. P_{10} measures the percentage of gold-standard paraphrases in the top-ten list of paraphrases as ranked by the system, and can be defined as follows (McCarthy and Navigli, 2007):

$$P_{10} = \frac{\Sigma_{s \in M \cap G} \, f(s)}{\Sigma_{s \in G} \, f(s)},$$

where M is the list of 10 paraphrase candidates top-ranked by the model, G is the corresponding annotated gold-standard data, and $f(s)$ is the weight of the individual paraphrases.

4.3 Experiment 1: Verb paraphrases

In our first experiment, we consider verb paraphrases using the same controlled subset of the

[1] We use version 1.6 of the parser. We modify the dependency trees by "folding" prepositions into the edge labels to make the relation between a head word and the head noun of a prepositional phrase explicit.

lexical substitution task data that had been used by TDP in an earlier study. We compare our model to various baselines and the models of TDP and E&P, and show that our new model substantially outperforms previous work.

Dataset. The dataset is identical to the one used by TDP and has been constructed in the same way as the dataset used by E&P: it contains those gold-standard instances of verbs that have—according to the analyses produced by the MiniPar parser (Lin, 1993)—an overtly realized subject and object. Gold-standard paraphrases that do not occur in the parsed British National Corpus are removed.[2] In total, the dataset contains 162 instances for 34 different verbs. On average, target verbs have 20.5 substitution candidates; for individual instances of a target verb, an average of 3.9 of the substitution candidates are annotated as correct paraphrases. Below, we will refer to this dataset as "LST/SO."

Experimental procedure. To compute the vector space, we consider only a subset of the complete set of dependency triples extracted from the parsed Gigaword corpus. We experimented with various strategies, and found that models which consider all dependency triples exceeding certain *pmi*- and frequency thresholds perform best.

Since the dataset is rather small, we use a four-fold cross-validation method for parameter tuning: We divide the dataset into four subsets, test various parameter settings on one subset and use the parameters that perform best (in terms of GAP) to evaluate the model on the three other subsets. We consider the following parameters: *pmi*-thresholds for the dependency triples used in the computation of the first- and second-order vectors, and frequency thresholds. The parameters differ only slightly between the four subsets, and the general tendency is that good results are obtained if a low *pmi*-threshold (≤ 2) is applied to filter dependency triples used in the computation of the second-order vectors, and a relatively high *pmi*-threshold (≥ 4) to filter dependency triples in the computation of the first-order vectors. Good performing frequency thresholds are 10 or 15. The threshold values for context vectors are slightly different: a medium *pmi*-threshold between 2 and 4 and a low frequency threshold of 3.

To rank paraphrases in context, we compute contextualized vectors for the verb in the input sentence, i.e., a second order vector for the verb that is contextually constrained by the first order vectors of all its arguments, and compare them to the unconstrained (second-order) vectors of each paraphrase candidate, using cosine similarity.[3] For the first sentence in Table 1, for example, we compute $[\![\text{acquire}_{\text{SUBJ:student,OBJ:knowledge}}]\!]$ and compare it to $[\![\text{gain}]\!]$, $[\![\text{amass}]\!]$, $[\![\text{buy}]\!]$, $[\![\text{purchase}]\!]$ and so on.

Baselines. We evaluate our model against a random baseline and two variants of our model: One variant ("2^{nd} order uncontexualized") simply uses contextually unconstrained second-order vectors to rank paraphrase candidates. Comparing the full model to this variant will show how effective our method of contextualizing vectors is. The second variant ("1^{st} order contextualized") represents verbs in context by their first order vectors that specify how often the verb co-occurs with its arguments in the parsed Gigaword corpus. We compare our model to this baseline to demonstrate the benefit of (contextualized) second-order vectors. As for the full model, we use *pmi* values rather than raw frequency counts as co-occurrence statistics.

Results. For the LST/SO dataset, the generalized average precision, averaged over all instances in the dataset, is 45.94%, and the average P_{10} is 73.11%.

Table 2 compares our model to the random baseline, the two variants of our model, and previous work. As can be seen, our model improves about 8% in terms of GAP and almost 7% in terms of P_{10} upon the two variants of our model, which in turn perform 10% above the random baseline. We conclude that both the use of second-order vectors, as well as the method used to contextualize them, are very effective for the task under consideration.

The table also compares our model to the model of TDP and two different instantiations of E&P's model. The results for these three models are cited from Thater et al. (2009). We can observe that our model improves about 9% in terms of GAP and about 7% in terms of P_{10} upon previous work. Note that the results for the E&P models are based

[2] Both TDP and E&P use the British National Corpus.

[3] Note that the context information is the same for both words. With our choice of pointwise multiplication for the composition operator $\times$ we have $(\vec{v}_1 \times \vec{w}) \cdot \vec{v}_2 = \vec{v}_1 \cdot (\vec{v}_2 \times \vec{w})$. Therefore the choice of which word is contextualized does not strongly influence their cosine similarity, and contextualizing both should not add any useful information. On the contrary we found that it even lowers performance. Although this could be repaired by appropriately modifying the operator $\times$, for this experiment we stick with the easier solution of only contextualizing one of the words.

Model	GAP	P_{10}
Random baseline	26.03	54.25
E&P (add, object)	29.93	66.20
E&P (min, subject & object)	32.22	64.86
TDP	36.54	63.32
1^{st} order contextualized	36.09	59.35
2^{nd} order uncontextualized	37.65	66.32
Full model	**45.94**	**73.11**

Table 2: Results of Experiment 1

on a reimplementation of E&P's original model—the P_{10}-scores reported by Erk and Padó (2009) range between 60.2 and 62.3, over a slightly lower random baseline.

According to a paired t-test the differences are statistically significant at $p < 0.01$.

Performance on the complete dataset. To find out how our model performs on less controlled datasets, we extracted all instances from the lexical substitution task dataset with a verb target, excluding only instances which could not be parsed by the Stanford parser, or in which the target was mistagged as a non-verb by the parser. The resulting dataset contains 496 instances. As for the LST/SO dataset, we ignore all gold-standard paraphrases that do not occur in the parsed (Gigaword) corpus.

If we use the best-performing parameters from the first experiment, we obtain a GAP score of 45.17% and a P_{10}-score of 75.43%, compared to random baselines of 27.42% (GAP) and 58.83% (P_{10}). The performance on this larger dataset is thus almost the same compared to our results for the more controlled dataset. We take this as evidence that our model is quite robust w.r.t. different realizations of a verb's subcategorization frame.

4.4 Experiment 2: Non-verb paraphrases

We now apply our model to parts of speech (POS) other than verbs. The main difference between verbs on the one hand, and nouns, adjectives, and adverbs on the other hand, is that verbs typically come with a rich context—subject, object, and so on—while non-verbs often have either no dependents at all or only closed class dependents such as determiners which provide only limited contextual informations, if any at all. While we can apply the same method as before also to non-verbs, we might expect it to work less well due to limited contextual information.

POS	Instances	M1	M2	Baseline
Noun	535	46.38	42.54	30.01
Adj	508	39.41	43.21	28.32
Adv	284	48.19	51.43	37.25

Table 3: GAP-scores for non-verb paraphrases using two different methods.

We therefore propose an alternative method to rank non-verb paraphrases: We take the second-order vector of the target's head and contextually constrain it by the first order vector of the target. For instance, if we want to rank the paraphrase candidates *hint* and *star* for the noun *lead* in the sentence

(1) Meet for coffee early, swap *leads* and get permission to contact if possible.

we compute $[\![\text{swap}_{\text{OBJ:lead}}]\!]$ and compare it to the lifted first-order vectors of all paraphrase candidates, $L_{\text{OBJ}}([\text{hint}])$ and $L_{\text{OBJ}}([\text{star}])$, using cosine similarity.

To evaluate the performance of the two methods, we extract all instances from the lexical substitution task dataset with a nominal, adjectival, or adverbial target, excluding instances with incorrect parse or no parse at all. As before, we ignore gold-standard paraphrases that do not occur in the parsed Gigaword corpus.

The results are shown in Table 3, where "M1" refers to the method we used before on verbs, and "M2" refers to the alternative method described above. As one can see, M1 achieves better results than M2 if applied to nouns, while M2 is better than M1 if applied to adjectives and adverbs. The second result is unsurprising, as adjectives and adverbs often have no dependents at all.

We can observe that the performance of our model is similarly strong on non-verbs. GAP scores on nouns (using M1) and adverbs are even higher than those on verbs. We take these results to show that our model can be successfully applied to all open word classes.

5 Experiment: Ranking Word Senses

In this section, we apply our model to a different word sense ranking task: Given a word w in context, the task is to decide to what extent the different

WordNet (Fellbaum, 1998) senses of *w* apply to this occurrence of *w*.

Dataset. We use the dataset provided by Erk and McCarthy (2009). The dataset contains ordinal judgments of the applicability of WordNet senses on a 5 point scale, ranging from *completely different* to *identical* for eight different lemmas in 50 different sentential contexts. In this experiment, we concentrate on the three verbs in the dataset: *ask*, *add* and *win*.

Experimental procedure. Similar to Pennacchiotti et al. (2008), we represent different word senses by the words in the corresponding synsets. For each word sense, we compute the centroid of the second-order vectors of its synset members. Since synsets tend to be small (they even may contain only the target word itself), we additionally add the centroid of the sense's hypernyms, scaled down by the factor 10 (chosen as a rough heuristic without any attempt at optimization).

We apply the same method as in Section 4.3: For each instance in the dataset, we compute the second-order vector of the target verb, contextually constrain it by the first-order vectors of the verb's arguments, and compare the resulting vector to the vectors that represent the different WordNet senses of the verb. The WordNet senses are then ranked according to the cosine similarity between their sense vector and the contextually constrained target verb vector.

To compare the predicted ranking to the gold-standard ranking, we use Spearman's ρ, a standard method to compare ranked lists to each other. We compute ρ between the similarity scores averaged over all three annotators and our model's predictions. Based on agreement between human judges, Erk and McCarthy (2009) estimate an upper bound ρ of 0.544 for the dataset.

Results. Table 4 shows the results of our experiment. The first column shows the correlation of our model's predictions with the human judgments from the gold-standard, averaged over all instances. All correlations are significant ($p < 0.001$) as tested by approximate randomization (Noreen, 1989).

The second column shows the results of a frequency-informed baseline, which predicts the ranking based on the order of the senses in WordNet. This (weakly supervised) baseline outperforms our unsupervised model for two of the three verbs. As a final step, we explored the effect of combining our rankings with those of the frequency baseline, by simply computing the average ranks of those two models. The results are shown in the third column. Performance is significantly higher than for both the original model and the frequency-informed baseline. This shows that our model captures an additional kind of information, and thus can be used to improve the frequency-based model.

Word	Present paper	WN-Freq	Combined
ask	0.344	0.369	0.431
add	0.256	0.164	0.270
win	0.236	0.343	0.381
average	*0.279*	*0.291*	*0.361*

Table 4: Correlation of model predictions and human judgments

6 Conclusion

We have presented a novel method for adapting the vector representations of words according to their context. In contrast to earlier approaches, our model incorporates detailed syntactic information. We solved the problems of data sparseness and incompatibility of dimensions which are inherent in this approach by modeling contextualization as an interplay between first- and second-order vectors.

Evaluating on the SemEval 2007 lexical substitution task dataset, our model performs substantially better than all earlier approaches, exceeding the state of the art by around 9% in terms of generalized average precision and around 7% in terms of precision out of ten. Also, our system is the first unsupervised method that has been applied to Erk and McCarthy's (2009) graded word sense assignment task, showing a substantial positive correlation with the gold standard. We further showed that a weakly supervised heuristic, making use of WordNet sense ranks, can be significantly improved by incorporating information from our system.

We studied the effect that context has on target words in a series of experiments, which vary the target word and keep the context constant. A natural objective for further research is the influence of varying contexts on the meaning of target expressions. This extension might also shed light on the status of the modelled semantic process, which we have been referring to in this paper as "contextualization". This process can be considered one of

mutual disambiguation, which is basically the view of E&P. Alternatively, one can conceptualize it as semantic composition: in particular, the head of a phrase incorporates semantic information from its dependents, and the final result may to some extent reflect the meaning of the whole phrase.

Another direction for further study will be the generalization of our model to larger syntactic contexts, including more than only the direct neighbors in the dependency graph, ultimately incorporating context information from the whole sentence in a recursive fashion.

Bootstrapping Semantic Analyzers from Non-Contradictory Texts

Ivan Titov **Mikhail Kozhevnikov**
Saarland University

{titov|m.kozhevnikov}@mmci.uni-saarland.de

Abstract

We argue that groups of unannotated texts with overlapping and non-contradictory semantics represent a valuable source of information for learning semantic representations. A simple and efficient inference method recursively induces joint semantic representations for each group and discovers correspondence between lexical entries and latent semantic concepts. We consider the generative semantics-text correspondence model (Liang et al., 2009) and demonstrate that exploiting the non-contradiction relation between texts leads to substantial improvements over natural baselines on a problem of analyzing human-written weather forecasts.

1 Introduction

In recent years, there has been increasing interest in statistical approaches to semantic parsing. However, most of this research has focused on supervised methods requiring large amounts of labeled data. The supervision was either given in the form of meaning representations aligned with sentences (Zettlemoyer and Collins, 2005; Ge and Mooney, 2005; Mooney, 2007) or in a somewhat more relaxed form, such as lists of candidate meanings for each sentence (Kate and Mooney, 2007; Chen and Mooney, 2008) or formal representations of the described world state for each text (Liang et al., 2009). Such annotated resources are scarce and expensive to create, motivating the need for unsupervised or semi-supervised techniques (Poon and Domingos, 2009). However, unsupervised methods have their own challenges: they are not always able to discover semantic equivalences of lexical entries or logical forms or, on the contrary, cluster semantically different or even opposite expressions (Poon and Domingos, 2009). Unsupervised approaches can only rely on distributional similarity of contexts (Harris, 1968) to decide on semantic relatedness of terms, but this information may be sparse and not reliable (Weeds and Weir, 2005). For example, when analyzing weather forecasts it is very hard to discover in an unsupervised way which of the expressions among "south wind", "wind from west" and "southerly" denote the same wind direction and which are not, as they all have a very similar distribution of their contexts. The same challenges affect the problem of identification of argument roles and predicates.

In this paper, we show that groups of unannotated texts with overlapping and non-contradictory semantics provide a valuable source of information. This form of weak supervision helps to discover implicit clustering of lexical entries and predicates, which presents a challenge for purely unsupervised techniques. We assume that each text in a group is independently generated from a full latent semantic state corresponding to the group. Importantly, the texts in each group do not have to be paraphrases of each other, as they can verbalize only specific parts (*aspects*) of the full semantic state, yet statements about the same aspects must not contradict each other. Simultaneous inference of the semantic state for the non-contradictory and semantically overlapping documents would restrict the space of compatible hypotheses, and, intuitively, 'easier' texts in a group will help to analyze the 'harder' ones.[1]

As an illustration of why this weak supervision may be valuable, consider a group of two non-contradictory texts, where one text mentions "2.2 bn GBP decrease in profit", whereas another one includes a passage "profit fell by 2.2 billion pounds". Even if the model has not observed

[1] This view on this form of supervision is evocative of co-training (Blum and Mitchell, 1998) which, roughly, exploits the fact that the same example can be 'easy' for one model but 'hard' for another one.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 958–967,
Uppsala, Sweden, 11-16 July 2010.

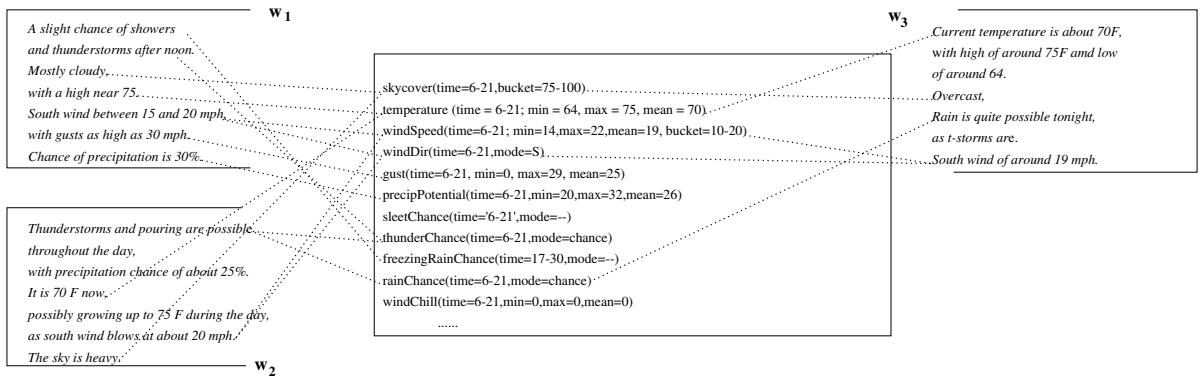

Figure 1: An example of three non-contradictory weather forecasts and their alignment to the semantic representation. Note that the semantic representation (the block in the middle) is not observable in training.

the word "fell" before, it is likely to align these phrases to the same semantic form because of similarity of their arguments. And this alignment would suggest that "fell" and "decrease" refer to the same process, and should be clustered together. This would not happen for the pair "fell" and "increase" as similarity of their arguments would normally entail contradiction. Similarly, in the example mentioned earlier, when describing a forecast for a day with expected south winds, texts in the group can use either "south wind" or "southerly" to indicate this fact but no texts would verbalize it as "wind from west", and therefore these expressions will be assigned to different semantic clusters. However, it is important to note that the phrase "wind from west" may still appear in the texts, but in reference to other time periods, underlying the need for modeling alignment between grouped texts and their latent meaning representation.

As much of the human knowledge is redescribed multiple times, we believe that non-contradictory and semantically overlapping texts are often easy to obtain. For example, consider semantic analysis of news articles or biographies. In both cases we can find groups of documents referring to the same events or persons, and though they will probably focus on different aspects and have different subjective passages, they are likely to agree on the core information (Shinyama and Sekine, 2003). Alternatively, if such groupings are not available, it may still be easier to give each semantic representation (or a state) to multiple annotators and ask each of them to provide a textual description, instead of annotating texts with semantic expressions. The state can be communicated to them in a visual or audio form (e.g., as a picture or a short video clip) ensuring that their interpretations are consistent.

Unsupervised learning with shared latent semantic representations presents its own challenges, as exact inference requires marginalization over possible assignments of the latent semantic state, consequently, introducing non-local statistical dependencies between the decisions about the semantic structure of each text. We propose a simple and fairly general approximate inference algorithm for probabilistic models of semantics which is efficient for the considered model, and achieves favorable results in our experiments.

In this paper, we do not consider models which aim to produce complete formal meaning of text (Zettlemoyer and Collins, 2005; Mooney, 2007; Poon and Domingos, 2009), instead focusing on a simpler problem studied in (Liang et al., 2009). They investigate grounded language acquisition set-up and assume that semantics (*world state*) can be represented as a set of *records* each consisting of a set of *fields*. Their model segments text into utterances and identifies records, fields and field values discussed in each utterance. Therefore, one can think of this problem as an extension of the semantic role labeling problem (Carreras and Marquez, 2005), where predicates (i.e. *records* in our notation) and their arguments should be identified in text, but here arguments are not only assigned to a specific role (*field*) but also mapped to an underlying equivalence class (*field value*). For example, in the weather forecast domain field *sky cover* should get the same value given expressions "overcast" and "very cloudy" but a different one if the expres-

sions are "clear" or "sunny". This model is hard to evaluate directly as text does not provide information about all the fields and does not necessarily provide it at the sufficient granularity level. Therefore, it is natural to evaluate their model on the database-text alignment problem (Snyder and Barzilay, 2007), i.e. measuring how well the model predicts the alignment between the text and the observable records describing the entire world state. We follow their set-up, but assume that instead of having access to the full semantic state for every training example, we have a very small amount of data annotated with semantic states and a larger number of unannotated texts with non-contradictory semantics.

We study our set-up on the weather forecast data (Liang et al., 2009) where the original textual weather forecasts were complemented by additional forecasts describing the same weather states (see figure 1 for an example). The average overlap between the verbalized fields in each group of non-contradictory forecasts was below 35%, and more than 60% of fields are mentioned only in a single forecast from a group. Our model, learned from 100 labeled forecasts and 259 groups of unannotated non-contradictory forecasts (750 texts in total), achieved 73.9% F_1. This compares favorably with 69.1% shown by a semi-supervised learning approach, though, as expected, does not reach the score of the model which, in training, observed semantics states for all the 750 documents (77.7% F_1).

The rest of the paper is structured as follows. In section 2 we describe our inference algorithm for groups of non-contradictory documents. Section 3 redescribes the semantics-text correspondence model (Liang et al., 2009) in the context of our learning scenario. In section 4 we provide an empirical evaluation of the proposed method. We conclude in section 5 with an examination of additional related work.

2 Inference with Non-Contradictory Documents

In this section we will describe our inference method on a higher conceptual level, not specifying the underlying meaning representation and the probabilistic model. An instantiation of the algorithm for the semantics-text correspondence model is given in section 3.2.

Statistical models of parsing can often be regarded as defining the probability distribution of meaning $\boldsymbol{m}$ and its alignment $\boldsymbol{a}$ with the given text $\boldsymbol{w}$, $P(\boldsymbol{m}, \boldsymbol{a}, \boldsymbol{w}) = P(\boldsymbol{a}, \boldsymbol{w}|\boldsymbol{m})P(\boldsymbol{m})$. The semantics $\boldsymbol{m}$ can be represented either as a logical formula (see, e.g., (Poon and Domingos, 2009)) or as a set of field values if database records are used as a meaning representation (Liang et al., 2009). The alignment $\boldsymbol{a}$ defines how semantics is verbalized in the text $\boldsymbol{w}$, and it can be represented by a meaning derivation tree in case of full semantic parsing (Poon and Domingos, 2009) or, e.g., by a hierarchical segmentation into utterances along with an utterance-field alignment in a more shallow variation of the problem. In semantic parsing, we aim to find the most likely underlying semantics and alignment given the text:

$$(\hat{\boldsymbol{m}}, \hat{\boldsymbol{a}}) = \arg\max_{\boldsymbol{m},\boldsymbol{a}} P(\boldsymbol{a}, \boldsymbol{w}|\boldsymbol{m})P(\boldsymbol{m}). \quad (1)$$

In the supervised case, where $\boldsymbol{a}$ and $\boldsymbol{m}$ are observable, estimation of the generative model parameters is generally straightforward. However, in a semi-supervised or unsupervised case variational techniques, such as the EM algorithm (Dempster et al., 1977), are often used to estimate the model. As common for complex generative models, the most challenging part is the computation of the posterior distributions $P(\boldsymbol{a}, \boldsymbol{m}|\boldsymbol{w})$ on the E-step which, depending on the underlying model $P(\boldsymbol{m}, \boldsymbol{a}, \boldsymbol{w})$, may require approximate inference.

As discussed in the introduction, our goal is to integrate groups of non-contradictory documents into the learning procedure. Let us denote by $\boldsymbol{w}_1,\ldots,\boldsymbol{w}_K$ a group of non-contradictory documents. As before, the estimation of the posterior probabilities $P(\boldsymbol{m}_i, \boldsymbol{a}_i|\boldsymbol{w}_1 \ldots \boldsymbol{w}_K)$ presents the main challenge. Note that the decision about $\boldsymbol{m}_i$ is now conditioned on all the texts $\boldsymbol{w}_j$ rather than only on $\boldsymbol{w}_i$. This conditioning is exactly what drives learning, as the information about likely semantics $\boldsymbol{m}_j$ of text j affects the decision about choice of $\boldsymbol{m}_i$:

$$P(\boldsymbol{m}_i|\boldsymbol{w}_1,\ldots,\boldsymbol{w}_K) \propto \sum_{a_i} P(\boldsymbol{a}_i, \boldsymbol{w}_i|\boldsymbol{m}_i) \times$$
$$\times \sum_{\boldsymbol{m}_{-i},\boldsymbol{a}_{-i}} P(\boldsymbol{m}_i|\boldsymbol{m}_{-i})P(\boldsymbol{m}_{-i}, \boldsymbol{a}_{-i}, \boldsymbol{w}_{-i}), \quad (2)$$

where $\boldsymbol{x}_{-i}$ denotes $\{\boldsymbol{x}_j : j \neq i\}$. $P(\boldsymbol{m}_i|\boldsymbol{m}_{-i})$ is the probability of the semantics $\boldsymbol{m}_i$ given all the meanings $\boldsymbol{m}_{-i}$. This probability assigns zero weight to inconsistent meanings, i.e. such mean-

ings $(\boldsymbol{m_1},...,\boldsymbol{m_K})$ that $\wedge_{i=1}^{K}\boldsymbol{m}_i$ is not satisfiable,[2] and models dependencies between components in the composite meaning representation (e.g., arguments values of predicates). As an illustration, in the forecast domain it may express that clouds, and not sunshine, are likely when it is raining. Note, that this probability is different from the probability that $\boldsymbol{m}_i$ is actually verbalized in the text.

Unfortunately, these dependencies between $\boldsymbol{m}_i$ and $\boldsymbol{w}_j$ are non-local. Even though the dependencies are only conveyed via $\{\boldsymbol{m}_j : j \neq i\}$ the space of possible meanings $\boldsymbol{m}$ is very large even for relatively simple semantic representations, and, therefore, we need to resort to efficient approximations.

One natural approach would be to use a form of belief propagation (Pearl, 1982; Murphy et al., 1999), where messages pass information about likely semantics between the texts. However, this approach is still expensive even for simple models, both because of the need to represent distributions over $\boldsymbol{m}$ and also because of the large number of iterations of message exchange needed to reach convergence (if it converges).

An even simpler technique would be to parse texts in a random order conditioning each meaning $\boldsymbol{m}_k^\star$ for $k \in \{1,...,K\}$ on all the previous semantics $\boldsymbol{m}_{<k}^\star = \boldsymbol{m}_1^\star,...,\boldsymbol{m}_{k-1}^\star$:

$$\boldsymbol{m}_k^\star = \arg\max_{\boldsymbol{m}_k} P(\boldsymbol{w}_k|\boldsymbol{m}_k)P(\boldsymbol{m}_k|\boldsymbol{m}_{<k}^\star).$$

Here, and in further discussion, we assume that the above search problem can be efficiently solved, exactly or approximately. However, a major weakness of this algorithm is that decisions about components of the composite semantic representation (e.g., argument values) are made only on the basis of a single text, which first mentions the corresponding aspects, without consulting any future texts $k' > k$, and these decisions cannot be revised later.

We propose a simple algorithm which aims to find an appropriate order of the greedy inference by estimating how well each candidate semantics $\hat{\boldsymbol{m}}_k$ would explain other texts and at each step selecting k (and $\hat{\boldsymbol{m}}_k$) which explains them best.

The algorithm, presented in figure 2[3], constructs an ordering of texts $\boldsymbol{n} = (n_1,...,n_K)$

1: $\boldsymbol{n} := (), \boldsymbol{m}^\star := ()$
2: **for** $i := 1 : K-1$ **do**
3: **for** $j \notin \boldsymbol{n}$ **do**
4: $\hat{\boldsymbol{m}}_j := \arg\max_{\boldsymbol{m}_j} P(\boldsymbol{m}_j, \boldsymbol{w}_j|\boldsymbol{m}^\star)$
5: **end for**
6: $n_i := \arg\max_{j\notin\boldsymbol{n}} P(\hat{\boldsymbol{m}}_j, \boldsymbol{w}_j|\boldsymbol{m}^\star)\times$
$\times \prod_{k\notin\boldsymbol{n}\cup\{j\}} \max_{\boldsymbol{m}_k} P(\boldsymbol{m}_k, \boldsymbol{w}_k|\boldsymbol{m}^\star, \hat{\boldsymbol{m}}_j)$
7: $\boldsymbol{m}_i^\star := \hat{\boldsymbol{m}}_{n_i}$
8: **end for**
9: $n_K := \{1,...,K\}\backslash\boldsymbol{n}$
10: $\boldsymbol{m}_K^\star := \arg\max_{\boldsymbol{m}_{n_K}} P(\boldsymbol{m}_{n_K}, \boldsymbol{w}_{n_K}|\boldsymbol{m}^\star)$

Figure 2: The approximate inference algorithm.

and corresponding meaning representations $\boldsymbol{m}^\star = (\boldsymbol{m}_1^\star,...,\boldsymbol{m}_K^\star)$, where $\boldsymbol{m}_k^\star$ is the predicted meaning representation of text $\boldsymbol{w}_{n_k}$. It starts with an empty ordering $\boldsymbol{n} = ()$ and an empty list of meanings $\boldsymbol{m}^\star = ()$ (line 1). Then it iteratively predicts meaning representations $\hat{\boldsymbol{m}}_j$ conditioned on the list of semantics $\boldsymbol{m}^\star = (\boldsymbol{m}_1^\star,...,\boldsymbol{m}_{i-1}^\star)$ fixed on the previous stages and does it for all the remaining texts $\boldsymbol{w}_j$ (lines 3-5). The algorithm selects a single meaning $\hat{\boldsymbol{m}}_j$ which maximizes the probability of all the remaining texts and excludes the text j from future consideration (lines 6-7).

Though the semantics $\boldsymbol{m}_k$ ($k \notin \boldsymbol{n}\cup\{j\}$) used in the estimates (line 6) can be inconsistent with each other, the final list of meanings $\boldsymbol{m}^\star$ is guaranteed to be consistent. It holds because on each iteration we add a single meaning $\hat{\boldsymbol{m}}_{n_i}$ to $\boldsymbol{m}^\star$ (line 7), and $\hat{\boldsymbol{m}}_{n_i}$ is guaranteed to be consistent with $\boldsymbol{m}^\star$, as the semantics $\hat{\boldsymbol{m}}_{n_i}$ was conditioned on the meaning $\boldsymbol{m}^\star$ during inference (line 4).

An important aspect of this algorithm is that unlike usual greedy inference, the remaining ('future') texts do affect the choice of meaning representations made on the earlier stages. As soon as semantics $\boldsymbol{m}_k^\star$ are inferred for every k, we find ourselves in the set-up of learning with unaligned semantic states considered in (Liang et al., 2009).

The induced alignments $\boldsymbol{a}_1,...,\boldsymbol{a}_K$ of semantics $\boldsymbol{m}^\star$ to texts $\boldsymbol{w}_1,...,\boldsymbol{w}_K$ at the same time induce alignments between the texts. The problem of producing multiple sequence alignment, especially in the context of sentence alignments, has been extensively studied in NLP (Barzilay and Lee, 2003). In this paper, we use semantic structures as a pivot for finding the best alignment in the hope that presence of meaningful text alignments will improve the quality of the resulting semantic structures by enforcing a form of agreement between them.

[2]Note that checking for satisfiability may be expensive or intractable depending on the formalism.

[3]We slightly abuse notation by using set operations with the lists $\boldsymbol{n}$ and $\boldsymbol{m}^\star$ as arguments. Also, for all the document indices j we use $j \notin S$ to denote $j \in \{1,...,K\}\backslash S$.

3 A Model of Semantics

In this section we redescribe the semantics-text correspondence model (Liang et al., 2009) with an extension needed to model examples with latent states, and also explain how the inference algorithm defined in section 2 can be applied to this model.

3.1 Model definition

Liang et al. (2009) considered a scenario where each text was annotated with a world state, even though alignment between the text and the state was not observable. This is a weaker form of supervision than the one traditionally considered in supervised semantic parsing, where the alignment is also usually provided in training (Chen and Mooney, 2008; Zettlemoyer and Collins, 2005). Nevertheless, both in training and testing the world state is observable, and the alignment and the text are conditioned on the state during inference. Consequently, there was no need to model the distribution of the world state. This is different for us, and we augment the generative story by adding a simplistic world state generation step.

As explained in the introduction, the world states $\boldsymbol{s}$ are represented by sets of records (see the block in the middle of figure 1 for an example of a world state). Each record is characterized by a record type $t \in \{1,...,T\}$, which defines the set of fields $\boldsymbol{F}^{(t)}$. There are $n^{(t)}$ records of type t and this number may change from document to document. For example, there may be more than a single record of type *wind speed*, as they may refer to different time periods but all these records have the same set of fields, such as minimal, maximal and average wind speeds. Each field has an associated type: in our experiments we consider only categorical and integer fields. We write $s^{(t)}_{n,f} = v$ to denote that n-th record of type t has field f set to value v.

Each document k verbalizes a subset of the entire world state, and therefore semantics $\boldsymbol{m}_k$ of the document is an assignment to $|\boldsymbol{m}_k|$ verbalized fields: $\wedge_{q=1}^{|\boldsymbol{m}_k|}(s^{(t_q)}_{n_q,f_q} = v_q)$, where t_q, n_q, f_q are the verbalized record types, records and fields, respectively, and v_q is the assigned field value. The probability of meaning m_k then equals the probability of this assignment with other state variables left non-observable (and therefore marginalized out). In this formalism checking for contradiction is trivial: two meaning representations contradict each other if they assign different values to the same field of the same record.

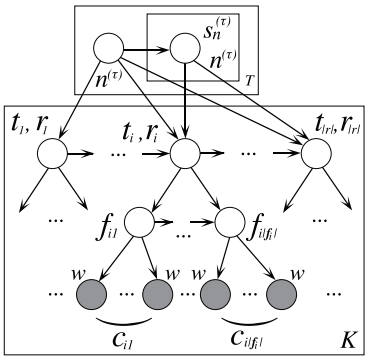

Figure 3: The semantics-text correspondence model with K documents sharing the same latent semantic state.

The semantics-text correspondence model defines a hierarchical segmentation of text: first, it segments the text into fragments discussing different records, then the utterances corresponding to each record are further segmented into fragments verbalizing specific fields of that record. An example of a segmented fragment is presented in figure 4. The model has a designated null-record which is aligned to words not assigned to any record. Additionally there is a null-field in each record to handle words not specific to any field. In figure 3 the corresponding graphical model is presented. The formal definition of the model for documents $\boldsymbol{w_1},..., \boldsymbol{w_K}$ sharing a semantic state is as follows:

- Generation of world state $\boldsymbol{s}$:
  - For each type $\tau \in \{1,...,T\}$ choose a number of records of that type $n^{(\tau)} \sim \text{Unif}(1,..., n_{max})$.
  - For each record $\boldsymbol{s}^{(\tau)}_n$, $n \in \{1,..,n^{(\tau)}\}$ choose field values $s^{(\tau)}_{nf}$ for all fields $f \in \boldsymbol{F}^{(\tau)}$ from the type-specific distribution.
- Generation of the verbalizations, for each document $\boldsymbol{w}_k$, $k \in \{1,..., K\}$:[4]
  - Record Types: Choose a sequence of verbalized record types $\boldsymbol{t} = (t_1,..., t_{|\boldsymbol{t}|})$ from the first-order Markov chain.
  - Records: For each type t_i choose a verbalized record $\boldsymbol{r}_i$ from all the records of that type: $l \sim \text{Unif}(1,..., n^{(\tau)})$, $\boldsymbol{r}_i := \boldsymbol{s}^{(t_i)}_l$.
  - Fields: For each record $\boldsymbol{r}_i$ choose a sequence of verbalized fields $\boldsymbol{f}_i = (f_{i1},..., f_{i|\boldsymbol{f}_i|})$ from the first-order Markov chain ($f_{ij} \in \boldsymbol{F}^{(t_i)}$).
  - Length: For each field f_{ij}, choose length $c_{ij} \sim \text{Unif}(1,..., c_{max})$.
  - Words: Independently generate c_{ij} words from the field-specific distribution $P(w|f_{ij}, r_{if_{ij}})$.

[4] We omit index k in the generative story and figure 3 to simplify the notation.

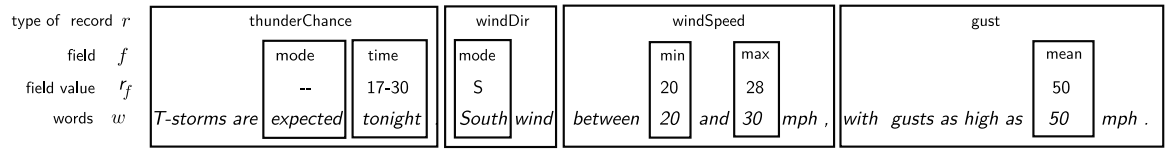

Figure 4: A segmentation of a text fragment into records and fields.

Note that, when generating fields, the Markov chain is defined over fields and the transition parameters are independent of the field values $r_{if_{ij}}$. On the contrary, when drawing a word, the distribution of words is conditioned on the value of the corresponding field.

The form of word generation distributions $P(w|f_{ij}, r_{if_{ij}})$ depends on the type of the field $f_{i,j}$. For categorical fields, the distribution of words is modeled as a distinct multinomial for each field value. Verbalizations of numerical fields are generated via a perturbation on the field value $r_{if_{ij}}$: the value $r_{if_{ij}}$ can be perturbed by either rounding it (up or down) or distorting (up or down, modeled by a geometric distribution). The parameters corresponding to each form of generation are estimated during learning. For details on these emission models, as well as for details on modeling record and field transitions, we refer the reader to the original publication (Liang et al., 2009).

In our experiments, when choosing a world state $\boldsymbol{s}$, we generate the field values independently. This is clearly a suboptimal regime as often there are very strong dependencies between field values: e.g., in the weather domain many record types contain groups of related fields defining minimal, maximal and average values of some parameter. Extending the method to model, e.g., pairwise dependencies between field values is relatively straightforward.

As explained above, semantics of a text $\boldsymbol{m}$ is defined by the assignment of state variables $\boldsymbol{s}$. Analogously, an alignment $\boldsymbol{a}$ between semantics $\boldsymbol{m}$ and a text $\boldsymbol{w}$ is represented by all the remaining latent variables: by the sequence of record types $\boldsymbol{t} = (t_1,...,t_{|\boldsymbol{t}|})$, choice of records $\boldsymbol{r}_i$ for each t_i, the field sequence $\boldsymbol{f}_i$ and the segment length c_{ij} for every field f_{ij}.

3.2 Learning and inference

We select the model parameters θ by maximizing the marginal likelihood of the data, where the data $\mathcal{D}$ is given in the form of groups $\boldsymbol{w} = \{\boldsymbol{w}_1,...,\boldsymbol{w}_K\}$ sharing the same latent state:[5]

$$\max_{\theta} \prod_{\boldsymbol{w}\in\mathcal{D}} \sum_{\boldsymbol{s}} P(\boldsymbol{s}) \prod_{k} \sum_{\boldsymbol{r},\boldsymbol{f},\boldsymbol{c}} P(\boldsymbol{r}, \boldsymbol{f}, \boldsymbol{c}, \boldsymbol{w}_k|\boldsymbol{s}, \theta).$$

To estimate the parameters, we use the Expectation-Maximization algorithm (Dempster et al., 1977). When the world state is observable, learning does not require any approximations, as dynamic programming (a form of the forward-backward algorithm) can be used to infer the posterior distribution on the E-step (Liang et al., 2009). However, when the state is latent, dependencies are not local anymore, and approximate inference is required.

We use the algorithm described in section 2 (figure 2) to infer the state. In the context of the semantics-text correspondence model, as we discussed above, semantics $\boldsymbol{m}$ defines the subset of admissible world states. In order to use the algorithm, we need to understand how the conditional probabilities of the form $P(\boldsymbol{m}'|\boldsymbol{m})$ are computed, as they play the key role in the inference procedure (see equation (2)). If there is a contradiction ($\boldsymbol{m}' \perp \boldsymbol{m}$) then $P(\boldsymbol{m}'|\boldsymbol{m}) = 0$, conversely, if $\boldsymbol{m}'$ is subsumed by $\boldsymbol{m}$ ($\boldsymbol{m} \rightarrow \boldsymbol{m}'$) then this probability is 1. Otherwise, $P(\boldsymbol{m}'|\boldsymbol{m})$ equals the probability of new assignments $\wedge_{q=1}^{|\boldsymbol{m}'\setminus\boldsymbol{m}|}(s_{n'_q,f'_q}^{(t'_q)} = v'_q)$ (defined by $\boldsymbol{m}'\setminus\boldsymbol{m}$) conditioned on the previously fixed values of $\boldsymbol{s}$ (given by $\boldsymbol{m}$). Summarizing, when predicting the most likely semantics $\hat{\boldsymbol{m}}_j$ (line 4), for each span the decoder weighs alternatives of either (1) aligning this span to the previously induced meaning $\boldsymbol{m}^\star$, or (2) aligning it to a new field and paying the cost of generation of its value.

The exact computation of the most probable semantics (line 4 of the algorithm) is intractable, and we have to resort to an approximation. Instead of predicting the most probable semantics $\hat{\boldsymbol{m}}_j$ we search for the most probable pair $(\hat{\boldsymbol{a}}_j, \hat{\boldsymbol{m}}_j)$, thus assuming that the probability mass is mostly concentrated on a single alignment. The alignment $\boldsymbol{a}_j$

[5]For simplicity, we assume here that all the examples are unlabeled.

is then discarded and not used in any other computations. Though the most likely alignment $\hat{\boldsymbol{a}}_j$ for a fixed semantic representation $\hat{\boldsymbol{m}}_j$ can be found efficiently using a Viterbi algorithm, computing the most probable pair $(\hat{\boldsymbol{a}}_j, \hat{\boldsymbol{m}}_j)$ is still intractable. We use a modification of the beam search algorithm, where we keep a set of candidate meanings (partial semantic representations) and compute an alignment for each of them using a form of the Viterbi algorithm.

As soon as the meaning representations $\boldsymbol{m}^\star$ are inferred, we find ourselves in the set-up studied in (Liang et al., 2009): the state $\boldsymbol{s}$ is no longer latent and we can run efficient inference on the E-step. Though some fields of the state $\boldsymbol{s}$ may still not be specified by $\boldsymbol{m}^\star$, we prohibit utterances from aligning to these non-specified fields.

On the M-step of EM the parameters are estimated as proportional to the expected marginal counts computed on the E-step. We smooth the distributions of values for numerical fields with convolution smoothing equivalent to the assumption that the fields are affected by distortion in the form of a two-sided geometric distribution with the success rate parameter equal to 0.67. We use add-0.1 smoothing for all the remaining multinomial distributions.

4 Empirical Evaluation

In this section, we consider the semi-supervised set-up, and present evaluation of our approach on on the problem of aligning weather forecast reports to the formal representation of weather.

4.1 Experiments

To perform the experiments we used a subset of the weather dataset introduced in (Liang et al., 2009). The original dataset contains 22,146 texts of 28.7 words on average, there are 12 types of records (predicates) and 36.0 records per forecast on average. We randomly chose 100 texts along with their world states to be used as the labeled data.[6] To produce groups of non-contradictory texts we have randomly selected a subset of weather states, represented them in a visual form (icons accompanied by numerical and symbolic parameters) and then manually annotated these illustrations. These newly-produced forecasts, when combined with the original texts, resulted in 259 groups of non-contradictory texts (650 texts, 2.5 texts per group). An example of such a group is given in figure 1.

The dataset is relatively noisy: there are inconsistencies due to annotation mistakes (e.g., number distortions), or due to different perception of the weather by the annotators (e.g., expressions such as 'warm' or 'cold' are subjective). The overlap between the verbalized fields in each group was estimated to be below 35%. Around 60% of fields are mentioned only in a single forecast from a group, consequently, the texts cannot be regarded as paraphrases of each other.

The test set consists of 150 texts, each corresponding to a different weather state. Note that during testing we no longer assume that documents share the state, we treat each document in isolation. We aimed to preserve approximately the same proportion of new and original examples as we had in the training set, therefore, we combined 50 texts originally present in the weather dataset with additional 100 newly-produced texts. We annotated these 100 texts by aligning each line to one or more records,[7] whereas for the original texts the alignments were already present. Following Liang et al. (2009) we evaluate the models on how well they predict these alignments.

When estimating the model parameters, we followed the training regime prescribed in (Liang et al., 2009). Namely, 5 iterations of EM with a basic model (with no segmentation or coherence modeling), followed by 5 iterations of EM with the model which generates fields independently and, at last, 5 iterations with the full model. Only then, in the semi-supervised learning scenarios, we added unlabeled data and ran 5 additional iterations of EM.

Instead of prohibiting records from crossing punctuation, as suggested by Liang et al. (2009), in our implementation we disregard the words not attached to specific fields (attached to the null-field, see section 3.1) when computing spans of records. To speed-up training, only a single record of each type is allowed to be generated when running inference for unlabeled examples on the E-

[6] In order to distinguish from completely unlabeled examples, we refer to examples labeled with world states as *labeled* examples. Note though that the alignments are not observable even for these labeled examples. Similarly, we call the models trained from this data *supervised* though full supervision was not available.

[7] The text was automatically tokenized and segmented into lines, with line breaks at punctuation characters. Information about the line breaks is not used during learning and inference.

	P	R	F_1

Table 1: Results (precision, recall and F_1) on the weather forecast dataset.

value	top words
0-25	clear, small, cloudy, gaps, sun
25-50	clouds, increasing, heavy, produce, could
50-75	cloudy, mostly, high, cloudiness, breezy
75-100	amounts, rainfall, inch, new, possibly

Table 2: Top 5 words in the word distribution for field *mode* of record *sky cover*, function words and punctuation are omitted.

step of the EM algorithm, as it significantly reduces the search space. Similarly, though we preserved all records which refer to the first time period, for other time periods we removed all the records which declare that the corresponding event (e.g., rain or snowfall) is not expected to happen. This preprocessing results in the oracle recall of 93%.

We compare our approach (*Semi-superv, non-contr*) with two baselines: the basic supervised training on 100 labeled forecasts (*Supervised BL*) and with the semi-supervised training which disregards the non-contradiction relations (*Semi-superv BL*). The learning regime, the inference procedure and the texts for the semi-supervised baseline were identical to the ones used for our approach, the only difference is that all the documents were modeled as independent. Additionally, we report the results of the model trained with all the 750 texts labeled (*Supervised UB*), its scores can be regarded as an upper bound on the results of the semi-supervised models. The results are reported in table 1.

4.2 Discussion

Our training strategy results in a substantially more accurate model, outperforming both the supervised and semi-supervised baselines. Surprisingly, its precision is higher than that of the model trained on 750 labeled examples, though admittedly it is achieved at a very different recall level. The estimation of the model with our approach takes around one hour on a standard desktop PC, which is comparable to 40 minutes required to train the semi-supervised baseline.

In these experiments, we consider the problem of predicting alignment between text and the corresponding observable world state. The direct evaluation of the meaning recognition (i.e. semantic parsing) accuracy is not possible on this dataset, as the data does not contain information which fields are discussed. Even if it would provide this information, the documents do not verbalize the state at the necessary granularity level to predict the field values. For example, it is not possible to decide to which bucket of the field *sky cover* the expression 'cloudy' refers to, as it has a relatively uniform distribution across 3 (out of 4) buckets. The problem of predicting text-meaning alignments is interesting in itself, as the extracted alignments can be used in training of a statistical generation system or information extractors, but we also believe that evaluation on this problem is an appropriate test for the relative comparison of the semantic analyzers' performance. Additionally, note that the success of our weakly-supervised scenario indirectly suggests that the model is sufficiently accurate in predicting semantics of an unlabeled text, as otherwise there would be no useful information passed in between semantically overlapping documents during learning and, consequently, no improvement from sharing the state.[8]

To confirm that the model trained by our approach indeed assigns new words to correct fields and records, we visualize top words for the field characterizing sky cover (table 2). Note that the words "sun", "cloudiness" or "gaps" were not appearing in the labeled part of the data, but seem to be assigned to correct categories. However, correlation between rain and overcast, as also noted in (Liang et al., 2009), results in the wrong assignment of the rain-related words to the field value corresponding to very cloudy weather.

5 Related Work

Probably the most relevant prior work is an approach to bootstrapping lexical choice of a generation system using a corpus of alternative pas-

[8] We conducted preliminary experiments on synthetic data generated from a random semantic-correspondence model. Our approach outperformed the baselines both in predicting 'text'-state correspondence and in the F_1 score on the predicted set of field assignments ('text meanings').

sages (Barzilay and Lee, 2002), however, in their work all the passages were annotated with unaligned semantic expressions. Also, they assumed that the passages are paraphrases of each other, which is stronger than our non-contradiction assumption. Sentence and text alignment has also been considered in the related context of paraphrase extraction (see, e.g., (Dolan et al., 2004; Barzilay and Lee, 2003)) but this prior work did not focus on inducing or learning semantic representations. Similarly, in information extraction, there have been approaches for pattern discovery using comparable monolingual corpora (Shinyama and Sekine, 2003) but they generally focused only on discovery of a single pattern from a pair of sentences or texts.

Radev (2000) considered types of potential relations between documents, including contradiction, and studied how this information can be exploited in NLP. However, this work considered primarily multi-document summarization and question answering problems.

Another related line of research in machine learning is clustering or classification with constraints (Basu et al., 2004), where supervision is given in the form of constraints. Constraints declare which pairs of instances are required to be assigned to the same class (or required to be assigned to different classes). However, we are not aware of any previous work that generalized these methods to structured prediction problems, as trivial equality/inequality constraints are probably too restrictive, and a notion of consistency is required instead.

6 Summary and Future Work

In this work we studied the use of weak supervision in the form of non-contradictory relations between documents in learning semantic representations. We argued that this type of supervision encodes information which is hard to discover in an unsupervised way. However, exact inference for groups of documents with overlapping semantic representation is generally prohibitively expensive, as the shared latent semantics introduces nonlocal dependences between semantic representations of individual documents. To combat it, we proposed a simple iterative inference algorithm. We showed how it can be instantiated for the semantics-text correspondence model (Liang et al., 2009) and evaluated it on a dataset of weather forecasts. Our approach resulted in an improvement over the scores of both the supervised baseline and of the traditional semi-supervised learning.

There are many directions we plan on investigating in the future for the problem of learning semantics with non-contradictory relations. A promising and challenging possibility is to consider models which induce full semantic representations of meaning. Another direction would be to investigate purely unsupervised set-up, though it would make evaluation of the resulting method much more complex. One potential alternative would be to replace the initial supervision with a set of posterior constraints (Graca et al., 2008) or generalized expectation criteria (McCallum et al., 2007).

Abstract

Most supervised language processing systems show a significant drop-off in performance when they are tested on text that comes from a domain significantly different from the domain of the training data. Semantic role labeling techniques are typically trained on newswire text, and in tests their performance on fiction is as much as 19% worse than their performance on newswire text. We investigate techniques for building open-domain semantic role labeling systems that approach the ideal of a train-once, use-anywhere system. We leverage recently-developed techniques for learning representations of text using latent-variable language models, and extend these techniques to ones that provide the kinds of features that are useful for semantic role labeling. In experiments, our novel system reduces error by 16% relative to the previous state of the art on out-of-domain text.

1 Introduction

In recent semantic role labeling (SRL) competitions such as the shared tasks of CoNLL 2005 and CoNLL 2008, supervised SRL systems have been trained on newswire text, and then tested on both an in-domain test set (Wall Street Journal text) and an out-of-domain test set (fiction). All systems tested on these datasets to date have exhibited a significant drop-off in performance on the out-of-domain tests, often performing 15% worse or more on the fiction test sets. Yet the baseline from CoNLL 2005 suggests that the fiction texts are actually easier than the newswire texts. Such observations expose a weakness of current supervised natural language processing (NLP) technology for SRL: systems learn to identify semantic roles for the subset of language contained in the training data, but are not yet good at generalizing to language that has not been seen before.

We aim to build an *open-domain* supervised SRL system; that is, one whose performance on out-of-domain tests approaches the same level of performance as that of state-of-the-art systems on in-domain tests. Importantly, an open-domain system must not use any new labeled data beyond what is included in the original training text when running on a new domain. This allows the system to be ported to any new domain without any manual effort. In particular, it ought to apply to arbitrary Web documents, which are drawn from a huge variety of domains.

Recent theoretical and empirical evidence suggests that the fault for poor performance on out-of-domain tests lies with the representations, or sets of features, traditionally used in supervised NLP. Building on recent efforts in domain adaptation, we develop unsupervised techniques for learning new representations of text. Using latent-variable language models, we learn representations of texts that provide novel kinds of features to our supervised learning algorithms. Similar representations have proven useful in domain-adaptation for part-of-speech tagging and phrase chunking (Huang and Yates, 2009). We demonstrate how to learn representations that are effective for SRL. Experiments on out-of-domain test sets show that our learned representations can dramatically improve out-of-domain performance, and narrow the gap between in-domain and out-of-domain performance by half.

The next section provides background information on learning representations for NLP tasks using latent-variable language models. Section 3 presents our experimental setup for testing open-domain SRL. Sections 4, 5, 6 describe our SRL system: first, how we identify predicates in open-domain text, then how our baseline technique

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 968–978,
Uppsala, Sweden, 11-16 July 2010.

identifies and classifies arguments, and finally how we learn representations for improving argument identification and classification on out-of-domain text. Section 7 presents previous work, and Section 8 concludes and outlines directions for future work.

2 Open-Domain Representations Using Latent-Variable Language Models

Let $\mathcal{X}$ be an instance set for a learning problem; for SRL, this is the set of all (sentence,predicate) pairs. Let $\mathcal{Y}$ be the space of possible labels for an instance, and let f: $\mathcal{X} \rightarrow \mathcal{Y}$ be the target function to be learned. A *representation* is a function R: $\mathcal{X} \rightarrow \mathcal{Z}$, for some suitable feature space $\mathcal{Z}$ (such as $\mathbb{R}^{\mathrm{d}}$). A *domain* is defined as a distribution $\mathcal{D}$ over the instance set $\mathcal{X}$. An open-domain system observes a set of training examples $(R(x), f(x))$, where instances $x \in \mathcal{X}$ are drawn from a *source* domain, to learn a hypothesis for classifying examples drawn from a separate *target* domain.

Previous work by Ben-David *et al.* (2007; 2009) uses Vapnik-Chervonenkis (VC) theory to prove theoretical bounds on an open-domain learning machine's performance. Their analysis shows that the choice of representation is crucial to open-domain learning. As is customary in VC theory, a good choice of representation must allow a learning machine to achieve low error rates during training. Just as important, however, is that *the representation must simultaneously make the source and target domains look as similar to one another as possible*.

For open-domain SRL, then, the traditional representations are problematic. Typical representations in SRL and NLP use features of the local context to produce a representation. For instance, one dimension of a traditional representation R might be +1 if the instance contains the word "bank" as the head of a noun-phrase chunk that occurs before the predicate in the sentence, and 0 otherwise. Although many previous studies have shown that these features allow learning systems to achieve impressively low error rates during training, they also make texts from different domains look very dissimilar. For instance, a feature based on the word "bank" or "CEO" may be common in a domain of newswire text, but scarce or nonexistent in, say, biomedical literature.

In our recent work (Huang and Yates, 2009) we show how to build systems that learn new representations for open-domain NLP using latent-variable language models like Hidden Markov Models (HMMs). An HMM is a generative probabilistic model that generates each word x_i in the corpus conditioned on a latent variable Y_i. Each Y_i in the model takes on integral values from 1 to K, and each one is generated by the latent variable for the preceding word, Y_{i-1}. The distribution for a corpus $\mathbf{x} = (x_1, \ldots, x_N)$ and a set of state vectors $\mathbf{s} = (s_1, \ldots, s_N)$ is given by:

$$P(\mathbf{x}, \mathbf{s}) = \prod_i P(x_i|s_i)P(s_i|s_{i-1})$$

Using Expectation-Maximization (Dempster et al., 1977), it is possible to estimate the distributions for $P(x_i|s_i)$ and $P(s_i|s_{i-1})$ from unlabeled data. The Viterbi algorithm (Rabiner, 1989) can then be used to produce the optimal sequence of latent states s_i for a given instance $\mathbf{x}$. The output of this process is an integer (ranging from 1 to K) for every word x_i in the corpus. We use the integer value of s_i as a new feature for every x_i in the sentence.

In POS-tagging and chunking experiments, these learned representations have proven to meet both of Ben-David *et al.*'s criteria for open-domain representations: first, they are useful in making predictions on the training text because the HMM latent states categorize tokens according to distributional similarity. And second, it would be difficult to tell two domains apart based on their HMM labels, since the same HMM state can generate similar words from a variety of domains. In what follows, we adapt these representation-learning concepts to open-domain SRL.

3 Experimental Setup

We test our open-domain semantic role labeling system using data from the CoNLL 2005 shared task (Carreras and Màrquez, 2005). We use the standard training set, consisting of sections 02-21 of the Wall Street Journal (WSJ) portion of the Penn Treebank, labeled with PropBank (Palmer et al., 2005) annotations for predicates and arguments. We perform our tests on the Brown corpus (Kucera and Francis, 1967) test data from CoNLL 2005, consisting of 3 sections (ck01-ck03) of propbanked Brown corpus data. This test set consists of 426 sentences containing 7,159 tokens, 804 propositions, and 2,177 arguments. While the

training data contains newswire text, the test sentences are drawn from the domain of "general fiction," and contain an entirely different style (or styles) of English. The data also includes a second test set of in-domain text (section 23 of the Treebank), which we refer to as the WSJ test set and use as a reference point.

Every sentence in the dataset is automatically annotated with a number of NLP pipeline systems, including part-of-speech (POS) tags, phrase chunk labels (Carreras and Màrquez, 2003), named-entity tags, and full parse information by multiple parsers. These pipeline systems are important for generating features for SRL, and one key reason for the poor performance of SRL systems on the Brown corpus is that the pipeline systems themselves perform worse. The Charniak parser, for instance, drops from an F1 of 88.25 on the WSJ test to a F1 of 80.84 on the Brown corpus. For the chunker and POS tagger, the drop-offs are less severe: 94.89 to 91.73, and 97.36 to 94.73.

Toutanova *et al.* (2008) currently have the best-performing SRL system on the Brown corpus test set with an F1 score of 68.81 (80.8 for the WSJ test). They use a discriminative reranking approach to jointly predict the best set of argument boundaries and the best set of argument labels for a predicate. Like the best systems from the CoNLL 2005 shared task (Punyakanok et al., 2008; Pradhan et al., 2005), they also use features from multiple parses to remain robust in the face of parser error. Owing to the established difficulty of the Brown test set and the different domains of the Brown test and WSJ training data, this dataset makes for an excellent testbed for open-domain semantic role labeling.

4 Predicate Identification

In order to perform true open-domain SRL, we must first consider a task which is not formally part of the CoNLL shared task: the task of identifying predicates in a given sentence. While this task is almost trivial in the WSJ test set, where all but two out of over 5000 predicates can be observed in the training data, it is significantly more difficult in an open-domain setting. In the Brown test set, 6.1% of the predicates do not appear in the training data, and 11.8% of the predicates appear at most twice in the training data (*c.f.* 1.5% of the WSJ test predicates that appear at most twice in training). In addition, many words which appear as predicates in training may not be predicates in the test set. In an open-domain setting, therefore, we cannot rely solely on a catalog of predicates from the training data.

	Baseline			HMM		
Freq	P	R	F1	P	R	F1
0	89.1	80.4	84.5	93.5	84.3	**88.7**
0-2	87.4	84.7	86.0	91.6	88.8	**90.2**
all	87.8	92.5	90.1	90.8	96.3	**93.5**

Table 1: Using HMM features in predicate identification reduces error in out-of-domain tests by 34.3% overall, and by 27.1% for OOV predicates. "Freq" refers to frequency in the training data. There were 831 predicates in total; 51 never appeared in training and 98 appeared at most twice.

To address the task of open-domain predicate identification, we construct a Conditional Random Field (CRF) (Lafferty et al., 2001) model with target labels of B-Pred, I-Pred, and O-Pred (for the beginning, interior, and outside of a predicate). We use an open source CRF software package to implement our CRF models.[1] We use words, POS tags, chunk labels, and the predicate label at the preceding and following nodes as features for our Baseline system. To learn an open-domain representation, we then trained an 80 state HMM on the unlabeled texts of the training and Brown test data, and used the Viterbi optimum states of each word as categorical features.

The results of our Baseline and HMM systems appear in Table 1. For predicates that never or rarely appear in training, the HMM features increase F1 by 4.2, and they increase the overall F1 of the system by 3.5 to 93.5, which approaches the F1 of 94.7 that the Baseline system achieves on the in-domain WSJ test set. Based on these results, we were satisfied that our system could find predicates in open-domain text. In all subsequent experiments, we fall back on the standard evaluation in which it is assumed that the boundaries of the predicate are given. This allows us to compare with previous work.

5 Semantic Role Labeling with HMM-based Representations

Following standard practice, we divide the SRL task into two parts: argument identification and

[1] Available from http://sourceforge.net/projects/crf/

argument classification. We treat both sub-tasks as sequence-labeling problems. During argument identification, the system must label each token with labels that indicate either the beginning or interior of an argument (B-Arg or I-Arg), or a label that indicates the token is not part of an argument (O-Arg). During argument classification, the system labels each token that is part of an argument with a class label, such as Arg0 or ArgM. Following argument classification, multi-word arguments may have different classification labels for each token. We post-process the labels by changing them to match the label of the first token. We use CRFs as our models for both tasks (Cohn and Blunsom, 2005).

Most previous approaches to SRL have relied heavily on parsers, and especially constituency parsers. Indeed, when SRL systems use gold standard parses, they tend to perform extremely well (Toutanova et al., 2008). However, as several previous studies have noted (Gildea, 2001; Pradhan et al., 2007), using parsers can cause problems for open-domain SRL. The parsers themselves may not port well to new domains, or the features they generate for SRL may not be stable across domains, and therefore may cause sparse data problems on new domains. Our first step is therefore to build an SRL system that relies on partial parsing, as was done in CoNLL 2004 (Carreras and Màrquez, 2004). We then gradually add in less-sparse alternatives for the syntactic features that previous systems derive from parse trees.

During argument identification we use the features below to predict the label A_i for token w_i:

- *words*: w_i, w_{i-1}, and w_{i+1}
- *parts of speech (POS)*: POS tags t_i, t_{i-1}, and t_{i+1}
- *chunk labels*: (*e.g.*, B-NP, I-VP, or O) chunk tags c_i, c_{i-1}, and c_{i+1}
- *combinations*: $c_i t_i$, $t_i w_i$, $c_i t_i w_i$
- *NE*: the named entity type n_i of w_i
- *position*: whether the word occurs before or after the predicate
- *distance*: the number of intervening tokens between w_i and the target predicate
- *POS before, after predicate*: the POS tag of the tokens immediately preceding and following the predicate
- *Chunk before, after predicate*: the chunk type of the tokens immediately preceding and following the predicate
- *Transition*: for prediction node A_i, we use $A_{i-1}$and A_{i+1} as features

For argument classification, we add the features below to those listed above:

- *arg ID*: the labels A_i produced by arg. identification (B-Arg, I-Arg, or O)
- *combination*: predicate + first argument word, predicate+ last argument word, predicate + first argument POS, predicate + last argument POS
- *head distance*: the number of tokens between the first token of the argument phrase and the target predicate
- *neighbors*: the words immediately before and after the argument.

We refer to the CRF model with these features as our Baseline SRL system; in what follows we extend the Baseline model with more sophisticated features.

5.1 Incorporating HMM-based Representations

As a first step towards an open-domain representation, we use an HMM with 80 latent state values, trained on the unlabeled text of the training and test sets, to produce Viterbi-optimal state values s_i for every token in the corpus. We then add the following features to our CRFs for both argument identification and classification:

- *HMM states*: HMM state values s_i, s_{i-1}, and s_{i+1}
- *HMM states before, after predicate*: the state value of the tokens immediately preceding and following the predicate

We call the resulting model our Baseline+HMM system.

5.2 Path Features

Despite all of the features above, the SRL system has very little information to help it determine the syntactic relationship between a target predicate and a potential argument. For instance, these baseline features provide only crude distance information to distinguish between multiple arguments that follow a predicate, and they make it difficult to correctly identify clause arguments or arguments that appear far from the predicate. Our system needs features that can help distinguish between different syntactic relationships, without being overly sensitive to the domain.

As a step in this direction, we introduce *path* features: features for the sequence of tokens be-

System	P	R	F1
Baseline	63.9	59.7	61.7
Baseline+HMM	68.5	62.7	65.5
Baseline+HMM+Paths	70.0	65.6	67.7
Toutanova *et al.* (2008)	NR	NR	**68.8**

Table 2: Naïve path features improve our baseline, but not enough to match the state-of-the-art. Toutanova *et al.* do not report (NR) separate values for precision and recall on this dataset. Differences in both precision and recall between the baseline and the other systems are statistically significant at $p < 0.01$ using the two-tailed Fisher's exact test.

tween a predicate and a potential argument. In standard SRL systems, these path features usually consist of a sequence of constituent parse nodes representing the shortest path through the parse tree between a word and the predicate (Gildea and Jurafsky, 2002). We substitute paths that do not depend on parse trees. We use four types of paths: word paths, POS paths, chunk paths, and HMM state paths. Given an input sentence labeled with POS tags, and chunks, we construct path features for a token w_i by concatenating words (or tags or chunk labels) between w_i and the predicate. For example, in the sentence "The HIV infection rate is expected to peak in 2010," the word path between "rate" and predicate "peak" would be "is expected to", and the POS path would be "VBZ VBD TO."

Since word, POS, and chunk paths are all subject to data sparsity for arguments that are far from the predicate, we build less-sparse path features by using paths of HMM states. If we use a reasonable number of HMM states, each category label is much more common in the training data than the average word, and paths containing the HMM states should be much less sparse than word paths, and even chunk paths. In our experiments, we use 80-state HMMs.

We call the result of adding path features to our feature set the Baseline+HMM+Paths system((BL). Table 2 shows the performance of our three baseline systems. In this open-domain SRL experiment, path features improve over the Baseline's F1 by 6 points, and by 2.2 points over Baseline+HMM, although the improvement is not enough to match the state-of-the-art system by Toutanova *et al.*

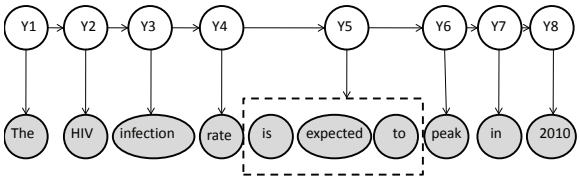

Figure 1: The Span-HMM over the sentence. It shows the span of length 3.

6 Representations for Word Spans

Despite partial success in improving our baseline SRL system with path features, these features still suffer from data sparsity — many paths in the test set are never or very rarely observed during training, so the CRF model has little or no data points from which to estimate accurate parameters for these features. In response, we introduce latent variable models of *word spans*, or sequences of words. As with the HMM models above, the latent states for word spans can be thought of as probabilistic categories for the spans. And like the HMM models, we can turn the word span models into representations by using the state value for a span as a feature in our supervised SRL system. Unlike path features, the features from our models of word spans consist of a single latent state value rather than a concatenation of state values, and as a consequence they tend to be much less sparse in the training data.

6.1 Span-HMM Representations

We build our latent-variable models of word spans using variations of Hidden Markov Models, which we call Span-HMMs. Figure 1 shows a graphical model of a Span-HMM. Each Span-HMM behaves just like a regular HMM, except that it includes one node, called a *span node*, that can generate an entire span rather than a single word. For instance, in the Span-HMM of Figure 1, node y_5 is a span node that generates a span of length 3: "is expected to."

Span-HMMs can be used to provide a single categorical value for any span of a sentence using the usual Viterbi algorithm for HMMs. That is, at test time, we generate a Span-HMM feature for word w_j by constructing a Span-HMM that has a span node for the sequence of words between w_j and the predicate. We determine the Viterbi optimal state of this span node, and use that state as the value of the new feature. In our example in Figure 1, the value of span node y_5 is used as a feature for

the token "rate", since y_5 generates the sequence of words between "rate" and the predicate "peak."

Notice that by using Span-HMMs to provide these features, we have condensed all paths in our data into a small number of categorical values. Whereas there are a huge number of variations to the spans themselves, we can constrain the number of categories for the Span-HMM states to a reasonable number such that each category is likely to appear often in the training data. The value of each Span-HMM state then represents a cluster of spans with similar delimiting words; some clusters will correlate with spans between predicates and arguments, and others with spans that do not connect predicates and arguments. As a result, Span-HMM features are not sparse, and they correlate with the target function, making them useful in learning an SRL model.

6.2 Parameter Estimation

We use a variant of the Baum-Welch algorithm to train our Span-HMMs on unlabeled text. In order for this to work, we need to provide Baum-Welch with a modified view of the data so that span nodes can generate multiple consecutive words in a sentence. First, we take every sentence S in our training data and generate the set $Spans(S)$ of all valid spans in the sentence. For efficiency's sake, we use only spans of length less than 15; approximately 95% of the arguments in our dataset were within 15 words of the predicate, so even with this restriction we are able to supply features for nearly all valid arguments. The second step of our training procedure is to create a separate data point for each span of S. For each span $t \in Spans(S)$, we construct a Span-HMM with a regular node generating each element of S, except that a span node generates all of t. Thus, our training data contains many different copies of each sentence S, with a different Span-HMM generating each copy.

Intuitively, running Baum-Welch over this data means that a span node with state k will be likely to generate two spans t_1 and t_2 if t_1 and t_2 tend to appear in similar contexts. That is, they should appear between words that are also likely to be generated by the same latent state. Thus, certain values of k will tend to appear for spans between predicates and arguments, and others will tend to appear between predicates and non-arguments. This makes the value k informative for both argument identification and argument classification.

6.3 Memory Considerations

Memory usage is a major issue for our Span-HMM models. We represent emission distributions as multinomials over discrete observations. Since there are millions of different spans in our data, a straightforward implementation would require millions of parameters for each latent state of the Span-HMM.

We use two related techniques to get around this problem. In both cases, we use a second HMM model, which we call the base HMM to distinguish from our Span-HMM, to back-off from the explicit word sequence. We use the largest number of states for HMMs that can be fit into memory. Let S be a sentence, and let $\hat{s}$ be the sequence of optimal latent state values for S produced by our base HMM. Our first approach trains the Span-HMM on $Spans(\hat{s})$, rather than $Spans(S)$. If we use a small enough number of latent states in the base HMM (in experiments, we use 10 latent states), we drastically reduce the number of different spans in the data set, and therefore the number of parameters required for our model. We call this representation Span-HMM-Base10. As with our other HMM-based models, we use the largest number of latent states that will allow the resulting model to fit in our machine's memory — our previous experiments on representations for part-of-speech tagging suggest that more latent states are usually better.

While our first technique solves the memory issue, it also loses some of the power of our original Span-HMM model by using a very coarse-grained base HMM clustering of the text into 10 categories. Our second approach trains a separate Span-HMM model for spans of different lengths. Since we need only one model in memory at a time, this allows each one to consume more memory. We therefore use base HMM models with more latent states (up to 20) to annotate our sentences, and then train on the resulting $Spans(\hat{s})$ as before. With this technique, we produce features that are combinations of the state value for span nodes and the length of the span, in order to indicate which of our Span-HMM models the state value came from. We call this representation Span-HMM-BaseByLength.

6.4 Combining Multiple Span-HMMs

So far, our Span-HMM models produce one new feature for every token during argument identifi-

System	P	R	F1
Baseline+HMM+Paths	70.0	65.6	67.7
Toutanova *et al.*	NR	NR	68.8
Span-HMM-Base10	74.5	69.3	71.8
Span-HMM-BaseByLength	76.3	70.2	73.1
Multi-Span-HMM	**77.0**	**70.9**	**73.8**

Table 3: Span-HMM features significantly improve over state-of-the-art results in out-of-domain SRL. Differences in both precision and recall between the baseline and the Span-HMM systems are statistically significant at $p < 0.01$ using the two-tailed Fisher's exact test.

System	WSJ	Brown	Diff
Multi-Span-HMM	79.2	**73.8**	**5.4**
Toutanova *et al.* (2008)	**80.8**	68.8	12.0
Pradhan *et al.* (2005)	78.6	68.4	10.2
Punyakanok *et al.* (2008)	79.4	67.8	11.6

Table 4: Multi-Span-HMM has a much smaller drop-off in F1 than comparable systems on out-of-domain test data vs in-domain test data.

cation and classification. While these new features may be very helpful, ideally we would like our learned representations to produce multiple useful features for the CRF model, so that the CRF can combine the signals from each feature to learn a sophisticated model. Towards this goal, we train N independent versions of our Span-HMM-BaseByLength models, each with a random initialization for the Baum-Welch algorithm. Since Baum-Welch is a hill-climbing algorithm, it should find local, but not necessarily global, optima for the parameters of each Span-HMM-BaseByLength model. When we decode each of the models on training and test texts, we will obtain N different sequences of latent states, one for each locally-optimized model. Thus we obtain N different, independent sources of features. We call the CRF model with these N Span-HMM features the Multi-Span-HMM model(MSH); in experiments we use $N = 5$.

6.5 Results and Discussion

Results for the Span-HMM models on the CoNLL 2005 Brown corpus are shown in Table 3. All three versions of the Span-HMM outperform Toutanova *et al.*'s system on the Brown corpus, with the Multi-Span-HMM gaining 5 points in F1. The Multi-Span-HMM model improves over the Baseline+HMM+Paths model by 7 points in precision, and 5.3 points in recall. Among the Span-HMM models, the use of more states in the Span-HMM-BaseByLength model evidently outweighed the cost of splitting the model into separate versions for different length spans. Using multiple independent copies of the Span-HMMs provides a small (0.7) gain in precision and recall. Differences among the different Span-HMM models were not statistically significant, except that the difference in precision between the Multi-Span-HMM and the Span-HMM-Base10 is significant at $p < .1$.

Table 4 shows the performance drop-off for top SRL systems when applied to WSJ test data and Brown corpus test data. The Multi-Span-HMM model performs near the state-of-the-art on the WSJ test set, and its F1 on out-of-domain data drops only about half as much as comparable systems. Note that several of the techniques used by other systems, such as using features from k-best parses or jointly modeling the dependencies among arguments, are complementary to our techniques, and may boost the performance of our system further.

Table 5 breaks our results down by argument type. Most of our improvement over the Baseline system comes from the core arguments A0 and A1, but also from a few adjunct types like AM-TMP and AM-LOC. Figure 2 shows that when the argument is close to the predicate, both systems perform well, but as the distance from the predicate grows, our Multi-Span-HMM system is better able to identify and classify arguments than the Baseline+HMM+Paths system.

Table 6 provides results for argument identification and classification separately. As Pradhan *et al.*previously showed (Pradhan et al., 2007), SRL systems tend to have an easier time with porting argument identification to new domains, but are less strong at argument classification on new domains. Our baseline system decreases in F-score from 81.5 to 78.9 for argument identification, but suffers a much larger 8% drop in argument classification. The Multi-Span-HMM model improves over the Baseline in both tasks and on both test sets, but the largest improvement (6%) is in argument classification on the Brown test set.

To help explain the success of the Span-HMM techniques, we measured the sparsity of our path

	Overall	A0	A1	A2	A3	A4	ADV	DIR	DIS	LOC	MNR	MOD	NEG	PNC	TMP	R-A0	R-A1
Num	2177	566	676	147	12	15	143	53	22	85	110	91	50	17	112	25	21
BL	67.7	76.2	70.6	64.8	59.0	71.2	52.7	54.8	71.9	67.5	58.3	90.9	90.0	50.0	76.5	76.5	71.3
MSH	73.8	82.5	73.6	63.9	60.3	73.3	50.8	52.9	70.0	70.3	52.7	94.2	92.9	51.6	81.6	84.4	75.7

Table 5: SRL results (F1) on the Brown test corpus broken down by role type. BL is the Baseline+HMM+Paths model, MSH is the Multi-Span-HMM model. Column 8 to 16 are all adjuncts (AM-). We omit roles with ten or fewer examples.

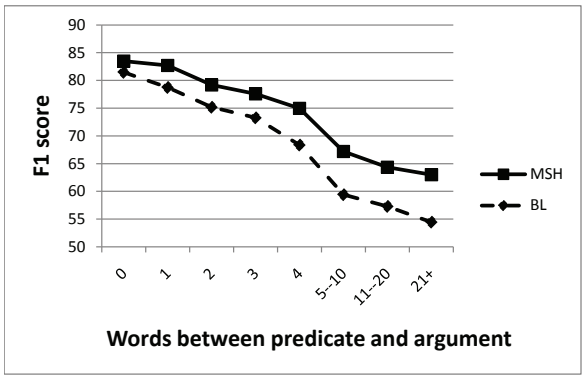

Figure 2: The Multi-Span-HMM (MSH) model is better able to identify and classify arguments that are far from the predicate than the Baseline+HMM+Paths (BL) model.

	Test	Id.F1	Accuracy
BL	WSJ	81.5	93.7
	Brown	78.9	85.8
MSH	WSJ	83.9	94.4
	Brown	80.3	91.9

Table 6: Baseline (BL) and Multi-Span-HMM (MSH) performance on argument identification (Id.F1) and argument classification.

and Span-HMM features. Figure 3 shows the percentage of feature values in the Brown corpus that appear more than twice, exactly twice, or exactly once in the training data. While word path features can be highly valuable when there is training data available for them, only about 11% of the word paths in the Brown test set also appeared at all in the training data. POS and chunk paths fared a bit better (22% and 33% respectively), but even then nearly 70% of all feature values had no available training data. HMM and Span-HMM-Base10 paths achieved far better success in this respect. Importantly, the improvement is mostly due to features that are seen *often* in training, rather than features that were seen just once or twice. Thus Span-

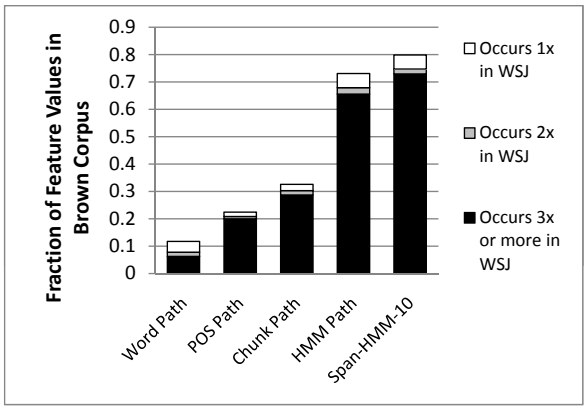

Figure 3: HMM path and Span-HMM features are far more likely to appear often in training data than the word, POS, and chunk path features. Over 70% of Span-HMM-Base10 features in the Brown corpus appear at least three times during training; in contrast, fewer than 33% of chunk path features in the Brown corpus appear at all during training.

HMMs derive their power as representations for open-domain SRL from the fact that they provide features that are mostly the same across domains; 80% of the features of our Span-HMM-Base10 in the Brown corpus were observed at least once in the training data.

Table 7 shows examples of spans that were clustered into the same Span-HMM state, along with word to either side. All four examples are cases where the Span-HMM-Base10 model correctly tagged the following argument, but the Baseline+HMM+Paths model did not. We can see that the paths of these four examples are completely different, but the words surrounding them are very similar. The emission from a span node are very sparse, so the Span-HMM has unsurprisingly learned to cluster spans according to the HMM states that precede and follow the span node. This is by design, as this kind of distributional clustering is helpful for identifying and classifying arguments. One potentially interesting

Predicate	Span	B-Arg

sat	over his second rock	in

Table 7: Example spans labeled with the same Span-HMM state. The examples are taken from sentences where the Span-HMM-Base10 model correctly identified the argument on the right, but the Baseline+HMM+Paths model did not.

question for future work is whether a less sparse model of the spans themselves, such as a Naïve Bayes model for the span node, would yield a better clustering for producing features for semantic role labeling.

7 Previous Work

Deschact and Moens (2009) use a latent-variable language model to provide features for an SRL system, and they show on CoNLL 2008 data that they can significantly improve performance when little labeled training data is available. They do not report on out-of-domain tests. They use HMM language models trained on unlabeled text, much like we use in our baseline systems, but they do not consider models of word spans, which we found to be most beneficial. Downey *et al.* (2007b) also incorporate HMM-based representations into a system for the related task of Web information extraction, and are able to show that the system improves performance on rare terms.

Fürstenau and Lapata (2009b; 2009a) use semi-supervised techniques to automatically annotate data for previously unseen predicates with semantic role information. This task differs from ours in that it focuses on previously unseen predicates, which may or may not be part of text from a new domain. Their techniques also result in relatively lower performance (F1 between 15 and 25), although their tests are on a more difficult and very different corpus. Weston *et al.* (2008) use deep learning techniques based on semi-supervised embeddings to improve an SRL system, though their tests are on in-domain data. Unsupervised SRL systems (Swier and Stevenson, 2004; Grenager and Manning, 2006; Abend et al., 2009) can naturally be ported to new domains with little trouble, but their accuracy thus far falls short of state-of-the-art supervised and semi-supervised systems.

The disparity in performance between in-domain and out-of-domain tests is by no means restricted to SRL. Past research in a variety of NLP tasks has shown that parsers (Gildea, 2001), chunkers (Huang and Yates, 2009), part-of-speech taggers (Blitzer et al., 2006), named-entity taggers (Downey et al., 2007a), and word sense disambiguation systems (Escudero et al., 2000) all suffer from a similar drop-off in performance on out-of-domain tests. Numerous domain adaptation techniques have been developed to address this problem, including self-training (McClosky et al., 2006) and instance weighting (Bacchiani et al., 2006) for parser adaptation and structural correspondence learning for POS tagging (Blitzer et al., 2006). Of these techniques, structural correspondence learning is closest to our technique in that it is a form of representation learning, but it does not learn features for word spans. None of these techniques have been successfully applied to SRL.

8 Conclusion and Future Work

We have presented novel representation-learning techniques for building an open-domain SRL system. By incorporating learned features from HMMs and Span-HMMs trained on unlabeled text, our SRL system is able to correctly identify predicates in out-of-domain text with an F1 of 93.5, and it can identify and classify arguments to predicates with an F1 of 73.8, outperforming comparable state-of-the-art systems. Our successes so far on out-of-domain tests bring hope that supervised NLP systems may eventually achieve the ideal where they no longer need new manually-labeled training data for every new domain. There are several potential avenues for further progress towards this goal, including the development of more portable SRL pipeline systems, and especially parsers. Developing techniques that can incrementally adapt to new domains without the computational expense of retraining the CRF model every time would help make open-domain SRL more practical.

Learning Script Knowledge with Web Experiments

Abstract

We describe a novel approach to unsupervised learning of the events that make up a script, along with constraints on their temporal ordering. We collect natural-language descriptions of script-specific event sequences from volunteers over the Internet. Then we compute a graph representation of the script's temporal structure using a multiple sequence alignment algorithm. The evaluation of our system shows that we outperform two informed baselines.

1 Introduction

A script is "a standardized sequence of events that describes some stereotypical human activity such as going to a restaurant or visiting a doctor" (Barr and Feigenbaum, 1981). Scripts are fundamental pieces of commonsense knowledge that are shared between the different members of the same culture, and thus a speaker assumes them to be tacitly understood by a hearer when a scenario related to a script is evoked: When one person says "I'm going shopping", it is an acceptable reply to say "did you bring enough money?", because the SHOPPING script involves a 'payment' event, which again involves the transfer of money.

It has long been recognized that text understanding systems would benefit from the implicit information represented by a script (Cullingford, 1977; Mueller, 2004; Miikkulainen, 1995). There are many other potential applications, including automated storytelling (Swanson and Gordon, 2008), anaphora resolution (McTear, 1987), and information extraction (Rau et al., 1989).

However, it is also commonly accepted that the large-scale manual formalization of scripts is infeasible. While there have been a few attempts at doing this (Mueller, 1998; Gordon, 2001), efforts in which expert annotators create script knowledge bases clearly don't scale. The same holds true of the script-like structures called "scenario frames" in FrameNet (Baker et al., 1998).

There has recently been a surge of interest in automatically learning script-like knowledge resources from corpora (Chambers and Jurafsky, 2008b; Manshadi et al., 2008); but while these efforts have achieved impressive results, they are limited by the very fact that a lot of scripts – such as SHOPPING – are shared implicit knowledge, and their events are therefore rarely elaborated in text.

In this paper, we propose a different approach to the unsupervised learning of script-like knowledge. We focus on the temporal event structure of scripts; that is, we aim to learn what phrases can describe the same event in a script, and what constraints must hold on the temporal order in which these events occur. We approach this problem by asking non-experts to describe typical event sequences in a given scenario over the Internet. This allows us to assemble large and varied collections of event sequence descriptions (ESDs), which are focused on a single scenario. We then compute a *temporal script graph* for the scenario by identifying corresponding event descriptions using a Multiple Sequence Alignment algorithm from bioinformatics, and converting the alignment into a graph. This graph makes statements about what phrases can describe the same event of a scenario, and in what order these events can take place. Crucially, our algorithm exploits the sequential structure of the ESDs to distinguish event descriptions that occur at different points in the script storyline, even when they are semantically similar. We evaluate our script graph algorithm on ten unseen scenarios, and show that it significantly outperforms a clustering-based baseline.

The paper is structured as follows. We will first position our research in the landscape of related work in Section 2. We will then define how

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 979–988,
Uppsala, Sweden, 11-16 July 2010.

we understand scripts, and what aspect of scripts we model here, in Section 3. Section 4 describes our data collection method, and Section 5 explains how we use Multiple Sequence Alignment to compute a temporal script graph. We evaluate our system in Section 6 and conclude in Section 7.

2 Related Work

Approaches to learning script-like knowledge are not new. For instance, Mooney (1990) describes an early attempt to acquire causal chains, and Smith and Arnold (2009) use a graph-based algorithm to learn temporal script structures. However, to our knowledge, such approaches have never been shown to generalize sufficiently for wide coverage application, and none of them was rigorously evaluated.

More recently, there have been a number of approaches to automatically learning event chains from corpora (Chambers and Jurafsky, 2008b; Chambers and Jurafsky, 2009; Manshadi et al., 2008). These systems typically employ a method for classifying temporal relations between given event descriptions (Chambers et al., 2007; Chambers and Jurafsky, 2008a; Mani et al., 2006). They achieve impressive performance at extracting high-level descriptions of procedures such as a CRIMINAL PROCESS. Because our approach involves directly asking people for event sequence descriptions, it can focus on acquiring specific scripts from arbitrary domains, and we can control the level of granularity at which scripts are described. Furthermore, we believe that much information about scripts is usually left implicit in texts and is therefore easier to learn from our more explicit data. Finally, our system automatically learns different phrases which describe the same event together with the temporal ordering constraints.

Jones and Thompson (2003) describe an approach to identifying different natural language realizations for the same event considering the temporal structure of a scenario. However, they don't aim to acquire or represent the temporal structure of the whole script in the end.

In its ability to learn paraphrases using Multiple Sequence Alignment, our system is related to Barzilay and Lee (2003). Unlike Barzilay and Lee, we do not tackle the general paraphrase problem, but only consider whether two phrases describe the same event in the context of the same script. Furthermore, the atomic units of our alignment process are entire phrases, while in Barzilay and Lee's setting, the atomic units are words.

Finally, it is worth pointing out that our work is placed in the growing landscape of research that attempts to learn linguistic information out of data directly collected from users over the Internet. Some examples are the general acquisition of commonsense knowledge (Singh et al., 2002), the use of browser games for that purpose (von Ahn and Dabbish, 2008), and the collaborative annotation of anaphoric reference (Chamberlain et al., 2009). In particular, the use of the Amazon Mechanical Turk, which we use here, has been evaluated and shown to be useful for language processing tasks (Snow et al., 2008).

3 Scripts

Before we delve into the technical details, let us establish some terminology. In this paper, we distinguish *scenarios*, as classes of human activities, from *scripts*, which are stereotypical models of the internal structure of these activities. Where EATING IN A RESTAURANT is a scenario, the script describes a number of events, such as ordering and leaving, that must occur in a certain order in order to constitute an EATING IN A RESTAURANT activity. The classical perspective on scripts (Schank and Abelson, 1977) has been that next to defining some events with temporal constraints, a script also defines their participants and their causal connections.

Here we focus on the narrower task of learning the events that a script consists of, and of modeling and learning the temporal ordering constraints that hold between them. Formally, we will specify a script (in this simplified sense) in terms of a directed graph $G_s = (E_s, T_s)$, where E_s is a set of nodes representing the events of a scenario s, and T_s is a set of edges (e_i, e_k) indicating that the event e_i typically happens before e_k in s. We call G_s the *temporal script graph (TSG)* for s.

Each event in a TSG can usually be expressed with many different natural-language phrases. As the TSG in Fig. 3 illustrates, the first event in the script for EATING IN A FAST FOOD RESTAURANT can be equivalently described as 'walk to the counter' or 'walk up to the counter'; even phrases like 'walk into restaurant', which would not usually be taken as paraphrases of these, can be accepted as describing the same event in the context

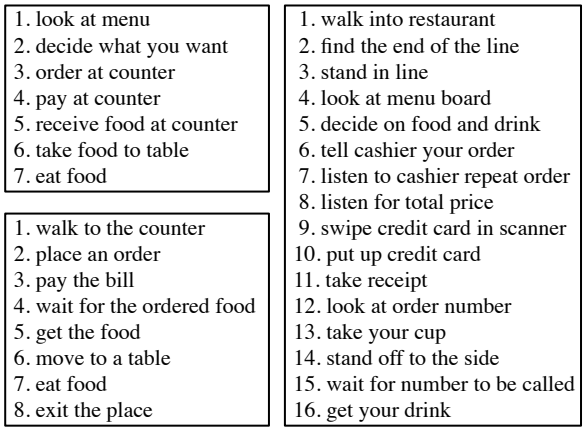

Figure 1: Three event sequence descriptions

of this scenario. We call a natural-language realization of an individual event in the script an *event description*, and we call a sequence of event descriptions that form one particular instance of the script an *event sequence description (ESD)*. Examples of ESDs for the FAST FOOD RESTAURANT script are shown in Fig. 1.

One way to look at a TSG is thus that its nodes are equivalence classes of different phrases that describe the same event; another is that valid ESDs can be generated from a TSG by randomly selecting phrases from some nodes and arranging them in an order that respects the temporal precedence constraints in T_s. Our goal in this paper is to take a set of ESDs for a given scenario as our input and then compute a TSG that clusters different descriptions of the same event into the same node, and contains edges that generalize the temporal information encoded in the ESDs.

4 Data Acquisition

In order to automatically learn TSGs, we selected 22 scenarios for which we collect ESDs. We deliberately included scenarios of varying complexity, including some that we considered hard to describe (CHILDHOOD, CREATE A HOMEPAGE), scenarios with highly variable orderings between events (MAKING SCRAMBLED EGGS), and scenarios for which we expected cultural differences (WEDDING).

We used the Amazon Mechanical Turk[1] to collect the data. For every scenario, we asked 25 people to enter a typical sequence of events in this scenario, in temporal order and in "bullet point style". We required the annotators to enter at least 5 and at most 16 events. Participants were allowed to skip a scenario if they felt unable to enter events for it, but had to indicate why. We did not restrict the participants (e.g. to native speakers).

In this way, we collected 493 ESDs for the 22 scenarios. People used the possibility to skip a form 57 times. The most frequent explanation for this was that they didn't know how a certain scenario works: The scenario with the highest proportion of skipped forms was CREATE A HOMEPAGE, whereas MAKING SCRAMBLED EGGS was the only one in which nobody skipped a form. Because we did not restrict the participants' inputs, the data was fairly noisy. For the purpose of this study, we manually corrected the data for orthography and filtered out forms that were written in broken English or did not comply with the task (e.g. when users misunderstood the scenario, or did not list the event descriptions in temporal order). Overall we discarded 15% of the ESDs.

Fig. 1 shows three of the ESDs we collected for EATING IN A FAST-FOOD RESTAURANT. As the example illustrates, descriptions differ in their starting points ('walk into restaurant' vs. 'walk to counter'), the granularity of the descriptions ('pay the bill' vs. event descriptions 8–11 in the third sequence), and the events that are mentioned in the sequence (not even 'eat food' is mentioned in all ESDs). Overall, the ESDs we collected consisted of 9 events on average, but their lengths varied widely: For most scenarios, there were significant numbers of ESDs both with the minimum length of 5 and the maximum length of 16 and everything in between. Combined with the fact that 93% of all individual event descriptions occurred only once, this makes it challenging to align the different ESDs with each other.

5 Temporal Script Graphs

We will now describe how we compute a temporal script graph out of the collected data. We proceed in two steps. First, we identify phrases from different ESDs that describe the same event by computing a Multiple Sequence Alignment (MSA) of all ESDs for the same scenario. Then we postprocess the MSA and convert it into a temporal script graph, which encodes and generalizes the temporal information contained in the original ESDs.

Figure 2: A MSA of four event sequence descriptions

5.1 Multiple Sequence Alignment

The problem of computing Multiple Sequence Alignments comes from bioinformatics, where it is typically used to find corresponding elements in proteins or DNA (Durbin et al., 1998).

A sequence alignment algorithm takes as its input some *sequences* $s_1, \ldots, s_n \in \Sigma^*$ over some alphabet Σ, along with a *cost function* $c_m : \Sigma \times \Sigma \to \mathbb{R}$ for substitutions and *gap costs* $c_{gap} \in \mathbb{R}$ for insertions and deletions. In bioinformatics, the elements of Σ could be nucleotides and a sequence could be a DNA sequence; in our case, Σ contains the individual event descriptions in our data, and the sequences are the ESDs.

A *Multiple Sequence Alignment* A of these sequences is then a matrix as in Fig. 2: The i-th column of A is the sequence s_i, possibly with some gaps ("⊘") interspersed between the symbols of s_i, such that each row contains at least one non-gap. If a row contains two non-gaps, we take these symbols to be *aligned*; aligning a non-gap with a gap can be thought of as an insertion or deletion.

Each sequence alignment A can be assigned a *cost* $c(A)$ in the following way:

$$c(A) = c_{gap} \cdot \Sigma_{\oslash} + \sum_{i=1}^{n} \sum_{\substack{j=1,\\ a_{ji} \neq \oslash}}^{m} \sum_{\substack{k=j+1,\\ a_{ki} \neq \oslash}}^{m} c_m(a_{ji}, a_{ki})$$

where $\Sigma_{\oslash}$ is the number of gaps in A, n is the number of rows and m the number of sequences. In other words, we sum up the alignment cost for any two symbols from Σ that are aligned with each other, and add the gap cost for each gap. There is an algorithm that computes cheapest pairwise alignments (i.e. $n = 2$) in polynomial time (Needleman and Wunsch, 1970). For $n > 2$, the problem is NP-complete, but there are efficient algorithms that approximate the cheapest MSAs by aligning two sequences first, considering the result as a single sequence whose elements are pairs, and repeating this process until all sequences are incorporated in the MSA (Higgins and Sharp, 1988).

5.2 Semantic similarity

In order to apply MSA to the problem of aligning ESDs, we choose Σ to be the set of all individual event descriptions in a given scenario. Intuitively, we want the MSA to prefer the alignment of two phrases if they are semantically similar, i.e. it should cost more to align 'exit' with 'eat' than 'exit' with 'leave'. Thus we take a measure of semantic (dis)similarity as the cost function c_m.

The phrases to be compared are written in bullet-point style. They are typically short and elliptic (no overt subject), they lack determiners and use infinitive or present progressive form for the main verb. Also, the lexicon differs considerably from usual newspaper corpora. For these reasons, standard methods for similarity assessment are not straightforwardly applicable: Simple bag-of-words approaches do not provide sufficiently good results, and standard taggers and parsers cannot process our descriptions with sufficient accuracy.

We therefore employ a simple, robust heuristics, which is tailored to our data and provides very

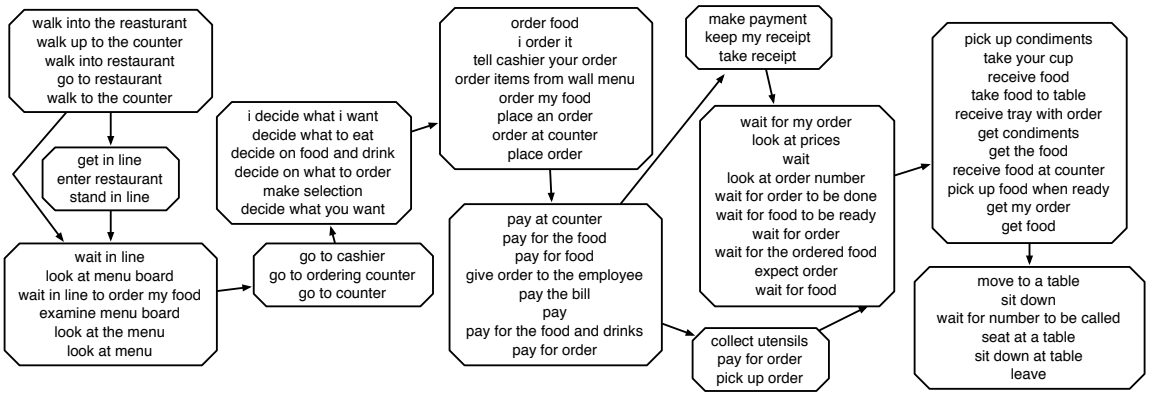

Figure 3: An extract from the graph computed for EATING IN A FAST FOOD RESTAURANT

shallow dependency-style syntactic information. We identify the first potential verb of the phrase (according to the POS information provided by WordNet) as the predicate, the preceding noun (if any) as subject, and all following potential nouns as objects. (With this fairly crude tagging method, we also count nouns in prepositional phrases as "objects".)

On the basis of this pseudo-parse, we compute the similarity measure sim:

$$sim = \alpha \cdot pred + \beta \cdot subj + \gamma \cdot obj$$

where $pred$, $subj$, and obj are the similarity values for predicates, subjects and objects respectively, and α, β, γ are weights. If a constituent is not present in one of the phrases to compare, we set its weight to zero and redistribute it over the other weights. We fix the individual similarity scores $pred$, $subj$, and obj depending on the WordNet relation between the most similar WordNet senses of the respective lemmas (100 for synonyms, 0 for lemmas without any relation, and intermediate numbers for different kind of WordNet links).

We optimized the values for $pred$, $subj$, and obj as well as the weights α, β and γ using a held-out development set of scenarios. Our experiments showed that in most cases, the verb contributes the largest part to the similarity (accordingly, α needs to be higher than the other factors). We achieved improved accuracy by distinguishing a class of verbs that contribute little to the meaning of the phrase (i.e., support verbs, verbs of movement, and the verb "get"), and assigning them a separate, lower α.

5.3 Building Temporal Script Graphs

We can now compute a low-cost MSA for each scenario out of the ESDs. From this alignment, we extract a temporal script graph, in the following way. First, we construct an initial graph which has one node for each row of the MSA as in Fig. 2. We interpret each node of the graph as representing a single event in the script, and the phrases that are collected in the node as different descriptions of this event; that is, we claim that these phrases are paraphrases in the context of this scenario. We then add an edge (u, v) to the graph iff (1) $u \neq v$, (2) there was at least one ESD in the original data in which some phrase in u directly preceded some phrase in v, and (3) if a single ESD contains a phrase from u and from v, the phrase from u directly precedes the one from v. In terms of the MSA, this means that if a phrase from u comes from the same column as a phrase from v, there are at most some gaps between them. This initial graph represents exactly the same information as the MSA, in a different notation.

The graph is automatically post-processed in a second step to simplify it and eliminate noise that caused MSA errors. At first we prune spurious nodes which contain only one event description. Then we refine the graph by merging nodes whose elements should have been aligned in the first place but were missed by the MSA. We merge two nodes if they satisfy certain structural and semantic constraints.

The *semantic* constraints check whether the event descriptions of the merged node would be sufficiently consistent according to the similarity measure from Section 5.2. To check whether we can merge two nodes u and v, we use an unsupervised clustering algorithm (Flake et al., 2004) to

first cluster the event descriptions in u and v separately. Then we combine the event descriptions from u and v and cluster the resulting set. If the union has more clusters than either u or v, we assume the nodes to be too dissimilar for merging.

The *structural* constraints depend on the graph structure. We only merge two nodes u and v if their event descriptions come from different sequences and one of the following conditions holds:

- u and v have the same parent;
- u has only one parent, v is its only child;
- v has only one child and is the only child of u;
- all children of u (except for v) are also children of v.

These structural constraints prevent the merging algorithm from introducing new temporal relations that are not supported by the input ESDs.

We take the output of this post-processing step as the temporal script graph. An excerpt of the graph we obtain for our running example is shown in Fig. 3. One node created by the node merging step was the top left one, which combines one original node containing 'walk into restaurant' and another with 'go to restaurant'. The graph mostly groups phrases together into event nodes quite well, although there are some exceptions, such as the 'collect utensils' node. Similarly, the temporal information in the graph is pretty accurate. But perhaps most importantly, our MSA-based algorithm manages to keep similar phrases like 'wait in line' and 'wait for my order' apart by exploiting the sequential structure of the input ESDs.

6 Evaluation

We evaluated the two core aspects of our system: its ability to recognize descriptions of the same event (*paraphrases*) and the resulting temporal constraints it defines on the event descriptions (*happens-before relation*). We compare our approach to two baseline systems and show that our system outperforms both baselines and sometimes even comes close to our upper bound.

6.1 Method

We selected ten scenarios which we did not use for development purposes, five of them taken from the corpus described in Section 4, the other five from the OMICS corpus.[2] The OMICS corpus is a freely available, web-collected corpus by the Open Mind Initiative (Singh et al., 2002). It contains several *stories* ($\approx$ scenarios) consisting of multiple ESDs. The corpus strongly resembles ours in language style and information provided, but is restricted to "indoor activities" and contains much more data than our collection (175 scenarios with more than 40 ESDs each).

For each scenario, we created a *paraphrase set* out of 30 randomly selected pairs of event descriptions which the system classified as paraphrases and 30 completely random pairs. The *happens-before set* consisted of 30 pairs classified as *happens-before*, 30 random pairs and additionally all 60 pairs in reverse order. We added the reversed pairs to check whether the raters really prefer one direction or whether they accept both and were biased by the order of presentation.

We presented each pair to 5 non-experts, all US residents, via Mechanical Turk. For the paraphrase set, an exemplary question we asked the rater looks as follows, instantiating the Scenario and the two descriptions to compare appropriately:

> Imagine two people, both telling a story about SCENARIO. Could the first one say *event*$_2$ to describe the same part of the story that the second one describes with *event*$_1$?

For the happens-before task, the question template was the following:

> Imagine somebody telling a story about SCENARIO in which the events *event*$_1$ and *event*$_2$ occur. Would *event*$_1$ normally happen before *event*$_2$?

We constructed a gold standard by a majority decision of the raters. An expert rater adjudicated the pairs with a 3:2 vote ratio.

6.2 Upper Bound and Baselines

To show the contributions of the different system components, we implemented two baselines:

Clustering Baseline: We employed an unsupervised clustering algorithm (Flake et al., 2004) and fed it all event descriptions of a scenario. We first created a similarity graph with one node per event description. Each pair of nodes is connected

Figure 4: Results for paraphrasing task; significance of difference to *sys*: • : $p \leq 0.01$, ○ : $p \leq 0.1$

with a weighted edge; the weight reflects the semantic similarity of the nodes' event descriptions as described in Section 5.2. To include all input information on inequality of events, we did not allow for edges between nodes containing two descriptions occurring together in one ESD. The underlying assumption here is that two different event descriptions of the same ESD always represent distinct events.

The clustering algorithm uses a parameter which influences the cluster granularity, without determining the exact number of clusters beforehand. We optimized this parameter automatically for each scenario: The system picks the value that yields the optimal result with respect to density and distance of the clusters (Flake et al., 2004), i.e. the elements of each cluster are as similar as possible to each other, and as dissimilar as possible to the elements of all other clusters.

The clustering baseline considers two phrases as paraphrases if they are in the same cluster. It claims a happens-before relation between phrases e and f if some phrase in e's cluster precedes some phrase in f's cluster in the original ESDs. With this baseline, we can show the contribution of MSA.

Levenshtein Baseline: This system follows the same steps as our system, but using Levenshtein distance as the measure of semantic similarity for MSA and for node merging (cf. Section 5.3). This lets us measure the contribution of the more fine-grained similarity function. We computed Levenshtein distance as the character-wise edit distance on the phrases, divided by the phrases' character length so as to get comparable values for shorter and longer phrases. The gap costs for MSA with Levenshtein were optimized on our development set so as to produce the best possible alignment.

Upper bound: We also compared our system to a human-performance upper bound. Because no single annotator rated all pairs of ESDs, we constructed a "virtual annotator" as a point of comparison, by randomly selecting one of the human annotations for each pair.

6.3 Results

We calculated precision, recall, and f-score for our system, the baselines, and the upper bound as follows, with all_{system} being the number of pairs labelled as *paraphrase* or *happens-before*, all_{gold} as the respective number of pairs in the gold standard and $correct$ as the number of pairs labeled correctly by the system.

$$precision = \frac{correct}{all_{system}} \qquad recall = \frac{correct}{all_{gold}}$$

$$f\text{-}score = \frac{2 * precision * recall}{precision + recall}$$

The tables in Fig. 4 and 5 show the results of our system and the reference values; Fig. 4 describes the paraphrasing task and Fig. 5 the happens-before task. The upper half of the tables describes the test sets from our own corpus, the remainder refers to OMICS data. The columns labelled *sys* contain the results of our system, *base$_{cl}$* describes the clustering baseline and *base$_{lev}$* the Levenshtein baseline. The f-score for the upper bound is in the column *upper*. For the f-score values, we calculated the significance for the difference between our system and the baselines as well as the upper bound, using a resampling test (Edgington, 1986). The values marked with • differ from our system significantly at a level of $p \leq 0.01$, ○ marks a level of $p \leq 0.1$. The remaining values are not significant with $p \leq 0.1$. (For the average values, no sig-

Figure 5: Results for happens-before task; significance of difference to *sys*: • : $p \leq 0.01$, ○ : $p \leq 0.1$

nificance is calculated because this does not make sense for scenario-wise evaluation.)

Paraphrase task: Our system outperforms both baselines clearly, reaching significantly higher f-scores in 17 of 20 cases. Moreover, for five scenarios, the upper bound does not differ significantly from our system. For judging the precision, consider that the test set is slightly biased: Labeling all pairs with the majority category (*no paraphrase*) would result in a precision of 0.64. However, recall and f-score for this trivial lower bound would be 0.

The only scenario in which our system doesn't score very well is BUY FROM A VENDING MACHINE, where the upper bound is not significantly better either. The clustering system, which can't exploit the sequential information from the ESDs, has trouble distinguishing semantically similar phrases (high recall, low precision). The Levenshtein similarity measure, on the other hand, is too restrictive and thus results in comparatively high precisions, but very low recall.

Happens-before task: In most cases, and on average, our system is superior to both baselines. Where a baseline system performs better than ours, the differences are not significant. In four cases, our system does not differ significantly from the upper bound. Regarding precision, our system outperforms both baselines in all scenarios except one (MAKE OMELETTE).

Again the clustering baseline is not fine-grained enough and suffers from poor precision, only slightly better than the majority baseline. The Levenshtein baseline gets mostly poor recall, except for ANSWER THE PHONE: to describe this scenario, people used very similar wording. In such a scenario, adding lexical knowledge to the sequential information makes less of a difference.

On average, the baselines do much better here than for the paraphrase task. This is because once a system decides on paraphrase clusters that are essentially correct, it can retrieve correct information about the temporal order directly from the original ESDs.

Both tables illustrate that the task complexity strongly depends on the scenario: Scripts that allow for a lot of variation with respect to ordering (such as COOK SCRAMBLED EGGS) are particularly challenging for our system. This is due to the fact that our current system can neither represent nor find out that two events can happen in arbitrary order (e.g., 'take out pan' and 'take out bowl').

One striking difference between the performance of our system on the OMICS data and on our own dataset is the relation to the upper bound: On our own data, the upper bound is almost always significantly better than our system, whereas significant differences are rare on OMICS. This difference bears further analysis; we speculate it might be caused either by the increased amount of training data in OMICS or by differences in language (e.g., fewer anaphoric references).

7 Conclusion

We conclude with a summary of this paper and some discussion along with hints to future work in the last part.

7.1 Summary

In this paper, we have described a novel approach to the unsupervised learning of temporal script information. Our approach differs from previous work in that we collect training data by directly asking non-expert users to describe a scenario, and

then apply a Multiple Sequence Alignment algorithm to extract scenario-specific paraphrase and temporal ordering information. We showed that our system outperforms two baselines and sometimes approaches human-level performance, especially because it can exploit the sequential structure of the script descriptions to separate clusters of semantically similar events.

7.2 Discussion and Future Work

We believe that we can scale this approach to model a large numbers of scenarios representing implicit shared knowledge. To realize this goal, we are going to automatize several processing steps that were done manually for the current study. We will restrict the user input to lexicon words to avoid manual orthography correction. Further, we will implement some heuristics to filter unusable instances by matching them with the remaining data. As far as the data collection is concerned, we plan to replace the web form with a browser game, following the example of von Ahn and Dabbish (2008). This game will feature an algorithm that can generate new candidate scenarios without any supervision, for instance by identifying suitable sub-events of collected scripts (e.g. inducing data collection for PAY as *sub*-event sequence of GO SHOPPING)

On the technical side, we intend to address the question of detecting participants of the scripts and integrating them into the graphs, Further, we plan to move on to more elaborate data structures than our current TSGs, and then identify and represent script elements like optional events, alternative events for the same step, and events that can occur in arbitrary order.

Because our approach gathers information from volunteers on the Web, it is limited by the knowledge of these volunteers. We expect it will perform best for general commonsense knowledge; culture-specific knowledge or domain-specific expert knowledge will be hard for it to learn. This limitation could be addressed by targeting specific groups of online users, or by complementing our approach with corpus-based methods, which might perform well exactly where ours does not.

Acknowledgements

We want to thank Dustin Smith for the OMICS data, Alexis Palmer for her support with Amazon Mechanical Turk, Nils Bendfeldt for the creation of all web forms and Ines Rehbein for her effort with several parsing experiments. In particular, we thank the anonymous reviewers for their helpful comments. – This work was funded by the Cluster of Excellence "Multimodal Computing and Interaction" in the German Excellence Initiative.

Abstract

A fundamental step in sentence comprehension involves assigning semantic roles to sentence constituents. To accomplish this, the listener must parse the sentence, find constituents that are candidate arguments, and assign semantic roles to those constituents. Each step depends on prior lexical and syntactic knowledge. Where do children learning their first languages begin in solving this problem? In this paper we focus on the parsing and argument-identification steps that precede Semantic Role Labeling (SRL) training. We combine a simplified SRL with an unsupervised HMM part of speech tagger, and experiment with psycholinguistically-motivated ways to label clusters resulting from the HMM so that they can be used to parse input for the SRL system. The results show that proposed shallow representations of sentence structure are robust to reductions in parsing accuracy, and that the contribution of alternative representations of sentence structure to successful semantic role labeling varies with the integrity of the parsing and argument-identification stages.

1 Introduction

In this paper we present experiments with an automatic system for semantic role labeling (SRL) that is designed to model aspects of human language acquisition. This simplified SRL system is inspired by the syntactic bootstrapping theory, and by an account of syntactic bootstrapping known as 'structure-mapping' (Fisher, 1996; Gillette et al., 1999; Lidz et al., 2003). Syntactic bootstrapping theory proposes that young children use their very partial knowledge of syntax to guide sentence comprehension. The structure-mapping account makes three key assumptions: First, sentence comprehension is grounded by the acquisition of an initial set of concrete nouns. Nouns are arguably less dependent on prior linguistic knowledge for their acquisition than are verbs; thus children are assumed to be able to identify the referents of some nouns via cross-situational observation (Gillette et al., 1999). Second, these nouns, once identified, yield a skeletal sentence structure. Children treat each noun as a candidate argument, and thus interpret the number of nouns in the sentence as a cue to its semantic predicate-argument structure (Fisher, 1996). Third, children represent sentences in an abstract format that permits generalization to new verbs (Gertner et al., 2006).

The structure-mapping account of early syntactic bootstrapping makes strong predictions, including predictions of tell-tale errors. In the sentence "Ellen and John laughed", an intransitive verb appears with two nouns. If young children rely on representations of sentences as simple as an ordered set of nouns, then they should have trouble distinguishing such sentences from transitive sentences. Experimental evidence suggests that they do: 21-month-olds mistakenly interpreted word order in sentences such as "The girl and the boy kradded" as conveying agent-patient roles (Gertner and Fisher, 2006).

Previous computational experiments with a system for automatic semantic role labeling (BabySRL: (Connor et al., 2008)) showed that it is possible to learn to assign basic semantic roles based on the shallow sentence representations proposed by the structure-mapping view. Furthermore, these simple structural features were robust to drastic reductions in the integrity of the semantic-role feedback (Connor et al., 2009). These experiments showed that representations of sentence structure as simple as 'first of two nouns' are useful, but the experiments relied on perfect

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 989–998,
Uppsala, Sweden, 11-16 July 2010.

knowledge of arguments and predicates as a start to classification.

Perfect built-in parsing finesses two problems facing the human learner. The first problem involves classifying words by part-of-speech. Proposed solutions to this problem in the NLP and human language acquisition literatures focus on distributional learning as a key data source (e.g., (Mintz, 2003; Johnson, 2007)). Importantly, infants are good at learning distributional patterns (Gomez and Gerken, 1999; Saffran et al., 1996). Here we use a fairly standard Hidden Markov Model (HMM) to generate clusters of words that occur in similar distributional contexts in a corpus of input sentences.

The second problem facing the learner is more contentious: Having identified clusters of distributionally-similar words, how do children figure out what role these clusters of words should play in a sentence interpretation system? Some clusters contain nouns, which are candidate arguments; others contain verbs, which take arguments. How is the child to know which are which? In order to use the output of the HMM tagger to process sentences for input to an SRL model, we must find a way to automatically label the clusters.

Our strategies for automatic argument and predicate identification, spelled out below, reflect core claims of the structure-mapping theory: (1) The meanings of some concrete nouns can be learned without prior linguistic knowledge; these concrete nouns are assumed based on their meanings to be possible arguments; (2) verbs are identified, not primarily by learning their meanings via observation, but rather by learning about their syntactic argument-taking behavior in sentences.

By using the HMM part-of-speech tagger in this way, we can ask how the simple structural features that we propose children start with stand up to reductions in parsing accuracy. In doing so, we move to a parser derived from a particular theoretical account of how the human learner might classify words, and link them into a system for sentence comprehension.

2 Model

We model language learning as a Semantic Role Labeling (SRL) task (Carreras and Màrquez, 2004). This allows us to ask whether a learner, equipped with particular theoretically-motivated representations of the input, can learn to understand sentences at the level of who did what to whom. The architecture of our system is similar to a previous approach to modeling early language acquisition (Connor et al., 2009), which is itself based on the standard architecture of a full SRL system (e.g. (Punyakanok et al., 2008)).

This basic approach follows a multi-stage pipeline, with each stage feeding in to the next. The stages are: (1) Parsing the sentence, (2) Identifying potential predicates and arguments based on the parse, (3) Classifying role labels for each potential argument relative to a predicate, (4) Applying constraints to find the best labeling of arguments for a sentence. In this work we attempt to limit the knowledge available at each stage to the automatic output of the previous stage, constrained by knowledge that we argue is available to children in the early stages of language learning.

In the parsing stage we use an unsupervised parser based on Hidden Markov Models (HMM), modeling a simple 'predict the next word' parser. Next the argument identification stage identifies HMM states that correspond to possible arguments and predicates. The candidate arguments and predicates identified in each input sentence are passed to an SRL classifier that uses simple abstract features based on the number and order of arguments to learn to assign semantic roles.

As input to our learner we use samples of natural child directed speech (CDS) from the CHILDES corpora (MacWhinney, 2000). During initial unsupervised parsing we experiment with incorporating knowledge through a combination of statistical priors favoring a skewed distribution of words into classes, and an initial hard clustering of the vocabulary into function and content words. The argument identifier uses a small set of frequent nouns to seed argument states, relying on the assumptions that some concrete nouns can be learned as a prerequisite to sentence interpretation, and are interpreted as candidate arguments.

The SRL classifier starts with noisy largely unsupervised argument identification, and receives feedback based on annotation in the PropBank style; in training, each word identified as an argument receives the true role label of the phrase that word is part of. This represents the assumption that learning to interpret sentences is naturally supervised by the fit of the learner's predicted meaning with the referential context. The provision

of perfect 'gold-standard' feedback over-estimates the real child's access to this supervision, but allows us to investigate the consequences of noisy argument identification for SRL performance. We show that even with imperfect parsing, a learner can identify useful abstract patterns for sentence interpretation. Our ultimate goal is to 'close the loop' of this system, by using learning in the SRL system to improve the initial unsupervised parse and argument identification.

The training data were samples of parental speech to three children (Adam, Eve, and Sarah; (Brown, 1973)), available via CHILDES. The SRL training corpus consists of parental utterances in samples Adam 01-20 (child age 2;3 - 3;1), Eve 01-18 (1;6 - 2;2), and Sarah 01-83 (2;3 - 3;11). All verb-containing utterances without symbols indicating disfluencies were automatically parsed with the Charniak parser (Charniak, 1997), annotated using an existing SRL system (Punyakanok et al., 2008) and then errors were hand-corrected. The final annotated sample contains about 16,730 propositions, with 32,205 arguments.

3 Unsupervised Parsing

As a first step of processing, we feed the learner large amounts of unlabeled text and expect it to learn some structure over this data that will facilitate future processing. The source of this text is child directed speech collected from various projects in the CHILDES repository[1]. We removed sentences with fewer than three words or markers of disfluency. In the end we used 160 thousand sentences from this set, totaling over 1 million tokens and 10 thousand unique words.

The goal of the parsing stage is to give the learner a representation permitting it to generalize over word forms. The exact parse we are after is a distributional and context-sensitive clustering of words based on sequential processing. We chose an HMM based parser for this since, in essence the HMM yields an unsupervised POS classifier, but without names for states. An HMM trained with expectation maximization (EM) is analogous to a simple process of predicting the next word in a stream and correcting connections accordingly for each sentence.

With HMM we can also easily incorporate additional knowledge during parameter estimation. The first (and simplest) parser we used was an HMM trained using EM with 80 hidden states. The number of hidden states was made relatively large to increase the likelihood of clusters corresponding to a single part of speech, while preserving some degree of generalization.

Johnson (2007) observed that EM tends to create word clusters of uniform size, which does not reflect the way words cluster into parts of speech in natural languages. The addition of priors biasing the system toward a skewed allocation of words to classes can help. The second parser was an 80 state HMM trained with Variational Bayes EM (VB) incorporating Dirichlet priors (Beal, 2003).[2]

In the third and fourth parsers we experiment with enriching the HMM POS-tagger with other psycholinguistically plausible knowledge. Words of different grammatical categories differ in their phonological as well as in their distributional properties (e.g., (Kelly, 1992; Monaghan et al., 2005; Shi et al., 1998)); combining phonological and distributional information improves the clustering of words into grammatical categories. The phonological difference between content and function words is particularly striking (Shi et al., 1998). Even newborns can categorically distinguish content and function words, based on the phonological difference between the two classes (Shi et al., 1999). Human learners may treat content and function words as distinct classes from the start.

To implement this division into function and content words[3], we start with a list of function word POS tags[4] and then find words that appear predominantly with these POS tags, using tagged WSJ data (Marcus et al., 1993). We allocated a fixed number of states for these function words, and left the rest of the states for the rest of the words. This amounts to initializing the emission matrix for the HMM with a block structure; words from one class cannot be emitted by states allocated to the other class. This trick has been used before in speech recognition work (Rabiner,

[1] We used parts of the Bloom (Bloom, 1970; Bloom, 1973), Brent (Brent and Siskind, 2001), Brown (Brown, 1973), Clark (Clark, 1978), Cornell, MacWhinney (MacWhinney, 2000), Post (Demetras et al., 1986) and Providence (Demuth et al., 2006) collections.

[2] We tuned the prior using the same set of 8 value pairs suggested by Gao and Johnson (2008), using a held out set of POS-tagged CDS to evaluate final performance.

[3] We also include a small third class for punctuation, which is discarded.

[4] TO,IN,EX,POS,WDT,PDT,WRB,MD,CC,DT,RP,UH

1989), and requires far fewer resources than the full tagging dictionary that is often used to intelligently initialize an unsupervised POS classifier (e.g. (Brill, 1997; Toutanova and Johnson, 2007; Ravi and Knight, 2009)).

Because the function and content word preclustering preceded parameter estimation, it can be combined with either EM or VB learning. Although this initial split forces sparsity on the emission matrix and allows more uniform sized clusters, Dirichlet priors may still help, if word clusters within the function or content word subsets vary in size and frequency. The third parser was an 80 state HMM trained with EM estimation, with 30 states pre-allocated to function words; the fourth parser was the same except that it was trained with VB EM.

3.1 Parser Evaluation

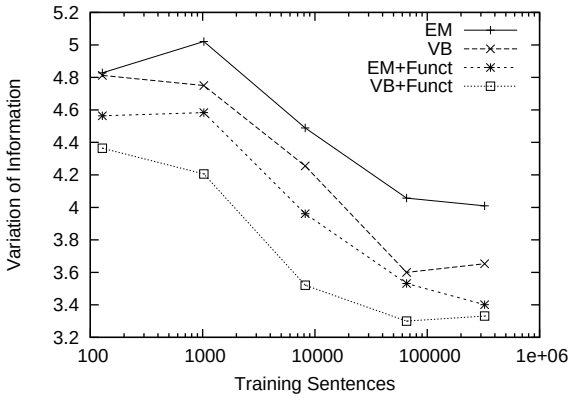

Figure 1: Unsupervised Part of Speech results, matching states to gold POS labels. All systems use 80 states, and comparison is to gold labeled CDS text, which makes up a subset of the HMM training data. Variation of Information is an information-theoretic measure summing mutual information between tags and states, proposed by (Meilă, 2002), and first used for Unsupervised Part of Speech in (Goldwater and Griffiths, 2007). Smaller numbers are better, indicating less information lost in moving from the HMM states to the gold POS tags. Note that incorporating function word precluster-ing allows both EM and VB algorithms to achieve the same performance with an order of magnitude fewer sentences.

We first evaluate these parsers (the first stage of our SRL system) on unsupervised POS tagging. Figure 1 shows the performance of the four systems using Variation of Information to measure match between gold states and unsupervised parsers as we vary the amount of text they receive. Each point on the graph represents the average result over 10 runs of the HMM with different samples of the unlabeled CDS. Another common measure for unsupervised POS (when there are more states than tags) is a many to one greedy mapping of states to tags. It is known that EM gives a better many to one score than VB trained HMM (Johnson, 2007), and likewise we see that here: with all data EM gives 0.75 matching, VB gives 0.74, while both EM+Funct and VB+Funct reach 0.80.

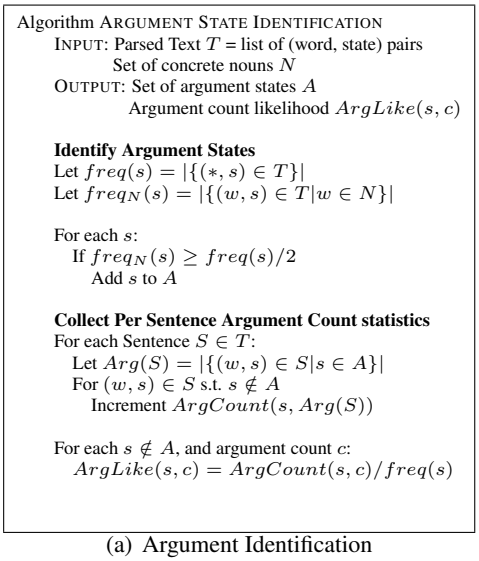
Adding the function/content word split to the HMM structure improves both EM and VB estimation in terms of both tag matching accuracy and information. However, these measures look at the parser only in isolation. What is more important to us is how useful the provided word clusters are for future semantic processing. In the next sections we use the outputs of our four parsers to identify arguments and predicates.

4 Argument Identification

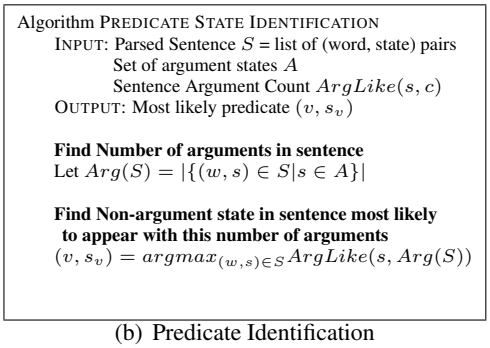
The unsupervised parser provides a state label for each word in each sentence; the goal of the argument identification stage is to use these states to label words as potential arguments, predicates or neither. As described in the introduction, core premises of the structure-mapping account offer routes whereby we could label some HMM states as argument or predicate states.

The structure-mapping account holds that sentence comprehension is grounded in the learning of an initial set of nouns. Children are assumed to identify the referents of some concrete nouns via cross-situational learning (Gillette et al., 1999; Smith and Yu, 2008). Children then assume, by virtue of the meanings of these nouns, that they are candidate arguments. This is a simple form of semantic bootstrapping, requiring the use of built-in links between semantics and syntax to identify the grammatical type of known words (Pinker, 1984). We use a small set of known nouns to transform unlabeled word clusters into candidate arguments for the SRL: HMM states that are dominated by known names for animate or inanimate objects are assumed to be argument states.

Given text parsed by the HMM parser and a list of known nouns, the argument identifier proceeds in multiple steps as illustrated in figure 2. The first stage identifies as argument states those states that appear at least half the time in the training data with known nouns. This use of a seed list and distributional clustering is similar to Prototype Driven Learning (Haghighi and Klein, 2006), except we are only providing information on one specific class.



(a) Argument Identification



(b) Predicate Identification

Figure 2: Argument identification algorithm. This is a two stage process: argument state identification based on statistics collected over entire text and per sentence predicate identification.

As a list of known nouns we collected all those nouns that appear three times or more in the child directed speech training data and judged to be either animate or inanimate nouns. The full set of 365 nouns covers over 93% of noun occurences in our data. In upcoming sections we experiment with varying the number of seed nouns used from this set, selecting the most frequent set of nouns. Reflecting the spoken nature of the child directed speech, the most frequent nouns are pronouns, but beyond the top 10 we see nouns naming people ('daddy', 'ursula') and object nouns ('chair', 'lunch').

What about verbs? A typical SRL model identifies candidate arguments and tries to assign roles to them relative to each verb in the sentence. In principle one might suppose that children learn the meanings of verbs via cross-situational observation just as they learn the meanings of concrete nouns. But identifying the meanings of verbs is much more troublesome. Verbs' meanings are abstract, therefore harder to identify based on scene information alone (Gillette et al., 1999). As a result, early vocabularies are dominated by nouns (Gentner, 2006). On the structure-mapping account, learners identify verbs, and begin to determine their meanings, based on sentence structure cues. Verbs take noun arguments; thus, learners could learn which words are verbs by detecting each verb's syntactic argument-taking behavior. Experimental evidence provides some support for this procedure: 2-year-olds keep track of the syntactic structures in which a new verb appears, even without a concurrent scene that provides cues to the verb's semantic content (Yuan and Fisher, 2009).

We implement this behavior by identifying as predicate states the HMM states that appear commonly with a particular number of previously identified arguments. First, we collect statistics over the entire HMM training corpus regarding how many arguments are identified per sentence, and which states that are not identified as argument states appear with each number of arguments. Next, for each parsed sentence that serves as SRL input, the algorithm chooses as the most likely predicate the word whose state is most likely to appear with the number of arguments found in the current input sentence. Note that this algorithm assumes exactly one predicate per sentence. Implicitly, the argument count likelihood divides predicate states up into transitive and intransitive predicates based on appearances in the simple sentences of CDS.

4.1 Argument Identification Evaluation

Figure 3 shows argument and predicate identification accuracy for each of the four parsers when provided with different numbers of known nouns. The known word list is very skewed with its most frequent members dominating the total noun occurrences in the data. The ten most frequent words[5] account for 60% of the total noun occurrences. We achieve the different occurrence coverage numbers of figure 3 by using the most frequent N words from the list that give the specific coverage[6]. Pronouns refer to people or objects, but are abstract in that they can refer to any person or object. The inclusion of pronouns in our list of

[5] you, it, I, what, he, me, ya, she, we, her

[6] N of 5, 10, 30, 83, 227 cover 50%, 60%, 70%, 80%, 90% of all noun occurrences

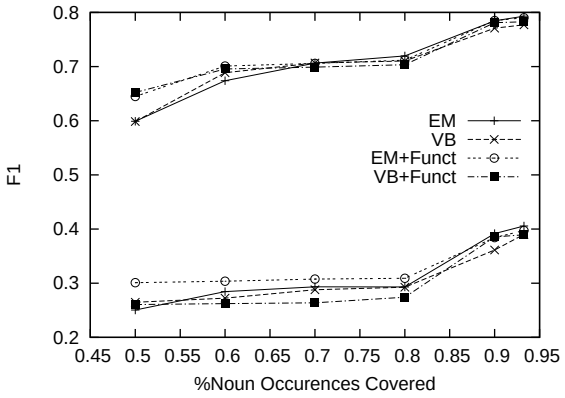


Figure 3: Effect of number of concrete nouns for seeding argument identification with various unsupervised parsers. Argument identification accuracy is computed against true argument boundaries from hand labeled data. The upper set of results show primary argument (A0-4) identification F1, and bottom lines show predicate identification F1.

known nouns represents the assumption that toddlers have already identified pronouns as referential terms. Even 19-month-olds assign appropriately different interpretations to novel verbs presented in simple transitive versus intransitive sentences with pronoun arguments ("He's kradding him!" vs. "He's kradding!"; (Yuan et al., 2007)). In ongoing work we experiment with other methods of identifying seed nouns.

Two groups of curves appear in figure 3: the upper group shows the primary argument identification accuracy and the bottom group shows the predicate identification accuracy. We evaluate compared to gold tagged data with true argument and predicate boundaries. The primary argument (A0-4) identification accuracy is the F1 value, with precision calculated as the proportion of identified arguments that appear as part of a true argument, and recall as the proportion of true arguments that have some state identified as an argument. F1 is calculated similarly for predicate identification, as one state per sentence is identified as the predicate.

As shown in figure 3, argument identification F1 is higher than predicate identification (which is to be expected, given that predicate identification depends on accurate arguments), and as we add more seed nouns the argument identification improves. Surprisingly, despite the clear differences in unsupervised POS performance seen in figure 1, the different parsers do not yield very different argument and predicate identification. As we will see in the next section, however, when the arguments identified in this step are used to train SRL classifier, distinctions between parsers reappear, suggesting that argument identification F1 masks systematic patterns in the errors.

5 Testing SRL Performance

Finally, we used the results of the previous parsing and argument-identification stages in training a simplified SRL classifier (BabySRL), equipped with sets of features derived from the structure-mapping account. For argument classification we used a linear classifier trained with a regularized perceptron update rule (Grove and Roth, 2001). In the results reported below the BabySRL did not use sentence-level inference for the final classification, every identified argument is classified independently; thus multiple nouns can have the same role. In what follows, we compare the performance of the BabySRL across the four parsers. We evaluated SRL performance by testing the BabySRL with constructed sentences like those used for the experiments with children described in the Introduction. All test sentences contained a novel verb, to test the model's ability to generalize.

We examine the performance of four versions of the BabySRL, varying in the features used to represent sentences. All four versions include lexical features consisting of the target argument and predicate (as identified in the previous steps). The baseline model has only these lexical features (Lexical). Following Connor et al. (2008; 2009), the key feature type we propose is noun pattern features (NounPat). Noun pattern features indicate how many nouns there are in the sentence and which noun the target is. For example, in "You dropped it!", 'you' has a feature active indicating that it is the first of two nouns, while 'it' has a feature active indicating that it is the second of two nouns. We compared the behavior of noun pattern features to another simple representation of word order, position relative to the verb (VerbPos). In the same example sentence, 'you' has a feature active indicating that it is pre-verbal; for 'it' a feature is active indicating that it is post-verbal. A fourth version of the BabySRL (Combined) used both NounPat and VerbPos features.

We structured our tests of the BabySRL to test the predictions of the structure-mapping account. (1) NounPat features will improve the SRL's ability to interpret simple transitive test sentences containing two nouns and a novel verb, relative

to a lexical baseline. Like 21-month-old children (Gertner et al., 2006), the SRL should interpret the first noun as an agent and the second as a patient. (2) Because NounPat features represent word order solely in terms of a sequence of nouns, an SRL equipped with these features will make the errors predicted by the structure-mapping account and documented in children (Gertner and Fisher, 2006). (3) NounPat features permit the SRL to assign different roles to the subjects of transitive and intransitive sentences that differ in their number of nouns. This effect follows from the nature of the NounPat features: These features partition the training data based on the number of nouns, and therefore learn separately the likely roles of the '1st of 1 noun' and the '1st of 2 nouns'.

These patterns contrast with the behavior of the VerbPos features: When the BabySRL was trained with perfect parsing, VerbPos promoted agent-patient interpretations of transitive test sentences, and did so even more successfully than NounPat features did, reflecting the usefulness of position relative to the verb in understanding English sentences. In addition, VerbPos features eliminated the errors with two-noun intransitive sentences. Given test sentences such as 'You and Mommy krad', VerbPos features represented both nouns as pre-verbal, and therefore identified both as likely agents. However, VerbPos features did not help the SRL assign different roles to the subjects of simple transitive and intransitive sentences: 'Mommy' in 'Mommy krads you' and 'Mommy krads' are both represented simply as pre-verbal.

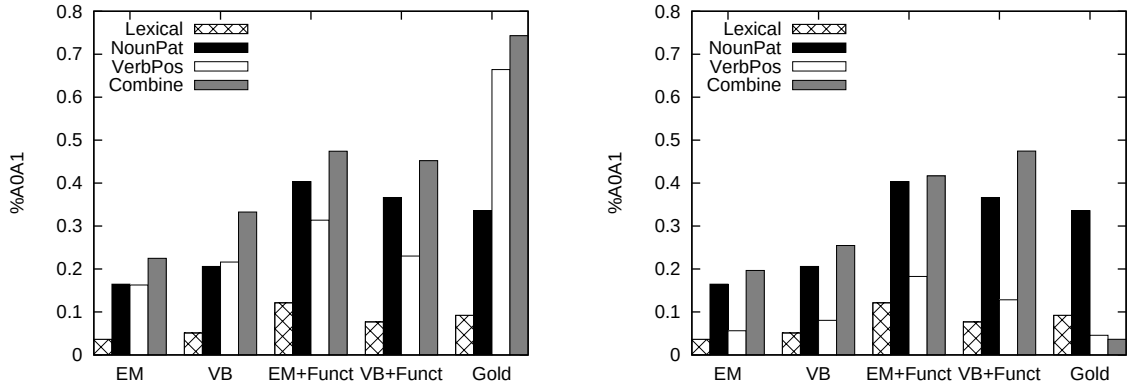
To test the system's predictions on transitive and intransitive two noun sentences, we constructed two test sentence templates: 'A krads B' and 'A and B krad', where A and B were replaced with familiar animate nouns. The animate nouns were selected from all three children's data in the training set and paired together in the templates such that all pairs are represented.

Figure 4 shows SRL performance on test sentences containing a novel verb and two animate nouns. Each plot shows the proportion of test sentences that were assigned an agent-patient (A0-A1) role sequence; this sequence is correct for transitive sentences but is an error for two-noun intransitive sentences. Each group of bars shows the performance of the BabySRL trained using one of the four parsers, equipped with each of our four feature sets. The top and bottom panels in Figure 4 differ in the number of nouns provided to seed the argument identification stage. The top row shows performance with 10 seed nouns (the 10 most frequent nouns, mostly animate pronouns), and the bottom row shows performance with 365 concrete (animate or inanimate) nouns treated as known. Relative to the lexical baseline, NounPat features fared well: they promoted the assignment of A0-A1 interpretations to transitive sentences, across all parser versions and both sets of known nouns. Both VB estimation and the content-function word split increased the ability of NounPat features to learn that the first of two nouns was an agent, and the second a patient. The NounPat features also promote the predicted error with two-noun intransitive sentences (Figures 4(b), 4(d)). Despite the relatively low accuracy of predicate identification noted in section 4.1, the VerbPos features did succeed in promoting an A0A1 interpretation for transitive sentences containing novel verbs relative to the lexical baseline. In every case the performance of the Combined model that includes both NounPat and VerbPos features exceeds the performance of either NounPat or VerbPos alone, suggesting both contribute to correct predictions for transitive sentences. However, the performance of VerbPos features did not improve with parsing accuracy as did the performance of the NounPat features. Most strikingly, the VerbPos features did not eliminate the predicted error with two-noun intransitive sentences, as shown in panels 4(b) and 4(d). The Combined model predicted an A0A1 sequence for these sentences, showing no reduction in this error due to the participation of VerbPos features.

Table 1 shows SRL performance on the same transitive test sentences ('A krads B'), compared to simple one-noun intransitive sentences ('A krads'). To permit a direct comparison, the table reports the proportion of transitive test sentences for which the first noun was assigned an agent (A0) interpretation, and the proportion of intransitive test sentences with the agent (A0) role assigned to the single noun in the sentence. Here we report only the results from the best-performing parser (trained with VB EM, and content/function word pre-clustering), compared to the same classifiers trained with gold standard argument identification. When trained on arguments identified via the unsupervised POS tagger, noun pattern features promoted agent interpretations of tran-

	Two Noun Transitive, % Agent First				One Noun Intransitive, % Agent Prediction			
	Lexical	NounPat	VerbPos	Combine	Lexical	NounPat	VerbPos	Combine
VB+Funct 10 seed	0.48	0.61	0.55	0.71	0.48	0.57	0.56	0.59
VB+Funct 365 seed	0.22	0.64	0.41	0.74	0.23	0.33	0.43	0.41
Gold Arguments	0.16	0.41	0.69	0.77	0.17	0.18	0.70	0.58

Table 1: SRL result comparison when trained with best unsupervised argument identifier versus trained with gold arguments. Comparison is between agent first prediction of two noun transitive sentences vs. one noun intransitive sentences. The unsupervised arguments lead the classifier to rely more on noun pattern features; when the true arguments and predicate are known the verb position feature leads the classifier to strongly indicate agent first in both settings.



(a) Two Noun Transitive Sentence, 10 seed nouns

(b) Two Noun Intransitive Sentence, 10 seed nouns

(c) Two Noun Transitive Sentence, 365 seed nouns

(d) Two Noun Intransitive Sentence, 365 seed nouns

Figure 4: SRL classification performance on transitive and intransitive test sentences containing two nouns and a novel verb. Performance with gold-standard argument identification is included for comparison. Across parses, noun pattern features promote agent-patient (A0A1) interpretations of both transitive ("You krad Mommy") and two-noun intransitive sentences ("You and Mommy krad"); the latter is an error found in young children. Unsupervised parsing is less accurate in identifying the verb, so verb position features fail to eliminate errors with two-noun intransitive sentences.

sitive subjects, but not for intransitive subjects. This differentiation between transitive and intransitive sentences was clearer when more known nouns were provided. Verb position features, in contrast, promote agent interpretations of subjects weakly with unsupervised argument identification, but equally for transitive and intransitive.

Noun pattern features were robust to increases in parsing noise. The behavior of verb position features suggests that variations in the identifiability of different parts of speech can affect the usefulness of alternative representations of sentence structure. Representations that reflect the position of the verb may be powerful guides for understanding simple English sentences, but representations reflecting only the number and order of nouns can dominate early in acquisition, depending on the integrity of parsing decisions.

6 Conclusion and Future Work

The key innovation in the present work is the combination of unsupervised part-of-speech tagging and argument identification to permit learning in a simplified SRL system. Children do not

have the luxury of treating part-of-speech tagging and semantic role labeling as separable tasks. Instead, they must learn to understand sentences starting from scratch, learning the meanings of some words, and using those words and their patterns of arrangement into sentences to bootstrap their way into more mature knowledge.

We have created a first step toward modeling this incremental process. We combined unsupervised parsing with minimal supervision to begin to identify arguments and predicates. An SRL classifier used simple representations built from these identified arguments to extract useful abstract patterns for classifying semantic roles. Our results suggest that multiple simple representations of sentence structure could co-exist in the child's system for sentence comprehension; representations that will ultimately turn out to be powerful guides to role identification may be less powerful early in acquisition because of the noise introduced by the unsupervised parsing.

The next step is to 'close the loop', using higher level semantic feedback to improve the earlier argument identification and parsing stages. Perhaps with the help of semantic feedback the system can automatically improve predicate identification, which in turn allows it to correct the observed intransitive sentence error. This approach will move us closer to the goal of using initial simple structural patterns and natural observation of the world (semantic feedback) to bootstrap more and more sophisticated representations of linguistic structure.

Modeling Norms of Turn-Taking in Multi-Party Conversation

Kornel Laskowski
Carnegie Mellon University
Pittsburgh PA, USA
kornel@cs.cmu.edu

Abstract

Substantial research effort has been invested in recent decades into the computational study and automatic processing of multi-party conversation. While most aspects of conversational speech have benefited from a wide availability of analytic, computationally tractable techniques, only qualitative assessments are available for characterizing multi-party turn-taking. The current paper attempts to address this deficiency by first proposing a framework for computing turn-taking model perplexity, and then by evaluating several multi-participant modeling approaches. Experiments show that direct multi-participant models do not generalize to held out data, and likely never will, for practical reasons. In contrast, the Extended-Degree-of-Overlap model represents a suitable candidate for future work in this area, and is shown to successfully predict the distribution of speech in time and across participants in previously unseen conversations.

1 Introduction

Substantial research effort has been invested in recent decades into the computational study and automatic processing of multi-party conversation. Whereas sociolinguists might argue that multi-party settings provide for the most natural form of conversation, and that dialogue and monologue are merely degenerate cases (Jaffe and Feldstein, 1970), computational approaches have found it most expedient to leverage past successes; these often involved at most one speaker. Consequently, even in multi-party settings, automatic systems generally continue to treat participants independently, fusing information across participants relatively late in processing.

This state of affairs has resulted in the near-exclusion from computational consideration and from semantic analysis of a phenomenon which occurs at the lowest level of speech exchange, namely the relative timing of the deployment of speech in arbitrary multi-party groups. This phenomenon, the implicit taking of turns at talk (Sacks et al., 1974), is important because unless participants adhere to its general rules, a conversation would simply not take place. It is therefore somewhat surprising that while most other aspects of speech enjoy a large base of computational methodologies for their study, there are few quantitative techniques for assessing the flow of turn-taking in general multi-party conversation.

The current work attempts to address this problem by proposing a simple framework, which, at least conceptually, borrows quite heavily from the standard language modeling paradigm. First, it defines the perplexity of a vector-valued Markov process whose multi-participant states are a concatenation of the binary states of individual speakers. Second, it presents some obvious evidence regarding the unsuitability of models defined directly over this space, under various assumptions of independence, for the inference of conversation-independent norms of turn-taking. Finally, it demonstrates that the extended-degree-of-overlap model of (Laskowski and Schultz, 2007), which models participants in an alternate space, achieves by far the best likelihood estimates for previously unseen conversations. This appears to be because the model can learn *across* conversations, regardless of the number of their participants. Experimental results show that it yields relative perplexity reductions of approximately 75% when compared to the ubiquitous single-participant model which ignores interlocutors, indicating that it can learn and generalize aspects of interaction which direct multi-participant models, and merely single-participant models, cannot.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 999–1008,
Uppsala, Sweden, 11-16 July 2010.

2 Data

Analysis and experiments are performed using the ICSI Meeting Corpus (Janin et al., 2003; Shriberg et al., 2004). The corpus consists of 75 meetings, held by various research groups at ICSI, which would have occurred even if they had not been recorded. This is important for studying naturally occurring interaction, since any form of intervention (including occurrence staging solely for the purpose of obtaining a record) may have an unknown but consistent impact on the emergence of turn-taking behaviors. Each meeting was attended by 3 to 9 participants, providing a wide variety of possible interaction types.

3 Conceptual Framework

3.1 Definitions

Turn-taking is a generally observed phenomenon in conversation (Sacks et al., 1974; Goodwin, 1981; Schegloff, 2007); one party talks while the others listen. Its description and analysis is an important problem, treated frequently as a subdomain of linguistic pragmatics (Levinson, 1983). In spite of this, linguists tend to disagree about what precisely constitutes a *turn* (Sacks et al., 1974; Edelsky, 1981; Goodwin, 1981; Traum and Heeman, 1997), or even a turn boundary. For example, a "yeah" produced by a listener to indicate attentiveness, referred to as a *backchannel* (Yngve, 1970), is often considered to not implement a turn (nor to delineate an ongoing turn of an interlocutor), as it bears no propositional content and does not "take the floor" from the current speaker.

To avoid being tied to any particular sociolinguistic theory, the current work equates "turn" with any contiguous interval of speech uttered by the same participant. Such intervals are commonly referred to as *talk spurts* (Norwine and Murphy, 1938). Because Norwine and Murphy's original definition is somewhat ambiguous and non-trivial to operationalize, this work relies on that proposed by (Shriberg et al., 2001), in which *spurts* are "defined as *speech regions uninterrupted by pauses longer than 500 ms*" (italics in the original). Here, a threshold of 300 ms is used instead, as recently proposed in NIST's Rich Transcription Meeting Recognition evaluations (NIST, 2002). The resulting definition of talk spurt, it is important to note, is in quite common use but frequently under different names. An oft-cited example is the *inter-pausal unit* of (Koiso et al., 1998)[1], where the threshold is 100 ms.

A consequence of this choice is that any *model of turn-taking behavior* inferred will effectively be a model of the distribution of speech, in time and across participants. If the parameters of such a model are maximum likelihood (ML) estimates, then that model will best account for what is most likely, or most "normal"; it will constitute a *norm*.

Finally, an important aspect of this work is that it analyzes turn-taking behavior as independent of the words spoken (and of the ways in which those words are spoken). As a result, strictly speaking, what is modeled is not the distribution of speech in time and across participants but of binary *speech activity* in time and across participants. Despite this seemingly dramatic simplification, it will be seen that important aspects of turn-taking are sufficiently rare to be problematic for modeling. Modeling them jointly alongside lexical information, in multi-party scenarios, is likely to remain intractable for the foreseeable future.

3.2 The Vocal Interaction Record Q

The notation used here, as in (Laskowski and Schultz, 2007), is a trivial extension of that proposed in (Rabiner, 1989) to vector-valued Markov processes.

At any instant t, each of K participants to a conversation is in a state drawn from $\Psi \equiv \{S_0, S_1\} \equiv \{\square, \blacksquare\}$, where $S_1 \equiv \blacksquare$ indicates speech (or, more precisely, "*intra*-talk-spurt instants") and $S_0 \equiv \square$ indicates non-speech (or "*inter*-talk-spurt instants"). The *joint* state of all participants at time t is described using the K-length column vector

$$\begin{aligned} \mathbf{q}_t \in \Psi^K &\equiv \Psi \times \Psi \times \ldots \times \Psi \\ &\equiv \left\{\mathbf{S}_0, \mathbf{S}_1, \ldots, \mathbf{S}_{2^K-1}\right\} . \end{aligned} \quad (1)$$

An entire conversation, from the point of view of this work, can be represented as the matrix

$$\begin{aligned} \mathbf{Q} &\equiv [\mathbf{q}_1, \mathbf{q}_2, \ldots, \mathbf{q}_T] \\ &\in \Psi^{K \times T} . \end{aligned} \quad (2)$$

$\mathbf{Q}$ is known as the (discrete) vocal interaction (Dabbs and Ruback, 1987) record. T is the total number of frames in the conversation, sampled at $T_s = 100$ ms intervals. This is approximately the duration of the shortest lexical productions in the ICSI Meeting Corpus.

[1] The inter-pausal unit differs from the *pause unit* of (Seligman et al., 1997) in that the latter is an intra-turn unit, requiring prior turn segmentation

3.3 Time-Independent First-Order Markov Modeling of $\mathbf{Q}$

Given this definition of $\mathbf{Q}$, a model $\mathbf{\Theta}$ is sought to account for it. Only time-independent models, whose parameters do not change over the course of the conversation, are considered in this work.

For simplicity, the state $\mathbf{q}_0 = \mathbf{S}_0 = [\square, \square, \ldots, \square]^*$, in which no participant is speaking (* indicates matrix transpose, to avoid confusion with conversation duration T) is first prepended to $\mathbf{Q}$. $P_0 = P(\mathbf{q}_0)$ therefore represents the unconditional probability of all participants being silent just prior to the start of any conversation[2]. Then

$$\begin{aligned} P(\mathbf{Q}) &= P_0 \cdot \prod_{t=1}^{T} P(\mathbf{q}_t \mid \mathbf{q}_0, \mathbf{q}_1, \cdots, \mathbf{q}_{t-1}) \\ &\doteq P_0 \cdot \prod_{t=1}^{T} P(\mathbf{q}_t \mid \mathbf{q}_{t-1}, \mathbf{\Theta}) \ , \end{aligned} \quad (3)$$

where in the second line the history is truncated to yield a standard first-order Markov form.

Each of the T factors in Equation 3 is independent of the instant t,

$$\begin{aligned} & P(\mathbf{q}_t \mid \mathbf{q}_{t-1}, \mathbf{\Theta}) \\ &\quad = P(\mathbf{q}_t = \mathbf{S}_j \mid \mathbf{q}_{t-1} = \mathbf{S}_i, \mathbf{\Theta}) \quad (4) \\ &\quad \equiv a_{ij} \ , \quad (5) \end{aligned}$$

as per the notation in (Rabiner, 1989). In particular, each factor is a function only of the state $\mathbf{S}_i$ in which the conversation was at time $t-1$ and the state $\mathbf{S}_j$ in which the conversation is at time t, and not of the instants $t-1$ or t. It may be expressed as the scalar a_{ij} which forms the ith row and jth column entry of the matrix $\{a_{ij}\} \equiv \mathbf{\Theta}$.

3.4 Perplexity

In language modeling practice, one finds the likelihood $P(\mathbf{w} \mid \mathbf{\Theta})$, of a word sequence $\mathbf{w}$ of length $\|\mathbf{w}\|$ under a model $\mathbf{\Theta}$, to be an inconvenient measure for comparison. Instead, the *negative log-likelihood* (NLL) and *perplexity* (PPL), defined as

$$\mathrm{NLL} = -\frac{1}{\|\mathbf{w}\|} \log_e P(\mathbf{w} \mid \mathbf{\Theta}) \quad (6)$$

$$\mathrm{PPL} = 10^{\mathrm{NLL}} \ , \quad (7)$$

[2] In reality, the instant $t = 0$ refers to the beginning of *the recording* of a conversation, rather than the beginning of the conversation itself; this detail is without consequence.

are often preferred (Jelinek, 1999). They are ubiquitously used to compare the complexity of different word sequences (or corpora) $\mathbf{w}$ and $\mathbf{w}'$ under the same model $\mathbf{\Theta}$, or the performance on a single word sequence (or corpus) $\mathbf{w}$ under competing models $\mathbf{\Theta}$ and $\mathbf{\Theta}'$.

Here, a similar metric is proposed, to be used for the same purposes, for the record $\mathbf{Q}$.

$$\mathrm{NLL} = -\frac{1}{KT} \log_2 P(\mathbf{Q} \mid \mathbf{\Theta}) \quad (8)$$

$$\begin{aligned} \mathrm{PPL} &= 2^{\mathrm{NLL}} \\ &= (P(\mathbf{Q} \mid \mathbf{\Theta}))^{-1/KT} \end{aligned} \quad (9)$$

are defined as measures of *turn-taking perplexity*. As can be seen in Equation 8, the negative log-likelihood is normalized by the number K of participants and the number T of frames in $\mathbf{Q}$; the latter renders the measure useful for making duration-independent comparisons. The normalization by K does not *per se* suggest that turn-taking in conversations with different K is necessarily similar; it merely provides similar bounds on the magnitudes of these metrics.

4 Direct Estimation of $\mathbf{\Theta}$

Direct application of bigram modeling techniques, defined over the states $\{\mathbf{S}\}$, is treated as a baseline.

4.1 The Case of $K = 2$ Participants

In contrast to multi-party conversation, dialogue has been extensively modeled in the ways described in this paper. Beginning with (Brady, 1969), Markov modeling techniques over the joint speech activity of two interlocutors have been explored by both the sociolinguist and the psycholinguist community (Jaffe and Feldstein, 1970; Dabbs and Ruback, 1987). The same models have also appeared in dialogue systems (Raux, 2008). Most recently, they have been augmented with duration models in a study of the Switchboard corpus (Grothendieck et al., 2009).

4.2 The Case of $K > 2$ Participants

In the general case beyond dialogue, such models have found less traction. This is partly due to the exponential growth in the number of states as K increases, and partly due to difficulties in interpretation. The only model for arbitrary K that the author is familiar with is the GroupTalk model (Dabbs and Ruback, 1987), which is unsuitable for the purposes here as it does not scale (with K,

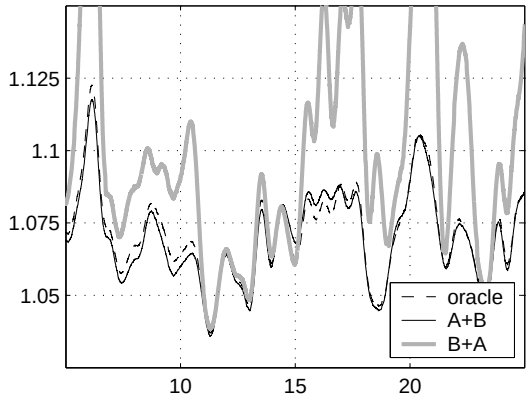

Figure 1: Perplexity (along y-axis) in time (along x-axis, in minutes) for meeting `Bmr024` under a conditionally dependent global oracle model, two "matched-half" models (A+B), and two "mismatched-half" models (B+A).

the number of participants) without losing track of speakers when two or more participants speak simultaneously (known as *overlap*).

4.2.1 Conditionally Dependent Participants

In a particular conversation with K participants, the state space of an ergodic process contains 2^K states, and the number of free parameters in a model $\mathbf{\Theta}$ which treats participant behavior as *conditionally dependent* (CD), henceforth $\mathbf{\Theta}^{CD}$, scales as $2^K \cdot \left(2^K - 1\right)$. It should be immediately obvious that many of the 2^K states are likely to not occur within a conversation of duration T, leading to misestimation of the desired probabilities.

To demonstrate this, three perplexity trajectories for a snippet of meeting `Bmr024` are shown in Figure 1, in the interval beginning 5 minutes into the meeting and ending 20 minutes later. (The meeting is actually just over 50 minutes long but only a snippet is shown to better appreciate small time-scale variation.) The depicted perplexities are not unweighted averages over the whole meeting of duration T as in Equation 8, but over a 60-second Hamming window centered on each t.

The first trajectory, the dashed black line, is obtained when the entire meeting is used to estimate $\mathbf{\Theta}^{CD}$, and is then scored by that same model (an "oracle" condition). Significant perplexity variation is observed throughout the depicted snippet.

The second trajectory, the continuous black line, is that obtained when the meeting is split into two equal-duration halves, one consisting of all instants prior to the midpoint and the other of all instants following it. These halves are hereafter referred to as A and B, respectively (the interval in Figure 1 falls entirely within the A half). Two separate models $\mathbf{\Theta}_A^{CD}$ and $\mathbf{\Theta}_B^{CD}$ are each trained on only one of the two halves, and then applied to those same halves. As can be seen at the scale employed, the matched A+B model, demonstrating the effect of training data ablation, deviates from the global oracle model only in the intervals $[7, 11]$ seconds and $[15, 18]$ seconds; otherwise it appears that more training data, from later in the conversation, does not affect model performance.

Finally, the third trajectory, the continuous gray line, is obtained when the two halves A and B of the meeting are scored using the mismatched models $\mathbf{\Theta}_B^{CD}$ and $\mathbf{\Theta}_A^{CD}$, respectively (this condition is henceforth referred to as the B+A condition). It can be seen that even when probabilities are estimated from the same participants, in exactly the same conversation, a direct conditionally dependent model exposed to over 25 minutes of a conversation cannot predict the turn-taking patterns observed later.

4.2.2 Conditionally Independent Participants

A potential reason for the gross misestimation of $\mathbf{\Theta}^{CD}$ under mismatched conditions is the size of the state space $\{\mathbf{S}\}$. The number of parameters in the model can be reduced by assuming that participants behave *independently* at instant t, but are conditioned on their *joint* behavior at $t-1$. The likelihood of $\mathbf{Q}$ under the resulting *conditionally independent model* $\mathbf{\Theta}^{CI}$ has the form

$$P\left(\mathbf{Q}\right) \doteq P_0 \cdot \prod_{t=1}^{T} \prod_{k=1}^{K} P\left(\mathbf{q}_t\left[k\right] \mid \mathbf{q}_{t-1}, \mathbf{\Theta}_k^{CI}\right) , \quad (10)$$

where each factor is time-independent,

$$P\left(\mathbf{q}_t\left[k\right] \mid \mathbf{q}_{t-1}, \mathbf{\Theta}_k^{CI}\right) = P\left(\mathbf{q}_t\left[k\right] = S_n \mid \mathbf{q}_{t-1} = \mathbf{S}_i, \mathbf{\Theta}_k^{CI}\right) \quad (11)$$

$$\equiv a_{k,in}^{CI} , \quad (12)$$

with $0 \leq i < 2^K$ and $0 \leq n < 2$. The complete model $\{\mathbf{\Theta}_k^{CI}\} \equiv \{\{a_{k,in}^{CI}\}\}$ consists of K matrices of size $2^K \times 2$ each. It therefore contains only $K \cdot 2^K$ free parameters, a significant reduction over the conditionally dependent model $\mathbf{\Theta}^{CD}$.

Panel (a) of Figure 2 shows the performance of this model on the same conversational snippet

as in Figure 1. The oracle, dashed black line of the latter is reproduced as a reference. The continuous black and gray lines show the smoothed perplexity for the matched (A+B) and the mismatched (B+A) conditions, respectively. In the matched condition, the CI model reproduces the oracle trajectory with relatively high fidelity, suggesting that participants' behavior may in fact be assumed to be conditionally independent in the sense discussed. Furthermore, the failures of the CI model under mismatched conditions are less severe in magnitude than those of the CD model.

Panel (b) of Figure 2 demonstrates the trivial fact that a conditionally independent model $\mathbf{\Theta}^{CI}_{any}$, tying the statistics of all K participants into a single model, is useless. This is of course because it cannot predict the next state of a generic participant for which the index k in $\mathbf{q}_{t-1}$ has been lost.

4.2.3 Mutually Independent Participants

A further reduction in the complexity of $\mathbf{\Theta}$ can be achieved by assuming that participants are *mutually independent* (MI), leading to the participant-specific $\mathbf{\Theta}^{MI}_k$ model:

$$P(\mathbf{Q}) \doteq P_0 \cdot \prod_{t=1}^{T} \prod_{k=1}^{K} P\left(\mathbf{q}_t[k] \mid \mathbf{q}_{t-1}[k], \mathbf{\Theta}^{MI}_k\right). \quad (13)$$

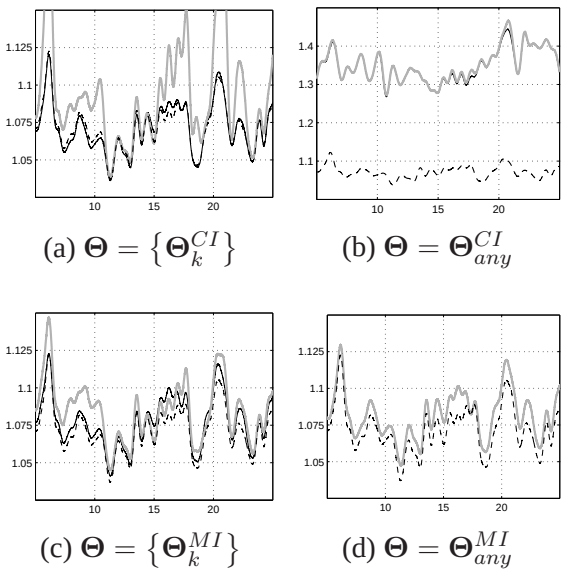
The factors are time-independent,

$$P\left(\mathbf{q}_t[k] \mid \mathbf{q}_{t-1}[k], \mathbf{\Theta}^{MI}_k\right) = P\left(\mathbf{q}_t[k] = S_n \mid \mathbf{q}_{t-1}[k] = S_m, \mathbf{\Theta}^{MI}_k\right) \quad (14)$$

$$\equiv a^{MI}_{k,mn}, \quad (15)$$

where $0 \leq m < 2$ and $0 \leq n < 2$. This model $\{\mathbf{\Theta}^{MI}_k\} \equiv \{\{a^{MI}_{k,mn}\}\}$ consists of K matrices of size 2×2 each, with only $K \cdot 2$ free parameters.

Panel (c) of Figure 2 shows that the MI model yields mismatched performance which is a much better approximation to its performance under matched conditions. However, its matched performance is worse than that of CD and CI models. When a single MI model $\mathbf{\Theta}^{MI}_{any}$ is trained instead for all participants, as shown in panel (d), both of these effects are exaggerated. In fact, the performance of $\mathbf{\Theta}^{MI}_{any}$ in matched and mismatched conditions is almost identical. The consistently higher perplexity is obtained, as mentioned, by smoothing over 60-second windows, and therefore underestimates poor performance at specific instants (which occur frequently).



(a) $\mathbf{\Theta} = \left\{\mathbf{\Theta}^{CI}_k\right\}$ (b) $\mathbf{\Theta} = \mathbf{\Theta}^{CI}_{any}$

(c) $\mathbf{\Theta} = \left\{\mathbf{\Theta}^{MI}_k\right\}$ (d) $\mathbf{\Theta} = \mathbf{\Theta}^{MI}_{any}$

Figure 2: Perplexity (along y-axis) in time (along x-axis, in minutes) for meeting `Bmr024` under a conditionally dependent global oracle model, and various matched (A+B) and mismatched (B+A) model pairs with relaxed dependence assumptions. Legend as in Figure 1.

5 Limitations and Desiderata

As the analyses in Section 4 reveal, direct estimation can be useful under oracle conditions, namely when all of a conversation has been observed and the task is to find intervals where multi-participant behavior deviates significantly from its *conversation-specific* norm. The assumption of conditional independence among participants was argued to lead to negligible degradation in the detectability of these intervals. However, the assumption of mutual independence consistently leads to higher surprise by the model.

5.1 Predicting the Future Within Conversations

In the more interesting setting in which only a part of a conversation has been seen and the task is to limit the perplexity of what is still to come, direct estimation exhibits relatively large failures under both conditionally dependent and conditionally independent participant assumptions. This appears to be due to the size of the state space, which scales as 2^K with the number K of participants. In the case of general K, more conversational data may be sought, from exactly the same group of participants, but that approach appears likely to be

insufficient, and, for practical reasons[3], impossible. One would instead like to be able to use other conversations, also exhibiting participant interaction, to limit the perplexity of speech occurrence in the conversation under study.

Unfortunately, there are two reasons why direct estimation cannot be tractably deployed across conversations. The first is that the direct models considered here, with the exception of $\mathbf{\Theta}^{MI}_{any}$, are K-*specific*. In particular, the number and the identity of conditioning states are both functions of K, for $\mathbf{\Theta}^{CD}$ and $\{\mathbf{\Theta}^{CI}_k\}$; the models may also consist of K distinct submodels, as for $\{\mathbf{\Theta}^{CI}_k\}$ and $\{\mathbf{\Theta}^{MI}_k\}$. No techniques for computing the turn-taking perplexity in conversations with K participants, using models trained on conversations with $K' \neq K$, are currently available.

The second reason is that these models, again with the exception of $\mathbf{\Theta}^{MI}_{any}$, are $\mathbf{R}$-*specific*, independently of K-specificity. By this it is meant that the models are sensitive to participant index permutation. Had a participant at index k in $\mathbf{Q}$ been assigned to another index $k'{\neq}k$, an alternate representation of the conversation, namely $\mathbf{Q}' = \mathbf{R}_{kk'} \cdot \mathbf{Q}$, would have been obtained. (Here, $\mathbf{R}_{kk'}$ is a matrix rotation operator obtained by exchanging columns k and k' of the $K \times K$ identity matrix $\mathbf{I}$.) Since index assignment is entirely arbitrary, useful direct models cannot be inferred from other conversations, even when their $K' = K$, unless K is small. The prospect of naively permuting every training conversation prior to parameter inference has complexity $K!$.

5.2 Comparing Perplexity Across Conversations

Until $\mathbf{R}$-specificity is comprehensively addressed, the only model from among those discussed so far, which exhibits no K-dependence, is $\mathbf{\Theta}^{MI}_{any}$, namely that which treats participants identically and independently. This model can be used to score the perplexity of *any* conversation, and facilitates the comparison of the distribution of speech activity *across* conversations.

Unfortunately, since the model captures only durational aspects of *one*-participant speech and non-speech intervals, it does not in any way encode a norm of turn-taking, an inherently interactive and hence *multi*-participant phenomenon. It therefore cannot be said to rank conversations according to their deviation from turn-taking norms.

[3]This pertains to the practicalities of re-inviting, instrumenting, recording and transcribing the same groups of participants, with necessarily more conversations for large groups than for small ones.

5.3 Theoretical Limitations

In addition to the concerns above, a fundamental limitation of the analyzed direct models, whether for conversation-specific or conversation-independent use, is that they are theoretically cumbersome if not vacuous. Given a solution to the problem of $\mathbf{R}$-specificity, the parameters $\{a^{CD}_{ij}\}$ may be robustly inferred, and the models may be applied to yield useful estimates of turn-taking perplexity. However, they cannot be said to directly validate or dispute the vast qualitative observations of sociolinguistics, and of conversation analysis in particular.

5.4 Prospects for Smoothing

To produce Figures 1 and 2, a small fraction of probability mass was reserved for unseen bigram transitions (as opposed to backing off to unigram probabilities). Furthermore, transitions into never-observed states were assigned uniform probabilities. This policy is simplistic, and there is significant scope for more detailed back-off and interpolation. However, such techniques infer values for under-estimated probabilities from *shorter truncations of the conditioning history*. As K-specificity and $\mathbf{R}$-specificity suggest, what appears to be needed here are back-off and interpolation *across states*. For example, in a conversation of $K = 5$ participants, estimates of the likelihood of the state $\mathbf{q}_t = [\square\blacksquare\blacksquare\blacksquare\square]^*$, which might have been unobserved in any training material, can be assumed to be related to those of $\mathbf{q}'_t = [\square\square\blacksquare\blacksquare\square]^*$ and $\mathbf{q}''_t = [\square\blacksquare\blacksquare\square\square]^*$, as well as those of $\mathbf{R}\mathbf{q}'_t$ and $\mathbf{R}\mathbf{q}''_t$, for arbitrary $\mathbf{R}$.

6 The Extended-Degree-of-Overlap Model

The limitations of direct models appear to be addressable by a form proposed by Laskowski and Schultz in (2006) and (2007). That form, the Extended-Degree-of-Overlap (EDO) model, was used to provide prior probabilities $P(\,\mathbf{Q}\,|\,\mathbf{\Theta}\,)$ of the speech states of multiple meeting participants simultaneously, for use in speech activity detection. The model was trained on *utterances* (rather than talk spurts) from a different corpus than that

used here, and the authors did not explore the turn-taking perplexities of their data sets.

Several of the equations in (Laskowski and Schultz, 2007) are reproduced here for comparison. The EDO model yields time-independent transition probabilities which assume conditional inter-participant dependence (cf. Equation 3),

$$P\left(\mathbf{q}_{t+1}=\mathbf{S}_j \,|\, \mathbf{q}_t=\mathbf{S}_i\right) \;=\; \alpha_{ij} \;\cdot \qquad (16)$$
$$P\left(\|\mathbf{q}_{t+1}\|=n_j,\, \|\mathbf{q}_{t+1}\cdot\mathbf{q}_t\|=o_{ij} \,|\, \|\mathbf{q}_t\|=n_i\right),$$

where $n_i \equiv \|\mathbf{S}_i\|$ and $n_j \equiv \|\mathbf{S}_j\|$, with $\|\mathbf{S}\|$ yielding the number of participants in ■ in the multi-participant state $\mathbf{S}$. In other words, n_i and n_j are the *numbers* of participants simultaneously speaking in states $\mathbf{S}_i$ and $\mathbf{S}_j$, respectively. The elements of the binary product $\mathbf{S}=\mathbf{S}_1\cdot\mathbf{S}_2$ are given by

$$\mathbf{S}\left[k\right] \;\equiv\; \begin{cases} \blacksquare, & \text{if } \mathbf{S}_1\left[k\right]=\mathbf{S}_2\left[k\right]=\blacksquare \\ \square, & \text{otherwise}, \end{cases} \qquad (17)$$

and o_{ij} is therefore the number of same participants speaking in $\mathbf{S}_i$ *and* $\mathbf{S}_j$. The discussion of the role of α_{ij} in Equation 16 is deferred to the end of this section.

The EDO model mitigates $\mathbf{R}$-specificity because it models each bigram $(\mathbf{q}_{t-1},\mathbf{q}_t)=(\mathbf{S}_i,\mathbf{S}_j)$ as the modified bigram $(n_i,[o_{ij},n_j])$, involving three scalars each of which is a *sum* — a commutative (and therefore rotation-invariant) operation. Because it sums across only those participants which are in the ■ state, completely ignoring their □-state interlocutors, it can also mitigate K-specificity if one additionally redefines

$$n_i \;=\; \min\left(\|\mathbf{S}_i\|,\, K_{max}\right) \qquad (18)$$
$$n_j \;=\; \min\left(\|\mathbf{S}_j\|,\, K_{max}\right) \qquad (19)$$
$$o_{ij} \;=\; \min\left(\|\mathbf{S}_i\cdot\mathbf{S}_j\|,\, n_i,\, n_j\right), \qquad (20)$$

as in (Laskowski and Schultz, 2007). K_{max} represents the maximum model-licensed degree of overlap, or the maximum number of participants allowed to be simultaneously speaking. The EDO model therefore represents a viable conversation-independent, K-independent, and $\mathbf{R}$-independent model of turn-taking for the purposes in the current work[4]. The factor α_{ij} in Equation 16 provides a deterministic mapping from the conversation-independent space $(n_i,[o_{ij},n_j])$ to the conversation-specific space $\{a_{ij}\}$. The mapping is deterministic because the model assumes that all participants are identical. This places the EDO model at a disadvantage with respect to the CD and CI models, as well as to $\{\mathbf{\Theta}_k^{MI}\}$, which allow each participant to be modeled differently.

7 Experiments

This section describes the performance of the discussed models on the entire ICSI Meeting Corpus.

7.1 Conversation-Specific Modeling

First to be explored is the prediction of yet-unobserved behavior in conversation-specific settings. For each meeting, models are trained on portions of that meeting only, and then used to score other portions of the same meeting. This is repeated over all meetings, and comprises the mismatched condition of Section 4; for contrast, the matched condition is also evaluated.

Each meeting is divided into two halves, in two different ways. The first way is the A/B split of Section 4, representing the first and second halves of each meeting; as has been shown, turn-taking patterns may vary substantially from A to B. The second split (C/D) places every even-numbered frame in one set and every odd-numbered frame in the other. This yields a much easier setting, of two halves which are on average maximally similar but still temporally disjoint.

The perplexities (of Equation 9) in these experiments are shown in the second, fourth, sixth and eighth columns of Table 1, under "all". In the matched A+B and C+D conditions, the conditionally dependent model $\mathbf{\Theta}^{CD}$ provides topline ML performance. Perplexities decrease as model complexities fall for direct models, as expected. However, in the more interesting mismatched B+A condition, the EDO model performs the best. This shows that its ability to generalize to unseen data is higher than that of direct models. However, in the easier mismatched D+C condition, it is outperformed by the CI model due to behavior differences among participants, which the EDO model

[4]There exists some empirical evidence to suggest that conversations of K participants should not be used to train models for predicting turn-taking behavior in conversations of K' participants, for $K'\neq K$, because turn-taking is inherently K-dependent. For example, (Fay et al., 2000) found that qualitative differences in turn-taking patterns between small groups and large groups, represented in their study by $K=5$ and $K=10$, and noted that there is a smooth transition between the two extremes; this provides some scope for interpolating small- and large- group models, and the EDO framework makes this possible.

Model	Hard split A/B (first/second halves)				Easy split C/D (odd/even frames)			
	A+B		B+A		C+D		D+C	
	"all"	"sub"	"all"	"sub"	"all"	"sub"	"all"	"sub"
$\mathbf{\Theta}^{CD}$	**1.0905**	**1.6444**	1.1225	1.8395	**1.0915**	**1.6555**	1.0991	1.7403
$\{\mathbf{\Theta}_k^{CI}\}$	1.0915	1.6576	1.1156	1.7809	1.0925	1.6695	**1.0956**	**1.7028**
$\{\mathbf{\Theta}_k^{MI}\}$	1.0978	1.7236	1.1086	1.7950	1.0991	1.7381	1.0992	1.7398
$\mathbf{\Theta}^{MI}$	1.1046	1.8047	1.1047	1.8059	1.1046	1.8050	1.1046	1.8052
$\mathbf{\Theta}^{EDO}$	1.0977	1.7257	**1.0985**	**1.7323**	1.0977	1.7268	1.0982	1.7313

Table 1: Perplexities for conversation-specific turn-taking models on the entire ICSI Meeting Corpus. Both "all" frames and the subset ("sub") for which $\mathbf{q}_{t-1} \neq \mathbf{q}_t$ are shown, for matched (A+B and C+D) and mismatched (B+A and D+C) conditions on splits A/B and C/D.

does not capture.

The numbers under the "all" columns in Table 1 were computed using all of each meeting's frames. For contrast, in the "sub" columns, perplexities are computed over only those frames for which $\mathbf{q}_{t-1} \neq \mathbf{q}_t$. This is a useful subset because, for the majority of time in conversations, one person simply continues to talk while all others remain silent[5]. Excluding $\mathbf{q}_{t-1} = \mathbf{q}_t$ bigrams (leading to 0.32M frames from 2.39M frames in "all") offers a glimpse of expected performance differences were duration modeling to be included in the models. Perplexities are much higher in these intervals, but the same general trend as for "all" is observed.

7.2 Conversation-Independent Modeling

The training of conversation-independent models, given a corpus of K-heterogeneous meetings, is achieved by iterating over all meetings and testing each using models trained on all of the other meetings. As discussed in the preceding section, $\mathbf{\Theta}_{any}^{MI}$ is the only one among the direct models which can be used for this purpose. It also models exclusively single-participant behavior, ignoring the interactive setting provided by other participants. As shown in Table 2, when all time is scored the EDO model with $K_{max} = 4$ is the best model (in Section 7.1, $K_{max} = K$ since the model was trained on the same meeting to which it was applied). Its perplexity gap to the oracle model is only a quarter of the gap exhibited by $\mathbf{\Theta}_{any}^{MI}$.

The relative performance of EDO models is even better when only those instants t are considered for which $\mathbf{q}_{t-1} \neq \mathbf{q}_t$. There, the perplexity gap to the oracle model is smaller than that of $\mathbf{\Theta}^{EDO}$ by 78%.

[5]Retaining only $\mathbf{q}_{t-1} \neq \mathbf{q}_t$ also retains instants of transition into and out of intervals of silence.

Model	PPL		ΔPPL (%)	
	"all"	"sub"	"all"	"sub"
$\mathbf{\Theta}^{CD}$	1.0921	1.6616	—	—
$\mathbf{\Theta}^{MI}$	1.1051	1.8170	14.1	23.5
$\mathbf{\Theta}^{EDO}$ (6)	1.0992	1.7405	7.7	11.9
$\mathbf{\Theta}^{EDO}$ (5)	1.0968	1.7127	5.1	7.7
$\mathbf{\Theta}^{EDO}$ (4)	**1.0953**	**1.6947**	3.5	5.0
$\mathbf{\Theta}^{EDO}$ (3)	1.1082	1.8502	17.5	28.5

Table 2: Perplexities for conversation-independent turn-taking models on the entire ICSI Meeting Corpus; the oracle $\mathbf{\Theta}^{CD}$ topline is included in the first row. Both "all" frames and the subset ("sub") for which $\mathbf{q}_{t-1} \neq \mathbf{q}_t$ are shown; relative increases over the topline (less unity, representing no perplexity) are shown in columns 4 and 5. The value of K_{max} (cf. Equations 18, 19, and 20) is shown in parentheses in the first column.

8 Discussion

The model perplexities as reported above may be somewhat different if the "talk spurt" were replaced by a more sociolinguistically motivated definition of "turn", but the ranking of models and their relative performance differences are likely to remain quite similar. On the one hand, many inter-talk-spurt gaps might find themselves to be within-turn, leading to more ■ entries in the record $\mathbf{Q}$ than observed in the current work. This would increase the apparent frequency and duration of intervals of overlap. On the other hand, alternative definitions of turn may exclude some speech activity, such as that implementing backchannels. Since backchannels are often produced in overlap

with the foreground speaker, their removal may eliminate some overlap from $\mathbf{Q}$. (However, as noted in (Shriberg et al., 2001), overlap rates in multi-party conversation remain high even after the exclusion of backchannels.) Both inter-talk-spurt gap inclusion and backchannel exclusion are likely to yield systematic differences, and therefore to be exploitable by the investigated models in similar ways.

The results presented may also be perturbed by modifying the way in which a (manually produced) talk spurt segmentation, with high-precision boundary time-stamps, is discretized to yield $\mathbf{Q}$. Two parameters have controlled the discretization in this work: (1) the frame step $T_s = 100$ ms; and (2) the proportion ρ of T_s for which a participant must be speaking within a frame in order for that frame to be considered ■ rather than □. $\rho = 0.5$ was chosen since this posits approximately as much more speech (than in the high-precision segmentation) as it eliminates. Higher values of ρ would lead to more ■, leading to more overlap than observed in this work. Meanwhile, at constant ρ, choosing a T_s value larger than 100 ms would occasionally miss the shortest talk spurts, but it would allow the models, which are all 1st-order Markovian, to learn temporally more distant dependencies. The trade-offs between these choices are currently under investigation.

From an operational, modeling perspective, it is important to recognize that the choices of the definition for "turn", and of the way in which segmentations are discretized, are essentially arbitrary. The investigated modeling alternatives, and the EDO model in particular, require only that the multi-participant vocal interaction record $\mathbf{Q}$ be *binary-valued*. This general applicability has been demonstrated in past work, in which the EDO model was trained on *utterances* for use in speech activity detection (Laskowski and Schultz, 2007), as well as in (Laskowski and Burger, 2007) where it was trained separately on talk spurts and *laugh bouts*, in the same data, to highlight the differences between speech and laughter deployment.

Finally, it should be remembered that the EDO model is both time-independent and participant-independent. This makes it suitable for comparison of conversational genres, in much the same way as are general language models of words. Accordingly, as for language models, density estimation in future turn-taking models may be improved by considering variability across participants and in time. Participant dependence is likely to be related to speakers' social characteristics and conversational roles, while time dependence may reflect opening and closing functions, topic boundaries, and periodic turn exchange failures. In the meantime, event types such as the latter may be detectable as EDO perplexity departures, potentially recommending the model's use for localizing conversational "hot spots" (Wrede and Shriberg, 2003). The EDO model, and turn-taking models in general, may also find use in diagnosing turn-taking naturalness in spoken dialogue systems.

9 Conclusions

This paper has presented a framework for quantifying the turn-taking perplexity in multi-party conversations. To begin with, it explored the consequences of modeling participants jointly by concatenating their binary speech/non-speech states into a single multi-participant vector-valued state. Analysis revealed that such models are particularly poor at generalization, even to subsequent portions of the same conversation. This is due to the size of their state space, which is factorial in the number of participants. Furthermore, because such models are both specific to the number of participants and to the order in which participant states are concatenated together, it is generally intractable to train them on material from other conversations. The only such model which may be trained on other conversations is that which completely ignores interlocutor interaction.

In contrast, the Extended-Degree-of-Overlap (EDO) construction of (Laskowski and Schultz, 2007) may be trained on other conversations, regardless of their number of participants, and usefully applied to approximate the turn-taking perplexity of an oracle model. This is achieved because it models entry into and egress out of specific degrees of overlap, and completely ignores the number of participants actually present or their modeled arrangement. In this sense, the EDO model can be said to implement the qualitative findings of conversation analysis. In predicting the distribution of speech in time and across participants, it reduces the unseen data perplexity of a model which ignores interaction by 75% relative to an oracle model.

Abstract

We present a novel approach to Information Presentation (IP) in Spoken Dialogue Systems (SDS) using a data-driven statistical optimisation framework for content planning and attribute selection. First we collect data in a Wizard-of-Oz (WoZ) experiment and use it to build a supervised model of human behaviour. This forms a baseline for measuring the performance of optimised policies, developed from this data using Reinforcement Learning (RL) methods. We show that the optimised policies significantly outperform the baselines in a variety of generation scenarios: while the supervised model is able to attain up to 87.6% of the possible reward on this task, the RL policies are significantly better in 5 out of 6 scenarios, gaining up to 91.5% of the total possible reward. The RL policies perform especially well in more complex scenarios. We are also the first to show that adding predictive "lower level" features (e.g. from the NLG realiser) is important for optimising IP strategies according to user preferences. This provides new insights into the nature of the IP problem for SDS.

1 Introduction

Work on evaluating SDS suggests that the Information Presentation (IP) phase is the primary contributor to dialogue duration (Walker et al., 2001), and as such, is a central aspect of SDS design. During this phase the system returns a set of items ("hits") from a database, which match the user's current search constraints. An inherent problem in this task is the trade-off between presenting "enough" information to the user (for example helping them to feel confident that they have a good overview of the search results) versus keeping the utterances short and understandable.

In the following we show that IP for SDS can be treated as a data-driven joint optimisation problem, and that this outperforms a supervised model of human 'wizard' behaviour on a particular IP task (presenting sets of search results to a user).

A similar approach has been applied to the problem of Referring Expression Generation in dialogue (Janarthanam and Lemon, 2010).

1.1 Previous work on Information Presentation in SDS

Broadly speaking, IP for SDS can be divided into two main steps: 1) IP strategy selection and 2) Content or Attribute Selection. Prior work has presented a variety of **IP strategies** for structuring information (see examples in Table 1). For example, the SUMMARY strategy is used to guide the user's "focus of attention". It draws the user's attention to relevant attributes by grouping the current results from the database into clusters, e.g. (Polifroni and Walker, 2008; Demberg and Moore, 2006). Other studies investigate a COMPARE strategy, e.g. (Walker et al., 2007; Nakatsu, 2008), while most work in SDS uses a RECOMMEND strategy, e.g. (Young et al., 2007). In a previous proof-of-concept study (Rieser and Lemon, 2009) we show that each of these strategies has its own strengths and drawbacks, dependent on the particular context in which information needs to be presented to a user. Here, we will also explore possible combinations of the strategies, for example SUMMARY followed by RECOMMEND, e.g. (Whittaker et al., 2002), see Figure 1.

Prior work on **Content or Attribute Selection** has used a "Summarize and Refine" approach (Polifroni and Walker, 2008; Polifroni and Walker, 2006; Chung, 2004). This method employs utility-based attribute selection with respect to how each attribute (e.g. price or food type in restaurant

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1009–1018,
Uppsala, Sweden, 11-16 July 2010.

search) of a set of items helps to narrow down the user's goal to a single item. Related work explores a user modelling approach, where attributes are ranked according to user preferences (Demberg and Moore, 2006; Winterboer et al., 2007). Our data collection (see Section 3) and training environment incorporate these approaches.

The work in this paper is the first to apply a data-driven method to this whole decision space (i.e. combinations of Information Presentation strategies as well as attribute selection), and to show the utility of both lower-level features (e.g. from the NLG realiser) and higher-level features (e.g. from Dialogue Management) for this problem. Previous work has only focused on individual aspects of the problem (e.g. how many attributes to generate, or when to use a SUMMARY), using a pipeline model for SDS with DM features as input, and where NLG has no knowledge of lower level features (e.g. behaviour of the realiser). In Section 4.3 we show that lower level features significantly influence users' ratings of IP strategies. In the following we use a Reinforcement Learning (RL) as a statistical planning framework (Sutton and Barto, 1998) to explore the contextual features for making these decisions, and propose a new joint optimisation method for IP strategies combining content structuring and attribute selection.

2 NLG as planning under uncertainty

We follow the overall framework of NLG as planning under uncertainty (Lemon, 2008; Rieser and Lemon, 2009; Lemon, 2010), where each NLG action is a sequential decision point, based on the current dialogue context and the expected long-term utility or "reward" of the action. Other recent approaches describe this task as planning, e.g. (Koller and Petrick, 2008), or as contextual decision making according to a cost function (van Deemter, 2009), but not as a statistical planning problem, where uncertainty in the stochastic environment is explicitly modelled. Below, we apply this framework to Information Presentation strategies in SDS using Reinforcement Learning, where the example task is to present a set of search results (e.g. restaurants) to users. In particular, we consider 7 possible policies for structuring the content (see Figure 1): Recommending one single item, comparing two items, summarising all of them, or ordered combinations of those actions, e.g. first summarise all the retrieved items and then recommend one of them. The IP module has to decide which action to take next, how many attributes to mention, and when to stop generating.

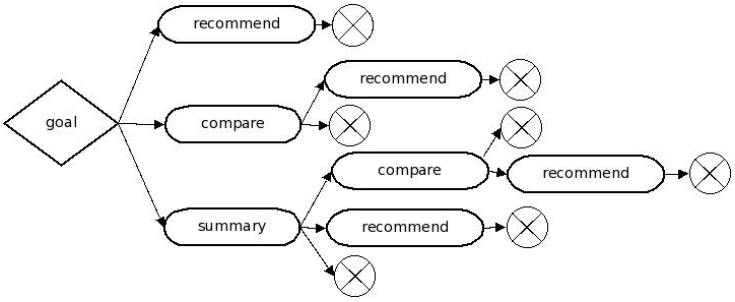

Figure 1: Possible Information Presentation structures (X=stop generation)

3 Wizard-of-Oz data collection

In an initial Wizard-of-Oz (WoZ) study, we asked humans (our "wizards") to produce good IP actions in different dialogue contexts, when interacting in spoken dialogues with other humans (the "users"), who believed that they were talking to an automated SDS. The wizards were experienced researchers in SDS and were familiar with the search domain (restaurants in Edinburgh). They were instructed to select IP structures and attributes for NLG so as to most efficiently allow users to find a restaurant matching their search constraints. They also received prior training on this task.

The task for the wizards was to decide which IP structure to use next (see Section 3.2 for a list of IP strategies to choose from), which attributes to mention (e.g. cuisine, price range, location, food quality, and/or service quality), and whether to stop generating, given varying numbers of database matches, varying prompt realisations, and varying user behaviour. Wizard utterances were synthesised using a state-of-the-art text-to-speech engine. The user speech input was delivered to the wizard using Voice Over IP. Figure 2 shows the web-based interface for the wizard.

3.1 Experimental Setup and Data collection

We collected 213 dialogues with 18 subjects and 2 wizards (Liu et al., 2009). Each user performed a total of 12 tasks, where no task set was seen twice by any one wizard. The majority of users were from a range of backgrounds in a higher education institute, in the age range 20-30, native speakers of English, and none had prior experience of

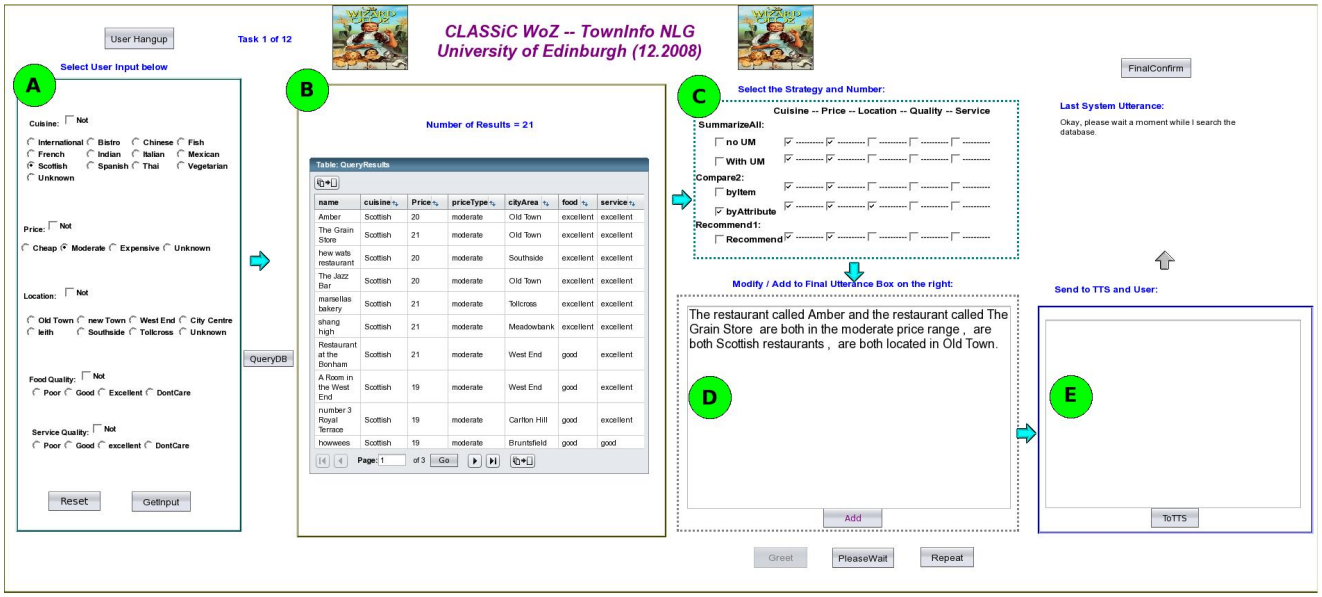

Figure 2: Wizard interface. [A:] The wizard selects attribute values as specified by the user's query. [B:] The retrieved database items are presented in an ordered list. We use a User Modelling approach for ranking the restaurants, see e.g. (Polifroni and Walker, 2008). [C:] The wizard then chooses which strategy and which attributes to generate next, by clicking radio buttons. The attribute/s specified in the last user query are pre-selected by default. The strategies can only be combined in the orders as specified in Figure 1. [D:] An utterance is automatically generated by the NLG realiser every time the wizard selects a strategy, and is displayed in an intermediate text panel. [E:] The wizard can decide to add the generated utterance to the final output panel or to start over again. The text in the final panel is sent to the user via TTS, once the wizard decides to stop generating.

Strategy	Example utterance
SUMMARY no UM	I found 26 restaurants, which have Indian cuisine. 11 of the restaurants are in the expensive price range. Furthermore, 10 of the restaurants are in the cheap price range and 5 of the restaurants are in the moderate price range.
SUMMARY UM	26 restaurants meet your query. There are 10 restaurants which serve Indian food and are in the cheap price range. There are also 16 others which are more expensive.
COMPARE by Item	The restaurant called Kebab Mahal is an Indian restaurant. It is in the cheap price range. And the restaurant called Saffrani, which is also an Indian restaurant, is in the moderate price range.
COMPARE by Attribute	The restaurant called Kebab Mahal and the restaurant called Saffrani are both Indian restaurants. However, Kebab Mahal is in the cheap price range while Saffrani is moderately priced.
RECOMMEND	The restaurant called Kebab Mahal has the best overall quality amongst the matching restaurants. It is an Indian restaurant, and it is in the cheap price range.

Table 1: Example realisations, generated when the user provided `cuisine=Indian`, and where the wizard has also selected the additional attribute `price` for presentation to the user.

Spoken Dialogue Systems. After each task the user answered a questionnaire on a 6 point Likert scale, regarding the perceived generation quality in that task. The wizards' IP strategies were highly ranked by the users on average (4.7), and users were able to select a restaurant in 98.6% of the cases. No significant difference between the wizards was observed.

The data contains 2236 utterances in total: 1465 wizard utterances and 771 user utterances. We automatically extracted 81 features (e.g #sentences, #DBhits, #turns, #ellipsis)[1] from the XML logfiles after each dialogue. Please see (Rieser et al., 2009) for more details.

[1]The full corpus and list of features is available at `https://www.classic-project.org/corpora/`

3.2 NLG Realiser

In the Wizard-of-Oz environment we implemented a NLG realiser for the chosen IP structures and attribute choices, in order to realise the wizards' choices in real time. This generator is based on data from the stochastic sentence planner SPaRKy (Stent et al., 2004). We replicated the variation observed in SPaRKy by analysing high-ranking example outputs (given the highest possible score by the SPaRKy judges) and implemented the variance using dynamic sentence generation. The realisations vary in sentence aggregation, aggregation operators (e.g. 'and', period, or ellipsis), contrasts

(e.g. 'however', 'on the other hand') and referring expressions (e.g. 'it', 'this restaurant') used. The length of an utterance also depends on the number of attributes chosen, i.e. the more attributes the longer the utterance. All of these variations were logged.

In particular, we realised the following IP strategies (see examples in Table 1):

- SUMMARY of all matching restaurants with or without a User Model (UM), following (Polifroni and Walker, 2008). The approach using a UM assumes that the user has certain preferences (e.g. cheap) and only tells him about the relevant items, whereas the approach with no UM lists all the matching items.
- COMPARE the top 2 restaurants by Item (i.e. listing all the attributes for the first item and then for the other) or by Attribute (i.e. directly comparing the different attribute values).
- RECOMMEND the top-ranking restaurant (according to UM).

Note that there was no discernible pattern in the data about the wizards' decisions between the UM/no UM and the byItem/byAttribute versions of the strategies. In this study we will therefore concentrate on the higher level decisions (SUMMARY VS. COMPARE VS. RECOMMEND) and model these different realisations as noise in the realiser.

3.3 Supervised Baseline strategy

We analysed the WoZ data to explore the best-rated strategies (the top scoring 50%, $n = 205$) that were employed by humans for this task. Here we used a variety of Supervised Learning methods to create a model of the highly rated wizard behaviour. Please see (Rieser et al., 2009) for further details. The best performing method was Rule Induction (JRip). [2] The model achieved an accuracy of 43.19% which is significantly ($p < .001$) better than the majority baseline of always choosing SUMMARY (34.65%). [3] The resulting rule set is shown in Figure 3.

```
IF (dbHits <= 9)& (prevNLG = summary):
   THEN nlgStrategy=compare;
IF (dbHits = 1):
   THEN nlgStrategy= Recommend;
IF(prevNLG=summaryRecommend)&(dbHits>=10):
   THEN nlgStrategy= Recommend;
ELSE nlgStrategy=summary;
```

Figure 3: Rules learned by JRip for the wizard model ('dbHits'= number of database matches, 'prevNLG'= previous NLG action)

The features selected by this model were only "high-level" features, i.e. the input (previous action, number of database hits) that an IP module receives as input from a Dialogue Manager (DM). We further analysed the importance of different features using feature ranking and selection methods (Rieser et al., 2009), finding that the human wizards in this specific setup did not pay significant attention to any lower level features, e.g. from surface realisation, although the generated output was displayed to them (see Figure 2).

Nevertheless, note that the supervised model achieves up to 87.6% of the possible reward on this task, as we show in Section 5.2, and so can be considered a serious baseline against which to measure performance. Below, we will show that Reinforcement Learning (RL) produces a significant improvement over the strategies present in the original data, especially in cases where RL has access to "lower level" features of the context.

4 The Simulation / Learning Environment

Here we "bootstrap" a simulated training environment from the WoZ data, following (Rieser and Lemon, 2008).

4.1 User Simulations

User Simulations are commonly used to train strategies for Dialogue Management, see for example (Young et al., 2007). A user simulation for NLG is very similar, in that it is a predictive model of the most likely next user act. [4] However, this NLG predicted user act does not actually change the overall dialogue state (e.g. by filling slots) but it only changes the generator state. In other words,

[2] The WEKA implementation of (Cohen, 1995)'s RIPPER.

[3] Note that the low accuracy is due to data sparsity and diverse behaviour of the wizards. However, in (Rieser et al., 2009) we show that this model is significantly different from the policy learned using the worse scoring 50%.

[4] Similar to the internal user models applied in recent work on POMDP (Partially Observable Markov Decision Process) dialogue managers (Young et al., 2007; Henderson and Lemon, 2008; Gasic et al., 2008) for estimation of user act probabilities.

the NLG user simulation tells us what the user is most likely to do next, *if we were to stop generating now*.

We are most interested in the following user reactions:

1. `select`: the user chooses one of the presented items, e.g. *"Yes, I'll take that one."*. This reply type indicates that the Information Presentation was sufficient for the user to make a choice.
2. `addInfo`: The user provides more attributes, e.g. *"I want something cheap."*. This reply type indicates that the user has more specific requests, which s/he wants to specify after being presented with the current information.
3. `requestMoreInfo`: The user asks for more information, e.g. *"Can you recommend me one?", "What is the price range of the last item?"*. This reply type indicates that the system failed to present the information the user was looking for.
4. `askRepeat`: The user asks the system to repeat the same message again, e.g. *"Can you repeat?"*. This reply type indicates that the utterance was either too long or confusing for the user to remember, or the TTS quality was not good enough, or both.
5. `silence`: The user does not say anything. In this case it is up to the system to take initiative.
6. `hangup`: The user closes the interaction.

We build user simulations using n-gram models of system (s) and user (u) acts, as first introduced by (Eckert et al., 1997). In order to account for data sparsity, we apply different *discounting* ("smoothing") techniques including *back-off*, using the CMU Statistical Language Modelling toolkit (Clarkson and Rosenfeld, 1997). We construct a **bi-gram** model[5] for the users' reactions to the system's IP structure decisions ($P(a_{u,t}|IP_{s,t})$), and a **tri-gram** (i.e. IP structure + attribute choice) model for predicting user reactions to the system's combined IP structure and attribute selection decisions: $P(a_{u,t}|IP_{s,t}, attributes_{s,t})$.

[5]Where $a_{u,t}$ is the predicted next user action at time t, $IP_{s,t}$ was the system's Information Presentation action at t, and $attributes_{s,t}$ is the attributes selected by the system at t.

We evaluate the performance of these models by measuring dialogue similarity to the original data, based on the Kullback-Leibler (KL) divergence, as also used by, e.g. (Cuayáhuitl et al., 2005; Jung et al., 2009; Janarthanam and Lemon, 2009). We compare the raw probabilities as observed in the data with the probabilities generated by our n-gram models using different discounting techniques for each context, see table 2. All the models have a small divergence from the original data (especially the bi-gram model), suggesting that they are reasonable simulations for training and testing NLG policies.

The absolute discounting method for the bi-gram model is most dissimilar to the data, as is the WittenBell method for the tri-gram model, i.e. the models using these discounting methods have the highest KL score. The best performing methods (i.e. most similar to the original data), are linear discounting for the bi-gram model and GoodTuring for the tri-gram. We use the most similar user models for system training, and the most dissimilar user models for testing NLG policies, in order to test whether the learned policies are robust and adaptive to unseen dialogue contexts.

discounting method	bi-gram US	tri-gram US
WittenBell	0.086	*0.512*
GoodTuring	0.086	**0.163**
absolute	*0.091*	0.246
linear	**0.011**	0.276

Table 2: Kullback-Leibler divergence for the different User Simulations (US)

4.2 Database matches and "Focus of attention"

An important task of Information Presentation is to support the user in choosing between all the available items (and ultimately in selecting the most suitable one) by structuring the current information returned from the database, as explained in Section 1.1. We therefore model the user's "focus of attention" as a feature in our learning experiments. This feature reflects how the different IP strategies structure information with different numbers of attributes. We implement this shift of the user's focus analogously to discovering the user's goal in Dialogue Management: every time the predicted next user act is to add in-

formation (addInfo), we infer that the user is therefore only interested in a subset of the previously presented results and so the system will focus on this new subset of database items in the rest of the generated utterance. For example, the user's focus after the SUMMARY (with UM) in Table 1 is $DBhits = 10$, since the user is only interested in cheap, Indian places.

4.3 Data-driven Reward function

The reward/evaluation function is constructed from the WoZ data, using a stepwise linear regression, following the PARADISE framework (Walker et al., 2000). This model selects the features which significantly influenced the users' ratings for the NLG strategy in the WoZ questionnaire. We also assign a value to the user's reactions ($valueUserReaction$), similar to optimising task success for DM (Young et al., 2007). This reflects the fact that good IP strategies should help the user to select an item ($valueUserReaction = +100$) or provide more constraints addInfo ($valueUserReaction = \pm 0$), but the user should not do anything else ($valueUserReaction = -100$). The regression in equation 1 ($R^2 = .26$) indicates that users' ratings are influenced by higher level and lower level features: Users like to be focused on a small set of database hits (where $\#DBhits$ ranges over [1-100]), which will enable them to choose an item ($valueUserReaction$), while keeping the IP utterances short (where $\#sentence$ is in the range [2-18]):

$$\begin{aligned} Reward = (-1.2) \times \#DBhits \\ +(.121) \times valueUserReaction \\ -(1.43) \times \#sentence \end{aligned} \quad (1)$$

Note that the worst possible reward for an NLG move is therefore $(-1.20 \times 100) - (.121 \times 100) - (18 \times 1.43) = -157.84$. This is achieved by presenting 100 items to the user in 18 sentences[6], in such a way that the user ends the conversation unsuccessfully. The top possible reward is achieved in the rare cases where the system can immediately present 1 item to the user using just 2 sentences, and the user then selects that item, i.e. Reward = $-(1.20 \times 1) + (.121 \times 100) - (2 \times 1.43) = 8.06$

[6]Note that the maximum possible number of sentences generated by the realizer is 18 for the full IP sequence SUMMARY+COMPARE+RECOMMEND using all the attributes.

5 Reinforcement Learning experiments

We now formulate the problem as a Markov Decision Process (MDP), where states are NLG dialogue contexts and actions are NLG decisions. Each state-action pair is associated with a transition probability, which is the probability of moving from state s at time t to state s' at time $t+1$ after having performed action a when in state s. This transition probability is computed by the environment model (i.e. the user simulation and realiser), and explicitly captures the uncertainty in the generation environment. This is a major difference to other non-statistical planning approaches. Each transition is also associated with a reinforcement signal (or "reward") r_{t+1} describing how good the result of action a was when performed in state s. The aim of the MDP is to maximise long-term expected reward of its decisions, resulting in a *policy* which maps each possible state to an appropriate action in that state.

We treat IP as a hierarchical joint optimisation problem, where first one of the IP structures (1-3) is chosen and then the number of attributes is decided, as shown in Figure 4. At each generation step, the MDP can choose 1-5 attributes (e.g. cuisine, price range, location, food quality, and/or service quality). Generation stops as soon as the user is predicted to select an item, i.e. the IP task is successful. (Note that the same constraint is operational for the WoZ baseline.)

$$\left[\begin{array}{l} \text{ACTION:} \left[\begin{array}{l} \textit{IP:} \left\{\begin{array}{l}\text{SUMMARY}\\ \text{COMPARE}\\ \text{RECOMMEND}\end{array}\right\} \left\{\text{attr: } 1\text{-}5\right\} \end{array}\right] \\ \text{STATE:} \left[\begin{array}{l} \texttt{attributes:}\left\{\texttt{1-15}\right\} \\ \texttt{sentence:}\left\{\texttt{2-18}\right\} \\ \texttt{dbHitsFocus:}\left\{\texttt{1-100}\right\} \\ \texttt{userSelect:}\left\{\texttt{0,1}\right\} \\ \texttt{userAddInfo:}\left\{\texttt{0,1}\right\} \\ \texttt{userElse:}\left\{\texttt{0,1}\right\} \end{array}\right] \end{array}\right]$$

Figure 4: State-Action space for the RL-NLG problem

States are represented as sets of NLG dialogue context features. The state space comprises "lower-level" features about the realiser behaviour (two discrete features representing the number of attributes and sentences generated so far) and three binary features representing the user's predicted next action, as well as "high-level" features pro-

vided by the DM (e.g. current database hits in the user's focus (`dbHitsFocus`)). We trained the policy using the SHARSHA algorithm (Shapiro and Langley, 2002) with linear function approximation (Sutton and Barto, 1998), and the simulation environment described in Section 4. The policy was trained for 60,000 iterations.

5.1 Experimental Set-up

We compare the learned strategies against the *WoZ baseline* as described in Section 3.3. For attribute selection we choose a majority baseline (randomly choosing between 3 or 4 attributes) since the attribute selection models learned by Supervised Learning on the WoZ data didn't show significant improvements.

For training, we used the user simulation model most similar to the data, see Section 4.1. For testing, we test with the *different* user simulation model (the one which is most dissimilar to the data).

We first investigate how well IP structure (without attribute choice) can be learned in increasingly complex generation **scenarios**. A generation scenario is a combination of a particular kind of NLG realiser (template vs. stochastic) along with different levels of variation introduced by certain features of the dialogue context. In general, the stochastic realiser introduces more variation in lower level features than the template-based realiser. The Focus model introduces more variation with respect to #DBhits and #attributes as described in Section 4.2. We therefore investigate the following cases:

1.1. IP structure choice, Template realiser: Predicted next user action varies according to the bi-gram model ($P(a_{u,t}|IP_{s,t})$); Number of sentences and attributes per IP strategy is set by defaults, reflecting a template-based realiser.

1.2. IP structure choice, Stochastic realiser: IP structure where number of attributes per NLG turn is given at the beginning of each episode (e.g. set by the DM); Sentence generation according to the SPaRKy stochastic realiser model as described in Section 3.2.

We then investigate different scenarios for *jointly* optimising IP structure (IPS) and attribute selection (Attr) decisions.

2.1. IPS+Attr choice, Template realiser: Predicted next user action varies according to tri-gram ($P(a_{u,t}|IP_{s,t}, attributes_{s,t})$) model; Number of sentences per IP structure set to default.

2.2. IPS+Attr choice, Template realiser+Focus model: Tri-gram user simulation with Template realiser and Focus of attention model with respect to #DBhits and #attributes as described in section 4.2.

2.3. IPS+Attr choice, Stochastic realiser: Tri-gram user simulation with sentence/attribute relationship according to Stochastic realiser as described in Section 3.2.

2.4. IPS+Attr choice, Stochastic realiser+Focus: i.e. the full model = Predicted next user action varies according to tri-gram model+ Focus of attention model + Sentence/attribute relationship according to stochastic realiser.

5.2 Results

We compare the average final reward (see Equation 1) gained by the baseline against the trained RL policies in the different scenarios for each 1000 test runs, using a paired samples t-test. The results are shown in Table 3. In 5 out of 6 scenarios the RL policy significantly ($p < .001$) outperforms the supervised baseline. We also report on the percentage of the top possible reward gained by the individual policies, and the raw percentage improvement of the RL policy. Note that the best possible (100%) reward can only be gained in rare cases (see Section 4.3).

The learned RL policies show that lower level features are important in gaining significant improvements over the baseline. The more complex the scenario, the harder it is to gain higher rewards for the policies in general (as more variation is introduced), but the relative improvement in rewards also increases with complexity: the baseline does not adapt well to the variations in lower level features whereas RL learns to adapt to the more challenging scenarios. [7]

An overview of the range of different IP strategies learned for each setup can be found in Table 4. Note that these strategies are context-dependent: the learner chooses how to proceed dependent on

[7] Note, that the baseline does reasonably well in scenarios with variation introduced by only higher level features (e.g. scenario 2.2).

Scenario	Wizard Baseline average Reward	RL average Reward	RL % - Baseline % = % improvement
1.1	-15.82(±15.53)	-9.90***(±15.38)	**89.2%** - 85.6%= 3.6%
1.2	-19.83(±17.59)	-12.83***(±16.88)	**87.4%** - 83.2%= 4.2%
2.1	-12.53(±16.31)	-6.03***(±11.89)	**91.5%** - 87.6%= 3.9%
2.2	-14.15(±16.60)	-14.18(±18.04)	**86.6%** - 86.6%= 0.0%
2.3	-17.43(±15.87)	-9.66***(±14.44)	**89.3%** - 84.6%= 4.7%
2.4	-19.59(±17.75)	-12.78***(±15.83)	**87.4%** - 83.3%= 4.1%

2.4	RECOMMEND(2) SUMMARY(2) SUMMARY(2)+COMPARE(4) SUMMARY(2)+RECOMMEND(2) SUMMARY(2)+COMPARE(4)+RECOMMEND(2) SUMMARY(2)+COMPARE(1)+RECOMMEND(2)

Table 4: RL strategies learned for the different scenarios, where (n) denotes the number of attributes generated.

For example, the RL policy for scenario 1.1 learned to start with a SUMMARY if the initial number of items returned from the database is high (>30). It will then stop generating if the user is predicted to select an item. Otherwise, it continues with a RECOMMEND. If the number of database items is low, it will start with a COMPARE and then continue with a RECOMMEND, unless the user selects an item. Also see Table 4. Note that the WoZ strategy behaves as described in Figure 3.

In addition, the RL policy for scenario 1.2 learns to adapt to a more complex scenario: the number of attributes requested by the DM and produced by the stochastic sentence realiser. It learns to generate the whole sequence (SUMMARY+COMPARE+RECOMMEND) if #attributes is low (<3), because the overall generated utterance (final #sentences) is still relatively short. Otherwise the policy is similar to the one for scenario 1.1.

The RL policies for jointly optimising IP strategy and attribute selection learn to select the number of attributes according to the generation scenarios 2.1-2.4. For example, the RL policy learned for scenario 2.1 generates a RECOMMEND with 5 attributes if the database hits are low (<13). Otherwise, it will start with a SUMMARY using 2 attributes. If the user is predicted to narrow down his focus after the SUMMARY, the policy continues with a COMPARE using 1 attribute only, otherwise it helps the user by presenting 4 attributes. It then continues with RECOMMEND(5), and stops as soon as the user is predicted to select one item.

The learned policy for scenario 2.1 generates 5.85 attributes per NLG turn on average (i.e. the cumulative number of attributes generated in the whole NLG sequence, where the same attribute may be repeated within the sequence). This strategy primarily adapts to the variations from the user simulation (tri-gram model). For scenario 2.2 the average number of attributes is higher (7.15) since the number of attributes helps to narrow down the user's focus via the DBhits/attribute relationship specified in section 4.2. For scenario 2.3 fewer attributes are generated on average (3.14), since here the number of attributes influences the sentence realiser, i.e. fewer attributes results in fewer sentences, but does not impact the user's focus. In scenario 2.4 all the conditions mentioned above influence the learned policy. The average number of attributes selected is still low (3.19).

In comparison, the average (cumulative) num-

ber of attributes for the WoZ baseline is 7.10. The WoZ baseline generates all the possible IP structures (with 3 or 4 attributes) but is restricted to use only "high-level" features (see Figure 3). By beating this baseline we show the importance of the "lower-level" features. Nevertheless, this wizard policy achieves up to 87.6% of the possible reward on this task, and so can be considered a serious baseline against which to measure performance.

The only case (scenario 2.2) where RL does not improve significantly over the baseline is where lower level features do not play an important role for learning good strategies: scenario 2.2 is only sensitive to higher level features (DBhits).

6 Conclusion

We have presented a new data-driven method for Information Presentation (IP) in Spoken Dialogue Systems using a statistical optimisation framework for content structure planning and attribute selection. This work is the first to apply a data-driven optimisation method to the IP decision space, and to show the utility of both lower-level and higher-level features for this problem.

We collected data in a Wizard-of-Oz (WoZ) experiment and showed that human "wizards" mostly pay attention to 'high-level' features from Dialogue Management. The WoZ data was used to build statistical models of user reactions to IP strategies, and a data-driven reward function for Reinforcement Learning (RL). We show that lower level features significantly influence users' ratings of IP strategies. We compared a model of human behaviour (the 'human wizard baseline') against policies optimised using Reinforcement Learning, in a variety of scenarios. Our optimised policies significantly outperform the IP structuring and attribute selection present in the WoZ data, especially when performing in complex generation scenarios which require adaptation to, e.g. number of database results, utterance length, etc. While the human wizards were able to attain up to 87.6% of the possible reward on this task, the RL policies are significantly better in 5 out of 6 scenarios, gaining up to 91.5% of the total possible reward.

We have also shown that adding predictive "lower level" features, e.g. from the NLG realiser and a user reaction model, is important for learning optimal IP strategies according to user preferences. Future work could include the predicted TTS quality (Boidin et al., 2009) as a feature.

We are now working on testing the learned policies with real users, outside of laboratory conditions, using a restaurant-guide SDS, deployed as a VOIP service. Previous work in SDS has shown that results for Dialogue Management obtained with simulated users are able to transfer to evaluations with real users (Lemon et al., 2006).

This methodology provides new insights into the nature of the IP problem, which has previously been treated as a module following dialogue management with no access to lower-level context features. The data-driven planning method applied here promises a significant upgrade in the performance of generation modules, and thereby of Spoken Dialogue Systems in general.

Abstract

English noun/verb (N/V) pairs (*contract*, *cement*) have undergone complex patterns of change between 3 stress patterns for several centuries. We describe a longitudinal dataset of N/V pair pronunciations, leading to a set of properties to be accounted for by any computational model. We analyze the dynamics of 5 dynamical systems models of linguistic populations, each derived from a model of learning by individuals. We compare each model's dynamics to a set of properties observed in the N/V data, and reason about how assumptions about individual learning affect population-level dynamics.

1 Introduction

The fascinating phenomena of language evolution and language change have inspired much work from computational perspectives in recent years. Research in this field considers populations of linguistic agents, and asks how the population dynamics are related to the behavior of individual agents. However, most such work makes little contact with empirical data (de Boer and Zuidema, 2009).[1] As pointed out by Choudhury (2007), most computational work on language change deals with data from cases of change either not at all, or at a relatively high level.[2]

Recent computational work has addressed "real world" data from change in several languages (Mitchener, 2005; Choudhury et al., 2006; Choudhury et al., 2007; Pearl and Weinberg, 2007; Daland et al., 2007; Landsbergen, 2009). In the same spirit, we use data from an ongoing stress shift in English noun/verb (N/V) pairs. Because stress has been listed in dictionaries for several centuries, we are able to trace stress longitudinally and at the level of individual words, and observe dynamics significantly more complicated than in changes previously considered in the computational literature. In §2, we summarize aspects of the dynamics to be accounted for by any computational model of the stress shift. We also discuss proposed sources of these dynamics from the literature, based on experimental work by psychologists and linguists.

In §3–4, we develop models in the mathematical framework of dynamical systems (DS), which over the past 15 years has been used to model the interaction between language learning and language change in a variety of settings (Niyogi and Berwick, 1995; Niyogi and Berwick, 1996; Niyogi, 2006; Komarova et al., 2001; Yang, 2001; Yang, 2002; Mitchener, 2005; Pearl and Weinberg, 2007).

We interpret 6 aspects of the N/V stress dynamics in DS terms; this gives a set of 6 desired properties to which any DS model's dynamics can be compared. We consider 5 models of language learning by individuals, based on the experimental findings relevant to the N/V stress shift, and evaluate the population-level dynamics of the dynamical system model resulting from each against the set of desired properties. We are thus able to reason about which theories of the source of language change — considered as hypotheses about how individuals learn — lead to the population-level patterns observed in change.

2 Data: English N/V pairs

The data considered here are the stress patterns of English homographic, disyllabic noun/verb pairs (Table 1); we refer to these throughout as "N/V pairs". Each of the N and V forms of a pair can have initial ($\acute{\sigma}\sigma$: *cónvict*, n.) or final ($\sigma\acute{\sigma}$: *convíct*,

[1] However, among language evolution researchers there has been significant recent interest in behavioral experiments, using the "iterated learning" paradigm (Griffiths and Kalish, 2007; Kalish et al., 2007; Kirby et al., 2008).

[2] We do not review the literature on computational studies of change due to space constraints; see (Baker, 2008; Wang et al., 2005; Niyogi, 2006) for reviews.

Table 1: Attested N/V pair stress patterns.

v.) stress. We use the notation {Nstress,Vstress} to denote the stress of an N/V pair, with 1=$\acute{\sigma}\sigma$, 2=$\sigma\acute{\sigma}$. Of the four logically possible stress patterns, all current N/V pairs follow one of the 3 patterns shown in Table 1: {1,1}, {1,2}, {2,2}.[3] No pair follows the fourth possible pattern, {2,1}.

N/V pairs have been undergoing variation and change between these 3 patterns since Middle English (ME, c. 1066-1470), especially change to {1,2}. The vast majority of stress shifts occurred after 1570 (Minkova, 1997), when the first dictionary listing English word stresses was published (Levens, 1570). Many dictionaries from the 17th century on list word stresses, making it possible to trace change in the stress of individual N/V pairs in considerable detail.

2.1 Dynamics

Expanding on dictionary pronunciation data collected by Sherman (1975) for the period 1570–1800, we have collected a corpus of pronunciations of 149 N/V pairs, as listed in 62 British dictionaries, published 1570–2007. Variation and change in N/V pair stress can be visualized by plotting *stress trajectories*: the moving average of N and V stress vs. time for a given pair. Some examples are shown in Fig. 1. The corpus is described in detail in (Sonderegger and Niyogi, 2010); here we summarize the relevant facts to be accounted for in a computational model.[4]

Change Four types of clear-cut change between the three stress patterns are observed:

{2,2}→{1,2} (Fig.1(a)) {1,2}→{1,1}
{1,1}→{1,2} (Fig. 1(b)) {1,2}→{2,2}

However, change to {1,2} is much more common than change from {1,2}; in particular, {2,2}→{1,2} is the most common change. When change occurs, it is often fairly sudden, as in Figs. 1(a), 1(b). Finally, change never occurs *directly* between {1,1} and {2,2}.

Stability Previous work on stress in N/V pairs (Sherman, 1975; Phillips, 1984) has emphasized change, in particular {2,2}→{1,2} (the most common change). However, an important aspect of the diachronic dynamics of N/V pairs is stability: most N/V pairs do *not* show variation or change.

The 149 N/V pairs, used both in our corpus and in previous work, were chosen by Sherman (1975) as those most likely to have undergone change, and thus are not suitable for studying how stable the three attested stress patterns are. In a *random* sample of N/V pairs (not the set of 149) in use over a fixed time period (1700–2007), we find that only 12% have shown variation or change in stress (Sonderegger and Niyogi, 2010). Most pairs maintain the {1,1}, {2,2}, or {1,2} stress pattern for hundreds of years. A model of the diachronic dynamics of N/V pair stress must explain how it can be the case both that some pairs show variation and change, and that many do not.

Variation N/V pair stress patterns show both synchronic and diachronic variation.

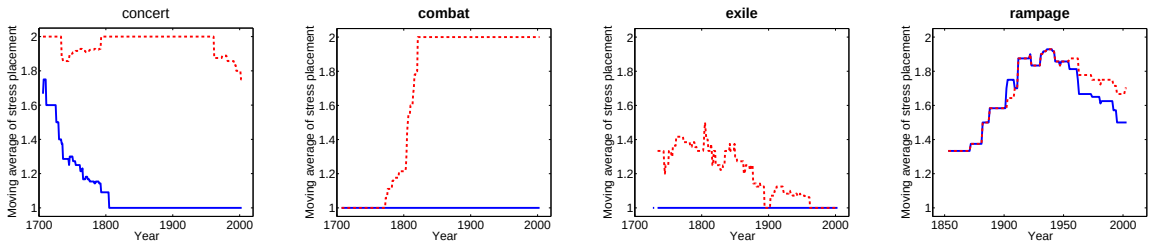
Synchronically, there is variation at the population level in the stress of some N/V pairs at any given time; this is reflected by the inclusion of more than one pronunciation for some N/V pairs in many dictionaries. An important question for modeling is whether there is variation within *individual* speakers. We show in (Sonderegger and Niyogi, 2010) that there is, for present-day American English speakers, using a corpus of radio speech. For several N/V pairs which have currently variable pronunciation, 1/3 of speakers show variation in the stress of the N form. Metrical evidence from poetry suggests that individual variation also existed in the past; the best evidence is for Shakespeare, who shows variation in the stress of over 20 N/V pairs (Kökeritz, 1953).

Diachronically, a relevant question for modeling is whether all variation is short-lived, or whether *stable variation* is possible. A particular type of stable variation is in fact observed relatively often in the corpus: *either* the N or V form stably vary (Fig. 1(c)), but not both at once. Stable variation where both N and V forms vary almost never occurs (Fig. 1(d)).

Frequency dependence Phillips (1984) hypoth-

[3] However, as variation and change in N/V pair stress is ongoing, a few pairs (e.g. *perfume*) currently have variable stress. By "stress", we always mean "primary stress". All present-day pronunciations are for British English, from CELEX (Baayen et al., 1996).

[4] The corpus is available on the first author's home page (currently, `people.cs.uchicago.edu/~morgan`).



(a) concert (b) combat (c) exile (d) rampage

Figure 1: Example N/V pair stress trajectories. Moving averages (60-year window) of stress placement (1=$\acute{\sigma}\sigma$, 2=$\sigma\acute{\sigma}$). Solid lines=nouns, dashed lines=verbs.

esizes that N/V pairs with lower frequencies (summed N+V word frequencies) are more likely to change to {1,2}. Sonderegger (2010) shows that this is the case for the most common change, {2,2}→{1,2}: among N/V pairs which were {2,2} in 1700 and are either {2,2} or {1,2} today, those which have undergone change have significantly lower frequencies, on average, than those which have not. In (Sonderegger and Niyogi, 2010), we give preliminary evidence from real-time frequency trajectories (for <10 N/V pairs) that it is not lower frequency *per se* which triggers change to {1,2}, but *falling* frequency. For example, change in *combat* from {1,1}→{1,2} around 1800 (Fig. 1(b)) coincides with falling word frequency from 1775–present.

2.2 Sources of change

The most salient facts about English N/V pair stress are that (a) change is most often to {1,2} (b) the {2,1} pattern never occurs. We summarize two types of explanation for these facts from the experimental literature, each of which exemplifies a commonly-proposed type of explanation for phonological change. In both cases, there is experimental evidence for biases in present-day English speakers reflecting (a–b). We assume that these biases have been active over the course of the N/V stress shift, and can thus be seen as possible sources of the diachronic dynamics of N/V pairs.[5]

Analogy/Lexicon In historical linguistics, analogical changes are those which make "...related forms more similar to each other in their phonetic (and morphological) structure" (Hock, 1991).[6] Proposed causes for analogical change thus often involve a speaker's production and perception of a form being influenced by similar forms in their lexicon.

The English lexicon shows a broad tendency, which we call *Ross' generalization*, which could be argued to be driving analogical change to {1,2}, and acting against the unobserved stress pattern {2,1}: "primary stress in English nouns is farther to the left than primary stress in English verbs" (Ross, 1973). Change to {1,2} could be seen as motivated by Ross' generalization, and {2,1} made impossible by it.

The argument is lent plausibility by experimental evidence that Ross' Generalization is reflected in production and perception. English listeners strongly prefer the typical stress pattern (N=$\acute{\sigma}\sigma$ or V=$\sigma\acute{\sigma}$) in novel English disyllables (Guion et al., 2003), and process atypical disyllables (N=$\sigma\acute{\sigma}$ or V=$\acute{\sigma}\sigma$) more slowly than typical ones (Arciuli and Cupples, 2003).

Mistransmission An influential line of research holds that many phonological changes are based in asymmetric transmission errors: because of articulatory or perceptual factors, listeners systematically mishear some sound α as β, but rarely mishear β as α.[7] We call such effects *mistransmission*. Asymmetric mistransmission (by individu-

[5] This type of assumption is necessary for any hypothesis about the sources of a completed or ongoing change, based on present-day experimental evidence, and is thus common in the literature. In the case of N/V pairs, it is implicitly made in Kelly's (1988 *et seq*) account, discussed below. Both biases discussed here stem from facts about English (Ross' Generalization; rhythmic context) that we believe have not changed over the time period considered here (≈1600–present), based on general accounts of English historical phonology during this period (Lass, 1992; MacMahon, 1998). We leave more careful verification of this claim to future work.

[6] "Forms" here means any linguistic unit; e.g. sounds, words, or paradigms, such as an N/V pair's stress pattern.

[7] A standard example is final obstruent devoicing, a common change cross-linguistically. There are several articulatory and perceptual reasons why final voiced obstruents could be heard as unvoiced, but no motivation for the reverse process (final unvoiced obstruents heard as voiced) (Blevins, 2006).

als) is argued to be a necessary condition for the change $\alpha \rightarrow \beta$ at the population level, and an explanation for why the change $\alpha \rightarrow \beta$ is common, while the change $\beta \rightarrow \alpha$ is rarely (or never) observed. Mistransmission-based explanations were pioneered by Ohala (1981, *et seq.*), and are the subject of much recent work (reviewed by Hansson, 2008)

For English N/V pairs, M. Kelly and collaborators have shown mistransmission effects which they propose are responsible for the directionality of the most common type of N/V pair stress shifts ($\{1,1\}$, $\{2,2\} \rightarrow \{1,2\}$), based on "rhythmic context" (Kelly, 1988; Kelly and Bock, 1988; Kelly, 1989). Word stress is misperceived more often as initial in "trochaic-biasing" contexts, where the preceding syllable is weak or the following syllable is heavy; and more often as final in analogously "iambic-biasing" contexts. Nouns occur more frequently in trochaic contexts, and verbs more frequently in iambic contexts; there is thus pressure for the V forms of $\{1,1\}$ pairs to be misperceived as $\sigma\acute{\sigma}$, and for the N forms of $\{2,2\}$ pairs to be misperceived as $\acute{\sigma}\sigma$.

3 Modeling preliminaries

We first describe assumptions and notation for models developed below (§4).

Because of the evidence for within-speaker variation in N/V pair stress (§2.1), in all models described below, we assume that what is learned for a given N/V pair are the *probabilities* of using the $\sigma\acute{\sigma}$ form for the N and V forms.

We also make several simplifying assumptions. There are discrete generations G_t, and learners in G_t learn from G_{t-1}. Each example a learner in G_t hears is equally likely to come from any member of G_{t-1}. Each learner receives an identical number of examples, and each generation has infinitely many members.

These are idealizations, adopted here to keep models simple enough to analyze; the effects of relaxing some of these assumptions have been explored by Niyogi (2006) and Sonderegger (2009). The infinite-population assumption in particular makes the dynamics fully deterministic; this rules out the possibility of change due to *drift* (or *sample variation*), where a form disappears from the population because no examples of it are encountered by learners in G_t in the input from G_{t-1}.

Notation For a fixed N/V pair, a learner in G_t hears N_1 examples of the N form, of which k_1^t are $\sigma\acute{\sigma}$ and (N_1-k_1^t) are $\acute{\sigma}\sigma$; N_2 and k_2^t are similarly defined for V examples. Each example is sampled i.i.d. from a random member of G_{t-1}. The N_i are *fixed* (each learner hears the same number of examples), while the k_i^t are random variables (over learners in G_t). Each learner applies an algorithm $\mathcal{A}$ to the N_1+N_2 examples to learn $\hat{\alpha}_t, \hat{\beta}_t \in [0,1]$, the probabilities of *producing* N and V examples as $\sigma\acute{\sigma}$. α_t, β_t are the expectation of $\hat{\alpha}_t$ and $\hat{\beta}_t$ over members of G_t: $\alpha_t = E(\hat{\alpha}_t)$, $\beta_t = E(\hat{\beta}_t)$. $\hat{\alpha}_t$ and $\hat{\beta}_t$ are thus random variables (over learners in G_t), while $\alpha_t, \beta_t \in [0,1]$ are numbers.

Because learners in G_t draw examples at random from members of G_{t-1}, the distributions of $\hat{\alpha}_t$ and $\hat{\beta}_t$ are determined by $(\alpha_{t-1}, \beta_{t-1})$. (α_t, β_t), the expectations of $\hat{\alpha}_t$ and $\hat{\beta}_t$, are thus determined by $(\alpha_{t-1}, \beta_{t-1})$ via an *iterated map* f:

$$f : [0,1]^2 \rightarrow [0,1]^2, \quad f(\alpha_t, \beta_t) = (\alpha_{t+1}, \beta_{t+1}).$$

3.1 Dynamical systems

We develop and analyze models of populations of language learners in the mathematical framework of (discrete) dynamical systems (DS) (Niyogi and Berwick, 1995; Niyogi, 2006). This setting allows us to determine the diachronic, population-level consequences of assumptions about the learning algorithm used by individuals, as well as assumptions about population structure or the input they receive.

Because it is in general impossible to solve a given iterated map as a function of t, the dynamical systems viewpoint is to understand its long-term behavior by finding its fixed points and *bifurcations*: changes in the number and stability of fixed points as system parameters vary.

Briefly, α_* is a *fixed point* (FP) of f if $f(\alpha_*) = \alpha_*$; it is *stable* if $\lim_{t \rightarrow \infty} \alpha_t = \alpha_*$ for α_0 sufficiently near α_*, and *unstable* otherwise; these are also called *stable states* and *unstable states*. Intuitively, α_* is stable iff the system is stable under small perturbations from α_*.[8]

In the context of a linguistic population, change from state α (100% of the population uses $\{1,1\}$) to state β (100% of the population uses $\{1,2\}$) corresponds to a bifurcation, where some system parameter (N) passes a critical value (N_0). For

[8] See (Strogatz, 1994; Hirsch et al., 2004) for introductions to dynamical systems in general, and (Niyogi, 2006) for the type of models considered here.

$N<N_0$, α is stable. For $N>N_0$, α is unstable, and β is stable; this triggers change from α to β.

3.2 DS interpretation of observed dynamics

Below, we describe 5 DS models of linguistic populations. To interpret whether each model has properties consistent with the N/V dataset, we translate the observations about the dynamics of N/V stress made above (§2.1) into DS terms. This gives a list of desired properties against which to evaluate the properties of each model.

1. $^*\{2,1\}$: $\{2,1\}$ is not a stable state.
2. *Stability of* $\{1,1\}$, $\{1,2\}$, $\{2,2\}$: These stress patterns correspond to stable states (for some system parameter values).
3. *Observed stable variation*: Stable states are possible (for some system parameter values) corresponding to variation in the N or V form, but not both.
4. *Sudden change*: Change from one stress pattern to another corresponds to a bifurcation, where the fixed point corresponding to the old stress pattern becomes unstable.
5. *Observed changes*: There are bifurcations corresponding to each of the four observed changes ($\{1,1\} \rightleftharpoons \{1,2\}$, $\{2,2\} \rightleftharpoons \{1,2\}$).
6. *Observed frequency dependence*: Change to $\{1,2\}$ corresponds to a bifurcation in frequency (N), where $\{2,2\}$ or $\{1,1\}$ loses stability as N is decreased.

4 Models

We now describe 5 DS models, each corresponding to a learning algorithm $\mathcal{A}$ used by individual language learners. Each $\mathcal{A}$ leads to an iterated map, $f(\alpha_t, \beta_t) = (\alpha_{t+1}, \beta_{t+1})$, which describes the state of the population of learners over successive generations. We give these evolution equations for each model, then discuss their dynamics, i.e. bifurcation structure. Each model's dynamics are evaluated with respect to the set of desired properties corresponding to patterns observed in the N/V data. Derivations have been mostly omitted for reasons of space, but are given in (Sonderegger, 2009).

The models differ along two dimensions, corresponding to assumptions about the learning algorithm ($\mathcal{A}$): whether or not it is assumed that the stress of examples is possibly mistransmitted (Models 1, 3, 5), and how the N and V probabilities acquired by a given learner are *coupled*. In Model 1 there is no coupling ($\hat{\alpha}_t$ and $\hat{\beta}_t$ learned independently), in Models 2–3 coupling takes the form of a hard constraint corresponding to Ross' generalization, and in Models 4–5 different stress patterns have different prior probabilities.[9]

4.1 Model 1: Mistransmission

Motivated by the evidence for asymmetric misperception of N/V pair stress (§2.2), suppose the stress of N=$\sigma\acute{\sigma}$ and V=$\acute{\sigma}\sigma$ examples may be misperceived (as N=$\acute{\sigma}\sigma$ and V=$\sigma\acute{\sigma}$), with *mistransmission probabilities* p and q.

Learners are assumed to simply probability match: $\hat{\alpha}_t = k_1^t/N_1$, $\hat{\beta}_t = k_2^t/N_2$, where k_1^t is the number of N and V examples *heard* as $\sigma\acute{\sigma}$ (etc.) The probabilities $p_{N,t}$ & $p_{V,t}$ of hearing an N or V example as final stressed at t are then

$$p_{N,t} = \alpha_{t-1}(1-p),\ p_{V,t} = \beta_{t-1} + (1-\beta_{t-1})q \quad (1)$$

k_1^t and k_2^t are binomially-distributed:

$$P_B(k_1^t, k_2^t) \equiv \binom{N_1}{k_1^t} {p_{N,t}}^{k_1^t} (1-p_{N,t})^{N_1-k_1^t} \times \binom{N_2}{k_2^t} {p_{V,t}}^{k_2^t} (1-p_{V,t})^{N_2-k_2^t} \quad (2)$$

α_t and β_t, the probability that a random member of G_t produces N and V examples as $\sigma\acute{\sigma}$, are the ensemble averages of $\hat{\alpha}_t$ and $\hat{\beta}_t$ over all members of G_t. Because we have assumed infinitely many learners per generation, α_t=$E(\hat{\alpha}_t)$ and β_t=$E(\hat{\beta}_t)$. Using (1), and the formula for the expectation of a binomially-distributed random variable:

$$\alpha_t = \alpha_{t-1}(1-p) \quad (3)$$
$$\beta_t = \beta_{t-1} + (1-\beta_{t-1})q \quad (4)$$

these are the *evolution equations* for Model 1. Due to space constraints we do not give the (more lengthy) derivations of the evolution equations in Models 2–5.

Dynamics There is a single, stable fixed point of evolution equations (3–4): $(\alpha_*, \beta_*) = (0, 1)$, corresponding to the stress pattern $\{1,2\}$. This model thus shows none of the desired properties discussed in §3.2, except that $\{1,2\}$ corresponds to a stable state.

[9] The sixth possible model (no coupling, no mistransmission) is a special case of Model 1, resulting in the identity map: $\alpha_{t+1} = \alpha_t$, $\beta_{t+1} = \beta_t$.

4.2 Model 2: Coupling by constraint

Motivated by the evidence for English speakers' productive knowledge of Ross' Generalization (§2.2), we consider a second learning model in which the learner attempts to probability match as above, but the $(\hat{\alpha}_t, \hat{\beta}_t)$ learned must satisfy the constraint that $\sigma\acute{\sigma}$ stress be more probable in the V form than in the N form.

Formally, the learner chooses $(\hat{\alpha}_t, \hat{\beta}_t)$ satisfying a quadratic optimization problem:

$$\text{minimize } [(\alpha - \frac{k_1^t}{N_1})^2 + (\beta - \frac{k_2^t}{N_2})^2] \text{ s.t. } \alpha \leq \beta$$

This corresponds to the following algorithm, $\mathcal{A}_2$:

1. If $\frac{k_1^t}{N_1} < \frac{k_2^t}{N_2}$, set $\hat{\alpha}_t = \frac{k_1^t}{N_1}$, $\hat{\beta}_t = \frac{k_2^t}{N_2}$.
2. Otherwise, set $\hat{\alpha}_t = \hat{\beta}_t = \frac{1}{2}(\frac{k_1^t}{N_1} + \frac{k_2^t}{N_2})$

The resulting evolution equations can be shown to be

$$\alpha_{t+1} = \alpha_t + \frac{A}{2}, \quad \beta_{t+1} = \beta_t - \frac{A}{2} \tag{5}$$

where $A = \sum_{\frac{k_1}{N_1} > \frac{k_2}{N_2}} P_B(k_1^t, k_2^t)(\frac{k_1^t}{N_1} - \frac{k_2^t}{N_2})$.

Dynamics Adding the equations in (5) gives that the (α_t, β_t) trajectories are lines of constant $\alpha_t + \beta_t$ (Fig. 2). All $(0, x)$ and $(x, 1)$ ($x \in [0, 1]$) are stable fixed points. This model thus has stable FPs corresponding to {1,1}, {1,2}, and {2,2}, does not have {2,1} as a stable FP (by construction), and allows for stable variation in exactly one of N or V. It does not have bifurcations, or the observed patterns of change and frequency dependence.

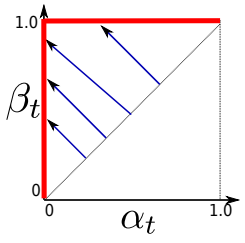


Figure 2: Dynamics of Model 2

4.3 Model 3: Coupling by constraint, with mistransmission

We now assume that each example is subject to mistransmission, as in Model 1; the learner then applies $\mathcal{A}_2$ to the *heard* examples. The evolution equations are thus the same as in (5), but with α_{t-1} and β_{t-1} changed to $p_{N,t}$, $p_{V,t}$ (Eqn. 1).

Dynamics There is a single, stable fixed point, corresponding to stable variation in both N and V. This model thus shows none of the desired properties, except that {2,1} is not a stable FP (by construction).

4.4 Model 4: Coupling by priors

The type of coupling assume in Models 2–3 — a constraint on the relative probability of $\sigma\acute{\sigma}$ stress for N and V forms — has the drawback that there is no way for the rest of the lexicon to affect a pair's N and V stress probabilities: there can be no influence of the stress of other N/V pairs, or in the lexicon as a whole, on the N/V pair being learned. Models 4–5 allow such influence by formalizing a simple intuitive explanation for the lack of $\{2, 1\}$ N/V pairs: learners cannot hypothesize a $\{2, 1\}$ pair because there is no support for this pattern in their lexicons.

We now assume that learners compute the probabilities of each possible N/V pair *stress pattern*, rather than separate probabilities for the N and V forms. We assume that learners keep two sets of probabilities (for $\{1, 1\}$, $\{1, 2\}$, $\{2, 1\}$, $\{2, 2\}$):

1. *Learned probabilities*:
   $\vec{P}$=$(P_{11}, P_{12}, P_{22}, P_{21})$, where

$$P_{11} = \frac{N_1 - k_1^t}{N_1}\frac{N_2 - k_2^t}{N_2}, \quad P_{12} = \frac{N_1 - k_1^t}{N_1}\frac{k_2^t}{N_2}$$
$$P_{22} = \frac{k_1^t}{N_1}\frac{k_2^t}{N_2}, \quad P_{21} = \frac{k_1^t}{N_1}\frac{N_2 - k_2^t}{N_2}$$

2. *Prior probabilities*: $\vec{\lambda} = (\lambda_{11}, \lambda_{12}, \lambda_{21}, \lambda_{22})$, based on the support for each stress pattern in the lexicon.

The learner then produces N forms as follows:

1. Pick a pattern $\{n_1, v_1\}$ according to $\vec{P}$.
2. Pick a pattern $\{n_2, v_2\}$ according to $\vec{\lambda}$
3. Repeat 1–2 until n_1=n_2, then produce N=n_1.

V forms are produced similarly, but checking whether $v_1 = v_2$ at step 3. Learners' production of an N/V pair is thus influenced by both their learning experience (for the particular N/V pair) and by how much support exists in their lexicon for the different stress patterns.

We leave the exact interpretation of the λ_{ij} ambiguous; they could be the percentage of N/V pairs already learned which follow each stress pattern, for example. Motivated by the absence of {2,1} N/V pairs in English, we assume that $\lambda_{21} = 0$.

By following the production algorithm above, the learner's probabilities of producing N and V forms as $\sigma\acute{\sigma}$ are:

$$\hat{\alpha}_t = \tilde{\alpha}(k_1^t, k_2^t) = \frac{\lambda_{22}P_{22}}{\lambda_{11}P_{11} + \lambda_{12}P_{12} + \lambda_{22}P_{22}} \quad (6)$$

$$\hat{\beta}_t = \tilde{\beta}(k_1^t, k_2^t) = \frac{\lambda_{12}P_{12} + \lambda_{22}P_{22}}{\lambda_{11}P_{11} + \lambda_{12}P_{12} + \lambda_{22}P_{22}} \quad (7)$$

Eqns. 6–7 are undefined when (k_1^t, k_2^t)=$(N_1, 0)$; in this case we set $\tilde{\alpha}(N_1, 0) = \lambda_{22}$ and $\tilde{\beta}(N_1, 0) = \lambda_{12} + \lambda_{22}$.

The evolution equations are then

$$\alpha_t = E(\hat{\alpha}_t) = \sum_{k_1=0}^{N_1}\sum_{k_2=0}^{N_2} P_B(k_1, k_2)\tilde{\alpha}(k_1, k_2) \quad (8)$$

$$\beta_t = E(\hat{\beta}_t) = \sum_{k_1=0}^{N_1}\sum_{k_2=0}^{N_2} P_B(k_1, k_2)\tilde{\beta}(k_1, k_2) \quad (9)$$

Dynamics The fixed points of (8–9) are $(0,0)$, $(0,1)$, and $(1,1)$; their stabilities depend on N_1, N_2, and $\vec{\lambda}$. Define

$$R = \left(\frac{N_2}{1 + (N_2 - 1)\frac{\lambda_{12}}{\lambda_{11}}}\right)\left(\frac{N_1}{1 + (N_1 - 1)\frac{\lambda_{12}}{\lambda_{22}}}\right) \quad (10)$$

There are 6 regions of parameter space in which different FPs are stable:

1. $\lambda_{11}, \lambda_{22} < \lambda_{12}$: $(0,1)$ stable
2. $\lambda_{22} > \lambda_{12}$, $R < 1$: $(0,1)$, $(1,1)$ stable
3. $\lambda_{11} < \lambda_{12} < \lambda_{22}$, $R > 1$: $(1,1)$ stable
4. $\lambda_{11}, \lambda_{22} > \lambda_{12}$: $(0,0)$, $(1,1)$ stable
5. $\lambda_{22} < \lambda_{12} < \lambda_{11}$, $R > 1$: $(0,0)$ stable
6. $\lambda_{11} > \lambda_{12}$, $R < 1$: $(0,0)$, $(0,1)$ stable

The parameter space is split into these regimes by three hyperplanes: λ_{11}=λ_{12}, λ_{22}=λ_{12}, and R=1. Given that λ_{21}=0, $\lambda_{12} = 1 - \lambda_{11} - \lambda_{22}$, and the parameter space is 4-dimensional: $(\lambda_{11}, \lambda_{22}, N_1, N_2)$. Fig. 3 shows An example phase diagram in $(\lambda_{11}, \lambda_2)$, with N_1 and N_2 fixed.

The bifurcation structure implies all 6 possible changes between the three FPs ($\{1,1\}$⇌$\{1,2\}$, $\{1,2\}$⇌$\{2,2\}$, $\{2,2\}$⇌$\{1,2\}$). For example, suppose the system is at stable FP $(1,1)$ (corresponding to $\{2,2\}$) in region 2. As λ_{22} is decreased, we move into region 1, $(1,1)$ becomes unstable, and the system shifts to stable FP $(0,1)$. This transition corresponds to change from $\{2,2\}$ to $\{1,2\}$.

Note that change to $\{1,2\}$ entails crossing the hyperplanes λ_{12}=λ_{22} and λ_{12}=λ_{11}. These hyperplanes do not change as N_1 and N_2 vary, so change to $\{1,2\}$ is *not* frequency-dependent. However, change from $\{1,2\}$ entails crossing the hyperplane R=1, which does change as N_1 and N_2 vary (Eqn. 10), so change from $\{1,2\}$ is frequency-dependent. Thus, although there is frequency dependence in this model, it is not as observed in the diachronic data, where change *to* $\{1,2\}$ is frequency-dependent.

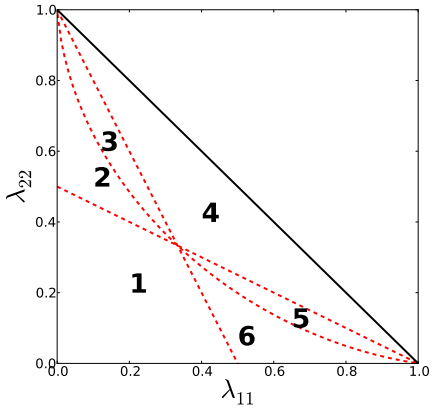

Figure 3: Example phase diagram in $(\lambda_{11}, \lambda_{22})$ for Model 4, with $N_1 = 5$, $N_2 = 10$. Numbers are regions of parameter space (see text).

Finally, no stable variation is possible: in every stable state, all members of the population categorically use a single stress pattern. $\{2,1\}$ is never a stable FP, by construction.

4.5 Model 5: Coupling by priors, with mistransmission

We now suppose that each example from a learner's data is possibly mistransmitted, as in Model 1; the learner then applies the algorithm from Model 4 to the *heard* examples (instead of using k_1^t, k_2^t) . The evolution equations are thus the same as (8–9), but with α_{t-1} and β_{t-1} changed to $p_{N,t}$, $p_{V,t}$ (Eqn. 1).

Dynamics $(0,1)$ is always a fixed point. For some regions of parameter space, there can be one fixed point of the form $(\kappa, 1)$, as well as one fixed point of the form $(0, \gamma)$, where $\kappa, \gamma \in (0,1)$. Define $R' = (1-p)(1-q)R$, $\lambda'_{12} = \lambda_{12}$, and

$$\lambda'_{11} = \lambda_{11}(1 - q\frac{N_2}{N_2 - 1}), \quad \lambda'_{22} = \lambda_{22}(1 - p\frac{N_1}{N_1 - 1})$$

There are 6 regions of parameter space corresponding to different stable FPs, identical to the 6 regions in Model 4, with the following substitu-

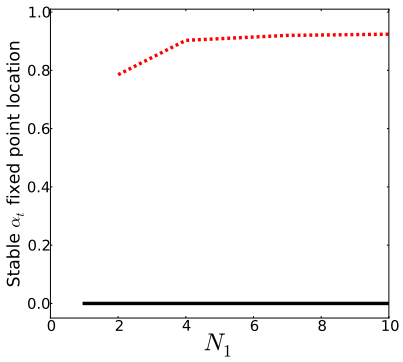

Figure 4: Example of falling N_1 triggering change from $(1,1)$ to $(0,1)$ for Model 5. Dashed line = stable FP of the form $(\gamma,1)$, solid line = stable FP $(0,1)$. For $N_1 > 4$, there is a stable FP near $(1,1)$. For $N_1 < 2$, $(0,1)$ is the only stable FP. $\lambda_{22} = 0.58$, $\lambda_{12} = 0.4$, $N_2 = 10$, $p = q = 0.05$.

tions made: $R \to R'$, $\lambda_{ij} \to \lambda'_{ij}$, $(0,0) \to (0,\kappa)$, $(1,1) \to (\gamma,1)$.

The parameter space is again split into these regions by three hyperplanes: λ'_{11}=λ'_{12}, λ'_{22}=λ'_{12}, and R'=1. As in Model 4, the bifurcation structure implies all 6 possible changes between the three FPs. However, change to {1,2} entails crossing the hyperplanes λ'_{11}=λ'_{12} and λ'_{2}=λ'_{12}, and is thus now frequency dependent.

In particular, consider a system at a stable FP $(\gamma,1)$, for some N/V pair. This FP becomes unstable if λ'_{22} becomes smaller than λ'_{12}. Assuming that the λ_{ij} are fixed, this occurs only if N_1 falls below a critical value, $N_1^* = (1 - \frac{\lambda_{22}}{\lambda_{12}}(1-p))^{-1}$; the system would then transition to $(0,1)$, the only stable state. By a similar argument, falling frequency can lead to change from $(0,\kappa)$ to $(0,1)$. Falling frequency can thus cause change to {1,2} in this model, as seen in the N/V data; Fig. 4 shows an example.

Unlike in Model 4, stable variation of the type seen in the N/V stress trajectories — one of N or V stably varying, but not both — is possible for some parameter values. $(0,0)$ and $(1,1)$ (corresponding to {1,1} and {2,2}) are technically never possible, but effectively occur for FPs of the form $(\kappa,0)$ and $(\gamma,1)$ when κ or γ are small. {2,1} is never a stable FP, by construction.

This model thus arguably shows all of the desired properties seen in the N/V data.

Property	Model

Obs. freq. depend.	✗	✗	✗	✗	✓

Table 2: Summary of model properties

4.6 Models summary, observations

Table 2 lists which of Models 1–5 show each of the desired properties (from §3.2), corresponding to aspects of the observed diachronic dynamics of N/V pair stress.

Based on this set of models, we are able to make some observations about the effect of different assumptions about learning by individuals on population-level dynamics. Models including asymmetric mistransmission (1, 3, 5) generally do not lead to stable states in which the entire population uses {1,1} or {2,2}. (In Model 5, stable variation very near {1,1} or {2,2} is possible.) However, {1,1} and {2,2} are diachronically very stable stress patterns, suggesting that at least for this model set, assuming mistransmission in the learner is problematic. Models 2–3, where analogy is implemented as a hard constraint based on Ross' generalization, do not give most desired properties. Models 4–5, where analogy is implemented as prior probabilities over N/V stress patterns, show crucial aspects of the observed dynamics: bifurcations corresponding to the changes observed in the stress data. Model 5 shows change to {1,2} triggered by falling frequency, a pattern observed in the stress data, and an *emergent* property of the model dynamics: this frequency effect is not present in Models 1 or 4, but is present in Model 5, where the learner combines mistransmission (Model 1) with coupling by priors (Model 4).

5 Discussion

We have developed 5 dynamical systems models for a relatively complex diachronic change, found one successful model, and were able to reason about the source of model behavior. Each model describes the diachronic, population-level consequences of assuming a particular learning algorithm for individuals. The algorithms considered

were motivated by different possible sources of change, from linguistics and psychology (§2.2). We discuss novel contributions of this work, and future directions.

The dataset used here shows more complex dynamics, to our knowledge, than in changes previously considered in the computational literature. By using a detailed, longitudinal dataset, we were able to strongly constrain the desired behavior of a computational model, so that the task of model building is not "doomed to success". While all models show *some* patterns observed in the data, only one shows all such properties. We believe detailed datasets are potentially very useful for evaluating and differentiating between proposed computational models of change.

This paper is a first attempt to integrate detailed data with a range of DS models. We have only considered some schematic properties of the dynamics observed in our dataset, and used these to qualitatively compare each model's predictions to the dynamics. Future work should consider the dynamics in more detail, develop more complex models (for example, by relaxing the infinite-population assumption, allowing for stochastic dynamics), and *quantitatively* compare model predictions and observed dynamics.

We were able to reason about how assumptions about individual learning affect population dynamics by analyzing a range of simple, related models. This approach is pursued in more depth in the larger set of models considered in (Sonderegger, 2009). Our use of model comparison contrasts with most recent computational work on change, where a small number (1–2) of very complex models are analyzed, allowing for much more detailed models of language learning and usage than those considered here (e.g. Choudhury et al., 2006; Minett & Wang, 2008; Baxter et al., 2009; Landsbergen, 2009). An advantage of our approach is an enhanced ability to evaluate a range of proposed causes for a particular case of language change.

By using simple models, we were able to consider a range of learning algorithms corresponding to different explanations for the observed diachronic dynamics. What makes this a useful exercise is the fundamentally non-trivial map, illustrated by Models 1–5, between individual learning and population-level dynamics. Although the type of individual learning assumed in each model was chosen with the same patterns of change in mind, and despite the simplicity of the models used, the resulting population-level dynamics differ greatly. This is an important point given that proposed explanations for change (e.g., mistransmission and analogy) operate at the level of individuals, while the phenomena being explained (patterns of change, or particular changes) are aspects of the population-level dynamics.

Finding Cognate Groups using Phylogenies

David Hall and **Dan Klein**

Abstract

A central problem in historical linguistics is the identification of historically related *cognate* words. We present a generative phylogenetic model for automatically inducing cognate group structure from unaligned word lists. Our model represents the process of transformation and transmission from ancestor word to daughter word, as well as the alignment between the words lists of the observed languages. We also present a novel method for simplifying complex weighted automata created during inference to counteract the otherwise exponential growth of message sizes. On the task of identifying cognates in a dataset of Romance words, our model significantly outperforms a baseline approach, increasing accuracy by as much as 80%. Finally, we demonstrate that our automatically induced groups can be used to successfully reconstruct ancestral words.

1 Introduction

A crowning achievement of historical linguistics is the comparative method (Ohala, 1993), wherein linguists use word similarity to elucidate the hidden phonological and morphological processes which govern historical descent. The comparative method requires reasoning about three important hidden variables: the overall *phylogenetic guide tree* among languages, the *evolutionary parameters* of the ambient changes at each branch, and the *cognate group structure* that specifies which words share common ancestors.

All three of these variables interact and inform each other, and so historical linguists often consider them jointly. However, linguists are currently required to make qualitative judgments regarding the relative likelihood of certain sound changes, cognate groups, and so on. Several recent statistical methods have been introduced to provide increased quantitative backing to the comparative method (Oakes, 2000; Bouchard-Côté et al., 2007; Bouchard-Côté et al., 2009); others have modeled the spread of language changes and speciation (Ringe et al., 2002; Daumé III and Campbell, 2007; Daumé III, 2009; Nerbonne, 2010). These automated methods, while providing robustness and scale in the induction of ancestral word forms and evolutionary parameters, assume that cognate groups are already known. In this work, we address this limitation, presenting a model in which cognate groups can be discovered automatically.

Finding cognate groups is not an easy task, because underlying morphological and phonological changes can obscure relationships between words, especially for distant cognates, where simple string overlap is an inadequate measure of similarity. Indeed, a standard string similarity metric like Levenshtein distance can lead to false positives. Consider the often cited example of Greek /maːti/ and Malay /mata/, both meaning "eye" (Bloomfield, 1938). If we were to rely on Levenshtein distance, these words would seem to be a highly attractive match as cognates: they are nearly identical, essentially differing in only a single character. However, no linguist would posit that these two words are related. To correctly learn that they are not related, linguists typically rely on two kinds of evidence. First, because sound change is largely regular, we would need to commonly see /i/ in Greek wherever we see /a/ in Malay (Ross, 1950). Second, we should look at languages closely related to Greek and Malay, to see if similar patterns hold there, too.

Some authors have attempted to automatically detect cognate words (Mann and Yarowsky, 2001; Lowe and Mazaudon, 1994; Oakes, 2000; Kondrak, 2001; Mulloni, 2007), but these methods

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1030–1039,
Uppsala, Sweden, 11-16 July 2010.

typically work on language pairs rather than on larger language families. To fully automate the comparative method, it is necessary to consider multiple languages, and to do so in a model which couples cognate detection with similarity learning.

In this paper, we present a new generative model for the automatic induction of cognate groups given only (1) a known family tree of languages and (2) word lists from those languages. A prior on word survival generates a number of cognate groups and decides which groups are attested in each modern language. An evolutionary model captures how each word is generated from its parent word. Finally, an alignment model maps the flat word lists to cognate groups. Inference requires a combination of message-passing in the evolutionary model and iterative bipartite graph matching in the alignment model.

In the message-passing phase, our model encodes distributions over strings as weighted finite state automata (Mohri, 2009). Weighted automata have been successfully applied to speech processing (Mohri et al., 1996) and more recently to morphology (Dreyer and Eisner, 2009). Here, we present a new method for automatically compressing our message automata in a way that can take into account prior information about the expected outcome of inference.

In this paper, we focus on a transcribed word list of 583 cognate sets from three Romance languages (Portuguese, Italian and Spanish), as well as their common ancestor Latin (Bouchard-Côté et al., 2007). We consider both the case where we know that all cognate groups have a surface form in all languages, and where we do not know that. On the former, easier task we achieve identification accuracies of 90.6%. On the latter task, we achieve F1 scores of 73.6%. Both substantially beat baseline performance.

2 Model

In this section, we describe a new generative model for vocabulary lists in multiple related languages given the phylogenetic relationship between the languages (their family tree). The generative process factors into three subprocesses: survival, evolution, and alignment, as shown in Figure 1(a). Survival dictates, for each cognate group, which languages have words in that group. Evolution describes the process by which daughter words are transformed from their parent word. Finally, alignment describes the "scrambling" of the word lists into a flat order that hides their lineage. We present each subprocess in detail in the following subsections.

2.1 Survival

First, we choose a number G of ancestral cognate groups from a geometric distribution. For each cognate group g, our generative process walks down the tree. At each branch, the word may either survive or die. This process is modeled in a "death tree" with a Bernoulli random variable $S_{\ell g}$ for each language ℓ and cognate group g specifying whether or not the word died before reaching that language. Death at any node in the tree causes all of that node's descendants to also be dead. This process captures the intuition that cognate words are more likely to be found clustered in sibling languages than scattered across unrelated languages.

2.2 Evolution

Once we know which languages will have an attested word and which will not, we generate the actual word forms. The evolution component of the model generates words according to a branch-specific transformation from a node's immediate ancestor. Figure 1(a) graphically describes our generative model for three Romance languages: Italian, Portuguese, and Spanish.[1] In each cognate group, each word W_ℓ is generated from its parent according to a conditional distribution with parameter φ_ℓ, which is specific to that edge in the tree, but shared between all cognate groups.

In this paper, each φ_ℓ takes the form of a parameterized edit distance similar to the standard Levenshtein distance. Richer models – such as the ones in Bouchard-Côté et al. (2007) – could instead be used, although with an increased inferential cost. The edit transducers are represented schematically in Figure 1(b). Characters x and y are arbitrary phonemes, and $\sigma(x, y)$ represents the cost of substituting x with y. ε represents the empty phoneme and is used as shorthand for insertion and deletion, which have parameters η and δ, respectively.

As an example, see the illustration in Figure 1(c). Here, the Italian word /fwɔko/ ("fire") is generated from its parent form /fokus/ ("hearth")

[1] Though we have data for Latin, we treat it as unobserved to represent the more common case where the ancestral language is unattested; we also evaluate our system using the Latin data.

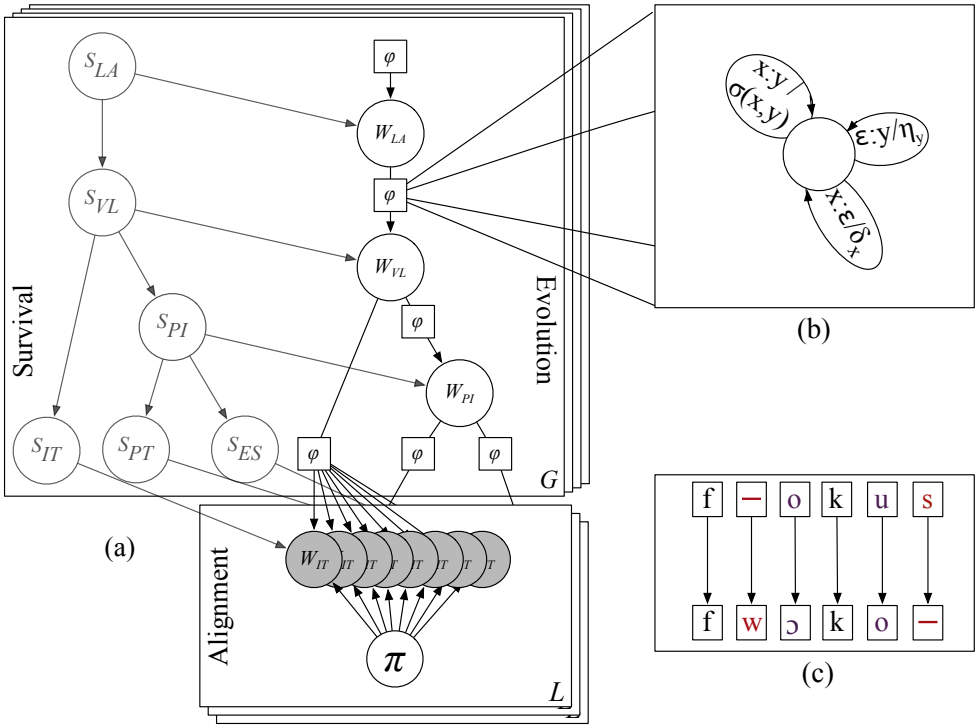

Figure 1: (a) The process by which cognate words are generated. Here, we show the derivation of Romance language words W_ℓ from their respective Latin ancestor, parameterized by transformations φ_ℓ and survival variables S_ℓ. Languages shown are Latin (LA), Vulgar Latin (VL), Proto-Iberian (PI), Italian (IT), Portuguese (PT), and Spanish (ES). Note that only modern language words are observed (shaded). (b) The class of parameterized edit distances used in this paper. Each pair of phonemes has a weight σ for deletion, and each phoneme has weights η and δ for insertion and deletion respectively. (c) A possible alignment produced by an edit distance between the Latin word *focus* ("hearth") and the Italian word *fuoco* ("fire").

by a series of edits: two matches, two substitutions (/u/→ /o/, and /o/→/ɔ/), one insertion (w) and one deletion (/s/). The probability of each individual edit is determined by φ. Note that the marginal probability of a specific Italian word conditioned on its Vulgar Latin parent is the sum over all possible derivations that generate it.

2.3 Alignment

Finally, at the leaves of the trees are the observed words. (We take non-leaf nodes to be unobserved.) Here, we make the simplifying assumption that in any language there is at most one word per language per cognate group. Because the assignments of words to cognates is unknown, we specify an unknown alignment parameter π_ℓ for each modern language which is an alignment of cognate groups to entries in the word list. In the case that every cognate group has a word in each language, each π_ℓ is a permutation. In the more general case that some cognate groups do not have words from all languages, this mapping is injective from words to cognate groups. From a generative perspective, π_ℓ generates observed positions of the words in some vocabulary list.

In this paper, our task is primarily to learn the alignment variables π_ℓ. All other hidden variables are auxiliary and are to be marginalized to the greatest extent possible.

3 Inference of Cognate Assignments

In this section, we discuss the inference method for determining cognate assignments under fixed parameters φ. We are given a set of languages and a list of words in each language, and our objective is to determine which words are cognate with each other. Because the parameters π_ℓ are either permutations or injections, the inference task is reduced to finding an alignment π of the respective word lists to maximize the log probability of the observed words.

$$\pi^* = \arg\max_{\pi} \sum_{g} \log p(w_{(\ell,\pi_\ell(g))} | \varphi, \pi, \mathbf{w}_{-\ell})$$

$w_{(\ell,\pi_\ell(g))}$ is the word in language ℓ that π_ℓ has assigned to cognate group g. Maximizing this quantity directly is intractable, and so instead we use a coordinate ascent algorithm to iteratively

maximize the alignment corresponding to a single language ℓ while holding the others fixed:

$$\pi_\ell^* = \arg\max_{\pi_\ell} \sum_g \log p(w_{(\ell,\pi_\ell(g))}|\varphi, \pi_{-\ell}, \pi_\ell, \mathbf{w}_{-\ell})$$

Each iteration is then actually an instance of bipartite graph matching, with the words in one language one set of nodes, and the current cognate groups in the other languages the other set of nodes. The edge affinities $\mathbf{aff}$ between these nodes are the conditional probabilities of each word w_ℓ belonging to each cognate group g:

$$\mathbf{aff}(w_\ell, g) = p(w_\ell|\mathbf{w}_{-\ell,\pi_{-\ell}(g)}, \varphi, \pi_{-\ell})$$

To compute these affinities, we perform inference in each tree to calculate the marginal distribution of the words from the language ℓ. For the marginals, we use an analog of the forward/backward algorithm. In the upward pass, we send messages from the leaves of the tree toward the root. For observed leaf nodes W_d, we have:

$$\mu_{d\to a}(w_a) = p(W_d = w_d|w_a, \varphi_d)$$

and for interior nodes W_i:

$$\mu_{i\to a}(w_a) = \sum_{w_i} p(w_i|w_a, \varphi_i) \prod_{d\in \text{child}(w_i)} \mu_{d\to i}(w_i) \quad (1)$$

In the downward pass (toward the language ℓ), we sum over ancestral words W_a:

$$\mu_{a\to d}(w_d) = \sum_{w_a} p(w_d|w_a, \varphi_d)\mu_{a'\to a}(w_a) \prod_{\substack{d'\in \text{child}(w_a)\\ d'\neq d}} \mu_{d'\to a}(w_a)$$

where a' is the ancestor of a. Computing these messages gives a posterior marginal distribution $\mu_\ell(w_\ell) = p(w_\ell|\mathbf{w}_{-\ell,\pi_{-\ell}(g)}, \varphi, \pi_{-\ell})$, which is precisely the affinity score we need for the bipartite matching. We then use the Hungarian algorithm (Kuhn, 1955) to find the optimal assignment for the bipartite matching problem.

One important final note is initialization. In our early experiments we found that choosing a random starting configuration unsurprisingly led to rather poor local optima. Instead, we started with empty trees, and added in one language per iteration until all languages were added, and then continued iterations on the full tree.

4 Learning

So far we have only addressed searching for Viterbi alignments π under fixed parameters. In practice, it is important to estimate better parametric edit distances φ_ℓ and survival variables S_ℓ. To motivate the need for good transducers, consider the example of English "day" */deɪ/* and Latin "diēs" */diːɛs/*, both with the same meaning. Surprisingly, these words are in no way related, with English "day" probably coming from a verb meaning "to burn" (OED, 1989). However, a naively constructed edit distance, which for example might penalize vowel substitutions lightly, would fail to learn that Latin words that are borrowed into English would not undergo the sound change */ɪ/→/eɪ/*. Therefore, our model must learn not only which sound changes are plausible (e.g. vowels turning into other vowels is more common than vowels turning into consonants), but which changes are appropriate for a given language.[2]

At a high level, our learning algorithm is much like Expectation Maximization with hard assignments: after we update the alignment variables π and thus form new potential cognate sets, we re-estimate our model's parameters to maximize the likelihood of those assignments.[3] The parameters can be learned through standard maximum likelihood estimation, which we detail in this section.

Because we enforce that a word in language d must be dead if its parent word in language a is dead, we just need to learn the conditional probabilities $p(S_d = \text{dead}|S_a = \text{alive})$. Given fixed assignments π, the maximum likelihood estimate can be found by counting the number of "deaths" that occurred between a child and a live parent, applying smoothing – we found adding 0.5 to be reasonable – and dividing by the total number of live parents.

For the transducers φ, we learn parameterized edit distances that model the probabilities of different sound changes. For each φ_ℓ we fit a non-uniform substitution, insertion, and deletion matrix $\sigma(x, y)$. These edit distances define a condi-

[2] We note two further difficulties: our model does not handle "borrowings," which would be necessary to capture a significant portion of English vocabulary; nor can it seamlessly handle words that are inherited later in the evolution of language than others. For instance, French borrowed words from its parent language Latin during the Renaissance and the Enlightenment that have not undergone the same changes as words that evolved "naturally" from Latin. See Bloomfield (1938). Handling these cases is a direction for future research.

[3] Strictly, we can cast this problem in a variational framework similar to mean field where we iteratively maximize parameters to minimize a KL-divergence. We omit details for clarity.

tional exponential family distribution when conditioned on an ancestral word. That is, for any fixed w_a:

$$\sum_{w_d} p(w_d|w_a,\sigma) = \sum_{w_d} \sum_{\substack{z\in \\ \text{align}(w_a,w_d)}} \text{score}(z;\sigma)$$
$$= \sum_{w_d} \sum_{\substack{z\in \\ \text{align}(w_a,w_d)}} \prod_{(x,y)\in z} \sigma(x,y) = 1$$

where $\text{align}(w_a, w_d)$ is the set of possible alignments between the phonemes in words w_a and w_d.

We are seeking the maximum likelihood estimate of each φ, given fixed alignments π:

$$\hat{\varphi}_\ell = \arg\max_{\varphi_\ell} p(\mathbf{w}|\varphi,\pi)$$

To find this maximizer for any given π_ℓ, we need to find a marginal distribution over the edges connecting any two languages a and d. With this distribution, we calculate the expected "alignment unigrams." That is, for each pair of phonemes x and y (or empty phoneme ε), we need to find the quantity:

$$E_{p(w_a,w_d)}[\#(x,y;z)] =$$
$$\sum_{w_a,w_d} \sum_{\substack{z\in \\ \text{align}(w_a,w_d)}} \#(x,y;z)p(z|w_a,w_d)p(w_a,w_d)$$

where we denote $\#(x,y;z)$ to be the number of times the pair of phonemes (x,y) are aligned in alignment z. The exact method for computing these counts is to use an expectation semiring (Eisner, 2001).

Given the expected counts, we now need to normalize them to ensure that the transducer represents a conditional probability distribution (Eisner, 2002; Oncina and Sebban, 2006). We have that, for each phoneme x in the ancestor language:

$$\eta_y = \frac{E[\#(\varepsilon,y;z)]}{E[\#(\cdot,\cdot;z)]}$$
$$\sigma(x,y) = (1-\sum_{y'}\eta_{y'})\frac{E[\#(x,y;z)]}{E[\#(x,\cdot;z)]}$$
$$\delta_x = (1-\sum_{y'}\eta_{y'})\frac{E[\#(x,\varepsilon;z)]}{E[\#(x,\cdot;z)]}$$

Here, we have $\#(\cdot,\cdot;z) = \sum_{x,y}\#(x,y;z)$ and $\#(x,\cdot;z) = \sum_y \#(x,y;z)$. The $(1-\sum_{y'}\eta_{y'})$ term ensure that for any ancestral phoneme x, $\sum_y \eta_y + \sum_y \sigma(x,y) + \delta_x = 1$. These equations ensure that the three transition types (insertion, substitution/match, deletion) are normalized for each ancestral phoneme.

5 Transducers and Automata

In our model, it is not just the edit distances that are finite state machines. Indeed, the words themselves are string-valued random variables that have, in principle, an infinite domain. To represent distributions and messages over these variables, we chose weighted finite state automata, which can compactly represent functions over strings. Unfortunately, while initially compact, these automata become unwieldy during inference, and so approximations must be used (Dreyer and Eisner, 2009). In this section, we summarize the standard algorithms and representations used for weighted finite state transducers. For more detailed treatment of the general transducer operations, we direct readers to Mohri (2009).

A weighted automaton (resp. transducer) encodes a function over strings (resp. pairs of strings) as weighted paths through a directed graph. Each edge in the graph has a real-valued weight[4] and a label, which is a single phoneme in some alphabet Σ or the empty phoneme ε (resp. pair of labels in some alphabet $\Sigma\times\Delta$). The weight of a string is then the sum of all paths through the graph that accept that string.

For our purposes, we are concerned with three fundamental operations on weighted transducers. The first is computing the sum of all paths through a transducer, which corresponds to computing the partition function of a distribution over strings. This operation can be performed in worst-case cubic time (using a generalization of the Floyd-Warshall algorithm). For acyclic or feed-forward transducers, this time can be improved dramatically by using a generalization of Djisktra's algorithm or other related algorithms (Mohri, 2009).

The second operation is the composition of two transducers. Intuitively, composition creates a new transducer that takes the output from the first transducer, processes it through the second transducer, and then returns the output of the second transducer. That is, consider two transducers T_1 and T_2. T_1 has input alphabet Σ and output alphabet Δ, while T_2 has input alphabet Δ and output alphabet Ω. The composition $T_1 \circ T_2$ returns a new transducer over Σ and Ω such that $(T_1 \circ T_2)(x,y) = \sum_u T_1(x,u)\cdot T_2(u,y)$. In this paper, we use composition for marginalization and factor products. Given a factor $f_1(x,u;T_1)$ and an-

[4]The weights can be anything that form a semiring, but for the sake of exposition we specialize to real-valued weights.

other factor $f_2(u, y; T_2)$, composition corresponds to the operation $\psi(x, y) = \sum_u f_1(x, u) f_2(u, y)$. For two messages $\mu_1(w)$ and $\mu_2(w)$, the same algorithm can be used to find the product $\mu(w) = \mu_1(w)\mu_2(w)$.

The third operation is transducer minimization. Transducer composition produces $O(nm)$ states, where n and m are the number of states in each transducer. Repeated compositions compound the problem: iterated composition of k transducers produces $O(n^k)$ states. Minimization alleviates this problem by collapsing indistinguishable states into a single state. Unfortunately, minimization does not always collapse enough states. In the next section we discuss approaches to "lossy" minimization that produce automata that are not exactly the same but are much smaller.

6 Message Approximation

Recall that in inference, when summing out interior nodes w_i we calculated the product over incoming messages $\mu_{d \to i}(w_i)$ (Equation 1), and that these products are calculated using transducer composition. Unfortunately, the maximal number of states in a message is exponential in the number of words in the cognate group. Minimization can only help so much: in order for two states to be collapsed, the distribution over transitions from those states must be indistinguishable. In practice, for the automata generated in our model, minimization removes at most half the states, which is not sufficient to counteract the exponential growth. Thus, we need to find a way to approximate a message $\mu(w)$ using a simpler automata $\tilde{\mu}(w; \theta)$ taken from a restricted class parameterized by θ.

In the context of transducers, previous authors have focused on a combination of n-best lists and unigram back-off models (Dreyer and Eisner, 2009), a schematic diagram of which is in Figure 2(d). For their problem, n-best lists are sensible: their nodes' local potentials already focus messages on a small number of hypotheses. In our setting, however, n-best lists are problematic; early experiments showed that a 10,000-best list for a typical message only accounts for 50% of message log perplexity. That is, the posterior marginals in our model are (at least initially) fairly flat.

An alternative approach might be to simply treat messages as unnormalized probability distributions, and to minimize the KL divergence between some approximating message $\tilde{\mu}(w)$ and the true message $\mu(w)$. However, messages are not always probability distributions and – because the number of possible strings is in principle infinite – they need not sum to a finite number.[5] Instead, we propose to minimize the KL divergence between the "expected" marginal distribution and the approximated "expected" marginal distribution:

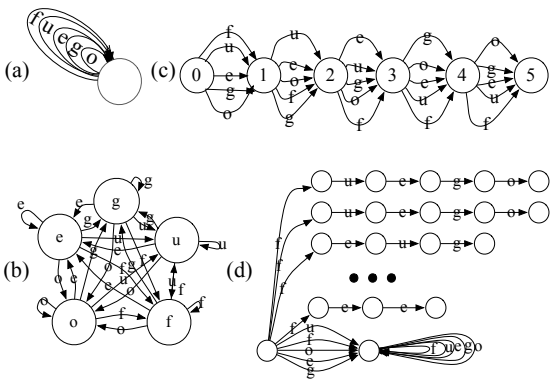

Figure 2: Various topologies for approximating topologies: (a) a unigram model, (b) a bigram model, (c) the anchored unigram model, and (d) the n-best plus backoff model used in Dreyer and Eisner (2009). In (c) and (d), the relative height of arcs is meant to convey approximate probabilities.

$$\begin{aligned}
\hat{\theta} &= \arg\min_{\theta} D_{KL}(\tau(w)\mu(w) || \tau(w)\tilde{\mu}(w; \theta)) \\
&= \arg\min_{\theta} \sum_w \tau(w)\mu(w) \log \frac{\tau(w)\mu(w)}{\tau(w)\tilde{\mu}(w; \theta)} \\
&= \arg\min_{\theta} \sum_w \tau(w)\mu(w) \log \frac{\mu(w)}{\tilde{\mu}(w; \theta)}
\end{aligned} \tag{2}$$

where τ is a term acting as a surrogate for the posterior distribution over w without the information from μ. That is, we seek to approximate μ not on its own, but as it functions in an environment representing its final context. For example, if $\mu(w)$ is a backward message, τ could be a stand-in for a forward probability.[6]

In this paper, $\mu(w)$ is a complex automaton with potentially many states, $\tilde{\mu}(w; \theta)$ is a simple parametric automaton with forms that we discuss below, and $\tau(w)$ is an arbitrary (but hopefully fairly simple) automaton. The actual method we use is

[5] As an extreme example, suppose we have observed that $W_d = w_d$ and that $p(W_d = w_d | w_a) = 1$ for all ancestral words w_a. Then, clearly $\sum_{w_d} \mu(w_d) = \sum_{w_d} \sum p(W_d = w_d | w_a) = \infty$ whenever there are an infinite number of possible ancestral strings w_a.

[6] This approach is reminiscent of Expectation Propagation (Minka, 2001).

as follows. Given a deterministic prior automaton τ, and a deterministic automaton topology $\tilde{\mu}^*$, we create the composed unweighted automaton $\tau \circ \tilde{\mu}^*$, and calculate arc transitions weights to minimize the KL divergence between that composed transducer and $\tau \circ \mu$. The procedure for calculating these statistics is described in Li and Eisner (2009), which amounts to using an expectation semiring (Eisner, 2001) to compute expected transitions in $\tau \circ \tilde{\mu}^*$ under the probability distribution $\tau \circ \mu$.

From there, we need to create the automaton $\tau^{-1} \circ \tau \circ \tilde{\mu}$. That is, we need to divide out the influence of $\tau(w)$. Since we know the topology and arc weights for τ ahead of time, this is often as simple as dividing arc weights in $\tau \circ \tilde{\mu}$ by the corresponding arc weight in $\tau(w)$. For example, if τ encodes a geometric distribution over word lengths and a uniform distribution over phonemes (that is, $\tau(w) \propto p^{|w|}$), then computing $\tilde{\mu}$ is as simple as dividing each arc in $\tau \circ \tilde{\mu}$ by p.[7]

There are a number of choices for τ. One is a hard maximum on the length of words. Another is to choose $\tau(w)$ to be a unigram language model over the language in question with a geometric probability over lengths. In our experiments, we find that $\tau(w)$ can be a geometric distribution over lengths with a uniform distribution over phonemes and still give reasonable results. This distribution captures the importance of shorter strings while still maintaining a relatively weak prior.

What remains is the selection of the topologies for the approximating message $\tilde{\mu}$. We consider three possible approximations, illustrated in Figure 2. The first is a plain unigram model, the second is a bigram model, and the third is an anchored unigram topology: a position-specific unigram model for each position up to some maximum length.

The first we consider is a standard unigram model, which is illustrated in Figure 2(a). It has $|\Sigma| + 2$ parameters: one weight σ_a for each phoneme $a \in \Sigma$, a starting weight λ, and a stopping probability ρ. $\tilde{\mu}$ then has the form:

$$\tilde{\mu}(w) = \lambda\rho \prod_{i \leq |w|} \sigma_{w_i}$$

Estimating this model involves only computing the expected count of each phoneme, along with the expected length of a word, $E[|w|]$. We then normalize the counts according to the maximum likelihood estimate, with arc weights set as:

$$\sigma_a \propto E[\#(a)]$$

Recall that these expectations can be computed using an expectation semiring.

Finally, λ can be computed by ensuring that the approximate and exact expected marginals have the same partition function. That is, with the other parameters fixed, solve:

$$\sum_w \tau(w)\tilde{\mu}(w) = \sum_w \tau(w)\mu(w)$$

which amounts to rescaling $\tilde{\mu}$ by some constant.

The second topology we consider is the bigram topology, illustrated in Figure 2(b). It is similar to the unigram topology except that, instead of a single state, we have a state for each phoneme in Σ, along with a special start state. Each state a has transitions with weights $\sigma_{b|a} = p(b|a) \propto E[\#(b|a)]$. Normalization is similar to the unigram case, except that we normalize the transitions from each state.

The final topology we consider is the positional unigram model in Figure 2(c). This topology takes positional information into account. Namely, for each position (up to some maximum position), we have a unigram model over phonemes emitted at that position, along with the probability of stopping at that position (i.e. a "sausage lattice"). Estimating the parameters of this model is similar, except that the expected counts for the phonemes in the alphabet are conditioned on their position in the string. With the expected counts for each position, we normalize each state's final and outgoing weights. In our experiments, we set the maximum length to seven more than the length of the longest observed string.

7 Experiments

We conduct three experiments. The first is a "complete data" experiment, in which we reconstitute the cognate groups from the Romance data set, where all cognate groups have words in all three languages. This task highlights the evolution and alignment models. The second is a much harder "partial data" experiment, in which we randomly prune 20% of the branches from the dataset according to the survival process described in Section 2.1. Here, only a fraction of words appear

[7] Also, we must be sure to divide each final weight in the transducer by $(1 - |\Sigma|p)$, which is the stopping probability for a geometric transducer.

in any cognate group, so this task crucially involves the survival model. The ultimate purpose of the induced cognate groups is to feed richer evolutionary models, such as full reconstruction models. Therefore, we also consider a proto-word reconstruction experiment. For this experiment, using the system of Bouchard-Côté et al. (2009), we compare the reconstructions produced from our automatic groups to those produced from gold cognate groups.

7.1 Baseline

As a novel but heuristic baseline for cognate group detection, we use an iterative bipartite matching algorithm where instead of conditional likelihoods for affinities we use Dice's coefficient, defined for sets X and Y as:

$$\text{Dice}(X, Y) = \frac{2|X \cap Y|}{|X| + |Y|} \quad (3)$$

Dice's coefficients are commonly used in bilingual detection of cognates (Kondrak, 2001; Kondrak et al., 2003). We follow prior work and use sets of bigrams within words. In our case, during bipartite matching the set X is the set of bigrams in the language being re-permuted, and Y is the union of bigrams in the other languages.

7.2 Experiment 1: Complete Data

In this experiment, we know precisely how many cognate groups there are and that every cognate group has a word in each language. While this scenario does not include all of the features of the real-world task, it represents a good test case of how well these models can perform without the non-parametric task of deciding how many clusters to use.

We scrambled the 583 cognate groups in the Romance dataset and ran each method to convergence. Besides the heuristic baseline, we tried our model-based approach using Unigrams, Bigrams and Anchored Unigrams, with and without learning the parametric edit distances. When we did not use learning, we set the parameters of the edit distance to (0, -3, -4) for matches, substitutions, and deletions/insertions, respectively. With learning enabled, transducers were initialized with those parameters.

For evaluation, we report two metrics. The first is pairwise accuracy for each pair of languages, averaged across pairs of words. The other is accuracy measured in terms of the number of correctly, completely reconstructed cognate groups.

		Pairwise Acc.	Exact Match
Heuristic			
Baseline		48.1	35.4
Model			
Transducers	Messages		
Levenshtein	Unigrams	37.2	26.2
Levenshtein	Bigrams	43.0	26.5
Levenshtein	Anch. Unigrams	68.6	56.8
Learned	Unigrams	0.1	0.0
Learned	Bigrams	38.7	11.3
Learned	Anch. Unigrams	**90.3**	**86.6**

Table 1: Accuracies for reconstructing cognate groups. Levenshtein refers to fixed parameter edit distance transducer. Learned refers to automatically learned edit distances. Pairwise Accuracy means averaged on each word pair; Exact Match refers to percentage of completely and accurately reconstructed groups. For a description of the baseline, see Section 7.1.

		Prec.	Recall	F1
Heuristic				
Baseline		49.0	43.5	46.1
Model				
Transducers	Messages			
Levenshtein	Anch. Unigrams	**86.5**	36.1	50.9
Learned	Anch. Unigrams	66.9	**82.0**	**73.6**

Table 2: Accuracies for reconstructing incomplete groups. Scores reported are precision, recall, and F1, averaged over all word pairs.

Table 1 shows the results under various configurations. As can be seen, the kind of approximation used matters immensely. In this application, positional information is important, more so than the context of the previous phoneme. Both Unigrams and Bigrams significantly under-perform the baseline, while Anchored Unigrams easily outperforms it both with and without learning.

An initially surprising result is that learning actually harms performance under the unanchored approximations. The explanation is that these topologies are not sensitive enough to context, and that the learning procedure ends up flattening the distributions. In the case of unigrams – which have the least context – learning degrades performance to chance. However, in the case of positional unigrams, learning reduces the error rate by more than two-thirds.

7.3 Experiment 2: Incomplete Data

As a more realistic scenario, we consider the case where we do not know that all cognate groups have words in all languages. To test our model, we ran-

domly pruned 20% of the branches according the survival process of our model.[8]

Because only Anchored Unigrams performed well in Experiment 1, we consider only it and the Dice's coefficient baseline. The baseline needs to be augmented to support the fact that some words may not appear in all cognate groups. To do this, we thresholded the bipartite matching process so that if the coefficient fell below some value, we started a new group for that word. We experimented on 10 values in the range (0,1) for the baseline's threshold and report on the one (0.2) that gives the best pairwise F1.

The results are in Table 2. Here again, we see that the positional unigrams perform much better than the baseline system. The learned transducers seem to sacrifice precision for the sake of increased recall. This makes sense because the default edit distance parameter settings strongly favor exact matches, while the learned transducers learn more realistic substitution and deletion matrices, at the expense of making more mistakes.

For example, the learned transducers enable our model to correctly infer that Portuguese /difemdu/, Spanish /defiendo/, and Italian /difɛndo/ are all derived from Latin /deːfendoː/ "defend." Using the simple Levenshtein transducers, on the other hand, our model keeps all three separated, because the transducers cannot know – among other things – that Portuguese /i/, Spanish /e/, and Italian /i/ are commonly substituted for one another. Unfortunately, because the transducers used cannot learn contextual rules, certain transformations can be over-applied. For instance, Spanish /nombrar/ "name" is grouped together with Portuguese /numirar/ "number" and Italian /numerare/ "number," largely because the rule Portuguese /u/ → Spanish /o/ is applied outside of its normal context. This sound change occurs primarily with final vowels, and does not usually occur word medially. Thus, more sophisticated transducers could learn better sound laws, which could translate into improved accuracy.

7.4 Experiment 3: Reconstructions

As a final trial, we wanted to see how each automatically found cognate group faired as compared to the "true groups" for actual reconstruction of proto-words. Our model is not optimized for faithful reconstruction, and so we used the Ancestry Resampling system of Bouchard-Côté et al. (2009). To evaluate, we matched each Latin word with the best possible cognate group for that word. The process for the matching was as follows. If two or three of the words in an constructed cognate group agreed, we assigned the Latin word associated with the true group to it. With the remainder, we executed a bipartite matching based on bigram overlap.

For evaluation, we examined the Levenshtein distance between the reconstructed word and the chosen Latin word. As a kind of "skyline," we compare to the edit distances reported in Bouchard-Côté et al. (2009), which was based on complete knowledge of the cognate groups. On this task, our reconstructed cognate groups had an average edit distance of 3.8 from the assigned Latin word. This compares favorably to the edit distances reported in Bouchard-Côté et al. (2009), who using oracle cognate assignments achieved an average Levenshtein distance of 3.0.[9]

8 Conclusion

We presented a new generative model of word lists that automatically finds cognate groups from scrambled vocabulary lists. This model jointly models the origin, propagation, and evolution of cognate groups from a common root word. We also introduced a novel technique for approximating automata. Using these approximations, our model can reduce the error rate by 80% over a baseline approach. Finally, we demonstrate that these automatically generated cognate groups can be used to automatically reconstruct proto-words faithfully, with a small increase in error.

An Exact A* Method for Deciphering Letter-Substitution Ciphers

Eric Corlett and **Gerald Penn**
Department of Computer Science
University of Toronto
{ecorlett,gpenn}@cs.toronto.edu

Abstract

Letter-substitution ciphers encode a document from a known or hypothesized language into an unknown writing system or an unknown encoding of a known writing system. It is a problem that can occur in a number of practical applications, such as in the problem of determining the encodings of electronic documents in which the language is known, but the encoding standard is not. It has also been used in relation to OCR applications. In this paper, we introduce an exact method for deciphering messages using a generalization of the Viterbi algorithm. We test this model on a set of ciphers developed from various web sites, and find that our algorithm has the potential to be a viable, practical method for efficiently solving decipherment problems.

1 Introduction

Letter-substitution ciphers encode a document from a known language into an unknown writing system or an unknown encoding of a known writing system. This problem has practical significance in a number of areas, such as in reading electronic documents that may use one of many different standards to encode text. While this is not a problem in languages like English and Chinese, which have a small set of well known standard encodings such as ASCII, Big5 and Unicode, there are other languages such as Hindi in which there is no dominant encoding standard for the writing system. In these languages, we would like to be able to automatically retrieve and display the information in electronic documents which use unknown encodings when we find them. We also want to use these documents for information retrieval and data mining, in which case it is important to be able to read through them automatically, without resorting to a human annotator. The holy grail in this area would be an application to archaeological decipherment, in which the underlying language's identity is only hypothesized, and must be tested. The purpose of this paper, then, is to simplify the problem of reading documents in unknown encodings by presenting a new algorithm to be used in their decipherment. Our algorithm operates by running a search over the n-gram probabilities of possible solutions to the cipher, using a generalization of the Viterbi algorithm that is wrapped in an A* search, which determines at each step which partial solutions to expand. It is guaranteed to converge on the language-model-optimal solution, and does not require restarts or risk falling into local optima. We specifically consider the problem of finding decodings of electronic documents drawn from the internet, and we test our algorithm on ciphers drawn from randomly selected pages of Wikipedia. Our testing indicates that our algorithm will be effective in this domain.

It may seem at first that automatically decoding (as opposed to deciphering) a document is a simple matter, but studies have shown that simple algorithms such as letter frequency counting do not always produce optimal solutions (Bauer, 2007). If the text from which a language model is trained is of a different genre than the plaintext of a cipher, the unigraph letter frequencies may differ substantially from those of the language model, and so frequency counting will be misleading. Because of the perceived simplicity of the problem, however, little work was performed to understand its computational properties until Peleg and Rosenfeld (1979), who developed a method that repeatedly swaps letters in a cipher to find a maximum probability solution. Since then, several different approaches to this problem have been suggested, some of which use word counts in the language to arrive at a solution (Hart, 1994), and some of

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1040–1047,
Uppsala, Sweden, 11-16 July 2010.

which treat the problem as an expectation maximization problem (Knight et al., 2006; Knight, 1999). These later algorithms are, however, highly dependent on their initial states, and require a number of restarts in order to find the globally optimal solution. A further contribution was made by (Ravi and Knight, 2008), which, though published earlier, was inspired in part by the method presented here, first discovered in 2007. Unlike the present method, however, Ravi and Knight (2008) treat the decipherment of letter-substitution ciphers as an integer programming problem. Clever though this constraint-based encoding is, their paper does not quantify the massive running times required to decode even very short documents with this sort of approach. Such inefficiency indicates that integer programming may simply be the wrong tool for the job, possibly because language model probabilities computed from empirical data are not smoothly distributed enough over the space in which a cutting-plane method would attempt to compute a linear relaxation of this problem. In any case, an exact method is available with a much more efficient A* search that is linear-time in the length of the cipher (though still horribly exponential in the size of the cipher and plain text alphabets), and has the additional advantage of being massively parallelizable. (Ravi and Knight, 2008) also seem to believe that short cipher texts are somehow inherently more difficult to solve than long cipher texts. This difference in difficulty, while real, is not inherent, but rather an artefact of the character-level n-gram language models that they (and we) use, in which preponderant evidence of differences in short character sequences is necessary for the model to clearly favour one letter-substitution mapping over another. Uniform character models equivocate regardless of the length of the cipher, and sharp character models with many zeroes can quickly converge even on short ciphers of only a few characters. In the present method, the role of the language model can be acutely perceived; both the time complexity of the algorithm and the accuracy of the results depend crucially on this characteristic of the language model. In fact, we must use add-one smoothing to decipher texts of even modest lengths because even one unseen plain-text letter sequence is enough to knock out the correct solution. It is likely that the method of (Ravi and Knight, 2008) is sensitive to this as well, but their experiments were apparently fixed on a single, well-trained model.

Applications of decipherment are also explored by (Nagy et al., 1987), who uses it in the context of optical character recognition (OCR). The problem we consider here is cosmetically related to the "L2P" (letter-to-phoneme) mapping problem of text-to-speech synthesis, which also features a prominent constraint-based approach (van den Bosch and Canisius, 2006), but the constraints in L2P are very different: two different instances of the same written letter may legitimately map to two different phonemes. This is not the case in letter-substitution maps.

2 Terminology

Substitution ciphers are ciphers that are defined by some permutation of a plaintext alphabet. Every character of a plaintext string is consistently mapped to a single character of an output string using this permutation. For example, if we took the string "$hello\_world$" to be the plaintext, then the string "$ifmmp\_xpsme$" would be a cipher that maps e to f, l to m, and so on. It is easy to extend this kind of cipher so that the plaintext alphabet is different from the ciphertext alphabet, but still stands in a one to one correspondence to it. Given a ciphertext C, we say that the set of characters used in C is the ciphertext alphabet Σ_C, and that its size is n_C. Similarly, the entire possible plaintext alphabet is Σ_P, and its size is is n_P. Since n_C is the number of letters actually used in the cipher, rather than the entire alphabet it is sampled from, we may find that $n_C < n_P$ even when the two alphabets are the same. We refer to the length of the cipher string C as c_{len}. In the above example, Σ_P is $\{\_, a, \ldots z\}$ and $n_P = 27$, while $\Sigma_C = \{\_, e, f, i, m, p, s, x\}$, $c_{len} = 11$ and $n_C = 8$.

Given the ciphertext C, we say that a *partial solution* of size k is a map $\sigma = \{p_1 : c_1, \ldots p_k : c_k\}$, where $c_1, \ldots, c_k \in \Sigma_C$ and are distinct, and $p_1, \ldots, p_k \in \Sigma_P$ and are distinct, and where $k \leq n_C$. If for a partial solution σ', we have that $\sigma \subset \sigma'$, then we say that σ' *extends* σ. If the size of σ' is $k+1$ and σ is size k, we say that σ' is an *immediate extension* of σ. A *full solution* is a partial solution of size n_C. In the above example, $\sigma_1 = \{\_ : \_, d : e\}$ would be a partial solution of size 2, and $\sigma_2 = \{\_ : \_, d : e, g : m\}$ would be a partial solution of size 3 that immediately extends σ_1. A partial solution $\sigma_T\{\_ : \_, d : e, e : f, h : i, l : m, o :$

$p, r : s, w : x\}$ would be both a full solution and the correct one. The full solution σ_T extends σ_1 but not σ_2.

Every possible full solution to a cipher C will produce a plaintext string with some associated language model probability, and we will consider the best possible solution to be the one that gives the highest probability. For the sake of concreteness, we will assume here that the language model is a character-level trigram model. This plaintext can be found by treating all of the length c_{len} strings S as being the output of different character mappings from C. A string S that results from such a mapping is *consistent* with a partial solution σ iff, for every $p_i : c_i \in \sigma$, the character positions of C that map to p_i are exactly the character positions with c_i in C.

In our above example, we had $C =$ "$ifmmp\_xpsme$", in which case we had $c_{len} = 11$. So mappings from C to "$hhhhh\_hhhhh$" or "$\_hhhhhhhhhh$" would be consistent with a partial solution of size 0, while "$hhhhh\_hhhhn$" would be consistent with the size 2 partial solution $\sigma = \{\_ : \_, n : e\}$.

3 The Algorithm

In order to efficiently search for the most likely solution for a ciphertext C, we conduct a search of the partial solutions using their trigram probabilities as a heuristic, where the trigram probability of a partial solution σ of length k is the maximum trigram probability over all strings consistent with it, meaning, in particular, that ciphertext letters not in its range can be mapped to any plaintext letter, and do not even need to be consistently mapped to the same plaintext letter in every instance. Given a partial solution σ of length n, we can extend σ by choosing a ciphertext letter c not in the range of σ, and then use our generalization of the Viterbi algorithm to find, for each p not in the domain of σ, a score to rank the choice of p for c, namely the trigram probability of the extension σ_p of σ. If we start with an empty solution and iteratively choose the most likely remaining partial solution in this way, storing the extensions obtained in a priority heap as we go, we will eventually reach a solution of size n_C. Every extension of σ has a probability that is, at best, equal to that of σ, and every partial solution receives, at worst, a score equal to its best extension, because the score is potentially based on an inconsistent mapping that does not qualify as an extension. These two observations taken together mean that one minus the score assigned by our method constitutes a cost function over which this score is an admissible heuristic in the A* sense. Thus the first solution of size n_C will be the best solution of size n_C.

The order by which we add the letters c to partial solutions is the order of the distinct ciphertext letters in right-to-left order of their final occurrence in C. Other orderings for the c, such as most frequent first, are also possible though less elegant.[1]

Algorithm 1 Search Algorithm

Order the letters $c_1 \ldots c_{n_C}$ by rightmost occurrence in C, $r_{n_C} < \ldots < r_1$.
Create a priority queue Q for partial solutions, ordered by highest probability.
Push the empty solution $\sigma_0 = \{\}$ onto the queue.
while Q is not empty **do**
  Pop the best partial solution σ from Q.
  $s = |\sigma|$.
  if $s = n_C$ **then**
    return σ
  else
    For all p not in the range of σ, push the immediate extension σ_p onto Q with the score assigned to table cell $G(r_{s+1}, p, p)$ by GVit$(\sigma, c_{s+1}, r_{s+1})$ if it is non-zero.
  end if
end while
Return "Solution Infeasible".

Our generalization of the Viterbi algorithm, depicted in Figure 1, uses dynamic programming to score every immediate extension of a given partial solution in tandem, by finding, in a manner consistent with the real Viterbi algorithm, the most probable input string given a set of output symbols, which in this case is the cipher C. Unlike the real Viterbi algorithm, we must also observe the constraints of the input partial solution's mapping.

[1] We have experimented with the most frequent first regimen as well, and it performs worse than the one reported here. Our hypothesis is that this is due to the fact that the most frequent character tends to appear in many high-frequency trigrams, and so our priority queue becomes very long because of a lack of low-probability trigrams to knock the scores of partial solutions below the scores of the extensions of their better scoring but same-length peers. A least frequent first regimen has the opposite problem, in which their rare occurrence in the ciphertext provides too few opportunities to potentially reduce the score of a candidate.

A typical decipherment involves multiple runs of this algorithm, each of which scores all of the immediate extensions, both tightening and lowering their scores relative to the score of the input partial solution. A call GVit(σ, c, r) manages this by filling in a table G such that for all $1 \leq i \leq r$, and $l, k \in \Sigma_P$, $G(i, l, k)$ is the maximum probability over every plaintext string S for which:

- len$(S) = i$,
- $S[i] = l$,
- for every p in the domain of σ, every $1 \leq j \leq i$, if $C[j] = \sigma(p)$ then $S[j] = p$, and
- for every position $1 \leq j \leq i$, if $C[j] = c$, then $S[j] = k$.

The real Viterbi algorithm lacks these final two constraints, and would only store a single cell at $G(i, l)$. There, G is called a trellis. Ours is larger, so so we will refer to G as a *greenhouse*.

The table is completed by filling in the columns from $i = 1$ to c_{len} in order. In every column i, we will iterate over the values of l and over the values of k such that $k : c$ and $l :$ are consistent with σ. Because we are using a trigram character model, the cells in the first and second columns must be primed with unigram and bigram probabilities. The remaining probabilities are calculated by searching through the cells from the previous two columns, using the entry at the earlier column to indicate the probability of the best string up to that point, and searching through the trigram probabilities over two additional letters. Backpointers are necessary to reference one of the two language model probabilities. Cells that would produce inconsistencies are left at zero, and these as well as cells that the language model assigns zero to can only produce zero entries in later columns.

In order to decrease the search space, we add the further restriction that the solutions of every three character sequence must be consistent: if the ciphertext indicates that two adjacent letters are the same, then only the plaintext strings that map the same letter to each will be considered. The number of letters that are forced to be consistent is three because consistency is enforced by removing inconsistent strings from consideration during trigram model evaluation.

Because every partial solution is only obtained by extending a solution of size one less, and extensions are only made in a predetermined order of cipher alphabet letters, every partial solution is only considered / extended once.

GVit is highly parallelizable. The $n_P \times n_P$ cells of every column i do not depend on each other — only on the cells of the previous two columns $i-1$ and $i-2$, as well as the language model. In our implementation of the algorithm, we have written the underlying program in C/C++, and we have used the CUDA library developed for NVIDIA graphics cards to in order to implement the parallel sections of the code.

4 Experiment

The above algorithm is designed for application to the transliteration of electronic documents, specifically, the transliteration of websites, and it has been tested with this in mind. In order to gain realistic test data, we have operated on the assumption that Wikipedia is a good approximation of the type of language that will be found in most internet articles. We sampled a sequence of English-language articles from Wikipedia using their random page selector, and these were used to create a set of reference pages. In order to minimize the common material used in each page, only the text enclosed by the paragraph tags of the main body of the pages were used. A rough search over internet articles has shown that a length of 1000 to 11000 characters is a realistic length for many articles, although this can vary according to the genre of the page. Wikipedia, for example, does have entries that are one sentence in length. We have run two groups of tests for our algorithm. In the first set of tests, we chose the mean of the above lengths to be our sample size, and we created and decoded 10 ciphers of this size (i.e., different texts, same size). We made these cipher texts by appending the contents of randomly chosen Wikipedia pages until they contained at least 6000 characters, and then using the first 6000 characters of the resulting files as the plaintexts of the cipher. The text length was rounded up to the nearest word where needed. In the second set of tests, we used a single long ciphertext, and measured the time required for the algorithm to finish a number of prefixes of it (i.e., same text, different sizes). The plaintext for this set of tests was developed in the same way as the first set, and the input ciphertext lengths considered were 1000, 3500, 6000, 8500, 11000, and 13500 characters.

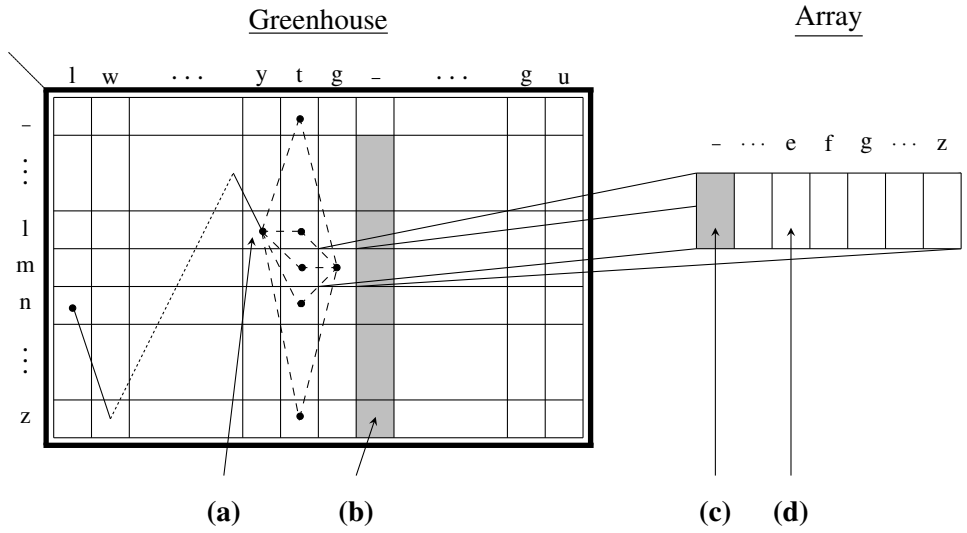

Figure 1: Filling the Greenhouse Table. Each cell in the greenhouse is indexed by a plaintext letter and a character from the cipher. Each cell consists of a smaller array. The cells in the array give the best probabilities of any path passing through the greenhouse cell, given that the index character of the array maps to the character in column c, where c is the next ciphertext character to be fixed in the solution. The probability is set to zero if no path can pass through the cell. This is the case, for example, in (b) and (c), where the knowledge that "_" maps to "_" would tell us that the cells indicated in gray are unreachable. The cell at (d) is filled using the trigram probabilities and the probability of the path at starting at (a).

In all of the data considered, the frequency of spaces was far higher than that of any other character, and so in any real application the character corresponding to the space can likely be guessed without difficulty. The ciphers we have considered have therefore been simplified by allowing the knowledge of which character corresponds to the space. It appears that Ravi and Knight (2008) did this as well. Our algorithm will still work without this assumption, but would take longer. In the event that a trigram or bigram would be found in the plaintext that was not counted in the language model, add one smoothing was used.

Our character-level language model used was developed from the first 1.5 million characters of the Wall Street Journal section of the Penn Treebank corpus. The characters used in the language model were the upper and lower case letters, spaces, and full stops; other characters were skipped when counting the frequencies. Furthermore, the number of sequential spaces allowed was limited to one in order to maximize context and to eliminate any long stretches of white space. As discussed in the previous paragraph, the space character is assumed to be known.

When testing our algorithm, we judged the time complexity of our algorithm by measuring the actual time taken by the algorithm to complete its runs, as well as the number of partial solutions placed onto the queue ("enqueued"), the number popped off the queue ("expanded"), and the number of zero-probability partial solutions not enqueued ("zeros") during these runs. These latter numbers give us insight into the quality of trigram probabilities as a heuristic for the A* search.

We judged the quality of the decoding by measuring the percentage of characters in the cipher alphabet that were correctly guessed, and also the word error rate of the plaintext generated by our solution. The second metric is useful because a low probability character in the ciphertext may be guessed wrong without changing as much of the actual plaintext. Counting the actual number of word errors is meant as an estimate of how useful or readable the plaintext will be. We did not count the accuracy or word error rate for unfinished ciphers.

We would have liked to compare our results with those of Ravi and Knight (2008), but the method presented there was simply not feasible

Algorithm 2 Generalized Viterbi Algorithm

GVit(σ, c, r)
Input: partial solution σ, ciphertext character c, and index r into C.
Output: greenhouse G.
Initialize G to 0.
i = 1
for All (l, k) such that $\sigma \cup \{k : c, l : C_i\}$ is consistent **do**
  $G(i, l, k) = P(l)$.
end for
i = 2
for All (l, k) such that $\sigma \cup \{k : c, l : C_i\}$ is consistent **do**
  for j such that $\sigma \cup \{k : c, l : C_i, j : C_{i-1}\}$ is consistent **do**
    $G(i, l, k) = \max(G(i, l, k), G(0, j, k) \times P(l|j))$
  end for
end for
i = 3
for (l, k) such that $\sigma \cup \{k : c, l : C_i\}$ is consistent **do**
  for j_1, j_2 such that $\sigma \cup \{k : c, j_2 : C[i-2], j_1 : C[i-1], l : C_i\}$ is consistent **do**
    $G(i, l, k) = \max(G(i, l, k), G(i-2, j_2, k) \times P(j_1|j_2) \times P(l|j_2 j_1))$.
  end for
end for
for $i = 4$ to r **do**
  for (l, k) such that $\sigma \cup \{k : c, l : C_i\}$ is consistent **do**
    for j_1, j_2 such that $\sigma \cup \{k : c, j_2 : C[i-2], j_1 : C[i-1], l : C_i\}$ is consistent **do**
      $G(i, l, k) = \max(G(i, l, k), G(i-2, j_2, k) \times P(j_1|j_2 j_{2(back)}) \times P(l|j_2 j_1))$.
    end for
  end for
end for

on texts and (case-sensitive) alphabets of this size with the computing hardware at our disposal.

5 Results

In our first set of tests, we measured the time consumption and accuracy of our algorithm over 10 ciphers taken from random texts that were 6000 characters long. The time values in these tables are given in the format of (H)H:MM:SS. For this set of tests, in the event that a test took more than 12 hours, we terminated it and listed it as unfinished. This cutoff was set in advance of the runs based upon our armchair speculation about how long one might at most be reasonably expected to wait for a web-page to be transliterated (an overnight run). The results from this run appear in Table 1. All running times reported in this section were obtained on a computer running Ubuntu Linux 8.04 with 4 GB of RAM and 8×2.5 GHz CPU cores. Column-level subcomputations in the greenhouse were dispatched to an NVIDIA Quadro FX 1700 GPU card that is attached through a 16-lane PCI Express adapter. The card has 512 MB of cache memory, a 460 MHz core processor and 32 shader processors operating in parallel at 920 MHz each.

In our second set of tests, we measured the time consumption and accuracy of our algorithm over several prefixes of different lengths of a single 13500-character ciphertext. The results of this run are given in Table 2.

The first thing to note in this data is that the accuracy of this algorithm is above 90 % for all of the test data, and 100% on all but the smallest 2 ciphers. We can also observe that even when there are errors (e.g., in the size 1000 cipher), the word error rate is very small. This is a Zipf's Law effect — misclassified characters come from poorly attested character trigrams, which are in turn found only in longer, rarer words. The overall high accuracy is probably due to the large size of the texts relative to the uniticity distance of an English letter-substitution cipher (Bauer, 2007). The results do show, however, that character trigram probabilities are an effective indicator of the most likely solution, even when the language model and test data are from very different genres (here, the Wall Street Journal and Wikipedia, respectively). These results also show that our algorithm is effective as a way of decoding simple ciphers. 80% of our runs finished before the 12 hour cutoff in the first experiment.

Cipher	Time	Enqueued	Expanded	Zeros	Accuracy	Word Error Rate
1	2:03:06	964	964	44157	100%	0%
2	0:13:00	132	132	5197	100%	0%

9	9:22:54	4814	4814	215086	100%	0%
10	1:23:21	950	950	42107	100%	0%

Table 1: Time consumption and accuracy on a sample of 10 6000-character texts.

Size	Time	Enqueued	Expanded	Zeros	Accuracy	Word Error Rate
1000	40:06:05	119759	119755	5172631	92.59%	1.89%
3500	0:38:02	615	614	26865	96.30%	0.17%
6000	0:12:34	147	147	5709	100%	0%
8500	8:52:25	1302	1302	60978	100%	0%
11000	1:03:58	210	210	8868	100%	0%
13500	0:54:30	219	219	9277	100%	0%

Table 2: Time consumption and accuracy on prefixes of a single 13500-character ciphertext.

As far as the running time of the algorithm goes, we see a substantial variance: from a few minutes to several hours for most of the longer ciphers, and that there are some that take longer than the threshold we gave in the experiment. Specifically, there is substantial variability in the the running times seen.

Desiring to reduce the variance of the running time, we look at the second set of tests for possible causes. In the second test set, there is a general decrease in both the running time and the number of solutions expanded as the length of the ciphers increases. Running time correlates very well with A* queue size.

Asymptotically, the time required for each sweep of the Viterbi algorithm increases, but this is more than offset by the decrease in the number of required sweeps.

The results, however, do not show that running time monotonically decreases with length. In particular, the length 8500 cipher generates more solutions than the length 3500 or 6000 ones. Recall that the ciphers in this section are all prefixes of the same string. Because the algorithm fixes characters starting from the end of the cipher, these prefixes have very different character orderings, $c_1, \ldots, c_{n_C}$, and thus a very different order of partial solutions. The running time of our algorithm depends very crucially on these initial conditions.

Perhaps most interestingly, we note that the number of enqueued partial solutions is in every case identical or nearly identical to the number of partial solutions expanded. From a theoretical perspective, we must also remember the zero-probability solutions, which should in a sense count when judging the effectiveness of our A* heuristic. Naturally, these are ignored by our implementation because they are so badly scored that they could never be considered. Nevertheless, what these numbers show is that scores based on character-level trigrams, while theoretically admissible, are really not all that clever when it comes to navigating through the search space of all possible letter substitution ciphers, apart from their very keen ability at assigning zeros to a large number of partial solutions. A more complex heuristic that can additionally rank non-zero probability solutions with more prescience would likely make a very great difference to the running time of this method.

6 Conclusions

In the above paper, we have presented an algorithm for solving letter-substitution ciphers, with an eye towards discovering unknown encoding standards in electronic documents on the fly. In a test of our algorithm over ciphers drawn from Wikipedia, we found its accuracy to be 100% on the ciphers that it solved within a threshold of 12 hours, this being 80% of the total attempted. We found that the running time of our algorithm is highly variable depending on the order of characters attempted, and, due to the linear-time theoretical complexity of this method, that running times tend to decrease with larger ciphertexts due to our character-level language model's facility at eliminating highly improbable solutions. There is, however, a great deal of room for improvement in the trigram model's ability to rank partial solutions that are not eliminated outright.

Perhaps the most valuable insight gleaned from this study has been on the role of the language model. This algorithm's asymptotic runtime complexity is actually a function of entropic aspects of the character-level language model that it uses — more uniform models provide less prominent separations between candidate partial solutions, and this leads to badly ordered queues, in which extended partial solutions can never compete with partial solutions that have smaller domains, leading to a blind search. We believe that there is a great deal of promise in characterizing natural language processing algorithms in this way, due to the prevalence of Bayesian methods that use language models as priors.

Our approach makes no explicit attempt to account for noisy ciphers, in which characters are erroneously mapped, nor any attempt to account for more general substitution ciphers in which a single plaintext (resp. ciphertext) letter can map to multiple ciphertext (resp. plaintext) letters, nor for ciphers in which ciphertext units corresponds to larger units of plaintext such syllables or words. Extensions in these directions are all very worthwhile to explore.

Abstract

In this paper we propose a method for the automatic decipherment of lost languages. Given a non-parallel corpus in a known related language, our model produces both alphabetic mappings and translations of words into their corresponding cognates. We employ a non-parametric Bayesian framework to simultaneously capture both low-level character mappings and high-level morphemic correspondences. This formulation enables us to encode some of the linguistic intuitions that have guided human decipherers. When applied to the ancient Semitic language Ugaritic, the model correctly maps 29 of 30 letters to their Hebrew counterparts, and deduces the correct Hebrew cognate for 60% of the Ugaritic words which have cognates in Hebrew.

1 Introduction

Dozens of lost languages have been deciphered by humans in the last two centuries. In each case, the decipherment has been considered a major intellectual breakthrough, often the culmination of decades of scholarly efforts. Computers have played no role in the decipherment any of these languages. In fact, skeptics argue that computers do not possess the "logic and intuition" required to unravel the mysteries of ancient scripts.[1] In this paper, we demonstrate that at least some of this logic and intuition *can* be successfully modeled, allowing computational tools to be used in the decipherment process.

[1] *"Successful archaeological decipherment has turned out to require a synthesis of logic and intuition ... that computers do not (and presumably cannot) possess."* A. Robinson, "Lost Languages: The Enigma of the World's Undeciphered Scripts" (2002)

Our definition of the computational decipherment task closely follows the setup typically faced by human decipherers (Robinson, 2002). Our input consists of texts in a lost language and a corpus of non-parallel data in a known related language. The decipherment itself involves two related subtasks: (i) finding the mapping between alphabets of the known and lost languages, and (ii) translating words in the lost language into corresponding cognates of the known language.

While there is no single formula that human decipherers have employed, manual efforts have focused on several guiding principles. A common starting point is to compare letter and word frequencies between the lost and known languages. In the presence of cognates the correct mapping between the languages will reveal similarities in frequency, both at the character and lexical level. In addition, morphological analysis plays a crucial role here, as highly frequent morpheme correspondences can be particularly revealing. In fact, these three strands of analysis (character frequency, morphology, and lexical frequency) are intertwined throughout the human decipherment process. Partial knowledge of each drives discovery in the others.

We capture these intuitions in a generative Bayesian model. This model assumes that each word in the lost language is composed of morphemes which were generated with latent counterparts in the known language. We model bilingual morpheme pairs as arising through a series of Dirichlet processes. This allows us to assign probabilities based both on character-level correspondences (using a character-edit base distribution) as well as higher-level morpheme correspondences. In addition, our model carries out an implicit morphological analysis of the lost language, utilizing the known morphological structure of the related language. This model structure allows us to capture the interplay between the character-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1048–1057,
Uppsala, Sweden, 11-16 July 2010.

and morpheme-level correspondences that humans have used in the manual decipherment process.

In addition, we introduce a novel technique for imposing structural sparsity constraints on character-level mappings. We assume that an accurate alphabetic mapping between related languages will be sparse in the following way: each letter will map to a very limited subset of letters in the other language. We capture this intuition by adapting the so-called "spike and slab" prior to the Dirichlet-multinomial setting. For each pair of characters in the two languages, we posit an indicator variable which controls the prior likelihood of character substitutions. We define a joint prior over these indicator variables which encourages sparse settings.

We applied our model to a corpus of Ugaritic, an ancient Semitic language discovered in 1928. Ugaritic was manually deciphered in 1932, using knowledge of Hebrew, a related language. We compare our method against the only existing decipherment baseline, an HMM-based character substitution cipher (Knight and Yamada, 1999; Knight et al., 2006). The baseline correctly maps the majority of letters — 22 out of 30 — to their correct Hebrew counterparts, but only correctly translates 29% of all cognates. In comparison, our method yields correct mappings for 29 of 30 letters, and correctly translates 60.4% of all cognates.

2 Related Work

Our work on decipherment has connections to three lines of work in statistical NLP. First, our work relates to research on cognate identification (Lowe and Mazaudon, 1994; Guy, 1994; Kondrak, 2001; Bouchard et al., 2007; Kondrak, 2009). These methods typically rely on information that is unknown in a typical deciphering scenario (while being readily available for living languages). For instance, some methods employ a hand-coded similarity function (Kondrak, 2001), while others assume knowledge of the phonetic mapping or require parallel cognate pairs to learn a similarity function (Bouchard et al., 2007).

A second related line of work is lexicon induction from non-parallel corpora. While this research has similar goals, it typically builds on information or resources unavailable for ancient texts, such as comparable corpora, a seed lexicon, and cognate information (Fung and McKeown, 1997; Rapp, 1999; Koehn and Knight, 2002; Haghighi et al., 2008). Moreover, distributional methods that rely on co-occurrence analysis operate over large corpora, which are typically unavailable for a lost language.

Finally, Knight and Yamada (1999) and Knight et al. (2006) describe a computational HMM-based method for deciphering an unknown script that represents a known spoken language. This method "makes the text speak" by gleaning character-to-sound mappings from non-parallel character and sound sequences. It does not relate words in different languages, thus it cannot encode deciphering constraints similar to the ones considered in this paper. More importantly, this method had not been applied to archaeological data. While lost languages are gaining increasing interest in the NLP community (Knight and Sproat, 2009), there have been no successful attempts of their automatic decipherment.

3 Background on Ugaritic

Manual Decipherment of Ugaritic Ugaritic tablets were first found in Syria in 1929 (Smith, 1955; Watson and Wyatt, 1999). At the time, the cuneiform writing on the tablets was of an unknown type. Charles Virolleaud, who lead the initial decipherment effort, recognized that the script was likely alphabetic, since the inscribed words consisted of only thirty distinct symbols. The location of the tablets discovery further suggested that Ugaritic was likely to have been a Semitic language from the Western branch, with properties similar to Hebrew and Aramaic. This realization was crucial for deciphering the Ugaritic script. In fact, German cryptographer and Semitic scholar Hans Bauer decoded the first two Ugaritic letters—*mem* and *lambda*—by mapping them to Hebrew letters with similar occurrence patterns in prefixes and suffixes. Bootstrapping from this finding, Bauer found words in the tablets that were likely to serve as cognates to Hebrew words—e.g., the Ugaritic word for *king* matches its Hebrew equivalent. Through this process a few more letters were decoded, but the Ugaritic texts were still unreadable. What made the final decipherment possible was a sheer stroke of luck—Bauer guessed that a word inscribed on an ax discovered in the Ras Shamra excavations was the Ugaritic word for *ax*. Bauer's guess was correct, though he selected the wrong phonetic sequence. Edouard Dhorme, another cryptographer

and Semitic scholar, later corrected the reading, expanding a set of translated words. Discoveries of additional tablets allowed Bauer, Dhorme and Virolleaud to revise their hypothesis, successfully completing the decipherment.

Linguistic Features of Ugaritic Ugaritic shares many features with other ancient Semitic languages, following the same word order, gender, number, and case structure (Hetzron, 1997). It is a morphologically rich language, with triliteral roots and many prefixes and suffixes.

At the same time, it exhibits a number of features that distinguish it from Hebrew. Ugaritic has a bigger phonemic inventory than Hebrew, yielding a bigger alphabet – 30 letters vs. 22 in Hebrew. Another distinguishing feature of Ugaritic is that vowels are only written with glottal stops while in Hebrew many long vowels are written using homorganic consonants. Ugaritic also does not have articles, while Hebrew nouns and adjectives take definite articles which are realized as prefixes. These differences result in significant divergence between Hebrew and Ugaritic cognates, thereby complicating the decipherment process.

4 Problem Formulation

We are given a corpus in a lost language and a non-parallel corpus in a related language from the same language family. Our primary goal is to translate words in the unknown language by mapping them to cognates in the known language. As part of this process, we induce a lower-level mapping between the letters of the two alphabets, capturing the regular phonetic correspondences found in cognates.

We make several assumptions about the writing system of the lost language. First, we assume that the writing system is alphabetic in nature. In general, this assumption can be easily validated by counting the number of symbols found in the written record. Next, we assume that the corpus has been transcribed into electronic format, where the graphemes present in the physical text have been unambiguously identified. Finally, we assume that words are explicitly separated in the text, either by white space or a special symbol.

We also make a mild assumption about the morphology of the lost language. We posit that each word consists of a stem, prefix, and suffix, where the latter two may be omitted. This assumption captures a wide range of human languages and a variety of morphological systems. While the correct morphological analysis of words in the lost language must be learned, we assume that the inventory and frequencies of prefixes and suffixes in the known language are given.

In summary, the observed input to the model consists of two elements: (i) a list of unanalyzed word types derived from a corpus in the lost language, and (ii) a morphologically analyzed lexicon in a known related language derived from a separate corpus, in our case non-parallel.

5 Model

5.1 Intuitions

Our goal is to incorporate the logic and intuition used by human decipherers in an unsupervised statistical model. To make these intuitions concrete, consider the following toy example, consisting of a lost language much like English, but written using numerals:

- 15234 *(asked)*
- 1525 *(asks)*
- 4352 *(desk)*

Analyzing the undeciphered corpus, we might first notice a pair of endings, -34, and -5, which both occur after the initial sequence 152- (and may likewise occur at the end of a variety of words in the corpus). If we know this lost language to be closely related to English, we can surmise that these two endings correspond to the English verbal suffixes *-ed* and *-s*. Using this knowledge, we can hypothesize the following character correspondences: (3 = *e*), (4 = *d*), (5 = *s*). We now know that (4252 = *des*2) and we can use our knowledge of the English lexicon to hypothesize that this word is *desk*, thereby learning the correspondence (2 = *k*). Finally, we can use similar reasoning to reveal that the initial character sequence 152- corresponds to the English verb *ask*.

As this example illustrates, human decipherment efforts proceed by discovering both character-level and morpheme-level correspondences. This interplay implicitly relies on a morphological analysis of words in the lost language, while utilizing knowledge of the known language's lexicon and morphology.

One final intuition our model should capture is the sparsity of the alphabetic correspondence between related languages. We know from comparative linguistics that the correct mapping will pre-

serve regular phonetic relationships between the two languages (as exemplified by cognates). As a result, each character in one language will map to a small number of characters in the other language (typically one, but sometimes two or three). By incorporating this structural sparsity intuition, we can allow the model to focus on on a smaller set of linguistically valid hypotheses.

Below we give an overview of our model, which is designed to capture these linguistic intuitions.

5.2 Model Structure

Our model posits that every observed word in the lost language is composed of a sequence of morphemes (prefix, stem, suffix). Furthermore we posit that each morpheme was probabilistically generated jointly with a latent counterpart in the known language.

Our goal is to find those counterparts that lead to high frequency correspondences both at the character and morpheme level. The technical challenge is that each level of correspondence (character and morpheme) can completely describe the observed data. A probabilistic mechanism based simply on one leaves no room for the other to play a role. We resolve this tension by employing a non-parametric Bayesian model: the distributions over bilingual morpheme pairs assign probability based on recurrent patterns at the morpheme level. These distributions are themselves drawn from a prior probabilistic process which favors distributions with consistent character-level correspondences.

We now give a formal description of the model (see Figure 1 for a graphical overview). There are four basic layers in the generative process:

1. **Structural sparsity**: draw a set of indicator variables $\vec{\lambda}$ corresponding to character-edit operations.

2. **Character-edit distribution**: draw a *base distribution* G_0 parameterized by weights on character-edit operations.

3. **Morpheme-pair distributions**: draw a set of distributions on bilingual morpheme pairs $G_{stm}, G_{pre|stm}, G_{suf|stm}$.

4. **Word generation**: draw pairs of cognates in the lost and known language, as well as words in the lost language with no cognate counterpart.

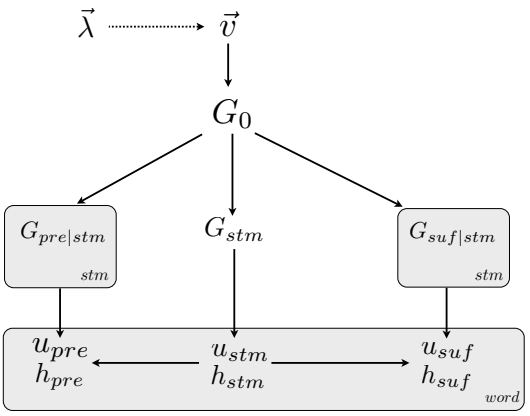

Figure 1: Plate diagram of the decipherment model. The structural sparsity indicator variables $\vec{\lambda}$ determine the values of the base distribution hyperparameters $\vec{v}$. The base distribution G_0 defines probabilities over string-pairs based solely on character-level edits. The morpheme-pair distributions $G_{stm}, G_{pre|stm}, G_{suf|stm}$ directly assign probabilities to highly frequent morpheme pairs.

We now go through each step in more detail.

Structural Sparsity The first step of the generative process provides a control on the sparsity of edit-operation probabilities, encoding the linguistic intuition that the correct character-level mappings should be sparse. The set of edit operations includes character substitutions, insertions, and deletions, as well as a special end symbol: $\{(u,h),(\epsilon,h),(u,\epsilon),END\}$ (where u and h range over characters in the lost and known languages, respectively). For each edit operation e we posit a corresponding indicator variable λ_e. The set of character substitutions with indicators set to one, $\{(u,h) : \lambda_{(u,h)} = 1\}$) conveys the set of phonetically valid correspondences. We define a joint prior over these variables to encourage sparse character mappings. This prior can be viewed as a distribution over *binary matrices* and is defined to encourage rows and columns to sum to low integer values (typically 1). More precisely, for each character u in the lost language, we count the number of mappings $c(u) = \sum_h \lambda_{(u,h)}$. We then define a set of features which count how many of these characters map to i other characters beyond some budget b_i: $f_i = \max(0, |\{u : c(u) = i\}| - b_i)$. Likewise, we define corresponding features f'_i and budgets b'_i for the characters h in the known lan-

guage. The prior over $\vec{\lambda}$ is then defined as

$$P(\vec{\lambda}) = \frac{\exp\left(\vec{f} \cdot \vec{w} + \vec{f}' \cdot \vec{w}\right)}{Z} \quad (1)$$

where the feature weight vector $\vec{w}$ is set to encourage sparse mappings, and Z is a corresponding normalizing constant, which we never need compute. We set $\vec{w}$ so that each character must map to at least one other character, and so that mappings to more than one other character are discouraged [2]

Character-edit Distribution The next step in the generative process is drawing a base distribution G_0 over character edit sequences (each of which yields a bilingual pair of morphemes). This distribution is parameterized by a set of weights $\vec{\phi}$ on edit operations, where the weights over substitutions, insertions, and deletions each individually sum to one. In addition, G_0 provides a fixed distribution q over the *number* of insertions and deletions occurring in any single edit sequence. Probabilities over edit sequences (and consequently on bilingual morpheme pairs) are then defined according to G_0 as:

$$P(\vec{e}) = \prod_i \phi_{e_i} \cdot q\left(\#_{ins}(\vec{e}), \#_{del}(\vec{e})\right)$$

We observe that the average Ugaritic word is over two letters longer than the average Hebrew word. Thus, occurrences of Hebrew character insertions are *a priori* likely, and Ugaritic character deletions are very unlikely. In our experiments, we set q to disallow Ugaritic deletions, and to allow one Hebrew insertion per morpheme (with probability 0.4).

The prior on the base distribution G_0 is a Dirichlet distribution with hyperparameters $\vec{v}$, i.e., $\vec{\phi} \sim Dirichlet(\vec{v})$. Each value v_e thus corresponds to a character edit operation e. Crucially, the value of each v_e depends deterministically on its corresponding indicator variable:

$$v_e = \begin{cases} 1 & \text{if } \lambda_e = 0, \\ K & \text{if } \lambda_e = 1. \end{cases}$$

where K is some constant value > 1.[3] The overall effect is that when $\lambda_e = 0$, the marginal prior density of the corresponding edit weight ϕ_e spikes at 0. When $\lambda_e = 1$, the corresponding marginal prior density remains relatively flat and unconstrained. See (Ishwaran and Rao, 2005) for a similar application of "spike-and-slab" priors in the regression scenario.

Morpheme-pair Distributions Next we draw a series of distributions which *directly* assign probability to morpheme pairs. The previously drawn base distribution G_0 along with a fixed concentration parameter α define a *Dirichlet process* (Antoniak, 1974): $DP(G_0, \alpha)$, which provides probabilities over morpheme-pair distributions. The resulting distributions are likely to be skewed in favor of a few frequently occurring morpheme-pairs, while remaining sensitive to the character-level probabilities of the base distribution.

Our model distinguishes between three types of morphemes: prefixes, stems, and suffixes. As a result, we model each morpheme type as arising from distinct Dirichlet processes, that share a single base distribution:

$$\begin{aligned} G_{stm} &\sim DP(G_0, \alpha_{stm}) \\ G_{pre|stm} &\sim DP(G_0, \alpha_{pre}) \\ G_{suf|stm} &\sim DP(G_0, \alpha_{suf}) \end{aligned}$$

We model prefix and suffix distributions as conditionally dependent on the part-of-speech of the stem morpheme-pair. This choice capture the linguistic fact that different parts-of-speech bear distinct affix frequencies. Thus, while we draw a single distribution G_{stm}, we maintain separate distributions $G_{pre|stm}$ and $G_{suf|stm}$ for each possible stem part-of-speech.

Word Generation Once the morpheme-pair distributions have been drawn, actual word pairs may now be generated. First the model draws a boolean variable c_i to determine whether word i in the lost language has a cognate in the known language, according to some prior $P(c_i)$. If $c_i = 1$, then a cognate word pair (u, h) is produced:

$$\begin{aligned} (u_{stm}, h_{stm}) &\sim G_{stm} \\ (u_{pre}, h_{pre}) &\sim G_{pre|stm} \\ (u_{suf}, h_{suf}) &\sim G_{suf|stm} \\ u &= u_{pre} u_{stm} u_{suf} \\ h &= h_{pre} h_{stm} h_{suf} \end{aligned}$$

Otherwise, a lone word u is generated, according a uniform character-level language model.

[2] We set $w_0 = -\infty, w_1 = 0, w_2 = -50, w_{>2} = -\infty$, with budgets $b'_2 = 7, b'_3 = 1$ (otherwise zero), reflecting the knowledge that there are eight more Ugaritic than Hebrew letters.

[3] Set to 50 in our experiments.

In summary, this model structure captures both character and lexical level correspondences, while utilizing morphological knowledge of the known language. An additional feature of this multi-layered model structure is that each distribution over morpheme pairs is derived from the single character-level base distribution G_0. As a result, any character-level mappings learned from one type of morphological correspondence will be propagated to all other morpheme distributions. Finally, the character-level mappings discovered by the model are encouraged to obey linguistically motivated structural sparsity constraints.

6 Inference

For each word u_i in our undeciphered language we predict a morphological segmentation $(u_{pre}u_{stm}u_{suf})_i$ and corresponding cognate in the known language $(h_{pre}h_{stm}h_{suf})_i$. Ideally we would like to predict the analysis with highest marginal probability under our model given the observed undeciphered corpus and related language lexicon. In order to do so, we need to integrate out all the other latent variables in our model. As these integrals are intractable to compute exactly, we resort to the standard Monte Carlo approximation. We collect samples of the variables over which we wish to marginalize but for which we cannot compute closed-form integrals. We then approximate the marginal probabilities for undeciphered word u_i by summing over all the samples, and predicting the analysis with highest probability.

In our sampling algorithm, we avoid sampling the base distribution G_0 and the derived morpheme-pair distributions (G_{stm} etc.), instead using analytical closed forms. We explicitly sample the sparsity indicator variables $\vec{\lambda}$, the cognate indicator variables c_i, and latent word analyses (segmentations and Hebrew counterparts). To do so tractably, we use Gibbs sampling to draw each latent variable conditioned on our current sample of the others. Although the samples are no longer independent, they form a Markov chain whose stationary distribution is the true joint distribution defined by the model (Geman and Geman, 1984).

6.1 Sampling Word Analyses

For each undeciphered word, we need to sample a morphological segmentation $(u_{pre}, u_{stm}, u_{suf})_i$ along with latent morphemes in the known language $(h_{pre}, h_{stm}, h_{suf})_i$. More precisely, we need to sample three character-edit sequences $\vec{e}_{pre}, \vec{e}_{stm}, \vec{e}_{suf}$ which together yield the observed word u_i.

We break this into two sampling steps. First we sample the morphological segmentation of u_i, along with the part-of-speech pos of the latent stem cognate. To do so, we enumerate each possible segmentation and part-of-speech and calculate its joint conditional probability (for notational clarity, we leave implicit the conditioning on the other samples in the corpus):

$$P(u_{pre}, u_{stm}, u_{suf}, pos) = \sum_{\vec{e}_{stm}} P(\vec{e}_{stm}) \sum_{\vec{e}_{pre}} P(\vec{e}_{pre}|pos) \sum_{\vec{e}_{suf}} P(\vec{e}_{suf}|pos) \quad (2)$$

where the summations over character-edit sequences are restricted to those which yield the segmentation $(u_{pre}, u_{stm}, u_{suf})$ and a latent cognate with part-of-speech pos.

For a particular stem edit-sequence $\vec{e}_{stm}$, we compute its conditional probability in closed form according to a Chinese Restaurant Process (Antoniak, 1974). To do so, we use counts from the other sampled word analyses: $count_{stm}(\vec{e}_{stm})$ gives the number of times that the entire edit-sequence $\vec{e}_{stm}$ has been observed:

$$P(\vec{e}_{stm}) \propto \frac{count_{stm}(\vec{e}_{stm}) + \alpha \prod_i p(e_i)}{n + \alpha}$$

where n is the number of other word analyses sampled, and α is a fixed concentration parameter. The product $\prod_i p(e_i)$ gives the probability of $\vec{e}_{stm}$ according to the *base distribution* G_0. Since the parameters of G_0 are left unsampled, we use the marginalized form:

$$p(e) = \frac{v_e + count(e)}{\sum_{e'} v_{e'} + k} \quad (3)$$

where $count(e)$ is the number of times that character-edit e appears in distinct edit-sequences (across prefixes, stems, and suffixes), and k is the sum of these counts across all character-edits. Recall that v_e is a hyperparameter for the Dirichlet prior on G_0 and depends on the value of the corresponding indicator variable λ_e.

Once the segmentation $(u_{pre}, u_{stm}, u_{suf})$ and part-of-speech pos have been sampled, we proceed to sample the actual edit-sequences (and thus

latent morphemes counterparts). Now, instead of summing over the values in Equation 2, we instead sample from them.

6.2 Sampling Sparsity Indicators

Recall that each sparsity indicator λ_e determines the value of the corresponding hyperparameter v_e of the Dirichlet prior for the character-edit base distribution G_0. In addition, we have an unnormalized joint prior $P(\vec{\lambda}) = \frac{g(\vec{\lambda})}{Z}$ which encourages a sparse setting of these variables. To sample a particular λ_e, we consider the set $\vec{\lambda}$ in which $\lambda_e = 0$ and $\vec{\lambda}'$ in which $\lambda_e = 1$. We then compute:

$$P(\vec{\lambda}) \propto g(\vec{\lambda}) \cdot \frac{v_e^{[count(e)]}}{\sum_{e'} v_{e'}^{[k]}}$$

where k is the sum of counts for all edit operations, and the notation $a^{[b]}$ indicates the ascending factorial. Likewise, we can compute a probability for $\vec{\lambda}'$ with corresponding values v'_e.

6.3 Sampling Cognate Indicators

Finally, for each word u_i, we sample a corresponding indicator variable c_i. To do so, we calculate Equation 2 for all possible segmentations and parts-of-speech and sum the resulting values to obtain the conditional likelihood $P(u_i|c_i = 1)$. We also calculate $P(u_i|c_i = 0)$ using a uniform unigram character-level language model (and thus depends only on the number of characters in u_i). We then sample from among the two values:

$$P(u_i|c_i = 1) \cdot P(c_i = 1)$$
$$P(u_i|c_i = 0) \cdot P(c_i = 0)$$

6.4 High-level Resampling

Besides the individual sampling steps detailed above, we also consider several larger sampling moves in order to speed convergence. For example, for each type of edit-sequence $\vec{e}$ which has been sampled (and may now occur many times throughout the data), we consider a single joint move to another edit-sequence $\vec{e'}$ (both of which yield the same lost language morpheme u). The details are much the same as above, and as before the set of possible edit-sequences is limited by the string u and the known language lexicon.

We also resample groups of the sparsity indicator variables $\vec{\lambda}$ in tandem, to allow a more rapid exploration of the probability space. For each character u, we block sample the entire set $\{\lambda_{(u,h)}\}_h$, and likewise for each character h.

6.5 Implementation Details

Many of the steps detailed above involve the consideration of all possible edit-sequences consistent with (i) a particular undeciphered word u_i and (ii) the entire lexicon of words in the known language (or some subset of words with a particular part-of-speech). In particular, we need to both sample from and sum over this space of possibilities repeatedly. Doing so by simple enumeration would needlessly repeat many sub-computations. Instead we use finite-state acceptors to compactly represent both the entire Hebrew lexicon as well as potential Hebrew word forms for each Ugaritic word. By intersecting two such FSAs and minimizing the result we can efficiently represent all potential Hebrew words for a particular Ugaritic word. We weight the edges in the FSA according to the base distribution probabilities (in Equation 3 above). Although these intersected acceptors have to be constantly reweighted to reflect changing probabilities, their topologies need only be computed once. One weighted correctly, marginals and samples can be computed using dynamic programming.

Even with a large number of sampling rounds, it is difficult to fully explore the latent variable space for complex unsupervised models. Thus a clever initialization is usually required to start the sampler in a high probability region. We initialize our model with the results of the HMM-based baseline (see section 8), and rule out character substitutions with probability < 0.05 according to the baseline.

7 Experiments

7.1 Corpus and Annotations

We apply our model to the ancient Ugaritic language (see Section 3 for background). Our undeciphered corpus consists of an electronic transcription of the Ugaritic tablets (Cunchillos et al., 2002). This corpus contains 7,386 unique word types. As our known language corpus, we use the Hebrew Bible, which is both geographically and temporally close to Ugaritic. To extract a Hebrew morphological lexicon we assume the existence of manual morphological and part-of-speech annotations (Groves and Lowery, 2006). We divide Hebrew stems into four main part-of-speech categories each with a distinct affix profile: Noun, Verb, Pronoun, and Particle. For each part-of-speech category, we determine the set of allowable affixes using the annotated Bible corpus.

	Words		Morphemes	
	type	token	type	token
Baseline	28.82%	46.00%	N/A	N/A
Our Model	60.42%	66.71%	75.07%	81.25%
No Sparsity	46.08%	54.01%	69.48%	76.10%

Table 1: Accuracy of cognate translations, measured with respect to complete word-forms and morphemes, for the HMM-based substitution cipher baseline, our complete model, and our model without the structural sparsity priors. Note that the baseline does not provide per-morpheme results, as it does not predict morpheme boundaries.

To evaluate the output of our model, we annotated the words in the Ugaritic lexicon with the corresponding Hebrew cognates found in the standard reference dictionary (del Olo Lete and Sanmartín, 2004). In addition, manual morphological segmentation was carried out with the guidance of a standard Ugaritic grammar (Schniedewind and Hunt, 2007). Although Ugaritic is an inflectional rather than agglutinative language, in its written form (which lacks vowels) words can easily be segmented (e.g. *wyplṭn* becomes *wy-plṭ-n*).

Overall, we identified Hebrew cognates for 2,155 word forms, covering almost 1/3 of the Ugaritic vocabulary.[4]

8 Evaluation Tasks and Results

We evaluate our model on four separate decipherment tasks: (i) Learning alphabetic mappings, (ii) translating cognates, (iii) identifying cognates, and (iv) morphological segmentation.

As a baseline for the first three of these tasks (learning alphabetic mappings and translating and identifying cognates), we adapt the HMM-based method of Knight et al. (2006) for learning letter substitution ciphers. In its original setting, this model was used to map written texts to spoken language, under the assumption that each character was emitted from a hidden phonemic state. In our adaptation, we assume instead that each Ugaritic character was generated by a hidden Hebrew letter. Hebrew character trigram transition probabilities are estimated using the Hebrew Bible, and Hebrew to Ugaritic character emission probabilities are learned using EM. Finally, the highest probability sequence of latent Hebrew letters is predicted for each Ugaritic word-form, using Viterbi decoding.

Alphabetic Mapping The first essential step towards successful decipherment is recovering the mapping between the symbols of the lost language and the alphabet of a known language. As a gold standard for this comparison, we use the well-established relationship between the Ugaritic and Hebrew alphabets (Hetzron, 1997). This mapping is not one-to-one but is generally quite sparse. Of the 30 Ugaritic symbols, 28 map predominantly to a single Hebrew letter, and the remaining two map to two different letters. As the Hebrew alphabet contains only 22 letters, six map to two distinct Ugaritic letters and two map to three distinct Ugaritic letters.

We recover our model's predicted alphabetic mappings by simply examining the sampled values of the binary indicator variables $\lambda_{u,h}$ for each Ugaritic-Hebrew letter pair (u, h). Due to our structural sparsity prior $P(\vec{\lambda})$, the predicted mappings are sparse: each Ugaritic letter maps to only a single Hebrew letter, and most Hebrew letters map to only a single Ugaritic letter. To recover alphabetic mappings from the HMM substitution cipher baseline, we predict the Hebrew letter h which maximizes the model's probability $P(h|u)$, for each Ugaritic letter u.

To evaluate these mappings, we simply count the number of Ugaritic letters that are correctly mapped to one of their Hebrew reflexes. By this measure, the baseline recovers correct mappings for 22 out of 30 Ugaritic characters (73.3%). Our model recovers correct mappings for all but one (very low frequency) Ugaritic characters, yielding 96.67% accuracy.

Cognate Decipherment We compare the decipherment accuracy for Ugaritic words that have corresponding Hebrew cognates. We evaluate our model's predictions on each distinct Ugaritic word-form at both the type and token level. As Table 1 shows, our method correctly translates over 60% of all distinct Ugaritic word-forms with Hebrew cognates and over 71% of the individual morphemes that compose them, outperforming the baseline by significant margins. Accuracy improves when the frequency of the word-forms is taken into account (token-level evaluation), indicating that the model is able to decipher frequent words more accurately than infre-

[4] We are confident that a large majority of Ugaritic words with known Hebrew cognates were thus identified. The remaining Ugaritic words include many personal and geographic names, words with cognates in other Semitic languages, and words whose etymology is uncertain.

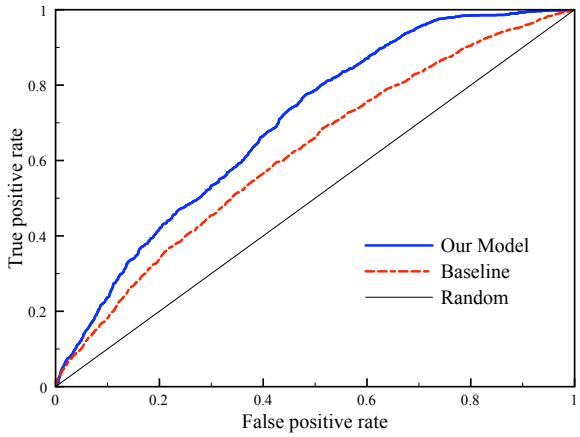

Figure 2: ROC curve for cognate identification.

quent words. We also measure the average Levenshtein distance between predicted and actual cognate word-forms. On average, our model's predictions lie 0.52 edit operations from the true cognate, whereas the baseline's predictions average a distance of 1.26 edit operations.

Finally, we evaluated the performance of our model when the structural sparsity constraints are not used. As Table 1 shows, performance degrades significantly in the absence of these priors, indicating the importance of modeling the sparsity of character mappings.

Cognate identification We evaluate our model's ability to identify cognates using the sampled indicator variables c_i. As before, we compare our performance against the HMM substitution cipher baseline. To produce baseline cognate identification predictions, we calculate the probability of each latent Hebrew letter sequence predicted by the HMM, and compare it to a uniform character-level Ugaritic language model (as done by our model, to avoid automatically assigning higher cognate probability to shorter Ugaritic words). For both our model and the baseline, we can vary the threshold for cognate identification by raising or lowering the cognate prior $P(c_i)$. As the prior is set higher, we detect more true cognates, but the false positive rate increases as well.

Figure 2 shows the ROC curve obtained by varying this prior both for our model and the baseline. At all operating points, our model outperforms the baseline, and both models always predict better than chance. In practice for our model, we use a high cognate prior, thus only ruling out those Ugaritic word-forms which are very unlikely to have Hebrew cognates.

	precision	recall	f-measure
Morfessor	88.87%	67.48%	76.71%
Our Model	86.62%	90.53%	88.53%

Table 2: Morphological segmentation accuracy for a standard unsupervised baseline and our model.

Morphological segmentation Finally, we evaluate the accuracy of our model's morphological segmentation for Ugaritic words. As a baseline for this comparison, we use Morfessor Categories-MAP (Creutz and Lagus, 2007). As Table 2 shows, our model provides a significant boost in performance, especially for recall. This result is consistent with previous work showing that morphological annotations can be projected to new languages lacking annotation (Yarowsky et al., 2000; Snyder and Barzilay, 2008), but generalizes those results to the case where parallel data is unavailable.

9 Conclusion and Future Work

In this paper we proposed a method for the automatic decipherment of lost languages. The key strength of our model lies in its ability to incorporate a range of linguistic intuitions in a statistical framework.

We hope to address several issues in future work. Our model fails to take into account the known *frequency* of Hebrew words and morphemes. In fact, the most common error is incorrectly translating the masculine plural suffix (*-m*) as the third person plural possessive suffix (*-m*) rather than the correct and much more common plural suffix (*-ym*). Also, even with the correct alphabetic mapping, many words can only be deciphered by examining their literary context. Our model currently operates purely on the vocabulary level and thus fails to take this contextual information into account. Finally, we intend to explore our model's predictive power when the family of the lost language is unknown.[5]

Abstract

Weighted tree transducers have been proposed as useful formal models for representing syntactic natural language processing applications, but there has been little description of inference algorithms for these automata beyond formal foundations. We give a detailed description of algorithms for application of cascades of weighted tree transducers to weighted tree acceptors, connecting formal theory with actual practice. Additionally, we present novel on-the-fly variants of these algorithms, and compare their performance on a syntax machine translation cascade based on (Yamada and Knight, 2001).

1 Motivation

Weighted finite-state transducers have found recent favor as models of natural language (Mohri, 1997). In order to make actual use of systems built with these formalisms we must first calculate the set of possible weighted outputs allowed by the transducer given some input, which we call *forward application*, or the set of possible weighted inputs given some output, which we call *backward application*. After application we can do some inference on this result, such as determining its k highest weighted elements.

We may also want to divide up our problems into manageable chunks, each represented by a transducer. As noted by Woods (1980), it is easier for designers to write several small transducers where each performs a simple transformation, rather than painstakingly construct a single complicated device. We would like to know, then, the result of transformation of input or output by a *cascade* of transducers, one operating after the other. As we will see, there are various strategies for approaching this problem. We will consider *offline composition*, *bucket brigade application*, and *on-the-fly application*.

Application of cascades of weighted string transducers (WSTs) has been well-studied (Mohri, 1997). Less well-studied but of more recent interest is application of cascades of weighted *tree* transducers (WTTs). We tackle application of WTT cascades in this work, presenting:

- explicit algorithms for application of WTT cascades
- novel algorithms for on-the-fly application of WTT cascades, and
- experiments comparing the performance of these algorithms.

2 Strategies for the string case

Before we discuss application of WTTs, it is helpful to recall the solution to this problem in the WST domain. We recall previous formal presentations of WSTs (Mohri, 1997) and note informally that they may be represented as directed graphs with designated start and end states and edges labeled with input symbols, output symbols, and weights.[1] Fortunately, the solution for WSTs is practically trivial—we achieve application through a series of *embedding*, *composition*, and *projection* operations. Embedding is simply the act of representing a string or regular string language as an identity WST. Composition of WSTs, that is, generating a single WST that captures the transformations of two input WSTs used in sequence, is not at all trivial, but has been well covered in, e.g., (Mohri, 2009), where directly implementable algorithms can be found. Finally, projection is another trivial operation—the domain or range language can be obtained from a WST by ignoring the output or input symbols, respectively, on its arcs, and summing weights on otherwise identical arcs. By embedding an input, composing the result with the given WST, and projecting the result, forward application is accomplished.[2] We are then left with a weighted string acceptor (WSA), essentially a weighted, labeled graph, which can be traversed

[1] We assume throughout this paper that weights are in $\mathbb{R}_+ \cup \{+\infty\}$, that the weight of a path is calculated as the product of the weights of its edges, and that the weight of a (not necessarily finite) set T of paths is calculated as the sum of the weights of the paths of T.

[2] For backward applications, the roles of input and output are simply exchanged.

by well-known algorithms to efficiently find the k-best paths.

Because WSTs can be freely composed, extending application to operate on a *cascade* of WSTs is fairly trivial. The only question is one of composition order: whether to initially compose the cascade into a single transducer (an approach we call *offline composition*) or to compose the initial embedding with the first transducer, trim useless states, compose the result with the second, and so on (an approach we call *bucket brigade*). The appropriate strategy generally depends on the structure of the individual transducers.

A third approach builds the result incrementally, as dictated by some algorithm that requests information about it. Such an approach, which we call *on-the-fly*, was described in (Pereira and Riley, 1997; Mohri, 2009; Mohri et al., 2000). If we can efficiently calculate the outgoing edges of a state of the result WSA on demand, without calculating all edges in the entire machine, we can maintain a *stand-in* for the result structure, a machine consisting at first of only the start state of the true result. As a calling algorithm (e.g., an implementation of Dijkstra's algorithm) requests information about the result graph, such as the set of outgoing edges from a state, we replace the current stand-in with a richer version by adding the result of the request. The on-the-fly approach has a distinct advantage over the other two methods in that the entire result graph need not be built. A graphical representation of all three methods is presented in Figure 1.

3 Application of tree transducers

Now let us revisit these strategies in the setting of trees and tree transducers. Imagine we have a tree or set of trees as input that can be represented as a weighted regular tree grammar[3] (WRTG) and a WTT that can transform that input with some weight. We would like to know the k-best trees the WTT can produce as output for that input, along with their weights. We already know of several methods for acquiring k-best trees from a WRTG (Huang and Chiang, 2005; Pauls and Klein, 2009), so we then must ask if, analogously to the string case, WTTs preserve recognizability[4] and we can form an application WRTG. Before we begin, however, we must define WTTs and WRTGs.

3.1 Preliminaries[5]

A *ranked alphabet* is a finite set Σ such that every member $\sigma \in \Sigma$ has a rank $rk(\sigma) \in \mathbb{N}$. We call $\Sigma^{(k)} \subseteq \Sigma, k \in \mathbb{N}$ the set of those $\sigma \in \Sigma$ such that $rk(\sigma) = k$. The set of *variables* is denoted $X = \{x_1, x_2, \ldots\}$ and is assumed to be disjoint from any ranked alphabet used in this paper. We use $\perp$ to denote a symbol of rank 0 that is not in any ranked alphabet used in this paper. A *tree* $t \in T_\Sigma$ is denoted $\sigma(t_1, \ldots, t_k)$ where $k \geq 0$, $\sigma \in \Sigma^{(k)}$, and $t_1, \ldots, t_k \in T_\Sigma$. For $\sigma \in \Sigma^{(0)}$ we

[3] This generates the same class of weighted tree languages as weighted tree automata, the direct analogue of WSAs, and is more useful for our purposes.

[4] A weighted tree language is recognizable iff it can be represented by a wrtg.

[5] The following formal definitions and notations are needed for understanding and reimplementation of the presented algorithms, but can be safely skipped on first reading and consulted when encountering an unfamiliar term.

write $\sigma \in T_\Sigma$ as shorthand for $\sigma()$. For every set S disjoint from Σ, let $T_\Sigma(S) = T_{\Sigma \cup S}$, where, for all $s \in S$, $rk(s) = 0$.

We define the *positions* of a tree $t = \sigma(t_1, \ldots, t_k)$, for $k \geq 0$, $\sigma \in \Sigma^{(k)}$, $t_1, \ldots, t_k \in T_\Sigma$, as a set $pos(t) \subset \mathbb{N}^*$ such that $pos(t) = \{\varepsilon\} \cup \{iv \mid 1 \leq i \leq k, v \in pos(t_i)\}$. The set of leaf positions $lv(t) \subseteq pos(t)$ are those positions $v \in pos(t)$ such that for no $i \in \mathbb{N}$, $vi \in pos(t)$. We presume standard lexicographic orderings $<$ and $\leq$ on pos.

Let $t, s \in T_\Sigma$ and $v \in pos(t)$. The *label* of t at position v, denoted by $t(v)$, the *subtree* of t at v, denoted by $t|_v$, and the *replacement* at v by s, denoted by $t[s]_v$, are defined as follows:

1. For every $\sigma \in \Sigma^{(0)}$, $\sigma(\varepsilon) = \sigma$, $\sigma|_\varepsilon = \sigma$, and $\sigma[s]_\varepsilon = s$.
2. For every $t = \sigma(t_1, \ldots, t_k)$ such that $k = rk(\sigma)$ and $k \geq 1$, $t(\varepsilon) = \sigma$, $t|_\varepsilon = t$, and $t[s]_\varepsilon = s$. For every $1 \leq i \leq k$ and $v \in pos(t_i)$, $t(iv) = t_i(v)$, $t|_{iv} = t_i|_v$, and $t[s]_{iv} = \sigma(t_1, \ldots, t_{i-1}, t_i[s]_v, t_{i+1}, \ldots, t_k)$.

The *size* of a tree t, $size(t)$ is $|pos(t)|$, the cardinality of its position set. The *yield set* of a tree is the set of labels of its leaves: for a tree t, $yd(t) = \{t(v) \mid v \in lv(t)\}$.

Let A and B be sets. Let $\varphi : A \to T_\Sigma(B)$ be a mapping. We extend φ to the mapping $\overline{\varphi} : T_\Sigma(A) \to T_\Sigma(B)$ such that for $a \in A$, $\overline{\varphi}(a) = \varphi(a)$ and for $k \geq 0$, $\sigma \in \Sigma^{(k)}$, and $t_1, \ldots, t_k \in T_\Sigma(A)$, $\overline{\varphi}(\sigma(t_1, \ldots, t_k)) = \sigma(\overline{\varphi}(t_1), \ldots, \overline{\varphi}(t_k))$. We indicate such extensions by describing φ as a *substitution mapping* and then using $\overline{\varphi}$ without further comment.

We use $\mathbb{R}_+$ to denote the set $\{w \in \mathbb{R} \mid w \geq 0\}$ and $\mathbb{R}_+^\infty$ to denote $\mathbb{R}_+ \cup \{+\infty\}$.

Definition 3.1 (cf. (Alexandrakis and Bozapalidis, 1987)) A weighted regular tree grammar (WRTG) is a 4-tuple $G = (N, \Sigma, P, n_0)$ where:

1. N is a finite set of *nonterminals*, with $n_0 \in N$ the start nonterminal.
2. Σ is a ranked alphabet of input symbols, where $\Sigma \cap N = \emptyset$.
3. P is a tuple (P', π), where P' is a finite set of *productions*, each production p of the form $n \to u$, $n \in N$, $u \in T_\Sigma(N)$, and $\pi : P' \to \mathbb{R}_+$ is a weight function of the productions. We will refer to P as a finite set of weighted productions, each production p of the form $n \xrightarrow{\pi(p)} u$.

A production p is a *chain production* if it is of the form $n_i \xrightarrow{w} n_j$, where $n_i, n_j \in N$.[6]

[6] In (Alexandrakis and Bozapalidis, 1987), chain productions are forbidden in order to avoid infinite summations. We explicitly allow such summations.

A WRTG G is in *normal form* if each production is either a chain production or is of the form $n \xrightarrow{w} \sigma(n_1, \ldots, n_k)$ where $\sigma \in \Sigma^{(k)}$ and $n_1, \ldots, n_k \in N$.

For WRTG $G = (N, \Sigma, P, n_0)$, $s, t, u \in T_\Sigma(N)$, $n \in N$, and $p \in P$ of the form $n \xrightarrow{w} u$, we obtain a *derivation step* from s to t by replacing some leaf nonterminal in s labeled n with u. Formally, $s \Rightarrow_G^p t$ if there exists some $v \in lv(s)$ such that $s(v) = n$ and $s[u]_v = t$. We say this derivation step is *leftmost* if, for all $v' \in lv(s)$ where $v' < v$, $s(v') \in \Sigma$. We henceforth assume all derivation steps are leftmost. If, for some $m \in \mathbb{N}$, $p_i \in P$, and $t_i \in T_\Sigma(N)$ for all $1 \leq i \leq m$, $n_0 \Rightarrow^{p_1} t_1 \ldots \Rightarrow^{p_m} t_m$, we say the sequence $d = (p_1, \ldots, p_m)$ is a *derivation* of t_m in G and that $n_0 \Rightarrow^* t_m$; the weight of d is $wt(d) = \pi(p_1) \cdot \ldots \cdot \pi(p_m)$. The weighted tree language recognized by G is the mapping $L_G : T_\Sigma \to \mathbb{R}_+^\infty$ such that for every $t \in T_\Sigma$, $L_G(t)$ is the sum of the weights of all (possibly infinitely many) derivations of t in G. A weighted tree language $f : T_\Sigma \to \mathbb{R}_+^\infty$ is *recognizable* if there is a WRTG G such that $f = L_G$.

We define a partial ordering $\preceq$ on WRTGs such that for WRTGs $G_1 = (N_1, \Sigma, P_1, n_0)$ and $G_2 = (N_2, \Sigma, P_2, n_0)$, we say $G_1 \preceq G_2$ iff $N_1 \subseteq N_2$ and $P_1 \subseteq P_2$, where the weights are preserved.

Definition 3.2 (cf. Def. 1 of (Maletti, 2008)) A weighted extended top-down tree transducer (WXTT) is a 5-tuple $M = (Q, \Sigma, \Delta, R, q_0)$ where:

1. Q is a finite set of states.
2. Σ and Δ are the ranked alphabets of input and output symbols, respectively, where $(\Sigma \cup \Delta) \cap Q = \emptyset$.
3. R is a tuple (R', π), where R' is a finite set of *rules*, each rule r of the form $q.y \to u$ for $q \in Q$, $y \in T_\Sigma(X)$, and $u \in T_\Delta(Q \times X)$. We further require that no variable $x \in X$ appears more than once in y, and that each variable appearing in u is also in y. Moreover, $\pi : R' \to \mathbb{R}_+^\infty$ is a weight function of the rules. As for WRTGs, we refer to R as a finite set of weighted rules, each rule r of the form $q.y \xrightarrow{\pi(r)} u$.

A WXTT is *linear* (respectively, *nondeleting*) if, for each rule r of the form $q.y \xrightarrow{w} u$, each $x \in yd(y) \cap X$ appears at most once (respectively, at least once) in u. We denote the class of all WXTTs as wxT and add the letters L and N to signify the subclasses of linear and nondeleting WTT, respectively. Additionally, if y is of the form $\sigma(x_1, \ldots, x_k)$, we remove the letter "x" to signify

the transducer is not extended (i.e., it is a "traditional" WTT (Fülöp and Vogler, 2009)).

For WXTT $M = (Q, \Sigma, \Delta, R, q_0)$, $s, t \in T_\Delta(Q \times T_\Sigma)$, and $r \in R$ of the form $q.y \xrightarrow{w} u$, we obtain a *derivation step* from s to t by replacing some leaf of s labeled with q and a tree matching y by a transformation of u, where each instance of a variable has been replaced by a corresponding subtree of the y-matching tree. Formally, $s \Rightarrow_M^r t$ if there is a position $v \in pos(s)$, a substitution mapping $\varphi : X \to T_\Sigma$, and a rule $q.y \xrightarrow{w} u \in R$ such that $s(v) = (q, \overline{\varphi}(y))$ and $t = s[\overline{\varphi'}(u)]_v$, where φ' is a substitution mapping $Q \times X \to T_\Delta(Q \times T_\Sigma)$ defined such that $\varphi'(q', x) = (q', \varphi(x))$ for all $q' \in Q$ and $x \in X$. We say this derivation step is *leftmost* if, for all $v' \in lv(s)$ where $v' < v$, $s(v') \in \Delta$. We henceforth assume all derivation steps are leftmost. If, for some $s \in T_\Sigma$, $m \in \mathbb{N}$, $r_i \in R$, and $t_i \in T_\Delta(Q \times T_\Sigma)$ for all $1 \leq i \leq m$, $(q_0, s) \Rightarrow^{r_1} t_1 \ldots \Rightarrow^{r_m} t_m$, we say the sequence $d = (r_1, \ldots, r_m)$ is a *derivation* of (s, t_m) in M; the weight of d is $wt(d) = \pi(r_1) \cdot \ldots \cdot \pi(r_m)$. The *weighted tree transformation* recognized by M is the mapping $\tau_M : T_\Sigma \times T_\Delta \to \mathbb{R}_+^\infty$, such that for every $s \in T_\Sigma$ and $t \in T_\Delta$, $\tau_M(s, t)$ is the sum of the weights of all (possibly infinitely many) derivations of (s, t) in M. The *composition* of two weighted tree transformations $\tau : T_\Sigma \times T_\Delta \to \mathbb{R}_+^\infty$ and $\mu : T_\Delta \times T_\Gamma \to \mathbb{R}_+^\infty$ is the weighted tree transformation $(\tau; \mu) : T_\Sigma \times T_\Gamma \to \mathbb{R}_+^\infty$ where for every $s \in T_\Sigma$ and $u \in T_\Gamma$, $(\tau; \mu)(s, u) = \sum_{t \in T_\Delta} \tau(s, t) \cdot \mu(t, u)$.

3.2 Applicable classes

We now consider transducer classes where recognizability is preserved under application. Table 1 presents known results for the top-down tree transducer classes described in Section 3.1. Unlike the string case, preservation of recognizability is not universal or symmetric. This is important for us, because we can only construct an *application* WRTG, i.e., a WRTG representing the result of application, if we can ensure that the language generated by application is in fact recognizable. Of the types under consideration, only wxLNT and wLNT preserve forward recognizability. The two classes marked as open questions and the other classes, which are superclasses of wNT, do not or are presumed not to. All subclasses of wxLT preserve backward recognizability.[7] We do not consider cases where recognizability is not preserved in the remainder of this paper. If a transducer M of a class that preserves forward recognizability is applied to a WRTG G, we can call the forward application WRTG $M(G)^\triangleright$ and if M preserves backward recognizability, we can call the backward application WRTG $M(G)^\triangleleft$.

Now that we have explained the application problem in the context of weighted tree transducers and determined the classes for which application is possible, let us consider how to build forward and backward application WRTGs. Our basic approach mimics that taken for WSTs by using an embed-compose-project strategy. As in string world, if we can embed the input in a transducer, compose with the given transducer, and project the result, we can obtain the application WRTG. Embedding a WRTG in a wLNT is a trivial operation—if the WRTG is in normal form and chain production-free,[8] for every production of the form $n \xrightarrow{w} \sigma(n_1, \ldots, n_k)$, create a rule of the form $n.\sigma(x_1, \ldots, x_k) \xrightarrow{w} \sigma(n_1.x_1, \ldots, n_k.x_k)$. Range projection of a wxLNT is also trivial—for every $q \in Q$ and $u \in T_\Delta(Q \times X)$ create a production of the form $q \xrightarrow{w} u'$ where u' is formed from u by replacing all leaves of the form $q.x$ with the leaf q, i.e., removing references to variables, and w is the sum of the weights of all rules of the form $q.y \to u$ in R.[9] Domain projection for wxLT is best explained by way of example. The left side of a rule is preserved, with variables leaves replaced by their associated states from the right side. So, the rule $q_1.\sigma(\gamma(x_1), x_2) \xrightarrow{w} \delta(q_2.x_2, \beta(\alpha, q_3.x_1))$ would yield the production $q_1 \xrightarrow{w} \sigma(\gamma(q_3), q_2)$ in the domain projection. However, a deleting rule such as $q_1.\sigma(x_1, x_2) \xrightarrow{w} \gamma(q_2.x_2)$ necessitates the introduction of a new nonterminal $\perp$ that can generate all of T_Σ with weight 1.

The only missing piece in our embed-compose-project strategy is composition. Algorithm 1, which is based on the declarative construction of Maletti (2006), generates the syntactic composition of a wxLT and a wLNT, a generalization of the basic composition construction of Baker (1979). It calls Algorithm 2, which determines the sequences of rules in the second transducer that match the right side of a single rule in the first transducer. Since the embedded WRTG is of type wLNT, it may be either the first or second argument provided to Algorithm 1, depending on whether the application is forward or backward. We can thus use the embed-compose-project strategy for forward application of wLNT and backward application of wxLT and wxLNT. Note that we *cannot* use this strategy for forward applica-

[7] Note that the introduction of weights limits recognizability preservation considerably. For example, (unweighted) xT preserves backward recognizability.

[8] Without loss of generality we assume this is so, since standard algorithms exist to remove chain productions (Kuich, 1998; Ésik and Kuich, 2003; Mohri, 2009) and convert into normal form (Alexandrakis and Bozapalidis, 1987).

[9] Finitely many such productions may be formed.

tion of wxLNT, even though that class preserves recognizability.

4 Application of tree transducer cascades

What about the case of an input WRTG and a cascade of tree transducers? We will revisit the three strategies for accomplishing application discussed above for the string case.

In order for offline composition to be a viable strategy, the transducers in the cascade must be closed under composition. Unfortunately, of the classes that preserve recognizability, only wLNT is closed under composition (Gécseg and Steinby, 1984; Baker, 1979; Maletti et al., 2009; Fülöp and Vogler, 2009).

However, the general lack of composability of tree transducers does *not* preclude us from conducting forward application of a cascade. We revisit the bucket brigade approach, which in Section 2 appeared to be little more than a choice of composition order. As discussed previously, application of a single transducer involves an embedding, a composition, and a projection. The embedded WRTG is in the class wLNT, and the projection forms another WRTG. As long as every transducer in the cascade can be composed with a wLNT to its left or right, depending on the application type, application of a cascade is possible. Note that this embed-compose-project process is somewhat more burdensome than in the string case. For strings, application is obtained by a *single* embedding, a series of compositions, and a *single* projection, whereas application for trees is obtained by a series of (embed, compose, project) operations.

Algorithm 2 COVER

inputs
  $u \in T_\Delta(Q_1 \times X)$
  wT $M_2 = (Q_2, \Delta, \Gamma, R_2, q_{2_0})$
  state $q_2 \in Q_2$
outputs
  set of pairs (z, w) with $z \in T_\Gamma((Q_1 \times Q_2) \times X)$ formed by one or more successful runs on u by rules in R_2, starting from q_2, and $w \in \mathbb{R}^\infty_+$ the sum of the weights of all such runs.
complexity
  $O(|R_2|^{size(u)})$

            $\theta'(vi, v'v'') \leftarrow q'_2$
            if $u(vi)$ is of the form $(q_1, x) \in Q_1 \times X$ **then**
              $\varphi(q'_2, x_i) \leftarrow ((q_1, q'_2), x)$
            else
              $\varphi(q'_2, x_i) \leftarrow \perp$
        $\Pi_v \leftarrow \Pi_v \cup \{(z[\overline{\varphi}(h)]_{v'}, \theta', w \cdot w')\}$
  $\Pi_{last} \leftarrow \Pi_v$
$Z \leftarrow \{z \mid (z, \theta, w) \in \Pi_{last}\}$
return $\{(z, \sum_{(z,\theta,w) \in \Pi_{last}} w) \mid z \in Z\}$

4.1 On-the-fly algorithms

We next consider on-the-fly algorithms for application. Similar to the string case, an on-the-fly approach is driven by a calling algorithm that periodically needs to know the productions in a WRTG with a common left side nonterminal. The embed-compose-project approach produces an entire application WRTG before any inference algorithm is run. In order to admit an on-the-fly approach we describe algorithms that only generate those productions in a WRTG that have a given left nonterminal. In this section we extend Definition 3.1 as follows: a WRTG is a 6-tuple $G = (N, \Sigma, P, n_0, \overline{M}, \overline{G})$ where N, Σ, P, and n_0 are defined as in Definition 3.1, and either $\overline{M} = \overline{G} = \emptyset$,[10] or $\overline{M}$ is a wxLNT and $\overline{G}$ is a normal form, chain production-free WRTG such that

[10] In which case the definition is functionally unchanged from before.

(b) Preservation of backward recognizability

Table 1: Preservation of forward and backward recognizability for various classes of top-down tree transducers. Here and elsewhere, the following abbreviations apply: w = weighted, x = extended LHS, L = linear, N = nondeleting, OQ = open question. Square brackets include a superposition of classes. For example, w[x]T signifies both wxT and wT.

Algorithm 3 PRODUCE

inputs
  WRTG $G_{in} = (N_{in}, \Delta, P_{in}, n_0, \overline{M}, \overline{G})$ such that $\overline{M} = (Q, \Sigma, \Delta, R, q_0)$ is a wxLNT and $\overline{G} = (N, \Sigma, P, n_0', M', G')$ is a WRTG in normal form with no chain productions
  $n_{in} \in N_{in}$
outputs
  WRTG G_{out} = $(N_{out}, \Delta, P_{out}, n_0, \overline{M}, \overline{G})$, such that $G_{in} \preceq G_{out}$ and $(n_{in} \xrightarrow{w} u) \in P_{out} \Leftrightarrow (n_{in} \xrightarrow{w} u) \in \overline{M}(\overline{G})^{\triangleright}$
complexity
  $O(|R||P|^{size(\tilde{y})})$, where $\tilde{y}$ is the largest left side tree in any rule in R

if P_{in} contains productions of the form $n_{in} \xrightarrow{w} u$ **then**
  return G_{in}
$N_{out} \leftarrow N_{in}$
$P_{out} \leftarrow P_{in}$
Let n_{in} be of the form (n, q), where $n \in N$ and $q \in Q$.
for all $(q.y \xrightarrow{w_1} u) \in R$ **do**
  for all $(\theta, w_2) \in$ REPLACE$(y, \overline{G}, n)$ **do**
    Form substitution mapping $\varphi : Q \times X \to T_{\Delta}(N \times Q)$ such that, for all $v \in yd(y)$ and $q' \in Q$, if there exist $n' \in N$ and $x \in X$ such that $\theta(v) = n'$ and $y(v) = x$, then $\varphi(q', x) = (n', q')$.
    $p' \leftarrow ((n, q) \xrightarrow{w_1 \cdot w_2} \overline{\varphi}(u))$
    for all $p \in$ NORM(p', N_{out}) **do**
      Let p be of the form $n_0 \xrightarrow{w} \delta(n_1, \ldots, n_k)$ for $\delta \in \Delta^{(k)}$.
      $N_{out} \leftarrow N_{out} \cup \{n_0, \ldots, n_k\}$
      $P_{out} \leftarrow P_{out} \cup \{p\}$
return CHAIN-REM(G_{out})

$G \preceq \overline{M}(\overline{G})^{\triangleright}$. In the latter case, G is a stand-in for $\overline{M}(\overline{G})^{\triangleright}$, analogous to the stand-ins for WSAs and WSTs described in Section 2.

Algorithm 3, PRODUCE, takes as input a WRTG $G_{in} = (N_{in}, \Delta, P_{in}, n_0, \overline{M}, \overline{G})$ and a desired nonterminal n_{in} and returns another WRTG, G_{out} that is different from G_{in} in that it has more productions, specifically those beginning with n_{in} that are in $\overline{M}(\overline{G})^{\triangleright}$. Algorithms using stand-ins should call PRODUCE to ensure the stand-in they are using has the desired productions beginning with the specific nonterminal. Note, then, that PRODUCE obtains the effect of forward applica-

$g_0a_0b_0 \xrightarrow{w_2 \cdot w_6 \cdot w_{10}} \alpha \quad g_1a_1b_0 \xrightarrow{w_3 \cdot w_7 \cdot w_{10}} \alpha$

(e) Complete $M_B(M_A(G)^{\triangleright})^{\triangleright}$

Figure 2: Forward application through a cascade of tree transducers using an on-the-fly method.

tion in an on-the-fly manner.[11] It makes calls to REPLACE, which is presented in Algorithm 4, as well as to a NORM algorithm that ensures normal form by replacing a single production not in normal form with several normal-form productions that can be combined together (Alexandrakis and Bozapalidis, 1987) and a CHAIN-REM algorithm that replaces a WRTG containing chain productions with an equivalent WRTG that does not (Mohri, 2009).

As an example of stand-in construction, consider the invocation PRODUCE(G_1, g_0a_0), where G_1 = ($\{g_0a_0\}$, $\{\sigma, \psi, \alpha, \rho\}$, $\emptyset$, g_0a_0, M_A, G), G is in Figure 2a,[12] and M_A is in 2b. The stand-in WRTG that is output contains the first three of the four productions in Figure 2d.

To demonstrate the use of on-the-fly application in a cascade, we next show the effect of PRODUCE when used with the cascade $G \circ M_A \circ M_B$, where M_B is in Figure 2c. Our driving algorithm in this case is Algorithm 5, MAKE-

$r_{\text{JJ}}.\text{JJ}(x_1, x_2, x_3) \rightarrow \text{JJ}(r_{\text{DT}}.x_1, r_{\text{JJ}}.x_2, r_{\text{VB}}.x_3)$
$r_{\text{VB}}.\text{VB}(x_1, x_2, x_3) \rightarrow \text{VB}(r_{\text{NNPS}}.x_1, r_{\text{NN}}.x_3, r_{\text{VB}}.x_2)$
t."gentle" $\rightarrow$ "gentle"

(a) Rotation rules

$i_{\text{VB}}.\text{NN}(x_1, x_2) \rightarrow \text{NN}(\text{INS } i_{\text{NN}}.x_1, i_{\text{NN}}.x_2)$
$i_{\text{VB}}.\text{NN}(x_1, x_2) \rightarrow \text{NN}(i_{\text{NN}}.x_1, i_{\text{NN}}.x_2)$
$i_{\text{VB}}.\text{NN}(x_1, x_2) \rightarrow \text{NN}(i_{\text{NN}}.x_1, i_{\text{NN}}.x_2, \text{INS})$

(b) Insertion rules

$t.\text{VB}(x_1, x_2, x_3) \rightarrow \text{X}(t.x_1, t.x_2, t.x_3)$
t."gentleman" $\rightarrow$ j1
t."gentleman" $\rightarrow$ EPS
t.INS $\rightarrow$ j1
t.INS $\rightarrow$ j2

(c) Translation rules

Figure 3: Example rules from transducers used in decoding experiment. j1 and j2 are Japanese words.

EXPLICIT, which simply generates the full application WRTG using calls to PRODUCE. The input to MAKE-EXPLICIT is G_2 = ($\{g_0a_0b_0\}$, $\{\sigma, \alpha\}$, $\emptyset$, $g_0a_0b_0$, M_B, G_1).[13] MAKE-EXPLICIT calls PRODUCE(G_2, $g_0a_0b_0$). PRODUCE then seeks to cover $b_0.\sigma(x_1, x_2) \xrightarrow{w_9} \sigma(b_0.x_1, b_0.x_2)$ with productions from G_1, which is a stand-in for $M_A(G)^{\triangleright}$. At line 14 of REPLACE, G_1 is improved so that it has the appropriate productions. The productions of $M_A(G)^{\triangleright}$ that must be built to form the complete $M_B(M_A(G)^{\triangleright})^{\triangleright}$ are shown in Figure 2d. The complete $M_B(M_A(G)^{\triangleright})^{\triangleright}$ is shown in Figure 2e. Note that because we used this on-the-fly approach, we were able to avoid building all the productions in $M_A(G)^{\triangleright}$; in particular we did not build $g_0a_2 \xrightarrow{w_2 \cdot w_8} \rho$, while a bucket brigade approach would have built this production. We have also designed an analogous on-the-fly PRODUCE algorithm for backward application on linear WTT.

We have now defined several on-the-fly and bucket brigade algorithms, and also discussed the possibility of embed-compose-project and offline composition strategies to application of cascades of tree transducers. Tables 2a and 2b summarize the available methods of forward and backward application of cascades for recognizability-preserving tree transducer classes.

5 Decoding Experiments

The main purpose of this paper has been to present novel algorithms for performing application. However, it is important to demonstrate these algorithms on real data. We thus demonstrate bucket-brigade and on-the-fly backward application on a typical NLP task cast as a cascade of wLNT. We adapt the Japanese-to-English transla-

[11] Note further that it allows forward application of class wxLNT, something the embed-compose-project approach did not allow.

[12] By convention the initial nonterminal and state are listed first in graphical depictions of WRTGs and WXTTs.

[13] Note that G_2 is the initial stand-in for $M_B(M_A(G)^{\triangleright})^{\triangleright}$, since G_1 is the initial stand-in for $M_A(G)^{\triangleright}$.

tion model of Yamada and Knight (2001) by transforming it from an English-tree-to-Japanese-string model to an English-tree-to-Japanese-*tree* model. The Japanese trees are unlabeled, meaning they have syntactic structure but all nodes are labeled "X". We then cast this modified model as a cascade of LNT tree transducers. Space does not permit a detailed description, but some example rules are in Figure 3. The rotation transducer $\mathcal{R}$, a sample of which is in Figure 3a, has 6,453 rules, the insertion transducer $\mathcal{I}$, Figure 3b, has 8,122 rules, and the translation transducer, $\mathcal{T}$, Figure 3c, has 37,311 rules.

We add an English syntax language model $\mathcal{L}$ to the cascade of transducers just described to better simulate an actual machine translation decoding task. The language model is cast as an identity WTT and thus fits naturally into the experimental framework. In our experiments we try several different language models to demonstrate varying performance of the application algorithms. The most realistic language model is a PCFG. Each rule captures the probability of a particular sequence of child labels given a parent label. This model has 7,765 rules.

To demonstrate more extreme cases of the usefulness of the on-the-fly approach, we build a language model that recognizes exactly the 2,087 trees in the training corpus, each with equal weight. It has 39,455 rules. Finally, to be ultra-specific, we include a form of the "specific" language model just described, but only allow the English counterpart of the particular Japanese sentence being decoded in the language.

The goal in our experiments is to apply a single tree t backward through the cascade $\mathcal{L} \circ \mathcal{R} \circ \mathcal{I} \circ \mathcal{T} \circ t$ and find the 1-best path in the application WRTG. We evaluate the speed of each approach: bucket brigade and on-the-fly. The algorithm we use to obtain the 1-best path is a modification of the k-best algorithm of Pauls and Klein (2009). Our algorithm finds the 1-best path in a WRTG and admits an on-the-fly approach.

The results of the experiments are shown in Table 3. As can be seen, on-the-fly application is generally faster than the bucket brigade, about double the speed per sentence in the traditional

LM type	method	time/sentence
pcfg	bucket	28s
pcfg	otf	17s
exact	bucket	>1m
exact	otf	24s
1-sent	bucket	2.5s
1-sent	otf	.06s

Table 3: Timing results to obtain 1-best from application through a weighted tree transducer cascade, using on-the-fly vs. bucket brigade backward application techniques. pcfg = model recognizes any tree licensed by a pcfg built from observed data, exact = model recognizes each of 2,000+ trees with equal weight, 1-sent = model recognizes exactly one tree.

experiment that uses an English PCFG language model. The results for the other two language models demonstrate more keenly the potential advantage that an on-the-fly approach provides—the simultaneous incorporation of information from all models allows application to be done more effectively than if each information source is considered in sequence. In the "exact" case, where a very large language model that simply recognizes each of the 2,087 trees in the training corpus is used, the final application is so large that it overwhelms the resources of a 4gb MacBook Pro, while the on-the-fly approach does not suffer from this problem. The "1-sent" case is presented to demonstrate the ripple effect caused by using on-the fly. In the other two cases, a very large language model generally overwhelms the timing statistics, regardless of the method being used. But a language model that represents exactly one sentence is very small, and thus the effects of simultaneous inference are readily apparent—the time to retrieve the 1-best sentence is reduced by two orders of magnitude in this experiment.

6 Conclusion

We have presented algorithms for forward and backward application of weighted tree transducer cascades, including on-the-fly variants, and demonstrated the benefit of an on-the-fly approach to application. We note that a more formal approach to application of WTTs is being developed,

independent from these efforts, by Fülöp et al. (2010).

A Tree Transducer Model for Synchronous Tree-Adjoining Grammars

Andreas Maletti

Avinguda de Catalunya 25, 43002 Tarragona, Spain.
andreas.maletti@urv.cat

Abstract

A characterization of the expressive power of synchronous tree-adjoining grammars (STAGs) in terms of tree transducers (or equivalently, synchronous tree substitution grammars) is developed. Essentially, a STAG corresponds to an extended tree transducer that uses explicit substitution in both the input and output. This characterization allows the easy integration of STAG into toolkits for extended tree transducers. Moreover, the applicability of the characterization to several representational and algorithmic problems is demonstrated.

1 Introduction

Machine translation has seen a multitude of formal translation models. Here we focus on syntax-based (or tree-based) models. One of the oldest models is the *synchronous context-free grammar* (Aho and Ullman, 1972). It is clearly too weak as a syntax-based model, but found use in the string-based setting. *Top-down tree transducers* (Rounds, 1970; Thatcher, 1970) have been heavily investigated in the formal language community (Gécseg and Steinby, 1984; Gécseg and Steinby, 1997), but as argued by Shieber (2004) they are still too weak for syntax-based machine translation. Instead Shieber (2004) proposes *synchronous tree substitution grammars* (STSGs) and develops an equivalent bimorphism (Arnold and Dauchet, 1982) characterization. This characterization eventually led to the rediscovery of *extended tree transducers* (Graehl and Knight, 2004; Knight and Graehl, 2005; Graehl et al., 2008), which are essentially as powerful as STSG. They had been studied already by Arnold and Dauchet (1982) in the form of bimorphisms, but received little attention until rediscovered.

Shieber (2007) claims that even STSGs might be too simple to capture naturally occuring translation phenomena. Instead Shieber (2007) suggests a yet more powerful mechanism, *synchronous tree-adjoining grammars* (STAGs) as introduced by Shieber and Schabes (1990), that can capture certain (mildly) context-sensitive features of natural language. In the tradition of Shieber (2004), a characterization of the power of STAGs in terms of bimorphims was developed by Shieber (2006). The bimorphisms used are rather unconventional because they consist of a regular tree language and two embedded tree transducers (instead of two tree homomorphisms). Such embedded tree transducers (Shieber, 2006) are particular macro tree transducers (Courcelle and Franchi-Zannettacci, 1982; Engelfriet and Vogler, 1985).

In this contribution, we try to unify the picture even further. We will develop a tree transducer model that can simulate STAGs. It turns out that the adjunction operation of an STAG can be explained easily by explicit substitution. In this sense, the slogan that an STAG is an STSG with adjunction, which refers to the syntax, also translates to the semantics. We prove that any tree transformation computed by an STAG can also be computed by an STSG using explicit substitution. Thus, a simple evaluation procedure that performs the explicit substitution is all that is needed to simulate an STAG in a toolkit for STSGs or extended tree transducers like TIBURON by May and Knight (2006).

We show that some standard algorithms on STAG can actually be run on the constructed STSG, which often is simpler and better understood. Further, it might be easier to develop new algorithms with the alternative characterization, which we demonstrate with a product construction for input restriction in the spirit of Nederhof (2009). Finally, we also present a complete tree transducer model that is as powerful as STAG, which is an extension of the embedded tree transducers of Shieber (2006).

Uppsala, Sweden, 11-16 July 2010.

2 Notation

We quickly recall some central notions about trees, tree languages, and tree transformations. For a more in-depth discussion we refer to Gécseg and Steinby (1984) and Gécseg and Steinby (1997). A finite set Σ of labels is an alphabet. The set of all strings over that alphabet is Σ^* where ε denotes the empty string. To simplify the presentation, we assume an infinite set $X = \{x_1, x_2, \dots\}$ of variables. Those variables are syntactic and represent only themselves. In particular, they are all different. For each $k \geq 0$, we let $X_k = \{x_1, \dots, x_k\}$. We can also form trees over the alphabet Σ. To allow some more flexibility, we will also allow leaves from a special set V. Formally, a Σ-tree over V is either:

- a leaf labeled with an element of $v \in \Sigma \cup V$, or
- a node that is labeled with an element of Σ with $k \geq 1$ children such that each child is a Σ-tree over V itself.[1]

The set of all Σ-trees over V is denoted by $T_\Sigma(V)$. We just write T_Σ for $T_\Sigma(\emptyset)$. The trees in Figure 1 are, for example, elements of $T_\Delta(Y)$ where

$$\Delta = \{\text{S}, \text{NP}, \text{VP}, \text{V}, \text{DT}, \text{N}\}$$
$$Y = \{\text{saw}, \text{the}\} \ .$$

We often present trees as terms. A leaf labeled v is simply written as v. The tree with a root node labeled σ is written $\sigma(t_1, \dots, t_k)$ where $t_1, \dots, t_k$ are the term representations of its k children.

A tree language is any subset of $T_\Sigma(V)$ for some alphabet Σ and set V. Given another alphabet Δ and a set Y, a tree transformation is a relation $\tau \subseteq T_\Sigma(V) \times T_\Delta(Y)$. In many of our examples we have $V = \emptyset = Y$. Occasionally, we also speak about the translation of a tree transformation $\tau \subseteq T_\Sigma \times T_\Delta$. The *translation* of τ is the relation $\{(\mathrm{yd}(t), \mathrm{yd}(u)) \mid (t, u) \in \tau\}$ where $\mathrm{yd}(t)$, the *yield* of t, is the sequence of leaf labels in a left-to-right tree traversal of t. The yield of the third tree in Figure 1 is "the N saw the N". Note that the translation is a relation $\tau' \subseteq \Sigma^* \times \Delta^*$.

3 Substitution

A standard operation on (labeled) trees is *substitution*, which replaces leaves with a specified label in one tree by another tree. We write $t[u]_A$ for (the result of) the substitution that replaces all leaves labeled A in the tree t by the tree u. If $t \in T_\Sigma(V)$ and $u \in T_\Delta(Y)$, then $t[u]_A \in T_{\Sigma\cup\Delta}(V \cup Y)$. We often use the variables of $X = \{x_1, x_2, \dots\}$ as substitution points and write $t[u_1, \dots, u_k]$ instead of $(\cdots(t[u_1]_{x_1})\dots)[u_k]_{x_k}$.

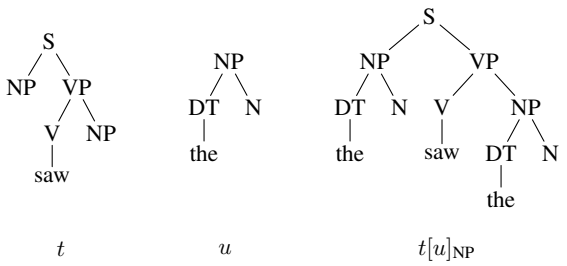

Figure 1: A substitution.

An example substitution is shown in Figure 1. The figure also illustrates a common problem with substitution. Occasionally, it is not desirable to replace all leaves with a certain label by the same tree. In the depicted example, we might want to replace one 'NP' by a different tree, which cannot be achieved with substitution. Clearly, this problem is avoided if the source tree t contains only one leaf labeled A. We call a tree *A-proper* if it contains exactly one leaf with label A.[2] The subset $C_\Sigma(X_k) \subseteq T_\Sigma(X_k)$ contains exactly those trees of $T_\Sigma(X_k)$ that are x_i-proper for every $1 \leq i \leq k$. For example, the tree t of Figure 1 is 'saw'-proper, and the tree u of Figure 1 is 'the'- and 'N'-proper.

In this contribution, we will also use substitution as an explicit operator. The tree $t[u]_{\text{NP}}$ in Figure 1 only shows the result of the substitution. It cannot be infered from the tree alone, how it was obtained (if we do not know t and u).[3] To make substitution explicit, we use the special binary symbols $\cdot[\cdot]_A$ where A is a label. Those symbols will always be used with exactly two children (i.e., as binary symbols). Since this property can easily be checked by all considered devices, we ignore trees that use those symbols in a non-binary manner. For every set Σ of labels, we let $\overline{\Sigma} = \Sigma \cup \{\cdot[\cdot]_A \mid A \in \Sigma\}$ be the extended set of labels containing also the substition symbols. The substitution of Figure 1 can then be ex-

[1] Note that we do not require the symbols to have a fixed rank; i.e., a symbol does not determine its number of children.

[2] A-proper trees are sometimes also called A-context in the literature.

[3] This remains true even if we know that the participating trees t and u are A-proper and the substitution $t[u]_A$ replacing leaves labeled A was used. This is due to the fact that, in general, the root label of u need not coincide with A.

pressed as the tree $\cdot[\cdot]_{\text{NP}}(t, u)$. To obtain $t[u]_{\text{NP}}$ (the right-most tree in Figure 1), we have to evaluate $\cdot[\cdot]_{\text{NP}}(t, u)$. However, we want to replace only one leaf at a time. Consequently, we restrict the evaluation of $\cdot[\cdot]_A(t, u)$ such that it applies only to trees t whose evaluation is A-proper. To enforce this restriction, we introduce an error signal $\perp$, which we assume not to occur in any set of labels. Let Σ be the set of labels. Then we define the function $\cdot^{\text{E}} \colon T_{\overline{\Sigma}} \to T_\Sigma \cup \{\perp\}$ by[4]

$$\sigma(t_1, \ldots, t_k)^{\text{E}} = \sigma(t_1^{\text{E}}, \ldots, t_k^{\text{E}})$$

$$\cdot[\cdot]_A(t, u)^{\text{E}} = \begin{cases} t^{\text{E}}[u^{\text{E}}]_A & \text{if } t^{\text{E}} \text{ is } A\text{-proper} \\ \perp & \text{otherwise} \end{cases}$$

for every $k \geq 0$, $\sigma \in \Sigma$, and $t, t_1, \ldots, t_k, u \in T_{\overline{\Sigma}}$.[5] We generally discard all trees that contain the error signal $\perp$. Since the devices that we will study later can also check the required A-properness using their state behavior, we generally do not discuss trees with error symbols explicitly.

4 Extended tree transducer

An extended tree transducer is a theoretical model that computes a tree transformation. Such transducers have been studied first by Arnold and Dauchet (1982) in a purely theoretic setting, but were later applied in, for example, machine translation (Knight and Graehl, 2005; Knight, 2007; Graehl et al., 2008; Graehl et al., 2009). Their popularity in machine translation is due to Shieber (2004), in which it is shown that extended tree transducers are essentially (up to a relabeling) as expressive as synchronous tree substitution grammars (STSG). We refer to Chiang (2006) for an introduction to synchronous devices.

Let us recall the formal definition. An *extended tree transducer* (for short: XTT)[6] is a system $M = (Q, \Sigma, \Delta, I, R)$ where

- Q is a finite set of *states*,
- Σ and Δ are alphabets of *input* and *output symbols*, respectively,
- $I \subseteq Q$ is a set of *initial states*, and
- R is a finite set of *rules* of the form

$$(q, l) \to (q_1 \cdots q_k, r)$$

where $k \geq 0$, $l \in C_\Sigma(X_k)$, and $r \in C_\Delta(X_k)$.

Recall that any tree of $C_\Sigma(X_k)$ contains each variable of $X_k = \{x_1, \ldots, x_k\}$ exactly once. In graphical representations of a rule

$$(q, l) \to (q_1 \cdots q_k, r) \in R \ ,$$

we usually

- add the state q as root node of the left-hand side[7], and
- add the states $q_1, \ldots, q_k$ on top of the nodes labeled $x_1, \ldots, x_k$, respectively, in the right-hand side of the rule.

Some example rules are displayed in Figure 2.

The rules are applied in the expected way (as in a term-rewrite system). The only additional feature are the states of Q, which can be used to control the derivation. A sentential form is a tree that contains exclusively output symbols towards the root and remaining parts of the input headed by a state as leaves. A derivation step starting from ξ then consists in

- selecting a leaf of ξ with remaining input symbols,
- matching the state q and the left-hand side l of a rule $(q, l) \to (q_1 \cdots q_k, r) \in R$ to the state and input tree stored in the leaf, thus matching input subtrees $t_1, \ldots, t_k$ to the variables $x_1, \ldots, x_k$,
- replacing all the variables $x_1, \ldots, x_k$ in the right-hand side r by the matched input subtrees $q_1(t_1), \ldots, q_k(t_k)$ headed by the corresponding state, respectively, and
- replacing the selected leaf in ξ by the tree constructed in the previous item.

The process is illustrated in Figure 3.

Formally, a sentential form of the XTT M is a tree of $\text{SF} = T_\Delta(Q(T_\Sigma))$ where

$$Q(T_\Sigma) = \{q(t) \mid q \in Q, t \in T_\Sigma\} \ .$$

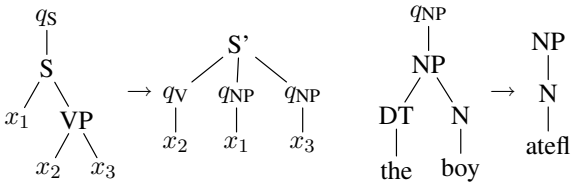

Figure 2: Example rules taken from Graehl et al. (2009). The term representation of the first rule is $(q_{\text{S}}, \text{S}(x_1, \text{VP}(x_2, x_3))) \to (w, \text{S}'(x_2, x_1, x_3))$ where $w = q_{\text{NP}} q_{\text{V}} q_{\text{NP}}$.

[4] Formally, we should introduce an evaluation function for each alphabet Σ, but we assume that the alphabet can be infered.

[5] This evaluation is a special case of a *yield*-mapping (Engelfriet and Vogler, 1985).

[6] Using the notions of Graehl et al. (2009) our extended tree transducers are linear, nondeleting extended top-down tree transducers.

[7] States are thus also special symbols that are exclusively used as unary symbols.

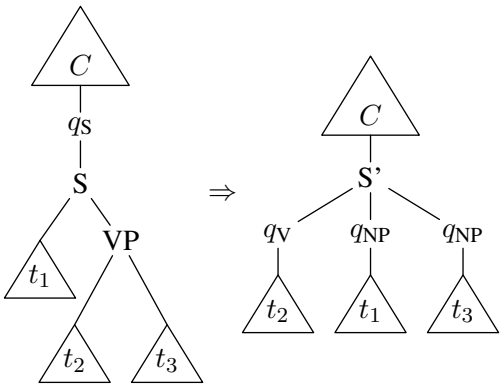

Figure 3: Illustration of a derivation step of an XTT using the left rule of Figure 2.

Given $\xi, \zeta \in \mathrm{SF}$, we write $\xi \Rightarrow \zeta$ if there exist $C \in C_\Delta(X_1)$, $t_1, \ldots, t_k \in T_\Sigma$, and a rule $(q, l) \to (q_1 \cdots q_k, r) \in R$ such that

- $\xi = C[q(l[t_1, \ldots, t_k])]$ and
- $\zeta = C[r[q_1(t_1), \ldots, q_k(t_k)]]$.

The tree transformation computed by M is the relation

$$\tau_M = \{(t, u) \in T_\Sigma \times T_\Delta \mid \exists q \in I \colon q(t) \Rightarrow^* u\}$$

where $\Rightarrow^*$ is the reflexive, transitive closure of $\Rightarrow$. In other words, the tree t can be transformed into u if there exists an initial state q such that we can derive u from $q(t)$ in several derivation steps.

We refer to Arnold and Dauchet (1982), Graehl et al. (2008), and Graehl et al. (2009) for a more detailed exposition to XTT.

5 Synchronous tree-adjoining grammar

XTT are a simple, natural model for tree transformations, however they are not suitably expressive for all applications in machine translation (Shieber, 2007). In particular, all tree transformations of XTT have a certain locality condition, which yields that the input tree and its corresponding translation cannot be separated by an unbounded distance. To overcome this problem and certain dependency problems, Shieber and Schabes (1990) and Shieber (2007) suggest a stronger model called *synchronous tree-adjoining grammar* (STAG), which in addition to the substitution operation of STSG (Chiang, 2005) also has an adjoining operation.

Let us recall the model in some detail. A tree-adjoining grammar essentially is a regular tree grammar (Gécseg and Steinby, 1984; Gécseg and Steinby, 1997) enhanced with an adjunction operation. Roughly speaking, an adjunction replaces a node (not necessarily a leaf) by an *auxiliary tree*, which has exactly one distinguished *foot node*. The original children of the replaced node will become the children of the foot node after adjunction. Traditionally, the root label and the label of the foot node coincide in an auxiliary tree aside from a star index that marks the foot node. For example, if the root node of an auxiliary tree is labeled A, then the foot node is traditionally labeled $A_\star$. The star index is not reproduced once adjoined. Formally, the adjunction of the auxiliary tree u with root label A (and foot node label $A_\star$) into a tree $t = C[A(t_1, \ldots, t_k)]$ with $C \in C_\Sigma(X_1)$ and $t_1, \ldots, t_k \in T_\Sigma$ is

$$C[u[A(t_1, \ldots, t_k)]_{A_\star}] \ .$$

Adjunction is illustrated in Figure 4.

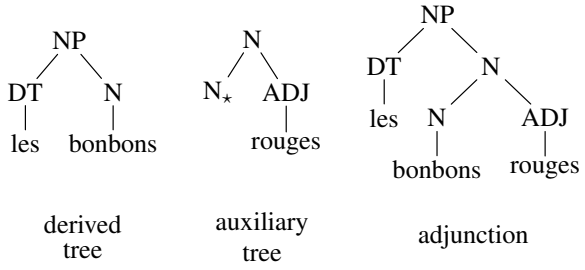

Figure 4: Illustration of an adjunction taken from Nesson et al. (2008).

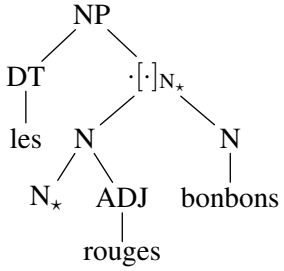

Figure 5: Illustration of the adjunction of Figure 4 using explicit substitution.

We note that adjunction can easily be expressed using explicit substitution. Essentially, only an additional node with the adjoined subtree is added. The result of the adjunction of Figure 4 using explicit substitution is displayed in Figure 5.

To simplify the development, we will make some assumptions on all tree-adjoining grammars (and synchronous tree-adjoining grammars). A *tree-adjoining grammar* (TAG) is a finite set of *initial trees* and a finite set of auxiliary trees. Our

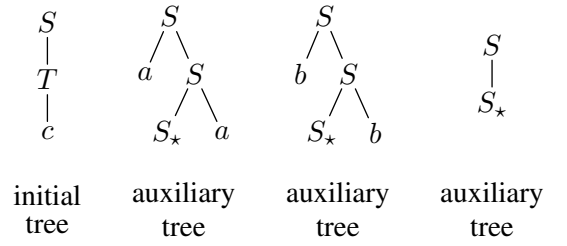

Figure 6: A TAG for the copy string language $\{wcw \mid w \in \{a, b\}^*\}$ taken from Shieber (2006).

TAG do not use substitution, but only adjunction. A derivation is a chain of trees that starts with an initial tree and each derived tree is obtained from the previous one in the chain by adjunction of an auxiliary tree. As in Shieber (2006) we assume that all adjunctions are mandatory; i.e., if an auxiliary tree can be adjoined, then we need to make an adjunction. Thus, a derivation starting from an initial tree to a derived tree is *complete* if no adjunction is possible in the derived tree. Moreover, we assume that to each node only one adjunction can be applied. This is easily achieved by labeling the root of each adjoined auxiliary tree by a special marker. Traditionally, the root label A of an auxiliary tree is replaced by $A_\emptyset$ once adjoined. Since we assume that there are no auxiliary trees with such a root label, no further adjunction is possible at such nodes. Another effect of this restriction is that the number of *operable nodes* (i.e., the nodes to which an adjunction must still be applied) is known at any given time.[8] A full TAG with our restrictions is shown in Figure 6.

Intuitively, a *synchronous tree-adjoining grammar* (STAG) is essentially a pair of TAGs. The synchronization is achieved by pairing the initial trees and the auxiliary trees. In addition, for each such pair (t, u) of trees, there exists a bijection between the operable nodes of t and u. Such nodes in bijection are *linked* and the links are preserved in derivations, in which we now use pairs of trees as sentential forms. In graphical representations we often indicate this bijection with integers; i.e., two nodes marked with the same integer are linked. A pair of auxiliary trees is then adjoined to linked nodes (one in each tree of the sentential form) in the expected manner. We will avoid a formal definition here, but rather present an example STAG and a derivation with it in Figures 7 and 8. For a

[8] Without the given restrictions, this number cannot be determined easily because no or several adjunctions can take place at a certain node.

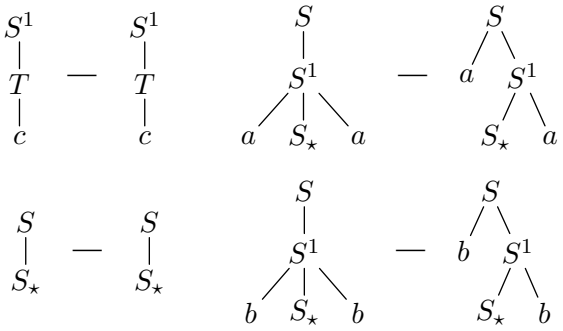

Figure 7: STAG that computes the translation $\{(wcw^{\mathrm{R}}, wcw) \mid w \in \{a, b\}^*\}$ where w^{R} is the reverse of w.

STAG G we write τ_G for the tree transformation computed by G.

6 Main result

In this section, we will present our main result. Essentially, it states that a STAG is as powerful as a STSG using explicit substitution. Thus, for every tree transformation computed by a STAG, there is an extended tree transducer that computes a representation of the tree transformation using explicit substitution. The converse is also true. For every extended tree transducer M that uses explicit substitution, we can construct a STAG that computes the tree transformation represented by τ_M up to a relabeling (a mapping that consistently replaces node labels throughout the tree). The additional relabeling is required because STAGs do not have states. If we replace the extended tree transducer by a STSG, then the result holds even without the relabeling.

Theorem 1 *For every STAG G, there exists an extended tree transducer M such that*

$$\tau_G = \{(t^{\mathrm{E}}, u^{\mathrm{E}}) \mid (t, u) \in \tau_M\} \ .$$

Conversely, for every extended tree transducer M, there exists a STAG G such that the above relation holds up to a relabeling.

6.1 Proof sketch

The following proof sketch is intended for readers that are familiar with the literature on embedded tree transducers, macro tree transducers, and bimorphisms. It can safely be skipped because we will illustrate the relevant construction on our example after the proof sketch, which contains the outline for the correctness.

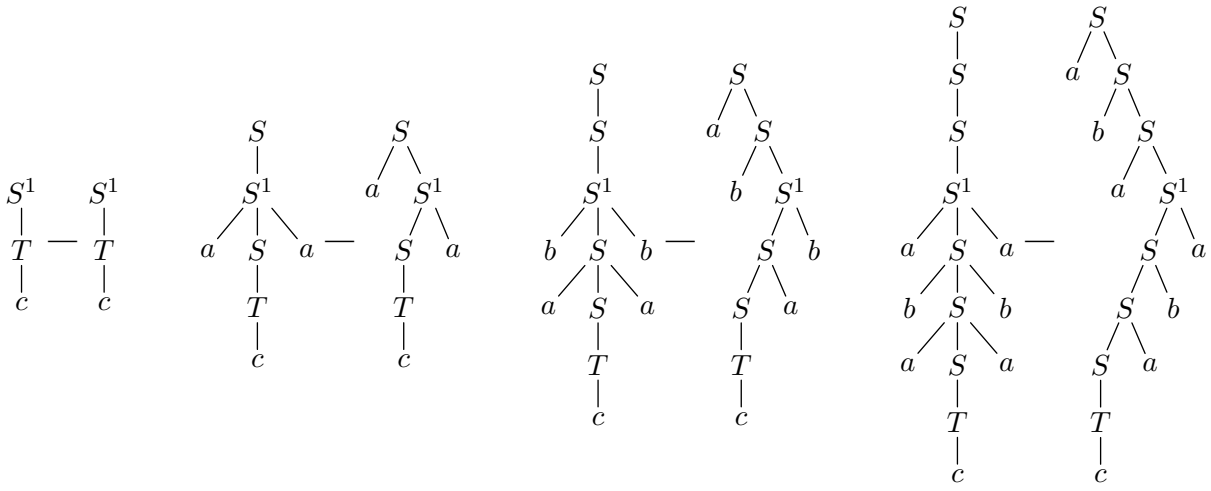

Figure 8: An incomplete derivation using the STAG of Figure 7.

Let $\tau \subseteq T_\Sigma \times T_\Delta$ be a tree transformation computed by a STAG. By Shieber (2006) there exists a regular tree language $L \subseteq T_\Gamma$ and two functions $e_1 \colon T_\Gamma \to T_\Sigma$ and $e_2 \colon T_\Gamma \to T_\Delta$ such that $\tau = \{(e_1(t), e_2(t)) \mid t \in L\}$. Moreover, e_1 and e_2 can be computed by *embedded tree transducers* (Shieber, 2006), which are particular 1-state, deterministic, total, 1-parameter, linear, and nondeleting macro tree transducers (Courcelle and Franchi-Zannettacci, 1982; Engelfriet and Vogler, 1985). In fact, the converse is also true up to a relabeling, which is also shown in Shieber (2006). The outer part of Figure 9 illustrates these relations. Finally, we remark that all involved constructions are effective.

Using a result of Engelfriet and Vogler (1985), each embedded tree transducer can be decomposed into a top-down tree transducer (Gécseg and Steinby, 1984; Gécseg and Steinby, 1997) and a yield-mapping. In our particular case, the top-down tree transducers are linear and nondeleting homomorphisms h_1 and h_2. Linearity and nondeletion are inherited from the corresponding properties of the macro tree transducer. The properties '1-state', 'deterministic', and 'total' of the macro tree transducer ensure that the obtained top-down tree transducer is also 1-state, deterministic, and total, which means that it is a homomorphism. Finally, the 1-parameter property yields that the used substitution symbols are binary (as our substitution symbols $\cdot[\cdot]_A$). Consequently, the yield-mapping actually coincides with our evaluation. Again, this decomposition actually is a characterization of embedded tree transducers. Now the set $\{(h_1(t), h_2(t)) \mid t \in L\}$ can be computed

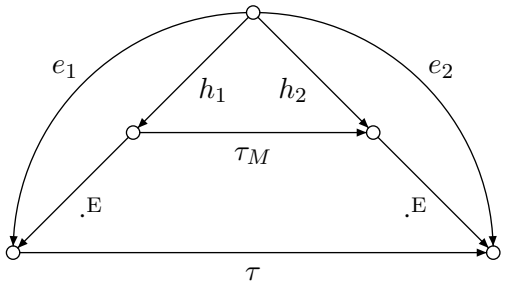

Figure 9: Illustration of the proof sketch.

by an extended tree transducer M due to results of Shieber (2004) and Maletti (2008). More precisely, every extended tree transducer computes such a set, so that also this step is a characterization. Thus we obtain that τ is an evaluation of a tree transformation computed by an extended tree transducer, and moreover, for each extended tree transducer, the evaluation can be computed (up to a relabeling) by a STAG. The overall proof structure is illustrated in Figure 9.

6.2 Example

Let us illustrate one direction (the construction of the extended tree transducer) on our example STAG of Figure 7. Essentially, we just prepare all operable nodes by inserting an explicit substitution just on top of them. The first subtree of that substitution will either be a variable (in the left-hand side of a rule) or a variable headed by a state (in the right-hand side of a rule). The numbers of the variables encode the links of the STAG. Two example rules obtained from the STAG of Figure 7 are presented in Figure 10. Using all XTT rules constructed for the STAG of Figure 7, we present

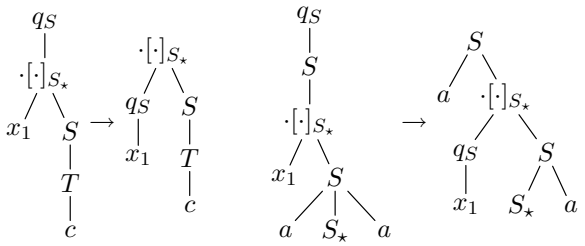

Figure 10: Two constructed XTT rules.

a complete derivation of the XTT in Figure 11 that (up to the final step) matches the derivation of the STAG in Figure 8. The matching is achieved by the evaluation $\cdot^{\mathrm{E}}$ introduced in Section 3 (i.e., applying the evaluation to the derived trees of Figure 11 yields the corresponding derived trees of Figure 8.

7 Applications

In this section, we will discuss a few applications of our main result. Those range from representational issues to algorithmic problems. Finally, we also present a tree transducer model that includes explicit substitution. Such a model might help to address algorithmic problems because derivation and evaluation are intertwined in the model and not separate as in our main result.

7.1 Toolkits

Obviously, our characterization can be applied in a toolkit for extended tree transducers (or STSG) such as TIBURON by May and Knight (2006) to simulate STAG. The existing infrastructure (input-output, derivation mechanism, etc) for extended tree transducers can be re-used to run XTTs encoding STAGs. The only additional overhead is the implementation of the evaluation, which is a straightforward recursive function (as defined in Section 3). After that any STAG can be simulated in the existing framework, which allows experiments with STAG and an evaluation of their expressive power without the need to develop a new toolkit. It should be remarked that some essential algorithms that are very sensitive to the input and output behavior (such as parsing) cannot be simulated by the corresponding algorithms for STSG. It remains an open problem whether the close relationship can also be exploited for such algorithms.

7.2 Algorithms

We already mentioned in the previous section that some algorithms do not easily translate from STAG to STSG (or vice versa) with the help of our characterization. However, many standard algorithms for STAG can easily be derived from the corresponding algorithms for STSG. The simplest example is the union of two STAG. Instead of taking the union of two STAG using the classical construction, we can take the union of the corresponding XTT (or STSG) that simulate the STAGs. Their union will simulate the union of the STAGs. Such properties are especially valuable when we simulate STAG in toolkits for XTT.

A second standard algorithm that easily translates is the algorithm computing the n-best derivations (Huang and Chiang, 2005). Clearly, the n-best derivation algorithm does not consider a particular input or output tree. Since the derivations of the XTT match the derivations of the STAG (in the former the input and output are encoded using explicit substitution), the n-best derivations will coincide. If we are additionally interested in the input and output trees for those n-best derivations, then we can simply evaluate the coded input and output trees returned by n-best derivation algorithm.

Finally, let us consider an algorithm that can be obtained for STAG by developing it for XTT using explicit substitution. We will develop a BAR-HILLEL (Bar-Hillel et al., 1964) construction for STAG. Thus, given a STAG G and a recognizable tree language L, we want to construct a STAG G' such that

$$\tau_{G'} = \{(t, u) \mid (t, u) \in \tau_G, t \in L\} \ .$$

In other words, we take the tree transformation τ_G but additionally require the input tree to be in L. Consequently, this operation is also called *input restriction*. Since STAG are symmetric, the corresponding output restriction can be obtained in the same manner. Note that a classical BAR-HILLEL construction restricting to a regular set of yields can be obtained easily as a particular input restriction. As in Nederhof (2009) a change of model is beneficial for the development of such an algorithm, so we will develop an input restriction for XTT using explicit substitution.

Let $M = (Q, \Sigma, \Delta, I, R)$ be an XTT (using explicit substitution) and $G = (N, \Sigma, I', P)$ be a tree substitution grammar (regular tree grammar) in normal form that recognizes L (i.e., $L(G) = L$). Let $S = \{A \in \Sigma \mid \cdot[\cdot]_A \in \Sigma\}$. A *context* is a mapping $c\colon S \to N$, which remembers a nonterminal of G for each substitution point. Given a rule

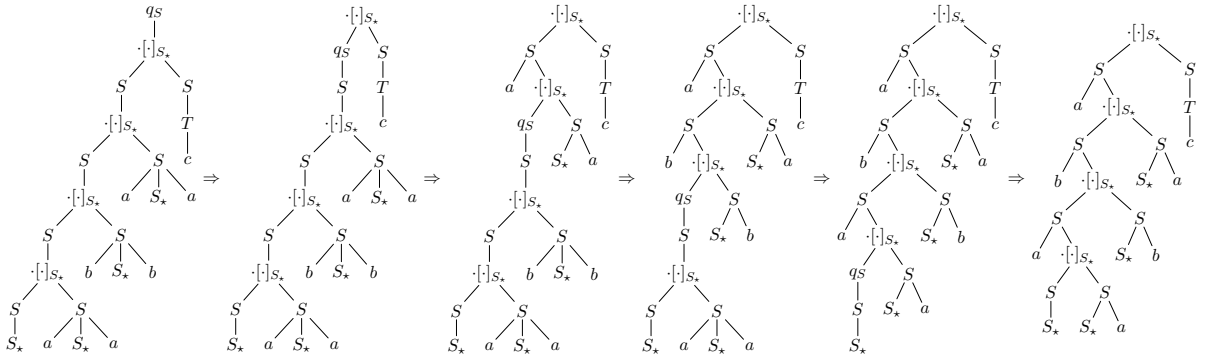

Figure 11: Complete derivation using the constructed XTT rules.

$(q, l) \to (q_1 \cdots q_k, r) \in R$, a nonterminal $p \in N$, and a context $c \in S$, we construct new rules corresponding to successful parses of l subject to the following restrictions:

- If $l = \cdot[\cdot]_A(l_1, l_2)$ for some $A \in \Sigma$, then select $p' \in N$, parse l_1 in p with context c' where $c' = c[A \mapsto p']$[9], and parse l_2 in p' with context c.
- If $l = A_\star$ with $A \in \Sigma$, then $p = c(A)$.
- Finally, if $l = \sigma(l_1, \ldots, l_k)$ for some $\sigma \in \Sigma$, then select $p \to \sigma(p_1, \ldots, p_k) \in P$ is a production of G and we parse l_i with nonterminal p_i and context c for each $1 \leq i \leq k$.

7.3 A complete tree transducer model

So far, we have specified a tree transducer model that requires some additional parsing before it can be applied. This parsing step has to annotate (and correspondingly restructure) the input tree by the adjunction points. This is best illustrated by the left tree in the last pair of trees in Figure 8. To run our constructed XTT on the trivially completed version of this input tree, it has to be transformed into the first tree of Figure 11, where the adjunctions are now visible. In fact, a second un-parsing step is required to evaluate the output.

To avoid the first additional parsing step, we will now modify our tree transducer model such that this parsing step is part of its semantics. This shows that it can also be done locally (instead of globally parsing the whole input tree). In addition, we arrive at a tree transducer model that exactly (up to a relabeling) matches the power of STAG, which can be useful for certain constructions. It is known that an embedded tree transducer (Shieber, 2006) can handle the mentioned un-parsing step.

An *extended embedded tree transducer with substitution* $M = (Q, \Sigma, \Delta, I, R)$ is simply an embedded tree transducer with extended left-hand sides (i.e., any number of input symbols is allowed in the left-hand side) that uses the special symbols $\cdot[\cdot]_A$ in the input. Formally, let

- $Q = Q_0 \cup Q_1$ be finite where Q_0 and Q_1 are the set of states that do not and do have a context parameter, respectively,
- Σ and Δ be ranked alphabets such that if $\cdot[\cdot]_A \in \Sigma$, then $A, A_\star \in \Sigma$,
- $Q\langle U \rangle$ be such that

$$Q\langle U \rangle = \{q\langle u \rangle \mid q \in Q_1, u \in U\} \cup \cup \{q\langle\rangle \mid q \in Q_0\} \ ,$$

- $I \subseteq Q\langle T_\Delta \rangle$, and
- R is a finite set of rules $l \to r$ such that there exists $k \geq 0$ with $l \in Q\langle\{y\}\rangle(C_\Sigma(X_k))$ and $r \in \mathrm{Rhs}_k$ where

$$\mathrm{Rhs}_k := \delta(\mathrm{Rhs}_k, \ldots, \mathrm{Rhs}_k) \mid \mid q_1\langle \mathrm{Rhs}_k \rangle(x) \mid q_0\langle\rangle(x)$$

with $\delta \in \Delta_k$, $q_1 \in Q_1$, $q_0 \in Q_0$, and $x \in X_k$. Moreover, each variable of l (including y) is supposed to occur exactly once in r.

We refer to Shieber (2006) for a full description of embedded tree transducers. As seen from the syntax, we write the context parameter y of a state $q \in Q_1$ as $q\langle y \rangle$. If $q \in Q_0$, then we also write $q\langle\rangle$ or $q\langle\varepsilon\rangle$. In each right-hand side, such a context parameter u can contain output symbols and further calls to input subtrees. The semantics of extended embedded tree transducers with substitution deviates slightly from the embedded tree transducer semantics. Roughly speaking, not its rules as such, but rather their evaluation are now applied in a term-rewrite fashion. Let

$$\mathrm{SF}' := \delta(\mathrm{SF}', \ldots, \mathrm{SF}') \mid \mid q_1\langle \mathrm{SF}' \rangle(t) \mid q_0\langle\rangle(t)$$

[9] c' is the same as c except that it maps A to p'.

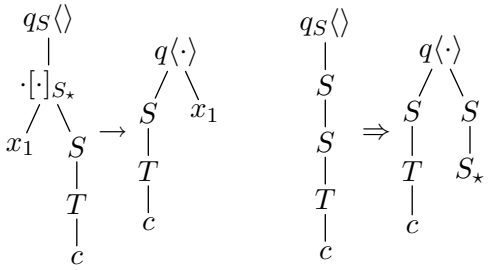

Figure 12: Rule and derivation step using the rule in an extended embedded tree transducer with substitution where the context parameter (if present) is displayed as first child.

where $\delta \in \Delta_k$, $q_1 \in Q_1$, $q_0 \in Q_0$, and $t \in T_\Sigma$.

Given $\xi, \zeta \in \mathrm{SF}'$, we write $\xi \Rightarrow \zeta$ if there exist $C \in C_\Delta(X_1)$, $t_1, \ldots, t_k \in T_\Sigma$, $u \in T_\Delta \cup \{\varepsilon\}$, and a rule $q\langle u\rangle(l) \to r \in R$[10] with $l \in C_\Sigma(X_k)$ such that

- $\xi = C[q\langle u\rangle(l[t_1, \ldots, t_k]^{\mathrm{E}})]$ and
- $\zeta = C[(r[t_1, \ldots, t_k])[u]_y]$.

Note that the essential difference to the "standard" semantics of embedded tree transducers is the evaluation in the first item. The tree transformation computed by M is defined as usual. We illustrate a derivation step in Figure 12, where the match $\cdot[\cdot]_{S_\star}(x_1, S(T(c)))^{\mathrm{E}} = S(S(T(c)))$ is successful for $x_1 = S(S_\star)$.

Theorem 2 *Every STAG can be simulated by an extended embedded tree transducer with substitution. Moreover, every extended embedded tree transducer computes a tree transformation that can be computed by a STAG up to a relabeling.*

8 Conclusions

We presented an alternative view on STAG using tree transducers (or equivalently, STSG). Our main result shows that the syntactic characterization of STAG as STSG plus adjunction rules also carries over to the semantic side. A STAG tree transformation can also be computed by an STSG using explicit substitution. In the light of this result, some standard problems for STAG can be reduced to the corresponding problems for STSG. This allows us to re-use existing algorithms for STSG also for STAG. Moreover, existing STAG algorithms can be related to the corresponding STSG algorithms, which provides further evidence of the close relationship between the two models. We used this relationship to develop a BAR-HILLEL construction for STAG. Finally, we hope that the alternative characterization is easier to handle and might provide further insight into general properties of STAG such as compositions and preservation of regularity.

Abstract

Incremental parsing techniques such as shift-reduce have gained popularity thanks to their efficiency, but there remains a major problem: the search is *greedy* and only explores a tiny fraction of the whole space (even with beam search) as opposed to dynamic programming. We show that, surprisingly, dynamic programming is in fact possible for many shift-reduce parsers, by merging "equivalent" stacks based on feature values. Empirically, our algorithm yields up to a five-fold speedup over a state-of-the-art shift-reduce dependency parser with no loss in accuracy. Better search also leads to better learning, and our final parser outperforms all previously reported dependency parsers for English and Chinese, yet is much faster.

1 Introduction

In terms of search strategy, most parsing algorithms in current use for data-driven parsing can be divided into two broad categories: *dynamic programming* which includes the dominant CKY algorithm, and *greedy search* which includes most incremental parsing methods such as shift-reduce.[1] Both have pros and cons: the former performs an *exact* search (in cubic time) over an exponentially large space, while the latter is much faster (in linear-time) and is psycholinguistically motivated (Frazier and Rayner, 1982), but its greedy nature may suffer from severe search errors, as it only explores a tiny fraction of the whole space even with a beam.

Can we combine the advantages of both approaches, that is, construct an incremental parser that runs in (almost) linear-time, yet searches over a huge space with dynamic programming?

Theoretically, the answer is negative, as Lee (2002) shows that context-free parsing can be used to compute matrix multiplication, where sub-cubic algorithms are largely impractical.

We instead propose a dynamic programming alogorithm for shift-reduce parsing which runs in polynomial time in theory, but linear-time (with beam search) in practice. The key idea is to merge equivalent stacks according to feature functions, inspired by Earley parsing (Earley, 1970; Stolcke, 1995) and generalized LR parsing (Tomita, 1991). However, our formalism is more flexible and our algorithm more practical. Specifically, we make the following contributions:

- *theoretically*, we show that for a large class of modern shift-reduce parsers, dynamic programming is in fact possible and runs in polynomial time as long as the feature functions are *bounded* and *monotonic* (which almost always holds in practice);
- *practically*, dynamic programming is up to five times faster (with the same accuracy) as conventional beam-search on top of a state-of-the-art shift-reduce dependency parser;
- as a by-product, dynamic programming can output a *forest* encoding exponentially many trees, out of which we can draw better and longer k-best lists than beam search can;
- finally, better and faster search also leads to better and faster learning. Our final parser achieves the best (unlabeled) accuracies that we are aware of in both English and Chinese among dependency parsers trained on the Penn Treebanks. Being linear-time, it is also much faster than most other parsers, even with a pure Python implementation.

[1] McDonald et al. (2005b) is a notable exception: the MST algorithm is exact search but not dynamic programming.

input: $w_0 \ldots w_{n-1}$

axiom $0 : \langle 0,\ \epsilon \rangle : 0$

$$\textsf{sh} \quad \frac{\ell : \langle j,\ S \rangle : c}{\ell + 1 : \langle j+1,\ S|w_j \rangle : c + \xi} \ j < n$$

$$\textsf{re}_{\curvearrowleft} \quad \frac{\ell : \langle j,\ S|s_1|s_0 \rangle : c}{\ell + 1 : \langle j,\ S|s_1{}^{\curvearrowleft}s_0 \rangle : c + \lambda}$$

$$\textsf{re}_{\curvearrowright} \quad \frac{\ell : \langle j,\ S|s_1|s_0 \rangle : c}{\ell + 1 : \langle j,\ S|s_1{}^{\curvearrowright}s_0 \rangle : c + \rho}$$

goal $2n - 1 : \langle n,\ s_0 \rangle : c$

where ℓ is the step, c is the cost, and the shift cost ξ and reduce costs λ and ρ are:

$$\xi = \mathbf{w} \cdot \mathbf{f}_{\textsf{sh}}(j, S) \quad (1)$$
$$\lambda = \mathbf{w} \cdot \mathbf{f}_{\textsf{re}_{\curvearrowleft}}(j, S|s_1|s_0) \quad (2)$$
$$\rho = \mathbf{w} \cdot \mathbf{f}_{\textsf{re}_{\curvearrowright}}(j, S|s_1|s_0) \quad (3)$$

Figure 1: Deductive system of vanilla shift-reduce.

For convenience of presentation and experimentation, we will focus on shift-reduce parsing for dependency structures in the remainder of this paper, though our formalism and algorithm can also be applied to phrase-structure parsing.

2 Shift-Reduce Parsing

2.1 Vanilla Shift-Reduce

Shift-reduce parsing performs a left-to-right scan of the input sentence, and at each step, choose one of the two actions: either *shift* the current word onto the stack, or *reduce* the top two (or more) items at the end of the stack (Aho and Ullman, 1972). To adapt it to dependency parsing, we split the reduce action into two cases, $\textsf{re}_{\curvearrowleft}$ and $\textsf{re}_{\curvearrowright}$, depending on which one of the two items becomes the head after reduction. This procedure is known as "arc-standard" (Nivre, 2004), and has been engineered to achieve state-of-the-art parsing accuracy in Huang et al. (2009), which is also the reference parser in our experiments.[2]

More formally, we describe a parser configuration by a *state* $\langle j, S \rangle$ where S is a stack of trees $s_0, s_1, \ldots$ where s_0 is the top tree, and j is the queue head position (current word q_0 is w_j). At each step, we choose one of the three actions:

1. sh: move the head of queue, w_j, onto stack S as a singleton tree;
2. $\textsf{re}_{\curvearrowleft}$: combine the top two trees on the stack, s_0 and s_1, and replace them with tree $s_1{}^{\curvearrowleft}s_0$.
3. $\textsf{re}_{\curvearrowright}$: combine the top two trees on the stack, s_0 and s_1, and replace them with tree $s_1{}^{\curvearrowright}s_0$.

Note that the shorthand notation $t^{\curvearrowleft}t'$ denotes a new tree by "attaching tree t' as the leftmost child of the root of tree t". This procedure can be summarized as a deductive system in Figure 1. States are organized according to step ℓ, which denotes the number of actions accumulated. The parser runs in linear-time as there are exactly $2n-1$ steps for a sentence of n words.

As an example, consider the sentence *"I saw Al with Joe"* in Figure 2. At step (4), we face a shift-reduce conflict: either combine "saw" and "Al" in a $\textsf{re}_{\curvearrowright}$ action (5a), or shift "with" (5b). To resolve this conflict, there is a **cost** c associated with each state so that we can pick the best one (or few, with a beam) at each step. Costs are accumulated in each step: as shown in Figure 1, actions sh, $\textsf{re}_{\curvearrowleft}$, and $\textsf{re}_{\curvearrowright}$ have their respective costs ξ, λ, and ρ, which are dot-products of the weights $\mathbf{w}$ and *features* extracted from the state and the action.

input: "I saw Al with Joe"

step	*action*	*stack*	*queue*
0	-		I ...
1	sh	I	saw ...
2	sh	I saw	Al ...
3	$\textsf{re}_{\curvearrowleft}$	I$^{\curvearrowleft}$saw	Al ...
4	sh	I$^{\curvearrowleft}$saw Al	with ...
5a	$\textsf{re}_{\curvearrowright}$	I$^{\curvearrowleft}$saw$^{\curvearrowright}$Al	with ...
5b	sh	I$^{\curvearrowleft}$saw Al with	Joe

Figure 2: A trace of vanilla shift-reduce. After step (4), the parser branches off into (5a) or (5b).

2.2 Features

We view features as "abstractions" or (partial) observations of the current state, which is an important intuition for the development of dynamic programming in Section 3. **Feature templates** are functions that draw information from the *feature window* (see Tab. 1(b)), consisting of the top few trees on the stack and the first few words on the queue. For example, one such feature template $f_{100} = s_0.\mathsf{w} \circ q_0.\mathsf{t}$ is a conjunction

[2] There is another popular variant, "arc-eager" (Nivre, 2004; Zhang and Clark, 2008), which is more complicated and less similar to the classical shift-reduce algorithm.

of two **atomic features** s_0.w and q_0.t, capturing the root word of the top tree s_0 on the stack, and the part-of-speech tag of the current head word q_0 on the queue. See Tab. 1(a) for the list of feature templates used in the full model. Feature templates are instantiated for a specific state. For example, at step (4) in Fig. 2, the above template f_{100} will generate a feature instance

$$(s_0.\mathsf{w} = \text{Al}) \circ (q_0.\mathsf{t} = \text{IN}).$$

More formally, we denote $\mathbf{f}$ to be the **feature function**, such that $\mathbf{f}(j, S)$ returns a vector of feature instances for state $\langle j, S\rangle$. To decide which action is the best for the current state, we perform a three-way classification based on $\mathbf{f}(j, S)$, and to do so, we further conjoin these feature instances with the action, producing action-conjoined instances like

$$(s_0.\mathsf{w} = \text{Al}) \circ (q_0.\mathsf{t} = \text{IN}) \circ (action = \mathsf{sh}).$$

We denote $\mathbf{f}_{\mathsf{sh}}(j, S)$, $\mathbf{f}_{\mathsf{re}_\frown}(j, S)$, and $\mathbf{f}_{\mathsf{re}_\smile}(j, S)$ to be the conjoined feature instances, whose dot-products with the weight vector decide the best action (see Eqs. (1-3) in Fig. 1).

2.3 Beam Search and Early Update

To improve on strictly greedy search, shift-reduce parsing is often enhanced with beam search (Zhang and Clark, 2008), where b states develop in parallel. At each step we extend the states in the current beam by applying one of the three actions, and then choose the best b resulting states for the next step. Our dynamic programming algorithm also runs on top of beam search in practice.

To train the model, we use the averaged perceptron algorithm (Collins, 2002). Following Collins and Roark (2004) we also use the "early-update" strategy, where an update happens whenever the gold-standard action-sequence falls off the beam, with the rest of the sequence neglected.[3] The intuition behind this strategy is that later mistakes are often caused by previous ones, and are irrelevant when the parser is on the wrong track. Dynamic programming turns out to be a great fit for early updating (see Section 4.3 for details).

3 Dynamic Programming (DP)

3.1 Merging Equivalent States

The key observation for dynamic programming is to merge "equivalent states" in the same beam (i.e., same step) if they have the same feature values, because they will have the same costs as shown in the deductive system in Figure 1. Thus we can define two states $\langle j, S\rangle$ and $\langle j', S'\rangle$ to be equivalent, notated $\langle j, S\rangle \sim \langle j', S'\rangle$, iff.

$$j = j' \quad \text{and} \quad \mathbf{f}(j, S) = \mathbf{f}(j', S'). \qquad (4)$$

Note that $j = j'$ is also needed because the queue head position j determines which word to shift next. In practice, however, a small subset of atomic features will be enough to determine the whole feature vector, which we call **kernel features** $\widetilde{\mathbf{f}}(j, S)$, defined as the *smallest set* of atomic templates such that

$$\widetilde{\mathbf{f}}(j, S) = \widetilde{\mathbf{f}}(j', S') \Rightarrow \langle j, S\rangle \sim \langle j', S'\rangle.$$

For example, the full list of 28 feature templates in Table 1(a) can be determined by just 12 atomic features in Table 1(c), which just look at the root words and tags of the top two trees on stack, as well as the tags of their left- and rightmost children, plus the root tag of the third tree s_2, and finally the word and tag of the queue head q_0 and the

where $\xi = \mathbf{w} \cdot \mathbf{f}_{\mathsf{sh}}(j, s_d...s_0)$, and $\delta = \xi' + \lambda$, with $\xi' = \mathbf{w} \cdot \mathbf{f}_{\mathsf{sh}}(i, s'_d...s'_0)$ and $\lambda = \mathbf{w} \cdot \mathbf{f}_{\mathsf{re}_\curvearrowright}(j, s_d...s_0)$.

Figure 3: Deductive system for shift-reduce parsing with dynamic programming. The predictor state set π is an implicit graph-structured stack (Tomita, 1988) while the prefix cost c is inspired by Stolcke (1995). The re$_\curvearrowright$ case is similar, replacing $s'_0 \curvearrowleft s_0$ with $s'_0 \curvearrowright s_0$, and λ with $\rho = \mathbf{w} \cdot \mathbf{f}_{\mathsf{re}_\curvearrowright}(j, s_d...s_0)$. Irrelevant information in a deduction step is marked as an underscore (_) which means "can match anything".

tag of the next word q_1. Since the queue is *static information* to the parser (unlike the stack, which changes dynamically), we can use j to replace features from the queue. So in general we write

$$\widetilde{\mathbf{f}}(j, S) = (j, \mathbf{f}_d(s_d), \ldots, \mathbf{f}_0(s_0))$$

if the feature window looks at top $d + 1$ trees on stack, and where $\mathbf{f}_i(s_i)$ extracts kernel features from tree s_i ($0 \le i \le d$). For example, for the full model in Table 1(a) we have

$$\widetilde{\mathbf{f}}(j, S) = (j, \mathbf{f}_2(s_2), \mathbf{f}_1(s_1), \mathbf{f}_0(s_0)), \qquad (5)$$

where $d = 2$, $\mathbf{f}_2(x) = x.\mathsf{t}$, and $\mathbf{f}_1(x) = \mathbf{f}_0(x) = (x.\mathsf{w}, x.\mathsf{t}, x.\mathsf{lc.t}, x.\mathsf{rc.t})$ (see Table 1(c)).

3.2 Graph-Structured Stack and Deduction

Now that we have the kernel feature functions, it is intuitive that we might only need to remember the relevant bits of information from only the *last* $(d + 1)$ *trees* on stack instead of the whole stack, because they provide all the relevant information for the features, and thus determine the costs. For shift, this suffices as the stack grows on the right; but for reduce actions the stack shrinks, and in order still to maintain $d + 1$ trees, we have to know something about the history. This is exactly why we needed the full stack for vanilla shift-reduce parsing in the first place, and why dynamic programming seems hard here.

To solve this problem we borrow the idea of "graph-structured stack" (GSS) from Tomita (1991). Basically, each state p carries with it a set $\pi(p)$ of **predictor states**, each of which can be combined with p in a reduction step. In a shift step, if state p generates state q (we say "p predicts q" in Earley (1970) terms), then p is added onto $\pi(q)$. When two equivalent shifted states get merged, their predictor states get combined. In a reduction step, state q tries to combine with every predictor state $p \in \pi(q)$, and the resulting state r inherits the predictor states set from p, i.e., $\pi(r) = \pi(p)$. Interestingly, when two equivalent reduced states get merged, we can prove (by induction) that their predictor states are identical (proof omitted).

Figure 3 shows the new deductive system with dynamic programming and GSS. A new state has the form

$$\ell : \langle i,\ j,\ s_d...s_0\rangle$$

where $[i..j]$ is the span of the top tree s_0, and $s_d..s_1$ are merely "left-contexts". It can be combined with some predictor state p spanning $[k..i]$

$$\ell' : \langle k,\ i,\ s'_d...s'_0\rangle$$

to form a larger state spanning $[k..j]$, with the resulting top tree being either $s_1 \curvearrowleft s_0$ or $s_1 \curvearrowright s_0$.

This style resembles CKY and Earley parsers. In fact, the *chart* in Earley and other agenda-based parsers is indeed a GSS when viewed left-to-right. In these parsers, when a state is popped up from the agenda, it looks for possible sibling states that can combine with it; GSS, however, *explicitly* maintains these predictor states so that the newly-popped state does not need to look them up.[4]

3.3 Correctness and Polynomial Complexity

We state the main theoretical result with the proof omitted due to space constraints:

Theorem 1. *The deductive system is optimal and runs in worst-case polynomial time as long as the kernel feature function satisfies two properties:*

- **bounded***:* $\widetilde{\mathbf{f}}(j, S) = (j, \mathbf{f}_d(s_d), \ldots, \mathbf{f}_0(s_0))$ *for some constant* d*, and each* $|\mathbf{f}_t(x)|$ *also bounded by a constant for all possible tree* x*.*
- **monotonic***:* $\mathbf{f}_t(x) = \mathbf{f}_t(y) \Rightarrow \mathbf{f}_{t+1}(x) = \mathbf{f}_{t+1}(y)$*, for all* t *and all possible trees* x*,* y*.*

Intuitively, boundedness means features can only look at a local window and can only extract bounded information on each tree, which is always the case in practice since we can not have infinite models. Monotonicity, on the other hand, says that features drawn from trees farther away from the top should *not* be more refined than from those closer to the top. This is also natural, since the information most relevant to the current decision is always around the stack top. For example, the kernel feature function in Eq. 5 is bounded and monotonic, since $\mathbf{f}_2$ is less refined than $\mathbf{f}_1$ and $\mathbf{f}_0$.

These two requirements are related to grammar refinement by annotation (Johnson, 1998), where annotations must be bounded and monotonic: for example, one cannot refine a grammar by only remembering the grandparent but not the parent symbol. The difference here is that the annotations are not vertical ((grand-)parent), but rather *horizontal* (left context). For instance, a context-free rule $A \rightarrow B\ C$ would become ${}^{D}A \rightarrow {}^{D}B\ {}^{B}C$ for some D if there exists a rule $E \rightarrow \alpha D A \beta$. This resembles the reduce step in Fig. 3.

The very high-level idea of the proof is that boundedness is crucial for polynomial-time, while monotonicity is used for the optimal substructure property required by the correctness of DP.

[4] In this sense, GSS (Tomita, 1988) is really not a new invention: an efficient implementation of Earley (1970) should already have it implicitly, similar to what we have in Fig. 3.

3.4 Beam Search based on Prefix Cost

Though the DP algorithm runs in polynomial-time, in practice the complexity is still too high, esp. with a rich feature set like the one in Table 1. So we apply the same beam search idea from Sec. 2.3, where each step can accommodate only the best b states. To decide the ordering of states in each beam we borrow the concept of **prefix cost** from Stolcke (1995), originally developed for weighted Earley parsing. As shown in Fig. 3, the prefix cost c is the total cost of the best action sequence from the initial state to the end of state p, i.e., it includes both the **inside cost** v (for Viterbi inside derivation), and the cost of the (best) path leading towards the beginning of state p. We say that a state p with prefix cost c is better than a state p' with prefix cost c', notated $p \prec p'$ in Fig. 3, if $c < c'$. We can also prove (by contradiction) that optimizing for prefix cost implies optimal inside cost (Nederhof, 2003, Sec. 4). [5]

As shown in Fig. 3, when a state q with costs (c, v) is combined with a predictor state p with costs (c', v'), the resulting state r will have costs

$$(c' + v + \delta,\ v' + v + \delta),$$

where the inside cost is intuitively the combined inside costs plus an additional combo cost δ from the combination, while the resulting prefix cost $c' + v + \delta$ is the sum of the prefix cost of the predictor state q, the inside cost of the current state p, and the combo cost. Note the prefix cost of q is irrelevant. The combo cost $\delta = \xi' + \lambda$ consists of shift cost ξ' of p and reduction cost λ of q.

The cost in the non-DP shift-reduce algorithm (Fig. 1) is indeed a prefix cost, and the DP algorithm subsumes the non-DP one as a special case where no two states are equivalent.

3.5 Example: Edge-Factored Model

As a concrete example, Figure 4 simulates an edge-factored model (Eisner, 1996; McDonald et al., 2005a) using shift-reduce with dynamic programming, which is similar to bilexical PCFG parsing using CKY (Eisner and Satta, 1999). Here the kernel feature function is

$$\widetilde{\mathbf{f}}(j, S) = (j, h(s_1), h(s_0))$$

[5] Note that using inside cost v for ordering would be a bad idea, as it will always prefer shorter derivations like in best-first parsing. As in A* search, we need some estimate of "outside cost" to predict which states are more promising, and the prefix cost includes an exact cost for the left outside context, but no right outside context.

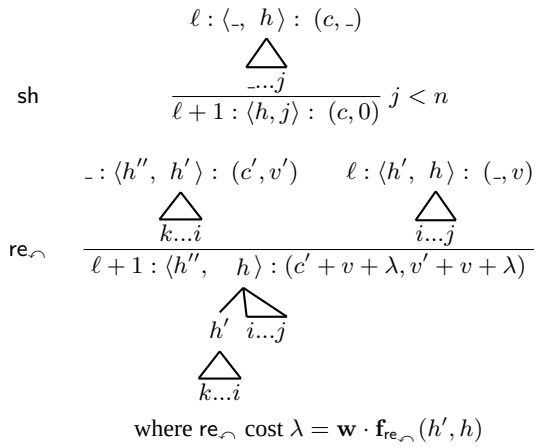

Figure 4: Example of shift-reduce with dynamic programming: simulating an edge-factored model. GSS is implicit here, and re$_\frown$ case omitted.

where $h(x)$ returns the head word index of tree x, because all features in this model are based on the head and modifier indices in a dependency link. This function is obviously bounded and monotonic in our definitions. The theoretical complexity of this algorithm is $O(n^7)$ because in a reduction step we have three span indices and three head indices, plus a step index ℓ. By contrast, the naïve CKY algorithm for this model is $O(n^5)$ which can be improved to $O(n^3)$ (Eisner, 1996).[6] The higher complexity of our algorithm is due to two factors: first, we have to maintain both h and h' in one state, because the current shift-reduce model can not draw features *across* different states (unlike CKY); and more importantly, we group states by step ℓ in order to achieve incrementality and linear runtime with beam search that is not (easily) possible with CKY or MST.

4 Experiments

We first reimplemented the reference shift-reduce parser of Huang et al. (2009) in Python (henceforth "non-DP"), and then extended it to do dynamic programing (henceforth "DP"). We evaluate their performances on the standard Penn Treebank (PTB) English dependency parsing task[7] using the standard split: secs 02-21 for training, 22 for development, and 23 for testing. Both DP and non-DP parsers use the same feature templates in Table 1. For Secs. 4.1-4.2, we use a baseline model trained with non-DP for both DP and non-DP, so that we can do a side-by-side comparison of search quality; in Sec. 4.3 we will retrain the model with DP and compare it against training with non-DP.

4.1 Speed Comparisons

To compare parsing speed between DP and non-DP, we run each parser on the development set, varying the beam width b from 2 to 16 (DP) or 64 (non-DP). Fig. 5a shows the relationship between search quality (as measured by the average model score per sentence, higher the better) and speed (average parsing time per sentence), where DP with a beam width of b=16 achieves the same search quality with non-DP at b=64, while being 5 times faster. Fig. 5b shows a similar comparison for dependency accuracy. We also test with an edge-factored model (Sec. 3.5) using feature templates (1)-(3) in Tab. 1, which is a subset of those in McDonald et al. (2005b). As expected, this difference becomes more pronounced (8 times faster in Fig. 5c), since the less expressive feature set makes more states "equivalent" and mergeable in DP. Fig. 5d shows the (almost linear) correlation between dependency accuracy and search quality, confirming that better search yields better parsing.

4.2 Search Space, Forest, and Oracles

DP achieves better search quality because it expores an exponentially large search space rather than only b trees allowed by the beam (see Fig. 6a). As a by-product, DP can output a *forest* encoding these exponentially many trees, out of which we can draw longer and better (in terms of oracle) k-best lists than those in the beam (see Fig. 6b). The forest itself has an oracle of 98.15 (as if $k \rightarrow \infty$), computed à la Huang (2008, Sec. 4.1). These candidate sets may be used for reranking (Charniak and Johnson, 2005; Huang, 2008).[8]

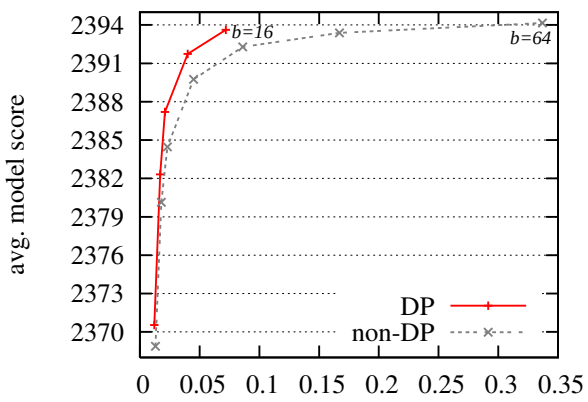
4.3 Perceptron Training and Early Updates

Another interesting advantage of DP over non-DP is the faster training with perceptron, even when both parsers use the same beam width. This is due to the use of early updates (see Sec. 2.3), which happen much more often with DP, because a gold-standard state p is often merged with an equivalent (but incorrect) state that has a higher model score, which triggers update immediately. By contrast, in non-DP beam search, states such as p might still

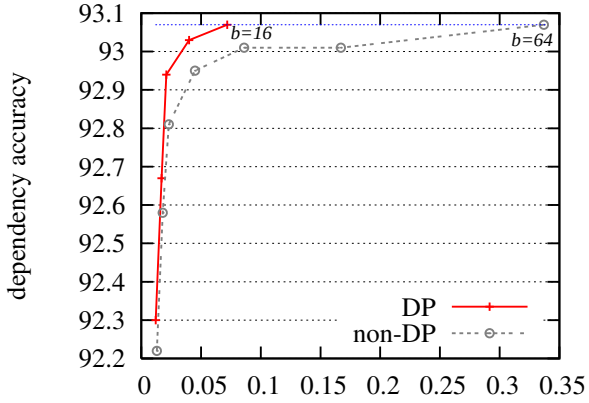
[6] Or $O(n^2)$ with MST, but including non-projective trees.

[7] Using the head rules of Yamada and Matsumoto (2003).

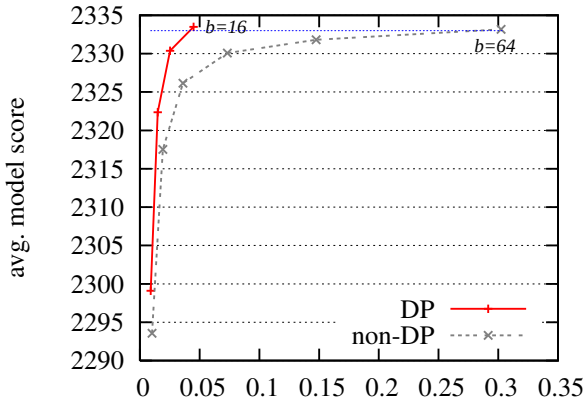
[8] DP's k-best lists are extracted from the forest using the algorithm of Huang and Chiang (2005), rather than those in the final beam as in the non-DP case, because many derivations have been merged during dynamic programming.



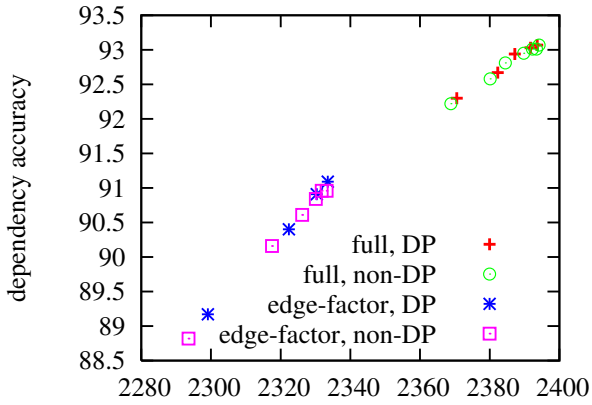
(a) search quality vs. time (full model)



(b) parsing accuracy vs. time (full model)

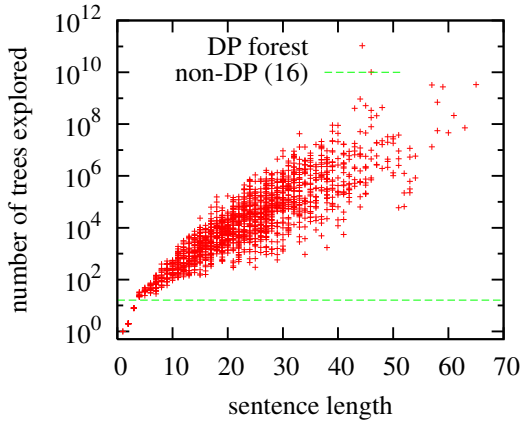


(c) search quality vs. time (edge-factored model)

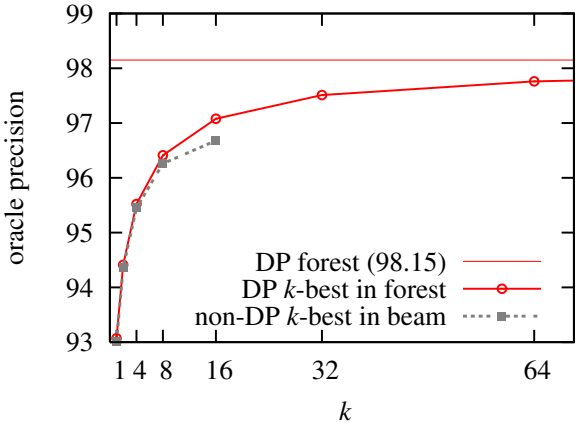


(d) correlation b/w parsing (y) and search (x)

Figure 5: Speed comparisons between DP and non-DP, with beam size b ranging 2∼16 for DP and 2∼64 for non-DP. Speed is measured by avg. parsing time (secs) per sentence on x axis. With the same level of search quality or parsing accuracy, DP (at b=16) is ∼4.8 times faster than non-DP (at b=64) with the full model in plots (a)-(b), or ∼8 times faster with the simplified edge-factored model in plot (c). Plot (d) shows the (roughly linear) correlation between parsing accuracy and search quality (avg. model score).



(a) sizes of search spaces



(b) oracle precision on dev

Figure 6: DP searches over a forest of *exponentially many* trees, which also produces better and longer k-best lists with higher oracles, while non-DP only explores b trees allowed in the beam ($b = 16$ here).

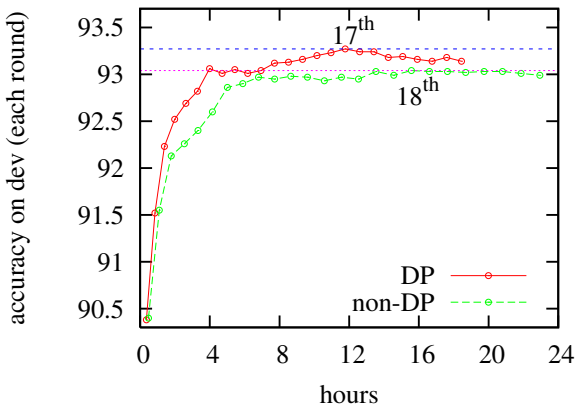


Figure 7: Learning curves (showing precision on dev) of perceptron training for 25 iterations (b=8). DP takes 18 hours, peaking at the 17th iteration (93.27%) with 12 hours, while non-DP takes 23 hours, peaking at the 18th (93.04%) with 16 hours.

survive in the beam throughout, even though it is no longer possible to rank the best in the beam.

The higher frequency of early updates results in faster iterations of perceptron training. Table 2 shows the percentage of early updates and the time per iteration during training. While the number of updates is roughly comparable between DP and non-DP, the rate of early updates is much higher with DP, and the time per iteration is consequently shorter. Figure 7 shows that training with DP is about 1.2 times faster than non-DP, and achieves +0.2% higher accuracy on the dev set (93.27%).

Besides training with gold POS tags, we also trained on noisy tags, since they are closer to the test setting (automatic tags on sec 23). In that case, we tag the dev and test sets using an automatic POS tagger (at 97.2% accuracy), and tag the training set using four-way jackknifing similar to Collins (2000), which contributes another +0.1% improvement in accuracy on the test set. Faster training also enables us to incorporate more features, where we found more lookahead features (q_2) results in another +0.3% improvement.

4.4 Final Results on English and Chinese

Table 3 presents the final test results of our DP parser on the Penn English Treebank, compared with other state-of-the-art parsers. Our parser achieves the highest (unlabeled) dependency accuracy among dependency parsers trained on the Treebank, and is also much faster than most other parsers even with a pure Python implementation

it	update	early%	time	update	early%	time
1	31943	98.9	22	31189	87.7	29
5	20236	98.3	38	19027	70.3	47

Table 3: Final test results on English (PTB). Our parser (in pure Python) has the highest accuracy among dependency parsers trained on the Treebank, and is also much faster than major parsers. †converted from constituency trees. C=C/C++, Py=Python, Ja=Java. Time is in seconds per sentence. Search spaces: ‡linear; others exponential.

(on a 3.2GHz Xeon CPU). Best-performing constituency parsers like Charniak (2000) and Berkeley (Petrov and Klein, 2007) do outperform our parser, since they consider more information during parsing, but they are at least 5 times slower. Figure 8 shows the parse time in seconds for each test sentence. The observed time complexity of our DP parser is in fact linear compared to the superlinear complexity of Charniak, MST (McDonald et al., 2005b), and Berkeley parsers. Additional techniques such as semi-supervised learning (Koo et al., 2008) and parser combination (Zhang and Clark, 2008) do achieve accuracies equal to or higher than ours, but their results are not directly comparable to ours since they have access to extra information like unlabeled data. Our technique is orthogonal to theirs, and combining these techniques could potentially lead to even better results.

We also test our final parser on the Penn Chinese Treebank (CTB5). Following the set-up of Duan et al. (2007) and Zhang and Clark (2008), we split CTB5 into training (secs 001-815 and 1001-

1136), development (secs 886-931 and 1148-1151), and test (secs 816-885 and 1137-1147) sets, assume gold-standard POS-tags for the input, and use the head rules of Zhang and Clark (2008). Table 4 summarizes the final test results, where our work performs the best in all four types of (unlabeled) accuracies: word, non-root, root, and complete match (all excluding punctuations). [9,10]

5 Related Work

This work was inspired in part by Generalized LR parsing (Tomita, 1991) and the graph-structured stack (GSS). Tomita uses GSS for exhaustive LR parsing, where the GSS is equivalent to a dynamic programming chart in chart parsing (see Footnote 4). In fact, Tomita's GLR is an instance of techniques for tabular simulation of nondeterministic pushdown automata based on deductive systems (Lang, 1974), which allow for cubic-time exhaustive shift-reduce parsing with context-free grammars (Billot and Lang, 1989).

Our work advances this line of research in two aspects. First, ours is more general than GLR in that it is not restricted to LR (a special case of shift-reduce), and thus does not require building an LR table, which is impractical for modern grammars with a large number of rules or features. In contrast, we employ the ideas behind GSS more flexibly to merge states based on features values, which can be viewed as constructing an implicit LR table *on-the-fly*. Second, unlike previous theoretical results about cubic-time complexity, we achieved linear-time performance by smart beam search with prefix cost inspired by Stolcke (1995), allowing for state-of-the-art data-driven parsing.

To the best of our knowledge, our work is the first linear-time incremental parser that performs dynamic programming. The parser of Roark and Hollingshead (2009) is also almost linear time, but they achieved this by discarding parts of the CKY chart, and thus do achieve incrementality.

6 Conclusion

We have presented a dynamic programming algorithm for shift-reduce parsing, which runs in linear-time in practice with beam search. This framework is general and applicable to a large-class of shift-reduce parsers, as long as the feature functions satisfy boundedness and monotonicity. Empirical results on a state-the-art dependency parser confirm the advantage of DP in many aspects: faster speed, larger search space, higher oracles, and better and faster learning. Our final parser outperforms all previously reported dependency parsers trained on the Penn Treebanks for both English and Chinese, and is much faster in speed (even with a Python implementation). For future work we plan to extend it to constituency parsing.

Abstract

For languages with (semi-) free word order (such as German), labelling grammatical functions on top of phrase-structural constituent analyses is crucial for making them interpretable. Unfortunately, most statistical classifiers consider only local information for function labelling and fail to capture important restrictions on the distribution of core argument functions such as subject, object etc., namely that there is at most one subject (etc.) per clause. We augment a statistical classifier with an integer linear program imposing hard linguistic constraints on the solution space output by the classifier, capturing global distributional restrictions. We show that this improves labelling quality, in particular for argument grammatical functions, in an intrinsic evaluation, and, importantly, grammar coverage for treebank-based (Lexical-Functional) grammar acquisition and parsing, in an extrinsic evaluation.

1 Introduction

Phrase or constituent structure is often regarded as an analysis step guiding semantic interpretation, while grammatical functions (i. e. subject, object, modifier etc.) provide important information relevant to determining predicate-argument structure.

In languages with restricted word order (e. g. English), core grammatical functions can often be recovered from configurational information in constituent structure analyses. By contrast, simple constituent structures are not sufficient for less configurational languages, which tend to encode grammatical functions by morphological means (Bresnan, 2001). Case features, for instance, can be important indicators of grammatical functions. Unfortunately, many of these languages (including German) exhibit strong syncretism where morphological cues can be highly ambiguous with respect to functional information.

Statistical classifiers have been successfully used to label constituent structure parser output with grammatical function information (Blaheta and Charniak, 2000; Chrupała and Van Genabith, 2006). However, as these approaches tend to use only limited and local context information for learning and prediction, they often fail to enforce simple yet important global linguistic constraints that exist for most languages, e. g. that there will be at most one subject (object) per sentence/clause.[1]

"Hard" linguistic constraints, such as these, tend to affect mostly the "core grammatical functions", i. e. the argument functions (rather than e. g. adjuncts) of a particular predicate. As these functions constitute the core meaning of a sentence (as in: who did what to whom), it is important to get them right. We present a system that adds grammatical function labels to constituent parser output for German in a postprocessing step. We combine a statistical classifier with an integer linear program (ILP) to model non-violable global linguistic constraints, restricting the solution space of the classifier to those labellings that comply with our set of global constraints. There are, of course, many other ways of including functional information into the output of a syntactic parser. Klein and Manning (2003) show that merging some linguistically motivated function labels with specific syntactic categories can improve the performance of a PCFG model on Penn-II En-

[1] Coordinate subjects/objects form a constituent that functions as a joint subject/object.

Uppsala, Sweden, 11-16 July 2010.

glish data.[2] Tsarfaty and Sim'aan (2008) present a statistical model (Relational-Realizational Parsing) that alternates between functional and configurational information for constituency tree parsing and Hebrew data. Dependency parsers like the MST parser (McDonald and Pereira, 2006) and Malt parser (Nivre et al., 2007) use function labels as core part of their underlying formalism. In this paper, we focus on phrase structure parsing with function labelling as a post-processing step.

Integer linear programs have already been successfully used in related fields including semantic role labelling (Punyakanok et al., 2004), relation and entity classification (Roth and Yih, 2004), sentence compression (Clarke and Lapata, 2008) and dependency parsing (Martins et al., 2009). Early work on function labelling for German (Brants et al., 1997) reports 94.2% accuracy on gold data (a very early version of the TiGer Treebank (Brants et al., 2002)) using Markov models. Klenner (2007) uses a system similar to – but more restricted than – ours to label syntactic chunks derived from the TiGer Treebank. His research focusses on the correct selection of predefined subcategorisation frames for a verb (see also Klenner (2005)). By contrast, our research does not involve subcategorisation frames as an external resource, instead opting for a less knowledge-intensive approach. Klenner's system was evaluated on gold treebank data and used a small set of 7 dependency labels. We show that an ILP-based approach can be scaled to a large and comprehensive set of 42 labels, achieving 97.99% label accuracy on gold standard trees. Furthermore, we apply the system to automatically parsed data using a state-of-the-art statistical phrase-structure parser with a label accuracy of 94.10%. In both cases, the ILP-based approach improves the quality of argument function labelling when compared with a non-ILP-approach. Finally, we show that the approach substantially improves the quality and coverage (from 93.6% to 98.4%) of treebank-based Lexical-Functional Grammars for German over previous work in Rehbein and van Genabith (2009).

The paper is structured as follows: Section 2 presents basic data demonstrating the challenges presented by German word order and case syncretism for the function labeller. Section 3 describes the labeller including the feature model of the classifier and the integer linear program used to pick the correct labelling. The evaluation part (Section 4) is split into an intrinsic evaluation measuring the quality of the labelling directly using the German TiGer Treebank (Brants et al., 2002), and an extrinsic evaluation where we test the impact of the constraint-based labelling on treebank-based automatic LFG grammar acquisition.

2 Data

Unlike English, German exhibits a relatively free word order, i. e. in main clauses, the verb occupies second position (the last position in subordinated clauses) and arguments and adjuncts can be placed (fairly) freely. The grammatical function of a noun phrase is marked morphologically on its constituting parts. Determiners, pronouns, adjectives and nouns carry case markings and in order to be well-formed, all parts of a noun phrase have to agree on their case features. German uses a nominative–accusative system to mark predicate arguments. Subjects are marked with nominative case, direct objects carry accusative case. Furthermore, indirect objects are mostly marked with dative case and sometimes genitive case.

(1) *Der Löwe* *gibt* *dem Wolf* *einen Besen.*
NOM DAT ACC
the lion gives the wolf a broom
The lion gives a broom to the wolf.

(1) shows a sentence containing the ditransitive verb *geben* (to give) with its three arguments. Here, the subject is unambiguously marked with nominative case (NOM), the indirect object with dative case (DAT) and the direct object with accusative case (ACC). (2) shows possible word orders for the arguments in this sentence.[3]

(2) Der Löwe gibt einen Besen dem Wolf.
Dem Wolf gibt der Löwe einen Besen.
Dem Wolf gibt einen Besen der Löwe.
Einen Besen gibt der Löwe dem Wolf.
Einen Besen gibt dem Wolf der Löwe.

Since all permutations of arguments are possible, there is no chance for a statistical classifier to decide on the correct function of a noun phrase by its position alone. Introducing adjuncts to this example makes matters even worse.

[2] Table 6 shows that for our data a model with merged category and function labels (but without hard constraints!) performs slightly worse than the ILP approach developed in this paper.

[3] Note that although (apart from the position of the finite verb) there are no syntactic restrictions on the word order, there are restrictions pertaining to phonological or information structure.

Case information for a given noun phrase can give a classifier some clue about the correct argument function, since functions are strongly related to case values. Unfortunately, the German case system is complex (see Eisenberg (2006) for a thorough description) and exhibits a high degree of case syncretism. (3) shows a sentence where both argument NPs are ambiguous between nominative or accusative case. In such cases, additional semantic or contextual information is required for disambiguation. A statistical classifier (with access to local information only) runs a high risk of incorrectly classifying both NPs as subjects, or both as direct objects or even as nominal predicates (which are also required to carry nominative case). This would leave us with uninterpretable results. Uninterpretability of this kind can be avoided if we are able to constrain the number of subjects and objects globally to one per clause.[4]

(3) *Das Schaf* *sieht* *das Mädchen.*
NOM/ACC NOM/ACC
the sheep sees the girl
EITHER The sheep sees the girl
OR The girl sees the sheep.

3 Grammatical Function Labelling

Our function labeller was developed and tested on the TiGer Treebank (Brants et al., 2002). The TiGer Treebank is a phrase-structure and grammatical function annotated treebank with 50,000 newspaper sentences from the *Frankfurter Rundschau* (Release 2, July 2006). Its overall annotation scheme is quite flat to account for the relatively free word order of German and does not allow for unary branching. The annotations use non-projective trees modelling long distance dependencies directly by crossing branches. Words are lemmatised and part-of-speech tagged with the *Stuttgart-Tübingen Tag Set (STTS)* (Schiller et al., 1999) and contain morphological annotations (Release 2). TiGer uses 25 syntactic categories and a set of 42 function labels to annotate the grammatical function of a phrase.

The function labeller consists of two main components, a maximum entropy classifier and an integer linear program. This basic architecture was introduced by Punyakanok et al. (2004) for the task of semantic role labelling and since then has been applied to different NLP tasks without significant changes. In our case, its input is a bare tree structure (as obtained by a standard phrase structure parser) and it outputs a tree structure where every node is labelled with the grammatical relation it bears to its mother node. For each possible label and for each node, the classifier assigns a probability that this node is labelled by this label. This results in a complete probability distribution over all labels for each node. An integer linear program then tries to find the optimal overall tree labelling by picking for each node the label with the highest probability without violating any of its constraints. These constraints implement linguistic rules like the *one-subject-per-sentence* rule mentioned above. They can also be used to capture treebank particulars, such as for example that punctuation marks never receive a label.

3.1 The Feature Model

Maximum entropy classifiers have been used in a wide range of applications in NLP for a long time (Berger et al., 1996; Ratnaparkhi, 1998). They usually give good results while at the same time allowing for the inclusion of arbitrarily complex features. They also have the advantage that they directly output probability distributions over their set of labels (unlike e. g. SVMs).

The classifier uses the following features:

- the lemma (if terminal node)
- the category (the POS for terminal nodes)
- the number of left/right sisters
- the category of the two left/right sisters
- the number of daughters
- the number of terminals covered
- the lemma of the left/right corner terminal
- the category of the left/right corner terminal
- the category of the mother node
- the category of the mother's head node
- the lemma of the mother's head node
- the category of the grandmother node
- the category of the grandmother's head node
- the lemma of the grandmother's head node
- the case features for noun phrases
- the category for PP objects
- the lemma for PP objects (if terminal node)

These features are also computed for the head of the phrase, determined using a set of head-finding rules in the style of Magerman (1995) adapted to TiGer. For lemmatisation, we use TreeTagger (Schmid, 1994) and case features of noun

[4] Although the classifier may, of course, still identify the wrong phrase as subject or object.

phrases are obtained from a full German morphological analyser based on (Schiller, 1994). If a noun phrase consists of a single word (e. g. pronouns, but also bare common nouns and proper nouns), all case values output by the analyser are used to reflect the case syncretism. For multi-word noun phrases, the case feature is computed by taking the intersection of all case-bearing words inside the noun phrase, i. e. determiners, pronouns, adjectives, common nouns and proper nouns. If, for some reason (e.g., due to a bracketing error in phrase structure parsing), the intersection turns out to be empty, all four case values are assigned to the phrase.[5]

3.2 Constrained Optimisation

In the second step, a binary integer linear program is used to select those labels that optimise the whole tree labelling. A linear program consists of a linear objective function that is to be maximised (or minimised) and a set of constraints which impose conditions on the variables of the objective function (see (Clarke and Lapata, 2008) for a short but readable introduction). Although solving a linear program has polynomial complexity, requiring the variables to be integral or binary makes finding a solution exponentially hard in the worst case. Fortunately, there are efficient algorithms which are capable of handling a large number of variables and constraints in practical applications.[6]

For the function labeller, we define the set of binary variables $V = N \times L$ to be the crossproduct of the set of nodes N and the set of labels L. Setting a variable $x_{n,l}$ to 1 means that node n is labelled by label l. Every variable is weighted by the probability $w_{n,l} = P(l|f(n))$ which the classifier has assigned to this node-label combination. The objective function that we seek to optimise is defined as the sum over all weighted variables:

$$\max \sum_{n \in N} \sum_{l \in L} w_{n,l} x_{n,l} \tag{4}$$

Since we want every node to receive exactly one label, we add a constraint that for every node n, exactly one of its variables is set to 1.

$$\sum_{l \in L} x_{n,l} = 1 \tag{5}$$

Up to now, the whole system is doing exactly the same as an ordinary classifier that always takes the most probable label for each node. We will now add additional global and local linguistic constraints.[7]

The first and most important constraint restricts the number of each argument function (as opposed to modifier functions) to at most one per clause. Let $D \subset N \times N$ be the direct dominance relation between the nodes of the current tree. For every node n with category S (sentence) or VP (verb phrase), at most one of its daughters is allowed to be labelled SB (subject). The single-subject-function condition is defined as:

$$cat(n) \in \{S, VP\} \longrightarrow \sum_{\langle n,m \rangle \in D} x_{m,SB} \leq 1 \tag{6}$$

Identical constraints are added for labels OA, OA2, DA, OG, OP, PD, OC, EP.[8]

We add further constraints to capture the following linguistic restrictions:

- Of all daughters of a phrase, only one is allowed to be labelled HD (head).

$$\sum_{\langle n,m \rangle \in D} x_{m,HD} \leq 1 \tag{7}$$

- If a noun phrase carries no case feature for nominative case, it cannot be labelled SB, PD or EP.

$$case(n) \neq nom \longrightarrow \sum_{l \in \{SB,PD,EP\}} x_{n,l} = 0 \tag{8}$$

- If a noun phrase carries no case feature for accusative case, it cannot be labelled OA or OA2.
- If a noun phrase carries no case feature for dative case, it cannot be labelled DA.
- If a noun phrase carries no case feature for genitive case, it cannot be labelled OG or AG[9].

[5] We decided to train the classifier on automatically assigned and possibly ambiguous morphological information instead of on the hand-annotated and manually disambiguated morphological information provided by TiGer because we want the classifier to learn the German case syncretism. This way, the classifier will perform better when presented with unseen data (e.g. from parser output) for which no hand-annotated morphological information is available.

[6] See lpsolve (http://lpsolve.sourceforge.net/) or GLPK (http://www.gnu.org/software/glpk/glpk.html) for open-source implementations

[7] Note that some of these constraints are language specific in that they represent linguistic facts about German and do not necessarily hold for other languages. Furthermore, the constraints are treebank specific to a certain degree in that they use a TiGer-specific set of labels and are conditioned on TiGer-specific configurations and categories.

[8] SB = subject, OA = accusative object, OA2 = second accusative object, DA = dative, OG = genitive object, OP = prepositional object, PD = predicate, OC = clausal object, EP = expletive es

[9] AG = genitive adjunct

Unlike Klenner (2007), we do not use predefined subcategorization frames, instead letting the statistical model choose arguments.

In TiGer, sentences whose main verbs are formed from auxiliary-participle combinations, are annotated by embedding the participle under an extra VP node and non-subject arguments are sisters to the participle. Therefore we add an extension of the constraint in (6) to the constraint set in order to also include the daughters of an embedded VP node in such a case.

Because of the particulars of the annotation scheme of TiGer, we can decide some labels in advance. As mentioned before, punctuation does not get a label in TiGer. We set the label for those nodes to $--$ (no label). Other examples are:

- If a node's category is PTKVZ (separated verb particle), it is labeled SVP (separable verb particle).

$$cat(n) = PTKVZ \longrightarrow x_{n,SVP} = 1 \quad (9)$$

- If a node's category is APPR, APPRART, APPO or APZR (prepositions), it is labeled AC (adpositional case marker).
- All daughters of an MTA node (multi-token adjective) are labeled ADC (adjective component).

These constraints are conditioned on part-of-speech tags and require high POS-tagging accuracy (when dealing with raw text).

Due to the constraints imposed on the classification, the function labeller can no longer assign two subjects to the same S node. Faced with two nodes whose most probable label is SB, it has to decide on one of them taking the next best label for the other. This way, it outputs the optimal solution with respect to the set of constraints. Note that this requires the feature model not only to rank the correct label highest but also to provide a reasonable ranking of the other labels as well.

4 Evaluation

We conducted a number of experiments using 1,866 sentences of the TiGer Dependency Bank (Forst et al., 2004) as our test set. The TiGerDB is a part of the TiGer Treebank semi-automatically converted into a dependency representation. We use the manually labelled TiGer trees corresponding to the sentences in the TiGerDB for assessing the labelling quality in the intrinsic evaluation, and the dependencies from TiGerDB for assessing the quality and coverage of the automatically acquired LFG resources in the extrinsic evaluation.

In order to test on real parser output, the test set was parsed with the Berkeley Parser (Petrov et al., 2006) trained on 48k sentences of the TiGer corpus (Table 1), excluding the test set. Since the Berkeley Parser assumes projective structures, the training data and test data were made projective by raising non-projective nodes in the tree (Kübler, 2005).

precision	83.60	recall	82.81
f-score	83.20	tagging acc.	97.97

Table 1: evalb unlabelled parsing scores on test set for Berkeley Parser trained on 48,000 sentences (sentence length ≤ 40)

The maximum entropy classifier of the function labeller was trained on 46,473 sentences of the TiGer Treebank (excluding the test set) which yields about 1.2 million nodes as training samples. For training the Maximum Entropy Model, we used the BLMVM algorithm (Benson and More, 2001) with a width factor of 1.0 (Kazama and Tsujii, 2005) implemented in an open-source C++ library from Tsujii Laboratory.[10] The integer linear program was solved with the simplex algorithm in combination with a branch-and-bound method using the freely available GLPK.[11]

4.1 Intrinsic Evaluation

In the intrinsic evaluation, we measured the quality of the labelling itself. We used the node span evaluation method of (Blaheta and Charniak, 2000) which takes only those nodes into account which have been recognised correctly by the parser, i.e. if there are two nodes in the parse and the reference treebank tree which cover the same word span. Unlike Blaheta and Charniak (2000) however, we do not require the two nodes to carry the same syntactic category label.[12]

Table 2 shows the results of the node span evaluation. The labeller achieves close to 98% label accuracy on gold treebank trees which shows that the feature model captures the differences between the individual labels well. Results on parser output are about 4 percentage points (absolute) lower as parsing errors can distort local context features for the classifier even if the node itself has been parsed

[10] http://www-tsujii.is.s.u-tokyo.ac.jp/∼tsuruoka/maxent/

[11] http://www.gnu.org/software/glpk/glpk.html

[12] We also excluded the root node, all punctuation marks and both nodes in unary branching sub-trees from evaluation.

correctly. The addition of the ILP constraints improves results only slightly since the constraints affect only (a small number of) argument labels while the evaluation considers all 40 labels occurring in the test set. Since the constraints restrict the selection of certain labels, a less probable label has to be picked by the labeller if the most probable is not available. If the classifier is ranking labels sensibly, the correct label should emerge. However, with an incorrect ranking, the ILP constraints might also introduce new errors.

	label accuracy	error red.
without constraints		
gold	44689/45691 = 97.81%	–
parser	40578/43140 = 94.06%	–
with constraints		
gold	44773/45691 = 97.99%*	8.21%
parser	40593/43140 = 94.10%	0.68%

Table 2: label accuracy and error reduction (all labels) for node span evaluation, * statistically significant, sign test, α = 0.01 (Koo and Collins, 2005)

As the main target of the constraint set are argument functions, we also tested the quality of argument labels. Table 3 shows the node span evaluation in terms of precision, recall and f-score for argument functions only, with clear statistically significant improvements.

	prec.	rec.	f-score
without constraints			
gold standard	92.41	91.86	92.13
parser output	88.14	86.43	87.28
with constraints			
gold standard	94.31	92.76	93.53*
parser output	89.51	86.73	88.09*

Table 3: node span results for the test set, argument functions only (SB, EP, PD, OA, OA2, DA, OG, OP, OC), * statistically significant, sign test, α = 0.01 (Koo and Collins, 2005)

For comparison and to establish a highly competitive baseline, we use the best-scoring system in (Chrupała and Van Genabith, 2006), trained and tested on exactly the same data sets. This purely statistical labeller achieves accuracy of 96.44% (gold) and 92.81% (parser) for all labels, and f-scores of 89.88% (gold) and 84.98% (parser) for argument labels. Tables 2 and 3 show that our system (with and even without ILP constraints) comprehensively outperforms all corresponding baseline scores.

The node span evaluation defines a correct labelling by taking only those nodes (in parser output) into account that have a corresponding node in the reference tree. However, as this restricts attention to correctly parsed nodes, the results are somewhat over-optimistic. Table 4 provides the results obtained from an evalb evaluation of the same data sets.[13] The gold standard scores are high confirming our previous findings about the performance of the function labeller. However, the results on parser output are much worse. The evaluation scores are now taking the parsing quality into account (Table 1). The considerable drop in quality between gold trees and parser output clearly shows that a good parse tree is an important prerequisite for reasonable function labelling. This is in accordance with previous findings by Punyakanok et al. (2008) who emphasise the importance of syntactic parsing for the closely related task of semantic role labelling.

	prec.	rec.	f-score

parser output	76.27	75.55	75.91
with constraints			
gold standard	96.21	96.21	96.21
parser output	76.36	75.64	76.00

Table 4: evalb results for the test set

4.1.1 Subcategorisation Frames

Early on in the paper we mention that, unlike e. g. Klenner (2007), we did not include predefined subcategorisation frames into the constraint set, but rather let the joint statistical and ILP models decide on the correct type of arguments assigned to a verb. The assumption is that if one uses predefined subcategorisation frames which fix the number and type of arguments for a verb, one runs the risk of excluding correct labellings due to missing subcat frames, unless a very comprehensive and high quality subcat lexicon resource is available.

In order to test this assumption, we run an additional experiment with about 10,000 verb frames for 4,508 verbs, which were automatically extracted from our training section. Following Klenner (2007), for each verb and for each subcat frame for this verb attested at least once in the training data, we introduce a new binary variable f_n to the ILP model representing the n-th frame (for the verb) weighted by its frequency.

We add an ILP constraint requiring exactly one of the frames to be set to one (each verb has to have a subcat frame) and replace the ILP constraint in (6) by:

[13] Function labels were merged with the category symbols.

$$\sum_{\langle n,m\rangle \in D} x_{m,SB} - \sum_{SB \in f_i} f_i = 0 \qquad (10)$$

This constraint requires the number of subjects in a phrase to be equal to the number of selected[14] verb frames that require a subject. As each verb is constrained to "select" exactly one subcat frame (see additional ILP constraint above), there is at most one subject per phrase, if the frame in question requires a subject. If the selected frame does not require a subject, then the constraint blocks the assignment of subjects for the entire phrase. The same was done for the other argument functions and as before we included an extension of this constraint to cover embedded VPs. For unseen verbs (i.e. verbs not attested in the training set) we keep the original constraints as a back-off.

	prec.	rec.	f-score
all labels (cmp. Table 2)			
gold standard	97.24	97.24	97.24
parser output	93.43	93.43	93.43
argument functions only (cmp. Table 3)			
gold standard	91.36	90.12	90.74
parser output	86.64	84.38	85.49

Table 5: node span results for the test set using constraints with automatically extracted subcat frames

Table 5 shows the results of the test set node span evaluation when using the ILP system enhanced with subcat frames. Compared to Tables 2 and 3, the results are clearly inferior, and particularly so for argument grammatical functions. This seems to confirm our assumption that, given our data, letting the joint statistical and ILP model decide argument functions is superior to an approach that involves subcat frames. However, and importantly, our results do not rule out that a more comprehensive subcat frame resource may in fact result in improvements.

4.2 Extrinsic Evaluation

Over the last number of years, treebank-based deep grammar acquisition has emerged as an attractive alternative to hand-crafting resources within the HPSG, CCG and LFG paradigms (Miyao et al., 2003; Clark and Hockenmaier, 2002; Cahill et al., 2004). While most of the initial development work focussed on English, more recently efforts have branched to other languages. Below we concentrate on LFG.

[14]The variable representing this frame has been set to 1.

Lexical-Functional Grammar (Bresnan, 2001) is a constraint-based theory of grammar with minimally two levels of representation: c(onstituent)-structure and f(unctional)-structure. C-structure (CFG trees) captures language specific surface configurations such as word order and the hierarchical grouping of words into phrases, while f-structure represents more abstract (and somewhat more language independent) grammatical relations (essentially bilexical labelled dependencies with some morphological and semantic information, approximating to basic predicate-argument structures) in the form of attribute-value structures. F-structures are defined in terms of equations annotated to nodes in c-structure trees (grammar rules). Treebank-based LFG acquisition was originally developed for English (Cahill, 2004; Cahill et al., 2008) and is based on an f-structure annotation algorithm that annotates c-structure trees (from a treebank or parser output) with f-structure equations, which are read off of the tree and passed on to a constraint solver producing an f-structure for the given sentence. The English annotation algorithm (for Penn-II treebank-style trees) relies heavily on configurational and categorial information, translating this into grammatical functional information (subject, object etc.) represented at f-structure. LFG is "functional" in the mathematical sense, in that argument grammatical functions have to be single valued (there cannot be two or more subjects etc. in the same clause). In fact, if two or more values are assigned to a single argument grammatical function in a local tree, the LFG constraint solver will produce a clash (i. e. it will fail to produce an f-structure) and the sentence will be considered ungrammatical (in other words, the corresponding c-structure tree will be uninterpretable).

Rehbein (2009) and Rehbein and van Genabith (2009) develop an f-structure annotation algorithm for German based on the TiGer treebank resource. Unlike the English annotation algorithm and because of the language-particular properties of German (see Section 2), the German annotation algorithm cannot rely on c-structure configurational information, but instead heavily uses TiGer function labels in the treebank. Learning function labels is therefore crucial to the German LFG annotation algorithm, in particular when parsing raw text. Because of the strong case syncretism in German, traditional classification models using local

information only run the risk of predicting multiple occurences of the same function (subject, object etc.) at the same level, causing feature clashes in the constraint solver with no f-structure being produced. Rehbein (2009) and Rehbein and van Genabith (2009) identify this as a major problem resulting in a considerable loss in coverage of the German annotation algorithm compared to English, in particular for parsing raw text, where TiGer function labels have to be supplied by a machine-learning-based method and where the coverage of the LFG annotation algorithm drops to 93.62% with corresponding drops in recall and f-scores for the f-structure evaluations (Table 6).

Below we test whether the coverage problems caused by incorrect multiple assignments of grammatical functions can be addressed using the combination of classifier with ILP constraints developed in this paper. We report experiments where automatically parsed and labelled data are handed over to an LFG f-structure computation algorithm. The f-structures produced are converted into a dependency triple representation (Crouch et al., 2002) and evaluated against TiGerDB.

	cov.	prec.	rec.	f-score

parser	93.62	79.20	68.86	73.67

Table 6: f-structure evaluation results for the test set against TigerDB

Table 6 shows the results of the f-structure evaluation against TiGerDB, with 84.07% f-score upper-bound results for the f-structure annotation algorithm on the original TiGer treebank trees with hand-annotated function labels. Using the function labeller without ILP constraints results in drastic drops in coverage (between 4.5% and 6.5% points absolute) and hence recall (6% and 12%) and f-score (3.5% and 9.5%) for both gold trees and parser output (compared to upper bounds). By contrast, with ILP constraints, the loss in coverage observed above almost completely disappears and recall and f-scores improve by between 4.4% and 5.5% (recall) and 3% (f-score) absolute (over without ILP constraints). For comparison, we repeated the experiment using the best-scoring method of Rehbein (2009). Rehbein trains the Berkeley Parser to learn an extended category set, merging TiGer function labels with syntactic categories, where the parser outputs fully-labelled trees. The results show that this approach suffers from the same drop in coverage as the classifier without ILP constraints, with recall about 7% and f-score about 4% (absolute) lower than for the classifier with ILP constraints.

Table 7 shows the dramatic effect of the ILP constraints on the number of sentences in the test set that have multiple argument functions of the same type within the same clause. With ILP constraints, the problem disappears and therefore, less feature-clashes occur during f-structure computation.

	no constraints	constraints
gold	185	0
parser	212	0

Table 7: Number of sentences in the test set with doubly annotated argument functions

In order to assess whether ILP constraints help with coverage only or whether they affect the quality of the f-structures as well, we repeat the experiment in Table 6, however this time evaluating only on those sentences that receive an f-structure, ignoring the rest. Table 8 shows that the impact of ILP constraints on quality is much less dramatic than on coverage, with only very small variations in precison, recall and f-scores across the board, and small increases over Rehbein (2009).

	cov.	prec.	rec.	f-score
no constr.	93.41	79.70	77.89	78.79
constraints	98.39	79.43	77.85	78.64
Rehbein	93.62	79.20	76.43	77.79

Table 8: f-structure evaluation results for parser output excluding sentences without f-structures

Early work on automatic LFG acquisition and parsing for German is presented in Cahill et al. (2003) and Cahill (2004), adapting the English Annotation Algorithm to an earlier and smaller version of the TiGer treebank (without morphological information) and training a parser to learn merged Tiger function-category labels, and reporting 95.75% coverage and an f-score of 74.56% f-structure quality against 2,000 gold treebank trees automatically converted into f-structures. Rehbein (2009) uses the larger Release 2 of the treebank (with morphological information) reporting 77.79% f-score and coverage of 93.62% (Ta-

ble 8) against the dependencies in the TiGerDB test set. The only rule-based approach to German LFG-parsing we are aware of is the hand-crafted German grammar in the ParGram Project (Butt et al., 2002). Forst (2007) reports 83.01% dependency f-score evaluated against a set of 1,497 sentences of the TiGerDB. It is very difficult to compare results across the board, as individual papers use (i) different versions of the treebank, (ii) different (sections of) gold-standards to evaluate against (gold TiGer trees in TigerDB, the dependency representations provided by TigerDB, automatically generated gold-standards etc.) and (iii) different label/grammatical function sets. Furthermore, (iv) coverage differs drastically (with the hand-crafted LFG resources achieving about 80% full f-structures) and finally, (v) some of the grammars evaluated having been used in the generation of the gold standards, possibly introducing a bias towards these resources: the German hand-crafted LFG was used to produce TiGerDB (Forst et al., 2004). In order to put the results into some perspective, Table 9 shows an evaluation of our resources against a set of automatically generated gold standard f-structures produced by using the f-structure annotation algorithm on the original hand-labelled TiGer gold trees in the section corresponding to TiGerDB: without ILP constraints we achieve a dependency f-score of 84.35%, with ILP constraints 87.23% and 98.89% coverage.

	cov.	prec.	rec.	f-score

5 Conclusion

In this paper, we addressed the problem of assigning grammatical functions to constituent structures. We have proposed an approach to grammatical function labelling that combines the flexibility of a statistical classifier with linguistic expert knowledge in the form of hard constraints implemented by an integer linear program. These constraints restrict the solution space of the classifier by blocking those solutions that cannot be correct. One of the strengths of an integer linear program is the unlimited context it can take into account by optimising over the entire structure, providing an elegant way of supporting classifiers with explicit linguistic knowledge while at the same time keeping feature models small and comprehensible. Most of the constraints are direct formalizations of linguistic generalizations for German. Our approach should generalise to other languages for which linguistic expertise is available.

We evaluated our system on the TiGer corpus and the TiGerDB and gave results on gold standard trees and parser output. We also applied the German f-structure annotation algorithm to the automatically labelled data and evaluated the system by measuring the quality of the resulting f-structures. We found that by using the constraint set, the function labeller ensures the interpretability and thus the usefulness of the syntactic structure for a subsequently applied processing step. In our f-structure evaluation, that means, the f-structure computation algorithm is able to produce an f-structure for almost all sentences.

Simple, Accurate Parsing with an All-Fragments Grammar

Mohit Bansal and **Dan Klein**
Computer Science Division
University of California, Berkeley
{mbansal, klein}@cs.berkeley.edu

Abstract

We present a simple but accurate parser which exploits both large tree fragments and symbol refinement. We parse with *all* fragments of the training set, in contrast to much recent work on tree selection in data-oriented parsing and tree-substitution grammar learning. We require only simple, deterministic grammar symbol refinement, in contrast to recent work on latent symbol refinement. Moreover, our parser requires no explicit lexicon machinery, instead parsing input sentences as character streams. Despite its simplicity, our parser achieves accuracies of over 88% F1 on the standard English WSJ task, which is competitive with substantially more complicated state-of-the-art lexicalized and latent-variable parsers. Additional specific contributions center on making implicit all-fragments parsing efficient, including a coarse-to-fine inference scheme and a new graph encoding.

1 Introduction

Modern NLP systems have increasingly used data-intensive models that capture many or even all substructures from the training data. In the domain of syntactic parsing, the idea that all training fragments[1] might be relevant to parsing has a long history, including tree-substitution grammar (data-oriented parsing) approaches (Scha, 1990; Bod, 1993; Goodman, 1996a; Chiang, 2003) and tree kernel approaches (Collins and Duffy, 2002). For machine translation, the key modern advancement has been the ability to represent and memorize large training substructures, be it in contiguous phrases (Koehn et al., 2003) or syntactic trees (Galley et al., 2004; Chiang, 2005; Deneefe and Knight, 2009). In all such systems, a central challenge is efficiency: there are generally a combinatorial number of substructures in the training data, and it is impractical to explicitly extract them all. On both efficiency and statistical grounds, much recent TSG work has focused on fragment selection (Zuidema, 2007; Cohn et al., 2009; Post and Gildea, 2009).

At the same time, many high-performance parsers have focused on *symbol refinement* approaches, wherein PCFG independence assumptions are weakened not by increasing rule sizes but by subdividing coarse treebank symbols into many subcategories either using structural annotation (Johnson, 1998; Klein and Manning, 2003) or lexicalization (Collins, 1999; Charniak, 2000). Indeed, a recent trend has shown high accuracies from models which are dedicated to inducing such subcategories (Henderson, 2004; Matsuzaki et al., 2005; Petrov et al., 2006). In this paper, we present a simplified parser which combines the two basic ideas, using both large fragments and symbol refinement, to provide non-local and local context respectively. The two approaches turn out to be highly complementary; even the simplest (deterministic) symbol refinement and a basic use of an all-fragments grammar combine to give accuracies substantially above recent work on tree-substitution grammar based parsers and approaching top refinement-based parsers. For example, our best result on the English WSJ task is an F1 of over 88%, where recent TSG parsers[2] achieve 82-84% and top refinement-based parsers[3] achieve 88-90% (e.g., Table 5).

Rather than select fragments, we use a simplification of the PCFG-reduction of DOP (Goodman,

[1] In this paper, a *fragment* means an elementary tree in a tree-substitution grammar, while a *subtree* means a fragment that bottoms out in terminals.

[2] Zuidema (2007), Cohn et al. (2009), Post and Gildea (2009). Zuidema (2007) incorporates deterministic refinements inspired by Klein and Manning (2003).

Uppsala, Sweden, 11-16 July 2010.

1996a) to work with all fragments. This reduction is a flexible, implicit representation of the fragments that, rather than extracting an intractably large grammar over fragment *types*, indexes all nodes in the training treebank and uses a compact grammar over indexed node *tokens*. This indexed grammar, when appropriately marginalized, is equivalent to one in which all fragments are explicitly extracted. Our work is the first to apply this reduction to *full-scale* parsing. In this direction, we present a coarse-to-fine inference scheme and a compact graph encoding of the training set, which, together, make parsing manageable. This tractability allows us to avoid selection of fragments, and work with all fragments.

Of course, having a grammar that includes all training substructures is only desirable to the extent that those structures can be appropriately weighted. Implicit representations like those used here do not allow arbitrary weightings of fragments. However, we use a simple weighting scheme which does decompose appropriately over the implicit encoding, and which is flexible enough to allow weights to depend not only on frequency but also on fragment size, node patterns, and certain lexical properties. Similar ideas have been explored in Bod (2001), Collins and Duffy (2002), and Goodman (2003). Our model empirically affirms the effectiveness of such a flexible weighting scheme in full-scale experiments.

We also investigate parsing without an explicit lexicon. The all-fragments approach has the advantage that parsing down to the character level requires no special treatment; we show that an explicit lexicon is not needed when sentences are considered as strings of characters rather than words. This avoids the need for complex unknown word models and other specialized lexical resources.

The main contribution of this work is to show practical, tractable methods for working with an all-fragments model, without an explicit lexicon. In the parsing case, the central result is that accuracies in the range of state-of-the-art parsers (i.e., over 88% F1 on English WSJ) can be obtained with no sampling, no latent-variable modeling, no smoothing, and even no explicit lexicon (hence negligible training overall). These techniques, however, are not limited to the case of monolingual parsing, offering extensions to models of machine translation, semantic interpretation, and other areas in which a similar tension exists between the desire to extract many large structures and the computational cost of doing so.

2 Representation of Implicit Grammars

2.1 All-Fragments Grammars

We consider an *all-fragments grammar* G (see Figure 1(a)) derived from a binarized treebank B. G is formally a tree-substitution grammar (Resnik, 1992; Bod, 1993) wherein each subgraph of each training tree in B is an elementary tree, or *fragment* f, in G. In G, each derivation d is a tree (multiset) of fragments (Figure 1(c)), and the weight of the derivation is the product of the weights of the fragments: $\omega(d) = \prod_{f \in d} \omega(f)$. In the following, the derivation weights, when normalized over a given sentence s, are interpretable as conditional probabilities, so G induces distributions of the form $P(d|s)$.

In models like G, many derivations will generally correspond to the same unsegmented tree, and the parsing task is to find the tree whose sum of derivation weights is highest: $t_{max} = \arg\max_t \sum_{d \in t} \omega(d)$. This final optimization is intractable in a way that is orthogonal to this paper (Sima'an, 1996); we describe minimum Bayes risk approximations in Section 4.

2.2 Implicit Representation of G

Explicitly extracting all fragment-rules of a grammar G is memory and space intensive, and impractical for full-size treebanks. As a tractable alternative, we consider an *implicit grammar* G^I (see Figure 1(b)) that has the same posterior probabilities as G. To construct G^I, we use a simplification of the PCFG-reduction of DOP by Goodman (1996a).[4] G^I has *base* symbols, which are the symbol types from the original treebank, as well as *indexed* symbols, which are obtained by assigning a unique index to each node token in the training treebank. The vast majority of symbols in G^I are therefore indexed symbols. While it may seem that such grammars will be overly large, they are in fact reasonably compact, being linear in the treebank size B, while G is exponential in the length of a sentence. In particular, we found that G^I was smaller than explicit extraction of all depth 1 and 2 unbinarized fragments for our

[4]The difference is that Goodman (1996a) collapses our BEGIN and END rules into the binary productions, giving a larger grammar which is less convenient for weighting.

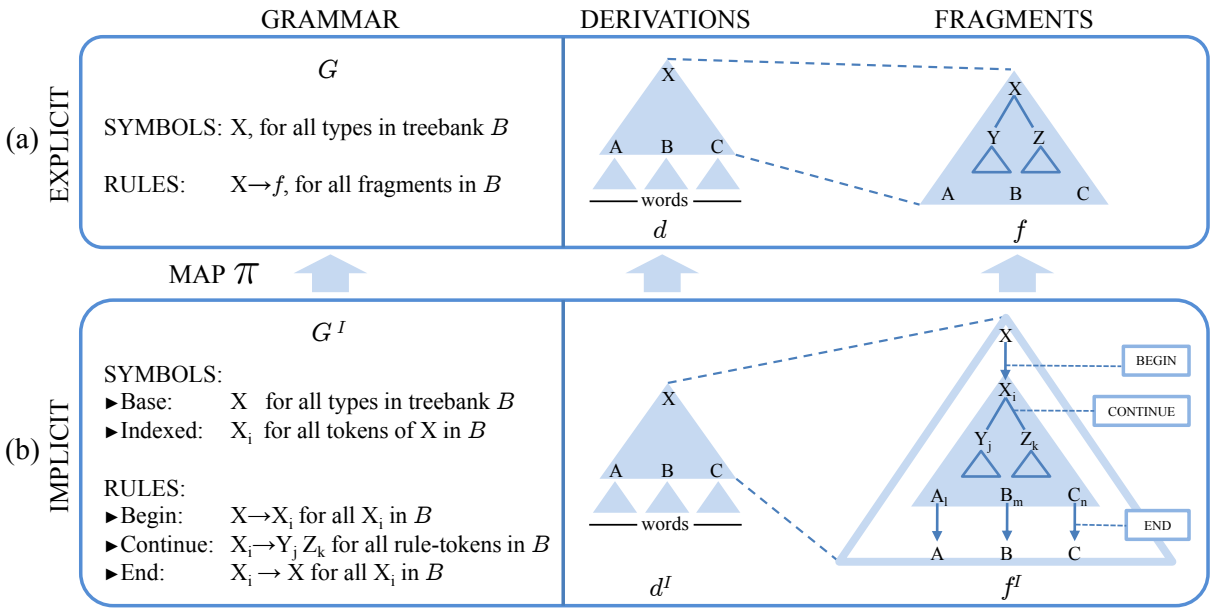

Figure 1: Grammar definition and sample derivations and fragments in the grammar for (a) the explicitly extracted all-fragments grammar G, and (b) its implicit representation G^I.

treebanks – in practice, even just the raw treebank grammar grows almost linearly in the size of B.[5]

There are 3 kinds of rules in G^I, which are illustrated in Figure 1(d). The BEGIN rules transition from a base symbol to an indexed symbol and represent the beginning of a fragment from G. The CONTINUE rules use only indexed symbols and correspond to specific depth-1 binary fragment tokens from training trees, representing the internal continuation of a fragment in G. Finally, END rules transition from an indexed symbol to a base symbol, representing the frontier of a fragment.

By construction, all derivations in G^I will segment, as shown in Figure 1(d), into regions corresponding to *tokens* of fragments from the training treebank B. Let π be the map which takes appropriate fragments in G^I (those that begin and end with base symbols and otherwise contain only indexed symbols), and maps them to the corresponding f in G. We can consider any derivation d^I in G^I to be a tree of fragments f^I, each fragment a token of a fragment type $f = \pi(f^I)$ in the original grammar G. By extension, we can therefore map any derivation d^I in G^I to the corresponding derivation $d = \pi(d^I)$ in G.

The mapping π is an onto mapping from G^I to G. In particular, each derivation d in G has a non-empty set of corresponding derivations $\{d^I\} = \pi^{-1}(d)$ in G^I, because fragments f in d correspond to multiple fragments f^I in G^I that differ only in their indexed symbols (one f^I per occurrence of f in B). Therefore, the set of derivations in G is preserved in G^I. We now discuss how weights can be preserved under π.

2.3 Equivalence for Weighted Grammars

In general, arbitrary weight functions ω on fragments in G do not decompose along the increased locality of G^I. However, we now consider a usefully broad class of weighting schemes for which the posterior probabilities under G of derivations d are preserved in G^I. In particular, assume that we have a weighting ω on rules in G^I which does not depend on the specific indices used. Therefore, any fragment f^I will have a weight in G^I of the form:

$$\omega_I(f^I) = \omega_{\text{BEGIN}}(b) \prod_{r \in \text{C}} \omega_{\text{CONT}}(r) \prod_{e \in \text{E}} \omega_{\text{END}}(e)$$

where b is the BEGIN rule, r are CONTINUE rules, and e are END rules in the fragment f^I (see Figure 1(d)). Because ω is assumed to not depend on the specific indices, all f^I which correspond to the same f under π will have the same weight $\omega_I(f)$ in G^I.

In this case, we can define an induced weight

[5] Just half the training set (19916 trees) itself had 1.7 million depth 1 and 2 unbinarized rules compared to the 0.9 million indexed symbols in G^I (after graph packing). Even extracting binarized fragments (depth 1 and 2, with one order of parent annotation) gives us 0.75 million rules, and, practically, we would need fragments of greater depth.

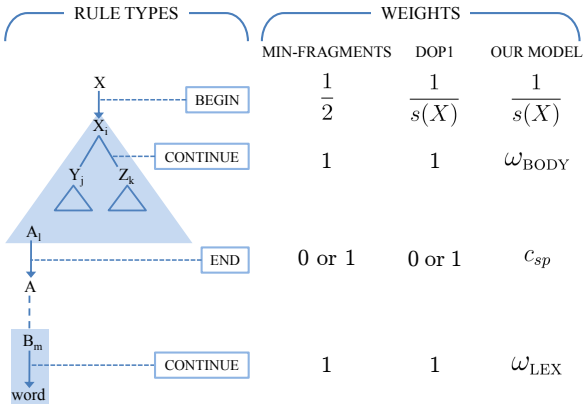

Figure 2: Rules defined for grammar G^I and weight schema for the DOP1 model, the Min-Fragments model (Goodman (2003)) and our model. Here $s(X)$ denotes the total number of fragments rooted at base symbol X.

for fragments f in G by

$$\omega_G(f) = \sum_{f^I \in \pi^{-1}(f)} \omega_I(f^I) = n(f)\omega_I(f)$$
$$= n(f)\omega_{\text{BEGIN}}(b') \prod_{r' \in \text{C}} \omega_{\text{CONT}}(r') \prod_{e' \in \text{E}} \omega_{\text{END}}(e')$$

where now b', r' and e' are non-indexed type abstractions of f's member productions in G^I and $n(f) = |\pi^{-1}(f)|$ is the number of tokens of f in B.

Under the weight function $\omega_G(f)$, any derivation d in G will have weight which obeys

$$\omega_G(d) = \prod_{f \in d} \omega_G(f) = \prod_{f \in d} n(f)\omega_I(f)$$
$$= \sum_{d^I \in d} \omega_I(d^I)$$

and so the posterior $P(d|s)$ of a derivation d for a sentence s will be the same whether computed in G or G^I. Therefore, provided our weighting function on fragments f in G decomposes over the derivational representation of f in G^I, we can equivalently compute the quantities we need for inference (see Section 4) using G^I instead.

3 Parameterization of Implicit Grammars

3.1 Classical DOP1

The original data-oriented parsing model 'DOP1' (Bod, 1993) is a particular instance of the general weighting scheme which decomposes appropriately over the implicit encoding, described in Section 2.3. Figure 2 shows rule weights for DOP1 in the parameter schema we have defined. The END rule weight is 0 or 1 depending on whether A is an intermediate symbol or not.[6] The local fragments in DOP1 were flat (non-binary) so this weight choice simulates that property by not allowing switching between fragments at intermediate symbols.

The original DOP1 model weights a fragment f in G as $\omega_G(f) = n(f)/s(X)$, i.e., the frequency of fragment f divided by the number of fragments rooted at base symbol X. This is simulated by our weight choices (Figure 2) where each fragment f^I in G^I has weight $\omega_I(f^I) = 1/s(X)$ and therefore, $\omega_G(f) = \sum_{f^I \in \pi^{-1}(f)} \omega_I(f^I) = n(f)/s(X)$. Given the weights used for DOP1, the recursive formula for the number of fragments $s(X_i)$ rooted at indexed symbol X_i (and for the CONTINUE rule $X_i \rightarrow Y_j\ Z_k$) is

$$s(X_i) = (1 + s(Y_j))(1 + s(Z_k)), \qquad (1)$$

where $s(Y_j)$ and $s(Z_k)$ are the number of fragments rooted at indexed symbols Y_j and Z_k (non-intermediate) respectively. The number of fragments $s(X)$ rooted at base symbol X is then $s(X) = \sum_{X_i} s(X_i)$.

Implicitly parsing with the full DOP1 model (no sampling of fragments) using the weights in Figure 2 gives a 68% parsing accuracy on the WSJ dev-set.[7] This result indicates that the weight of a fragment should depend on more than just its frequency.

3.2 Better Parameterization

As has been pointed out in the literature, large-fragment grammars can benefit from weights of fragments depending not only on their frequency but also on other properties. For example, Bod (2001) restricts the size and number of words in the frontier of the fragments, and Collins and Duffy (2002) and Goodman (2003) both give larger fragments smaller weights. Our model can incorporate both size and lexical properties. In particular, we set $\omega_{\text{CONT}}(r)$ for each binary CONTINUE rule r to a learned constant ω_{BODY}, and we set the weight for each rule with a POS parent to a

[6] Intermediate symbols are those created during binarization.

[7] For DOP1 experiments, we use no symbol refinement. We annotate with full left binarization history to imitate the flat nature of fragments in DOP1. We use mild coarse-pass pruning (Section 4.1) without which the basic all-fragments chart does not fit in memory. Standard WSJ treebank splits used: sec 2-21 training, 22 dev, 23 test.

Rule score: $r(A \rightarrow B\ C, i, k, j) = \sum_x \sum_y \sum_z O(A_x, i, j)\omega(A_x \rightarrow B_y\ C_z)I(B_y, i, k)I(C_z, k, j)$

Max-Constituent:	$q(A, i, j) = \frac{\sum_x O(A_x,i,j)I(A_x,i,j)}{\sum_r I(root_r,0,n)}$	$t_{max} = \operatorname{argmax}_t \sum_{c \in t} q(c)$
Max-Rule-Sum:	$q(A \rightarrow B\ C, i, k, j) = \frac{r(A \rightarrow B\ C,i,k,j)}{\sum_r I(root_r,0,n)}$	$t_{max} = \operatorname{argmax}_t \sum_{e \in t} q(e)$
Max-Variational:	$q(A \rightarrow B\ C, i, k, j) = \frac{r(A \rightarrow B\ C,i,k,j)}{\sum_x O(A_x,i,j)I(A_x,i,j)}$	$t_{max} = \operatorname{argmax}_t \prod_{e \in t} q(e)$

Figure 3: Inference: Different objectives for parsing with posteriors. A, B, C are base symbols, A_x, B_y, C_z are indexed symbols and i,j,k are between-word indices. Hence, (A_x, i, j) represents a constituent labeled with A_x spanning words i to j. $I(A_x, i, j)$ and $O(A_x, i, j)$ denote the inside and outside scores of this constituent, respectively. For brevity, we write $c \equiv (A, i, j)$ and $e \equiv (A \rightarrow B\ C, i, k, j)$. Also, t_{max} is the highest scoring parse. Adapted from Petrov and Klein (2007).

constant ω_{LEX} (see Figure 2). Fractional values of these parameters allow the weight of a fragment to depend on its size and lexical properties.

Another parameter we introduce is a 'switching-penalty' c_{sp} for the END rules (Figure 2). The DOP1 model uses binary values (0 if symbol is intermediate, 1 otherwise) as the END rule weight, which is equivalent to prohibiting fragment switching at intermediate symbols. We learn a fractional constant a_{sp} that allows (but penalizes) switching between fragments at annotated symbols through the formulation $c_{sp}(X_{intermediate}) = 1 - a_{sp}$ and $c_{sp}(X_{non-intermediate}) = 1 + a_{sp}$. This feature allows fragments to be assigned weights based on the binarization status of their nodes.

With the above weights, the recursive formula for $s(X_i)$, the total weighted number of fragments rooted at indexed symbol X_i, is different from DOP1 (Equation 1). For rule $X_i \rightarrow Y_j\ Z_k$, it is

$$s(X_i) = \omega_{\text{BODY}}.(c_{sp}(Y_j)+s(Y_j))(c_{sp}(Z_k)+s(Z_k)).$$

The formula uses ω_{LEX} in place of ω_{BODY} if r is a lexical rule (Figure 2).

The resulting grammar is primarily parameterized by the training treebank B. However, each setting of the hyperparameters $(\omega_{\text{BODY}}, \omega_{\text{LEX}}, a_{sp})$ defines a different conditional distribution on trees. We choose amongst these distributions by directly optimizing parsing F1 on our development set. Because this objective is not easily differentiated, we simply perform a grid search on the three hyperparameters. The tuned values are $\omega_{\text{BODY}} = 0.35$, $\omega_{\text{LEX}} = 0.25$ and $a_{sp} = 0.018$. For generalization to a larger parameter space, we would of course need to switch to a learning approach that scales more gracefully in the number of tunable hyperparameters.[8]

[8]Note that there has been a long history of DOP estimators. The generative DOP1 model was shown to be inconsistent by Johnson (2002). Later, Zollmann and Sima'an (2005) presented a statistically consistent estimator, with the basic insight of optimizing on a held-out set. Our estimator is not intended to be viewed as a generative model of trees at all, but simply a loss-minimizing conditional distribution within our parametric family.

	dev ($\leq$ 40)		test ($\leq$ 40)		test (all)

4 Efficient Inference

The previously described implicit grammar G^I defines a posterior distribution $P(d^I|s)$ over a sentence s via a large, indexed PCFG. This distribution has the property that, when marginalized, it is equivalent to a posterior distribution $P(d|s)$ over derivations in the correspondingly-weighted all-fragments grammar G. However, even with an explicit representation of G, we would not be able to tractably compute the parse that maximizes $P(t|s) = \sum_{d \in t} P(d|s) = \sum_{d^I \in t} P(d^I|s)$ (Sima'an, 1996). We therefore approximately maximize over trees by computing various existing approximations to $P(t|s)$ (Figure 3). Goodman (1996b), Petrov and Klein (2007), and Matsuzaki et al. (2005) describe the details of constituent, rule-sum and variational objectives respectively. Note that all inference methods depend on the posterior $P(t|s)$ only through marginal expectations of labeled constituent counts and anchored local binary tree counts, which are easily computed from $P(d^I|s)$ and equivalent to those from $P(d|s)$. Therefore, no additional approximations are made in G^I over G.

As shown in Table 1, our model (an all-fragments grammar with the weighting scheme

shown in Figure 2) achieves an accuracy of 88.5% (using simple parent annotation) which is 4-5% (absolute) better than the recent TSG work (Zuidema, 2007; Cohn et al., 2009; Post and Gildea, 2009) and also approaches state-of-the-art refinement-based parsers (e.g., Charniak and Johnson (2005), Petrov and Klein (2007)).[9]

4.1 Coarse-to-Fine Inference

Coarse-to-fine inference is a well-established way to accelerate parsing. Charniak et al. (2006) introduced multi-level coarse-to-fine parsing, which extends the basic pre-parsing idea by adding more rounds of pruning. Their pruning grammars were coarse versions of the raw treebank grammar. Petrov and Klein (2007) propose a multi-stage coarse-to-fine method in which they construct a sequence of increasingly refined grammars, reparsing with each refinement. In particular, in their approach, which we adopt here, coarse-to-fine pruning is used to quickly compute approximate marginals, which are then used to prune subsequent search. The key challenge in coarse-to-fine inference is the construction of coarse models which are much smaller than the target model, yet whose posterior marginals are close enough to prune with safely.

Our grammar G^I has a very large number of indexed symbols, so we use a coarse pass to prune away their unindexed abstractions. The simple, intuitive, and effective choice for such a coarse grammar G^C is a minimal PCFG grammar composed of the base treebank symbols X and the minimal depth-1 binary rules $X \rightarrow Y\ Z$ (and with the same level of annotation as in the full grammar). If a particular base symbol X is pruned by the coarse pass for a particular span (i, j) (i.e., the posterior marginal $P(X, i, j|s)$ is less than a certain threshold), then in the full grammar G^I, we do not allow building any indexed symbol X_l of type X for that span. Hence, the projection map for the coarse-to-fine model is π^C : $X_l\ (indexed\ symbol) \rightarrow X\ (base\ symbol)$.

We achieve a substantial improvement in speed and memory-usage from the coarse-pass pruning. Speed increases by a factor of 40 and memory-usage decreases by a factor of 10 when we go from no pruning to pruning with a -6.2 log posterior threshold.[10] Figure 4 depicts the variation in parsing accuracies in response to the amount of pruning done by the coarse-pass. Higher posterior pruning thresholds induce more aggressive pruning. Here, we observe an effect seen in previous work (Charniak et al. (1998), Petrov and Klein (2007), Petrov et al. (2008)), that a certain amount of pruning helps accuracy, perhaps by promoting agreement between the coarse and full grammars (model intersection). However, these 'fortuitous' search errors give only a small improvement and the peak accuracy is almost equal to the parsing accuracy without any pruning (as seen in Figure 5).[11] This outcome suggests that the coarse-pass pruning is critical for tractability but not for performance.

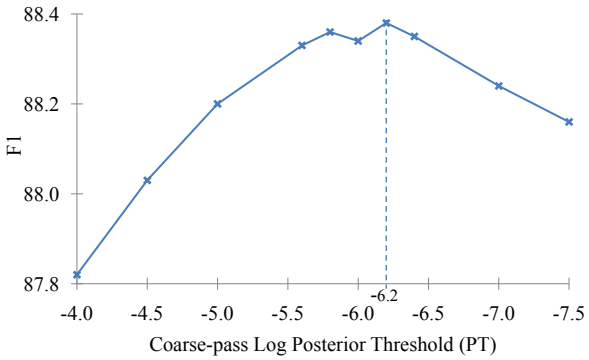

Figure 4: Effect of coarse-pass pruning on parsing accuracy (for WSJ dev-set, $\leq$ 40 words). Pruning increases to the left as log posterior threshold (PT) increases.

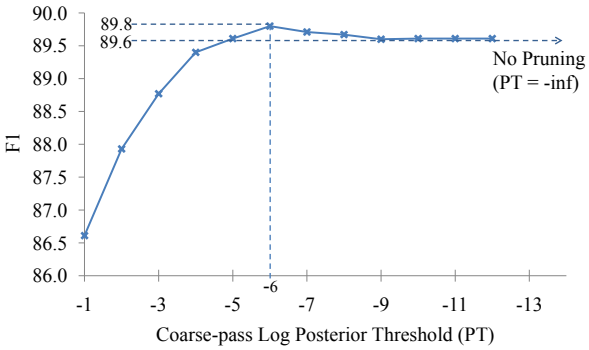

Figure 5: Effect of coarse-pass pruning on parsing accuracy (WSJ, training $\leq$ 20 words, tested on dev-set $\leq$ 20 words). This graph shows that the fortuitous improvement due to pruning is very small and that the peak accuracy is almost equal to the accuracy without pruning (the dotted line).

[9] All our experiments use the constituent objective except when we report results for max-rule-sum and max-variational parsing (where we use the parameters tuned for max-constituent, therefore they unsurprisingly do not perform as well as max-constituent). Evaluations use EVALB, see `http://nlp.cs.nyu.edu/evalb/`.

[10] Unpruned experiments could not be run for 40-word test sentences even with 50GB of memory, therefore we calculated the improvement factors using a smaller experiment with full training and sixty 30-word test sentences.

[11] To run experiments without pruning, we used training and dev sentences of length $\leq$ 20 for the graph in Figure 5.

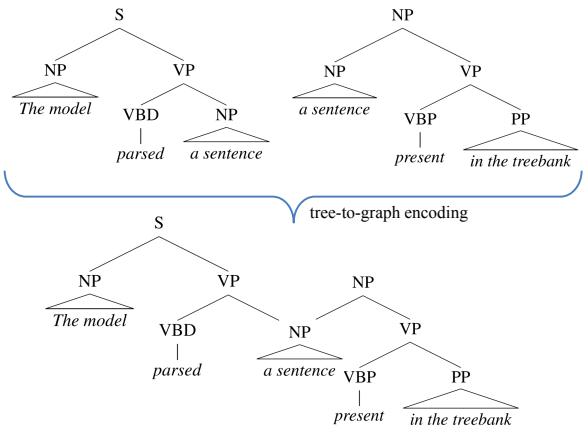

Figure 6: Collapsing the duplicate training subtrees converts them to a graph and reduces the number of indexed symbols significantly.

Parsing Model	No. of Indexed Symbols
Word-level Trees	1,900,056
Word-level Graph	903,056
Character-level Trees	12,280,848
Character-level Graph	1,109,399

Table 2: Number of indexed symbols for word-level and character-level parsing and their graph versions (for all-fragments grammar with parent annotation and one level of markovization).

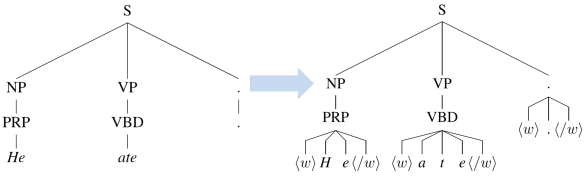

Figure 7: Character-level parsing: treating the sentence as a string of characters instead of words.

4.2 Packed Graph Encoding

The implicit all-fragments approach (Section 2.2) avoids explicit extraction of all rule fragments. However, the number of indexed symbols in our implicit grammar G^I is still large, because every node in each training tree (i.e., every symbol token) has a unique indexed symbol. We have around 1.9 million indexed symbol tokens in the word-level parsing model (this number increases further to almost 12.3 million when we parse character strings in Section 5.1). This large symbol space makes parsing slow and memory-intensive.

We reduce the number of symbols in our implicit grammar G^I by applying a compact, packed graph encoding to the treebank training trees. We collapse the duplicate *subtrees* (fragments that bottom out in terminals) over all training trees. This keeps the grammar unchanged because in an tree-substitution grammar, a node is defined (identified) by the subtree below it. We maintain a hashmap on the subtrees which allows us to easily discover the duplicates and bin them together. The collapsing converts all the training trees in the treebank to a graph with multiple parents for some nodes as shown in Figure 6. This technique reduces the number of indexed symbols significantly as shown in Table 2 (1.9 million goes down to 0.9 million, reduction by a factor of 2.1). This reduction increases parsing speed by a factor of 1.4 (and by a factor of 20 for character-level parsing, see Section 5.1) and reduces memory usage to under 4GB.

We store the duplicate-subtree counts for each indexed symbol of the collapsed graph (using a hashmap). When calculating the number of fragments $s(X_i)$ parented by an indexed symbol X_i (see Section 3.2), and when calculating the inside and outside scores during inference, we account for the collapsed subtree tokens by expanding the counts and scores using the corresponding multiplicities. Therefore, we achieve the compaction with negligible overhead in computation.

5 Improved Treebank Representations

5.1 Character-Level Parsing

The all-fragments approach to parsing has the added advantage that parsing below the word level requires no special treatment, i.e., we do not need an explicit lexicon when sentences are considered as strings of characters rather than words.

Unknown words in test sentences (unseen in training) are a major issue in parsing systems for which we need to train a complex lexicon, with various unknown classes or suffix tries. Smoothing factors need to be accounted for and tuned. With our implicit approach, we can avoid training a lexicon by building up the parse tree from characters instead of words. As depicted in Figure 7, each word in the training trees is split into its corresponding characters with start and stop boundary tags (and then binarized in a standard right-branching style). A test sentence's words are split up similarly and the test-parse is built from training fragments using the same model and inference procedure as defined for word-level parsing (see Sections 2, 3 and 4). The lexical items (alphabets, digits etc.) are now all known, so unlike word-level parsing, no sophisticated lexicon is needed.

We choose a slightly richer weighting scheme

Model	dev ($\leq$ 40) F1	dev ($\leq$ 40) EX	test ($\leq$ 40) F1	test ($\leq$ 40) EX	test (all) F1	test (all) EX
Constituent	**88.2**	33.6	**88.0**	31.9	**87.1**	29.8
Rule-Sum	88.0	33.9	87.8	**33.1**	87.0	**30.9**
Variational	87.6	**34.4**	87.2	32.3	86.4	30.2

Table 3: All-fragments WSJ results for the character-level parsing model, using parent annotation and one level of markovization.

Parsing Model	F1
No Refinement (P=0, H=0)*	71.3
Basic Refinement (P=1, H=1)*	80.0
All-Fragments + No Refinement (P=0, H=0)	85.7
All-Fragments + Basic Refinement (P=1, H=1)	88.4

Table 4: F1 for a basic PCFG, and incorporation of basic refinement, all-fragments and both, for WSJ dev-set ($\leq$ 40 words). $P = 1$ means parent annotation of all non-terminals, including the preterminal tags. $H = 1$ means one level of markovization. *Results from Klein and Manning (2003).

for this representation by extending the two-weight schema for CONTINUE rules (ω_{LEX} and ω_{BODY}) to a three-weight one: ω_{LEX}, ω_{WORD}, and ω_{SENT} for CONTINUE rules in the lexical layer, in the portion of the parse that builds words from characters, and in the portion of the parse that builds the sentence from words, respectively. The tuned values are $\omega_{\text{SENT}} = 0.35$, $\omega_{\text{WORD}} = 0.15$, $\omega_{\text{LEX}} = 0.95$ and $a_{sp} = 0$. The character-level model achieves a parsing accuracy of 88.0% (see Table 3), *despite lacking an explicit lexicon*.[12]

Character-level parsing expands the training trees (see Figure 7) and the already large indexed symbol space size explodes (1.9 million increases to 12.3 million, see Table 2). Fortunately, this is where the packed graph encoding (Section 4.2) is most effective because duplication of character strings is high (e.g., suffixes). The packing shrinks the symbol space size from 12.3 million to 1.1 million, a reduction by a factor of 11. This reduction increases parsing speed by almost a factor of 20 and brings down memory-usage to under 8GB.[13]

5.2 Basic Refinement: Parent Annotation and Horizontal Markovization

In a pure all-fragments approach, compositions of units which would have been independent in a basic PCFG are given joint scores, allowing the representation of certain non-local phenomena, such as lexical selection or agreement, which in fully local models require rich state-splitting or lexicalization. However, at substitution sites, the coarseness of raw unrefined treebank symbols still creates unrealistic factorization assumptions. A standard solution is symbol refinement; Johnson (1998) presents the particularly simple case of parent annotation, in which each node is marked with its parent in the underlying treebank. It is reasonable to hope that the gains from using large fragments and the gains from symbol refinement will be complementary. Indeed, previous work has shown or suggested this complementarity. Sima'an (2000) showed modest gains from enriching structural relations with semi-lexical (prehead) information. Charniak and Johnson (2005) showed accuracy improvements from composed local tree features on top of a lexicalized base parser. Zuidema (2007) showed a slight improvement in parsing accuracy when enough fragments were added to learn enrichments beyond manual refinements. Our work reinforces this intuition by demonstrating how complementary they are in our model ($\sim$20% error reduction on adding refinement to an all-fragments grammar, as shown in the last two rows of Table 4).

Table 4 shows results for a basic PCFG, and its augmentation with either basic refinement (parent annotation and one level of markovization), with all-fragments rules (as in previous sections), or both. The basic incorporation of large fragments alone does not yield particularly strong performance, nor does basic symbol refinement. However, the two approaches are quite additive in our model and combine to give nearly state-of-the-art parsing accuracies.

5.3 Additional Deterministic Refinement

Basic symbol refinement (parent annotation), in combination with all-fragments, gives test-set accuracies of 88.5% ($\leq$ 40 words) and 87.6% (all), shown as the Basic Refinement model in Table 5. Klein and Manning (2003) describe a broad set of simple, deterministic symbol refinements beyond parent annotation. We included ten of their simplest annotation features, namely: UNARY-DT, UNARY-RB, SPLIT-IN, SPLIT-AUX, SPLIT-CC, SPLIT-%, GAPPED-S, POSS-NP, BASE-NP and DOMINATES-V. None of these annotation schemes use any head information. This additional annotation (see Ad-

[12]Note that the word-level model yields a higher accuracy of 88.5%, but uses 50 complex unknown word categories based on lexical, morphological and position features (Petrov et al., 2006). Cohn et al. (2009) also uses this lexicon.

[13]Full char-level experiments (w/o packed graph encoding) could not be run even with 50GB of memory. We calculate the improvement factors using a smaller experiment with 70% training and fifty 20-word test sentences.

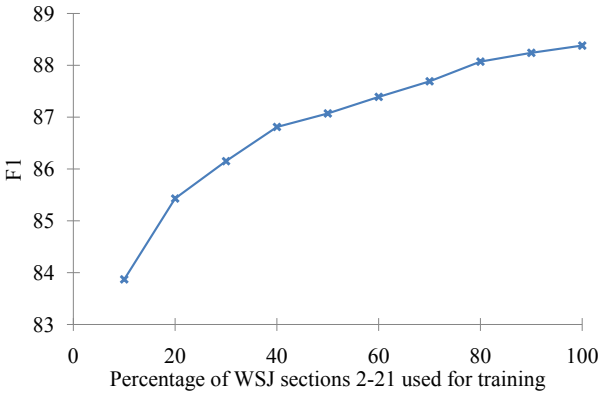

Figure 8: Parsing accuracy F1 on the WSJ dev-set ($\leq$ 40 words) increases with increasing percentage of training data.

Parsing Model	test ($\leq$ 40) F1	test ($\leq$ 40) EX	test (all) F1	test (all) EX
FRAGMENT-BASED PARSERS

REFINEMENT-BASED PARSERS				
Collins (1999)	88.6	–	88.2	–
Petrov and Klein (2007)	90.6	39.1	90.1	37.1

Table 5: Our WSJ test set parsing accuracies, compared to recent fragment-based parsers and top refinement-based parsers. Basic Refinement is our all-fragments grammar with parent annotation. Additional Refinement adds deterministic refinement of Klein and Manning (2003) (Section 5.3). *Results on the dev-set ($\leq$ 100).

ditional Refinement, Table 5) improves the test-set accuracies to 88.7% ($\leq$ 40 words) and 88.1% (all), which is equal to a strong lexicalized parser (Collins, 1999), even though our model does not use lexicalization or latent symbol-split induction.

6 Other Results

6.1 Parsing Speed and Memory Usage

The word-level parsing model using the whole training set (39832 trees, all-fragments) takes approximately 3 hours on the WSJ test set (2245 trees of $\leq$40 words), which is equivalent to roughly 5 seconds of parsing time per sentence; and runs in under 4GB of memory. The character-level version takes about twice the time and memory. This novel tractability of an all-fragments grammar is achieved using both coarse-pass pruning and packed graph encoding. Micro-optimization may further improve speed and memory usage.

6.2 Training Size Variation

Figure 8 shows how WSJ parsing accuracy increases with increasing amount of training data (i.e., percentage of WSJ sections 2-21). Even if we train on only 10% of the WSJ training data (3983 sentences), we still achieve a reasonable parsing accuracy of nearly 84% (on the development set, $\leq$ 40 words), which is comparable to the full-system results obtained by Zuidema (2007), Cohn et al. (2009) and Post and Gildea (2009).

6.3 Other Language Treebanks

On the French and German treebanks (using the standard dataset splits mentioned in Petrov and Klein (2008)), our simple all-fragments parser achieves accuracies in the range of top refinement-based parsers, even though the model parameters were tuned out of domain on WSJ. For German, our parser achieves an F1 of 79.8% compared to 81.5% by the state-of-the-art and substantially more complex Petrov and Klein (2008) work. For French, our approach yields an F1 of 78.0% vs. 80.1% by Petrov and Klein (2008).[14]

7 Conclusion

Our approach of using all fragments, in combination with basic symbol refinement, and even without an explicit lexicon, achieves results in the range of state-of-the-art parsers on full scale treebanks, across multiple languages. The main takeaway is that we can achieve such results in a very knowledge-light way with (1) no latent-variable training, (2) no sampling, (3) no smoothing beyond the existence of small fragments, and (4) no explicit unknown word model at all. While these methods offer a simple new way to construct an accurate parser, we believe that this general approach can also extend to other large-fragment tasks, such as machine translation.

Abstract

This paper explores joint syntactic and semantic parsing of Chinese to further improve the performance of both syntactic and semantic parsing, in particular the performance of semantic parsing (in this paper, semantic role labeling). This is done from two levels. Firstly, an integrated parsing approach is proposed to integrate semantic parsing into the syntactic parsing process. Secondly, semantic information generated by semantic parsing is incorporated into the syntactic parsing model to better capture semantic information in syntactic parsing. Evaluation on Chinese TreeBank, Chinese PropBank, and Chinese NomBank shows that our integrated parsing approach outperforms the pipeline parsing approach on n-best parse trees, a natural extension of the widely used pipeline parsing approach on the top-best parse tree. Moreover, it shows that incorporating semantic role-related information into the syntactic parsing model significantly improves the performance of both syntactic parsing and semantic parsing. To our best knowledge, this is the first research on exploring syntactic parsing and semantic role labeling for both verbal and nominal predicates in an integrated way.

1 Introduction

Semantic parsing maps a natural language sentence into a formal representation of its meaning. Due to the difficulty in deep semantic parsing, most previous work focuses on shallow semantic parsing, which assigns a simple structure (such as WHO did WHAT to WHOM, WHEN, WHERE, WHY, HOW) to each predicate in a sentence. In particular, the well-defined semantic role labeling (SRL) task has been drawing increasing attention in recent years due to its importance in natural language processing (NLP) applications, such as question answering (Narayanan and Harabagiu, 2004), information extraction (Surdeanu et al., 2003), and co-reference resolution (Kong et al., 2009). Given a sentence and a predicate (either a verb or a noun) in the sentence, SRL recognizes and maps all the constituents in the sentence into their corresponding semantic arguments (roles) of the predicate. In both English and Chinese PropBank (Palmer et al., 2005; Xue and Palmer, 2003), and English and Chinese NomBank (Meyers et al., 2004; Xue, 2006), these semantic arguments include core arguments (e.g., Arg0 for agent and Arg1 for recipient) and adjunct arguments (e.g., ArgM-LOC for locative argument and ArgM-TMP for temporal argument). According to predicate type, SRL can be divided into SRL for verbal predicates (verbal SRL, in short) and SRL for nominal predicates (nominal SRL, in short).

With the availability of large annotated corpora such as FrameNet (Baker et al., 1998), PropBank, and NomBank in English, data-driven techniques, including both feature-based and kernel-based methods, have been extensively studied for SRL (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005; Pradhan et al., 2005; Liu and Ng, 2007). Nevertheless, for both verbal and nominal SRL, state-of-the-art systems depend heavily on the top-best parse tree and there exists a large performance gap between SRL based on the gold parse tree and the top-best parse tree. For example, Pradhan et al. (2005) suffered a performance drop of 7.3 in F1-measure on English PropBank when using the top-best parse tree returned from Charniak's parser (Charniak, 2001). Liu and Ng (2007) reported a performance drop of 4.21 in F1-measure on English NomBank.

Compared with English SRL, Chinese SRL suffers more seriously from syntactic parsing. Xue (2008) evaluated on Chinese PropBank and showed that the performance of Chinese verbal SRL drops by about 25 in F1-measure when replacing gold parse trees with automatic ones. Likewise, Xue (2008) and Li et al. (2009) reported a performance drop of about 12 in F1-measure in Chinese NomBank SRL.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1108–1117,
Uppsala, Sweden, 11-16 July 2010.

While it may be difficult to further improve syntactic parsing, a promising alternative is to perform both syntactic and semantic parsing in an integrated way. Given the close interaction between the two tasks, joint learning not only allows uncertainty about syntactic parsing to be carried forward to semantic parsing but also allows useful information from semantic parsing to be carried backward to syntactic parsing.

This paper explores joint learning of syntactic and semantic parsing for Chinese texts from two levels. Firstly, an integrated parsing approach is proposed to benefit from the close interaction between syntactic and semantic parsing. This is done by integrating semantic parsing into the syntactic parsing process. Secondly, various semantic role-related features are directly incorporated into the syntactic parsing model to better capture semantic role-related information in syntactic parsing. Evaluation on Chinese TreeBank, Chinese PropBank, and Chinese NomBank shows that our method significantly improves the performance of both syntactic and semantic parsing. This is promising and encouraging. To our best knowledge, this is the first research on exploring syntactic parsing and SRL for verbal and nominal predicates in an integrated way.

The rest of this paper is organized as follows. Section 2 reviews related work. Section 3 presents our baseline systems for syntactic and semantic parsing. Section 4 presents our proposed method of joint syntactic and semantic parsing for Chinese texts. Section 5 presents the experimental results. Finally, Section 6 concludes the paper.

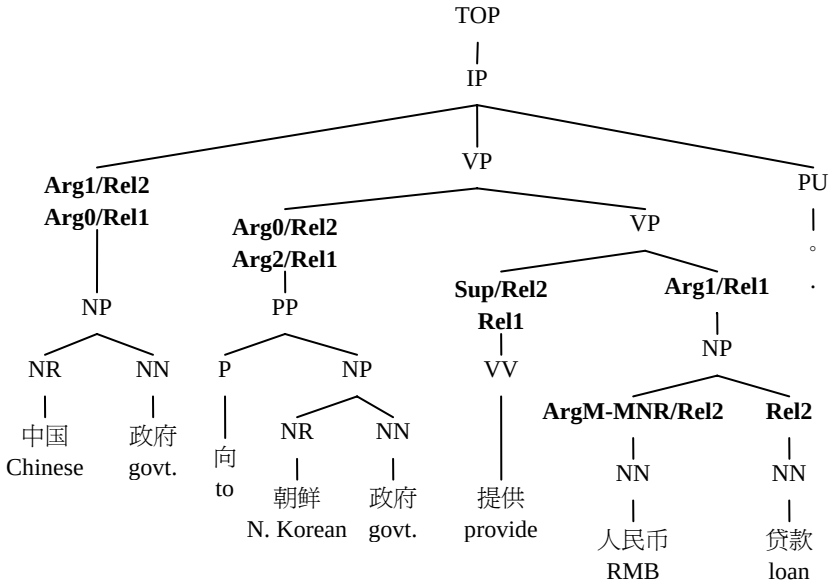
2 Related Work

Compared to the large body of work on either syntactic parsing (Ratnaparkhi, 1999; Collins, 1999; Charniak, 2001; Petrov and Klein, 2007), or SRL (Carreras and Màrquez, 2004; Carreras and Màrquez, 2005; Jiang and Ng, 2006), there is relatively less work on their joint learning.

Koomen et al. (2005) adopted the outputs of multiple SRL systems (each on a single parse tree) and combined them into a coherent predicate argument output by solving an optimization problem. Sutton and McCallum (2005) adopted a probabilistic SRL system to re-rank the N-best results of a probabilistic syntactic parser. However, they reported negative results, which they blamed on the inaccurate probability estimates from their locally trained SRL model.

As an alternative to the above pseudo-joint learning methods (strictly speaking, they are still pipeline methods), one can augment the syntactic label of a constituent with semantic information, like what function parsing does (Merlo and Musillo, 2005). Yi and Palmer (2005) observed that the distributions of semantic labels could potentially interact with the distributions of syntactic labels and redefined the boundaries of constituents. Based on this observation, they incorporated semantic role information into syntactic parse trees by extending syntactic constituent labels with their coarse-grained semantic roles (core argument or adjunct argument) in the sentence, and thus unified semantic parsing and syntactic parsing. The actual fine-grained semantic roles are assigned, as in other methods, by an ensemble classifier. However, the results obtained with this method were negative, and they concluded that semantic parsing on PropBank was too difficult due to the differences between chunk annotation and tree structure. Motivated by Yi and Palmer (2005), Merlo and Musillo (2008) first extended a statistical parser to produce a richly annotated tree that identifies and labels nodes with semantic role labels as well as syntactic labels. Then, they explored both rule-based and machine learning techniques to extract predicate-argument structures from this enriched output. Their experiments showed that their method was biased against these roles in general, thus lowering recall for them (e.g., precision of 87.6 and recall of 65.8).

There have been other efforts in NLP on joint learning with various degrees of success. In particular, the recent shared tasks of CoNLL 2008 and 2009 (Surdeanu et al., 2008; Hajic et al., 2009) tackled joint parsing of syntactic and semantic dependencies. However, all the top 5 reported systems decoupled the tasks, rather than building joint models. Compared with the disappointing results of joint learning on syntactic and semantic parsing, Miller et al. (2000) and Finkel and Manning (2009) showed the effectiveness of joint learning on syntactic parsing and some simple NLP tasks, such as information extraction and name entity recognition. In addition, attempts on joint Chinese word segmentation and part-of-speech (POS) tagging (Ng and Low, 2004; Zhang and Clark, 2008) also illustrate the benefits of joint learning.



Chinese government provides RMB loan to North Korean government.

Figure 1: Two predicates (Rel1 and Rel2) and their arguments in the style of Chinese PropBank and NomBank.

3 Baseline: Pipeline Parsing on Top-Best Parse Tree

In this section, we briefly describe our approach to syntactic parsing and semantic role labeling, as well as the baseline system with pipeline parsing on the top-best parse tree.

3.1 Syntactic Parsing

Our syntactic parser re-implements Ratnaparkhi (1999), which adopts the maximum entropy principle. The parser recasts a syntactic parse tree as a sequence of decisions similar to those of a standard shift-reduce parser and the parsing process is organized into three left-to-right passes via four procedures, called TAG, CHUNK, BUILD, and CHECK.

First pass. The first pass takes a tokenized sentence as input, and uses TAG to assign each word a part-of-speech.

Second pass. The second pass takes the output of the first pass as input, and uses CHUNK to recognize basic chunks in the sentence.

Third pass. The third pass takes the output of the second pass as input, and always alternates between BUILD and CHECK in structural parsing in a recursive manner. Here, BUILD decides whether a subtree will start a new constituent or join the incomplete constituent immediately to its left. CHECK finds the most recently proposed constituent, and decides if it is complete.

3.2 Semantic Role Labeling

Figure 1 demonstrates an annotation example of Chinese PropBank and NomBank. In the figure, the verbal predicate "提供/provide" is annotated with three core arguments (i.e., "NP (中国/Chinese 政府/govt.)" as Arg0, "PP (向/to 朝鲜/N. Korean 政府/govt.)" as Arg2, and "NP (人民币/RMB 贷款/loan)" as Arg1), while the nominal predicate "贷款/loan" is annotated with two core arguments (i.e., "NP (中国/Chinese 政府/govt.)" as Arg1 and "PP (向/to 朝鲜/N. Korean 政府/govt.)" as Arg0), and an adjunct argument (i.e., "NN (人民币/RMB)" as ArgM-MNR, denoting the manner of loan). It is worth pointing out that there is a (Chinese) NomBank-specific label in Figure 1, Sup (support verb) (Xue, 2006), to help introduce the arguments which occur outside the nominal predicate-headed noun phrase. In (Chinese) NomBank, a verb is considered to be a support verb only if it shares at least an argument with the nominal predicate.

3.2.1 Automatic Predicate Recognition

Automatic predicate recognition is a prerequisite for the application of SRL systems. For verbal predicates, it is very easy. For example, 99% of verbs are annotated as predicates in Chinese PropBank. Therefore, we can simply select any word with a part-of-speech (POS) tag of VV, VA, VC, or VE as verbal predicate.

Unlike verbal predicate recognition, nominal predicate recognition is quite complicated. For

example, only 17.5% of nouns are annotated as predicates in Chinese NomBank. It is quite common that a noun is annotated as a predicate in some cases but not in others. Therefore, automatic predicate recognition is vital to nominal SRL. In principle, automatic predicate recognition can be cast as a binary classification (e.g., Predicate vs. Non-Predicate) problem. For nominal predicates, a binary classifier is trained to predict whether a noun is a nominal predicate or not. In particular, any word POS-tagged as NN is considered as a predicate candidate in both training and testing processes. Let the nominal predicate candidate be w_0, and its left and right neighboring words/POSs be $w_{-1}/p_{-1}$and w_1/p_1, respectively. Table 1 lists the feature set used in our model. In Table 1, local features present the candidate's contextual information while global features show its statistical information in the whole training set.

Type	Description
local features	w_0, w_{-1}, w_1, p_{-1}, p_1 The first and last characters of the candidate
global features	Whether w_0 is ever tagged as a verb in the training data? Yes/No Whether w_0 is ever annotated as a nominal predicate in the training data? Yes/No The most likely label for w_0 when it occurs together with w_{-1} and w_1. The most likely label for w_0 when it occurs together with w_{-1}. The most likely label for w_0 when it occurs together with w_1.

Table 1: Feature set for nominal predicate recognition

3.2.2 SRL for Chinese Predicates

Our Chinese SRL models for both verbal and nominal predicates adopt the widely-used SRL framework, which divides the task into three sequential sub-tasks: argument pruning, argument identification, and argument classification. In particular, we follow Xue (2008) and Li et al. (2009) to develop verbal and nominal SRL models, respectively. Moreover, we have further improved the performance of Chinese verbal SRL by exploring additional features, e.g., voice position that indicates the voice maker (BA, BEI) is before or after the constituent in focus, the rule that expands the parent of the constituent in focus, and the core arguments defined in the predicate's frame file. For nominal SRL, we simply use the final feature set of Li et al. (2009). As a result, our Chinese verbal and nominal SRL systems achieve performance of 92.38 and 72.67 in F1-measure respectively (on golden parse trees and golden predicates), which are comparable to Xue (2008) and Li et al. (2009). For more details, please refer to Xue (2008) and Li et al. (2009).

3.3 Pipeline Parsing on Top-best Parse Tree

Similar to most of the state-of-the-art systems (Pradhan et al., 2005; Xue, 2008; Li et al., 2009), the top-best parse tree is first returned from our syntactic parser and then fed into the SRL system. Specifically, the verbal (nominal) SRL labeler is in charge of verbal (nominal) predicates, respectively. For each sentence, since SRL is only performed on one parse tree, only constituents in it are candidates for semantic arguments. Therefore, if no constituent in the parse tree can map the same text span to an argument in the manual annotation, the system will not get a correct annotation.

4 Joint Syntactic and Semantic Parsing

In this section, we first explore pipeline parsing on N-best parse trees, as a natural extension of pipeline parsing on the top-best parse tree. Then, joint syntactic and semantic parsing is explored for Chinese texts from two levels. Firstly, an integrated parsing approach to joint syntactic and semantic parsing is proposed. Secondly, various semantic role-related features are directly incorporated into the syntactic parsing model for better interaction between the two tasks.

4.1 Pipeline Parsing on N-best Parse Trees

The pipeline parsing approach employed in this paper is largely motivated by the general framework of re-ranking, as proposed in Sutton and McCallum (2005). The idea behind this approach is that it allows uncertainty about syntactic parsing to be carried forward through an N-best list, and that a reliable SRL system, to a certain extent, can reflect qualities of syntactic parse trees. Given a sentence *x*, a joint parsing model is defined over a semantic frame *F* and a parse tree *t* in a log-linear way:

$$\begin{aligned} &Score(F,t \mid x) \\ &= (1-\alpha)\log P(F \mid t,x) + \alpha \log P(t \mid x) \end{aligned} \quad (1)$$

where *P(t|x)* is returned by a probabilistic syntactic parsing model, e.g., our syntactic parser, and *P(F|t, x)* is returned by a probabilistic semantic parsing model, e.g. our verbal & nominal

Algorithm 1. The algorithm integrating syntactic parsing and SRL.

```
Assume:
  t: constituent which is complete with "YES" decision of CHECK procedure
  P: number of predicates
  P_i: i^th predicate
  S: SRL result, set of predicates and its arguments
BEGIN
  srl_prob = 0.0;
  FOR i=1 to P DO
    IF t covers P_i THEN
      T = number of children of t;
      FOR j=1 to T DO
        IF t's j^th child Ch_j does not cover P_i THEN
          Run SRL given predicate P_i and constituent Ch_j to get their semantic role
            lbl and its probability prob;
          IF lbl does not indicate non-argument THEN
            srl_prob += log( prob );
            S = S ∪ {(P_i, Ch_j, lbl)};
          END IF
        END IF
      END FOR
    END IF
  END FOR
  return srl_prob;
END
```

SRL systems. In our pipeline parsing approach, $P(t|x)$ is calculated as the product of all involved decisions' probabilities in the syntactic parsing model, and $P(F|t, x)$ is calculated as the product of all the semantic role labels' probabilities in a sentence (including both verbal and nominal SRL). That is to say, we only consider those constituents that are supposed to be arguments. Here, the parameter α is a balance factor indicating the importance of the semantic parsing model.

In particular, (F^*, t^*) with maximal $Score(F, t|x)$ is selected as the final syntactic and semantic parsing results. Given a sentence, N-best parse trees are generated first using the syntactic parser, and then for each parse tree, we predict the best SRL frame using our verbal and nominal SRL systems.

4.2 Integrated Parsing

Although pipeline parsing on N-best parse trees could relieve severe dependence on the quality of the top-best parse tree, there is still a potential drawback: this method suffers from the limited scope covered by the N-best parse trees since the items in the parse tree list may be too similar, especially for long sentences. For example, 50-best parse trees can only represent a combination of 5 to 6 binary ambiguities since 2^5 < 50 < 2^6.

Ideally, we should perform SRL on as many parse trees as possible, so as to enlarge the search scope. However, pipeline parsing on all possible parse trees is time-consuming and thus unrealistic. As an alternative, we turn to integrated parsing, which aims to perform syntactic and semantic parsing synchronously. The key idea is to construct a parse tree in a bottom-up way so that it is feasible to perform SRL at suitable moments, instead of only when the whole parse tree is built. Integrated parsing is practicable, mostly due to the following two observations: (1) Given a predicate in a parse tree, its semantic arguments are usually siblings of the predicate, or siblings of its ancestor. Actually, this special observation has been widely employed in SRL to prune non-arguments for a verbal or nominal predicate (Xue, 2008; Li et al., 2009). (2) SRL feature spaces (both in feature-based method and kernel-based method) mostly focus on the predicate-argument structure of a given (predicate, argument) pair. That is to say, once a predicate-argument structure is formed (i.e., an argument candidate is connected with the given predicate), there is enough contextual information to predict their SRL relation.

As far as our syntactic parser is concerned, we invoke the SRL systems once a new constituent covering a predicate is complete with a "YES" decision from the CHECK procedure. Algorithm

1 illustrates the integration of syntactic and semantic parsing. For the example shown in Figure 2, the CHECK procedure predicts a "YES" decision, indicating the immediately proposed constituent "VP (提供/provide 人民币/RMB 贷款/loan)" is complete. So, at this moment, the verbal SRL system is invoked to predict the semantic label of the constituent "NP (人民币/RMB 贷款/loan)", given the verbal predicate "VV (提供/provide)". Similarly, "PP (向/to 朝鲜/N. Korean 政府/govt.)" would also be semantically labeled as soon as "PP (向/to 朝鲜/N. Korean 政府/govt.)" and "VP (提供/provide 人民币/RMB 贷款/loan)" are merged into a bigger VP. In this way, both syntactic and semantic parsing are accomplished when the root node TOP is formed. It is worth pointing out that all features (Xue, 2008; Li et al., 2009) used in our SRL model can be instantiated and their values are same as the ones when the whole tree is available. In particular, the probability computed from the SRL model is interpolated with that of the syntactic parsing model in a log-linear way (with equal weights in our experiments). This is due to our hypothesis that the probability returned from SRL model is helpful to joint syntactic and semantic parsing, considering the close interaction between the two tasks.

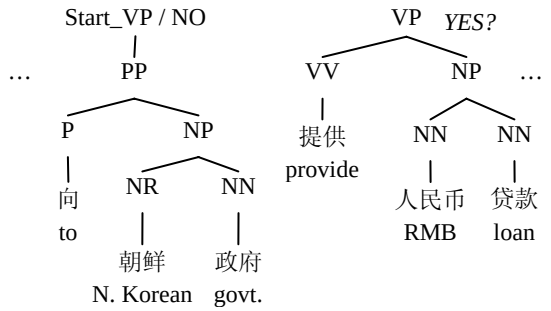


Figure 2: An application of CHECK with *YES* as the decision. Thus, VV (提供/provide) and NP (人民币/RMB 贷款/loan) reduce to a big VP.

4.3 Integrating Semantic Role-related Features into Syntactic Parsing Model

The integrated parsing approach as shown in Section 4.2 performs syntactic and semantic parsing synchronously. In contrast to traditional syntactic parsers where no semantic role-related information is used, it may be interesting to investigate the contribution of such information in the syntactic parsing model, due to the availability of such information in the syntactic parsing process. In addition, it is found that 11% of predicates in a sentence are speculatively attached with two or more core arguments with the same label due to semantic parsing errors (partly caused by syntactic parsing errors in automatic parse trees). This is abnormal since a predicate normally only allows at most one argument of each core argument role (i.e., Arg0-Arg4). Therefore, such syntactic errors should be avoidable by considering those arguments already obtained in the bottom-up parsing process. On the other hand, taking those expected semantic roles into account would help the syntactic parser. In terms of our syntactic parsing model, this is done by directly incorporating various semantic role-related features into the syntactic parsing model (i.e., the BUILD procedure) when the newly-formed constituent covers one or more predicates.

For the example shown in Figure 2, once the constituent "VP (提供/provide 人民币/RMB 贷款/loan)", which covers a verbal predicate "VV (提供/provide)", is complete, the verbal SRL model would be triggered first to mark constituent "NP (人民币/RMB 贷款/loan)" as ARG1, given predicate "VV (提供/provide)". Then, the BUILD procedure is called to make the BUILD decision for the newly-formed constituent "VP (提供/provide 人民币/RMB 贷款/loan)". Table 2 lists various semantic role-related features explored in our syntactic parsing model and their instantiations with regard to the example shown in Figure 2. In Table 2, feature sf4 gives the possible core semantic roles that the focus predicate may take, according to its frame file; feature sf5 presents the semantic roles that the focus predicate has already occupied; feature sf6 indicates the semantic roles that the focus predicate is expecting; and SF1-SF8 are combined features. Specifically, if the current constituent covers *n* predicates, then *14 * n* features would be instantiated. Moreover, we differentiate whether the focus predicate is verbal or nominal, and whether it is the head word of the current constituent.

Feature Selection. Some features proposed above may not be effective in syntactic parsing. Here we adopt the greedy feature selection algorithm as described in Jiang and Ng (2006) to select useful features empirically and incrementally according to their contributions on the development data. The algorithm repeatedly selects one feature each time which contributes the most, and stops when adding any of the remain-

ing features fails to improve the syntactic parsing performance.

Feat.	Description
sf1	Path: the syntactic path from C to P. *(VP>VV)*
sf2	Predicate: the predicate itself. *(提供/provide)*
sf3	Predicate class (Xue, 2008): the class that P belongs to. *(C3b)*
sf4	Possible roles: the core semantic roles P may take. *(Arg0, Arg1, Arg2)*
sf5	Detected roles: the core semantic roles already assigned to P. *(Arg1)*
sf6	Expected roles: possible semantic roles P is still expecting. *(Arg0, Arg2)*
SF1	For each already detected argument, its role label + its path from P. *(Arg1+VV<VP>NP)*
SF2	sf1 + sf2. *(VP>VV+提供/provide)*
SF3	sf1 + sf3. *(VP>VV+C3b)*
SF4	Combined possible argument roles. *(Arg0+Arg1+Arg2)*
SF5	Combined detected argument roles. *(Arg1)*
SF6	Combined expected argument roles. *(Arg0+Arg2)*
SF7	For each expected semantic role, sf1 + its role label. *(VP>VV+Arg0, VP>VV+Arg2)*
SF8	For each expected semantic role, sf2 + its role label. *(提供/provide+Arg0, 提供/provide+Arg2)*

Table 2: SRL-related features and their instantiations for syntactic parsing, with "VP (提供/provide 人民币/RMB 贷款/loan)" as the current constituent C and "提供/provide" as the focus predicate P, based on Figure 2.

5 Experiments and Results

We have evaluated our integrated parsing approach on Chinese TreeBank 5.1 and corresponding Chinese PropBank and NomBank.

5.1 Experimental Settings

This version of Chinese PropBank and Chinese NomBank consists of standoff annotations on the file (chtb 001 to 1151.fid) of Chinese Penn TreeBank 5.1. Following the experimental settings in Xue (2008) and Li et al. (2009), 648 files (chtb 081 to 899.fid) are selected as the training data, 72 files (chtb 001 to 040.fid and chtb 900 to 931.fid) are held out as the test data, and 40 files (chtb 041 to 080.fid) are selected as the development data. In particular, the training, test, and development data contain 31,361 (8,642), 3,599 (1,124), and 2,060 (731) verbal (nominal) propositions, respectively.

For the evaluation measurement on syntactic parsing, we report labeled recall, labeled precision, and their F1-measure. Also, we report recall, precision, and their F1-measure for evaluation of SRL on automatic predicates, combining verbal SRL and nominal SRL. An argument is correctly labeled if there is an argument in manual annotation with the same semantic label that spans the same words. Moreover, we also report the performance of predicate recognition. To see whether an improvement in F1-measure is statistically significant, we also conduct significance tests using a type of stratified shuffling which in turn is a type of compute-intensive randomized tests. In this paper, '>>>', '>>', and '>' denote p-values less than or equal to 0.01, in-between (0.01, 0.05], and bigger than 0.05, respectively.

We are not aware of any SRL system combing automatic predicate recognition, verbal SRL and nominal SRL on Chinese PropBank and NomBank. Xue (2008) experimented independently with verbal and nominal SRL and assumed correct predicates. Li et al. (2009) combined nominal predicate recognition and nominal SRL on Chinese NomBank. The CoNLL-2009 shared task (Hajic et al., 2009) included both verbal and nominal SRL on dependency parsing, instead of constituent-based syntactic parsing. Thus the SRL performances of their systems are not directly comparable to ours.

5.2 Results and Discussions

Results of pipeline parsing on N-best parse trees. While performing pipeline parsing on N-best parse trees, 20-best (the same as the heap size in our syntactic parsing) parse trees are obtained for each sentence using our syntactic parser as described in Section 3.1. The balance factor α is set to 0.5 indicating that the two components in formula (1) are equally important. Table 3 compares the two pipeline parsing approaches on the top-best parse tree and the N-best parse trees. It shows that the approach on N-best parse trees outperforms the one on the top-best parse tree by 0.42 (>>>) in F1-measure on SRL. In addition, syntactic parsing also benefits from the N-best parse trees approach with improvement of 0.17 (>>>) in F1-measure. This suggests that pipeline parsing on N-best parse trees can improve both syntactic and semantic parsing.

It is worth noting that our experimental results in applying the re-ranking framework in Chinese pipeline parsing on N-best parse trees are very encouraging, considering the pessimistic results of Sutton and McCallum (2005), in which the re-ranking framework failed to improve the performance on English SRL. It may be because,

unlike Sutton and McCallum (2005), $P(F, t|x)$ defined in this paper only considers those constituents which are identified as arguments. This can effectively avoid the noises caused by the predominant non-argument constituents. Moreover, the huge performance gap between Chinese semantic parsing on the gold parse tree and that on the top-best parse tree leaves much room for performance improvement.

Method	Task	R (%)	P (%)	F1
Pipeline on top -best parse tree	Syntactic	76.68	79.12	77.88
	SRL	62.96	65.04	63.98
	Predicate	94.18	92.28	93.22
	V-SRL	65.33	68.52	66.88
	V-Predicate	89.52	93.12	91.29
	N-SRL	49.58	48.19	48.88
	N-Predicate	86.83	71.76	78.58
Pipeline on 20 -best parse trees	Syntactic	76.89	79.25	78.05
	SRL	62.99	65.88	64.40
	Predicate	94.07	92.22	93.13
	V-SRL	65.41	69.09	67.20
	V-Predicate	89.66	93.02	91.31
	N-SRL	49.24	49.46	49.35
	N-Predicate	86.65	72.15	78.74
Integrated parsing	Syntactic	77.14	79.01	78.07
	SRL	62.67	67.67	65.07
	Predicate	93.97	92.42	93.19
	V-SRL	65.37	70.27	67.74
	V-Predicate	90.08	92.87	91.45
	N-SRL	48.02	52.83	50.31
	N-Predicate	85.41	73.23	78.85
Integrated parsing with semantic role-related features	Syntactic	77.47	79.58	78.51
	SRL	63.14	68.17	65.56
	Predicate	93.97	92.52	93.24
	V-SRL	65.74	70.98	68.26
	V-Predicate	89.86	93.17	91.49
	N-SRL	48.80	52.67	50.66
	N-Predicate	85.85	72.78	78.78

Table 3: Syntactic and semantic parsing performance on test data (using gold standard word boundaries). "V-" denotes "verbal" while "N-"denotes "nominal".

Results of integrated parsing. Table 3 also compares the integrated parsing approach with the two pipeline parsing approaches. It shows that the integrated parsing approach improves the performance of both syntactic and semantic parsing by 0.19 (>) and 1.09 (>>>) respectively in F1-measure over the pipeline parsing approach on the top-best parse tree. It is also not surprising to find out that the integrated parsing approach outperforms the pipeline parsing approach on 20-best parse trees by 0.67 (>>>) in F1-measure on SRL, due to its exploring a larger search space, although the integrated parsing approach integrates the SRL probability and the syntactic parsing probability in the same manner as the pipeline parsing approach on 20-best parse trees. However, the syntactic parsing performance gap between the integrated parsing approach and the pipeline parsing approach on 20-best parse trees is negligible.

Results of integrated parsing with semantic role-related features. After performing the greedy feature selection algorithm on the development data, features {SF3, SF2, sf5, sf6, SF4} as proposed in Section 4.3 are sequentially selected for syntactic parsing. As what we have assumed, knowledge about the detected semantic roles and expected semantic roles is helpful for syntactic parsing. Table 3 also lists the performance achieved with those selected features. It shows that the integration of semantic role-related features in integrated parsing significantly enhances both the performance of syntactic and semantic parsing by 0.44 (>>>) and 0.49 (>>) respectively in F1-measure. In addition, it shows that it outperforms the widely-used pipeline parsing approach on top-best parse tree by 0.63 (>>>) and 1.58 (>>>) in F1-measure on syntactic and semantic parsing, respectively. Finally, it shows that it outperforms the widely-used pipeline parsing approach on 20-best parse trees by 0.46 (>>>) and 1.16 (>>>) in F1-measure on syntactic and semantic parsing, respectively. This is very encouraging, considering the notorious difficulty and complexity of both the syntactic and semantic parsing tasks.

Table 3 also shows that our proposed method works well for both verbal SRL and nominal SRL. In addition, it shows that the performance of predicate recognition is very stable due to its high dependence on POS tagging results, rather than syntactic parsing results. Finally, it is not surprising to find out that the performance of predicate recognition when mixing verbal and nominal predicates is better than the performance of either verbal predicates or nominal predicates.

5.3 Extending the Word-based Syntactic Parser to a Character-based Syntactic Parser

The above experimental results on a word-based syntactic parser (assuming correct word segmentation) show that both syntactic and semantic parsing benefit from our integrated parsing approach. However, observing the great challenge of word segmentation in Chinese informa-

tion processing, it is still unclear whether and how much joint learning benefits character-based syntactic and semantic parsing. In this section, we extended the Ratnaparkhi parser (1999) to a character-based parser (with automatic word segmentation), and then examined the effectiveness of joint learning.

Given the three-pass process in the word-based syntactic parser, it is easy to extend it to a character-based parser for Chinese texts. This can be done by only replacing the TAG procedure in the first pass with a POSCHUNK procedure, which integrates Chinese word segmentation and POS tagging in one step, following the method described in (Ng and Low 2004). Here, each character is annotated with both a boundary tag and a POS tag. The 4 possible boundary tags include "B" for a character that begins a word and is followed by another character, "M" for a character that occurs in the middle of a word, "E" for a character that ends a word, and "S" for a character that occurs as a single-character word. For example, "北京市/Beijing city/NR" would be decomposed into three units: "北/north/B_NR", "京/capital/M_NR", and "市/city/E_NR". Also, "是/is/VC" would turn into "是/is/S_VC". Through POSCHUNK, all characters in a sentence are first assigned with POS chunk labels which must be compatible with previous ones, and then merged into words with their POS tags. For example, "北/north/B_NR", "京/capital/M_NR", and "市/city/E_NR" will be merged as "北京市/Beijing/NR", "是/is/S_VC" will become "是/is/VC". Finally the merged results of the POSCHUNK are fed into the CHUNK procedure of the second pass.

Using the same data split as the previous experiments, word segmentation achieves performance of 96.3 in F1-measure on the test data. Table 4 lists the syntactic and semantic parsing performance by adopting the character-based parser.

Table 4 shows that integrated parsing benefits syntactic and semantic parsing when automatic word segmentation is considered. However, the improvements are smaller due to the extra noise caused by automatic word segmentation. For example, our experiments show that the performance of predicate recognition drops from 93.2 to 90.3 in F1-measure when replacing correct word segmentations with automatic ones.

Method	Task	R (%)	P (%)	F1
Pipeline on top-best parse tree	Syntactic	82.23	84.28	83.24
	SRL	60.40	62.75	61.55
Pipeline on 20-best parse trees	Syntactic	82.25	84.29	83.26
	SRL	60.17	63.63	61.85
Integrated parsing with semantic role-related features	Syntactic	82.51	84.31	83.40
	SRL	60.09	65.35	62.61

Table 4: Performance with the character-based parser[1] (using automatically recognized word boundaries).

6 Conclusion

In this paper, we explore joint syntactic and semantic parsing to improve the performance of both syntactic and semantic parsing, in particular that of semantic parsing. Evaluation shows that our integrated parsing approach outperforms the pipeline parsing approach on N-best parse trees, a natural extension of the widely-used pipeline parsing approach on the top-best parse tree. It also shows that incorporating semantic information into syntactic parsing significantly improves the performance of both syntactic and semantic parsing. This is very promising and encouraging, considering the complexity of both syntactic and semantic parsing.

To our best knowledge, this is the first successful research on exploring syntactic parsing and semantic role labeling for verbal and nominal predicates in an integrated way.

Cross-Language Text Classification using Structural Correspondence Learning

Peter Prettenhofer and **Benno Stein**

Bauhaus-Universität Weimar
D-99421 Weimar, Germany
{peter.prettenhofer,benno.stein}@uni-weimar.de

Abstract

We present a new approach to cross-language text classification that builds on structural correspondence learning, a recently proposed theory for domain adaptation. The approach uses unlabeled documents, along with a simple word translation oracle, in order to induce task-specific, cross-lingual word correspondences. We report on analyses that reveal quantitative insights about the use of unlabeled data and the complexity of inter-language correspondence modeling.

We conduct experiments in the field of cross-language sentiment classification, employing English as source language, and German, French, and Japanese as target languages. The results are convincing; they demonstrate both the robustness and the competitiveness of the presented ideas.

1 Introduction

This paper deals with cross-language text classification problems. The solution of such problems requires the transfer of classification knowledge between two languages. Stated precisely: We are given a text classification task γ in a target language $\mathcal{T}$ for which no labeled documents are available. γ may be a spam filtering task, a topic categorization task, or a sentiment classification task. In addition, we are given *labeled* documents for the identical task in a different source language $\mathcal{S}$.

Such type of cross-language text classification problems are addressed by constructing a classifier $f_{\mathcal{S}}$ with training documents written in $\mathcal{S}$ and by applying $f_{\mathcal{S}}$ to unlabeled documents written in $\mathcal{T}$. For the application of $f_{\mathcal{S}}$ under language $\mathcal{T}$ different approaches are current practice: machine translation of unlabeled documents from $\mathcal{T}$ to $\mathcal{S}$, dictionary-based translation of unlabeled documents from $\mathcal{T}$ to $\mathcal{S}$, or language-independent concept modeling by means of comparable corpora. The mentioned approaches have their pros and cons, some of which are discussed below.

Here we propose a different approach to cross-language text classification which adopts ideas from the field of multi-task learning (Ando and Zhang, 2005a). Our approach builds upon structural correspondence learning, SCL, a recently proposed theory for domain adaptation in the field of natural language processing (Blitzer et al., 2006).

Similar to SCL, our approach induces correspondences among the words from both languages by means of a small number of so-called *pivots*. In our context a pivot is a pair of words, $\{w_{\mathcal{S}}, w_{\mathcal{T}}\}$, from the source language $\mathcal{S}$ and the target language $\mathcal{T}$, which possess a similar semantics. Testing the occurrence of $w_{\mathcal{S}}$ or $w_{\mathcal{T}}$ in a set of unlabeled documents from $\mathcal{S}$ and $\mathcal{T}$ yields two equivalence classes *across* these languages: one class contains the documents where either $w_{\mathcal{S}}$ or $w_{\mathcal{T}}$ occur, the other class contains the documents where neither $w_{\mathcal{S}}$ nor $w_{\mathcal{T}}$ occur. Ideally, a pivot splits the set of unlabeled documents with respect to the semantics that is associated with $\{w_{\mathcal{S}}, w_{\mathcal{T}}\}$. The correlation between $w_{\mathcal{S}}$ or $w_{\mathcal{T}}$ and other words w, $w \notin \{w_{\mathcal{S}}, w_{\mathcal{T}}\}$ is modeled by a linear classifier, which then is used as a language-independent predictor for the two equivalence classes. As we will see, a small number of pivots can capture a sufficiently large part of the correspondences between $\mathcal{S}$ and $\mathcal{T}$ in order to (1) construct a cross-lingual representation and (2) learn a classifier $f_{\mathcal{ST}}$ for the task γ that operates on this representation. Several advantages follow from our approach:

- Task specificity. The approach exploits the words' pragmatics since it considers—during the pivot selection step—task-specific characteristics of language use.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1118–1127,
Uppsala, Sweden, 11-16 July 2010.

- Efficiency in terms of linguistic resources. The approach uses unlabeled documents from both languages along with a small number (100 - 500) of translated words, instead of employing a parallel corpus or an extensive bilingual dictionary.

- Efficiency in terms of computing resources. The approach solves the classification problem directly, instead of resorting to a more general and potentially much harder problem such as machine translation. Note that the use of such technology is prohibited in certain situations (market competitors) or restricted by environmental constraints (offline situations, high latency, bandwidth capacity).

Contributions Our contributions to the outlined field are threefold: First, the identification and utilization of the theory of SCL to cross-language text classification, which has, to the best of our knowledge, not been investigated before. Second, the further development and adaptation of SCL towards a technology that is competitive with the state-of-the-art in cross-language text classification. Third, an in-depth analysis with respect to important hyperparameters such as the ratio of labeled and unlabeled documents, the number of pivots, and the optimum dimensionality of the cross-lingual representation. In this connection we compile extensive corpora in the languages English, German, French, and Japanese, and for different sentiment classification tasks.

The paper is organized as follows: Section 2 surveys related work. Section 3 states the terminology for cross-language text classification. Section 4 describes our main contribution, a new approach to cross-language text classification based on structural correspondence learning. Section 5 presents experimental results in the context of cross-language sentiment classification.

2 Related Work

Cross-Language Text Classification Bel et al. (2003) belong to the first who explicitly considered the problem of cross-language text classification. Their research, however, is predated by work in cross-language information retrieval, CLIR, where similar problems are addressed (Oard, 1998). Traditional approaches to cross-language text classification and CLIR use linguistic resources such as bilingual dictionaries or parallel corpora to induce correspondences between two languages (Lavrenko et al., 2002; Olsson et al., 2005). Dumais et al. (1997) is considered as seminal work in CLIR: they propose a method which induces semantic correspondences between two languages by performing latent semantic analysis, LSA, on a parallel corpus. Li and Taylor (2007) improve upon this method by employing kernel canonical correlation analysis, CCA, instead of LSA. The major limitation of these approaches is their computational complexity and, in particular, the dependence on a parallel corpus, which is hard to obtain—especially for less resource-rich languages. Gliozzo and Strapparava (2005) circumvent the dependence on a parallel corpus by using so-called multilingual domain models, which can be acquired from comparable corpora in an unsupervised manner. In (Gliozzo and Strapparava, 2006) they show for particular tasks that their approach can achieve a performance close to that of monolingual text classification.

Recent work in cross-language text classification focuses on the use of automatic machine translation technology. Most of these methods involve two steps: (1) translation of the documents into the source or the target language, and (2) dimensionality reduction or semi-supervised learning to reduce the noise introduced by the machine translation. Methods which follow this two-step approach include the EM-based approach by Rigutini et al. (2005), the CCA approach by Fortuna and Shawe-Taylor (2005), the information bottleneck approach by Ling et al. (2008), and the co-training approach by Wan (2009).

Domain Adaptation Domain adaptation refers to the problem of adapting a statistical classifier trained on data from one (or more) source domains (e.g., newswire texts) to a different target domain (e.g., legal texts). In the basic domain adaptation setting we are given labeled data from the source domain and unlabeled data from the target domain, and the goal is to train a classifier for the target domain. Beyond this setting one can further distinguish whether a small amount of labeled data from the target domain is available (Daume, 2007; Finkel and Manning, 2009) or not (Blitzer et al., 2006; Jiang and Zhai, 2007). The latter setting is referred to as unsupervised domain adaptation.

Note that, cross-language text classification can be cast as an unsupervised domain adaptation problem by considering each language as a separate domain. Blitzer et al. (2006) propose an effective algorithm for unsupervised domain adaptation, called structural correspondence learning. First, SCL identifies features that generalize across domains, which the authors call pivots. SCL then models the correlation between the pivots and all other features by training linear classifiers on the unlabeled data from both domains. This information is used to induce correspondences among features from the different domains and to learn a shared representation that is meaningful across both domains. SCL is related to the structural learning paradigm introduced by Ando and Zhang (2005a). The basic idea of structural learning is to constrain the hypothesis space of a learning task by considering multiple different but related tasks on the same input space. Ando and Zhang (2005b) present a semi-supervised learning method based on this paradigm, which generates related tasks from unlabeled data. Quattoni et al. (2007) apply structural learning to image classification in settings where little labeled data is given.

3 Cross-Language Text Classification

This section introduces basic models and terminology.

In standard text classification, a document d is represented under the bag-of-words model as $|V|$-dimensional feature vector $\mathbf{x} \in X$, where V, the vocabulary, denotes an ordered set of words, $x_i \in \mathbf{x}$ denotes the normalized frequency of word i in d, and X is an inner product space. $D_{\mathcal{S}}$ denotes the training set and comprises tuples of the form $(\mathbf{x}, y)$, which associate a feature vector $\mathbf{x} \in X$ with a class label $y \in Y$. The goal is to find a classifier $f : X \rightarrow Y$ that predicts the labels of new, previously unseen documents. Without loss of generality we restrict ourselves to binary classification problems and linear classifiers, i.e., $Y = \{+1, -1\}$ and $f(\mathbf{x}) = sign(\mathbf{w}^T\mathbf{x})$. $\mathbf{w}$ is a weight vector that parameterizes the classifier, $[\cdot]^T$ denotes the matrix transpose. The computation of $\mathbf{w}$ from $D_{\mathcal{S}}$ is referred to as model estimation or training. A common choice for $\mathbf{w}$ is given by a vector $\mathbf{w}^*$ that minimizes the regularized training error:

$$\mathbf{w}^* = \underset{\mathbf{w}\in\mathbf{R}^{|V|}}{\operatorname{argmin}} \sum_{(\mathbf{x},y)\in D_{\mathcal{S}}} L(y,\, \mathbf{w}^T\mathbf{x}) + \frac{\lambda}{2}\|\mathbf{w}\|^2 \quad (1)$$

L is a loss function that measures the quality of the classifier, λ is a non-negative regularization parameter that penalizes model complexity, and $\|\mathbf{w}\|^2 = \mathbf{w}^T\mathbf{w}$. Different choices for L entail different classifier types; e.g., when choosing the hinge loss function for L one obtains the popular Support Vector Machine classifier (Zhang, 2004).

Standard text classification distinguishes between labeled (training) documents and unlabeled (test) documents. Cross-language text classification poses an extra constraint in that training documents and test documents are written in different languages. Here, the language of the training documents is referred to as source language $\mathcal{S}$, and the language of the test documents is referred to as target language $\mathcal{T}$. The vocabulary V divides into $V_{\mathcal{S}}$ and $V_{\mathcal{T}}$, called vocabulary of the source language and vocabulary of the target language, with $V_{\mathcal{S}} \cap V_{\mathcal{T}} = \emptyset$. I.e., documents from the training set and the test set map on two non-overlapping regions of the feature space. Thus, a linear classifier $f_{\mathcal{S}}$ trained on $D_{\mathcal{S}}$ associates non-zero weights only with words from $V_{\mathcal{S}}$, which in turn means that $f_{\mathcal{S}}$ cannot be used to classify documents written in $\mathcal{T}$.

One way to overcome this "feature barrier" is to find a cross-lingual representation for documents written in $\mathcal{S}$ and $\mathcal{T}$, which enables the transfer of classification knowledge between the two languages. Intuitively, one can understand such a cross-lingual representation as a concept space that underlies both languages. In the following, we will use θ to denote a map that associates the original $|V|$-dimensional representation of a document d written in $\mathcal{S}$ or $\mathcal{T}$ with its cross-lingual representation. Once such a mapping is found the cross-language text classification problem reduces to a standard classification problem in the cross-lingual space. Note that the existing methods for cross-language text classification can be characterized by the way θ is constructed. For instance, cross-language latent semantic indexing (Dumais et al., 1997) and cross-language explicit semantic analysis (Potthast et al., 2008) estimate θ using a parallel corpus. Other methods use linguistic resources such as a bilingual dictionary to obtain θ (Bel et al., 2003; Olsson et al., 2005).

4 Cross-Language Structural Correspondence Learning

We now present a novel method for learning a map θ by exploiting relations from unlabeled documents written in $\mathcal{S}$ and $\mathcal{T}$. The proposed method, which we call cross-language structural correspondence learning, CL-SCL, addresses the following learning setup (see also Figure 1):

- Given a set of labeled training documents $D_{\mathcal{S}}$ written in language $\mathcal{S}$, the goal is to create a text classifier for documents written in a different language $\mathcal{T}$. We refer to this classification task as the *target task*. An example for the target task is the determination of sentiment polarity, either positive or negative, of book reviews written in German ($\mathcal{T}$) given a set of training reviews written in English ($\mathcal{S}$).

- In addition to the labeled training documents $D_{\mathcal{S}}$ we have access to unlabeled documents $D_{\mathcal{S},u}$ and $D_{\mathcal{T},u}$ from both languages $\mathcal{S}$ and $\mathcal{T}$. Let D_u denote $D_{\mathcal{S},u} \cup D_{\mathcal{T},u}$.

- Finally, we are given a budget of calls to a word translation oracle (e.g., a domain expert) to map words in the source vocabulary $V_{\mathcal{S}}$ to their corresponding translations in the target vocabulary $V_{\mathcal{T}}$. For simplicity and without loss of applicability we assume here that the word translation oracle maps each word in $V_{\mathcal{S}}$ to exactly one word in $V_{\mathcal{T}}$.

CL-SCL comprises three steps: In the first step, CL-SCL selects word pairs $\{w_{\mathcal{S}}, w_{\mathcal{T}}\}$, called pivots, where $w_{\mathcal{S}} \in V_{\mathcal{S}}$ and $w_{\mathcal{T}} \in V_{\mathcal{T}}$. Pivots have to satisfy the following conditions:

Confidence Both words, $w_{\mathcal{S}}$ and $w_{\mathcal{T}}$, are predictive for the target task.

Support Both words, $w_{\mathcal{S}}$ and $w_{\mathcal{T}}$, occur frequently in $D_{\mathcal{S},u}$ and $D_{\mathcal{T},u}$ respectively.

The confidence condition ensures that, in the second step of CL-SCL, only those correlations are modeled that are useful for discriminative learning. The support condition, on the other hand, ensures that these correlations can be estimated accurately. Considering our sentiment classification example, the word pair $\{\text{excellent}_{\mathcal{S}}, \text{exzellent}_{\mathcal{T}}\}$ satisfies both conditions: (1) the words are strong indicators of positive sentiment, and (2) the words occur frequently in book reviews from both languages. Note that the support of $w_{\mathcal{S}}$ and $w_{\mathcal{T}}$ can be determined from the unlabeled data D_u. The confidence, however, can only be determined for $w_{\mathcal{S}}$ since the setting gives us access to labeled data from $\mathcal{S}$ only.

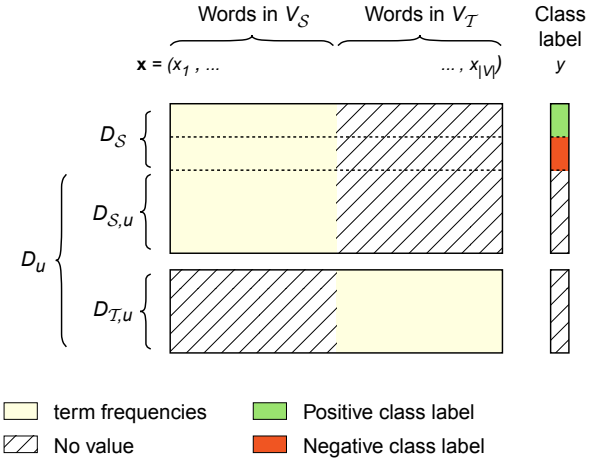

Figure 1: The document sets underlying CL-SCL. The subscripts $_{\mathcal{S}}$, $_{\mathcal{T}}$, and $_u$ designate "source language", "target language", and "unlabeled".

We use the following heuristic to form an ordered set P of pivots: First, we choose a subset V_P from the source vocabulary $V_{\mathcal{S}}$, $|V_P| \ll |V_{\mathcal{S}}|$, which contains those words with the highest mutual information with respect to the class label of the target task in $D_{\mathcal{S}}$. Second, for each word $w_{\mathcal{S}} \in V_P$ we find its translation in the target vocabulary $V_{\mathcal{T}}$ by querying the translation oracle; we refer to the resulting set of word pairs as the candidate pivots, P':

$$P' = \{\{w_{\mathcal{S}}, \textsc{translate}(w_{\mathcal{S}})\} \mid w_{\mathcal{S}} \in V_P\}$$

We then enforce the support condition by eliminating in P' all candidate pivots $\{w_{\mathcal{S}}, w_{\mathcal{T}}\}$ where the document frequency of $w_{\mathcal{S}}$ in $D_{\mathcal{S},u}$ or of $w_{\mathcal{T}}$ in $D_{\mathcal{T},u}$ is smaller than some threshold ϕ:

$$P = \textsc{candidateElimination}(P', \phi)$$

Let m denote $|P|$, the number of pivots.

In the second step, CL-SCL models the correlations between each pivot $\{w_{\mathcal{S}}, w_{\mathcal{T}}\} \in P$ and all other words $w \in V \setminus \{w_{\mathcal{S}}, w_{\mathcal{T}}\}$. This is done by training linear classifiers that predict whether or not $w_{\mathcal{S}}$ or $w_{\mathcal{T}}$ occur in a document, based on the other words. For this purpose a training set D_l is created for each pivot $p_l \in P$:

$$D_l = \{(\textsc{mask}(\mathbf{x}, p_l), \textsc{in}(\mathbf{x}, p_l)) \mid \mathbf{x} \in D_u\}$$

MASK$(\mathbf{x}, p_l)$ is a function that returns a copy of $\mathbf{x}$ where the components associated with the two words in p_l are set to zero—which is equivalent to removing these words from the feature space. IN$(\mathbf{x}, p_l)$ returns +1 if one of the components of $\mathbf{x}$ associated with the words in p_l is non-zero and -1 otherwise. For each D_l a linear classifier, characterized by the parameter vector $\mathbf{w}_l$, is trained by minimizing Equation (1) on D_l. Note that each training set D_l contains documents from both languages. Thus, for a pivot $p_l = \{w_\mathcal{S}, w_\mathcal{T}\}$ the vector $\mathbf{w}_l$ captures both the correlation between $w_\mathcal{S}$ and $V_\mathcal{S} \setminus \{w_\mathcal{S}\}$ and the correlation between $w_\mathcal{T}$ and $V_\mathcal{T} \setminus \{w_\mathcal{T}\}$.

In the third step, CL-SCL identifies correlations *across* pivots by computing the singular value decomposition of the $|V| \times m$-dimensional parameter matrix $\mathbf{W}$, $\mathbf{W} = \begin{bmatrix}\mathbf{w}_1 & \dots & \mathbf{w}_m\end{bmatrix}$:

$$\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T = \text{SVD}(\mathbf{W})$$

Recall that $\mathbf{W}$ encodes the correlation structure between pivot and non-pivot words in the form of multiple linear classifiers. Thus, the columns of $\mathbf{U}$ identify common substructures among these classifiers. Choosing the columns of $\mathbf{U}$ associated with the largest singular values yields those substructures that capture most of the correlation in $\mathbf{W}$. We define θ as those columns of $\mathbf{U}$ that are associated with the k largest singular values:

$$\theta = \mathbf{U}^T_{[1:k,\, 1:|V|]}$$

Algorithm 1 summarizes the three steps of CL-SCL. At training and test time, we apply the projection θ to each input instance $\mathbf{x}$. The vector $\mathbf{v}^*$ that minimizes the regularized training error for $D_\mathcal{S}$ in the projected space is defined as follows:

$$\mathbf{v}^* = \operatorname*{argmin}_{\mathbf{v} \in \mathbf{R}^k} \sum_{(\mathbf{x},y) \in D_\mathcal{S}} L(y,\, \mathbf{v}^T\theta\mathbf{x}) + \frac{\lambda}{2}\|\mathbf{v}\|^2 \quad (2)$$

The resulting classifier $f_{\mathcal{ST}}$, which will operate in the cross-lingual setting, is defined as follows:

$$f_{\mathcal{ST}}(\mathbf{x}) = sign(\mathbf{v}^{*T}\theta\mathbf{x})$$

4.1 An Alternative View of CL-SCL

An alternative view of cross-language structural correspondence learning is provided by the framework of structural learning (Ando and Zhang, 2005a). The basic idea of structural learning is to constrain the hypothesis space, i.e., the space of possible weight vectors, of the target task by considering multiple different but related prediction tasks. In our context these auxiliary tasks are represented by the pivot predictors, i.e., the columns of $\mathbf{W}$. Each column vector $\mathbf{w}_l$ can be considered as a linear classifier which performs well in both languages. I.e., we regard the column space of $\mathbf{W}$ as an approximation to the *subspace of bilingual classifiers*. By computing SVD$(\mathbf{W})$ one obtains a compact representation of this column space in the form of an orthonormal basis θ^T.

The subspace is used to constrain the learning of the target task by restricting the weight vector $\mathbf{w}$ to lie in the subspace defined by θ^T. Following Ando and Zhang (2005a) and Quattoni et al. (2007) we choose $\mathbf{w}$ for the target task to be $\mathbf{w}^* = \theta^T\mathbf{v}^*$, where $\mathbf{v}^*$ is defined as follows:

$$\mathbf{v}^* = \operatorname*{argmin}_{\mathbf{v} \in \mathbf{R}^k} \sum_{(\mathbf{x},y) \in D_\mathcal{S}} L(y,\, (\theta^T\mathbf{v})^T\mathbf{x}) + \frac{\lambda}{2}\|\mathbf{v}\|^2 \quad (3)$$

Since $(\theta^T\mathbf{v})^T = \mathbf{v}^T\theta$ it follows that this view of CL-SCL corresponds to the induction of a new feature space given by Equation 2.

Algorithm 1 CL-SCL

Input: Labeled source data $D_\mathcal{S}$
Unlabeled data $D_u = D_{\mathcal{S},u} \cup D_{\mathcal{T},u}$

Parameters: m, k, λ, and ϕ

Output: $k \times |V|$-dimensional matrix θ

1. SELECTPIVOTS$(D_\mathcal{S}, m)$
$V_P = \text{MUTUALINFORMATION}(D_\mathcal{S})$
$P' = \{\{w_\mathcal{S}, \text{TRANSLATE}(w_\mathcal{S})\} \mid w_\mathcal{S} \in V_P\}$
$P = \text{CANDIDATEELIMINATION}(P', \phi)$

2. TRAINPIVOTPREDICTORS(D_u, P)
for $l = 1$ **to** m **do**
$D_l = \{(\text{MASK}(\mathbf{x}, p_l),\ \text{IN}(\mathbf{x}, p_l)) \mid \mathbf{x} \in D_u\}$
$\mathbf{w}_l = \operatorname*{argmin}_{\mathbf{w} \in \mathbf{R}^{|V|}} \sum_{(\mathbf{x},y) \in D_l} L(y, \mathbf{w}^T\mathbf{x})) + \frac{\lambda}{2}\|\mathbf{w}\|^2$
end for
$\mathbf{W} = \begin{bmatrix}\mathbf{w}_1 & \dots & \mathbf{w}_m\end{bmatrix}$

3. COMPUTESVD$(\mathbf{W}, k)$
$\mathbf{U}\mathbf{\Sigma}\mathbf{V}^T = \text{SVD}(\mathbf{W})$
$\theta = \mathbf{U}^T_{[1:k,\, 1:|V|]}$

output $\{\theta\}$

5 Experiments

We evaluate CL-SCL for the task of cross-language sentiment classification using English as source language and German, French, and Japanese as target languages. Special emphasis is put on corpus construction, determination of upper bounds and baselines, and a sensitivity analysis of important hyperparameters. All data described in the following is publicly available from our project website.[1]

5.1 Dataset and Preprocessing

We compiled a new dataset for cross-language sentiment classification by crawling product reviews from Amazon.{de | fr | co.jp}. The crawled part of the corpus contains more than 4 million reviews in the three languages German, French, and Japanese. The corpus is extended with English product reviews provided by Blitzer et al. (2007). Each review contains a category label, a title, the review text, and a rating of 1-5 stars. Following Blitzer et al. (2007) a review with >3 (<3) stars is labeled as positive (negative); other reviews are discarded. For each language the labeled reviews are grouped according to their category label, whereas we restrict our experiments to three categories: books, dvds, and music.

Since most of the crawled reviews are positive (80%), we decide to balance the number of positive and negative reviews. In this study, we are interested in whether the cross-lingual representation induced by CL-SCL captures the difference between positive and negative reviews; by balancing the reviews we ensure that the imbalance does not affect the learned model. Balancing is achieved by deleting reviews from the majority class uniformly at random for each language-specific category. The resulting sets are split into three disjoint, balanced sets, containing training documents, test documents, and unlabeled documents; the respective set sizes are 2,000, 2,000, and 9,000-50,000. See Table 1 for details.

For each of the nine target-language-category-combinations a text classification task is created by taking the training set of the product category in $\mathcal{S}$ and the test set of the same product category in $\mathcal{T}$. A document d is described as normalized feature vector $\mathbf{x}$ under a unigram bag-of-words document representation. The morphological analyzer MeCab is used for Japanese word segmentation.[2]

5.2 Implementation

Throughout the experiments linear classifiers are employed; they are trained by minimizing Equation (1), using a stochastic gradient descent (SGD) algorithm. In particular, the learning rate schedule from PEGASOS is adopted (Shalev-Shwartz et al., 2007), and the modified Huber loss, introduced by Zhang (2004), is chosen as loss function L.[3]

SGD receives two hyperparameters as input: the number of iterations T, and the regularization parameter λ. In our experiments T is always set to 10^6, which is about the number of iterations required for SGD to converge. For the target task, λ is determined by 3-fold cross-validation, testing for λ all values $10^{-i}, i \in [0; 6]$. For the pivot prediction task, λ is set to the small value of 10^{-5}, in order to favor model accuracy over generalizability.

The computational bottleneck of CL-SCL is the SVD of the dense parameter matrix $\mathbf{W}$. Here we follow Blitzer et al. (2006) and set the negative values in $\mathbf{W}$ to zero, which yields a sparse representation. For the SVD computation the Lanczos algorithm provided by SVDLIBC is employed.[4] We investigated an alternative approach to obtain a sparse $\mathbf{W}$ by directly enforcing sparse pivot predictors $\mathbf{w}_l$ through L1-regularization (Tsuruoka et al., 2009), but didn't pursue this strategy due to unstable results. Since SGD is sensitive to feature scaling the projection $\theta\mathbf{x}$ is post-processed as follows: (1) Each feature of the cross-lingual representation is standardized to zero mean and unit variance, where mean and variance are estimated on $D_{\mathcal{S}} \cup D_u$. (2) The cross-lingual document representations are scaled by a constant α such that $|D_{\mathcal{S}}|^{-1} \sum_{\mathbf{x} \in D_{\mathcal{S}}} \|\alpha\theta\mathbf{x}\| = 1$.

We use Google Translate as word translation oracle, which returns a single translation for each query word.[5] Though such a context free translation is suboptimum we do not sanitize the returned words to demonstrate the robustness of CL-SCL with respect to translation noise. To ensure the reproducibility of our results we cache all queries to the translation oracle.

Table 1: Cross-language sentiment classification results. For each task, the number of unlabeled documents from $\mathcal{S}$ and $\mathcal{T}$ is given. Accuracy scores (mean μ and standard deviation σ of 10 repetitions of SGD) on the test set of the target language $\mathcal{T}$ are reported. Δ gives the difference in accuracy to the upper bound. CL-SCL uses $m = 450$, $k = 100$, and $\phi = 30$.

5.3 Upper Bound and Baseline

To get an upper bound on the performance of a cross-language method we first consider the monolingual setting. For each target-language-category-combination a linear classifier is learned on the training set and tested on the test set. The resulting accuracy scores are referred to as upper bound; it informs us about the expected performance on the target task if training data in the target language is available.

We chose a machine translation baseline to compare CL-SCL to another cross-language method. Statistical machine translation technology offers a straightforward solution to the problem of cross-language text classification and has been used in a number of cross-language sentiment classification studies (Hiroshi et al., 2004; Bautin et al., 2008; Wan, 2009). Our baseline CL-MT works as follows: (1) learn a linear classifier on the training data, and (2) translate the test documents into the source language,[6] (3) predict the sentiment polarity of the translated test documents. Note that the baseline CL-MT does not make use of unlabeled documents.

[6] Again we use Google Translate.

5.4 Performance Results and Sensitivity

Table 1 contrasts the classification performance of CL-SCL with the upper bound and with the baseline. Observe that the upper bound does not exhibit a great variability across the three languages. The average accuracy is about 82%, which is consistent with prior work on monolingual sentiment analysis (Pang et al., 2002; Blitzer et al., 2007). The performance of CL-MT, however, differs considerably between the two European languages and Japanese: for Japanese, the average difference between the upper bound and CL-MT (9.9%) is about twice as much as for German and French (5.3%). This difference can be explained by the fact that machine translation works better for European than for Asian languages such as Japanese.

Recall that CL-SCL receives three hyperparameters as input: the number of pivots m, the dimensionality of the cross-lingual representation k,

Pivot	English		German	
	Semantics	Pragmatics	Semantics	Pragmatics
{beautiful$_{\mathcal{S}}$, schön$_{\mathcal{T}}$}	amazing, beauty, lovely	picture, pattern, poetry, photographs, paintings	schöner (more beautiful), traurig (sad)	bilder (pictures), illustriert (illustrated)
{boring$_{\mathcal{S}}$, langweilig$_{\mathcal{T}}$}	plain, asleep, dry, long	characters, pages, story	langatmig (lengthy), einfach (plain), enttäuscht (disappointed)	charaktere (characters), handlung (plot), seiten (pages)

Table 2: Semantic and pragmatic correlations identified for the two pivots {beautiful$_{\mathcal{S}}$, schön$_{\mathcal{T}}$} and {boring$_{\mathcal{S}}$, langweilig$_{\mathcal{T}}$} in English and German book reviews.

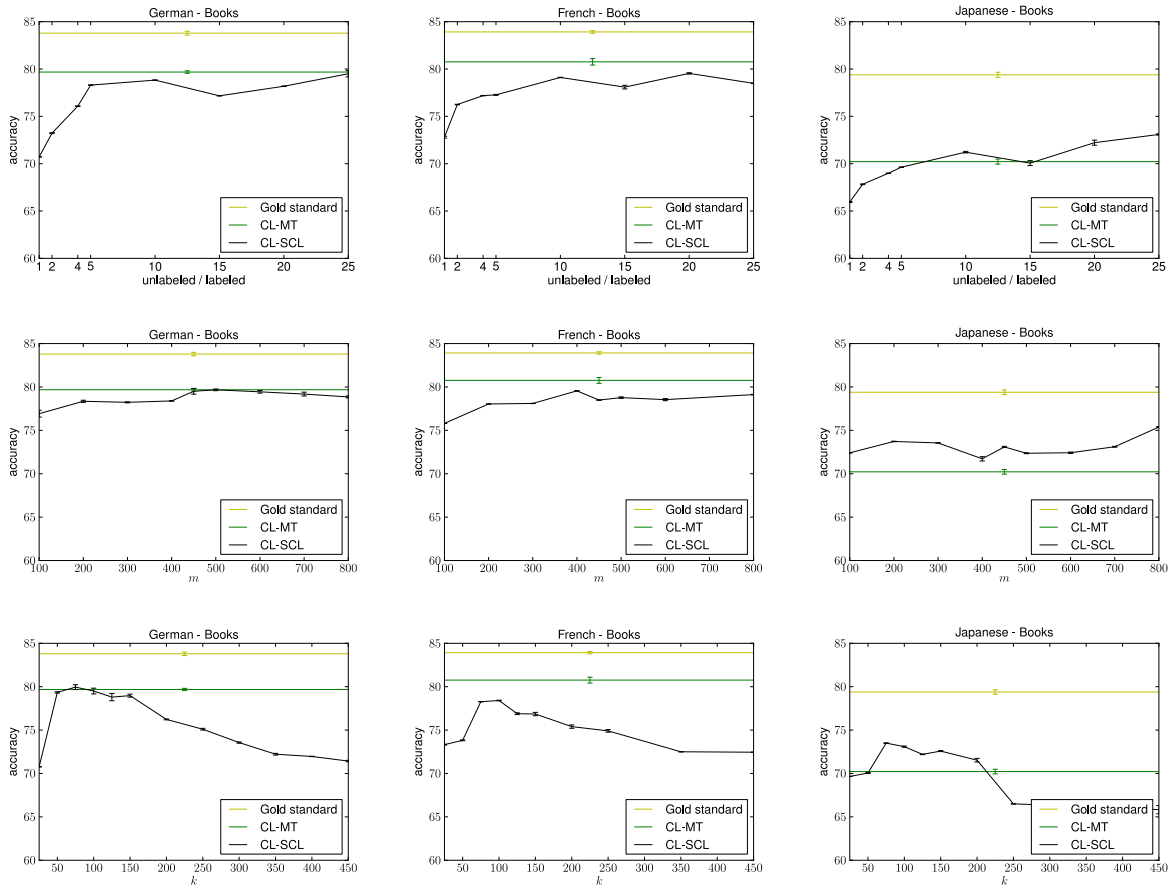

Figure 2: Influence of unlabeled data and hyperparameters on the performance of CL-SCL. The rows show the performance of CL-SCL as a function of (1) the ratio between labeled and unlabeled documents, (2) the number of pivots m, and (3) the dimensionality of the cross-lingual representation k.

and the minimum support ϕ of a pivot in $D_{\mathcal{S},u}$ and $D_{\mathcal{T},u}$. For comparison purposes we use fixed values of $m = 450$, $k = 100$, and $\phi = 30$. The results show the competitiveness of CL-SCL compared to CL-MT. Although CL-MT outperforms CL-SCL on most tasks for German and French, the difference in accuracy can be considered as small (<1%); merely for French book and music reviews the difference is about 2%. For Japanese, however, CL-SCL outperforms CL-MT on most tasks with a difference in accuracy of about 3%. The results indicate that if the difference between the upper bound and CL-MT is large, CL-SCL can circumvent the loss in accuracy. Experiments with language-specific settings revealed that for Japanese a smaller number of pivots ($150<m<250$) performs significantly better. Thus, the reported results for Japanese can be considered as pessimistic.

Primarily responsible for the effectiveness of CL-SCL is its task specificity, i.e., the ways in which context contributes to meaning (pragmatics). Due to the use of task-specific, unlabeled data, relevant characteristics are captured by the pivot classifiers. Table 2 exemplifies this with two pivots for German book reviews. The rows of the table show those words which have the highest correlation with the pivots $\{\text{beautiful}_{\mathcal{S}}, \text{schön}_{\mathcal{T}}\}$ and $\{\text{boring}_{\mathcal{S}}, \text{langweilig}_{\mathcal{T}}\}$. We can distinguish between (1) correlations that reflect similar meaning, such as “amazing”, “lovely”, or “plain”, and (2) correlations that reflect the pivot pragmatics with respect to the task, such as “picture”, “poetry”, or “pages”. Note in this connection that authors of book reviews tend to use the word “beautiful” to refer to illustrations or poetry. While the first type of word correlations can be obtained by methods that operate on parallel corpora, the second type of correlation requires an understanding of the task-specific language use.

In the following we discuss the sensitivity of each hyperparameter in isolation while keeping

the others fixed at $m = 450$, $k = 100$, and $\phi = 30$. The experiments are illustrated in Figure 2.

Unlabeled Data The first row of Figure 2 shows the performance of CL-SCL as a function of the ratio of labeled and unlabeled documents. A ratio of 1 means that $|D_{\mathcal{S},u}| = |D_{\mathcal{T},u}| = 2{,}000$, while a ratio of 25 corresponds to the setting of Table 1. As expected, an increase in unlabeled documents results in an improved performance, however, we observe a saturation at a ratio of 10 across all nine tasks.

Number of Pivots The second row shows the influence of the number of pivots m on the performance of CL-SCL. Compared to the size of the vocabularies $V_{\mathcal{S}}$ and $V_{\mathcal{T}}$, which is in 10^5 order of magnitude, the number of pivots is very small. The plots show that even a small number of pivots captures a significant amount of the correspondence between $\mathcal{S}$ and $\mathcal{T}$.

Dimensionality of the Cross-Lingual Representation The third row shows the influence of the dimensionality of the cross-lingual representation k on the performance of CL-SCL. Obviously the SVD is crucial to the success of CL-SCL if m is sufficiently large. Observe that the value of k is task-insensitive: a value of $75{<}k{<}150$ works equally well across all tasks.

6 Conclusion

The paper introduces a novel approach to cross-language text classification, called cross-language structural correspondence learning. The approach uses unlabeled documents along with a word translation oracle to automatically induce task-specific, cross-lingual correspondences. Our contributions include the adaptation of SCL for the problem of cross-language text classification and a well-founded empirical analysis. The analysis covers performance and robustness issues in the context of cross-language sentiment classification with English as source language and German, French, and Japanese as target languages. The results show that CL-SCL is competitive with state-of-the-art machine translation technology while requiring fewer resources.

Future work includes the extension of CL-SCL towards a general approach for cross-lingual adaptation of natural language processing technology.

Abstract

Probabilistic latent topic models have recently enjoyed much success in extracting and analyzing latent topics in text in an unsupervised way. One common deficiency of existing topic models, though, is that they would not work well for extracting cross-lingual latent topics simply because words in different languages generally do not co-occur with each other. In this paper, we propose a way to incorporate a bilingual dictionary into a probabilistic topic model so that we can apply topic models to extract shared latent topics in text data of different languages. Specifically, we propose a new topic model called Probabilistic Cross-Lingual Latent Semantic Analysis (PCLSA) which extends the Probabilistic Latent Semantic Analysis (PLSA) model by regularizing its likelihood function with soft constraints defined based on a bilingual dictionary. Both qualitative and quantitative experimental results show that the PCLSA model can effectively extract cross-lingual latent topics from multilingual text data.

1 Introduction

As a robust unsupervised way to perform shallow latent semantic analysis of topics in text, probabilistic topic models (Hofmann, 1999a; Blei et al., 2003b) have recently attracted much attention. The common idea behind these models is the following. A topic is represented by a multinomial word distribution so that words characterizing a topic generally have higher probabilities than other words. We can then hypothesize the existence of multiple topics in text and define a generative model based on the hypothesized topics. By fitting the model to text data, we can obtain an estimate of all the word distributions corresponding to the latent topics as well as the topic distributions in text. Intuitively, the learned word distributions capture clusters of words that co-occur with each other probabilistically.

Although many topic models have been proposed and shown to be useful (see Section 2 for more detailed discussion of related work), most of them share a common deficiency: they are designed to work only for mono-lingual text data and would not work well for extracting cross-lingual latent topics, i.e. topics shared in text data in two different natural languages. The deficiency comes from the fact that all these models rely on co-occurrences of words forming a topical cluster, but words in different language generally do not co-occur with each other. Thus with the existing models, we can only extract topics from text in each language, but cannot extract common topics shared in multiple languages.

In this paper, we propose a novel topic model, called Probabilistic Cross-Lingual Latent Semantic Analysis (PCLSA) model, which can be used to mine shared latent topics from *unaligned* text data in different languages. PCLSA extends the Probabilistic Latent Semantic Analysis (PLSA) model by regularizing its likelihood function with soft constraints defined based on a bilingual dictionary. The dictionary-based constraints are key to bridge the gap of different languages and would force the captured co-occurrences of words in each language by PCLSA to be "synchronized" so that related words in the two languages would have similar probabilities. PCLSA can be estimated efficiently using the General Expectation-Maximization (GEM) algorithm. As a topic extraction algorithm, PCLSA would take a pair of unaligned document sets in different languages and a bilingual dictionary as input, and output a set of aligned word distributions in both languages that can characterize the shared topics in the two languages. In addition, it also outputs a topic cov-

Uppsala, Sweden, 11-16 July 2010.

erage distribution for each language to indicate the relative coverage of different shared topics in each language.

To the best of our knowledge, no previous work has attempted to solve this topic extraction problem and generate the same output. The closest existing work to ours is the MuTo model proposed in (Boyd-Graber and Blei, 2009) and the JointLDA model published recently in (Jagarlamudi and Daumé III, 2010). Both used a bilingual dictionary to bridge the language gap in a topic model. However, the goals of their work are different from ours in that their models mainly focus on mining cross-lingual topics of matching word pairs and discovering the correspondence at the vocabulary level. Therefore, the topics extracted using their model cannot indicate how a common topic is covered *differently* in the two languages, because the words in each word pair share the same probability in a common topic. Our work focuses on discovering correspondence at the topic level. In our model, since we only add a soft constraint on word pairs in the dictionary, their probabilities in common topics are generally different, naturally capturing which shows the different variations of a common topic in different languages.

We use a cross-lingual news data set and a review data set to evaluate PCLSA. We also propose a "cross-collection" likelihood measure to quantitatively evaluate the quality of mined topics. Experimental results show that the PCLSA model can effectively extract cross-lingual latent topics from multilingual text data, and it outperforms a baseline approach using the standard PLSA on text data in each language.

2 Related Work

Many topic models have been proposed, and the two basic models are the Probabilistic Latent Semantic Analysis (PLSA) model (Hofmann, 1999a) and the Latent Dirichlet Allocation (LDA) model (Blei et al., 2003b). They and their extensions have been successfully applied to many problems, including hierarchical topic extraction (Hofmann, 1999b; Blei et al., 2003a; Li and McCallum, 2006), author-topic modeling (Steyvers et al., 2004), contextual topic analysis (Mei and Zhai, 2006), dynamic and correlated topic models (Blei and Lafferty, 2005; Blei and Lafferty, 2006), and opinion analysis (Mei et al., 2007; Branavan et al., 2008). Our work is an extension of PLSA by incorporating the knowledge of a bilingual dictionary as soft constraints. Such an extension is similar to the extension of PLSA for incorporating social network analysis (Mei et al., 2008a) but our constraint is different.

Some previous work on multilingual topic models assume documents in multiple languages are aligned either at the document level, sentence level or by time stamps (Mimno et al., 2009; Zhao and Xing, 2006; Kim and Khudanpur, 2004; Ni et al., 2009; Wang et al., 2007). However, in many applications, we need to mine topics from *unaligned* text corpus. For example, mining topics from search results in different languages can facilitate summarization of multilingual search results.

Besides all the multilingual topic modeling work discussed above, comparable corpora have also been studied extensively (e.g. (Fung, 1995; Franz et al., 1998; Masuichi et al., 2000; Sadat et al., 2003; Gliozzo and Strapparava, 2006)), but most previous work aims at acquiring word translation knowledge or cross-lingual text categorization from comparable corpora. Our work differs from this line of previous work in that our goal is to discover shared latent topics from multi-lingual text data that are *weakly* comparable (e.g. the data does not have to be aligned by time).

3 Problem Formulation

In general, the problem of cross-lingual topic extraction can be defined as to extract a set of common cross-lingual latent topics covered in text collections in different natural languages. A cross-lingual latent topic will be represented as a multinomial word distribution over the words in *all* the languages, i.e. a multilingual word distribution. For example, given two collections of news articles in English and Chinese, respectively, we would like to extract common topics simultaneously from the two collections. A discovered common topic, such as the terrorist attack on September 11, 2001, would be characterized by a word distribution that would assign relatively high probabilities to words related to this event in both English and Chinese (e.g. "terror", "attack", "afghanistan", "taliban", and their translations in Chinese).

As a computational problem, our input is a multi-lingual text corpus, and output is a set of cross-lingual latent topics. We now define this problem more formally.

Definition 1 (Multi-Lingual Corpus) A ***multi-lingual corpus*** $\mathcal{C}$ is a set of text collections $\{\mathcal{C}_1, \mathcal{C}_2, \ldots, \mathcal{C}_s\}$, where $\mathcal{C}_i = \{d_1^i, d_2^i, \ldots, d_{M_i}^i\}$ is a collection of documents in language L_i with vocabulary $V_i = \{w_1^i, w_2^i, \ldots, w_{N_i}^i\}$. Here, M_i is the total number of documents in $\mathcal{C}_i$, N_i is the total number of words in V_i, and d_j^i is a document in collection $\mathcal{C}_i$.

Following the common assumption of bag-of-words representation, we represent document d_j^i with a bag of words $\{w_{j_1}^i, w_{j_2}^i, \ldots, w_{j_d}^i\}$, and use $c(w_k^i, d_j^i)$ to denote the count of word w_k^i in document d_j^i.

Definition 2 (Cross-Lingual Topic): A cross-lingual topic θ is a semantically coherent multinomial distribution over all the words in the vocabularies of languages L_1, ..., L_s. That is, $p(w|\theta)$ would give the probability of a word w which can be in any of the s languages under consideration. θ is semantically coherent if it assigns high probabilities to words that are semantically related either in the same language or across different languages. Clearly, we have $\sum_{i=1}^{s} \sum_{w \in V_i} p(w|\theta) = 1$ for any cross-lingual topic θ.

Definition 3 (Cross-Lingual Topic Extraction) Given a multi-lingual corpus $\mathcal{C}$, the task of cross-lingual topic extraction is to model and extract k major cross-lingual topics $\{\theta_1, \theta_2, \ldots, \theta_k\}$ from $\mathcal{C}$, where θ_i is a cross-lingual topic, and k is a user specified parameter.

The extracted cross-lingual topics can be directly used as a summary of the common content of the multi-lingual data set. Note that once a cross-lingual topic is extracted, we can easily obtain its representation in each language L_i by "splitting" the cross-lingual topic into multiple word distributions in different languages. Formally, the word distribution of a cross-lingual topic θ in language L_i is given by $p_i(w^i|\theta) = \frac{p(w^i|\theta)}{\sum_{w \in V_i} p(w|\theta)}$.

These aligned language-specific word distributions can directly review the variations of topics in different languages. They can also be used to analyze the difference of the coverage of the same topic in different languages. Moreover, they are also useful for retrieving relevant articles or passages in each language and aligning them to the same common topic, thus essentially also allowing us to integrate and align articles in multiple languages.

4 Probabilistic Cross-Lingual Latent Semantic Analysis

In this section, we present our probabilistic cross-lingual latent semantic analysis (PCLSA) model and discuss how it can be used to extract cross-lingual topics from multi-lingual text data.

The main reason why existing topic models can't be used for cross-lingual topic extraction is because they cannot cross the language barrier. Intuitively, in order to cross the language barrier and extract a common topic shared in articles in different languages, we must rely on some kind of linguistic knowledge. Our PCLSA model assumes the availability of bi-lingual dictionaries for at least some language pairs, which are generally available for major language pairs. Specifically, for text data in languages L_1, ..., L_s, if we represent each language as a node in a graph and connect those language pairs for which we have a bilingual dictionary, the minimum requirement is that the whole graph is connected. Thus, as a minimum, we will need $s-1$ distinct bilingual dictionaries. This is so that we can potentially cross all the language barriers.

Our key idea is to "synchronize" the extraction of monolingual "component topics" of a cross-lingual topic from individual languages by forcing a cross-lingual topic word distribution to assign similar probabilities to words that are potential translations according to a L_i-L_j bilingual dictionary. We achieve this by adding such preferences formally to the likelihood function of a probabilistic topic model as "soft constraints" so that when we estimate the model, we would try to not only fit the text data well (which is necessary to extract coherent component topics from each language), but also satisfy our specified preferences (which would ensure the extracted component topics in different languages are semantically related). Below we present how we implement this idea in more detail.

A bilingual dictionary for languages L_i and L_j generally would give us a many-to-many mapping between the vocabularies of the two languages. With such a mapping, we can construct a bipartite graph $G_{ij} = (V_{ij}, E_{ij})$ between the two languages where if one word can be potentially translated into another word, the two words would be connected with an edge. An edge can be weighted based on the probability of the corresponding translation. An example graph for

Chinese-English dictionary is shown in Figure 1.

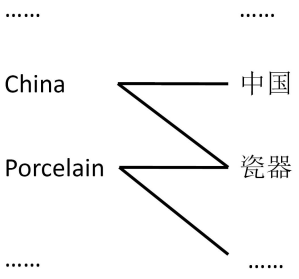

Figure 1: A Dictionary based Word Graph

With multiple bilingual dictionaries, we can merge the graphs to generate a multi-partite graph $G = (V, E)$. Based on this graph, the PCLSA model extends the standard PLSA by adding a constraint to the likelihood function to "smooth" the word distributions of topics in PLSA on the multi-partite graph so that we would encourage the words that are connected in the graph (i.e. possible translations of each other) to be given similar probabilities by every cross-lingual topic. Thus when a cross-lingual topic picks up words that co-occur in mono-lingual text, it would prefer picking up word pairs whose translations in other languages also co-occur with each other, giving us a coherent multilingual word distribution that characterizes well the content of text in different languages.

Specifically, let $\Theta = \{\theta_j\}$ $(j = 1, ..., k)$ be a set of k cross-lingual topic models to be discovered from a multilingual text data set with s languages such that $p(w|\theta_i)$ is the probability of word w according to the topic model θ_i.

If we are to use the regular PLSA to model our data, we would have the following log-likelihood and we usually use a maximum likelihood estimator to estimate parameters and discover topics.

$$L(\mathcal{C}) = \sum_{i=1}^{s} \sum_{d \in \mathcal{C}_i} \sum_{w} c(w, d) \log \sum_{j=1}^{k} p(\theta_j|d) p(w|\theta_j)$$

Our main extension is to add to $L(\mathcal{C})$ a cross-lingual constraint term $R(\mathcal{C})$ to incorporate the knowledge of bilingual dictionaries. $R(\mathcal{C})$ is defined as

$$R(\mathcal{C}) = \frac{1}{2} \sum_{\langle u,v \rangle \in E} w(u, v) \sum_{j=1}^{k} \left(\frac{p(w_u|\theta_j)}{Deg(u)} - \frac{p(w_v|\theta_j)}{Deg(v)}\right)^2$$

where $w(u, v)$ is the weight on the edge between u and v in the multi-partite graph $G = (V, E)$, which in our experiments is set to 1, and $Deg(u)$ is the degree of word u, i.e. the sum of the weights of all the edges ending with u.

Intuitively, $R(\mathcal{C})$ measures the difference between $p(w_u|\theta_j)$ and $p(w_v|\theta_j)$ for each pair (u, v) in a bilingual dictionary; the more they differ, the larger $R(\mathcal{C})$ would be. So it can be regarded as a "loss function" to help us assess how well the "component word distributions" in multiple languages are correlated semantically. Clearly, we would like the extracted topics to have a small $R(\mathcal{C})$. We choose this specific form of loss function because it would make it convenient to solve the optimization problem of maximizing the corresponding regularized maximum likelihood (Mei et al., 2008b). The normalization with $Deg(u)$ and $Deg(v)$ can be regarded as a way to compensate for the potential ambiguity of u and v in their translations.

Putting $L(\mathcal{C})$ and $R(\mathcal{C})$ together, we would like to maximize the following objective function which is a regularized log-likelihood:

$$O(\mathcal{C}, G) = (1 - \lambda) L(\mathcal{C}) - \lambda R(\mathcal{C}) \quad (1)$$

where $\lambda \in (0, 1)$ is a parameter to balance the likelihood and the regularizer. When $\lambda = 0$, we recover the standard PLSA.

Specifically, we will search for a set of values for all our parameters that can maximize the objective function defined above. Our parameters include all the cross-lingual topics and the coverage distributions of the topics in all documents, which we denote by $\Psi = \{p(w|\theta_j), p(\theta_j|d)\}_{d,w,j}$ where $j = 1, ..., k$, w varies over the entire vocabularies of all the languages , d varies over all the documents in our collection. This optimization problem can be solved using a Generalized Expectation-Maximization (GEM) algorithm as described in (Mei et al., 2008a).

Specifically, in the **E-step** of the algorithm, the distribution of hidden variables is computed using Eq. 2.

$$z(w, d, j) = \frac{p(\theta_j|d) p(w|\theta_j)}{\sum_{j'} p(\theta_{j'}|d) p(w|\theta_{j'})} \quad (2)$$

Then in the **M-step**, we need to maximize the complete data likelihood $Q(\Psi; \Psi_n)$:

$$Q(\Psi; \Psi_n) = (1 - \lambda) L'(\mathcal{C}) - \lambda R(\mathcal{C})$$

where

$$L'(\mathcal{C}) = \sum_d \sum_w c(w,d) \sum_j z(w,d,j) \log p(\theta_j|d) p(w|\theta_j), \quad (3)$$

with the constraints that $\sum_j p(\theta_j|d) = 1$ and $\sum_w p(w|\theta_j) = 1$.

There is a closed form solution if we only want to maximize the $L'(\mathcal{C})$ part:

$$\begin{aligned} p^{(n+1)}(\theta_j|d) &= \frac{\sum_w c(w,d) z(w,d,j)}{\sum_w \sum_{j'} c(w,d) z(w,d,j')} \\ p^{(n+1)}(w|\theta_j) &= \frac{\sum_d c(w,d) z(w,d,j)}{\sum_d \sum_w' c(w',d) z(w',d,j)} \end{aligned} \quad (4)$$

However, there is no closed form solution in the M-step for the whole objective function. Fortunately, according to GEM we do not need to find the local maximum of $Q(\Psi; \Psi_n)$ in every M-step, and we only need to find a new value Ψ_{n+1} to improve the complete data likelihood, i.e. to make sure $Q(\Psi_{n+1}; \Psi_n) \geq Q(\Psi_n; \Psi_n)$. So our method is to first maximize the $L'(\mathcal{C})$ part using Eq. 4 and then use Eq. 5 to gradually increase the $R(\mathcal{C})$ part.

$$\begin{aligned} p^{(t+1)}(w_u|\theta_j) &= (1-\alpha) p^{(t)}(w_u|\theta_j) \\ &+ \alpha \sum_{\langle u,v \rangle \in E} \frac{w(u,v)}{Deg(v)} p^{(t)}(w_v|\theta_j) \end{aligned} \quad (5)$$

Here, parameter α is the length of each smoothing step. Obviously, after each smoothing step, the sum of the probabilities of all the words in one topic is still equal to 1. We smooth the parameters until we cannot get a better parameter set Ψ_{n+1}. Then, we continue to the next E-step. If there is no Ψ_{n+1} s.t. $Q(\Psi_{n+1}; \Psi_n) \geq Q(\Psi_n; \Psi_n)$, then we consider Ψ_n to be the local maximum point of the objective function Eq. 1.

5 Experiment Design

5.1 Data Set

The data set we used in our experiment is collected from news articles of Xinhua English and Chinese newswires. The whole data set is quite big, containing around 40,000 articles in Chinese and 35,000 articles in English. For different purpose of our experiments, we randomly selected different number of documents from the whole corpus, and we will describe the concrete statistics in each experiment. To process the Chinese corpus, we use a simple segmenter[1] to split the data into Chinese phrases. Both Chinese and English stopwords are removed from our data.

The dictionary file we used for our PCLSA model is from mandarintools.com[2]. For each Chinese phrase, if it has several English meanings, we add an edge between it and each of its English translation. If one English translation is an English phrase, we add an edge between the Chinese phrase and each English word in the phrase.

5.2 Baseline Method

As a baseline method, we can apply the standard PLSA (Hofmann, 1999a) directly to the multilingual corpus. Since PLSA takes advantage of the word co-occurrences in the document level to find semantic topics, directly using it for a multilingual corpus will result in finding topics mainly reflecting a single language (because words in different languages would not co-occur in the same document in general). That is, the discovered topics are mostly monolingual. These monolingual topics can then be aligned based on a bilingual dictionary to suggest a possible cross-lingual topic.

6 Experimental Results

6.1 Qualitative Comparison

To qualitatively compare PCLSA with the baseline method, we compare the word distributions of topics extracted by them. The data set we used in this experiment is selected from the Xinhua News data during the period from Jun. 8th, 2001 to Jun. 15th, 2001. There are totally 1799 English articles and 1485 Chinese articles in the data set. The number of topics to be extracted is set to 10 for both methods.

Table 1 shows the experimental results. To make it easier to understand, we add an English translation to each Chinese phrase in our results. The first ten rows show sample topics of the modeling results of traditional PLSA model. We can see that it only contains mono-language topics, i.e. the topics are either in Chinese or in English. The next ten rows are the results from our PCLSA model. Compared with the baseline method, PCLSA can not only find coherent topics from the cross-lingual corpus, but it can also show the content about one topic from both two language corpora. For example, in 'Topic 2'

[1] http://www.mandarintools.com/segmenter.html
[2] http://www.mandarintools.com/cedict.html

Table 2: Synthetic Data Set from Xinhua News

English	Shrine 90	Olympic 101	Championship 70
Chinese	CPC Anniversary 95	Afghan War 206	Championship 72

which is about 'Israel' and 'Palestinian', the Chinese corpus mentions a lot about 'Arafat' who is the leader of 'Palestinian', while the English corpus discusses more on topics such as 'cease fire' and 'women'. Similarly, in 'Topic 9', the topic is related to Philippine, the Chinese corpus mentions some environmental situation in Philippine, while the English corpus mentions a lot about 'Abu Sayyaf'.

6.2 Discovering Common Topics

To demonstrate the ability of PCLSA for finding common topics in cross-lingual corpus, we use some event names, e.g. 'Shrine' and 'Olympic', as queries and randomly select a certain number of documents from the whole corpus, which are related to the queries. The number of documents for each query in the synthetic data set is shown in Table 2. In either the English corpus or the Chinese corpus, we select a smaller number of documents about topic 'Championship' combined with the other two topics in the same corpus. In this way, when we want to extract two topics from either English or Chinese corpus, the 'Championship' topic may not be easy to extract, because the other two topics have more documents in the corpus. However, when we use PCLSA to extract four topics from the two corpora together, we expect that the topic 'Championship' will be found, because now the sum of English and Chinese documents related to 'Championship' is larger than other topics. The experimental result is shown in Table 3. The first two columns are the two topics extracted from Engish corpus, the third and the forth columns are two topics from Chinese corpus, and the other four columns are the results from cross-lingual corpus. We can see that in either the Chinese sub-collection or the English sub-collection, the topic 'Championship' is not extracted as a significant topic. But, as expected, the topic 'Championship' is extracted from the cross-lingual corpus, while the topic 'Olympic' and topic 'Shrine' are merged together. This demonstrate that PCLSA is capable of extracting common topics from a cross-lingual corpus.

6.3 Quantitative Evaluation

We also quantitatively evaluate how well our PCLSA model can discover common topics among corpus in different languages. We propose a "cross-collection" likelihood measure for this purpose. The basic idea is: suppose we got k cross-lingual topics from the whole corpus, then for each topic, we split the topic into two separate set of topics, English topics and Chinese topics, using the splitting formula described before, i.e. $p_i(w^i|\theta) = \frac{p(w^i|\theta)}{\sum_{w \in V_i} p(w|\theta)}$. Then, we use the word distribution of the Chinese topics (translating the words into English) to fit the English Corpus and use the word distribution of the English topics (translating the words into Chinese) to fit the Chinese Corpus. If the topics mined are common topics in the whole corpus, then such a "cross-collection" likelihood should be larger than those topics which are not commonly shared by the English and the Chinese corpus. To calculate the likelihood of fitness, we use the folding-in method proposed in (Hofmann, 2001). To translate topics from one language to another, e.g. Chinese to English, we look up the bilingual dictionary and do word-to-word translation. If one Chinese word has several English translations, we simply distribute its probability mass equally to each English translation.

For comparison, we use the standard PLSA model as the baseline. Basically, suppose PLSA mined k semantic topics in the Chinese corpus and k semantic topics in the English corpus. Then, we also use the "cross-collection" likelihood measure to see how well those k semantic Chinese topics fit the English corpus and those k semantic English topics fit the Chinese corpus.

We totally collect three data sets to compare the performance. For the first data set, (English_1, Chinese_1), both the Chinese and English corpus are chosen from the Xinhua News Data during the period from 2001.06.08 to 2001.06.15, which has 1799 English articles and 1485 Chinese articles. For the second data set, (English_2, Chinese_2), the Chinese corpus Chinese_2 is the same as Chinese_1, but the English corpus is chosen from 2001.06.14 to 2001.06.19 which has 1547 documents. For the third data set, (English_3, Chinese_3), the Chinese corpus is the same as in data set one, but the English corpus is chosen from 2001.10.02 to 2001.10.07 which contains 1530 documents. In other words, in the first data set,

the English corpus and Chinese corpus are comparable with each other, because they cover similar events during the same period. In the second data set, the English and Chinese corpora share some common topics during the overlap period. The third data is the most tough one since the two corpora are from different periods. The purpose of using these three different data sets for evaluation is to test how well PCLSA can mine common topics from either a data set where the English corpus and the Chinese corpus are comparable or a data set where the English corpus and the Chinese corpus rarely share common topics.

The experimental results are shown in Table 4. Each row shows the "cross-collection" likelihood of using the "cross-collection" topics to fit the data set named in the first column. For example, in the first row, the values are the "cross-collection" likelihood of using Chinese topics found by different methods from the first data set to fit English_1. The last collum shows how much improvement we got from PCLSA compared with PLSA. From the results, we can see that in all the data sets, our PCLSA has higher "cross-collection" likelihood value, which means it can find better common topics compared to the baseline method. Notice that the Chinese corpora are the same in all three data sets. The results show that both PCLSA and PLSA get lower "cross-collection" likelihood for fitting the Chinese corpora when the data set becomes "tougher", i.e. less topic overlapping, but the improvement of PCLSA over PLSA does not drop much. On the other hand, the improvement of PCLSA over PLSA on the three English corpora does not show any correlation with the difficulty of the data set.

Table 4: Quantitative Evaluation of Common Topic Finding ("cross-collection" log-likelihood)

	PCLSA	PLSA	Rel. Imprv.
English_1	-2.86294E+06	-3.03176E+06	5.6%

English_3	-2.44714E+06	-2.60540E+06	6.1%
Chinese_3	-4.79639E+06	-4.94273E+06	3.0%

6.4 Extracting from Multi-Language Corpus

In the previous experiments, we have shown the capability and effectiveness of the PCLSA model in latent topic extraction from two language corpora. In fact, the proposed model is general and capable of extracting latent topics from multi-language corpus. For example, if we have dictionaries among multiple languages, we can construct a multi-partite graph based on the correspondence between those vocabularies, and then smooth the PCLSA model with this graph.

To show the effectiveness of PCLSA in mining multiple language corpus, we first construct a simulated data set based on 1115 reviews of three brands of laptops, namely IBM (303), Apple(468) and DELL(344). To simulate a three language cor-

device(ibm)	maco(apple)	toshiba(ibm)	hour(ibm)	view(dell)	plug(ibm)	power(apple)	card(dell)

pus, we use an 'IBM' word, an 'Apple' word, and a 'Dell' word to replace an English word in their corpus. For example, we use 'IBM10', 'Apple10', 'Dell10' to replace the word 'CD' whenever it appears in an IBM's, Apple's, or Dell's review. After the replacement, the reviews about IBM, Apple, and Dell will not share vocabularies with each other. On the other hand, for any three created words which represent the same English word, we add three edges among them, and therefore we get a simulated dictionary graph for our PCLSA model.

The experimental result is shown in Table 5, in which we try to extract 8 topics from the cross-lingual corpus. The first ten rows show the result of our PCLSA model, in which we set a very small value to the weight parameter λ for the regularizer part. This can be used as an approximation of the result from the traditional PLSA model on this three language corpus. We can see that the extracted topics are mainly written in mono-language. As we set the value of parameter λ larger, the extracted topics become multi-lingual, which is shown in the next ten rows. From this result, we can see the difference between the reviews of different brands about the similar topic. In addition, if we set the λ even larger, we will get topics that are mostly made of the same words from the three different brands, which means the extracted topics are very smooth on the dictionary graph now.

7 Conclusion

In this paper, we study the problem of cross-lingual latent topic extraction where the task is to extract a set of common latent topics from multi-lingual text data. We propose a novel probabilistic topic model (i.e. the Probabilistic Cross-Lingual Latent Semantic Analysis (PCLSA) model) that can incorporate translation knowledge in bilingual dictionaries as a regularizer to constrain the parameter estimation so that the learned topic models would be synchronized in multiple languages. We evaluated the model using several data sets. The experimental results show that PCLSA is effective in extracting common latent topics from multilingual text data, and it outperforms the baseline method which uses the standard PLSA to fit each monolingual text data set.

Our work opens up some interesting future research directions to further explore. First, in this paper, we have only experimented with uniform weighting of edge in the bilingual graph. It should be very interesting to explore how to assign weights to the edges and study whether weighted graphs can further improve performance. Second, it would also be interesting to further extend PCLSA to accommodate discovering topics in each language that aren't well-aligned with other languages.

Abstract

This paper presents a probabilistic model for sense disambiguation which chooses the best sense based on the conditional probability of sense paraphrases given a context. We use a topic model to decompose this conditional probability into two conditional probabilities with latent variables. We propose three different instantiations of the model for solving sense disambiguation problems with different degrees of resource availability. The proposed models are tested on three different tasks: coarse-grained word sense disambiguation, fine-grained word sense disambiguation, and detection of literal vs. nonliteral usages of potentially idiomatic expressions. In all three cases, we outperform state-of-the-art systems either quantitatively or statistically significantly.

1 Introduction

Word sense disambiguation (WSD) is the task of automatically determining the correct sense for a target word given the context in which it occurs. WSD is an important problem in NLP and an essential preprocessing step for many applications, including machine translation, question answering and information extraction. However, WSD is a difficult task, and despite the fact that it has been the focus of much research over the years, state-of-the-art systems are still often not good enough for real-world applications. One major factor that makes WSD difficult is a relative lack of manually annotated corpora, which hampers the performance of supervised systems.

To address this problem, there has been a significant amount of work on unsupervised WSD that does not require manually sense-disambiguated training data (see McCarthy (2009) for an overview). Recently, several researchers have experimented with topic models (Brody and Lapata, 2009; Boyd-Graber et al., 2007; Boyd-Graber and Blei, 2007; Cai et al., 2007) for sense disambiguation and induction. Topic models are generative probabilistic models of text corpora in which each document is modelled as a mixture over (latent) topics, which are in turn represented by a distribution over words.

Previous approaches using topic models for sense disambiguation either embed topic features in a supervised model (Cai et al., 2007) or rely heavily on the structure of hierarchical lexicons such as WordNet (Boyd-Graber et al., 2007). In this paper, we propose a novel framework which is fairly resource-poor in that it requires only 1) a large unlabelled corpus from which to estimate the topics distributions, and 2) paraphrases for the possible target senses. The paraphrases can be user-supplied or can be taken from existing resources.

We approach the sense disambiguation task by choosing the best sense based on the conditional probability of sense paraphrases given a context. We propose three models which are suitable for different situations: Model I requires knowledge of the prior distribution over senses and directly maximizes the conditional probability of a sense given the context; Model II maximizes this conditional probability by maximizing the cosine value of two topic-document vectors (one for the sense and one for the context). We apply these models to coarse- and fine-grained WSD and find that they outperform comparable systems for both tasks.

We also test our framework on the related task of idiom detection, which involves distinguishing literal and nonliteral usages of potentially ambiguous expressions such as *rock the boat*. For this task, we propose a third model. Model III calculates the probability of a sense given a context according to the component words of the sense

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1138–1147,
Uppsala, Sweden, 11-16 July 2010.

paraphrase. Specifically, it chooses the sense type which maximizes the probability (given the context) of the paraphrase component word with the highest likelihood of occurring in that context. This model also outperforms state-of-the-art systems.

2 Related Work

There is a large body of work on WSD, covering supervised, unsupervised (word sense induction) and knowledge-based approaches (see McCarthy (2009) for an overview). While most supervised approaches treat the task as a classification task and use hand-labelled corpora as training data, most unsupervised systems automatically group word tokens into similar groups using clustering algorithms, and then assign labels to each sense cluster. Knowledge-based approaches exploit information contained in existing resources. They can be combined with supervised machine-learning models to assemble semi-supervised approaches.

Recently, a number of systems have been proposed that make use of topic models for sense disambiguation. Cai et al. (2007), for example, use LDA to capture global context. They compute topic models from a large unlabelled corpus and include them as features in a supervised system. Boyd-Graber and Blei (2007) propose an unsupervised approach that integrates McCarthy et al.'s (2004) method for finding predominant word senses into a topic modelling framework. In addition to generating a topic from the document's topic distribution and sampling a word from that topic, the enhanced model also generates a distributional neighbour for the chosen word and then assigns a sense based on the word, its neighbour and the topic. Boyd-Graber and Blei (2007) test their method on WSD and information retrieval tasks and find that it can lead to modest improvements over state-of-the-art results.

In another unsupervised system, Boyd-Graber et al. (2007) enhance the basic LDA algorithm by incorporating WordNet senses as an additional latent variable. Instead of generating words directly from a topic, each topic is associated with a random walk through the WordNet hierarchy which generates the observed word. Topics and synsets are then inferred together. While Boyd-Graber et al. (2007) show that this method can lead to improvements in accuracy, they also find that idiosyncracies in the hierarchical structure of WordNet can harm performance. This is a general problem for methods which use hierarchical lexicons to model semantic distance (Budanitsky and Hirst, 2006). In our approach, we circumvent this problem by exploiting paraphrase information for the target senses rather than relying on the structure of WordNet as a whole.

Topic models have also been applied to the related task of word sense induction. Brody and Lapata (2009) propose a method that integrates a number of different linguistic features into a single generative model.

Topic models have been previously considered for metaphor extraction and estimating the frequency of metaphors (Klebanov et al., 2009; Bethard et al., 2009). However, we have a different focus in this paper, which aims to distinguish literal and nonliteral usages of potential idiomatic expressions. A number of methods have been applied to this task. Katz and Giesbrecht (2006) devise a supervised method in which they compute the meaning vectors for the literal and nonliteral usages of a given expression in the trainning data. Birke and Sarkar (2006) use a clustering algorithm which compares test instances to two automatically constructed seed sets (one literal and one nonliteral), assigning the label of the closest set. An unsupervised method that computes cohesive links between the component words of the target expression and its context have been proposed (Sporleder and Li, 2009; Li and Sporleder, 2009). Their system predicts literal usages when strong links can be found.

3 The Sense Disambiguation Model

3.1 Topic Model

As pointed out by Hofmann (1999), the starting point of topic models is to decompose the conditional word-document probability distribution $p(w|d)$ into two different distributions: the word-topic distribution $p(w|z)$, and the topic-document distribution $p(z|d)$ (see Equation 1). This allows each semantic topic z to be represented as a multinominal distribution of words $p(w|z)$, and each document d to be represented as a multinominal distribution of semantic topics $p(z|d)$. The model introduces a conditional independence assumption that document d and word w are independent con-

ditioned on the hidden variable, topic z.

$$p(w|d) = \sum_z p(z|d)p(w|z) \quad (1)$$

LDA is a Bayesian version of this framework with Dirichlet hyper-parameters (Blei et al., 2003).

The inference of the two distributions given an observed corpus can be done through Gibbs Sampling (Geman and Geman, 1987; Griffiths and Steyvers, 2004). For each turn of the sampling, each word in each document is assigned a semantic topic based on the current word-topic distribution and topic-document distribution. The resulting topic assignments are then used to re-estimate a new word-topic distribution and topic-document distribution for the next turn. This process repeats until convergence. To avoid statistical coincidence, the final estimation of the distributions is made by the average of all the turns after convergence.

3.2 The Sense Disambiguation Model

Assigning the correct sense s to a target word w occurring in a context c involves finding the sense which maximizes the conditional probability of senses given a context:

$$s = \arg\max_{s_i} p(s_i|c) \quad (2)$$

In our model, we represent a sense (s_i) as a collection of 'paraphrases' that capture (some aspect of) the meaning of the sense. These paraphrases can be taken from an existing resource such as WordNet (Miller, 1995) or supplied by the user (see Section 4).

This conditional probability is decomposed by incorporating a hidden variable, topic z, introduced by the topic model. We propose three variations of the basic model, depending on how much background information is available, i.e., knowledge of the prior sense distribution available and type of sense paraphrases used. In Model I and Model II, the sense paraphrases are obtained from WordNet, and both the context and the sense paraphrases are treated as documents, $c = dc$ and $s = ds$.

WordNet is a fairly rich resource which provides detailed information about word senses (glosses, example sentences, synsets, semantic relations between senses, etc.). Sometimes such detailed information may not be available, for instance for languages for which such a resource does not exist or for expressions that are not very well covered in WordNet, such as idioms. For those situations, we propose another model, Model III, in which contexts are treated as documents while sense paraphrases are treated as sequences of independent words.[1]

Model I directly maximizes the conditional probability of the sense given the context, where the sense is modeled as a 'paraphrase document' ds and the context as a 'context document' dc. The conditional probability of sense given context $p(ds|dc)$ can be rewritten as a joint probability divided by a normalization factor:

$$p(ds|dc) = \frac{p(ds, dc)}{p(dc)} \quad (3)$$

This joint probability can be rewritten as a generative process by introducing a hidden variable z. We make the conditional independence assumption that, conditioned on the topic z, a paraphrase document ds is generated independently of the specific context document dc:

$$p(ds, dc) = \sum_z p(ds)p(z|ds)p(dc|z) \quad (4)$$

We apply the same process to the conditional probability $p(dc|z)$. It can be rewritten as:

$$p(dc|z) = \frac{p(dc)p(z|dc)}{p(z)} \quad (5)$$

Now, the disambiguation model $p(ds|dc)$ can be rewritten as a prior $p(ds)$ times a topic function $f(z)$:

$$p(ds|dc) = p(ds) \sum_z \frac{p(z|dc)p(z|ds)}{p(z)} \quad (6)$$

As $p(z)$ is a uniform distribution according to the uniform Dirichlet priors assumption, Equation 6 can be rewritten as:

$$p(ds|dc) \propto p(ds) \sum_z p(z|dc)p(z|ds) \quad (7)$$

Model I:

$$\arg\max_{ds_i} p(ds_i) \sum_z p(z|dc)p(z|ds_i) \quad (8)$$

Model I has the disadvantage that it requires information about the prior distribution of senses

[1] The idea is that these key words capture the meaning of the idioms.

$p(ds)$, which is not always available. We use sense frequency information from WordNet to estimate the prior sense distribution, although it must be kept in mind that, depending on the genre of the texts, it is possible that the distribution of senses in the testing corpus may diverge greatly from the WordNet-based estimation. If there is no means for estimating the prior sense distribution of an experimental corpus, generally a uniform distribution must be assumed. However, this assumption does not hold, as the true distribution of word senses is often highly skewed (McCarthy, 2009).

To overcome this problem, we propose Model II, which indirectly maximizes the sense-context probability by maximizing the cosine value of two document vectors that encode the document-topic frequencies from sampling, $v(z|dc)$ and $v(z|ds)$. The document vectors are represented by topics, with each dimension representing the number of times that the tokens in this document are assigned to a certain topic.

Model II:

$$\arg\max_{ds_i} \cos(v(z|dc), v(z|ds_i)) \tag{9}$$

If the prior distribution of senses is known, Model I is the best choice. However, Model II has to be chosen instead when this knowledge is not available. In our experiments, we test the performance of both models (see Section 5).

If the sense paraphrases are very short, it is difficult to reliably estimate $p(z|ds)$. In order to solve this problem, we treat the sense paraphrase ds as a 'query', a concept which is used in information retrieval. One model from information retrieval takes the conditional probability of the query given the document as a product of all the conditional probabilities of words in the query given the document. The assumption is that the query is generated by a collection of conditionally independent words (Song and Croft, 1999).

We make the same assumption here. However, instead of taking the product of all the conditional probabilities of words given the document, we take the maximum. There are two reasons for this: (i) taking the product may penalize longer paraphrases since the product of probabilities decreases as there are more words; (ii) we do not want to model the probability of generating specific paraphrases, but rather the probability of generating a sense, which might only be represented by one or two words in the paraphrases (e.g., the potentially idiomatic phrase 'rock the boat' can be paraphrased as 'break the norm' or 'cause trouble'. A similar topic distribution to that of the individual words 'norm' or 'trouble' would be strong supporting evidence of the corresponding idiomatic reading.). We propose **Model III**:

$$\arg\max_{qs_i} \max_{w_i \in qs} \sum_z p(w_i|z)p(z|dc) \tag{10}$$

where qs is a collection of words contained in the sense paraphrases.

3.3 Inference

One possible inference approach is to combine the context documents and sense paraphrases into a corpus and run Gibbs sampling on this corpus. The problem with this approach is that the test set and sense paraphrase set are relatively small, and topic models running on a small corpus are less likely to capture rich semantic topics. One simple explanation for this is that a small corpus usually has a relatively small vocabulary, which is less representative of topics, i.e., $p(w|z)$ cannot be estimated reliably.

In order to overcome this problem, we infer the word-topic distribution from a very large corpus (Wikipedia dump, see Section 4). All the following inference experiments on the test corpus are based on the assumption that the word-topic distribution $p(w|z)$ is the same as the one estimated from the Wikipedia dump. Inference of topic-document distributions for context and sense paraphrases is done by fixing the word-topic distribution as a constant.

4 Experimental Setup

We evaluate our models on three different tasks: coarse-grained WSD, fine-grained WSD and literal vs. nonliteral sense detection. In this section we discuss our experimental set-up. We start by describing the three datasets for evaluation and another dataset for probability estimation. We also discuss how we choose sense paraphrases and instance contexts.

Data We use three datasets for evaluation. The coarse-grained task is evaluated on the Semeval-2007 Task-07 benchmark dataset released by Navigli et al. (2009). The dataset consists of 5377 words of running text from five different articles: the first three were obtained from the WSJ corpus, the fourth was the Wikipedia entry for *computer programming*, and the fifth was an excerpt of

Amy Steedman's *Knights of the Art*, biographies of Italian painters. The proportion of the non news text, the last two articles, constitutes 51.87% of the whole testing set. It consists of 1108 nouns, 591 verbs, 362 adjectives, and 208 adverbs. The data were annotated with coarse-grained senses which were obtained by clustering senses from the WordNet 2.1 sense inventory based on the procedure proposed by Navigli (2006).

To determine whether our model is also suitable for fine-grained WSD, we test on the data provided by Pradhan et al. (2009) for the Semeval-2007 Task-17 (English fine-grained all-words task). This dataset is a subset of the set from Task-07. It comprises the three WSJ articles from Navigli et al. (2009). A total of 465 lemmas were selected as instances from about 3500 words of text. There are 10 instances marked as 'U' (undecided sense tag). Of the remaining 455 instances, 159 are nouns and 296 are verbs. The sense inventory is from WordNet 2.1.

Finally, we test our model on the related sense disambiguation task of distinguishing literal and nonliteral usages of potentially ambiguous expressions such as *break the ice*. For this, we use the dataset from Sporleder and Li (2009) as a test set. This dataset consists of 3964 instances of 17 potential English idioms which were manually annotated as *literal* or *nonliteral*.

A Wikipedia dump[2] is used to estimate the multinomial word-topic distribution. This dataset, which consists of 320,000 articles,[3] is significantly larger than SemCor, which is the dataset used by Boyd-Graber et al. (2007). All markup from the Wikipedia dump was stripped off using the same filter as the ESA implementation (Sorg and Cimiano, 2008), and stopwords were filtered out using the Snowball (Porter, October 2001) stopword list. In addition, words with a Wikipedia document frequency of 1 were filtered out. The lemmatized version of the corpus consists of 299,825 lexical units.

The test sets were POS-tagged and lemmatized using RASP (Briscoe and Carroll, 2006). The inference processes are run on the lemmatized version of the corpus. For the Semeval-2007 Task 17 English all-words, the organizers do not supply the part-of-speech and lemma information of the target instances. In order to avoid the wrong predictions caused by tagging or lemmatization errors, we manually corrected any bad tags and lemmas for the target instances.[4]

Sense Paraphrases For word sense disambiguation tasks, the paraphrases of the sense keys are represented by information from WordNet 2.1. (Miller, 1995). To obtain the paraphrases, we use the **word forms**, **glosses** and **example sentences** of the *synset itself* and a set of selected *reference synsets* (i.e., synsets linked to the target synset by specific semantic relations, see Table 1). We excluded the 'hypernym reference synsets', since information common to all of the child synsets may confuse the disambiguation process.

For the literal vs. nonliteral sense detection task, we selected the paraphrases of the nonliteral meaning from several online idiom dictionaries. For the literal senses, we used 2-3 manually selected words with which we tried to capture (aspects of) the literal meaning of the expression.[5] For instance, the literal 'paraphrases' that we chose for 'break the ice' were *ice, water* and *snow*. The paraphrases are shorter for the idiom task than for the WSD task, because the meaning descriptions from the idiom dictionaries are shorter than what we get from WordNet. In the latter case, each sense can be represented by its synset as well as its reference synsets.

Instance Context We experimented with different context sizes for the disambiguation task. The five different context settings that we used for the WSD tasks are: collocations (1w), $\pm$5-word window (5w), $\pm$10-word window (10w), current sentence, and whole text. Because the idiom corpus also includes explicitly marked paragraph boundaries, we included 'paragraph' as a sixth type of context size for the idiom sense detection task.

5 Experiments

As mentioned above, we test our proposed sense disambiguation framework on three tasks. We start by describing the sampling experiments for

[2]We use the English snapshot of 2009-07-13

[3]All articles of fewer than 100 words were discarded.

[4]This was done by comparing the predicted sense keys and the gold standard sense keys. We only checked instances for which the POS-tags in the predicted sense keys are not consistent with those in the gold standard. This was the case for around 20 instances.

[5]Note that we use the word 'paraphrase' in a fairly wide sense in this paper. Sometimes it is not possible to obtain exact paraphrases. This applies especially to the task of distinguishing literal from nonliteral senses of multi-word expressions. In this case we take as paraphrases some key words which capture salient aspects of the meaning.

POS	Paraphrase reference synsets
N	hyponyms, instance hyponyms, member holonyms, substance holonyms, part holonyms, member meronyms, part meronyms, substance meronyms, attributes, topic members, region members, usage members, topics, regions, usages
V	Troponyms, entailments, outcomes, phrases, verb groups, topics, regions, usages, sentence frames
A	similar, pertainym, attributes, related, topics, regions, usages
R	pertainyms, topics, regions, usages

Table 1: Selected reference synsets from WordNet that were used for different parts-of-speech to obtain word sense paraphrase. N(noun), V(verb), A(adj), R(adv).

estimating the word-topic distribution from the Wikipedia dump. We used the package provided by Wang et al. (2009) with the suggested Dirichlet hyper-parameters [6]. In order to avoid statistical instability, the final result is averaged over the last 50 iterations. We did four rounds of sampling with 1000, 500, 250, and 125 topics respectively. The final word-topic distribution is a normalized concatenate of the four distributions estimated in each round. In average, the sampling program run on the Wikipedia dump consumed 20G memory, and each round took about one week on a single AMD Dual-Core 1000MHZ processor.

5.1 Coarse-Grained WSD

In this section we first describe the landscape of similar systems against which we compare our models, then present the results of the comparison. The systems that participated in the SemEval-2007 coarse-grained WSD task (Task-07) can be divided into three categories, depending on whether training data is needed and whether other types of background knowledge are required: What we call Type I includes all the systems that need annotated training data. All the participating systems that have the mark *TR* fall into this category (see Navigli et al. (2009) for the evaluation for all the participating systems). Type II consists of systems that do not need training data but require prior knowledge of the sense distribution (estimated sense frequency). All the participating systems that have the mark *MFS* belong to this category. Systems that need neither training data nor prior sense distribution knowledge are categorized as Type III.

We make this distinction based on two principles: (i) the cost of building a system; (ii) the portability of the established resource. Type III is the cheapest system to build, while Type I and Type II both need extra resources. Type II has an advantage over Type I since the prior knowledge of the sense distribution can be estimated from annotated corpora (e.g.: SemCor, Senseval). In contrast, training data in Type I may be system specific (e.g.: different input format, different annotation guidelines). McCarthy (2009) also addresses the issue of performance and cost by comparing supervised word sense disambiguation systems with unsupervised ones.

We exclude the system provided by one of the organizers (UoR-SSI) from our categorization. The reason is that although this system is claimed to be unsupervised, and it performs better than all the participating systems (including the supervised systems) in the SemEval-2007 shared task, it still needs to incorporate a lot of prior knowledge, specifically information about co-occurrences between different word senses, which was obtained from a number of resources (SSI+LKB) including: (i) SemCor (manually annotated); (ii) LDC-DSO (partly manually annotated); (iii) collocation dictionaries which are then disambiguated semi-automatically. Even though the system is not "trained", it needs a lot of information which is largely dependent on manually annotated data, so it does not fit neatly into the categories Type II or Type III either.

Table 2 lists the best participating systems of each type in the SemEval-2007 task (Type I: NUS-PT (Chan et al., 2007); Type II: UPV-WSD (Buscaldi and Rosso, 2007); Type III: TKB-UO (Anaya-Sánchez et al., 2007)). Our Model I belongs to Type II, and our Model II belongs to Type III.

Table 2 compares the performance of our models with the Semeval-2007 participating systems. We only compare the F-score, since all the compared systems have an attempted rate[7] of 1.0,

[6] They were set as: $\alpha = \frac{50}{\#topics}$ and $\beta = 0.01$.

[7] Attempted rate is defined as the total number of disambiguated output instances divided by the total number of input

which makes both the precision and recall rates the same as the F-score. We focus on comparisons between our models and the best SemEval-2007 participating systems within the same type. Model I is compared with UPV-WSD, and Model II is compared with TKB-UO. In addition, we also compare our system with the most frequent sense baseline which was not outperformed by any of the systems of Type II and Type III in the SemEval-2007 task.

Comparison on Type III is marked with $'$, while comparison on Type II is marked with $*$. We find that Model II performs statistically significantly better than the best participating system of the same type TKB-UO ($p<<0.01$, χ^2 test). When encoded with the prior knowledge of sense distribution, Model I outperforms by 1.36% the best Type II system UPV-WSD, although the difference is not statistically significant. Furthermore, Model I also quantitatively outperforms the most frequent sense baseline BL_{mfs}, which, as mentioned above, was not beat by any participating systems that do not use training data.

We also find that our model works best for nouns. The unsupervised Type III model Model II achieves better results than the most frequent sense baseline on nouns, but not on other parts-of-speech. This is in line with results obtained by previous systems (Griffiths et al., 2005; Boyd-Graber and Blei, 2008; Cai et al., 2007). While the performance on verbs can be increased to outperform the most frequent sense baseline by including the prior sense probability, the performance on adjectives and adverbs remains below the most frequent sense baseline. We think that there are three reasons for this: first, adjectives and adverbs have fewer reference synsets for paraphrases compared with nouns and verbs (see Table 1); second, adjectives and adverbs tend to convey less key semantic content in the document, so they are more difficult to capture by the topic model; and third, adjectives and adverbs are a small portion of the test set, so their performances are statistically unstable. For example, if 'already' appears 10 times out of 20 adverb instances, a system may get bad result on adverbs only because of its failure to disambiguate the word 'already'.

Paraphrase analysis Table 2 also shows the effect of different ways of choosing sense paraphrases. MII+ref is the result of including the reference synsets, while MII-ref excludes the reference synsets. As can be seen from the table, including all reference synsets in sense paraphrases increases performance. Longer paraphrases contain more information, and they are statistically more stable for inference.

instances.

System	Noun	Verb	Adj	Adv	All
UoR-SSI	84.12	78.34	85.36	88.46	83.21
NUS-PT	82.31	78.51	85.64	89.42	82.50
UPV-WSD	79.33	72.76	84.53	81.52	**78.63***
TKB-UO	70.76	62.61	78.73	74.04	**70.21**$'$
MII–ref	78.16	70.39	79.56	81.25	76.64
MII+ref	80.05	70.73	82.04	82.21	**78.14**$'$
MI+ref	79.96	75.47	83.98	86.06	**79.99***
BL_{mfs}	77.44	75.30	84.25	87.50	**78.99***

Table 2: Model performance (F-score) on the coarse-grained dataset (context=sentence). Paraphrases with/without reference synsets (+ref/-ref).

Context	Ate.	Pre.	Rec.	F1
$\pm 1w$	91.67	75.05	68.80	71.79
$\pm 5w$	99.29	77.14	76.60	76.87
$\pm 10w$	100	77.92	77.92	77.92
text	100	76.86	76.86	76.86
sent.	100	**78.14**	**78.14**	**78.14**

Table 3: Model II performance on different context size. attempted rate (Ate.), precision (Pre.), recall (Rec.), F-score (F1).

We find that nouns get the greatest performance boost from including reference synsets, as they have the largest number of different types of synsets. We also find the 'similar' reference synset for adjectives to be very useful. Performance on adjectives increases by 2.75% when including this reference synset.

Context analysis In order to study how the context influences the performance, we experiment with Model II on different context sizes (see Table 3). We find *sentence context* is the best size for this disambiguation task. Using a smaller context not only reduces the precision, but also reduces the recall rate, which is caused by the all-zero topic assignment by the topic model for documents only containing words that are not in the vocabulary. As a result, the model is unable to disambiguate. The context based on the whole text (article) does not perform well either, possibly because using the full text folds in too much noisy information.

System	F-score
RACAI	52.7 ±4.5
BL_{mfs}	55.91±4.5
MI+ref	**56.99**±4.5

Table 4: Model performance (F-score) for the fine-grained word sense disambiguation task.

5.2 Fine-grained WSD

We saw in the previous section that our framework performs well on coarse-grained WSD. Fine-grained WSD, however, is a more difficult task. To determine whether our framework is also able to detect subtler sense distinctions, we tested Model I on the English all-words subtask of SemEval-2007 Task-17 (see Table 4).

We find that Model I performs better than both the best unsupervised system, RACAI (Ion and Tufiş, 2007) and the most frequent sense baseline (BL_{mfs}), although these differences are not statistically significant due to the small size of the available test data (465).

5.3 Idiom Sense Disambiguation

In the previous section, we provided the results of applying our framework to coarse- and fine-grained word sense disambiguation tasks. For both tasks, our models outperform the state-of-the-art systems of the same type either quantitatively or statistically significantly. In this section, we apply Model III to another sense disambiguation task, namely distinguishing literal and nonliteral senses of ambiguous expressions.

WordNet has a relatively low coverage for idiomatic expressions. In order to represent nonliteral senses, we replace the paraphrases obtained automatically from WordNet by words selected manually from online idiom dictionaries (for the nonliteral sense) and by linguistic introspection (for the literal sense). We then compare the topic distributions of literal and nonliteral senses.

As the paraphrases obtained from the idiom dictionary are very short, we treat the paraphrase as a sequence of independent words instead of as a document and apply Model III (see Section 3). Table 5 shows the results of our proposed model compared with state-of-the-art systems. We find that the system significantly outperforms the majority baseline ($p<<0.01$, χ^2 test) and the cohesion-graph based approach proposed by Sporleder and Li (2009) ($p<<0.01$, χ^2 test). The system also outperforms the bootstrapping system by Li and Sporleder (2009), although not statistically significantly. This shows how a limited amount of human knowledge (e.g., paraphrases) can be added to an unsupervised system for a strong boost in performance (Model III compared with the cohesion-graph and the bootstrapping approaches).

System	$Prec_l$	Rec_l	F_l	Acc.
$Base_{maj}$	-	-	-	78.25
co-graph	50.04	69.72	58.26	78.38
boot.	71.86	66.36	69.00	87.03
Model III	67.05	81.07	73.40	87.24

Table 5: Performance on the literal or nonliteral sense disambiguation task on idioms. literal precision ($Prec_l$), literal recall (Rec_l), literal F-score (F_l), accuracy(Acc.).

For obvious reasons, this approach is sensitive to the quality of the paraphrases. The paraphrases chosen to characterise (aspects of) the meaning of a sense should be non-ambiguous between the literal or idiomatic meaning. For instance, 'fire' is not a good choice for a paraphrase of the literal reading of 'play with fire', since this word can be interpreted literally as 'fire' or metaphorically as 'something dangerous'. The verb component word 'play' is a better literal paraphrase.

For the same reason, this approach works well for expressions where the literal and nonliteral readings are well separated (i.e., occur in different contexts), while the performance drops for expressions whose literal and idiomatic readings can appear in a similar context. We test the performance on individual idioms on the five most frequent idioms in our corpus[8] (see Table 6). We find that 'drop the ball' is a difficult case. The words 'fault', 'mistake', 'fail' or 'miss' can be used as the nonliteral paraphrases. However, it is also highly likely that these words are used to describe a scenario in a baseball game, in which 'drop the ball' is used literally. In contrast, the performance on 'rock the boat' is much better, since the nonliteral reading of the phrases 'break the norm' or 'cause trouble' are less likely to be linked with the literal reading 'boat'. This may also be because 'boat' is not often used metaphorically in the corpus.

As the topic distribution of nouns and verbs exhibit different properties, topic comparisons across parts-of-speech do not make sense. We

[8]We tested only on the most frequent idioms in order to avoid statistically unreliable observations.

Idiom	Acc.
drop the ball	75.86
play with fire	91.17
break the ice	87.43
rock the boat	95.82
set in stone	89.39

Table 6: Performance on individual idioms.

make the topic distributions comparable by making sure each type of paraphrase contains the same sets of parts-of-speech. For instance, we do not permit combinations of literal paraphrases which only consist of nouns and nonliteral paraphrases which only consist of verbs.

6 Conclusion

We propose three models for sense disambiguation on words and multi-word expressions. The basic idea of these models is to compare the topic distribution of a target instance with the candidate sense paraphrases and choose the most probable one. While Model I and Model III model the problem in a probabilistic way, Model II uses a vector space model by comparing the cosine values of two topic vectors. Model II and Model III are completely unsupervised, while Model I needs the prior sense distribution. Model I and Model II treat the sense paraphrases as documents, while Model III treats the sense paraphrases as a collection of independent words.

We test the proposed models on three tasks. We apply Model I and Model II to the WSD tasks due to the availability of more paraphrase information. Model III is applied to the idiom detection task since the paraphrases from the idiom dictionary are smaller. We find that all models outperform comparable state-of-the-art systems either quantitatively or statistically significantly.

By testing our framework on three different sense disambiguation tasks, we show that the framework can be used flexibly in different application tasks. The system also points out a promising way of solving the granularity problem of word sense disambiguation, as new application tasks which need different sense granularities can utilize this framework when new paraphrases of sense clusters are available. In addition, this system can also be used in a larger context such as figurative language identification (*literal* or *figurative*) and sentiment detection (*positive* or *negative*).

PCFGs, Topic Models, Adaptor Grammars and Learning Topical Collocations and the Structure of Proper Names

Mark Johnson
Department of Computing
Macquarie University
mjohnson@science.mq.edu.au

Abstract

This paper establishes a connection between two apparently very different kinds of probabilistic models. Latent Dirichlet Allocation (LDA) models are used as "topic models" to produce a low-dimensional representation of documents, while Probabilistic Context-Free Grammars (PCFGs) define distributions over trees. The paper begins by showing that LDA topic models can be viewed as a special kind of PCFG, so Bayesian inference for PCFGs can be used to infer Topic Models as well. Adaptor Grammars (AGs) are a hierarchical, non-parameteric Bayesian extension of PCFGs. Exploiting the close relationship between LDA and PCFGs just described, we propose two novel probabilistic models that combine insights from LDA and AG models. The first replaces the unigram component of LDA topic models with multi-word sequences or collocations generated by an AG. The second extension builds on the first one to learn aspects of the internal structure of proper names.

1 Introduction

Over the last few years there has been considerable interest in Bayesian inference for complex hierarchical models both in machine learning and in computational linguistics. This paper establishes a theoretical connection between two very different kinds of probabilistic models: Probabilistic Context-Free Grammars (PCFGs) and a class of models known as Latent Dirichlet Allocation (Blei et al., 2003; Griffiths and Steyvers, 2004) models that have been used for a variety of tasks in machine learning. Specifically, we show that an LDA model can be expressed as a certain kind of PCFG, so Bayesian inference for PCFGs can be used to learn LDA topic models as well. The importance of this observation is primarily theoretical, as current Bayesian inference algorithms for PCFGs are less efficient than those for LDA inference. However, once this link is established it suggests a variety of extensions to the LDA topic models, two of which we explore in this paper. The first involves extending the LDA topic model so that it generates collocations (sequences of words) rather than individual words. The second applies this idea to the problem of automatically learning internal structure of proper names (NPs), which is useful for definite NP coreference models and other applications.

The rest of this paper is structured as follows. The next section reviews Latent Dirichlet Allocation (LDA) topic models, and the following section reviews Probabilistic Context-Free Grammars (PCFGs). Section 4 shows how an LDA topic model can be expressed as a PCFG, which provides the fundamental connection between LDA and PCFGs that we exploit in the rest of the paper, and shows how it can be used to define a "sticky topic" version of LDA. The following section reviews Adaptor Grammars (AGs), a non-parametric extension of PCFGs introduced by Johnson et al. (2007b). Section 6 exploits the connection between LDA and PCFGs to propose an AG-based topic model that extends LDA by defining distributions over collocations rather than individual words, and section 7 applies this extension to the problem of finding the structure of proper names.

2 Latent Dirichlet Allocation Models

Latent Dirichlet Allocation (LDA) was introduced as an explicit probabilistic counterpart to Latent Semantic Indexing (LSI) (Blei et al., 2003). Like LSI, LDA is intended to produce a low-dimensional characterisation or summary of a doc-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1148–1157,
Uppsala, Sweden, 11-16 July 2010.

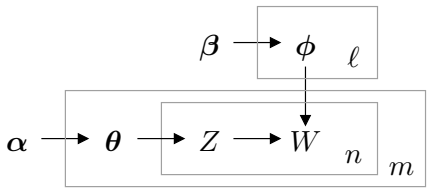

Figure 1: A graphical model "plate" representation of an LDA topic model. Here ℓ is the number of topics, m is the number of documents and n is the number of words per document.

ument in a collection of documents for information retrieval purposes. Both LSI and LDA do this by mapping documents to points in a relatively low-dimensional real-valued vector space; distance in this space is intended to correspond to document similarity.

An LDA model is an explicit generative probabilistic model of a collection of documents. We describe the "smoothed" LDA model here (see page 1006 of Blei et al. (2003)) as it corresponds precisely to the Bayesian PCFGs described in section 4. It generates a collection of documents by first generating multinomials $\boldsymbol{\phi}_i$ over the vocabulary V for each topic $i \in 1, \ldots, \ell$, where ℓ is the number of topics and $\phi_{i,w}$ is the probability of generating word w in topic i. Then it generates each document $D_j, j = 1, \ldots, m$ in turn by first generating a multinomial $\boldsymbol{\theta}_j$ over topics, where $\theta_{j,i}$ is the probability of topic i appearing in document j. ($\boldsymbol{\theta}_j$ serves as the low-dimensional representation of document D_j). Finally it generates each of the n words of document D_j by first selecting a topic z for the word according to $\boldsymbol{\theta}_j$, and then drawing a word from $\boldsymbol{\phi}_z$. Dirichlet priors with parameters $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$ respectively are placed on the $\boldsymbol{\phi}_i$ and the $\boldsymbol{\theta}_j$ in order to avoid the zeros that can arise from maximum likelihood estimation (i.e., sparse data problems).

The LDA generative model can be compactly expressed as follows, where "$\sim$" should be read as "is distributed according to".

$$\begin{array}{rcll} \boldsymbol{\phi}_i & \sim & \mathrm{Dir}(\boldsymbol{\beta}) & i = 1, \ldots, \ell \\ \boldsymbol{\theta}_j & \sim & \mathrm{Dir}(\boldsymbol{\alpha}) & j = 1, \ldots, m \\ z_{j,k} & \sim & \boldsymbol{\theta}_j & j = 1, \ldots, m; k = 1, \ldots, n \\ w_{j,k} & \sim & \boldsymbol{\phi}_{z_{j,k}} & j = 1, \ldots, m; k = 1, \ldots, n \end{array}$$

In inference, the parameters $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ of the Dirichlet priors are either fixed (i.e., chosen by the model designer), or else themselves inferred, e.g., by Bayesian inference. (The adaptor grammar software we used in the experiments described below automatically does this kind of hyper-parameter inference).

The inference task is to find the topic probability vector $\boldsymbol{\theta}_j$ of each document D_j given the words $w_{j,k}$ of the documents; in general this also requires inferring the topic to word distributions $\boldsymbol{\phi}$ and the topic assigned to each word $z_{j,k}$. Blei et al. (2003) describe a Variational Bayes inference algorithm for LDA models based on a mean-field approximation, while Griffiths and Steyvers (2004) describe an Markov Chain Monte Carlo inference algorithm based on Gibbs sampling; both are quite effective in practice.

3 Probabilistic Context-Free Grammars

Context-Free Grammars are a simple model of hierarchical structure often used to describe natural language syntax. A *Context-Free Grammar* (CFG) is a quadruple (N, W, R, S) where N and W are disjoint finite sets of *nonterminal* and *terminal* symbols respectively, R is a finite set of productions or *rules* of the form $A \rightarrow \beta$ where $A \in N$ and $\beta \in (N \cup W)^\star$, and $S \in N$ is the *start symbol*.

In what follows, it will be useful to interpret a CFG as generating sets of finite, labelled, ordered trees $\mathcal{T}_A$ for each $X \in N \cup W$. Informally, $\mathcal{T}_X$ consists of all trees t rooted in X where for each *local tree* (B, β) in t (i.e., where B is a parent's label and β is the sequence of labels of its immediate children) there is a rule $B \rightarrow \beta \in R$.

Formally, the sets $\mathcal{T}_X$ are the smallest sets of trees that satisfy the following equations.

If $X \in W$ (i.e., if X is a terminal) then $\mathcal{T}_X = \{X\}$, i.e., $\mathcal{T}_X$ consists of a single tree, which in turn only consists of a single node labelled X.

If $X \in N$ (i.e., if X is a nonterminal) then

$$\mathcal{T}_X = \bigcup_{X \rightarrow B_1 \ldots B_n \in R_X} \textsc{Tree}_X(\mathcal{T}_{B_1}, \ldots, \mathcal{T}_{B_n})$$

where $R_A = \{A \rightarrow \beta : A \rightarrow \beta \in R\}$ for each $A \in N$, and

$$\textsc{Tree}_X(\mathcal{T}_{B_1}, \ldots, \mathcal{T}_{B_n}) = \left\{ \overbrace{t_1 \ldots t_n}^{X} : \begin{array}{l} t_i \in \mathcal{T}_{B_i}, \\ i = 1, \ldots, n \end{array} \right\}$$

That is, $\textsc{Tree}_X(\mathcal{T}_{B_1}, \ldots, \mathcal{T}_{B_n})$ consists of the set of trees with whose root node is labelled X and whose ith child is a member of $\mathcal{T}_{B_i}$.

The set of trees generated by the CFG is $\mathcal{T}_S$, where S is the start symbol, and the set of strings generated by the CFG is the set of yields (i.e., terminal strings) of the trees in $\mathcal{T}_S$.

A *Probabilistic Context-Free Grammar* (PCFG) is a pair consisting of a CFG and set of multinomial probability vectors $\boldsymbol{\theta}_X$ indexed by nonterminals $X \in N$, where $\boldsymbol{\theta}_X$ is a distribution over the rules R_X (i.e., the rules expanding X). Informally, $\theta_{X\to\beta}$ is the probability of X expanding to β using the rule $X \to \beta \in R_X$. More formally, a PCFG associates each $X \in N \cup W$ with a distribution G_X over the trees $\mathcal{T}_X$ as follows.

If $X \in W$ (i.e., if X is a terminal) then G_X is the distribution that puts probability 1 on the single-node tree labelled X.

If $X \in N$ (i.e., if X is a nonterminal) then:

$$G_X = \sum_{X\to B_1 \ldots B_n \in R_X} \theta_{X\to B_1\ldots B_n} \mathrm{TD}_X(G_{B_1}, \ldots, G_{B_n}) \quad (1)$$

where:

$$\mathrm{TD}_A(G_1, \ldots, G_n)\left(\begin{array}{c} X \\ \diagup\ \diagdown \\ t_1\ \ldots\ t_n \end{array}\right) = \prod_{i=1}^{n} G_i(t_i).$$

That is, $\mathrm{TD}_A(G_1, \ldots, G_n)$ is a distribution over $\mathcal{T}_A$ where each subtree t_i is generated independently from G_i. These equations have solutions (i.e., the PCFG is said to be "consistent") when the rule probabilities $\boldsymbol{\theta}_A$ obey certain conditions; see e.g., Wetherell (1980) for details.

The PCFG generates the distribution over trees G_S, where S is the start symbol. The distribution over the strings it generates is obtained by marginalising over the trees.

In a Bayesian PCFG one puts Dirichlet priors $\mathrm{Dir}(\boldsymbol{\alpha}_X)$ on each of the multinomial rule probability vectors $\boldsymbol{\theta}_X$ for each nonterminal $X \in N$. This means that there is one Dirichlet parameter $\alpha_{X\to\beta}$ for each rule $X \to \beta \in R$ in the CFG.

In the "unsupervised" inference problem for a PCFG one is given a CFG, parameters $\boldsymbol{\alpha}_X$ for the Dirichlet priors over the rule probabilities, and a corpus of strings. The task is to infer the corresponding posterior distribution over rule probabilities $\boldsymbol{\theta}_X$. Recently Bayesian inference algorithms for PCFGs have been described. Kurihara and Sato (2006) describe a Variational Bayes algorithm for inferring PCFGs using a mean-field approximation, while Johnson et al. (2007a) describe a Markov Chain Monte Carlo algorithm based on Gibbs sampling.

4 LDA topic models as PCFGs

This section explains how to construct a PCFG that generates the same distribution over a collection of documents as an LDA model, and where Bayesian inference for the PCFG's rule probabilities yields the corresponding distributions as Bayesian inference of the corresponding LDA models. (There are several different ways of encoding LDA models as PCFGs; the one presented here is not the most succinct — it is possible to collapse the Doc and Doc' nonterminals — but it has the advantage that the LDA distributions map straight-forwardly onto PCFG nonterminals).

The terminals W of the CFG consist of the vocabulary V of the LDA model plus a set of special "document identifier" terminals "$\_j$" for each document $j \in 1, \ldots, m$, where m is the number of documents. In the PCFG encoding strings from document j are prefixed with "$\_j$"; this indicates to the grammar which document the string comes from. The nonterminals consist of the start symbol $\mathrm{Sentence}$, Doc_j and Doc'_j for each $j \in 1, \ldots, m$, and Topic_i for each $i \in 1, \ldots, \ell$, where ℓ is the number of topics in the LDA model.

The rules of the CFG are all instances of the following schemata:

$\mathrm{Sentence} \to \mathrm{Doc}'_j$	$j \in 1, \ldots, m$
$\mathrm{Doc}'_j \to \_j$	$j \in 1, \ldots, m$
$\mathrm{Doc}'_j \to \mathrm{Doc}'_j\ \mathrm{Doc}_j$	$j \in 1, \ldots, m$
$\mathrm{Doc}_j \to \mathrm{Topic}_i$	$i \in 1, \ldots, \ell; j \in 1, \ldots, m$
$\mathrm{Topic}_i \to w$	$i \in 1, \ldots, \ell; w \in V$

Figure 2 depicts a tree generated by such a CFG. The relationship between the LDA model and the PCFG can be understood by studying the trees generated by the CFG. In these trees the left-branching spine of nodes labelled Doc'_j propagate the document identifier throughout the whole tree. The nodes labelled Topic_i indicate the topics assigned to particular words, and the local trees expanding Doc_j to Topic_i (one per word in the document) indicate the distribution of topics in the document.

The corresponding Bayesian PCFG associates probabilities with each of the rules in the CFG. The probabilities $\boldsymbol{\theta}_{\mathrm{Topic}_i}$ associated with the rules expanding the Topic_i nonterminals indicate how words are distributed across topics; the $\boldsymbol{\theta}_{\mathrm{Topic}_i}$ probabilities correspond exactly to to the $\boldsymbol{\phi}_i$ probabilities in the LDA model. The probabilities

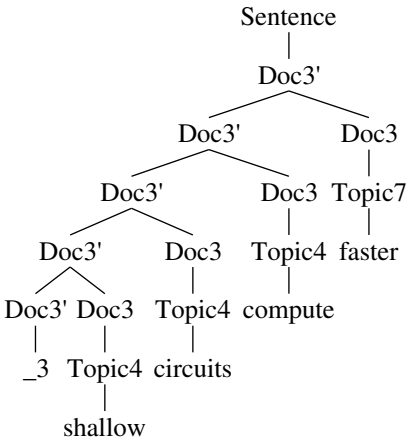

Figure 2: A tree generated by the CFG encoding an LDA topic model. The prefix "_3" indicates that this string belongs to document 3. The tree also indicates the assignment of words to topics.

$\boldsymbol{\theta}_{\mathrm{Doc}_j}$ associated with rules expanding Doc_j specify the distribution of topics in document j; they correspond exactly to the probabilities $\boldsymbol{\theta}_j$ of the LDA model. (The PCFG also specifies several other distributions that are suppressed in the LDA model. For example $\boldsymbol{\theta}_{\mathrm{Sentence}}$ specifies the distribution of documents in the corpus. However, it is easy to see that these distributions do not influence the topic distributions; indeed, the expansions of the $\mathrm{Sentence}$ nonterminal are completely determined by the document distribution in the corpus, and are not affected by $\boldsymbol{\theta}_{\mathrm{Sentence}}$).

A Bayesian PCFG places Dirichlet priors $\mathrm{Dir}(\boldsymbol{\alpha}_A)$ on the corresponding rule probabilities $\boldsymbol{\theta}_A$ for each $A \in N$. In the PCFG encoding an LDA model, the $\boldsymbol{\alpha}_{\mathrm{Topic}_i}$ parameters correspond exactly to the $\boldsymbol{\beta}$ parameters of the LDA model, and the $\boldsymbol{\alpha}_{\mathrm{Doc}_j}$ parameters correspond to the $\boldsymbol{\alpha}$ parameters of the LDA model.

As suggested above, each document D_j in the LDA model is mapped to a string in the corpus used to train the corresponding PCFG by prefixing it with a document identifier "$\_j$". Given this training data, the posterior distribution over rule probabilities $\theta_{\mathrm{Doc}_j \rightarrow \mathrm{Topic}_i}$ is the same as the posterior distribution over topics given documents $\theta_{j,i}$ in the original LDA model.

As we will see below, this connection between PCFGs and LDA topic models suggests a number of interesting variants of both PCFGs and topic models. Note that we are *not* suggesting that Bayesian inference for PCFGs is necessarily a good way of estimating LDA topic models. Current Bayesian PCFG inference algorithms require time proportional to the cube of the length of the longest string in the training corpus, and since these strings correspond to entire documents in our embedding, blindly applying a Bayesian PCFG inference algorithm is likely to be impractical.

A little reflection shows that the embedding still holds if the strings in the PCFG corpus correspond to sentences or even smaller units of the original document collection, so a single document would be mapped to multiple strings in the PCFG inference task. In this way the cubic time complexity of PCFG inference can be mitigated. Also, the trees generated by these CFGs have a very specialized left-branching structure, and it is straightforward to modify the general-purpose CFG inference procedures to avoid the cubic time complexity for such grammars: thus it may be practical to estimate topic models via grammatical inference.

However, we believe that the primary value of the embedding of LDA topic models into Bayesian PCFGs is theoretical: it suggests a number of novel extensions of both topic models and grammars that may be worth exploring. Our claim here is not that these models are the best algorithms for performing these tasks, but that the relationship we described between LDA models and PCFGs suggests a variety of interesting novel models.

We end this section with a simple example of such a modification to LDA. Inspired by the standard embedding of HMMs into PCFGs, we propose a "sticky topic" variant of LDA in which adjacent words are more likely to be assigned the same topic. Such an LDA extension is easy to describe as a PCFG (see Fox et al. (2008) for a similar model presented as an extended HMM). The nonterminals $\mathrm{Sentence}$ and Topic_i for $i = 1, \ldots, \ell$ have the same interpretation as before, but we introduce new nonterminals $\mathrm{Doc}_{j,i}$ that indicate we have just generated a nonterminal in document j belonging to topic i. Given a collection of m documents and ℓ topics, the rule schemata are as follows:

$\mathrm{Sentence} \rightarrow \mathrm{Doc}_{j,i}$	$i \in 1, \ldots, \ell;$ $j \in 1, \ldots, m$
$\mathrm{Doc}_{j,1} \rightarrow \_j$	$j \in 1, \ldots, m$
$\mathrm{Doc}_{j,i} \rightarrow \mathrm{Doc}_{j,i'}\ \mathrm{Topic}_i$	$i, i' \in 1, \ldots, \ell;$ $j \in 1, \ldots, m$
$\mathrm{Topic}_i \rightarrow w$	$i \in 1, \ldots, \ell; w \in V$

A sample parse generated by a "sticky topic"

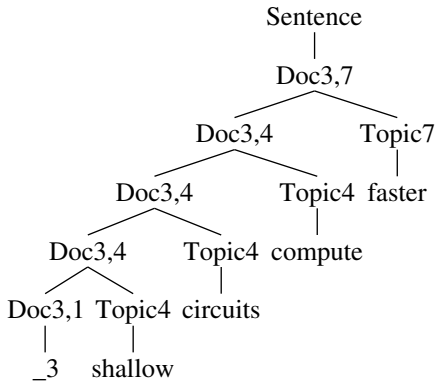

Figure 3: A tree generated by the "sticky topic" CFG. Here a nonterminal $\mathrm{Doc}3,7$ indicates we have just generated a word in document 3 belonging to topic 7.

CFG is shown in Figure 3. The probabilities of the rules $\mathrm{Doc}_{j,i} \rightarrow \mathrm{Doc}_{j,i'}\ \mathrm{Topic}_i$ in this PCFG encode the probability of shifting from topic i to topic i' (this PCFG can be viewed as generating the string from right to left).

We can use non-uniform sparse Dirichlet priors on the probabilities of these rules to encourage "topic stickiness". Specifically, by setting the Dirichlet parameters for the "topic shift" rules $\mathrm{Doc}_{j,i'} \rightarrow \mathrm{Doc}_{j,i}\ \mathrm{Topic}_i$ where $i' \neq i$ much lower than the parameters for the "topic preservation" rules $\mathrm{Doc}_{j,i} \rightarrow \mathrm{Doc}_{j,i}\ \mathrm{Topic}_i$, Bayesian inference will be biased to find distributions in which adjacent words will tend to have the same topic.

5 Adaptor Grammars

Non-parametric Bayesian inference, where the inference task involves learning not just the values of a finite vector of parameters but which parameters are relevant, has been the focus of intense research in machine learning recently. In the topic-modelling community this has lead to work on Dirichlet Processes and Chinese Restaurant Processes, which can be used to estimate the number of topics as well as their distribution across documents (Teh et al., 2006).

There are two obvious non-parametric extensions to PCFGs. In the first we regard the set of nonterminals N as potentially unbounded, and try to learn the set of nonterminals required to describe the training corpus. This approach goes under the name of the "infinite HMM" or "infinite PCFG" (Beal et al., 2002; Liang et al., 2007; Liang et al., 2009). Informally, we are given a set of "basic categories", say NP, VP, etc., and a set of rules that use these basic categories, say $\mathrm{S} \rightarrow \mathrm{NP}\ \mathrm{VP}$. The inference task is to learn a set of refined categories and rules (e.g., $\mathrm{S}_7 \rightarrow \mathrm{NP}_2\ \mathrm{VP}_5$) as well as their probabilities; this approach can therefore be viewed as a Bayesian version of the "split-merge" approach to grammar induction (Petrov and Klein, 2007).

In the second approach, which we adopt here, we regard the set of rules R as potentially unbounded, and try to learn the rules required to describe a training corpus as well as their probabilities. Adaptor grammars are an example of this approach (Johnson et al., 2007b), where entire subtrees generated by a "base grammar" can be viewed as distinct rules (in that we learn a separate probability for each subtree). The inference task is non-parametric if there are an unbounded number of such subtrees.

We review the adaptor grammar generative process below; for an informal introduction see Johnson (2008) and for details of the adaptor grammar inference procedure see Johnson and Goldwater (2009).

An adaptor grammar $(N, W, R, S, \theta, A, C)$ consists of a PCFG (N, W, R, S, θ) in which a subset $A \subseteq N$ of the nonterminals are *adapted*, and where each adapted nonterminal $X \in A$ has an associated adaptor C_X. An *adaptor* C_X for X is a function that maps a distribution over trees $\mathcal{T}_X$ to a distribution over distributions over $\mathcal{T}_X$ (we give examples of adaptors below).

Just as for a PCFG, an adaptor grammar defines distributions G_X over trees $\mathcal{T}_X$ for each $X \in N \cup W$. If $X \in W$ or $X \notin A$ then G_X is defined just as for a PCFG above, i.e., using (1). However, if $X \in A$ then G_X is defined in terms of an additional distribution H_X as follows:

$$\begin{aligned} G_X &\sim C_X(H_X) \\ H_X &= \sum_{X \rightarrow Y_1 \ldots Y_m \in R_X} \theta_{X \rightarrow Y_1 \ldots Y_m} \mathrm{TD}_X(G_{Y_1}, \ldots, G_{Y_m}) \end{aligned}$$

That is, the distribution G_X associated with an adapted nonterminal $X \in A$ is a sample from adapting (i.e., applying C_X to) its "ordinary" PCFG distribution H_X. In general adaptors are chosen for the specific properties they have. For example, with the adaptors used here G_X typically concentrates mass on a smaller subset of the trees $\mathcal{T}_X$ than H_X does.

Just as with the PCFG, an adaptor grammar generates the distribution over trees G_S, where $S \in N$

is the start symbol. However, while G_S in a PCFG is a fixed distribution (given the rule probabilities θ), in an adaptor grammar the distribution G_S is itself a random variable (because each G_X for $X \in A$ is random), i.e., an adaptor grammar generates a distribution over distributions over trees $\mathcal{T}_S$. However, the posterior joint distribution $\Pr(\boldsymbol{t})$ of a sequence $\boldsymbol{t} = (t_1, \ldots, t_n)$ of trees in $\mathcal{T}_S$ is well-defined:

$$\Pr(\boldsymbol{t}) \;=\; \int G_S(t_1) \ldots G_S(t_n)\, d\boldsymbol{G}$$

where the integral is over all of the random distributions $G_X, X \in A$. The adaptors we use in this paper are Dirichlet Processes or two-parameter Poisson-Dirichlet Processes, for which it is possible to compute this integral. One way to do this uses the predictive distributions:

$$\Pr(t_{n+1} \mid \boldsymbol{t}, H_X) \;\propto\; \int G_X(t_1) \ldots G_X(t_{n+1}) C_X(G_X \mid H_X)\, dG_X$$

where $\boldsymbol{t} = (t_1, \ldots, t_n)$ and each $t_i \in \mathcal{T}_X$. The predictive distribution for the Dirichlet Process is the (labeled) *Chinese Restaurant Process* (CRP), and the predictive distribution for the two-parameter Poisson-Dirichlet process is the (labeled) *Pitman-Yor Process* (PYP).

In the context of adaptor grammars, the CRP is:

$$\mathrm{CRP}(t \mid \boldsymbol{t}, \alpha_X, H_X) \;\propto\; n_t(\boldsymbol{t}) + \alpha_X H_X(t)$$

where $n_t(\boldsymbol{t})$ is the number of times t appears in $\boldsymbol{t}$ and $\alpha_X > 0$ is a user-settable "concentration parameter". In order to generate the next tree t_{n+1} a CRP either reuses a tree t with probability proportional to number of times t has been previously generated, or else it "backs off" to the "base distribution" H_X and generates a fresh tree t with probability proportional to $\alpha_X H_X(t)$.

The PYP is a generalization of the CRP:

$$\mathrm{PYP}(t \mid \boldsymbol{t}, a_X, b_X, H_X) \;\propto\; \max(0, n_t(\boldsymbol{t}) - m_t\, a_X) + (m a_X + b_X) H_X(t)$$

Here $a_X \in [0, 1]$ and $b_X > 0$ are user-settable parameters, and m_t is the number of times the PYP has generated t in $\boldsymbol{t}$ from the base distribution H_X, and $m = \sum_{t \in \mathcal{T}_X} m_t$ is the number of times any tree has been generated from H_X. (In the Chinese Restaurant metaphor, m_t is the number of tables labeled with t, and m is the number of occupied tables). If $a_X = 0$ then the PYP is equivalent to a CRP with $\alpha_X = b_X$, while if $a_X = 1$ then the PYP generates samples from H_X.

Informally, the CRP has a strong preference to regenerate trees that have been generated frequently before, leading to a "rich-get-richer" dynamics. The PYP can mitigate this somewhat by reducing the effective count of previously generated trees and redistributing that probability mass to new trees generated from H_X. As Goldwater et al. (2006) explain, Bayesian inference for H_X given samples from G_X is effectively performed from types if $a_X = 0$ and from tokens if $a_X = 1$, so varying a_X smoothly interpolates between type-based and token-based inference.

Adaptor grammars have previously been used primarily to study grammatical inference in the context of language acquisition. The *word segmentation task* involves segmenting a corpus of unsegmented phonemic utterance representations into words (Elman, 1990; Bernstein-Ratner, 1987). For example, the phoneme string corresponding to "you want to see the book" (with its correct segmentation indicated) is as follows:

y ▵ u ▴ w ▵ a ▵ n ▵ t ▴ t ▵ u ▴ s ▵ i ▴ D ▵ 6 ▴ b ▵ U ▵ k

We can represent any possible segmentation of any possible sentence as a tree generated by the following *unigram adaptor grammar*.

Sentence → <u>Word</u>
Sentence → <u>Word</u> Sentence
<u>Word</u> → Phonemes
Phonemes → Phoneme
Phonemes → Phoneme Phonemes

The trees generated by this adaptor grammar are the same as the trees generated by the CFG rules. For example, the following skeletal parse in which all but the Word nonterminals are suppressed (the others are deterministically inferrable) shows the parse that corresponds to the correct segmentation of the string above.

(Word y u) (Word w a n t) (Word t u)
(Word s i) (Word d 6) (Word b u k)

Because the Word nonterminal is *adapted* (indicated here by underlining) the adaptor grammar learns the probability of the entire Word subtrees (e.g., the probability that *b u k* is a Word); see Johnson (2008) for further details.

6 Topic models with collocations

Here we combine ideas from the unigram word segmentation adaptor grammar above and the PCFG encoding of LDA topic models to present a novel topic model that learns topical collocations. (For a non-grammar-based approach to this problem see Wang et al. (2007)). Specifically, we take the PCFG encoding of the LDA topic model described above, but modify it so that the Topic_i nodes generate sequences of words rather than single words. Then we adapt each of the Topic_i nonterminals, which means that we learn the probability of each of the sequences of words it can expand to.

$$
\begin{array}{ll}
\text{Sentence} \rightarrow \text{Doc}_j & j \in 1, \ldots, m \\
\text{Doc}_j \rightarrow \_j & j \in 1, \ldots, m \\
\text{Doc}_j \rightarrow \text{Doc}_j\ \text{Topic}_i & i \in 1, \ldots, \ell; \\
 & j \in 1, \ldots, m \\
\underline{\text{Topic}}_i \rightarrow \text{Words} & i \in 1, \ldots, \ell \\
\text{Words} \rightarrow \text{Word} & \\
\text{Words} \rightarrow \text{Words Word} & \\
\text{Word} \rightarrow w & w \in V
\end{array}
$$

In order to demonstrate that this model works, we implemented this using the publically-available adaptor grammar inference software,[1] and ran it on the NIPS corpus (composed of published NIPS abstracts), which has previously been used for studying collocation-based topic models (Griffiths et al., 2007). Because there is no generally accepted evaluation for collocation-finding, we merely present some of the sample analyses found by our adaptor grammar. We ran our adaptor grammar with $\ell = 20$ topics (i.e., 20 distinct Topic_i nonterminals). Adaptor grammar inference on this corpus is actually relatively efficient because the corpus provided by Griffiths et al. (2007) is already segmented by punctuation, so the terminal strings are generally rather short. Rather than set the Dirichlet parameters by hand, we placed vague priors on them and estimated them as described in Johnson and Goldwater (2009).

The following are some examples of collocations found by our adaptor grammar:

$\text{Topic}_0 \rightarrow$ cost function
$\text{Topic}_0 \rightarrow$ fixed point
$\text{Topic}_0 \rightarrow$ gradient descent
$\text{Topic}_0 \rightarrow$ learning rates
$\text{Topic}_1 \rightarrow$ associative memory
$\text{Topic}_1 \rightarrow$ hamming distance
$\text{Topic}_1 \rightarrow$ randomly chosen
$\text{Topic}_1 \rightarrow$ standard deviation
$\text{Topic}_3 \rightarrow$ action potentials
$\text{Topic}_3 \rightarrow$ membrane potential
$\text{Topic}_3 \rightarrow$ primary visual cortex
$\text{Topic}_3 \rightarrow$ visual system
$\text{Topic}_{10} \rightarrow$ nervous system
$\text{Topic}_{10} \rightarrow$ action potential
$\text{Topic}_{10} \rightarrow$ ocular dominance
$\text{Topic}_{10} \rightarrow$ visual field

The following are skeletal sample parses, where we have elided all but the adapted nonterminals (i.e., all we show are the Topic nonterminals, since the other structure can be inferred deterministically). Note that because Griffiths et al. (2007) segmented the NIPS abstracts at punctuation symbols, the training corpus contains more than one string from each abstract.

_3 (Topic_5 polynomial size)
(Topic_{15} threshold circuits)

_4 (Topic_{11} studied)
(Topic_{19} pattern recognition algorithms)

_4 (Topic_2 feedforward neural network)
(Topic_1 implementation)

_5 (Topic_{11} single)
(Topic_{10} ocular dominance stripe)
(Topic_{12} low) (Topic_3 ocularity)
(Topic_{12} drift rate)

7 Finding the structure of proper names

Grammars offer structural and positional sensitivity that is not exploited in the basic LDA topic models. Here we explore the potential for using Bayesian inference for learning linear ordering constraints that hold between elements within proper names.

The Penn WSJ treebank is a widely used resource within computational linguistics (Marcus et al., 1993), but one of its weaknesses is that it does not indicate any structure internal to base noun phrases (i.e., it presents "flat" analyses of the pre-head NP elements). For many applications it would be extremely useful to have a more elaborated analysis of this kind of NP structure. For example, in an NP coreference application, if we could determine that *Bill* and *Hillary* are both first

[1] http://web.science.mq.edu.au/ ˜mjohnson/Software.htm

names then we could infer that *Bill Clinton* and *Hillary Clinton* are likely to refer to distinct individuals. On the other hand, because *Mr* in *Mr Clinton* is not a first name, it is possible that *Mr Clinton* and *Bill Clinton* refer to the same individual (Elsner et al., 2009).

Here we present an adaptor grammar based on the insights of the PCFG encoding of LDA topic models that learns some of the structure of proper names. The key idea is that elements in proper names typically appear in a fixed order; we expect honorifics to appear before first names, which appear before middle names, which in turn appear before surnames, etc. Similarly, many company names end in fixed phrases such as *Inc.* Here we think of first names as a kind of topic, albeit one with a restricted positional location. One of the challenges is that some of these structural elements can be filled by multiword expressions; e.g., *de Groot* can be a surname. We deal with this by permitting multi-word collocations to fill the corresponding positions, and use the adaptor grammar machinery to learn these collocations.

Inspired by the grammar presented in Elsner et al. (2009), our adaptor grammar is as follows, where adapted nonterminals are indicated by underlining as before.

$$
\begin{aligned}
&\mathrm{NP} \rightarrow (\mathrm{A0})\ (\mathrm{A1})\ \ldots\ (\mathrm{A6})\\
&\mathrm{NP} \rightarrow (\mathrm{B0})\ (\mathrm{B1})\ \ldots\ (\mathrm{B6})\\
&\mathrm{NP} \rightarrow \mathrm{Unordered}^{+}\\
&\underline{\mathrm{A0}} \rightarrow \mathrm{Word}^{+}\\
&\quad \ldots\\
&\underline{\mathrm{A6}} \rightarrow \mathrm{Word}^{+}\\
&\underline{\mathrm{B0}} \rightarrow \mathrm{Word}^{+}\\
&\quad \ldots\\
&\underline{\mathrm{B6}} \rightarrow \mathrm{Word}^{+}\\
&\underline{\mathrm{Unordered}} \rightarrow \mathrm{Word}^{+}
\end{aligned}
$$

In this grammar parentheses indicate optionality, and the Kleene plus indicates iteration (these were manually expanded into ordinary CFG rules in our experiments). The grammar provides three different expansions for proper names. The first expansion says that a proper name can consist of some subset of the six different collocation classes A0 through A6 in that order, while the second expansion says that a proper name can consist of some subset of the collocation classes B0 through B6, again in that order. Finally, the third expansion says that a proper name can consist of an arbitrary sequence of "unordered" collocations (this is intended as a "catch-all" expansion to provide analyses for proper names that don't fit either of the first two expansions).

We extracted all of the proper names (i.e., phrases of category NNP and NNPS) in the Penn WSJ treebank and used them as the training corpora for the adaptor grammar just described. The adaptor grammar inference procedure found skeletal sample parses such as the following:

(A0 barrett) (A3 smith)
(A0 albert) (A2 j.) (A3 smith) (A4 jr.)
(A0 robert) (A2 b.) (A3 van dover)
(B0 aim) (B1 prime rate) (B2 plus) (B5 fund) (B6 inc.)
(B0 balfour) (B1 maclaine) (B5 international) (B6 ltd.)
(B0 american express) (B1 information services) (B6 co)
(U abc) (U sports)
(U sports illustrated)
(U sports unlimited)

While a full evaluation will have to await further study, in general it seems to distinguish person names from company names reasonably reliably, and it seems to have discovered that person names consist of a first name (A0), a middle name or initial (A2), a surname (A3) and an optional suffix (A4). Similarly, it seems to have uncovered that company names typically end in a phrase such as *inc*, *ltd* or *co*.

8 Conclusion

This paper establishes a connection between two very different kinds of probabilistic models; LDA models of the kind used for topic modelling, and PCFGs, which are a standard model of hierarchical structure in language. The embedding we presented shows how to express an LDA model as a PCFG, and has the property that Bayesian inference of the parameters of that PCFG produces an equivalent model to that produced by Bayesian inference of the LDA model's parameters.

The primary value of this embedding is theoretical rather than practical; we are not advocating the use of PCFG estimation procedures to infer LDA models. Instead, we claim that the embedding suggests novel extensions to both the LDA topic models and PCFG-style grammars. We justified this claim by presenting several hybrid models that combine aspects of both topic models and

grammars. We don't claim that these are necessarily the best models for performing any particular tasks; rather, we present them as examples of models inspired by a combination of PCFGs and LDA topic models. We showed how the LDA to PCFG embedding suggested a "sticky topic" model extension to LDA. We then discussed adaptor grammars, and inspired by the LDA topic models, presented a novel topic model whose primitive elements are multi-word collocations rather than words. We concluded with an adaptor grammar that learns aspects of the internal structure of proper names.

Acknowledgments

This research was funded by US NSF awards 0544127 and 0631667, as well as by a start-up award from Macquarie University. I'd like to thank the organisers and audience at the Topic Modeling workshop at NIPS 2009, my former colleagues at Brown University (especially Eugene Charniak, Micha Elsner, Sharon Goldwater, Tom Griffiths and Erik Sudderth), my new colleagues at Macquarie University and the ACL reviewers for their excellent suggestions and comments on this work. Abstract

We report on an experiment to track complex decision points in linguistic meta-data annotation where the decision behavior of annotators is observed with an eye-tracking device. As experimental conditions we investigate different forms of textual context and linguistic complexity classes relative to syntax and semantics. Our data renders evidence that annotation performance depends on the semantic and syntactic complexity of the decision points and, more interestingly, indicates that full-scale context is mostly negligible – with the exception of semantic high-complexity cases. We then induce from this observational data a cognitively grounded cost model of linguistic meta-data annotations and compare it with existing non-cognitive models. Our data reveals that the cognitively founded model explains annotation costs (expressed in annotation time) more adequately than non-cognitive ones.

1 Introduction

Today's NLP systems, in particular those relying on supervised ML approaches, are meta-data greedy. Accordingly, in the past years, we have witnessed a massive quantitative growth of annotated corpora. They differ in terms of the natural languages and domains being covered, the types of linguistic meta-data being solicited, and the text genres being served. We have seen large-scale efforts in syntactic and semantic annotations in the past related to POS tagging and parsing, on the one hand, and named entities and relations (propositions), on the other hand. More recently, we are dealing with even more challenging issues such as subjective language, a large variety of co-reference and (e.g., RST-style) text structure phenomena, Since the NLP community is further extending their work into these more and more sophisticated semantic and pragmatic analytics, there seems to be no end in sight for increasingly complex and diverse annotation tasks.

Yet, producing annotations is pretty expensive. So the question comes up, how we can rationally manage these investments so that annotation campaigns are economically doable without loss in annotation quality. The economics of annotations are at the core of *Active Learning* (AL) where those linguistic samples are focused on in the entire document collection, which are estimated as being most informative to learn an effective classification model (Cohn et al., 1996). This intentional selection bias stands in stark contrast to prevailing sampling approaches where annotation examples are randomly chosen.

When different approaches to AL are compared with each other, or with standard random sampling, in terms of annotation efficiency, up until now, the AL community assumed *uniform* annotation costs for each linguistic unit, e.g. words. This claim, however, has been shown to be invalid in several studies (Hachey et al., 2005; Settles et al., 2008; Tomanek and Hahn, 2010). If uniformity does not hold and, hence, the number of annotated units does not indicate the true annotation efforts required for a specific sample, empirically more adequate cost models are needed.

Building predictive models for annotation costs has only been addressed in few studies for now (Ringger et al., 2008; Settles et al., 2008; Arora et al., 2009). The proposed models are based on easy-to-determine, yet not so explanatory variables (such as the number of words to be annotated), indicating that accurate models of annotation costs remain a desideratum. We here, alternatively, consider different classes of syntactic and semantic complexity that might affect the cognitive load during the annotation process, with

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1158–1167,
Uppsala, Sweden, 11-16 July 2010.

the overall goal to find additional and empirically more adequate variables for cost modeling.

The complexity of linguistic utterances can be judged either by structural or by behavioral criteria. Structural complexity emerges, e.g., from the static topology of phrase structure trees and procedural graph traversals exploiting the topology of parse trees (see Szmrecsányi (2004) or Cheung and Kemper (1992) for a survey of metrics of this type). However, structural complexity criteria do not translate directly into empirically justified cost measures and thus have to be taken with care.

The behavioral approach accounts for this problem as it renders observational data of the annotators' eye movements. The technical vehicle to gather such data are eye-trackers which have already been used in psycholinguistics (Rayner, 1998). Eye-trackers were able to reveal, e.g., how subjects deal with ambiguities (Frazier and Rayner, 1987; Rayner et al., 2006; Traxler and Frazier, 2008) or with sentences which require re-analysis, so-called garden path sentences (Altmann et al., 2007; Sturt, 2007).

The rationale behind the use of eye-tracking devices for the observation of annotation behavior is that the length of gaze durations and behavioral patterns underlying gaze movements are considered to be indicative of the hardness of the linguistic analysis and the expenditures for the search of clarifying linguistic evidence (anchor words) to resolve hard decision tasks such as phrase attachments or word sense disambiguation. Gaze duration and search time are then taken as empirical correlates of linguistic complexity and, hence, uncover the *real* costs. We therefore consider eye-tracking as a promising means to get a better understanding of the nature of the linguistic annotation processes with the ultimate goal of identifying predictive factors for annotation cost models.

In this paper, we first describe an empirical study where we observed the annotators' reading behavior while annotating a corpus. Section 2 deals with the design of the study, Section 3 discusses its results. In Section 4 we then focus on the implications this study has on building cost models and compare a simple cost model mainly relying on word and character counts and additional simple descriptive characteristics with one that can be derived from experimental data as provided from eye-tracking. We conclude with experiments which reveal that cognitively grounded models outperform simpler ones relative to cost prediction using annotation time as a cost measure. Based on this finding, we suggest that cognitive criteria are helpful for uncovering the real costs of corpus annotation.

2 Experimental Design

In our study, we applied, for the first time ever to the best of our knowledge, eye-tracking to study the cognitive processes underlying the annotation of linguistic meta-data, named entities in particular. In this task, a human annotator has to decide for each word whether or not it belongs to one of the entity types of interest.

We used the English part of the MUC7 corpus (Linguistic Data Consortium, 2001) for our study. It contains *New York Times* articles from 1996 reporting on plane crashes. These articles come already annotated with three types of named entities considered important in the newspaper domain, *viz.* "persons", "locations", and "organizations".

Annotation of these entity types in newspaper articles is admittedly fairly easy. We chose this rather simple setting because the participants in the experiment had no previous experience with document annotation and no serious linguistic background. Moreover, the limited number of entity types reduced the amount of participants' training prior to the actual experiment, and positively affected the design and handling of the experimental apparatus (see below).

We triggered the annotation processes by giving our participants specific *annotation examples*. An example consists of a text document having one single *annotation phrase* highlighted which then had to be semantically annotated with respect to named entity mentions. The annotation task was defined such that the correct entity type had to be assigned to each word in the annotation phrase. If a word belongs to none of the three entity types a fourth class called "no entity" had to be assigned.

The phrases highlighted for annotation were *complex noun phrases* (CNPs), each a sequence of words where a noun (or an equivalent nominal expression) constitutes the syntactic head and thus dominates dependent words such as determiners, adjectives, or other nouns or nominal expressions (including noun phrases and prepositional phrases). CNPs with even more elaborate internal syntactic structures, such as coordinations, appositions, or relative clauses, were isolated from

their syntactic host structure and the intervening linguistic material containing these structures was deleted to simplify overly long sentences. We also discarded all CNPs that did not contain at least one *entity-critical* word, i.e., one which might be a named entity according to its orthographic appearance (e.g., starting with an upper-case letter). It should be noted that such orthographic signals are by no means a sufficient condition for the presence of a named entity mention within a CNP.

The choice of CNPs as stimulus phrases is motivated by the fact that named entities are usually fully encoded by this kind of linguistic structure. The chosen stimulus – an annotation example with one phrase highlighted for annotation – allows for an exact localization of the cognitive processes and annotation actions performed relative to that specific phrase.

2.1 Independent Variables

We defined two measures for the complexity of the annotation examples: The *syntactic* complexity was given by the number of nodes in the constituent parse tree which are dominated by the annotation phrase (Szmrecsányi, 2004).[1] According to a threshold on the number of nodes in such a parse tree, we classified CNPs as having either high or low syntactic complexity.

The *semantic* complexity of an annotation example is based on the inverse document frequency df of the words in the annotation phrase according to a reference corpus.[2] We calculated the semantic complexity score of an annotation phrase as $max_i \frac{1}{df(w_i)}$, where w_i is the i-th word of the annotation phrase. Again, we empirically determined a threshold classifying annotation phrases as having either high or low semantic complexity. Additionally, this automatically generated classification was manually checked and, if necessary, revised by two annotation experts. For instance, if an annotation phrase contained a strong trigger (e.g., a social role or job title, as with *"spokeswoman"* in the annotation phrase *"spokeswoman Arlene"*), it was classified as a low-semantic-complexity item even though it might have been assigned a high inverse document frequency (due to the infrequent word *"Arlene"*).

[1]Constituency parse structure was obtained from the OpenNLP parser (`http://opennlp.sourceforge.net/`) trained on PennTreeBank data.

[2]We chose the English part of the Reuters RCV2 corpus as the reference corpus for our experiments.

Two experimental groups were formed to study different contexts. In the *document context* condition the whole newspaper article was shown as annotation example, while in the *sentence context* condition only the sentence containing the annotation phrase was presented. The participants[3] were randomly assigned to one of these groups. We decided for this between-subjects design to avoid any irritation of the participants caused by constantly changing contexts. Accordingly, the participants were assigned to one of the experimental groups and corresponding context condition already in the second training phase that took place shortly before the experiment started (see below).

2.2 Hypotheses and Dependent Variables

We tested the following two hypotheses:

Hypothesis H1: *Annotators perform differently in the two context conditions.*

H1 is based on the linguistically plausible assumption that annotators are expected to make heavy use of the surrounding context because such context could be helpful for the correct disambiguation of entity classes. Accordingly, lacking context, an annotator is expected to annotate worse than under the condition of full context. However, the availability of (too much) context might overload and distract annotators, with a presumably negative effect on annotation performance.

Hypothesis H2: *The complexity of the annotation phrases determines the annotation performance.*

The assumption is that high syntactic or semantic complexity significantly lowers the annotation performance.

In order to test these hypotheses we collected data for the following dependent variables: *(a)* the annotation accuracy – we identified erroneous entities by comparison with the original gold annotations in the MUC7 corpus, *(b)* the time needed per annotation example, and *(c)* the distribution and duration of the participants' eye gazes.

[3]20 subjects (12 female) with an average age of 24 years (mean = 24, standard deviation (SD) = 2.8) and normal or corrected-to-normal vision capabilities took part in the study. All participants were students with a computing-related study background, with good to very good English language skills (mean = 7.9, SD = 1.2, on a ten-point scale with 1 = "poor" and 10 = "excellent", self-assessed), but without any prior experience in annotation and without previous exposure to linguistic training.

2.3 Stimulus Material

According to the above definition of complexity, we automatically preselected annotation examples characterized by either a low or a high degree of semantic and syntactic complexity. After manual fine-tuning of the example set assuring an even distribution of entity types and syntactic correctness of the automatically derived annotation phrases, we finally selected 80 annotation examples for the experiment. These were divided into four subsets of 20 examples each falling into one of the following complexity classes:

sem-syn: low semantic/low syntactic complexity
SEM-syn: high semantic/low syntactic complexity
sem-SYN: low semantic/high syntactic complexity
SEM-SYN: high semantic/high syntactic complexity

2.4 Experimental Apparatus and Procedure

The annotation examples were presented in a custom-built tool and its user interface was kept as simple as possible not to distract the eye movements of the participants. It merely contained one frame showing the text of the annotation example, with the annotation phrase being highlighted. A blank screen was shown after each annotation example to reset the eyes and to allow a break, if needed. The time the blank screen was shown was not counted as annotation time. The 80 annotation examples were presented to all participants in the same randomized order, with a balanced distribution of the complexity classes. A variation of the order was hardly possible for technical and analytical reasons but is not considered critical due to extensive, pre-experimental training (see below). The limitation on 80 annotation examples reduces the chances of errors due to fatigue or lack of attention that can be observed in long-lasting annotation activities.

Five introductory examples (not considered in the final evaluation) were given to get the subjects used to the experimental environment. All annotation examples were chosen in a way that they completely fitted on the screen (i.e., text length was limited) to avoid the need for scrolling (and eye distraction). The position of the CNP within the respective context was randomly distributed, excluding the first and last sentence.

The participants used a standard keyboard to assign the entity types for each word of the annotation example. All but 5 keys were removed from the keyboard to avoid extra eye movements for finger coordination (three keys for the positive entity classes, one for the negative "no entity" class, and one to confirm the annotation). Pre-tests had shown that the participants could easily issue the annotations without looking down at the keyboard.

We recorded the participant's eye movements on a Tobii T60 eye-tracking device which is invisibly embedded in a 17" TFT monitor and comparatively tolerant to head movements. The participants were seated in a comfortable position with their head in a distance of 60-70 cm from the monitor. Screen resolution was set to 1280 x 1024 px and the annotation examples were presented in the middle of the screen in a font size of 16 px and a line spacing of 5 px. The presentation area had no fixed height and varied depending on the context condition and length of the newspaper article. The text was always vertically centered on the screen.

All participants were familiarized with the annotation task and the guidelines in a pre-experimental workshop where they practiced annotations on various exercise examples (about 60 minutes). During the next two days, one after the other participated in the actual experiment which took between 15 and 30 minutes, including calibration of the eye-tracking device. Another 20-30 minutes of training time directly preceded the experiment. After the experiment, participants were interviewed and asked to fill out a questionnaire. Overall, the experiment took about two hours for each participant for which they were financially compensated. Participants were instructed to focus more on annotation accuracy than on annotation time as we wanted to avoid random guessing. Accordingly, as an extra incentive, we rewarded the three participants with the highest annotation accuracy with cinema vouchers. None of the participants reported serious difficulties with the newspaper articles or annotation tool and all understood the annotation task very well.

3 Results

We used a mixed-design analysis of variance (ANOVA) model to test the hypotheses, with the context condition as between-subjects factor and the two complexity classes as within-subject factors.

3.1 Testing Context Conditions

To test hypothesis H1 we compared the number of annotation errors on entity-critical words made

	above	before	anno phrase	after	below
percentage of participants looking at a sub-area	35%	32%	100%	34%	16%
average number of fixations per sub-area	2.2		14.1		1.3

Table 1: Distribution of annotators' attention among sub-areas per annotation example.

by the annotators in the two contextual conditions (complete document *vs.* sentence). Surprisingly, on the total of 174 entity-critical words within the 80 annotation examples, we found exactly the same mean value of 30.8 errors per participant in both conditions. There were also no significant differences in the average time needed to annotate an example in both conditions (means of 9.2 and 8.6 seconds, respectively, with $F(1, 18) = 0.116$, $p = 0.74$).[4] These results seem to suggest that it makes no difference (neither for annotation accuracy nor for time) whether or not annotators are shown textual context beyond the sentence that contains the annotation phrase.

To further investigate this finding we analyzed eye-tracking data of the participants gathered for the document context condition. We divided the whole text area into five sub-areas as schematically shown in Figure 1. We then determined the average proportion of participants that directed their gaze at least once at these sub-areas. We considered all fixations with a minimum duration of 100 ms, using a fixation radius (i.e., the smallest distance that separates fixations) of 30 px and excluded the first second (mainly used for orientation and identification of the annotation phrase).

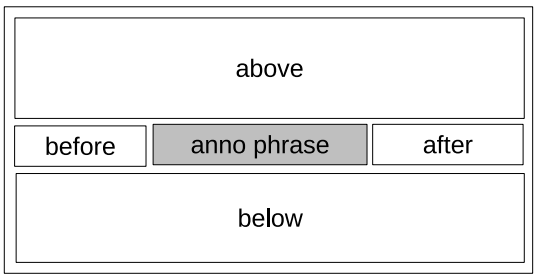

Figure 1: Schematic visualization of the sub-areas of an annotation example.

Table 1 reveals that on average only 35% of the participants looked in the textual context above the annotation phrase embedding sentence, and even less perceived the context below (16%). The sentence parts before and after the annotation phrase were, on the average, visited by one third (32% and 34%, respectively) of the participants. The uneven distribution of the annotators' attention becomes even more apparent in a comparison of the total number of fixations on the different text parts: 14 out of an average of 18 fixations per example were directed at the annotation phrase and the surrounding sentence, the text context above the annotation chunk received only 2.2 fixations on the average and the text context below only 1.3.

Thus, the eye-tracking data indicates that the textual context is not as important as might have been expected for quick and accurate annotation. This result can be explained by the fact that participants of the document-context condition used the context whenever they thought it might help, whereas participants of the sentence-context condition spent more time thinking about a correct answer, overall with the same result.

3.2 Testing Complexity Classes

To test hypothesis H2 we also compared the average annotation time and the number of errors on entity-critical words for the complexity subsets (see Table 2). The ANOVA results show highly significant differences for both annotation time and errors.[5] A pairwise comparison of all subsets in both conditions with a t-test showed non-significant results only between the SEM-syn and syn-SEM subsets.[6]

Thus, the empirical data generally supports hypothesis H2 in that the annotation performance seems to correlate with the complexity of the annotation phrase, on the average.

[4] In general, we observed a high variance in the number of errors and time values between the subjects. While, e.g., the fastest participant handled an example in 3.6 seconds on the average, the slowest one needed 18.9 seconds; concerning the annotation errors on the 174 entity-critical words, these ranged between 21 and 46 errors.

[5] Annotation time results: $F(1, 18) = 25$, $p < 0.01$ for the semantic complexity and $F(1, 18) = 76.5$, $p < 0.01$ for the syntactic complexity; Annotation complexity results: $F(1, 18) = 48.7$, $p < 0.01$ for the semantic complexity and $F(1, 18) = 184$, $p < 0.01$ for the syntactic complexity.

[6] $t(9) = 0.27$, $p = 0.79$ for the annotation time in the document context condition, and $t(9) = 1.97$, $p = 0.08$ for the annotation errors in the sentence context condition.

experimental condition	complexity class	e.-c. words	time mean	time SD	errors mean	errors SD	errors rate
document condition	sem-syn	36	4.0s	2.0	2.7	2.1	.075
	SEM-syn	25	9.2s	6.7	5.1	1.4	.204
	sem-SYN	51	9.6s	4.0	9.1	2.9	.178
	SEM-SYN	62	14.2s	9.5	13.9	4.5	.224
sentence condition	sem-syn	36	3.9s	1.3	1.1	1.4	.031
	SEM-syn	25	7.5s	2.8	6.2	1.9	.248
	sem-SYN	51	9.6s	2.8	9.0	3.9	.176
	SEM-SYN	62	13.5s	5.0	14.5	3.4	.234

Table 2: Average performance values for the 10 subjects of each experimental condition and 20 annotation examples of each complexity class: number of entity-critical words, mean annotation time and standard deviations (SD), mean annotation errors, standard deviations, and error rates (number of errors divided by number of entity-critical words).

3.3 Context and Complexity

We also examined whether the need for inspecting the context increases with the complexity of the annotation phrase. Therefore, we analyzed the eye-tracking data in terms of the average number of fixations on the annotation phrase and on its embedding contexts for each complexity class (see Table 3). The values illustrate that while the number of fixations on the annotation phrase rises generally with both the semantic and the syntactic complexity, the number of fixations on the context rises only with semantic complexity. The number of fixations on the context is nearly the same for the two subsets with low semantic complexity (sem-syn and sem-SYN, with 1.0 and 1.5), while it is significantly higher for the two subsets with high semantic complexity (5.6 and 5.0), independent of the syntactic complexity.[7]

complexity class	fix. on phrase mean	fix. on phrase SD	fix. on context mean	fix. on context SD
sem-syn	4.9	4.0	1.0	2.9
SEM-syn	8.1	5.4	5.6	5.6
sem-SYN	18.1	7.7	1.5	2.0
SEM-SYN	25.4	9.3	5.0	4.1

Table 3: Average number of fixations on the annotation phrase and context for the document condition and 20 annotation examples of each complexity class.

These results suggest that the need for context mainly depends on the semantic complexity of the annotation phrase, while it is less influenced by its syntactic complexity.

[7] ANOVA result of $F(1, 19) = 19.7$, $p < 0.01$ and significant differences also in all pairwise comparisons.

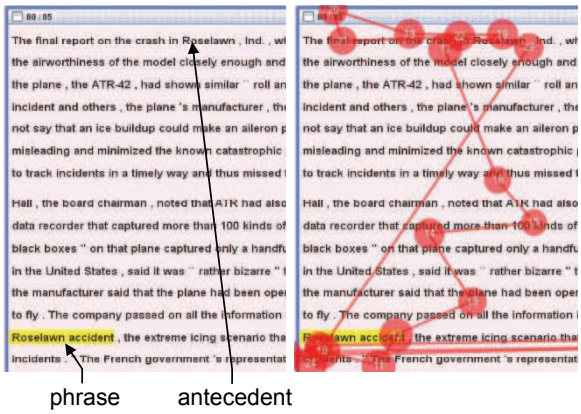

Figure 2: Annotation example with annotation phrase and the antecedent for *"Roselawn"* in the text (left), and gaze plot of one participant showing a scanning-for-coreference behavior (right).

This finding is also qualitatively supported by the gaze plots we generated from the eye-tracking data. Figure 2 shows a gaze plot for one participant that illustrates a scanning-for-coreference behavior we observed for several annotation phrases with high semantic complexity. In this case, words were searched in the upper context, which according to their orthographic signals might refer to a named entity but which could not completely be resolved only relying on the information given by the annotation phrase itself and its embedding sentence. This is the case for *"Roselawn"* in the annotation phrase *"Roselawn accident"*. The context reveals that Roselawn, which also occurs in the first sentence, is a location. A similar procedure is performed for acronyms and abbreviations which cannot be resolved from the immediate local context – searches mainly visit the upper context. As indicated by the gaze movements, it also became apparent that texts were rather scanned for hints instead of being deeply read.

4 Cognitively Grounded Cost Modeling

We now discuss whether the findings on dependent variables from our eye-tracking study are fruitful for actually modeling annotation costs. Therefore, we learn a linear regression model with time (an operationalization of annotation costs) as the dependent variable. We compare our 'cognitive' model against a baseline model which relies on some simple formal text features only, and test whether the newly introduced features help predict annotation costs more accurately.

4.1 Features

The features for the baseline model, character- and word-based, are similar to the ones used by Ringger et al. (2008) and Settles et al. (2008).[8] Our cognitive model, however, makes additional use of features based on linguistic complexity, and includes syntactic and semantic criteria related to the annotation phrases. These features were inspired by the insights provided by our eye-tracking experiments. All features are designed such that they can automatically be derived from *unlabeled* data, a necessary condition for such features to be practically applicable.

To account for our findings that syntactic and semantic complexity correlates with annotation performance, we added three features based on syntactic, and two based on semantic complexity measures. We decided for the use of multiple measures because there is no single agreed-upon metric for either syntactic or semantic complexity. This decision is further motivated by findings which reveal that different measures are often complementary to each other so that their combination better approximates the inherent degrees of complexity (Roark et al., 2007).

As for syntactic complexity, we use two measures based on structural complexity including *(a)* the number of nodes of a constituency parse tree which are dominated by the annotation phrase (cf. Section 2.1), and *(b)* given the dependency graph of the sentence embedding the annotation phrase, we consider the distance between words for each dependency link within the annotation phrase and consider the maximum over such distance values as another metric for syntactic complexity. Lin (1996) has already shown that human performance on sentence processing tasks can be predicted using such a measure. Our third syntactic complexity measure is based on the probability of part-of-speech (POS) 2-grams. Given a POS 2-gram model, which we learned from the automatically POS-tagged MUC7 corpus, the complexity of an annotation phrase is defined by $\sum_{i=2}^{n} P(\text{POS}_i|\text{POS}_{i-1})$ where POS_i refers to the POS-tag of the i-th word of the annotation phrase. A similar measure has been used by Roark et al. (2007) who claim that complex syntactic structures correlate with infrequent or surprising combinations of POS tags.

As far as the quantification of semantic complexity is concerned, we use *(a)* the inverse document frequency $df(w_i)$ of each word w_i (cf. Section 2.1), and a measure based on the semantic ambiguity of each word, i.e., the number of meanings contained in WORDNET,[9] within an annotation phrase. We consider the maximum ambiguity of the words within the annotation phrase as the overall ambiguity of the respective annotation phrase. This measure is based on the assumption that annotation phrases with higher semantic ambiguity are harder to annotate than low-ambiguity ones. Finally, we add the Flesch-Kincaid Readability Score (Klare, 1963), a well-known metric for estimating the comprehensibility and reading complexity of texts.

As already indicated, some of the hardness of annotations is due to tracking co-references and abbreviations. Both often cannot be resolved locally so that annotators need to consult the context of an annotation chunk (cf. Section 3.3). Thus, we also added features providing information whether the annotation phrases contain entity-critical words which may denote the referent of an antecedent of an anaphoric relation. In the same vein, we checked whether an annotation phrase contains expressions which can function as an abbreviation by virtue of their orthographical appearance, e.g., consist of at least two upper-case letters.

Since our participants were sometimes scanning for entity-critical words, we also added features providing information on the number of entity-critical words within the annotation phrase. Table 4 enumerates all feature classes and single features used for determining our cost model.

[8] In preliminary experiments our set of basic features comprised additional features providing information on the usage of stop words in the annotation phrase and on the number of paragraphs, sentences, and words in the respective annotation example. However, since we found these features did not have any significant impact on the model, we removed them.

[9] `http://wordnet.princeton.edu/`

Feature Group	# Features	Feature Description
characters (basic)	6	number of characters and words per annotation phrase; test whether words in a phrase start with capital letters, consist of capital letters only, have alphanumeric characters, or are punctuation symbols
words	2	number of entity-critical words and percentage of entity-critical words in the annotation phrase
complexity	6	syntactic complexity: number of dominated nodes, POS n-gram probability, maximum dependency distance; semantic complexity: inverse document frequency, max. ambiguity; general linguistic complexity: Flesch-Kincaid Readability Score
semantics	3	test whether entity-critical word in annotation phrase is used in document (preceding or following current phrase); test whether phrase contains an abbreviation

Table 4: Features for cost modeling.

4.2 Evaluation

To test how well annotation costs can be modeled by the features described above, we used the MUC7$_\mathcal{T}$ corpus, a re-annotation of the MUC7 corpus (Tomanek and Hahn, 2010). MUC7$_\mathcal{T}$ has time tags attached to the sentences and CNPs. These time tags indicate the time it took to annotate the respective phrase for named entity mentions of the types *person*, *location*, and *organization*. We here made use of the time tags of the 15,203 CNPs in MUC7$_\mathcal{T}$. MUC7$_\mathcal{T}$ has been annotated by two annotators (henceforth called *A* and *B*) and so we evaluated the cost models for both annotators. We learned a simple linear regression model with the annotation time as dependent variable and the features described above as independent variables. The baseline model only includes the basic feature set, whereas the 'cognitive' model incorporates all features described above.

Table 5 depicts the performance of both models induced from the data of annotator A and B. The coefficient of determination (R^2) describes the proportion of the variance of the dependent variable that can be described by the given model. We report adjusted R^2 to account for the different numbers of features used in both models.

model	R^2 on A's data	R^2 on B's data
baseline	0.4695	0.4640
cognitive	0.6263	0.6185

Table 5: Adjusted R^2 values on both models and for annotators A and B.

For both annotators, the baseline model is significantly outperformed in terms of R^2 by our 'cognitive' model ($p < 0.05$). Considering the features that were inspired from the eye-tracking study, R^2 is increased from 0.4695 to 0.6263 on the timing data of annotator A, and from 0.464 to 0.6185 on the data of annotator B. These numbers clearly demonstrate that annotation costs are more adequately modelled by the additional features we identified through our eye-tracking study.

Our 'cognitive' model now consists of 21 coefficients. We tested for the significance of this model's regression terms. For annotator A we found all coefficients to be significant with respect to the model ($p < 0.05$), for annotator B all coefficients except one were significant. Figure 6 shows the coefficients of annotator A's 'cognitive' model along with the standard errors and t-values.

5 Summary and Conclusions

In this paper, we explored the use of eye-tracking technology to investigate the behavior of human annotators during the assignment of three types of named entities – persons, organizations and locations – based on the eye-mind assumption. We tested two main hypotheses – one relating to the amount of contextual information being used for annotation decisions, the other relating to different degrees of syntactic and semantic complexity of expressions that had to be annotated. We found experimental evidence that the textual context is searched for decision making on assigning semantic meta-data at a surprisingly low rate (with

Table 6: 'Cognitive' model of annotator A.

the exception of tackling high-complexity semantic cases and resolving co-references) and that annotation performance correlates with semantic and syntactic complexity.

The results of these experiments were taken as a heuristic clue to focus on cognitively plausible features of learning empirically rooted cost models for annotation. We compared a simple cost model (basically taking the number of words and characters into account) with a cognitively grounded model and got a much higher fit for the cognitive model when we compared cost predictions of both model classes on the recently released time-stamped version of the MUC7 corpus.

We here want to stress the role of cognitive evidence from eye-tracking to determine *empirically relevant* features for the cost model. The alternative, more or less mechanical feature engineering, suffers from the shortcoming that is has to deal with large amounts of (mostly irrelevant) features – a procedure which not only requires increased amounts of training data but also is often computationally very expensive.

Instead, our approach introduces empirical, theory-driven relevance criteria into the feature selection process. Trying to relate observables of complex cognitive tasks (such as gaze duration and gaze movements for named entity annotation) to explanatory models (in our case, a time-based cost model for annotation) follows a much warranted avenue in research in NLP where feature farming becomes a theory-driven, explanatory process rather than a much deplored theory-blind engineering activity (cf. ACL-WS-2005 (2005)).

In this spirit, our focus has not been on fine-tuning this cognitive cost model to achieve even higher fits with the time data. Instead, we aimed at testing whether the findings from our eye-tracking study can be exploited to model annotation costs more accurately.

Still, future work will be required to optimize a cost model for eventual application where even more accurate cost models may be required. This optimization may include both exploration of additional features (such as domain-specific ones) as well as experimentation with other, presumably non-linear, regression models. Moreover, the impact of improved cost models on the efficiency of (cost-sensitive) selective sampling approaches, such as Active Learning (Tomanek and Hahn, 2009), should be studied.

A Rational Model of Eye Movement Control in Reading

Abstract

A number of results in the study of real-time sentence comprehension have been explained by computational models as resulting from the rational use of probabilistic linguistic information. Many times, these hypotheses have been tested in reading by linking predictions about relative word difficulty to word-aggregated eye tracking measures such as go-past time. In this paper, we extend these results by asking to what extent reading is well-modeled as rational behavior at a finer level of analysis, predicting not aggregate measures, but the duration and location of each fixation. We present a new rational model of eye movement control in reading, the central assumption of which is that eye movement decisions are made to obtain noisy visual information as the reader performs Bayesian inference on the identities of the words in the sentence. As a case study, we present two simulations demonstrating that the model gives a rational explanation for between-word regressions.

1 Introduction

The language processing tasks of reading, listening, and even speaking are remarkably difficult. Good performance at each one requires integrating a range of types of probabilistic information and making incremental predictions on the basis of noisy, incomplete input. Despite these requirements, empirical work has shown that humans perform very well (e.g., Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). Sophisticated models have been developed that explain many of these effects using the tools of computational linguistics and large-scale corpora to make normative predictions for optimal performance in these tasks (Genzel & Charniak, 2002, 2003; Keller, 2004; Levy & Jaeger, 2007; Jaeger, 2010). To the extent that the behavior of these models looks like human behavior, it suggests that humans are making rational use of all the information available to them in language processing. In the domain of incremental language comprehension, especially, there is a substantial amount of computational work suggesting that humans behave rationally (e.g., Jurafsky, 1996; Narayanan & Jurafsky, 2001; Levy, 2008; Levy, Reali, & Griffiths, 2009). Most of this work has taken as its task predicting the difficulty of each word in a sentence, a major result being that a large component of the difficulty of a word appears to be a function of its probability in context (Hale, 2001; Smith & Levy, 2008). Much of the empirical basis for this work comes from studying reading, where word difficulty can be related to the amount of time that a reader spends on a particular word. To relate these predictions about word difficulty to the data obtained in eye tracking experiments, the eye movement record has been summarized through word aggregate measures, such as the average duration of the first fixation on a word, or the amount of time between when a word is first fixated and when the eyes move to its right ('go-past time').

It is important to note that this notion of word difficulty is an abstraction over the actual task of reading, which is made up of more fine-grained decisions about how long to leave the eyes in their current position, and where to move them next, producing the series of relatively stable periods (fixations) and movements (saccades) that characterize the eye tracking record. While there has been much empirical work on reading at this fine-grained scale (see Rayner, 1998 for an overview), and there are a number of successful models (Reichle, Pollatsek, & Rayner, 2006; Engbert, Nuthmann, Richter, & Kliegl, 2005), little is known about the extent to which human reading behavior appears to be rational at this finer

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1168–1178,
Uppsala, Sweden, 11-16 July 2010.

grained scale. In this paper, we present a new rational model of eye movement control in reading, the central assumption of which is that eye movement decisions are made to obtain noisy visual information, which the reader uses in Bayesian inference about the form and structure of the sentence. As a case study, we show that this model gives a rational explanation for between-word regressions.

In Section 2, we briefly describe the leading models of eye movements in reading, and in Section 3, we describe how these models account for between-word regressions and the intuition behind our model's account of them. Section 4 describes the model and its implementation and Sections 5–6 describe two simulations we performed with the model comparing behavioral policies that make regressions to those that do not. In Simulation 1, we show that specific regressive policies outperform specific non-regressive policies, and in Simulation 2, we use optimization to directly find optimal policies for three performance measures. The results show that the regressive policies outperform non-regressive policies across a wide range of performance measures, demonstrating that our model predicts that making between-word regressions is a rational strategy for reading.

2 Models of eye movements in reading

The two most successful models of eye movements in reading are *E-Z* Reader (Reichle, Pollatsek, Fisher, & Rayner, 1998; Reichle et al., 2006) and SWIFT (Engbert, Longtin, & Kliegl, 2002; Engbert et al., 2005). Both of these models characterize the problem of reading as one of word identification. In *E-Z* Reader, for example, the system identifies each word in the sentence serially, moving attention to the next word in the sentence only after processing the current word is complete, and (to slightly oversimplify), the eyes then follow the attentional shifts at some lag. SWIFT works similarly, but with the main difference being that processing and attention are distributed over multiple words, such that adjacent words can be identified in parallel. While both of these models provide a good fit to eye tracking data from reading, neither model asks the higher level question of what a rational solution to the problem would look like.

The first model to ask this question, Mr. Chips (Legge, Klitz, & Tjan, 1997; Legge, Hooven, Klitz, Mansfield, & Tjan, 2002), predicts the optimal sequence of saccade targets to read a text based on a principle of minimizing the expected entropy in the distribution over identities of the current word. Unfortunately, however, the Mr. Chips model simplifies the problem of reading in a number of ways: First, it uses a unigram model as its language model, and thus fails to use any information in the linguistic context to help with word identification. Second, it only moves on to the next word after unambiguous identification of the current word, whereas there is experimental evidence that comprehenders maintain some uncertainty about the word identities. In other work, we have extended the Mr. Chips model to remove these two limitations, and show that the resulting model more closely matches human performance (Bicknell & Levy, 2010). The larger problem, however, is that each of these models uses an unrealistic model of visual input, which obtains absolute knowledge of the characters in its visual window. Thus, there is no reason for the model to spend longer on one fixation than another, and the model only makes predictions for *where* saccades are targeted, and not *how long* fixations last.

Reichle and Laurent (2006) presented a rational model that overcame the limitations of Mr. Chips to produce predictions for both fixation durations and locations, focusing on the ways in which eye movement behavior is an adaptive response to the particular constraints of the task of reading. Given this focus, Reichle and Laurent used a very simple word identification function, for which the time required to identify a word was a function only of its length and the relative position of the eyes. In this paper, we present another rational model of eye movement control in reading that, like Reichle and Laurent, makes predictions for fixation durations and locations, but which focuses instead on the dynamics of word identification at the core of the task of reading. Specifically, our model identifies the words in a sentence by performing Bayesian inference combining noisy input from a realistic visual model with a language model that takes context into account.

3 Explaining between-word regressions

In this paper, we use our model to provide a novel explanation for between-word regressive saccades. In reading, about 10–15% of saccades are regressive – movements from right-to-left (or to previous lines). To understand how models such as *E-Z* Reader or SWIFT account for re-

gressive saccades to previous words, recall that the system identifies words in the sentence (generally) left to right, and that identification of a word in these models takes a certain amount of time and then is completed. In such a setup, why should the eyes ever move backwards? Three major answers have been put forward. One possibility given by *E-Z* Reader is as a response to overshoot; i.e., the eyes move backwards to a previous word because they accidentally landed further forward than intended due to motor error. Such an explanation could only account for small between-word regressions, of about the magnitude of motor error. The most recent version, *E-Z* Reader 10 (Reichle, Warren, & McConnell, 2009), has a new component that can produce longer between-word regressions. Specifically, the model includes a flag for postlexical integration failure, that – when triggered – will instruct the model to produce a between-word regression to the site of the failure. That is, between-word regressions in *E-Z* Reader 10 can arise because of postlexical processes external to the model's main task of word identification. A final explanation for between-word regressions, which arises as a result of normal processes of word identification, comes from the SWIFT model. In the SWIFT model, the reader can fail to identify a word but move past it and continue reading. In these cases, there is a chance that the eyes will at some point move back to this unidentified word to identify it. From the present perspective, however, it is unclear how it could be rational to move past an unidentified word and decide to revisit it only much later.

Here, we suggest a new explanation for between-word regressions that arises as a result of word identification processes (unlike that of *E-Z* Reader) and can be understood as rational (unlike that of SWIFT). Whereas in SWIFT and *E-Z* Reader, word recognition is a process that takes some amount of time and is then 'completed', some experimental evidence suggests that word recognition may be best thought of as a process that is never 'completed', as comprehenders appear to both maintain uncertainty about the identity of previous input and to update that uncertainty as more information is gained about the rest of the sentence (Connine, Blasko, & Hall, 1991; Levy, Bicknell, Slattery, & Rayner, 2009). Thus, it is possible that later parts of a sentence can cause a reader's confidence in the identity of the previous regions to fall. In these cases, a rational way to respond might be to make a between-word regressive saccade to get more visual information about the (now) low confidence previous region.

To illustrate this idea, consider the case of a language composed of just two strings, *AB* and *BA*, and assume that the eyes can only get noisy information about the identity of one character at a time. After obtaining a little information about the identity of the first character, the reader may be reasonably confident that its identity is *A* and move on to obtaining visual input about the second character. If the first noisy input about the second character also indicates that it is probably *A*, then the normative probability that the first character is *A* (and thus a rational reader's confidence in its identity) will fall. This simple example just illustrates the point that if a reader is combining noisy visual information with a language model, then confidence in previous regions will sometimes fall.

There are two ways that a rational agent might deal with this problem. The first option would be to reach a higher level of confidence in the identity of each word before moving on to the right, i.e., slowing down reading left-to-right to prevent having to make right-to-left regressions. The second option is to read left-to-right relatively more quickly, and then make occasional right-to-left regressions in the cases where probability in previous regions falls. In this paper, we present two simulations suggesting that when using a rational model to read natural language, the best strategies for coping with the problem of confidence about previous regions dropping – for any tradeoff between speed and accuracy – involve making between-word regressions. In the next section, we present the details of our model of reading and its implementation, and then we present our two simulations in the sections following.

4 Reading as Bayesian inference

At its core, the framework we are proposing is one of reading as Bayesian inference. Specifically, the model begins reading with a prior distribution over possible identities of a sentence given by its language model. On the basis of that distribution, the model decides whether or not to move its eyes (and if so where to move them to) and obtains noisy visual input about the sentence at the eyes' position. That noisy visual input then gives the likelihood term in a Bayesian belief update, where the

model's prior distribution over the identity of the sentence given the language model is updated to a posterior distribution taking into account both the language model and the visual input obtained thus far. On the basis of that new distribution, the model again selects an action and the cycle repeats.

This framework is unique among models of eye movement control in reading (except Mr. Chips) in having a fully explicit model of how visual input is used to discriminate word identity. This approach stands in sharp contrast to other models, which treat the time course of word identification as an exogenous function of other influencing factors (such as word length, frequency, and predictability). The hope in our approach is that the influence of these key factors on the eye movement record will fall out as a natural consequence of rational behavior itself. For example, it is well known that the higher the conditional probability of a word given preceding material, the more rapidly that word is read (Boston, Hale, Kliegl, Patil, & Vasishth, 2008; Demberg & Keller, 2008; Ehrlich & Rayner, 1981; Smith & Levy, 2008). *E-Z* Reader and SWIFT incorporate this finding by specifying a dependency on word predictability in the exogenous function determining word processing time. In our framework, in contrast, we would expect such an effect to emerge as a byproduct of Bayesian inference: words with high prior probability (conditional on preceding fixations) will require less visual input to be reliably identified.

An implemented model in this framework must formalize a number of pieces of the reading problem, including the possible actions available to the reader and their consequences, the nature of visual input, a means of combining visual input with prior expectations about sentence form and structure, and a control policy determining how the model will choose actions on the basis of its posterior distribution over the identities of the sentence. In the remainder of this section, we present these details of the formalization of the reading problem we used for the simulations reported in this paper: actions (4.1), visual input (4.2), formalization of the Bayesian inference problem (4.3), control policy (4.4), and finally, implementation of the model using weighted finite state automata (4.5).

4.1 Formal problem of reading: Actions

For our model, we assume a series of discrete timesteps, and on each time step, the model first obtains visual input around the current location of the eyes, and then chooses between three actions: (a) continuing to fixate the currently fixated position, (b) initiating a saccade to a new position, or (c) stopping reading of the sentence. If on the *i*th timestep, the model chooses option (a), the timestep advances to $i+1$ and another sample of visual input is obtained around the current position. If the model chooses option (c), the reading immediately ends. If a saccade is initiated (b), there is a lag of two timesteps, roughly representing the time required to plan and execute a saccade, during which the model again obtains visual input around the current position and then the eyes move – with some motor error – toward the intended target t_i, landing on position ℓ_i. On the next time step, visual input is obtained around ℓ_i and another decision is made. The motor error for saccades follows the form of random error used by all major models of eye movements in reading: the landing position ℓ_i is normally distributed around the intended target t_i with standard deviation given by a linear function of the intended distance[1]

$$\ell_i \sim \mathcal{N}\left(t_i, (\delta_0 + \delta_1 |t_i - \ell_{i-1}|)^2\right) \qquad (1)$$

for some linear coefficients δ_0 and δ_1. In the experiments reported in this paper, we follow the SWIFT model in using $\delta_0 = 0.87, \delta_1 = 0.084$.

4.2 Noisy visual input

As stated earlier, the role of noisy visual input in our model is as the likelihood term in a Bayesian inference about sentence form and identity. Therefore, if we denote the input obtained thus far from a sentence as $\mathcal{I}$, all the information pertinent to the reader's inferences can be encapsulated in the form $p(\mathcal{I}|w)$ for possible sentences w. We assume that the inputs deriving from each character position are conditionally independent given sentence identity, so that if w_j denotes letter j of the sentence and $\mathcal{I}(j)$ denotes the component of visual input associated with that letter, then we can decompose $p(\mathcal{I}|w)$ as $\prod_j p(\mathcal{I}(j)|w_j)$. For simplicity, we assume that each character is either a lowercase letter or a space. The visual input obtained from an individual fixation can thus be summarized as a vector of likelihoods $p(\mathcal{I}(j)|w_j)$, as shown in

[1] In the terminology of the literature, the model has only random motor error (variance), not systematic error (bias). Following Engbert and Krügel (2010), systematic error may arise from Bayesian estimation of the best saccade distance.

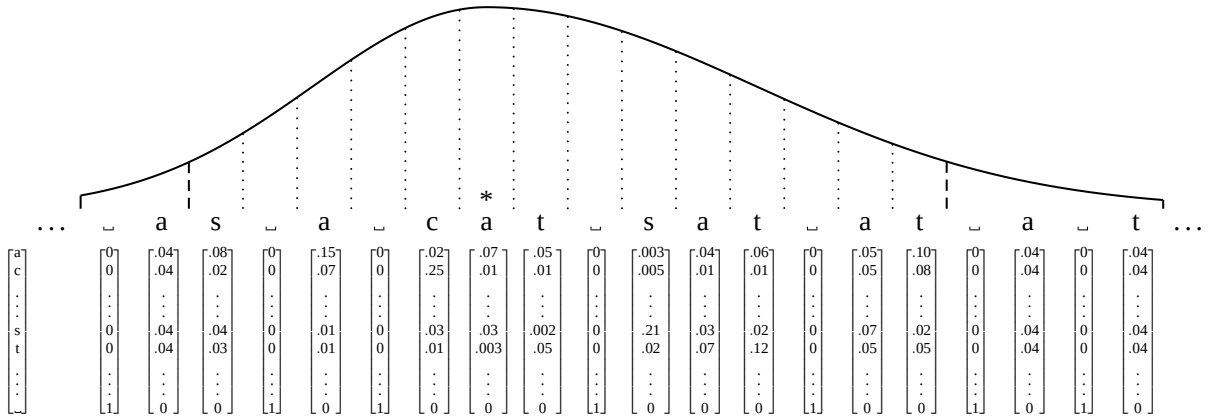

Figure 1: Peripheral and foveal visual input in the model. The asymmetric Gaussian curve indicates declining perceptual acuity centered around the fixation point (marked by $*$). The vector underneath each letter position denotes the likelihood $p(\mathcal{I}(j)|w_j)$ for each possible letter w_j, taken from a single input sample with $\Lambda = 1/\sqrt{3}$ (see vector at the left edge of the figure for key, and Section 4.2). In peripheral vision, the letter/whitespace distinction is veridical, but no information about letter identity is obtained. Note in this particular sample, input from the fixated character and the following one is rather inaccurate.

Figure 1. As in the real visual system, our visual acuity function decreases with retinal eccentricity; we follow the SWIFT model in assuming that the spatial distribution of visual processing rate follows an asymmetric Gaussian with $\sigma_L = 2.41, \sigma_R = 3.74$, which we discretize into processing rates for each character position. If ε denotes a character's eccentricity in characters from the center of fixation, then the proportion of the total processing rate at that eccentricity $\lambda(\varepsilon)$ is given by integrating the asymmetric Gaussian over a character width centered on that position,

$$\lambda(\varepsilon) = \int_{\varepsilon-.5}^{\varepsilon+.5} \frac{1}{Z} \exp\left(-\frac{x^2}{2\sigma^2}\right) dx, \sigma = \begin{cases} \sigma_L, & x < 0 \\ \sigma_R, & x \geq 0 \end{cases}$$

where the normalization constant Z is given by

$$Z = \sqrt{\frac{\pi}{2}}(\sigma_L + \sigma_R).$$

From this distribution, we derive two types of visual input, *peripheral* input giving word boundary information and *foveal* input giving information about letter identity.

4.2.1 Peripheral visual input

In our model, any eccentricity with a processing rate proportion $\lambda(\varepsilon)$ at least 0.5% of the rate proportion for the centrally fixated character ($\varepsilon \in [-7, 12]$), yields peripheral visual input, defined as veridical word boundary information indicating whether each character is a letter or a space. This roughly corresponds to empirical estimates that humans obtain useful information in reading from about 19 characters, more from the right of fixation than the left (Rayner, 1998). Hence in Figure 1, for example, left-peripheral visual input can be represented as veridical knowledge of the initial whitespace (denoted ␣), and a uniform distribution over the 26 letters of English for the letter `a`.

4.2.2 Foveal visual input

In addition, for those eccentricities with a processing rate proportion $\lambda(\varepsilon)$ that is at least 1% of the total processing rate ($\varepsilon \in [-5, 8]$) the model receives foveal visual input, defined only for letters[2] to give noisy information about the letter's identity. This threshold of 1% roughly corresponds to estimates that readers get information useful for letter identification from about 4 characters to the left and 8 to the right of fixation (Rayner, 1998).

In our model, each letter is equally confusable with all others, following Norris (2006, 2009), but ignoring work on letter confusability (which could be added to future model revisions; Engel, Dougherty, & Jones, 1973; Geyer, 1977). Visual information about each character is obtained by sampling. Specifically, we represent each letter as a 26-dimensional vector, where a single element is 1 and the other 25 are zeros, and given this representation, foveal input for a letter is given as a sample from a 26-dimensional Gaussian with a

[2] For white space, the model is already certain of the identity because of peripheral input.

mean equal to the letter's true identity and a diagonal covariance matrix $\Sigma(\varepsilon) = \lambda(\varepsilon)^{-1/2}I$. It is relatively straightforward to show that under these conditions, if we take the processing rate to be the expected change in log-odds of the true letter identity relative to any other that a single sample brings about, then the rate equals $\lambda(\varepsilon)$. We scale the overall processing rate by multiplying each rate by Λ. For the experiments in this paper, we set $\Lambda = 4$. For each fixation, we sample independently from the appropriate distribution for each character position and then compute the likelihood given each possible letter, as illustrated in the non-peripheral region of Figure 1.

4.3 Inference about sentence identity

Given the visual input and a language model, inferences about the identity of the sentence w can be made by standard Bayesian inference, where the prior is given by the language model and the likelihood is a function of the total visual input obtained from the first to the ith timestep $\mathcal{I}_1^i$,

$$p(w|\mathcal{I}_1^i) = \frac{p(w)p(\mathcal{I}_1^i|w)}{\sum_{w'}(w')p(\mathcal{I}_1^i|w')}. \quad (2)$$

If we let $\mathcal{I}(j)$ denote the input received about character position j and let w_j denote the jth character in sentence identity w, then the likelihood can be broken down by character position as

$$p(\mathcal{I}_1^i|w) = \prod_{j=1}^{n} p(\mathcal{I}_1^i(j)|w_j)$$

where n is the final character about which there is any visual input. Similarly, we can decompose this into the product of the likelihoods of each sample

$$p(\mathcal{I}_1^i|w) = \prod_{j=1}^{n}\prod_{t=1}^{i} p(\mathcal{I}_t(j)|w_j). \quad (3)$$

If the eccentricity of the jth character on the tth timestep ε_t^j is outside of foveal input or the character is a space, the inner term is 0 or 1. If the sample was from a letter in foveal input $\varepsilon_t^j \in [-5, 8]$, it is the probability of sampling $\mathcal{I}_t(j)$ from the multivariate Gaussian $\mathcal{N}(w_j, \Lambda\Sigma(\varepsilon_t^j))$.

4.4 Control policy

The model uses a simple policy to decide between actions based on the marginal probability m of the most likely character c in position j,

$$m(j) = \max_c p(w_n = c|\mathcal{I}_1^i) = \max_c \sum_{w':w'_n=c} p(w'|\mathcal{I}_1^i). \quad (4)$$

Intuitively, a high value of m means that the model is relatively confident about the character's identity, and a low value that it is relatively uncertain.

Given the values of this statistic, our model decides between four possible actions, as illustrated in Figure 2. If the value of this statistic for the current position of the eyes $m(\ell_i)$ is less than a parameter α, the model chooses to continue fixating the current position (2a). Otherwise, if the value of $m(j)$ is less than β for some leftward position $j < \ell_i$, the model initiates a saccade to the closest such position (2b). If $m(j) \geq \beta$ for all $j < \ell_i$, then the model initiates a saccade to n characters past the closest position to the right $j > \ell_i$ for which $m(j) < \alpha$ (2c).[3] Finally, if no such positions exist to the right, the model stops reading the sentence (2d). Intuitively, then, the model reads by making a rightward sweep to bring its confidence in each character up to α, but pauses to move left if confidence in a previous character falls below β.

(a) $m = [.6, .7, \mathbf{.6}, .4, .3, .6]$: Keep fixating (3)
(b) $m = [.6, .4, \mathbf{.9}, .4, .3, .6]$: Move back (to 2)
(c) $m = [.6, .7, \mathbf{.9}, .4, .3, .6]$: Move forward (to 6)
(d) $m = [.6, .7, \mathbf{.9}, .8, .7, .7]$: Stop reading

Figure 2: Values of m for a 6 character sentence under which a model fixating position 3 would take each of its four actions, if $\alpha = .7$ and $\beta = .5$.

4.5 Implementation with wFSAs

This model can be efficiently and simply implemented using weighted finite-state automata (wFSAs; Mohri, 1997) as follows: First, we begin with a wFSA representation of the language model, where each arc emits a single character (or is an epsilon-transition emitting nothing). To perform belief update given a new visual input, we create a new wFSA to represent the likelihood of each character from the sample. Specifically, this wFSA has only a single chain of states, where, e.g., the first and second state in the chain are connected by 27 (or fewer) arcs, which emit each of

[3] The role of n is to ensure that the model does not center its visual field on the first uncertain character. We did not attempt to optimize this parameter, but fixed n at 2.

the possible characters for w_1 along with their respective likelihoods given the visual input (as in the inner term of Equation 3). Next, these two wFSAs may simply be composed and then normalized, which completes the belief update, resulting in a new wFSA giving the posterior distribution over sentences. To calculate the statistic m, while it is possible to calculate it in closed form from such a wFSA relatively straightforwardly, for efficiency we use Monte Carlo estimation based on samples from the wFSA.

5 Simulation 1

With the description of our model in place, we next proceed to describe the first simulation in which we used the model to test the hypothesis that making regressions is a rational way to cope with confidence in previous regions falling. Because there is in general no single rational tradeoff between speed and accuracy, our hypothesis is that, for any given level of speed and accuracy achieved by a non-regressive policy, there is a faster and more accurate policy that makes a faster left-to-right pass but occasionally does make regressions. In the terms of our model's policy parameters α and β described above, non-regressive policies are exactly those with $\beta = 0$, and a policy that is faster on the left-to-right pass but does make regressions is one with a lower value of α but a non-zero β. Thus, we tested the performance of our model on the reading of a corpus of text typical of that used in reading experiments at a range of reasonable non-regressive policies, as well as a set of regressive policies with lower α and positive β. Our prediction is that the former set will be strictly dominated in terms of both speed and accuracy by the latter.

5.1 Methods

5.1.1 Policy parameters

We test 4 non-regressive policies (i.e., those with $\beta = 0$) with values of $\alpha \in \{.90, .95, .97, .99\}$, and in addition, test regressive policies with a lower range of $\alpha \in \{.85, .90, .95, .97\}$ and $\beta \in \{.4, .7\}$.[4]

5.1.2 Language model

Our reader's language model was an unsmoothed bigram model created using a vocabulary set consisting of the 500 most frequent words in the British National Corpus (BNC) as well as all the words in our test corpus. From this vocabulary, we constructed a bigram model using the counts from every bigram in the BNC for which both words were in vocabulary (about 222,000 bigrams).

5.1.3 wFSA implementation

We implemented our model with wFSAs using the OpenFST library (Allauzen, Riley, Schalkwyk, Skut, & Mohri, 2007). Specifically, we constructed the model's initial belief state (i.e., the distribution over sentences given by its language model) by directly translating the bigram model into a wFSA in the log semiring. We then composed this wFSA with a weighted finite-state transducer (wFST) breaking words down into characters. This was done in order to facilitate simple composition with the visual likelihood wFSA defined over characters. In the Monte Carlo estimation of m, we used 5000 samples from the wFSA. Finally, to speed performance, we bounded the wFSA to have exactly the number of characters present in the actual sentence and then renormalized.

5.1.4 Test corpus

We tested our model's performance by simulating reading of the Schilling corpus (Schilling, Rayner, & Chumbley, 1998). To ensure that our results did not depend on smoothing, we only tested the model on sentences in which every bigram occurred in the BNC. Unfortunately, only 8 of the 48 sentences in the corpus met this criterion. Thus, we made single-word changes to 25 more of the sentences (mostly changing proper names and rare nouns) to produce a total of 33 sentences to read, for which every bigram did occur in the BNC.

5.2 Results and discussion

For each policy we tested, we measured the average number of timesteps it took to read the sentences, as well as the average (natural) log probability of the correct sentence identity under the model's beliefs after reading ended 'Accuracy'. The results are plotted in Figure 3. As shown in the graph, for each non-regressive policy (the circles), there is a regressive policy that outperforms it, both in terms of average number of timesteps taken to read (further to the left) and the average log probability of the sentence identity (higher). Thus, for a range of policies, these results suggest

[4] We tested all combinations of these values of α and β except for $[\alpha, \beta] = [.97, .4]$, because we did not believe that a value of β so low in relation to α would be very different from a non-regressive policy.

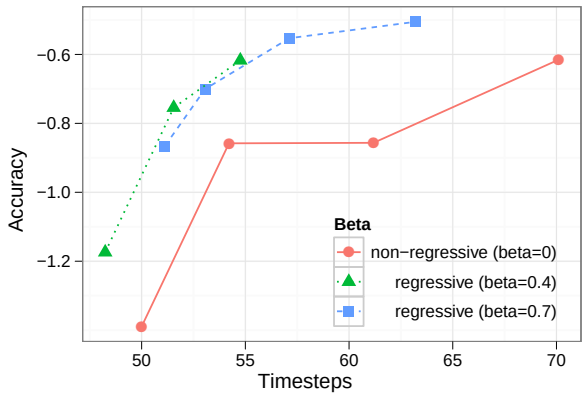

Figure 3: Mean number of timesteps taken to read a sentence and (natural) log probability of the true identity of the sentence 'Accuracy' for a range of values of α and β. Values of α are not labeled, but increase with the number of timesteps for a constant value of β. For each non-regressive policy ($\beta = 0$), there is a policy with a lower α and higher β that achieves better accuracy in less time.

that making regressions when confidence about previous regions falls is a rational reader strategy, in that it appears to lead to better performance, both in terms of speed and accuracy.

6 Simulation 2

In Simulation 2, we perform a more direct test of the idea that making regressions is a rational response to the problem of confidence falling about previous regions using optimization techniques. Specifically, we search for optimal policy parameter values (α, β) for three different measures of performance, each representing a different tradeoff between the importance of accuracy and speed.

6.1 Methods

6.1.1 Performance measures

We examine performance measures interpolating between speed and accuracy of the form

$$L(1-\gamma) - T\gamma \quad (5)$$

where L is the log probability of the true identity of the sentence under the model's beliefs at the end of reading, and T is the total number of timesteps before the model decided to stop reading. Thus, each different performance measure is determined by the weighting for time γ. We test three values of $\gamma \in \{.025, .1, .4\}$. The first of these weights accuracy highly, while the final one weights 1 timestep almost as much as 1 unit of log probability.

6.1.2 Optimization of policy parameters

Searching directly for optimal values of α and β for our stochastic reading model is difficult because each evaluation of the model with a particular set of parameters produces a different result. We use the PEGASUS method (Ng & Jordan, 2000) to transform this stochastic optimization problem into a deterministic one on which we can use standard optimization algorithms.[5] Then, we evaluate the model's performance at each value of α and β by reading the full test corpus and averaging performance. We then simply use coordinate ascent (in logit space) to find the optimal values of α and β for each performance measure.

6.1.3 Language model

The language model used in this simulation begins with the same vocabulary set as in Sim. 1, i.e., the 500 most frequent words in the BNC and every word that occurs in our test corpus. Because the search algorithm demands that we evaluate the performance of our model at a number of parameter values, however, it is too slow to optimize α and β using the full language model that we used for Sim. 1. Instead, we begin with the same set of bigrams used in Sim. 1 – i.e., those that contain two in-vocabulary words – and trim this set by removing rare bigrams that occur less than 200 times in the BNC (except that we do not trim any bigrams that occur in our test corpus). This reduces our set of bigrams to about 19,000.

6.1.4 wFSA implementation

The implementation was the same as in Sim. 1.

6.1.5 Test corpus

The test corpus was the same as in Sim. 1.

6.2 Results and discussion

The optimal values of α and β for each $\gamma \in \{.025, .1, .4\}$ are given in Table 1 along with the mean values for L and T found at those parameter values. As the table shows, the optimization procedure successfully found values of α and β, which go up (slower reading) as γ goes down (valuing accuracy more than time). In addition, we see that the average results of reading at these parameter values are also as we would expect, with T and L going up as γ goes down. As predicted, the optimal

[5] Specifically, this involves fixing the random number generator for each run to produce the same values, resulting in minimizing the variance in performance across evaluations.

γ	α	β	Timesteps	Log probability
.025	.90	.99	41.2	-0.02
.1	.36	.80	25.8	-0.90
.4	.18	.38	16.4	-4.59

Table 1: Optimal values of α and β found for each performance measure γ tested and mean performance at those values, measured in timesteps T and (natural) log probability L.

values of β found are non-zero across the range of policies, which include policies that value speed over accuracy much more than in Sim. 1. This provides more evidence that whatever the particular performance measure used, policies making regressive saccades when confidence in previous regions falls perform better than those that do not.

There is one interesting difference between the results of this simulation and those of Sim. 1, which is that here, the optimal policies all have a value of $\beta > \alpha$. That may at first seem surprising, since the model's policy is to fixate a region until its confidence becomes greater than α and then return if it falls below β. It would seem, then, that the only reasonable values of β are those that are strictly below α. In fact, this is not the case because of the two time step delay between the decision to move the eyes and the execution of that saccade. Because of this delay, the model's confidence when it leaves a region (relevant to β) will generally be higher than when it decided to leave (determined by α). In Simulation 2, because of the smaller grammar that was used, the model's confidence in a region's identity rises more quickly and this difference is exaggerated.

7 Conclusion

In this paper, we presented a model that performs Bayesian inference on the identity of a sentence, combining a language model with noisy information about letter identities from a realistic visual input model. On the basis of these inferences, it uses a simple policy to determine how long to continue fixating the current position and where to fixate next, on the basis of information about where the model is uncertain about the sentence's identity. As such, it constitutes a rational model of eye movement control in reading, extending the insights from previous results about rationality in language comprehension.

The results of two simulations using this model support a novel explanation for between-word regressive saccades in reading: that they are used to gather visual input about previous regions when confidence about them falls. Simulation 1 showed that a range of policies making regressions in these cases outperforms a range of non-regressive policies. In Simulation 2, we directly searched for optimal values for the policy parameters for three different performance measures, representing different speed-accuracy trade-offs, and found that the optimal policies in each case make substantial use of between-word regressions when confidence in previous regions falls. In addition to supporting a novel motivation for between-word regressions, these simulations demonstrate the possibility for testing a range of questions that were impossible with previous models of reading related to the goals of a reader, such as how should reading behavior change as accuracy is valued more.

There are a number of obvious ways for the model to move forward. One natural next step is to make the model more realistic by using letter confusability matrices. In addition, the link to previous work in sentence processing can be made tighter by incorporating syntax-based language models. It also remains to compare this model's predictions to human data more broadly on standard benchmark measures for models of reading. The most important future development, however, will be moving toward richer policy families, which enable more intelligent decisions about eye movement control, based not just on simple confidence statistics calculated independently for each character position, but rather which utilize the rich structure of the model's posterior beliefs about the sentence identity (and of language itself) to make more informed decisions about the best time to move the eyes and the best location to direct them next.

The Influence of Discourse on Syntax
A Psycholinguistic Model of Sentence Processing

Amit Dubey

Abstract

Probabilistic models of sentence comprehension are increasingly relevant to questions concerning human language processing. However, such models are often limited to syntactic factors. This paper introduces a novel sentence processing model that consists of a parser augmented with a probabilistic logic-based model of coreference resolution, which allows us to simulate how context interacts with syntax in a reading task. Our simulations show that a Weakly Interactive cognitive architecture can explain data which had been provided as evidence for the Strongly Interactive hypothesis.

1 Introduction

Probabilistic grammars have been found to be useful for investigating the architecture of the human sentence processing mechanism (Jurafsky, 1996; Crocker and Brants, 2000; Hale, 2003; Boston et al., 2008; Levy, 2008; Demberg and Keller, 2009). For example, probabilistic models shed light on so-called locality effects: contrast the non-probabilistic hypothesis that dependants which are far away from their head *always* cause processing difficulty for readers due to the cost of storing the intervening material in memory (Gibson, 1998), compared to the probabilistic prediction that there are cases when faraway dependants facilitate processing, because readers have more time to predict the head (Levy, 2008). Using a computational model to address fundamental questions about sentence comprehension motivates the work in this paper.

So far, probabilistic models of sentence processing have been largely limited to syntactic factors. This is unfortunate because many outstanding questions in psycholinguistics concern interactions between different levels of processing. This paper addresses this gap by building a computational model which simulates the influence of discourse on syntax.

Going beyond the confines of syntax alone is a sufficiently important problem that it has attracted attention from other authors. In the literature on probabilistic modeling, though, the bulk of this work is focused on lexical semantics (e.g. Padó et al., 2006; Narayanan and Jurafsky, 1998) or only considers syntactic decisions in the preceeding text (e.g. Dubey et al., 2009; Levy and Jaeger, 2007). This is the first model we know of which introduces a broad-coverage sentence processing model which takes the effect of coreference and discourse into account.

A major question concerning discourse-syntax interactions involves the strength of communication between discourse and syntactic information. The **Weakly Interactive** (Altmann and Steedman, 1988) hypothesis states that a discourse context can reactively prune syntactic choices that have been proposed by the parser, whereas the **Strongly Interactive** hypothesis posits that context can proactively suggest choices to the syntactic processor.

Support for Weak Interaction comes from experiments in which there are temporary ambiguities, or *garden paths*, which cause processing difficulty. The general finding is that supportive contexts can reduce the effect of the garden path. However, Grodner et al. (2005) found that supportive contexts even facilitate the processing of *unambiguous* sentences. As there are no incorrect analyses to prune in unambiguous structures, the authors claimed their results were not consistent with the Weakly Interactive hypothesis, and suggested that their results were best explained by a Strongly Interactive processor.

The model we present here implements the Weakly Interactive hypothesis, but we will show that it can nonetheless successfully simulate the results of Grodner et al. (2005). There are three main parts of the model: a syntactic processor, a coreference resolution system, and a simple pragmatics processor which computes certain limited forms of discourse coherence. Following Hale (2001) and Levy (2008), among others, the syntactic processor uses an incremental probabilistic Earley parser to compute a metric which correlates with increased reading difficulty. The coreference resolution system is implemented

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1179–1188,
Uppsala, Sweden, 11-16 July 2010.

in a *probabilistic logic* known as Markov Logic (Richardson and Domingos, 2006). Finally, the pragmatics processing system contains a small set of probabilistic constraints which convey some intuitive facts about discourse processing. The three components form a pipeline, where each part is probabilistically dependent on the previous one. This allows us to combine all three into a single probability for each reading of an input sentence.

The rest of the paper is structured as follows. In Section 2, we discuss the details two experiments showing support of the Weakly and Strongly Interactive hypotheses: we discuss Grodner et al.'s result on unambiguous syntactic structures and we present a new experiment on involving a garden path which was designed to be similar to the Grodner et al. experiment. Section 3 introduces technical details of model, and Section 4 shows the predictions of the model on the experiments discussed in Section 2. Finally, we discuss the theoretical consequences of these predictions in Section 5.

2 Cognitive Experiments

2.1 Discourse and Ambiguity Resolution

There is a fairly large literature on garden path experiments involving context (Crain and Steedman, 1985; Mitchell et al., 1992, ibid). The experiments by Altmann and Steedman (1988) involved PP attachment ambiguity. Other authors (e.g. Spivey and Tanenhaus, 1998) have used reduced relative clause attachment ambiguity. In order to be more consistent with the design of the experiment in Section 2.2, however, we performed our own reading-time experiment which partially replicated previous results.[1]

The experimental items all had a target sentence containing a relative clause, and one of two possible context sentences, one of which supports the relative clause reading and the other which does not.

The context sentence was one of:

(1) a. There were two postmen, one of whom was injured and carried by paramedics, and another who was unhurt.
b. Although there was a medical emergency at the post office earlier today, regular mail delivery was unaffected.

[1]This experiment was previously reported by Dubey et al. (2010).

The target sentences, which were drawn from the experiment of McRae et al. (1998), were either the reduced or unreduced sentences similar to:

(2) The postman *who was* carried by the paramedics was having trouble breathing.

The reduced version of the sentence is produced by removing the words *who was*. We measured reading times in the underlined region, which is the first point at which there is evidence for the relative clause interpretation. The key evidence is given by the word 'by', but the previous word is included as readers often do not fixate on short function words, but rather process them while overtly fixating on the previous word (Rayner, 1998).

The relative clauses in the target sentence act as *restrictive* relative clauses, selecting one referent from a larger set. The target sentences are therefore more coherent in a context where a restricted set and a contrast set are easily available, than one in which these sets are absent. This makes the context in Example (1-a) supportive of a reduced relative reading, and the context in Example (1-b) unsupportive of a reduced relative clause. Other experiments, for instance Spivey and Tanenhaus (1998), used an unsupportive context where only one postman was mentioned. Our experiments used a neutral context, where no postmen are mentioned, to be more similar to the Grodner et al. experiment, as described below.

Overall, there were 28 items, and 28 participants read these sentences using an EyeLink II eyetracker. Each participant read items one at a time, with fillers between subsequent items so as to obfuscate the nature of the experiment.

Results An ANOVA revealed that all conditions with a supportive context were read faster than one with a neutral context (i.e. a main effect of context), and all conditions with unambiguous syntax were read faster than those with a garden path (i.e. a main effect of ambiguity). Finally, there was a statisically significant interaction between syntax and discourse whereby context decreases reading times much more when a garden path is present compared to an unambiguous structure. In other words, a supportive context helped reduce the effect of a garden path. This is the prediction made by both the Weakly Interactive and Strongly Interactive hypothesis. The pattern of results are shown in Figure 2a in Section 4, where they are directly compared to the model results.

2.2 Discourse and Unambiguous Syntax

As mentioned in the Introduction, Grodner et al. (2005) proposed an experiment with a supportive or unsupportive discourse followed by an unambiguous target sentence. In their experiment, the target sentence was one of the following:

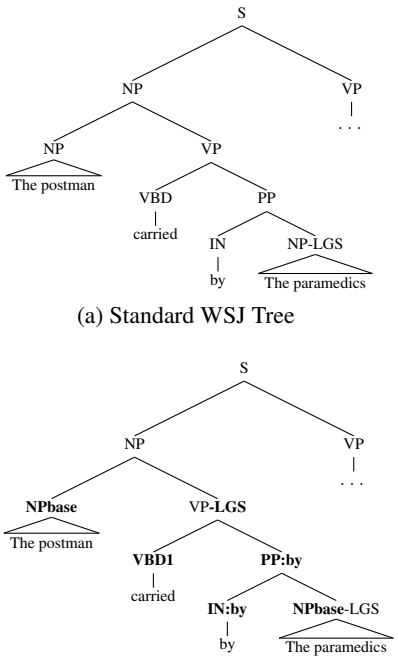
(3) a. The director that the critics praised at a banquet announced that he was retiring to make room for young talent in the industry.
b. The director, who the critics praised at a banquet, announced that he was retiring to make room for young talent in the industry.

They also manipulated the context, which was either supportive of the target, or a null context. The two supportive contexts are:

(4) a. A group of film critics praised a director at a banquet and another director at a film premiere.
b. A group of film critics praised a director and a producer for lifetime achievement.

The target sentence in (3-a) is a restrictive relative clause, as in the garden path experiments. However, the sentence in (3-b) is a non-restrictive relative clause, which does not assume the presence of a constrast set. Therefore, the context (4-a) is only used with the restrictive relative clause, and the context (4-b), where only one director is mentioned, is used as the context for the non-restrictive relative clause. In the conditions with a null context, the target sentence was not preceded by any contextual sentence.

Results Grodner et al. measured residual reading times, i.e. reading times compared to a baseline in the embedded subject NP ('the critics'). They found that the supportive contexts decreased reading time, and that this effect was stronger for restrictive relatives compared to non-restricted relatives. As there was no garden path, and hence no incorrect structure for the discourse processor to prune, the authors conclude that this must be evidence for the Strongly Interactive hypothesis. Unlike the garden path experiment above, these results do not appear to be consistent with a Weakly Interactive model. We plot their results in Figure 3a in Section 4, where they are directly compared to the model results. Because these results are computed as regressions against a baseline, a reading time of 0ms indicates average difficulty, with negative numbers showing some facilitation has occured, and positive number indicating reading difficulty.



(a) Standard WSJ Tree

(b) Minimally Modified Tree

Figure 1: A schematic representation of the smallest set of grammar transformations which we found were required to accurately parse the experimental items.

3 Model

The model comprises three parts: a parser, a coreference resolution system, and a pragmatics subsystem. Let us look at each individually.

3.1 Parser

The parser is an incremental unlexicalized probabilistic Earley parser, which is capable of computing prefix probabilities. A PCFG parser outputs the generative probability $P_{parser}(w, t)$, where w is the text and t is a parse tree. A probabilistic Earley parser can retrieve all possible derivations at word i (Stolcke, 1995), allowing us to compute the probability $P(w_i \dots w_0) = \sum_t P_{parser}(w_i \dots w_0, t)$.

Using the prefix probability, we can compute the word-by-word Surprisal (Hale, 2001), by taking the log ratio of the previous word's prefix probability against this word's prefix probability:

$$\log \left(\frac{P(w_{i-1} \dots w_0)}{P(w_i \dots w_0)} \right) \quad (1)$$

Higher Surprisal scores are interpreted as

being correlated with more reading difficulty, and likewise lower scores with greater reading ease. For most of the remainder of the paper we will simply refer to the prefix probability at word i as $P(w)$. While the prefix probability as presented here is suitable for syntax-based computations, a main technical contribution of our model, detailed in Sections 3.2 and 3.3 below, is that we include non-syntactic probabilities in the computation of Surprisal.

As per Hale's original suggestion, our parser can compute Surprisal using an exhaustive search, which entails summing over each licensed derivation. This can be done efficiently using the packed representation of an Earley chart. However, as the coreference processor takes trees as input, we must therefore unpack parses before resolving referential ambiguity. Given the ambiguity of our grammar, this is not tractable. Therefore, we only consider an n-best list when computing Surprisal. As other authors have found that a relatively small set of analyses can give meaningful predictions (Brants and Crocker, 2000; Boston et al., 2008), we set $n = 10$.

The parser is trained on the Wall Street Journal (WSJ) section of the Penn treebank. Unfortunately, the standard WSJ grammar is not able to give correct incremental parses to our experimental items. We found we could resolve this problem by using four simple transformations, which are shown in Figure 1: (i) adding valency information to verb POS tags (e.g. VBD1 represents a transitive verb); (ii) we lexicalize 'by' prepositions; (iii) VPs containing a logical subject (i.e. the agent), get the -LGS label; (iv) non-recursive NPs are renamed NPbase (the coreference system treats each NPbase as a markable).

3.2 Discourse Processor

The primary function of the discourse processing module is to perform coreference resolution for each mention in an incrementally processed text. Because each mention in a coreference chains is transitive, we cannot use a simple classifier, as they cannot enforce global transitivity constraints. Therefore, this system is implemented in Markov Logic (Richardson and Domingos, 2006), a probabilistic logic, which does allow us to include such constraints.

Markov Logic attempts to combine logic with probabilities by using a Markov random field where logical formulas are features. The Markov Logic Network (MLN) we used for our system uses similar predicates as the MLN-based coreference resolution system of Huang et al. (2009).[2] Our MLN uses the predicates listed in Table 1. Two of these predicates, $Coref$ and $First$, are the output of the MLN – they provide a labelling of coreference mentions into entity classes. Note that, unlike Huang et al., we assume an ordering on x and y if $Coref(x, y)$ is true: y must occur earlier in the document than x. The remaining predicates in Table 1 are a subset of features used by other coreference resolution systems (cf. Soon et al., 2001). The predicates we use involve matching strings (checking if two mentions share a head word or if they are exactly the same string), matching argreement features (if the gender, number or person of pairs of NPs are the same; especially important for pronouns), the distance between mentions, and if mentions have the same entity type (i.e. do they refer to a person, organization, etc.) As our main focus is not to produce a state-of-the-art coreference system, we do not include predicates which are irrevelant for our simulations even if they have been shown to be effective for coreference resolution. For example, we do not have predicates if two mentions are in an apposition relationship, or if two mentions are synonyms for each other.

Expression	Meaning
$Coref(x, y)$	x is coreferent with y.
$First(x)$	x is a first mention.
$Order(x, y)$	x occurs before y.
$SameHead(x, y)$	Do x and y share the same syntactic head?
$ExactMatch(x, y)$	x and y are same string.
$SameNumber(x, y)$	x and y match in number.
$SameGender(x, y)$	x and y match in gender.
$SamePerson(x, y)$	x and y match in person.
$Distance(x, y, d)$	The distance between x and y, in sentences.
$Pronoun(x)$	x is a pronoun.
$EntityType(x, e)$	x has entity type e (person, organization, etc.)

Table 1: Predicates used in the Markov Logic Network

Table 2 lists the actual logical formulae which are used as features in the MLN. It should be

[2] As we are not interested in unsupervised inference, the system of Poon and Domingos (2008) was unsuitable for our needs.

Description	Rule
Transitivity	$Coref(x,z) \wedge Coref(y,z) \wedge Order(x,y) \Rightarrow Coref(x,y)$
	$Coref(x,y) \wedge Coref(y,z) \Rightarrow Coref(x,z)$
	$Coref(x,y) \wedge Coref(x,z) \wedge Order(y,z) \Rightarrow Coref(y,z)$
First Mentions	$Coref(x,y) \Rightarrow \neg First(x)$
	$First(x) \Rightarrow \neg Coref(x,y)$
String Match	$ExactMatch(x,y) \Rightarrow Coref(x,y)$
	$SameHead(x,y) \Rightarrow Coref(x,y)$
Pronoun	$Pronoun(x) \wedge Pronoun(y) \wedge SameGender(x,y) \Rightarrow Coref(x,y)$
	$Pronoun(x) \wedge Pronoun(y) \wedge SameNumber(x,y) \Rightarrow Coref(x,y)$
	$Pronoun(x) \wedge Pronoun(y) \wedge SamePerson(x,y) \Rightarrow Coref(x,y)$
Other	$EntityType(x,e) \wedge EntityType(y,e) \Rightarrow Coref(x,y)$
	$Distance(x,y,+d) \Rightarrow Coref(x,y)$

Table 2: Rules used in the Markov Logic Network

noted that, because we are assuming an order on the arguments of $Coref(x,y)$, we need three formulae to capture transivity relationships. To test that the coreference resolution system was producing meaningful results, we evaluated our system on the test section of the ACE-2 dataset. Using b^3 scoring (Bagga and Baldwin, 1998), which computes the overlap of a proposed set with the gold set, the system achieves an F-score of 65.4%. While our results are not state-of-the-art, they are reasonable considering the brevity of our feature list.

The discourse model is run iteratively at each word. This allows us to find a globally best assignment at each word, which can be reanalyzed at a later point in time. It assumes there is a mention for each base NP outputted by the parser, and for all ordered pairs of mentions x, y, it outputs all the 'observed' predicates (i.e. everything but $First$ and $Coref$), and feeds them to the Markov Logic system. At each step, we compute both the maximum a posteriori (MAP) assignment of coreference relationships as well as the probability that each individual coreference assignment is true. Taken together, they allow us to calculate, for a coreference assignment c, $P_{coref}(c|w,t)$ where w is the text input (of the entire document until this point), and t is the parse of each tree in the document up to and including the current incremental parse. As we have previously calculated $P_{parser}(w,t)$, it is then possible to compute the joint probability $P(c,w,t)$ at each word, and therefore the prefix probability $P(w)$ due to syntax and coreference. Overall, we have:

$$\begin{aligned} P(w) &= \sum_c \sum_t P(c,w,t) \\ &= \sum_c \sum_t P_{coref}(c|w,t) P_{parser}(w,t) \end{aligned}$$

Note that we only consider *one* possible assignment of NPs to coreference entities per parse, as we only retrieve the probabilities of the MAP solution.

3.3 Pragmatics Processor

The effect of context in the experiments described in Section 2 cannot be fully explained using a coreference resolution system alone. In the case of restrictive relative clauses, the referential 'mismatch' in the unsupported conditions is caused by an expectation elicited by a restrictive relative clause which is inconsistent with the previous discourse when there is no salient restricted subset of a larger set. When the larger set is not found in the discourse, the relative clause becomes incoherent given the context, causing reading difficulty. Modeling this coherence constraint is essentially a pragmatics problem, and is under the purview of the pragmatics processor in our system. The pragmatics processor is quite specialised and, although the information it encapsulates is quite intuitive, it nonetheless relies on hand-coded expert knowledge.

The pragmatics processor takes as input an incremental pragmatics configuration p and computes the probability $P_{prag}(p|w,t,c)$. The pragmatics configuration we consider is quite simple. It is a 3-tuple where one element is true if the current noun phrase being processed is a discourse new definite noun phrase, the second

element is true if the current NP is a discourse new indefinite noun phrase, and the final element is true if we encounter an unsupported restrictive relative clause. We simply conjecture that there is little processing cost (and hence a high probability) if the entire vector is false; there is a small processing cost for discourse new indefinites, a slightly larger processing cost for discourse new definites and a large processing cost for an incoherent reduced relative clause.

The first two elements of the 3-tuple depend on the identity of the determiner as recovered by the parser, and on whether the coreference system adduces the predicate $First$ for the current NP. As the coreference system wasn't designed to find anaphoric contrast sets, these sets were found using a simple post-processing check. This post-processing approach worked well for our experimental items, but finding such sets is, in general, quite a difficult problem (Modjeska et al., 2003).

The distribution $P_{prag}(p|w,t,c)$ applies a processing penalty for an unsupported restrictive relative clause whenever a restrictive relative clause is in the n best list. Because Surprisal computes a ratio of probabilities, this in effect means we only pay this penality when an unsupported restrictive relative clause first appears in the n best list (otherwise the effect is cancelled out). The penalty for discourse new entities is applied on the first word (ignoring punctuation) following the end of the NP. This spillover processing effect is simply a matter of modeling convenience: without it, we would have to compute Surprisal probabilities over regions rather than individual words. Thus, the overall prefix probability can be computed as: $P(w) = \sum_{p,c,t} P_{prag}(p|w,t,c)P_{coref}(c|w,t)P_{parser}(w,t)$, which is then substituted in Equation (1) to get a Surprisal prediction for the current word.

4 Evaluation

4.1 Method

When modeling the garden path experiment we presented in Section 2.1, we compute Surprisal values on the word 'by', which is the earliest point at which there is evidence for a relative clause interpretation. For the Grodner et al. experiment, we compute Surprisal values on the relativiser 'who' or 'that'. Again, this is the earliest point at which there is evidence for a relative clause, and depending upon the presence or absence of a preceding comma, it will be known to be restrictive or nonrestrictive clause. In addition to the overall Surprisal values, we also compute syntactic Surprisal scores, to test if there is any benefit from the discourse and pragmatics subsystems. As we are outputting n best lists for each parse, it is also straightforward to compute other measures which predict reading difficulty, including pruning (Jurafsky, 1996), whereby processing difficulty is predicted when a parse is removed from the n best list, and attention shift (Crocker and Brants, 2000), which predicts parsing difficulty at words where the most highly ranked parse flips from one interpretation to another.

For the garden path experiment, the simulation was run on each of the 28 experimental items in each of the 4 conditions, resulting in a total of 112 runs. For the Grodner et al. experiment, the simulation was run on each of the 20 items in each of the 4 conditions, resulting in a total of 80 runs. For each run, the model was reset, purging all discourse information gained while reading earlier items. As the system is not stochastic, two runs using the exact same items in the same condition will produce the same result. Therefore, we made no attempt to model by-subject variability, but we did perform by-item ANOVAs on the system output.

4.2 Results

Garden Path Experiment The simulated results of our experiment are shown in Figure 2. Comparing the full simulated results in Figure 2b to the experimental results in Figure 2a, we find that the simulation, like the actual experiment, finds both main effects and an interaction: there is a main effect of context whereby a supportive context facilitates reading, a main effect of syntax whereby the garden path slows down reading, and an interaction in that the effect of context is strongest in the garden path condition. All these effects were highly significant at $p < 0.01$. The pattern of results between the full simulation and the experiment differed in two ways. First, the simulated results suggested a much larger reading difficulty due to ambiguity than the experimental results. Also, in the unambiguous case, the model predicted a null cost of an unsupportive context on the word 'by', because the model bears the cost of an unsupportive context earlier in the sentence, and assumes no spillover to the word 'by'. Finally, we note that the syntax-only simulation, shown in Figure 2c, only produced a main effect of ambigu-

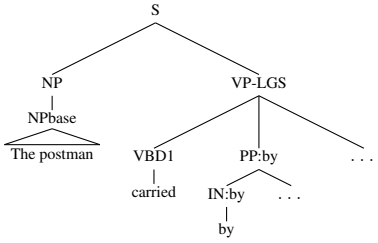
ity, and was not able to model the effect of context.

Grodner et al. Experiment The simulated results of the Grodner et al. experiment are shown in Figure 3. In this experiment, the pattern of simulated results in Figure 3b showed a much closer resemblance to the experimental results in Figure 3a than the garden path experiment. There is a main effect of context, which is much stronger in the restrictive relative case compared to non-restrictive relatives. As with the garden path experiment, the ANOVA reported that all effects were significant at the $p < 0.01$ level. Again, as we can see from Figure 3c, there was no effect of context in the syntax-only simulation. The numerical trend did show a slight facilitation in the unrestricted supported condition, with a Surprisal of 4.39 compared to 4.41 in the supported case, but this difference was not significant.

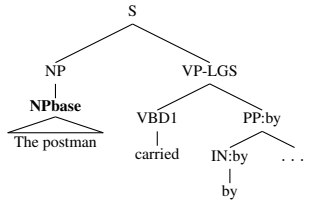
4.3 Discussion

We have shown that our incremental sentence processor augmented with discourse processing can successfully simulate syntax-discourse interaction effects which have been shown in the literature. The difference between a Weakly Interactive and Strongly Interactive model can be thought of computationally in terms of a pipeline architecture versus joint inference. In a weaker sense, even a pipeline architecture where the discourse can influence syntactic probabilities could be claimed to be a Strongly Interactive model. However, as our model uses a pipeline where syntactic probabilities are independent of the discourse, we claim that our model is Weakly Interactive. Unlike Altmann and Steedman, who posited that the discourse processor actually removes parsing hypotheses, we were able to simulate this pruning behaviour by simply re-weighting parses in our coreference and pragmatics modules.

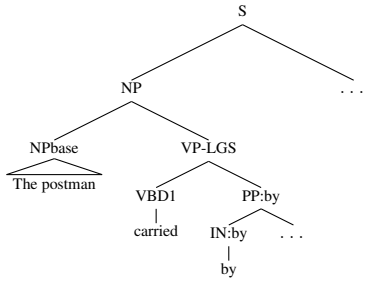
The fact that a Weakly Interactive system can simulate the result of an experiment proposed in support of the Strongly Interactive hypothesis is initially counter-intuitive. However, this naturally falls out from our decision to use a probabilistic



(a) Best parse: $p = 9.99 \times 10^{-10}$ main clause, expecting more dependents



(b) 2^{nd} parse: $p = 9.93 \times 10^{-10}$ main clause, no more dependents



(c) 3^{rd} parse: $p = 7.69\times^{-10}$ relative clause

Figure 4: The top three parses on the word 'by' in the our first experimental item.

model: a lower probability, even in an unambiguous structure, is associated with increased reading difficulty. As an aside, we note that when using realistic computational grammars, even the structures used in the Grodner et al. experiment are not unambiguous. In the restrictive relative clause condition, even though there was not any competition between a relative and main clause reading, our n best list was at all times filled with analyses. For example, on the word 'who' in the restricted relative clause condition, the parser is already predicting both the subject-relative ('the postman who was bit by the dog') and object-relative ('the postman who the dog bit') readings.

Overall, these results are supportive of the growing importance of probabilistic reasoning as a model of human cognitive behaviour. Therefore, especially with respect to sentence processing, it is necessary to have a proper understanding of how probabilities are linked to real-world behaviours. We note that Surprisal does indeed show processing difficulty on the word 'by' in the garden path experiment. However, Figure 4 (which shows the top three parses on the word 'by') indicates that not only are there still main clause interpretations present, but in fact, the top two parses are main clause interpretations. This is also true if we limit ourselves to syntactic probabilities (which are the probabilities listed in Figure 4). This suggests that neither Jurafsky (1996)'s notion of pruning as processing difficulty nor Crocker and Brants (2000) notion of attention shifts would correctly predict higher reading times on a region containing the word 'by'. In fact, the main clause interpretation remains the highest-ranked interpretation until it is finally pruned at an auxiliary of the main verb of the sentence ('The postman carried by the paramedics was *having*').

This result is curious as our experimental items closely match some of those simulated by Crocker and Brants (2000). We conjecture that the difference between our attention shift prediction and theirs is due to differences in the grammar. It is possible that using a more highly tuned grammar would result in attention shift making the correct prediction, but this possibly shows one benefit of using Surprisal as a linking hypothesis. Because Surprisal sums over several derivations, it is not as reliant upon the grammar as the attention shift or pruning linking hypotheses.

5 Conclusions

The main result of this paper is that it is possible to produce a Surprisal-based sentence processing model which can simulate the influence of discourse on syntax in both garden path and unambiguous sentences. Computationally, the inclusion of Markov Logic allowed the discourse module to compute well-formed coreference chains, and opens two avenues of future research. First, it ought to be possible to make the probabilistic logic more naturally incremental, rather than re-running from scratch at each word. Second, we would like to make greater use of the logical elements by applying it to problems where inference is necessary, such as resolving bridging anaphora (Haviland and Clark, 1974).

Our primary cognitive finding that our model, which assumes the Weakly Interactive hypothesis (whereby discourse is influenced by syntax in a reactive manner), is nonetheless able to simulate the experimental results of Grodner et al. (2005), which were claimed by the authors to be in

support of the Strongly Interactive hypothesis. This suggests that the evidence is in favour of the Strongly Interactive hypothesis may be weaker than thought.

Finally, we found that the attention shift (Crocker and Brants, 2000) and pruning (Jurafsky, 1996) linking theories are unable to correctly simulate the results of the garden path experiment. Although our main results above underscore the usefulness of probabilistic modeling, this observation emphasizes the importance of finding a tenable link between probabilities and behaviours.

Abstract

Hierarchical HMM (HHMM) parsers make promising cognitive models: while they use a bounded model of working memory and pursue incremental hypotheses in parallel, they still achieve parsing accuracies competitive with chart-based techniques. This paper aims to validate that a right-corner HHMM parser is also able to produce *complexity metrics*, which quantify a reader's incremental difficulty in understanding a sentence. Besides defining standard metrics in the HHMM framework, a new metric, *embedding difference*, is also proposed, which tests the hypothesis that HHMM store elements represents syntactic working memory. Results show that HHMM surprisal outperforms all other evaluated metrics in predicting reading times, and that embedding difference makes a significant, independent contribution.

1 Introduction

Since the introduction of a parser-based calculation for surprisal by Hale (2001), statistical techniques have been become common as models of reading difficulty and linguistic complexity. Surprisal has received a lot of attention in recent literature due to nice mathematical properties (Levy, 2008) and predictive ability on eye-tracking movements (Demberg and Keller, 2008; Boston et al., 2008a). Many other complexity metrics have been suggested as mutually contributing to reading difficulty; for example, entropy reduction (Hale, 2006), bigram probabilities (McDonald and Shillcock, 2003), and split-syntactic/lexical versions of other metrics (Roark et al., 2009).

A parser-derived complexity metric such as surprisal can only be as good (empirically) as the model of language from which it derives (Frank, 2009). Ideally, a psychologically-plausible language model would produce a surprisal that would correlate better with linguistic complexity. Therefore, the specification of how to encode a syntactic language model is of utmost importance to the quality of the metric.

However, it is difficult to quantify linguistic complexity and reading difficulty. The two commonly-used empirical quantifications of reading difficulty are eye-tracking measurements and word-by-word reading times; this paper uses reading times to find the predictiveness of several parser-derived complexity metrics. Various factors (i.e., from syntax, semantics, discourse) are likely necessary for a full accounting of linguistic complexity, so current computational models (with some exceptions) narrow the scope to syntactic or lexical complexity.

Three complexity metrics will be calculated in a Hierarchical Hidden Markov Model (HHMM) parser that recognizes trees in right-corner form (the left-right dual of left-corner form). This type of parser performs competitively on standard parsing tasks (Schuler et al., 2010); also, it reflects plausible accounts of human language processing as incremental (Tanenhaus et al., 1995; Brants and Crocker, 2000), as considering hypotheses probabilistically in parallel (Dahan and Gaskell, 2007), as bounding memory usage to short-term memory limits (Cowan, 2001), and as requiring more memory storage for center-embedding structures than for right- or left-branching ones (Chomsky and Miller, 1963; Gibson, 1998). Also, unlike most other parsers, this parser preserves the *arc-eager/arc-standard* ambiguity of Abney and John-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1189–1198,
Uppsala, Sweden, 11-16 July 2010.

son (1991). Typical parsing strategies are arc-standard, keeping all right-descendants open for subsequent attachment; but since there can be an unbounded number of such open constituents, this assumption is not compatible with simple models of bounded memory. A consistently arc-eager strategy acknowledges memory bounds, but yields dead-end parses. Both analyses are considered in right-corner HHMM parsing.

The purpose of this paper is to determine whether the language model defined by the HHMM parser can also predict reading times — it would be strange if a psychologically plausible model did not also produce viable complexity metrics. In the course of showing that the HHMM parser does, in fact, predict reading times, we will define surprisal and entropy reduction in the HHMM parser, and introduce a third metric called *embedding difference*.

Gibson (1998; 2000) hypothesized two types of syntactic processing costs: *integration cost*, in which incremental input is combined with existing structures; and *memory cost*, where unfinished syntactic constructions may incur some short-term memory usage. HHMM surprisal and entropy reduction may be considered forms of integration cost. Though typical PCFG surprisal has been considered a forward-looking metric (Demberg and Keller, 2008), the incremental nature of the right-corner transform causes surprisal and entropy reduction in the HHMM parser to measure the likelihood of grammatical structures that were hypothesized before evidence was observed for them. Therefore, these HHMM metrics resemble an integration cost encompassing both backward-looking and forward-looking information.

On the other hand, embedding difference is designed to model the cost of storing center-embedded structures in working memory. Chen, Gibson, and Wolf (2005) showed that sentences requiring more syntactic memory during sentence processing increased reading times, and it is widely understood that center-embedding incurs significant syntactic processing costs (Miller and Chomsky, 1963; Gibson, 1998). Thus, we would expect for the usage of the center-embedding memory store in an HHMM parser to correlate with reading times (and therefore linguistic complexity).

The HHMM parser processes syntactic constructs using a bounded number of store states, defined to represent short-term memory elements; additional states are utilized whenever center-embedded syntactic structures are present. Similar models such as Crocker and Brants (2000) implicitly allow an infinite memory size, but Schuler et al. (2008; 2010) showed that a right-corner HHMM parser can parse most sentences in English with 4 or fewer center-embedded-depth levels. This behavior is similar to the hypothesized size of a human short-term memory store (Cowan, 2001). A positive result in predicting reading times will lend additional validity to the claim that the HHMM parser's bounded memory corresponds to bounded memory in human sentence processing.

The rest of this paper is organized as follows: Section 2 defines the language model of the HHMM parser, including definitions of the three complexity metrics. The methodology for evaluating the complexity metrics is described in Section 3, with actual results in Section 4. Further discussion on results, and comparisons to other work, are in Section 5.

2 Parsing Model

This section describes an incremental parser in which surprisal and entropy reduction are simple calculations (Section 2.1). The parser uses a Hierarchical Hidden Markov Model (Section 2.2) and recognizes trees in a right-corner form (Section 2.3 and 2.4). The new complexity metric, embedding difference (Section 2.5), is a natural consequence of this HHMM definition. The model is equivalent to previous HHMM parsers (Schuler, 2009), but reorganized into 5 cases to clarify the right-corner structure of the parsed sentences.

2.1 Surprisal and Entropy in HMMs

Hidden Markov Models (HMMs) probabilistically connect sequences of observed states o_t and hidden states q_t at corresponding time steps t. In parsing, observed states are words; hidden states can be a conglomerate state of linguistic information, here taken to be syntactic.

The HMM is an incremental, time-series structure, so one of its by-products is the *prefix probability*, which will be used to calculate surprisal. This is the probability that that words $o_{1..t}$ have been observed at time t, regardless of which syntactic states $q_{1..t}$ produced them. Bayes' Law and Markov independence assumptions allow this to

be calculated from two generative probability distributions.[1]

$$\mathsf{Pre}(o_{1..t}) = \sum_{q_{1..t}} \mathsf{P}(o_{1..t}\, q_{1..t}) \quad (1)$$

$$\stackrel{\text{def}}{=} \sum_{q_{1..t}} \prod_{\tau=1}^{t} \mathsf{P}_{\Theta_\mathrm{A}}(q_\tau \mid q_{\tau-1}) \cdot \mathsf{P}_{\Theta_\mathrm{B}}(o_\tau \mid q_\tau) \quad (2)$$

Here, probabilities arise from a *Transition Model* (Θ_A) between hidden states and an *Observation Model* (Θ_B) that generates an observed state from a hidden state. These models are so termed for historical reasons (Rabiner, 1990).

Surprisal (Hale, 2001) is then a straightforward calculation from the prefix probability.

$$\text{Surprisal}(t) = \log_2 \frac{\mathsf{Pre}(o_{1..t-1})}{\mathsf{Pre}(o_{1..t})} \quad (3)$$

This framing of prefix probability and surprisal in a time-series model is equivalent to Hale's (2001; 2006), assuming that $q_{1..t} \in \mathcal{D}_t$, i.e., that the syntactic states we are considering form derivations $\mathcal{D}_t$, or partial trees, consistent with the observed words. We will see that this is the case for our parser in Sections 2.2–2.4.

Entropy is a measure of uncertainty, defined as $H(x) = -\mathsf{P}(x) \log_2 \mathsf{P}(x)$. Now, the entropy H_t of a t-word string $o_{1..t}$ in an HMM can be written:

$$H_t = \sum_{q_{1..t}} \mathsf{P}(q_{1..t}\, o_{1..t}) \log_2 \mathsf{P}(q_{1..t}\, o_{1..t}) \quad (4)$$

and *entropy reduction* (Hale, 2003; Hale, 2006) at the t^{th} word is then

$$\text{ER}(o_t) = \max(0, H_{t-1} - H_t) \quad (5)$$

Both of these metrics fall out naturally from the time-series representation of the language model. The third complexity metric, embedding difference, will be discussed after additional background in Section 2.5.

In the implementation of an HMM, candidate states at a given time q_t are kept in a trellis, with step-by-step backpointers to the highest-probability $q_{1..t-1}$.[2] Also, the best q_t are often kept in a beam $\mathcal{B}_t$, discarding low-probability states. This mitigates the problems of large state spaces (e.g., that of all possible grammatical derivations). Since beams have been shown to perform well (Brants and Crocker, 2000; Roark, 2001; Boston et al., 2008b), complexity metrics in this paper are calculated on a beam rather than over all (unbounded) possible derivations $\mathcal{D}_t$. The equations above, then, will replace the assumption $q_{1..t} \in \mathcal{D}_t$ with $q_t \in \mathcal{B}_t$.

[1] Technically, a prior distribution over hidden states, $\mathsf{P}(q_0)$, is necessary. This q_0 is factored and taken to be a deterministic constant, and is therefore unimportant as a probability model.

[2] Typical tasks in an HMM include finding the most likely sequence via the Viterbi algorithm, which stores these backpointers to maximum-probability previous states and can uniquely find the most likely sequence.

2.2 Hierarchical Hidden Markov Models

Hidden states q can have internal structure; in Hierarchical HMMs (Fine et al., 1998; Murphy and Paskin, 2001), this internal structure will be used to represent syntax trees and looks like several HMMs stacked on top of each other. As such, q_t is factored into sequences of depth-specific variables — one for each of D levels in the HMM hierarchy. In addition, an intermediate variable f_t is introduced to interface between the levels.

$$q_t \stackrel{\text{def}}{=} \langle q_t^1 \ldots q_t^D \rangle \quad (6)$$

$$f_t \stackrel{\text{def}}{=} \langle f_t^1 \ldots f_t^D \rangle \quad (7)$$

Transition probabilities $\mathsf{P}_{\Theta_\mathrm{A}}(q_t \mid q_{t-1})$ over complex hidden states q_t are calculated in two phases:

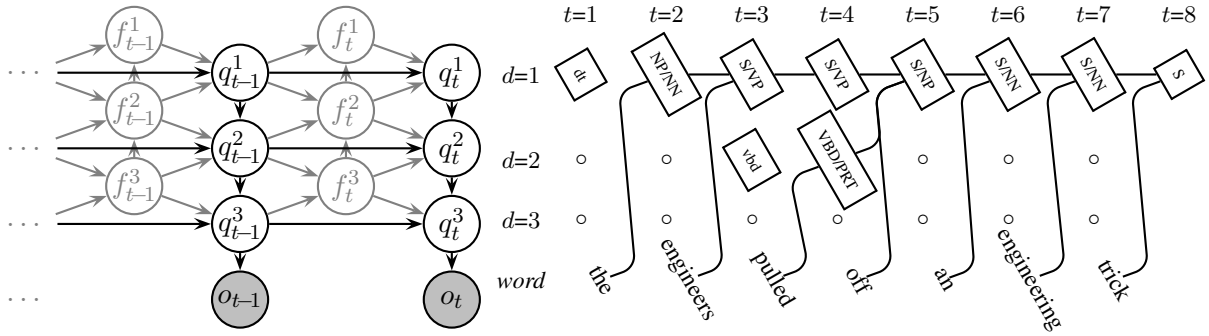
- *Reduce phase.* Yields an intermediate state f_t, in which component HMMs may terminate. This f_t tells "higher" HMMs to hold over their information if "lower" levels are in operation at any time step t, and tells lower HMMs to signal when they're done.
- *Shift phase.* Yields a modeled hidden state q_t, in which unterminated HMMs transition, and terminated HMMs are re-initialized from their parent HMMs.

Each phase is factored according to *level-specific* reduce and shift models, Θ_F and Θ_Q:

$$\mathsf{P}_{\Theta_\mathrm{A}}(q_t|q_{t-1}) = \sum_{f_t} \mathsf{P}(f_t|q_{t-1}) \cdot \mathsf{P}(q_t|f_t\, q_{t-1}) \quad (8)$$

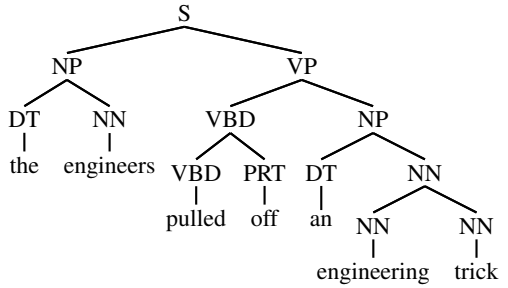
$$\stackrel{\text{def}}{=} \sum_{f_t^{1..D}} \prod_{d=1}^{D} \mathsf{P}_{\Theta_\mathrm{F}}(f_t^d|f_t^{d+1} q_{t-1}^d q_{t-1}^{d-1}) \cdot \mathsf{P}_{\Theta_\mathrm{Q}}(q_t^d|f_t^{d+1} f_t^d\, q_{t-1}^d q_t^{d-1}) \quad (9)$$

with f_t^{D+1} and q_t^0 defined as constants. Note that only q_t is present at the end of the probability calculation. In step t, f_{t-1} will be unused, so the marginalization of Equation 9 does not lose any information.

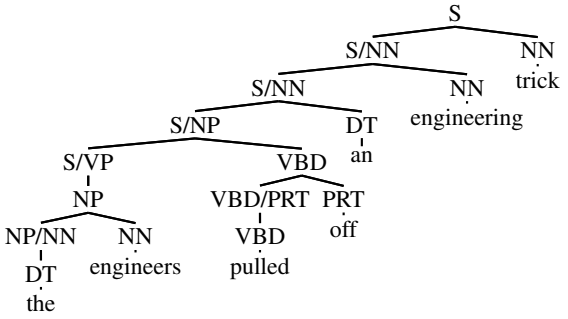


(a) Dependency structure in the HHMM parser. Conditional probabilities at a node are dependent on incoming arcs.

(b) HHMM parser as a store whose elements at each time step are listed vertically, showing a good hypothesis on a sample sentence out of many kept in parallel. Variables corresponding to q_t^d are shown.



(c) A sample sentence in CNF.



(d) The right-corner transformed version of (c).

Figure 1: Various graphical representations of HHMM parser operation. (a) shows probabilistic dependencies. (b) considers the q_t^d store to be incremental syntactic information. (c)–(d) demonstrate the right-corner transform, similar to a left-to-right traversal of (c). In 'NP/NN' we say that NP is the *active* constituent and NN is the *awaited*.

The Observation Model Θ_{B} is comparatively much simpler. It is only dependent on the syntactic state at D (or the deepest active HHMM level).

$$\mathsf{P}_{\Theta_{\mathrm{B}}}(o_t \mid q_t) \stackrel{\text{def}}{=} \mathsf{P}(o_t \mid q_t^D) \tag{10}$$

Figure 1(a) gives a schematic of the dependency structure of Equations 8–10 for $D = 3$. Evaluations in this paper are done with $D = 4$, following the results of Schuler, et al. (2008).

2.3 Parsing right-corner trees

In this HHMM formulation, states and dependencies are optimized for parsing right-corner trees (Schuler et al., 2008; Schuler et al., 2010). A sample transformation between CNF and right-corner trees is in Figures 1(c)–1(d).

Figure 1(b) shows the corresponding store-element interpretation[3] of the right corner tree in 1(d). These can be used as a case study to see what kind of operations need to occur in an HHMM when parsing right-corner trees. There is one unique set of HHMM state values for each tree, so the operations can be seen on either the tree or the store elements.

At each time step t, a certain number of elements (maximum D) are kept in memory, i.e., in the store. New words are observed input, and the bottom occupied element (the "frontier" of the store) is the context; together, they determine what the store will look like at $t{+}1$. We can characterize the types of store-element changes by when they happen in Figures 1(b) and 1(d):

Cross-level Expansion (CLE). Occupies a new store element at a given time step. For example, at $t = 1$, a new store element is occupied which can interact with the observed word, "the." At $t = 3$, an expansion occupies the second store element.

In-level Reduction (ILR). Completes an active constituent that is a unary child in the right-corner tree; always accompanied by an in-level expansion. At $t = 2$, "engineers" completes the active NP constituent; however, the

[3] This is technically a pushdown automoton (PDA), where the store is limited to D elements. When referring to directions (e.g., up, down), PDAs are typically described opposite of the one in Figure 1(b); here, we push "up" instead of down.

level is not yet complete since the NP is along the left-branching trunk of the tree.

In-level Expansion (ILE). Starts a new active constituent at an already-occupied store element; always follows an in-level reduction. With the NP complete in $t=2$, a new active constituent S is produced at $t=3$.

In-level Transition (ILT). Transitions the store to a new state in the next time step at the same level, where the awaited constituent changes and the active constituent remains the same. This describes each of the steps from $t=4$ to $t=8$ at $d=1$.

Cross-level Reduction (CLR). Vacates a store element on seeing a complete active constituent. This occurs after $t = 4$; "off" completes the active (at depth 2) VBD constituent, and vacates store element 2. This is accompanied with an in-level transition at depth 1, producing the store at $t=5$. It should be noted that with some probability, completing the active constituent does not vacate the store element, and the in-level reduction case would have to be invoked.

The in-level/cross-level ambiguity occurs in the expansion as well as the reduction, similar to Abney and Johnson's arc-eager/arc-standard composition strategies (1991). At $t=3$, another possible hypothesis would be to remain on store element 1 using an ILE instead of a CLE. The HHMM parser, unlike most other parsers, will preserve this in-level/cross-level ambiguity by considering both hypotheses in parallel.

2.4 Reduce and Shift Models

With the understanding of what operations need to occur, a formal definition of the language model is in order. Let us begin with the relevant variables.

A shift variable q_t^d at depth d and time step t is a syntactic state that must represent the active and awaited constituents of right-corner form:

$$q_t^d \stackrel{\text{def}}{=} \langle g^{\text{A}}_{q_t^d}, g^{\text{W}}_{q_t^d} \rangle \tag{11}$$

e.g., in Figure 1(b), q_2^1=⟨NP,NN⟩=NP/NN. Each g is a constituent from the pre-right-corner grammar, G.

Reduce variables f are then enlisted to ensure that in-level and cross-level operations are correct.

$$f_t^d \stackrel{\text{def}}{=} \langle k_{f_t^d}, g_{f_t^d} \rangle \tag{12}$$

First, $k_{f_t^d}$ is a switching variable that differentiates between ILT, CLE/CLR, and ILE/ILR. This switching is the most important aspect of f_t^d, so regardless of what $g_{f_t^d}$ is, we will use:

- $f_t^d \in F_0$ when $k_{f_t^d} = \mathbf{0}$, (ILT/no-op)
- $f_t^d \in F_1$ when $k_{f_t^d} = \mathbf{1}$, (CLE/CLR)
- $f_t^d \in F_G$ when $k_{f_t^d} \in G$. (ILE/ILR)

Then, $g_{f_t^d}$ is used to keep track of a completely-recognized constituent whenever a reduction occurs (ILR or CLR). For example, in Figure 1(b), after time step 2, an NP has been completely recognized and precipitates an ILR. The NP gets stored in $g_{f_3^1}$ for use in the ensuing ILE instead of appearing in the store-elements.

This leads us to a specification of the reduce and shift probability models. The reduce step happens first at each time step. True to its name, the reduce step handles in-level and cross-level reductions (the second and third case below):

$$\mathsf{P}_{\Theta_{\text{F}}}(f_t^d \mid f_t^{d+1} q_{t-1}^d q_{t-1}^{d-1}) \stackrel{\text{def}}{=}$$
$$\begin{cases} \text{if } f_t^{d+1} \notin F_G & : [\![f_t^d = \mathbf{0}]\!] \\ \text{if } f_t^{d+1} \in F_G, f_t^d \in F_1 & : \tilde{\mathsf{P}}_{\Theta_{\text{F-ILR},d}}(f_t^d \mid q_{t-1}^d \, q_{t-1}^{d-1}) \\ \text{if } f_t^{d+1} \in F_G, f_t^d \in F_G & : \tilde{\mathsf{P}}_{\Theta_{\text{F-CLR},d}}(f_t^d \mid q_{t-1}^d \, q_{t-1}^{d-1}) \end{cases} \tag{13}$$

with edge cases q_t^0 and f_t^{D+1} defined as appropriate constants. The first case is just store-element maintenance, in which the variable is not on the "frontier" and therefore inactive.

Examining $\Theta_{\text{F-ILR},d}$ and $\Theta_{\text{F-CLR},d}$, we see that the produced f_t^d variables are also used in the "if" statement. These models can be thought of as picking out a f_t^d first, finding the matching case, then applying the probability models that matches. These models are actually two parts of the same model when learned from trees.

Probabilities in the shift step are also split into cases based on the reduce variables. More maintenance operations (first case) accompany transitions producing new awaited constituents (second case below) and expansions producing new active constituents (third and fourth case):

$$\mathsf{P}_{\Theta_{\text{Q}}}(q_t^d \mid f_t^{d+1} f_t^d \, q_{t-1}^d q_t^{d-1}) \stackrel{\text{def}}{=}$$
$$\begin{cases} \text{if } f_t^{d+1} \notin F_G & : [\![q_t^d = q_{t-1}^d]\!] \\ \text{if } f_t^{d+1} \in F_G, \, f_t^d \in F_0 & : \tilde{\mathsf{P}}_{\Theta_{\text{Q-ILT},d}}(q_t^d \mid f_t^{d+1} \, q_{t-1}^d \, q_t^{d-1}) \\ \text{if } f_t^{d+1} \in F_G, \, f_t^d \in F_1 & : \tilde{\mathsf{P}}_{\Theta_{\text{Q-ILE},d}}(q_t^d \mid f_t^d \, q_{t-1}^d \, q_t^{d-1}) \\ \text{if } f_t^{d+1} \in F_G, \, f_t^d \in F_G & : \tilde{\mathsf{P}}_{\Theta_{\text{Q-CLE},d}}(q_t^d \mid q_t^{d-1}) \end{cases} \tag{14}$$

FACTOR	DESCRIPTION	EXPECTED
Word order in narrative	For each story, words were indexed. Subjects would tend to read faster later in a story.	negative slope
Reciprocal length	Log of the reciprocal of the number of letters in each word. A decrease in the reciprocal (increase in length) might mean longer reading times.	positive slope
Unigram frequency	A log-transformed empirical count of word occurrences in the Brown Corpus section of the Penn Treebank. Higher frequency should indicate shorter reading times.	negative slope
Bigram probability	A log-transformed empirical count of two-successive-word occurrences, with Good-Turing smoothing on words occuring less than 10 times.	negative slope
Embedding difference	Amount of change in HHMM weighted-average embedding depth. Hypothesized to increase with larger working memory requirements, which predict longer reading times.	positive slope
Entropy reduction	Amount of decrease in the HHMM's uncertainty about the sentence. Larger reductions in uncertainty are hypothesized to take longer.	positive slope
Surprisal	"Surprise value" of a word in the HHMM parser; models were trained on the Wall Street Journal, sections 02–21. More surprising words may take longer to read.	positive slope

Table 1: A list of factors hypothesized to contribute to reading times. All data was mean-centered.

A final note: the notation $\tilde{\mathsf{P}}_\Theta(\cdot \mid \cdot)$ has been used to indicate probability models that are empirical, trained directly from frequency counts of right-corner transformed trees in a large corpus. Alternatively, a standard PCFG could be trained on a corpus (or hand-specified), and then the grammar itself can be right-corner transformed (Schuler, 2009).

Taken together, Equations 11–14 define the probabilistic structure of the HHMM for parsing right-corner trees.

2.5 Embedding difference in the HHMM

It should be clear from Figure 1 that at any time step while parsing depth-bounded right-corner trees, the candidate hidden state q_t will have a "frontier" depth $d(q_t)$. At time t, the beam of possible hidden states q_t stores the syntactic state (and a backpointer) along with its probability, $\mathsf{P}(o_{1..t}\, q_{1..t})$. The *average embedding depth* at a time step is then

$$\mu_{\text{EMB}}(o_{1..t}) = \sum_{q_t \in \mathcal{B}_t} d(q_t) \cdot \frac{\mathsf{P}(o_{1..t}\, q_{1..t})}{\sum_{q'_t \in \mathcal{B}_t} \mathsf{P}(o_{1..t}\, q'_{1..t})} \tag{15}$$

where we have directly used the beam notation. The *embedding difference* metric is:

$$\text{EmbDiff}(o_{1..t}) = \mu_{\text{EMB}}(o_{1..t}) - \mu_{\text{EMB}}(o_{1..t-1}) \tag{16}$$

There is a strong computational correspondence between this definition of embedding difference and the previous definition of surprisal. To see this, we rewrite Equations 1 and 3:

$$\mathsf{Pre}(o_{1..t}) = \sum_{q_t \in \mathcal{B}_t} \mathsf{P}(o_{1..t}\, q_{1..t}) \tag{1'}$$

$$\text{Surprisal}(t) = \log_2 \mathsf{Pre}(o_{1..t-1}) - \log_2 \mathsf{Pre}(o_{1..t}) \tag{3'}$$

Both surprisal and embedding difference include summations over the elements of the beam, and are calculated as a difference between previous and current beam states.

Most differences between these metrics are relatively inconsequential. For example, the difference in order of subtraction only assures that a positive correlation with reading times is expected. Also, the presence of a logarithm is relatively minor. Embedding difference weighs the probabilities with center-embedding depths and then normalizes the values; since the measure is a weighted average of embedding depths rather than a probability distribution, μ_{EMB} is not always less than 1 and the correspondence with Kullback-Leibler divergence (Levy, 2008) does not hold, so it does not make sense to take the logs.

Therefore, the inclusion of the embedding depth, $d(q_t)$, is the only significant difference between the two metrics. The result is a metric that, despite numerical correspondence to surprisal, models the HHMM's hypotheses about memory cost.

3 Evaluation

Surprisal, entropy reduction, and embedding difference from the HHMM parser were evaluated against a full array of factors (Table 1) on a corpus of word-by-word reading times using a linear mixed-effects model.

The corpus of reading times for 23 native English speakers was collected on a set of four narratives (Bachrach et al., 2009), each composed of sentences that were syntactically complex but constructed to appear relatively natural. Using Linger 2.88, words appeared one-by-one on the screen, and required a button-press in order to advance; they were displayed in lines with 11.5 words on average.

Following Roark et al.'s (2009) work on the same corpus, reading times above 1500 ms (for diverted attention) or below 150 ms (for button presses planned before the word appeared) were discarded. In addition, the first and last word of each line on the screen were removed; this left 2926 words out of 3540 words in the corpus.

For some tests, a division between open- and closed-class words was made, with 1450 and 1476 words, respectively. Closed-class words (e.g., determiners or auxiliary verbs) usually play some kind of syntactic function in a sentence; our evaluations used Roark et al.'s list of stop words. Open class words (e.g., nouns and other verbs) more commonly include new words. Thus, one may expect reading times to differ for these two types of words.

Linear mixed-effect regression analysis was used on this data; this entails a set of *fixed effects* and another of *random effects*. Reading times y were modeled as a linear combination of factors x, listed in Table 1 (fixed effects); some random variation in the corpus might also be explained by groupings according to subject i, word j, or sentence k (random effects).

$$y_{ijk} = \beta_0 + \sum_{\ell=1}^{m} \beta_\ell x_{ijk\ell} + b_i + b_j + b_k + \varepsilon \qquad (17)$$

This equation is solved for each of m fixed-effect coefficients β with a measure of confidence (t-value $= \hat{\beta}/\mathrm{SE}(\hat{\beta})$, where SE is the standard error). β_0 is the standard intercept to be estimated along with the rest of the coefficients, to adjust for affine relationships between the dependent and independent variables. We report factors as statistically significant contributors to reading time if the absolute value of the t-value is greater than 2.

Two more types of comparisons will be made to see the significance of factors. First, a model of data with the full list of factors can be compared to a model with a subset of those factors. This is done with a likelihood ratio test, producing (for mixed-effects models) a χ^2_1 value and corresponding probability that the smaller model could have produced the same estimates as the larger model. A lower probability indicates that the additional factors in the larger model are significant.

Second, models with different fixed effects can be compared to each other through various information criteria; these trade off between having a more explanatory model vs. a simpler model, and can be calculated on any model. Here, we use Akaike's Information Criterion (AIC), where lower values indicate better models.

All these statistics were calculated in R, using the `lme4` package (Bates et al., 2008).

4 Results

Using the full list of factors in Table 1, fixed-effect coefficients were estimated in Table 2. Fitting the best model by AIC would actually prune away some of the factors as relatively insignificant, but these smaller models largely accord with the significance values in the table and are therefore not presented.

The first data column shows the regression on all data; the second and third columns divide the data into open and closed classes, because an evaluation (not reported in detail here) showed statistically significant interactions between word class and 3 of the predictors. Additionally, this facilitates comparison with Roark et al. (2009), who make the same division.

Out of the non-parser-based metrics, word order and bigram probability are statistically significant regardless of the data subset; though reciprocal length and unigram frequency do not reach significance here, likelihood ratio tests (not shown) confirm that they contribute to the model as a whole. It can be seen that nearly all the slopes have been estimated with signs as expected, with the exception of reciprocal length (which is not statistically significant).

Most notably, HHMM surprisal is seen here to be a standout predictive measure for reading times regardless of word class. If the HHMM parser is a good psycholinguistic model, we would expect it to at least produce a viable surprisal metric, and Table 2 attests that this is indeed the case. Though it seems to be less predictive of open classes, a surprisal-only model has the best AIC (-7804) out of any open-class model. Considering the AIC on the full data, the worst model *with* surprisal

Table 3: Correlations in the full model.

(AIC=-10589) outperformed the best model *without* it (AIC=-10478), indicating that the HHMM surprisal is well worth including in the model regardless of the presence of other significant factors.

HHMM entropy reduction predicts reading times on the full dataset and on closed-class words. However, its effect on open-class words is insignificant; if we compare the model of column 2 against one without entropy reduction, a likelihood ratio test gives $\chi^2_1 = 0.0022, p = 0.9623$ (the smaller model could easily generate the same data).

The HHMM's average embedding difference is also significant except in the case of open-class words — removing embedding difference on open-class data yields $\chi^2_1 = 0.2739, p = 0.6007$. But what is remarkable is that there is any significance for this metric at all. Embedding difference and surprisal were relatively correlated compared to other predictors (see Table 3), which is expected because embedding difference is calculated like a weighted version of surprisal. Despite this, it makes an independent contribution to the full-data and closed-class models. Thus, we can conclude that the average embedding depth component affects reading times — i.e., the HHMM's notion of working memory behaves as we would expect human working memory to behave.

5 Discussion

As with previous work on large-scale parser-derived complexity metrics, the linear mixed-effect models suggest that sentence-level factors are effective predictors for reading difficulty — in these evaluations, better than commonly-used lexical and near-neighbor predictors (Pollatsek et al., 2006; Engbert et al., 2005). The fact that HHMM surprisal outperforms even n-gram metrics points to the importance of including a notion of sentence structure. This is particularly true when the sentence structure is defined in a language model that is psycholinguistically plausible (here, bounded-memory right-corner form).

This accords with an understated result of Boston et al.'s eye-tracking study (2008a): a richer language model predicts eye movements during reading better than an oversimplified one. The comparison there is between phrase structure surprisal (based on Hale's (2001) calculation from an Earley parser), and dependency grammar surprisal (based on Nivre's (2007) dependency parser). Frank (2009) similarly reports improvements in the reading-time predictiveness of unlexicalized surprisal when using a language model that is more plausible than PCFGs.

The difference in predictivity due to word class is difficult to explain. One theory may be that closed-class words are less susceptible to random effects because there is a finite set of them for any language, making them overall easier to predict via parser-derived metrics. Or, we could note that since closed-class words often serve grammatical functions in addition to their lexical content, they contribute more information to parser-derived measures than open-class words. Previous work with complexity metrics on this corpus (Roark et al., 2009) suggests that these explanations only account for part of the word-class variation in the performance of predictors.

Further comparsion to Roark et al. will show other differences, such as the lesser role of word length and unigram frequency, lower overall correlations between factors, and the greater predictivity of their entropy metric. In addition, their metrics are different from ours in that they are designed to tease apart lexical and syntactic contributions to reading difficulty. Their notion of entropy, in particular, estimates Hale's definition of entropy on whole derivations (2006) by isolating the predictive entropy; they then proceed to define separate lexical and syntactic predictive entropies. Drawing more directly from Hale, our definition is a whole-derivation metric based on the conditional entropy of the words, given the root. (The root constituent, though unwritten in our definitions, is always included in the HHMM start state, q_0.)

More generally, the parser used in these evaluations differs from other reported parsers in that it is not lexicalized. One might expect for this to be a weakness, allowing distributions of probabilities at each time step in places not licensed by the observed words, and therefore giving poor probability-based complexity metrics. However, we see that this language model performs well despite its lack of lexicalization. This indicates that lexicalization is not a requisite part of syntactic parser performance with respect to predicting linguistic complexity, corroborating the evidence of Demberg and Keller's (2008) 'unlexicalized' (POS-generating, not word-generating) parser.

Another difference is that previous parsers have produced useful complexity metrics without maintaining arc-eager/arc-standard ambiguity. Results show that including this ambiguity in the HHMM at least does not invalidate (and may in fact improve) surprisal or entropy reduction as reading-time predictors.

6 Conclusion

The task at hand was to determine whether the HHMM could consistently be considered a plausible psycholinguistic model, producing viable complexity metrics while maintaining other characteristics such as bounded memory usage. The linear mixed-effects models on reading times validate this claim. The HHMM can straightforwardly produce highly-predictive, standard complexity metrics (surprisal and entropy reduction). HHMM surprisal performs very well in predicting reading times regardless of word class. Our formulation of entropy reduction is also significant except in open-class words.

The new metric, embedding difference, uses the average center-embedding depth of the HHMM to model syntactic-processing memory cost. This metric can only be calculated on parsers with an explicit representation for short-term memory elements like the right-corner HHMM parser. Results show that embedding difference does predict reading times except in open-class words, yielding a significant contribution independent of surprisal despite the fact that its definition is similar to that of surprisal.

Abstract

We challenge the NLP community to participate in a large-scale, distributed effort to design and build resources for developing and evaluating solutions to new and existing NLP tasks in the context of Recognizing Textual Entailment. We argue that the single global label with which RTE examples are annotated is insufficient to effectively evaluate RTE system performance; to promote research on smaller, related NLP tasks, we believe more detailed annotation and evaluation are needed, and that this effort will benefit not just RTE researchers, but the NLP community as a whole. We use insights from successful RTE systems to propose a model for identifying and annotating textual inference phenomena in textual entailment examples, and we present the results of a pilot annotation study that show this model is feasible and the results immediately useful.

1 Introduction

Much of the work in the field of Natural Language Processing is founded on an assumption of semantic compositionality: that there are identifiable, separable components of an unspecified inference process that will develop as research in NLP progresses. Tasks such as Named Entity and coreference resolution, syntactic and shallow semantic parsing, and information and relation extraction have been identified as worthwhile tasks and pursued by numerous researchers. While many have (nearly) immediate application to real world tasks like search, many are also motivated by their potential contribution to more ambitious Natural Language tasks. It is clear that the components/tasks identified so far do not suffice in themselves to solve tasks requiring more complex reasoning and synthesis of information; many other tasks must be solved to achieve human-like performance on tasks such as Question Answering. But there is no clear process for identifying potential tasks (other than consensus by a sufficient number of researchers), nor for quantifying their potential contribution to existing NLP tasks, let alone to Natural Language Understanding.

Recent "grand challenges" such as *Learning by Reading*, *Learning To Read*, and *Machine Reading* are prompting more careful thought about the way these tasks relate, and what tasks must be solved in order to understand text sufficiently well to reliably reason with it. This is an appropriate time to consider a **systematic process for identifying semantic analysis tasks relevant to natural language understanding, and for assessing their potential impact on NLU system performance**.

Research on Recognizing Textual Entailment (RTE), largely motivated by a "grand challenge" now in its sixth year, has already begun to address some of the problems identified above. Techniques developed for RTE have now been successfully applied in the domains of Question Answering (Harabagiu and Hickl, 2006) and Machine Translation (Pado et al., 2009), (Mirkin et al., 2009). The RTE challenge examples are drawn from multiple domains, providing a relatively task-neutral setting in which to evaluate contributions of different component solutions, and RTE researchers have already made incremental progress by identifying sub-problems of entailment, and developing ad-hoc solutions for them.

In this paper we challenge the NLP community to contribute to a joint, long-term effort to identify, formalize, and solve textual inference problems motivated by the Recognizing Textual Entailment setting, in the following ways:

(a) Making the Recognizing Textual Entailment setting a central component of evaluation for

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1199–1208,
Uppsala, Sweden, 11-16 July 2010.

relevant NLP tasks such as NER, Coreference, parsing, data acquisition and application, and others. While many "component" tasks are considered (almost) solved in terms of expected improvements in performance on task-specific corpora, it is not clear that this translates to strong performance in the RTE domain, due either to problems arising from unrelated, unsolved entailment phenomena that co-occur in the same examples, or to domain change effects. The RTE task offers an application-driven setting for evaluating a broad range of NLP solutions, and will reinforce good practices by NLP researchers. The RTE task has been designed specifically to exercise textual inference capabilities, in a format that would make RTE systems potentially useful components in other "deep" NLP tasks such as Question Answering and Machine Translation. [1]

(b) Identifying relevant linguistic phenomena, interactions between phenomena, and their likely impact on RTE/textual inference. Determining the correct label for a single textual entailment example requires human analysts to make many smaller, localized decisions which may depend on each other. A broad, carefully conducted effort to identify and annotate such local phenomena in RTE corpora would allow their distributions in RTE examples to be quantified, and allow evaluation of NLP solutions in the context of RTE. It would also allow assessment of the potential impact of a solution to a specific sub-problem on the RTE task, and of interactions between phenomena. Such phenomena will almost certainly correspond to elements of linguistic theory; but this approach brings a data-driven approach to focus attention on those phenomena that are well-represented in the RTE corpora, and which can be identified with sufficiently close agreement.

(c) Developing resources and approaches that allow more detailed assessment of RTE systems. At present, it is hard to know what specific capabilities different RTE systems have, and hence, which aspects of successful systems are worth emulating or reusing. An evaluation framework that could offer insights into the kinds of sub-problems a given system can reliably solve would make it easier to identify significant advances, and thereby promote more rapid advances through reuse of successful solutions and focus on unresolved problems.

In this paper we demonstrate that Textual Entailment systems are already "interesting", in that they have made significant progress beyond a "smart" lexical baseline that is surprisingly hard to beat (section 2). We argue that Textual Entailment, as an application that clearly requires sophisticated textual inference to perform well, requires the solution of a range of sub-problems, some familiar and some not yet known. We therefore propose RTE as a promising and worthwhile task for large-scale community involvement, as it motivates the study of many other NLP problems in the context of general textual inference.

We outline the limitations of the present model of evaluation of RTE performance, and identify kinds of evaluation that would promote understanding of the way individual components can impact Textual Entailment system performance, and allow better objective evaluation of RTE system behavior without imposing additional burdens on RTE participants. We use this to motivate a large-scale annotation effort to provide data with the mark-up sufficient to support these goals.

To stimulate discussion of suitable annotation and evaluation models, we propose a candidate model, and provide results from a pilot annotation effort (section 3). This pilot study establishes the feasibility of an inference-motivated annotation effort, and its results offer a quantitative insight into the difficulty of the TE task, and the distribution of a number of entailment-relevant linguistic phenomena over a representative sample from the NIST TAC RTE 5 challenge corpus. We argue that such an evaluation and annotation effort can identify relevant subproblems whose solution will benefit not only Textual Entailment but a range of other long-standing NLP tasks, and can stimulate development of new ones. We also show how this data can be used to investigate the behavior of some of the highest-scoring RTE systems from the most recent challenge (section 4).

2 NLP Insights from Textual Entailment

The task of Recognizing Textual Entailment (RTE), as formulated by (Dagan et al., 2006), requires automated systems to identify when a human reader would judge that given one span of text (the Text) and some unspecified (but restricted) world knowledge, a second span of text (the Hy-

[1] The *Parser Training and Evaluation using Textual Entailment* track of SemEval 2 takes this idea one step further, by evaluating performance of an isolated NLP task using the RTE methodology.

Text:	The purchase of LexCorp by BMI for $2Bn prompted widespread sell-offs by traders as they sought to minimize exposure.
Hyp 1:	BMI acquired another company.
Hyp 2:	BMI bought LexCorp for $3.4Bn.

Figure 1: **Some representative RTE examples.**

pothesis) is true. The task was extended in (Giampiccolo et al., 2007) to include the additional requirement that systems identify when the Hypothesis contradicts the Text. In the example shown in figure 1, this means recognizing that the Text entails Hypothesis 1, while Hypothesis 2 contradicts the Text. This operational definition of Textual Entailment avoids commitment to any specific knowledge representation, inference method, or learning approach, thus encouraging application of a wide range of techniques to the problem.

2.1 An Illustrative Example

The simple RTE examples in figure 1 (most RTE examples have much longer Texts) illustrate some typical inference capabilities demonstrated by human readers in determining whether one span of text contains the meaning of another.

To recognize that Hypothesis 1 is entailed by the text, a human reader must recognize that "another company" in the Hypothesis can match "LexCorp". She must also identify the nominalized relation "purchase", and determine that "A purchased by B" implies "B acquires A".

To recognize that Hypothesis 2 contradicts the Text, similar steps are required, together with the inference that because the stated purchase price is different in the Text and Hypothesis, but with high probability refers to the same transaction, Hypothesis 2 contradicts the Text.

It could be argued that this particular example might be resolved by simple lexical matching; but it should be evident that the Text can be made lexically very dissimilar to Hypothesis 1 while maintaining the Entailment relation, and that conversely, the lexical overlap between the Text and Hypothesis 2 can be made very high, while maintaining the Contradiction relation. This intuition is borne out by the results of the RTE challenges, which show that lexical similarity-based systems are outperformed by systems that use other, more structured analysis, as shown in the next section.

J						**1.000** (224,178)

Table 2: In each cell, top row shows observed agreement and bottom row shows the number of correct (positive, negative) examples on which the pair of systems agree.

2.2 The State of the Art in RTE 5

The outputs for all systems that participated in the RTE 5 challenge were made available to participants. We compared these to each other and to a smart lexical baseline (Do et al., 2010) (lexical match augmented with a WordNet similarity measure, stemming, and a large set of low-semantic-content stopwords) to assess the diversity of the approaches of different research groups. To get the fullest range of participants, we used results from the two-way RTE task. We have anonymized the system names.

Table 1 shows that many participating systems significantly outperform our smart lexical baseline. Table 2 reports the observed agreement between systems and the lexical baseline in terms of the percentage of examples on which a pair of systems gave the same label. The agreement between most systems and the baseline is about 67%, which suggests that systems are not simply augmented versions of the lexical baseline, and are also distinct from each other in their behaviors.[2]

Common characteristics of RTE systems re-

[2]Note that the expected agreement between two random RTE decision-makers is 0.5, so the agreement scores according to Cohen's Kappa measure (Cohen, 1960) are between 0.3 and 0.4.

ported by their designers were the use of structured representations of shallow semantic content (such as augmented dependency parse trees and semantic role labels); the application of NLP resources such as Named Entity recognizers, syntactic and dependency parsers, and coreference resolvers; and the use of special-purpose ad-hoc modules designed to address specific entailment phenomena the researchers had identified, such as the need for numeric reasoning. However, it is not possible to objectively assess the role these capabilities play in each system's performance from the system outputs alone.

2.3 The Need for Detailed Evaluation

An ablation study that formed part of the official RTE 5 evaluation attempted to evaluate the contribution of publicly available knowledge resources such as WordNet (Fellbaum, 1998), VerbOcean (Chklovski and Pantel, 2004), and DIRT (Lin and Pantel, 2001) used by many of the systems. The observed contribution was in most cases limited or non-existent. It is premature, however, to conclude that these resources have little potential impact on RTE system performance: most RTE researchers agree that the real contribution of individual resources is difficult to assess. As the example in figure 1 illustrates, most RTE examples require a number of phenomena to be correctly resolved in order to reliably determine the correct label (the Interaction problem); a perfect coreference resolver might as a result yield little improvement on the standard RTE evaluation, even though coreference resolution is clearly required by human readers in a significant percentage of RTE examples.

Various efforts have been made by individual research teams to address specific capabilities that are intuitively required for good RTE performance, such as (de Marneffe et al., 2008), and the formal treatment of entailment phenomena in (MacCartney and Manning, 2009) depends on and formalizes a divide-and-conquer approach to entailment resolution. But the phenomena-specific capabilities described in these approaches are far from complete, and many are not yet invented. To devote real effort to identify and develop such capabilities, researchers must be confident that the resources (and the will!) exist to create and evaluate their solutions, and that the resource can be shown to be relevant to a sufficiently large subset of the NLP community. While there is widespread belief that there are many relevant entailment phenomena, though each individually may be relevant to relatively few RTE examples (the Sparseness problem), we know of no systematic analysis to determine what those phenomena are, and how sparsely represented they are in existing RTE data.

If it were even known what phenomena were relevant to specific entailment examples, it might be possible to more accurately distinguish system capabilities, and promote adoption of successful solutions to sub-problems. An annotation-side solution also maintains the desirable agnosticism of the RTE problem formulation, by not imposing the requirement on system developers of generating an explanation for each answer. Of course, if examples were also annotated with explanations in a consistent format, this could form the basis of a new evaluation of the kind essayed in the pilot study in (Giampiccolo et al., 2007).

3 Annotation Proposal and Pilot Study

As part of our challenge to the NLP community, we propose a distributed OntoNotes-style approach (Hovy et al., 2006) to this annotation effort: distributed, because it should be undertaken by a diverse range of researchers with interests in different semantic phenomena; and similar to the OntoNotes annotation effort because it should not presuppose a fixed, closed ontology of entailment phenomena, but rather, iteratively hypothesize and refine such an ontology using inter-annotator agreement as a guiding principle. Such an effort would require a steady output of RTE examples to form the underpinning of these annotations; and in order to get sufficient data to represent less common, but nonetheless important, phenomena, a large body of data is ultimately needed.

A research team interested in annotating a new phenomenon should use examples drawn from the common corpus. Aside from any task-specific gold standard annotation they add to the entailment pairs, they should augment existing explanations by indicating in which examples their phenomenon occurs, and at which point in the existing explanation for each example. In fact, this latter effort – identifying phenomena relevant to textual inference, marking relevant RTE examples, and generating explanations – itself enables other researchers to select from known problems, assess their likely impact, and automatically generate rel-

evant corpora.

To assess the feasibility of annotating RTE-oriented local entailment phenomena, we developed an inference model that could be followed by annotators, and conducted a pilot annotation study. We based our initial effort on observations about RTE data we made while participating in RTE challenges, together with intuitive conceptions of the kinds of knowledge that might be available in semi-structured or structured form. In this section, we present our annotation inference model, and the results of our pilot annotation effort.

3.1 Inference Process

To identify and annotate RTE sub-phenomena in RTE examples, we need a defensible model for the entailment process that will lead to consistent annotation by different researchers, and to an extensible framework that can accommodate new phenomena as they are identified.

We modeled the entailment process as one of manipulating the text and hypothesis to be as similar as possible, by first identifying parts of the text that matched parts of the hypothesis, and then identifying connecting structure. Our inherent assumption was that the meanings of the Text and Hypothesis could be represented as sets of n-ary relations, where relations could be connected to other relations (i.e., could take other relations as arguments). As we followed this procedure for a given example, we marked which entailment phenomena were required for the inference. We illustrate the process using the example in figure 1.

First, we would identify the arguments "BMI" and "another company" in the Hypothesis as matching "BMI" and "LexCorp" respectively, requiring 1) *Parent-Sibling* to recognize that "LexCorp" can match "company". We would tag the example as requiring 2) *Nominalization Resolution* to make "purchase" the active relation and 3) *Passivization* to move "BMI" to the subject position. We would then tag it with 4) *Simple Verb Rule* to map "A purchase B" to "A acquire B". These operations make the relevant portion of the Text identical to the Hypothesis, so we are done.

For the same Text, but with Hypothesis 2 (a negative example), we follow the same steps 1-3. We would then use 4) *Lexical Relation* to map "purchase" to "buy". We would then observe that the only possible match for the hypothesis argument "for $3.4Bn" is the text argument "for $2Bn". We would label this as a 5) *Numerical Quantity Mismatch* and 6) *Excluding Argument* (it can't be the case that in the same transaction, the same company was sold for two different prices).

Note that neither explanation mentions the anaphora resolution connecting "they" to "traders", because it is not strictly required to determine the entailment label.

As our example illustrates, this process makes sense for both positive and negative examples. It also reflects common approaches in RTE systems, many of which have explicit alignment components that map parts of the Hypothesis to parts of the Text prior to a final decision stage.

3.2 Annotation Labels

We sought to identify roles for background knowledge in terms of domains and general inference steps, and the types of linguistic phenomena that are involved in representing the same information in different ways, or in detecting key differences in two similar spans of text that indicate a difference in meaning. We annotated examples with domains (such as "Work") for two reasons: to establish whether some phenomena are correlated with particular domains; and to identify domains that are sufficiently well-represented that a knowledge engineering study might be possible.

While we did not generate an explicit representation of our entailment process, i.e. explanations, we tracked which phenomena were strictly required for inference. The annotated corpora and simple CGI scripts for annotation are available at *http://cogcomp.cs.illinois.edu/Data/ACL2010_RTE.php*.

The phenomena that we considered during annotation are presented in Tables 3, 4, 5, and 6. We tried to define each phenomenon so that it would apply to both positive and negative examples, but ran into a problem: often, negative examples can be identified principally by structural differences: the components of the Hypothesis all match components in the Text, but they are not connected by the appropriate structure in the Text. In the case of contradictions, it is often the case that a key relation in the Hypothesis must be matched to an incompatible relation in the Text. We selected names for these structural behaviors, and tagged them when we observed them, but the counterpart for positive examples must always hold: it must necessarily be the case that the structure in the Text linking the arguments that match those in the

Hypothesis must be comparable to the Hypothesis structure. We therefore did not tag this for positive examples.

We selected a subset of 210 examples from the NIST TAC RTE 5 (Bentivogli et al., 2009) Test set drawn equally from the three sub-tasks (IE, IR and QA). Each example was tagged by both annotators. Two passes were made over the data: the first covered 50 examples from each RTE sub-task, while the second covered an additional 20 examples from each sub-task. Between the two passes, concepts the annotators identified as difficult to annotate were discussed and more carefully specified, and several new concepts were introduced based on annotator observations.

Tables 3, 4, 5, and 6 present information about the distribution of the phenomena we tagged, and the inter-annotator agreement (Cohen's Kappa (Cohen, 1960)) for each. "Occurrence" lists the average percentage of examples labeled with a phenomenon by the two annotators.

Domain	Occurrence	Agreement
work	16.90%	0.918
name	12.38%	0.833
die kill injure	12.14%	0.979
group	9.52%	0.794
be in	8.57%	0.888
kinship	7.14%	1.000
create	6.19%	1.000
cause	6.19%	0.854
come from	5.48%	0.879
win compete	3.10%	0.813
Others	29.52%	0.864

Table 3: Occurrence statistics for domains in the annotated data.

Phenomenon	Occurrence	Agreement
Named Entity	91.67%	0.856
locative	17.62%	0.623
Numerical Quantity	14.05%	0.905
temporal	5.48%	0.960
nominalization	4.05%	0.245
implicit relation	1.90%	0.651

Table 4: Occurrence statistics for hypothesis structure features.

From the tables it is apparent that good performance on a range of phenomena in our inference model are likely to have a significant effect on RTE results, with coreference being deemed essential to the inference process for 35% of examples, and a number of other phenomena are sufficiently well represented to merit near-future attention (assuming that RTE systems do not already handle these phenomena, a question we address in section 4). It is also clear from the predominance of *Simple Rewrite Rule* instances, together with the frequency of most of the domains we selected, that knowledge engineering efforts also have a key role in improving RTE performance.

Phenomenon	Occurrence	Agreement
coreference	35.00%	0.698
simple rewrite rule	32.62%	0.580
lexical relation	25.00%	0.738
implicit relation	23.33%	0.633
factoid	15.00%	0.412
parent-sibling	11.67%	0.500
genetive relation	9.29%	0.608
nominalization	8.33%	0.514
event chain	6.67%	0.589
coerced relation	6.43%	0.540
passive-active	5.24%	0.583
numeric reasoning	4.05%	0.847
spatial reasoning	3.57%	0.720

Table 5: Occurrence statistics for entailment phenomena and knowledge resources

Phenomenon	Occurrence	Agreement
missing argument	16.19%	0.763
missing relation	14.76%	0.708
excluding argument	10.48%	0.952
Named Entity mismatch	9.29%	0.921
excluding relation	5.00%	0.870
disconnected relation	4.52%	0.580
missing modifier	3.81%	0.465
disconnected argument	3.33%	0.764
Numeric Quant. mismatch	3.33%	0.882

Table 6: Occurrences of negative-only phenomena

3.3 Discussion

Perhaps surprisingly, given the difficulty of the task, inter-annotator agreement was consistently good to excellent (above 0.6 and 0.8, respectively), with few exceptions, indicating that for most targeted phenomena, the concepts were well-specified. The results confirmed our initial intuition about some phenomena: for example, that coreference resolution is central to RTE, and that detecting the connecting structure is crucial in discerning negative from positive examples. We also found strong evidence that the difference between contradiction and unknown entailment examples is often due to the behavior of certain relations that either preclude certain other relations holding between the same arguments (for example, winning a contest vs. losing a contest), or which can only hold for a single referent in one argument position (for example, "work" relations such as job title are typically constrained so that a single person holds one position).

We found that for some examples, there was more than one way to infer the hypothesis from the text. Typically, for positive examples this involved overlap between phenomena; for example, Coreference might be expected to resolve implicit rela-

tions induced from appositive structures. In such cases we annotated every way we could find.

In future efforts, annotators should record the entailment steps they used to reach their decision. This will make disagreement resolution simpler, and could also form a possible basis for generating gold standard explanations. At a minimum, each inference step must identify the spans of the Text and Hypothesis that are involved and the name of the entailment phenomenon represented; in addition, a partial order over steps must be specified when one inference step requires that another has been completed.

Future annotation efforts should also add a category "Other", to indicate for each example whether the annotator considers the listed entailment phenomena sufficient to identify the label. It might also be useful to assess the difficulty of each example based on the time required by the annotator to determine an explanation, for comparison with RTE system errors.

These, together with specifications that minimize the likely disagreements between different groups of annotators, are processes that must be refined as part of the broad community effort we seek to stimulate.

4 Pilot RTE System Analysis

In this section, we sketch out ways in which the proposed analysis can be applied to learn something about RTE system behavior, even when those systems do not provide anything beyond the output label. We present the analysis in terms of sample questions we hope to answer with such an analysis.

1. If a system needs to improve its performance, which features should it concentrate on? To answer this question, we looked at the top-5 systems and tried to find which phenomena are active in the mistakes they make.

(a) Most systems seem to fail on examples that need *numeric reasoning* to get the entailment decision right. For example, system H got all 10 examples with numeric reasoning wrong.

(b) All top-5 systems make consistent errors in cases where identifying a mismatch in named entities (NE) or numerical quantities (NQ) is important to make the right decision. System G got 69% of cases with NE/NQ mismatches wrong.

(c) Most systems make errors in examples that have a disconnected or exclusion component (argument/relation). System J got 81% of cases with a disconnected component wrong.

(d) Some phenomena are handled well by certain systems, but not by others. For example, failing to recognize a parent-sibling relation between entities/concepts seems to be one of the top-5 phenomena active in systems E and H. System H also fails to correctly label over 53% of the examples having kinship relation.

2. Which phenomena have strong correlations to the entailment labels among hard examples? We called an example hard if at least 4 of the top 5 systems got the example wrong. In our annotation dataset, there were 41 hard examples. Some of the phenomena that strongly correlate with the TE labels on hard examples are: deeper lexical relation between words ($\rho = 0.542$), and need for external knowledge ($\rho = 0.345$). Further, we find that the top-5 systems tend to make mistakes in cases where the lexical approach also makes mistakes ($\rho = 0.355$).

3. What more can be said about individual systems? In order to better understand the system behavior, we wanted to check if we could predict the system behavior based on the phenomena we identified as important in the examples. We learned SVM classifiers over the identified phenomena and the lexical similarity score to predict both the labels and errors systems make for each of the top-5 systems. We could predict all 10 system behaviors with over 70% accuracy, and could predict labels and mistakes made by two of the top-5 systems with over 77% accuracy. This indicates that although the identified phenomena are indicative of the system performance, it is probably too simplistic to assume that system behavior can be easily reproduced solely as a disjunction of phenomena present in the examples.

4. Does identifying the phenomena correctly help learn a better TE system? We tried to learn an entailment classifier over the phenomenon identified and the top 5 system outputs. The results are summarized in Table 7. All reported numbers are 20-fold cross-validation accuracy from an SVM classifier learned over the features mentioned. The results show that correctly identifying the named-entity and numeric quantity mis-

No.	Feature description	No. of feats	Accuracy over which features	
			phenomena	pheno. + sys. labels
(0)	Only system labels	5	—	0.714
(1)	Domain and hypothesis features (Tables 3, 4)	16	0.510	0.705
(2)	(1) + NE + NQ	18	0.619	0.762
(3)	(1) + Knowledge resources (subset of Table 5)	22	0.662	0.762
(4)	(3) + NE + NQ	24	0.738	0.805
(5)	(1) + Entailment and Knowledge resources (Table 5)	29	0.748	0.791
(6)	(5) + negative-only phenomena (Table 6)	38	0.971	0.943

Table 7: Accuracy in predicting the label based on the phenomena and top-5 system labels.

matches improves the overall accuracy significantly. If we further recognize the need for knowledge resources correctly, we can correctly explain the label for 80% of the examples. Adding the entailment and negation features helps us explain the label for 97% of the examples in the annotated corpus.

It must be clarified that the results do not show the textual entailment problem itself is solved with 97% accuracy. However, we believe that if a system could recognize key negation phenomena such as *Named Entity mismatch*, presence of *Excluding arguments*, etc. correctly and consistently, it could model them as a *Contradiction* features in the final inference process to significantly improve its overall accuracy. Similarly, identifying and resolving the key entailment phenomena in the examples, would boost the inference process in positive examples. However, significant effort is still required to obtain near-accurate knowledge and linguistic resources.

5 Discussion

NLP researchers in the broader community continually seek new problems to solve, and pose more ambitious tasks to develop NLP and NLU capabilities, yet recognize that even solutions to problems which are considered "solved" may not perform as well on domains different from the resources used to train and develop them. Solutions to such NLP tasks could benefit from evaluation and further development on corpora drawn from a range of domains, like those used in RTE evaluations.

It is also worthwhile to consider each task as part of a larger inference process, and therefore motivated not just by performance statistics on special-purpose corpora, but as part of an interconnected web of resources; and the task of Recognizing Textual Entailment has been designed to exercise a wide range of linguistic and reasoning capabilities.

The entailment setting introduces a potentially broader context to resource development and assessment, as the hypothesis and text provide context for each other in a way different than local context from, say, the same paragraph in a document: in RTE's positive examples, the Hypothesis either restates some part of the Text, or makes statements inferable from the statements in the Text. This is not generally true of neighboring sentences in a document. This distinction opens the door to "purposeful", or goal-directed, inference in a way that may not be relevant to a task studied in isolation.

The RTE community seems mainly convinced that incremental advances in local entailment phenomena (including application of world knowledge) are needed to make significant progress. They need ways to identify sub-problems of textual inference, and to evaluate those solutions both in isolation and in the context of RTE. RTE system developers are likely to reward well-engineered solutions by adopting them and citing their authors, because such solutions are easier to incorporate into RTE systems. They are also more likely to adopt solutions with established performance levels. These characteristics promote publication of software developed to solve NLP tasks, attention to its usability, and publication of materials supporting reproduction of results presented in technical papers.

For these reasons, we assert that RTE is a natural motivator of new NLP tasks, as researchers look for components capable of improving performance; and that RTE is a natural setting for evaluating solutions to a broad range of NLP problems, though not in its present formulation: we must solve the problem of credit assignment, to recognize component contributions. We have therefore proposed a suitable annotation effort, to provide the resources necessary for more detailed evaluation of RTE systems.

We have presented a linguistically-motivated

analysis of entailment data based on a step-wise procedure to resolve entailment decisions, intended to allow independent annotators to reach consistent decisions, and conducted a pilot annotation effort to assess the feasibility of such a task.

We do not claim that our set of domains or phenomena are complete: for example, our illustrative example could be tagged with a domain *Mergers and Acquisitions*, and a different team of researchers might consider *Nominalization Resolution* to be a subset of *Simple Verb Rules*. This kind of disagreement in coverage is inevitable, but we believe that in many cases it suffices to introduce a new domain or phenomenon, and indicate its relation (if any) to existing domains or phenomena. In the case of introducing a non-overlapping category, no additional information is needed. In other cases, the annotators can simply indicate the phenomena being merged or split (or even replaced). This information will allow other researchers to integrate different annotation sources and maintain a consistent set of annotations.

6 Conclusions

In this paper, we have presented a case for a broad, long-term effort by the NLP community to coordinate annotation efforts around RTE corpora, and to evaluate solutions to NLP tasks relating to textual inference in the context of RTE. We have identified limitations in the existing RTE evaluation scheme, proposed a more detailed evaluation to address these limitations, and sketched a process for generating this annotation. We have proposed an initial annotation scheme to prompt discussion, and through a pilot study, demonstrated that such annotation is both feasible and useful.

We ask that researchers not only contribute task specific annotation to the general pool, and indicate how their task relates to those already added to the annotated RTE corpora, but also invest the additional effort required to augment the cross-domain annotation: marking the examples in which their phenomenon occurs, and augmenting the annotator-generated explanations with the relevant inference steps.

These efforts will allow a more meaningful evaluation of RTE systems, and of the component NLP technologies they depend on. We see the potential for great synergy between different NLP subfields, and believe that all parties stand to gain from this collaborative effort. We therefore respectfully suggest that you "ask not what RTE can do for you, but what you can do for RTE..."

Abstract

Discourse references, notably coreference and bridging, play an important role in many text understanding applications, but their impact on textual entailment is yet to be systematically understood. On the basis of an in-depth analysis of entailment instances, we argue that discourse references have the potential of substantially improving textual entailment recognition, and identify a number of research directions towards this goal.

1 Introduction

The detection and resolution of *discourse references* such as coreference and bridging anaphora play an important role in text understanding applications, like question answering and information extraction. There, reference resolution is used for the purpose of combining knowledge from multiple sentences. Such knowledge is also important for Textual Entailment (TE), a generic framework for modeling semantic inference. TE reduces the inference requirements of many text understanding applications to the problem of determining whether the meaning of a given textual assertion, termed *hypothesis* (H), can be inferred from the meaning of certain *text* (T) (Dagan et al., 2006).

Consider the following example:

(1) T: "*Not only had he developed an aversion to the* ***President***$_1$ *and politics in general,* ***Oswald***$_2$ *was also a failure with Marina, his wife. [...] Their relationship was supposedly responsible for why* ***he***$_2$ *killed* ***Kennedy***$_1$."

H: "*Oswald killed President Kennedy.*"

The understanding that the second sentence of the text entails the hypothesis draws on two coreference relationships, namely that *he* is *Oswald*, and that the *Kennedy* in question is *President Kennedy*. However, the utilization of discourse information for such inferences has been so far limited mainly to the substitution of nominal coreferents, while many aspects of the interface between discourse and semantic inference needs remain unexplored.

The recently held Fifth Recognizing Textual Entailment (RTE-5) challenge (Bentivogli et al., 2009a) has introduced a *Search* task, where the text sentences are interpreted in the context of their full discourse, as in Example 1 above. Accordingly, TE constitutes an interesting framework – and the Search task an adequate dataset – to study the interrelation between discourse and inference.

The goal of this study is to analyze the roles of discourse references for textual entailment inference, to provide relevant findings and insights to developers of both reference resolvers and entailment systems and to highlight promising directions for the better incorporation of discourse phenomena into inference. Our focus is on a manual, in-depth assessment that results in a classification and quantification of discourse reference phenomena and their utilization for inference. On this basis, we develop an account of formal devices for incorporating discourse references into the inference computation. An additional point of interest is the interrelation between entailment knowledge and coreference. E.g., in Example 1 above, knowing that Kennedy was a president can alleviate the need for coreference resolution. Conversely, coreference resolution can often be used to overcome gaps in entailment knowledge.

Structure of the paper. In Section 2, we provide background on the use of discourse references in natural language processing (NLP) in general and specifically in TE. Section 3 describes the goals of this study, followed by our analysis scheme (Section 4) and the required inference

mechanisms (Section 5). Section 6 presents quantitative findings and further observations. Conclusions are discussed in Section 7.

2 Background

2.1 Discourse in NLP

Discourse information plays a role in a range of NLP tasks. It is obviously central to *discourse processing* tasks such as text segmentation (Hearst, 1997). Reference information provided by discourse is also useful for *text understanding* tasks such as question answering (QA), information extraction (IE) and information retrieval (IR) (Vicedo and Ferrndez, 2006; Zelenko et al., 2004; Na and Ng, 2009), as well as for the acquisition of lexical-semantic "narrative schema" knowledge (Chambers and Jurafsky, 2009). Discourse references have been the subject of attention in both the Message Understanding Conference (Grishman and Sundheim, 1996) and the Automatic Content Extraction program (Strassel et al., 2008).

The simplest form of information that discourse provides is *coreference*, i.e., information that two linguistic expressions refer to the same entity or event. Coreference is particularly important for processing pronouns and other anaphoric expressions, such as *he* in Example 1. Ability to resolve this reference translates directly into, e.g., a QA system's ability to answer questions like *Who killed Kennedy?*.

A second, more complex type of information stems from *bridging references*, such as in the following discourse (Asher and Lascarides, 1998):

(2) "*I've just **arrived**. The **camel** is outside.*"

While coreference indicates equivalence, bridging points to the existence of a salient semantic relation between two distinct entities or events. Here, it is (informally) *'means of transport'*, which would make the discourse (2) relevant for a question like *How did I arrive here?*. Other types of bridging relations include set-membership, roles in events and consequence (Clark, 1975).

Note, however, that text understanding systems are generally limited to the resolution of entity (or even just pronoun) coreference, e.g. (Li et al., 2009; Dali et al., 2009). An important reason is the unavailability of tools to resolve the more complex (and difficult) forms of discourse reference such as event coreference and bridging.[1] Another reason is uncertainty about their practical importance.

2.2 Discourse in Textual Entailment

Textual Entailment has been introduced in Section 1 as a common-sense notion of inference. It has spawned interest in the computational linguistics community as a common denominator of many NLP tasks including IE, summarization and tutoring (Romano et al., 2006; Harabagiu et al., 2007; Nielsen et al., 2009).

Architectures for Textual Entailment. Over the course of recent RTE challenges (Giampiccolo et al., 2007; Giampiccolo et al., 2008), the main benchmark for TE technology, two architectures for modeling TE have emerged as dominant: *transformations* and *alignment*. The goal of ***transformation***-based TE models is to determine the entailment relation $T \Rightarrow H$ by finding a "proof", i.e., a sequence of consequents, $(T, T_1, \ldots, T_n)$, such that T_n=H (Bar-Haim et al., 2008; Harmeling, 2009), and that in each transformation, $T_i \rightarrow T_{i+1}$, the consequent T_{i+1} is entailed by T_i. These transformations commonly include lexical modifications and the generation of syntactic alternatives. The second major approach constructs an ***alignment*** between the linguistic entities of the trees (or graphs) of T and H, which can represent syntactic structure, semantic structure, or non-hierarchical phrases (Zanzotto et al., 2009; Burchardt et al., 2009; MacCartney et al., 2008). H is assumed to be entailed by T if its entities are aligned "well" to corresponding entities in T. Alignment quality is generally determined based on features that assess the validity of the local replacement of the T entity by the H entity.

While transformation- and alignment-based entailment models look different at first glance, they ultimately have the same goal, namely obtaining a maximal *coverage* of H by T, i.e. to identify matches of as many elements of H within T as possible.[2] To do so, both architectures typically make use of *inference rules* such as '*Y was purchased by X* $\rightarrow$ *X paid for Y*', either by directly applying them as transformations, or by using them

[1] Some studies, e.g. (Markert et al., 2003; Poesio et al., 2004), address the resolution of a few specific kinds of bridging relations; yet, wide-scope systems for bridging resolution are unavailable.

[2] Clearly, the details of how the final entailment decision is made based on the attained coverage differ substantially among models.

to score alignments. Rules are generally drawn from external knowledge resources, such as WordNet (Fellbaum, 1998) or DIRT (Lin and Pantel, 2001), although knowledge gaps remain a key obstacle (Bos, 2005; Balahur et al., 2008; Bar-Haim et al., 2008).

Discourse in previous RTE challenges. The first two rounds of the RTE challenge used "self-contained" texts and hypotheses, where discourse considerations played virtually no role. A first step towards a more comprehensive notion of entailment was taken with RTE-3 (Giampiccolo et al., 2007), when paragraph-length texts were first included and constituted 17% of the texts in the test set. Chambers et al. (2007) report that in a sample of $T - H$ pairs drawn from the development set, 25% involved discourse references.

Using the concepts introduced above, the impact of discourse references can be generally described as a *coverage problem*, independent of the system's architecture. In Example 1, the hypothesis word *Oswald* cannot be safely linked to the text pronoun *he* without further knowledge about *he*; the same is true for '*Kennedy* $\rightarrow$ *President Kennedy*' which involves a specialization that is only warranted in the specific discourse.

A number of systems have tried to address the question of coreference in RTE as a preprocessing step prior to inference proper, with most systems using off-the-shelf coreference resolvers such as JavaRap (Qiu et al., 2004) or OpenNLP[3]. Generally, anaphoric expressions were textually replaced by their antecedents. Results were inconclusive, however, with several reports about errors introduced by automatic coreference resolution (Agichtein et al., 2008; Adams et al., 2007). Specific evaluations of the contribution of coreference resolution yielded both small negative (Bar-Haim et al., 2008) and insignificant positive (Chambers et al., 2007) results.

3 Motivation and Goals

The results of recent studies, as reported in Section 2.2, seem to show that current resolution of discourse references in RTE systems hardly affects performance. However, our intuition is that these results can be attributed to four major limitations shared by these studies: (1) the datasets, where discourse phenomena were not well represented; (2) the off-the-shelf coreference resolution systems which may have been not robust enough; (3) the limitation to nominal coreference; and (4) overly simple integration of reference information into the inference engines.

The goal of this paper is to assess the impact of discourse references on entailment with an annotation study which removes these limitations. To counteract (1), we use the recent RTE-5 Search dataset (details below). To avoid (2), we perform a manual analysis, assuming discourse references as predicted by an oracle. With regards to (3), our annotation scheme covers coreference and bridging relations of all syntactic categories and classifies them. As for (4), we suggest several operations necessary to integrate the discourse information into an entailment engine.

In contrast to the numerous existing datasets annotated for discourse references (Hovy et al., 2006; Strassel et al., 2008), we do not annotate exhaustively. Rather, we are interested specifically in those references instances that impact inference. Furthermore, we analyze each instance from an entailment perspective, characterizing the relevant factors that have an impact on inference. To our knowledge, this is the first such in-depth study.[4]

The results of our study are of twofold interest. First, they provide guidance for the developers of reference resolvers who might prioritize the scope of their systems to make them more valuable for inference. Second, they point out potential directions for the developers of inference systems by specifying what additional inference mechanisms are needed to utilize discourse information.

The RTE-5 Search dataset. We base our annotation on the Search task dataset, a new addition to the recent Fifth RTE challenge (Bentivogli et al., 2009a) that is motivated by the needs of NLP applications and drawn from the TAC summarization track. In the Search task, TE systems are required to find *all* individual sentences in a given corpus which entail the hypothesis – a setting that is sensible not only for summarization, but also for information access tasks like QA. Sentences are judged individually, but "are to be interpreted in the context of the corpus as they rely on explicit and implicit references to entities, events, dates, places, etc., mentioned elsewhere in the corpus" (Bentivogli et al., 2009b).

Table 1: Examples for discourse-dependent entailment in the RTE-5 dataset, where the inference of H depends on reference information from the discourse sentences T' / T''. Referring terms (in T) and target terms (in H) are shown in boldface.

4 Analysis Scheme

For annotating the RTE-5 data, we operationalize reference relations that are *relevant* for entailment as those that improve *coverage*. Recall from Section 2.2 that the concept of coverage is applicable to both transformation and alignment models, all of which aim at maximizing coverage of H by T.

We represent T and H as syntactic trees, as common in the RTE literature (Zanzotto et al., 2009; Agichtein et al., 2008). Specifically, we assume MINIPAR-style (Lin, 1993) dependency trees where nodes represent text expressions and edges represent the syntactic relations between them. We use "term" to refer to text expressions, and "components" to refer to nodes, edges, and subtrees. Dependency trees are a popular choice in RTE since they offer a fairly semantics-oriented account of the sentence structure that can still be constructed robustly. In an ideal case of entailment, all nodes *and* dependency edges of H are covered by T.

For each $T - H$ pair, we annotate all relevant discourse references in terms of three items: the *target component* in H, the *focus term* in T, and the *reference term* which stands in a reference relation to the focus term. By resolving this reference, the target component can usually be inferred; sometimes, however, more than one reference term needs to be found. We now define and illustrate these concepts on examples from Table 1.[5]

The ***target component*** is a tree component in H that cannot be covered by the "local" material from T. An example for a tree component is Example (v), where the target component *AS-28 mini submarine* in H cannot be inferred from the pronoun *it* in T. Example (vi) demonstrates an edge as target component. In this case, the edge in H connecting *melt* with the modifier *in the Arctic* is not found in T. Although each of the hypothesis' nodes can be covered separately via knowledge-based rules (e.g. '*Siberia* → *Arctic*', '*permafrost* → *ice*', '*thaw* ↔ *melt*'), the resulting fragments in T are unconnected without the (intra-sentential) coreference between *them* and *lakes in Siberia*.

For each target component, we identify its ***focus term*** as the expression in T that does not cover the target component itself but participates in a reference relation that can help covering it.

We follow the focus term's reference chain to a ***reference term*** which can, either separately or in combination with the focus term, help covering the target component. In Example (ii), where the

[5] In our annotation, we assume throughout that some knowledge about basic admissible transformations is available, such as passive to active or derivational transformations; for brevity, we ignore articles in the examples and treat named entities as single nodes.

target component in H is *2003 UB313*, *Xena* is the focus term in T and the reference term is a mention of *2003 UB313* in a previous sentence, T'. In this case, the reference term covers the entire target component on its own.

An additional attribute that we record for each instance is whether resolving the discourse reference is *mandatory* for determining entailment, or *optional*. In Example (v), it is mandatory: the inference cannot be completed without the knowledge provided by the discourse. In contrast, in Example (ii), inferring *2003 UB313* from *Xena* is optional. It can be done either by identifying their coreference relation, or by using background knowledge in the form of an entailment rule, '*Xena* $\leftrightarrow$ *2003 UB313*', that is applicable in the context of astronomy. Optional discourse references represent instances where discourse information and TE knowledge are interchangeable. As mentioned, knowledge gaps constitute a major obstacle for TE systems, and we cannot rely on the availability of any ceratin piece of knowledge to the inference process. Thus, in our scheme, mandatory references provide a "lower bound" with regards to the necessity to resolve discourse references, even in the presence of *complete knowledge*; optional references, on the other hand, set an "upper bound" for the contribution of discourse resolution to inference, when *no knowledge* is available. At the same time, this scheme allows investigating how much TE knowledge can be replaced by (perfect) discourse processing.

When choosing a reference term, we search the reference chain of the focus term for the nearest expression that is identical to the target component or a subcomponent of it. If we find such an expression, covering the identical part of the target component requires no entailment knowledge. If no identical reference term exists, we choose the semantically 'closest' term from the reference chain, i.e. the term which requires the least knowledge to infer the target component. For instance, we may pick *permafrost* as the semantically closet term to the target *ice* if the latter is not found in the focus term's reference chain.

Finally, for each reference relation that we annotate, we record four additional attributes which we assumed to be informative in an evaluation. First, the *reference type*: Is the relation a coreference or a bridging reference? Second, the *syntactic type* of the focus and reference terms. Third, the *focus/reference terms entailment status* – does some kind of entailment relation hold between the two terms? Fourth, the *operation* that should be performed on the focus and reference terms to obtain coverage of the target component (as specified in Section 5).

5 Integrating Discourse References into Entailment Recognition

In initial analysis we found that the standard substitution operation applied by virtually all previous studies for integrating coreference into entailment is insufficient. We identified three distinct cases for the integration of discourse reference knowledge in entailment, which correspond to different relations between the target component, the focus term and the reference term. This section describes the three cases and characterizes them in terms of tree transformations. An initial version of these transformations is described in (Abad et al., 2010). We assume a transformation-based entailment architecture (cf. Section 2.2), although we believe that the key points of our account are also applicable to alignment-based architecture. Transformations create revised trees that cover previously uncovered target components in H. The output of each transformation, T_1, is comprised of copies of the components used to construct it, and is appended to the discourse forest, which includes the dependency trees of all sentences and their generated consequents.

We assume that we have access to a dependency tree for H, a dependency forest for T and its discourse context, as well as the output of a perfect discourse processor, i.e., a complete set of both coreference and bridging relations, including the type of bridging relation (e.g. *part-of*, *cause*).

We use the following notation. We use x, y for tree nodes, and S_x to denote a (sub-)tree with root x. $lab(x)$ is the label of the incoming edge of x (i.e., its grammatical function). We write $C(x, y)$ for a coreference relation between S_x and S_y, the corresponding trees of the focus and reference terms, respectively. We write $B_r(x, y)$ for a bridging relation, where r is its type.

(1) Substitution: This is the most intuitive and widely-used transformation, corresponding to the treatment of discourse information in existing systems. It applies to coreference relations, when an expression found elsewhere in the text (the reference term) can cover all missing information (the

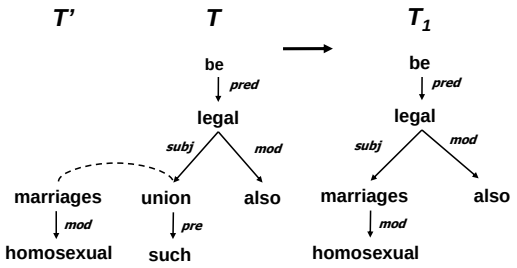

Figure 1: The *Substitution* transformation, demonstrated on the relevant subtrees of Example (i). The dashed line denotes a discourse reference.

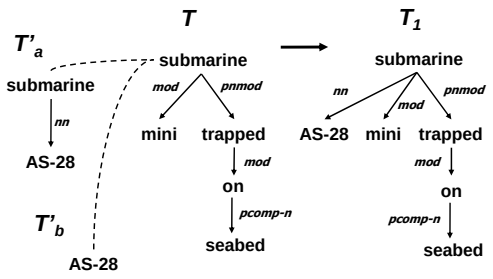

Figure 2: The *dependent-merge* (T'_a) and *head-merge* (T'_b) transformations (Example (iii)).

target component) on its own. In such cases, the reference term can replace the entire focus term. Apparently (cf. Section 6), substitution applies also to some types of bridging relations, such as *set-membership*, when the member is sufficient for representing the entire set for the necessary inference. For example, in "*I met two people yesterday. The woman told me a story.*" (Clark, 1975), substituting *two people* with *woman* results in a text which is entailed from the discourse, and which allows inferring "*I met a woman yesterday.*"

In a parse tree representation, given a coreference relation $C(x, y)$ (or $B_r(x, y)$), the newly generated tree, T_1, consists of a copy of T, where the entire tree S_x is replaced by a copy of S_y . In Figure 1, which shows Example (i) from Table 1, *such unions* is substituted by *homosexual marriages*.

Head-substitution. Occasionally, substituting only the head of the focus term is sufficient. In such cases, only the root nodes x and y are substituted. This is the case, for example, with synonymous verbs with identical subcategorization frames (like *melt* and *thaw*). As verbs typically constitute tree roots in dependency parses, substituting or merging (see below) their entire trees might be inappropriate or wasteful. In such cases, the simpler head-substitution may be applied.

(2) Merge: In contrast to substitution, where a match for the entire target component is found elsewhere in the text, this transformation is required when parts of the missing information are scattered among multiple locations in the text. We distinguish between two types of merge transformations: (a) *dependent-merge*, and (b) *head-merge*, depending on the syntactic roles of the merged components.

(a) Dependent-Merge. This operation is applicable when the head of either the focus or reference terms (of both) matches the head node of the target component, but modifiers from both of them are required to cover the target component's dependents. The modifiers are therefore merged as dependents of a single head node, to create a tree that covers the entire target component. Dependent-merge is illustrated in Figure 2, using Example (iii). The component we wish to cover in H is the noun phrase *AS-28 mini submarine*. Unfortunately, the focus term in T, "*mini submarine trapped on the seabed*", covers only the modifier *mini*, but not *AS-28*. This modifier can however be provided by the coreferent term in T'_a (left upper corner). Once merged, the inference engine can, e.g., employ the rule '*on seabed* → *underwater*' to cover H completely.

Formally, assume without loss of generality that y, the reference term's head, matches the root node of the target component. Given $C(x, y)$, we define T_1 as a copy of T, where (i) the subtree S_x is replaced by S_y, and (ii) for all children c of x, a copy of S_c is placed under the copy of y in T_1 with its original edge label, $lab(c)$.

(b) Head-merge. An alternative way to recover the missing information in Example (iii) is to find a reference term whose head word itself (rather than one of its modifiers) matches the target component's missing dependent, as with *AS-28* in Figure 2 in the bottom left corner (T'_b). In terms of parse trees, we need to add one tree as a dependent of the other. Formally, given $C(x, y)$, similarly to dependent-merge, T_1 is created as a copy of T where the subtree S_x is replaced by either S_x or S_y, depending on whichever of x and y matches the target component's head. Assume it is x, for example. Then, a copy of S_y is added as a new child to x. In our sample, head-merge operations correspond to internal coreferences within nominal target components (such as between *AS-28* and *mini submarine* in this case). The appropriate label, $lab(y)$, in these cases is nn (nominal modi-

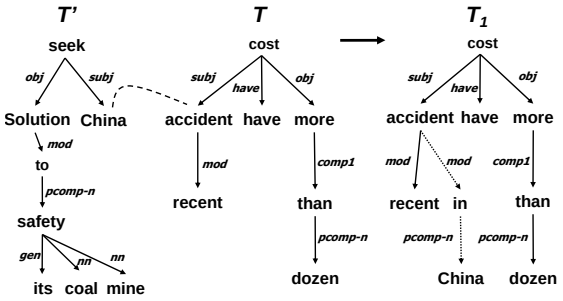

Figure 3: The *insertion* transformation. Dotted edges mark the newly inserted path (Ex. (iv)).

fier). Further analysis is required to specify what other dependencies can hold between such coreferring heads.

(3) Insertion: The last transformation, insertion, is used when a relation that is realized in H is missing from T and is only implied via a bridging relation. In Example (iv), the location that is explicitly mentioned in H can only be covered by T by resolving a bridging reference with *China* in T'. To connect the bridging referents, a new tree component representing the bridging relation is inserted into the consequent tree T_1. In this example, the component connects *China* and *recent accident* via the *in* preposition. Formally, given a bridging relation $B_r(x, y)$, we introduce a new subtree S^r_z into T_1, where z is a child of x and $lab(z) = lab_r$. S^r_z must contain a variable node that is instantiated with a copy of $S(y)$.

This transformation stands out from the others in that it introduces new material. For each bridging relation, it adds a specific subtrees S^r via an edge labeled with lab_r. These two items form the dependency representation of the bridging relation B_r and must be provided by the interface between the discourse and the inference systems. Clearly, their exact form depends on the set of bridging relations provided by the discourse resolver as well as the details of the dependency parses.

As shown in Figure 3, the bridging relation *located-in* (r) is represented by inserting a subtree S^r_z headed by *in* (z) into T_1 and connecting it to *accident* (x) as a modifier (lab_r). The subtree S^r_z consists of a variable node which is connected to *in* with a *pcomp-n* dependency (a nominal head of a prepositional phrase), and which is instantiated with the node *China* (y) when the transformation is applied. Note that the structure of S^r_z and the way it is inserted into T_1 are predefined by the abovementioned interface; only the node to which it is attached and the contents of the variable node are determined at transformation-time.

As another example, consider the following short text from (Clark, 1975): *John was murdered yesterday. The knife lay nearby*. Here, the bridging relation between the murder event and the instrument, *the knife* (x), can be addressed by inserting under x a subtree for the clause *with which* as S^r_z, with a variable which is instantiated by the parse-tree (headed by *murdered*, y) of the entire first sentence *John was murdered yesterday*.

Transformation chaining. Since our transformations are defined to be minimal, some cases require the application of multiple transformations to achieve coverage. Consider Example (v), Table 1. We wish to cover *AS-28 mini submarine* in H from the coreferring *it* in T, *mini submarine* in T' and *AS-28 vehicle* in T''. A substitution of *it* by either coreference does not suffice, since none of the antecedents contains all necessary modifiers. It is therefore necessary to substitute *it* first by one of the coreferences and then merge it with the other.

6 Results

We analyzed 120 sentence-hypothesis pairs of the RTE-5 development set (21 different hypotheses, 111 distinct sentences, 53 different documents). Below, we summarize our findings, focusing on the relation between our findings and the assumptions of previous studies as discussed in Section 3.

General statistics. We found that 44% of the pairs contained reference relations whose resolution was mandatory for inference. In another 28%, references could optionally support the inference of the hypothesis. In the remaining 28%, references did not contribute towards inference. The total number of relevant references was 137, and 37 pairs (27%) contained multiple relevant references. These numbers support our assumption that discourse references play an important role in inference.

Reference types. 73% of the identified references are coreferences and 27% are bridging relations. The most common bridging relation was the location of events (e.g. *Arctic* in ice melting events), generally assumed to be known throughout the document. Other bridging relations we encountered include cause (e.g. between *injured* and *attack*), event participants and set membership.

Coreference	62	38	-
Bridging	30	-	70
Total	54	28	18

Table 3: Distribution of transformation types

Syntactic types. Table 2 shows that 77% of all focus terms and 86% of the reference terms were nominal phrases, which justifies their prominent position in work on anaphora and coreference resolution. However, almost a quarter of the focus terms were verbal phrases. We found these focus terms to be frequently crucial for entailment since they included the main predicate of the hypothesis.[6] This calls for an increased focus on the resolution of event references.

Transformations. Table 3 shows the relative frequencies of all transformations. Again, we found that the "default" transformation, substitution, is the most frequent one, and is helpful for both coreference and bridging relations. Substitution is particularly useful for handling pronouns (14% of all substitution instances), the replacement of named entities by synonymous names (32%), the replacement of other NPs (38%), and the substitution of verbal head nodes in event coreference (16%). Yet, in nearly half the cases, a different transformation had to be applied. Insertion accounts for the majority of bridging cases. Head-merge is necessary to integrate proper nouns as modifiers of other head nouns. Dependent-merge, responsible for 85% of the merge transformations, can be used to complete nominal focus terms with missing modifiers (e.g., adjectives), as well as for merging other dependencies between coreferring predicates. This result indicates the importance of incorporating other transformations into inference systems.

Distance of reference terms. The distance between the focus and the reference terms varied considerably, ranging from intra-sentential reference relations and up to several dozen sentences. For more than a quarter of the focus terms, we had to go to other documents to find reference terms that, possibly in conjunction with the focus term, could cover the target components. Interestingly, all such cases involved coreference (about equally divided between the merge transformations and substitutions), while bridging was always "document-local". This result reaffirms the usefulness of cross-document coreference resolution for inference (Huang et al., 2009).

Discourse resolution as preprocessing? In existing RTE systems, discourse references are typically resolved as a preprocessing step. While our annotation was manual and cannot yield direct results about processing considerations, we observed that discourse relations often hold between complex, and deeply embedded, expressions, which makes their automatic resolution difficult. Of course, many RTE systems attempt to normalize and simplify H and T, e.g., by splitting conjunctions or removing irrelevant clauses, but these operations are usually considered a part of the inference rather the preprocessing phase (cf. e.g., Bar-Haim et al. (2007)). Since the resolution of discourse references is likely to profit from these steps, it seems desirable to "postpone" it until after simplification. In transformation-based systems, it might be natural to add discourse-based transformations to the set of inference operations, while in alignment-based systems, discourse references can be integrated into the computation of alignment scores.

Discourse references vs. entailment knowledge. We have stated before that even if a discourse reference is not strictly necessary for entailment, it may be interesting because it represents an alternative to the use of knowledge rules to cover the hypothesis. Sometimes, these rules are generally applicable (e.g., '*Alaska* → *Arctic*'). However, often they are context-specific. Consider the following sentence as T for the hypothesis H: "*The ice is melting in the Arctic*":

(3) T: "*The scene at the* ***receding*** *edge of the Exit Glacier was part festive gathering, part nature tour with an apocalyptic edge.*"

While it is possible to cover *melting* using a rule '*melting* ↔ *receding*', this rule is only valid under quite specific conditions (e.g., for the subject *ice*). Instead of determining the applicability of the rule, a discourse-aware system can take the next sen-

[6] The lower proportion of VPs among reference terms stems from bridging relations between VPs and nominal dependents, such as the abovementioned "location" relation.

tence into account, which contains a coreferring event to *receding* that can cover *melting* in H:

(4) T': "*... people moved closer to the rope line near the glacier as it shied away, practically groaning and* ***melting*** *before their eyes.*"

Discourse relations can in fact encode arbitrarily complex world knowledge, as in the following pair:

(5) H: "*The* ***serial*** *killer BTK was accused of at least 7 killings starting in the 1970's.*"

T: "*Police say BTK may have killed as many as 10 people between 1974 and 1991.*"

Here, the H modifier *serial*, which does not occur in T, can be covered either by world knowledge (a person who killed 10 people is a serial killer), or by resolving the coreference of *BTK* to the term *the serial killer BTK* which occurs in the discourse around T. Our conclusion is that not only can discourse references often replace world knowledge in principle, in practice it often seems easier to resolve discourse references than to determine whether a rule is applicable in a given context or to formalize complex world knowledge as inference rules. Our annotation provides further empirical support to this claim: An entailment relation exists between the focus and reference terms in 60% of the focus-reference term pairs, and in many of the remainder, entailment holds between the terms' heads. Thus, discourse provides relations which are many times equivalent to entailment knowledge rules and can therefore be utilized in their stead.

7 Conclusions

This work has presented an analysis of the relation between discourse references and textual entailment. We have identified a set of limitations common to the handling of discourse relations in virtually all entailment systems. They include the use of off-the-shelf resolvers that concentrate on nominal coreference, the integration of reference information through substitution, and the RTE evaluation schemes, which played down the role of discourse. Since in practical settings, discourse plays an important role, our goal was to develop an agenda for improving the handling of discourse references in entailment-based inference.

Our manual analysis of the RTE-5 dataset shows that while the majority of discourse references that affect inference are nominal coreference relations, another substantial part is made up by verbal terms and bridging relations. Furthermore, we have demonstrated that substitution alone is insufficient to extract all relevant information from the wide range of discourse references that are frequently relevant for inference. We identified three general cases, and suggested matching operations to obtain the relevant inferences, formulated as tree transformations. Furthermore, our evidence suggests that for practical reasons, the resolution of discourse references should be tightly integrated into entailment systems instead of treating it as a preprocessing step.

A particularly interesting result concerns the interplay between discourse references and entailment knowledge. While semantic knowledge (e.g., from WordNet or Wikipedia) has been used beneficially for coreference resolution (Soon et al., 2001; Ponzetto and Strube, 2006), reference resolution has, to our knowledge, not yet been employed to validate entailment rules' applicability. Our analyses suggest that in the context of deciding textual entailment, reference resolution and entailment knowledge can be seen as complementary ways of achieving the same goal, namely enriching T with additional knowledge to allow the inference of H. Given that both of the technologies are still imperfect, we envisage the way forward as a joint strategy, where reference resolution and entailment rules mutually fill each other's gaps (cf. Example 3).

In sum, our study shows that textual entailment can profit substantially from better discourse handling. The next challenge is to translate the theoretical gain into practical benefit. Our analysis demonstrates that improvements are necessary both on the side of discourse reference resolution systems, which need to cover more types of references, as well as a better integration of discourse information in entailment systems, even for those relations which are within the scope of available resolvers.

Abstract

We propose a global algorithm for learning entailment relations between predicates. We define a graph structure over predicates that represents entailment relations as directed edges, and use a global transitivity constraint on the graph to learn the optimal set of edges, by formulating the optimization problem as an Integer Linear Program. We motivate this graph with an application that provides a hierarchical summary for a set of propositions that focus on a target concept, and show that our global algorithm improves performance by more than 10% over baseline algorithms.

1 Introduction

The *Textual Entailment (TE)* paradigm (Dagan et al., 2009) is a generic framework for applied semantic inference. The objective of TE is to recognize whether a target meaning can be inferred from a given text. For example, a Question Answering system has to recognize that *'alcohol affects blood pressure'* is inferred from *'alcohol reduces blood pressure'* to answer the question *'What affects blood pressure?'*

TE systems require extensive knowledge of entailment patterns, often captured as *entailment rules:* rules that specify a directional inference relation between two text fragments (when the rule is bidirectional this is known as paraphrasing). An important type of entailment rule refers to *propositional templates*, i.e., propositions comprising a predicate and arguments, possibly replaced by variables. The rule required for the previous example would be *'X reduce Y* $\rightarrow$ *X affect Y'*. Because facts and knowledge are mostly expressed by propositions, such entailment rules are central to the TE task. This has led to active research on broad-scale acquisition of entailment rules for predicates, e.g. (Lin and Pantel, 2001; Sekine, 2005; Szpektor and Dagan, 2008).

Previous work has focused on learning each entailment rule in isolation. However, it is clear that there are interactions between rules. A prominent example is that entailment is a transitive relation, and thus the rules '$X \rightarrow Y$' and '$Y \rightarrow Z$' imply the rule '$X \rightarrow Z$'. In this paper we take advantage of these global interactions to improve entailment rule learning.

First, we describe a structure termed an *entailment graph* that models entailment relations between propositional templates (Section 3). Next, we show that we can present propositions according to an entailment hierarchy derived from the graph, and suggest a novel hierarchical presentation scheme for corpus propositions referring to a target concept. As in this application each graph focuses on a single concept, we term those *focused entailment graphs* (Section 4).

In the core section of the paper, we present an algorithm that uses a global approach to learn the entailment relations of focused entailment graphs (Section 5). We define a global function and look for the graph that maximizes that function under a transitivity constraint. The optimization problem is formulated as an *Integer Linear Program (ILP)* and solved with an ILP solver. We show that this leads to an optimal solution with respect to the global function, and demonstrate that the algorithm outperforms methods that utilize only local information by more than 10%, as well as methods that employ a greedy optimization algorithm rather than an ILP solver (Section 6).

2 Background

Entailment learning Two information types have primarily been utilized to learn entailment rules between predicates: lexicographic resources and distributional similarity resources. Lexicographic

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1220–1229,
Uppsala, Sweden, 11-16 July 2010.

resources are manually-prepared knowledge bases containing information about semantic relations between lexical items. WordNet (Fellbaum, 1998), by far the most widely used resource, specifies relations such as *hyponymy*, *derivation*, and *entailment* that can be used for semantic inference (Budanitsky and Hirst, 2006). WordNet has also been exploited to automatically generate a training set for a hyponym classifier (Snow et al., 2005), and we make a similar use of WordNet in Section 5.1.

Lexicographic resources are accurate but tend to have low coverage. Therefore, distributional similarity is used to learn broad-scale resources. Distributional similarity algorithms predict a semantic relation between two predicates by comparing the arguments with which they occur. Quite a few methods have been suggested (Lin and Pantel, 2001; Bhagat et al., 2007; Yates and Etzioni, 2009), which differ in terms of the specifics of the ways in which predicates are represented, the features that are extracted, and the function used to compute feature vector similarity. Details on such methods are given in Section 5.1.

Global learning It is natural to describe entailment relations between predicates by a graph. Nodes represent predicates, and edges represent entailment between nodes. Nevertheless, using a graph for global learning of entailment between predicates has attracted little attention. Recently, Szpektor and Dagan (2009) presented the resource *Argument-mapped WordNet*, providing entailment relations for predicates in WordNet. Their resource was built on top of WordNet, and makes simple use of WordNet's global graph structure: new rules are suggested by transitively chaining graph edges, and verified against corpus statistics.

The most similar work to ours is Snow et al.'s algorithm for taxonomy induction (2006). Snow et al.'s algorithm learns the hyponymy relation, under the constraint that it is a *transitive relation*. Their algorithm incrementally adds hyponyms to an existing taxonomy (WordNet), using a greedy search algorithm that adds at each step the set of hyponyms that maximize the probability of the evidence while respecting the transitivity constraint.

In this paper we tackle a similar problem of learning a transitive relation, but we use linear programming. A *Linear Program (LP)* is an optimization problem, where a linear function is minimized (or maximized) under linear constraints. If the variables are integers, the problem is termed an *Integer Linear Program (ILP)*. Linear programming has attracted attention recently in several fields of NLP, such as semantic role labeling, summarization and parsing (Roth and tau Yih, 2005; Clarke and Lapata, 2008; Martins et al., 2009). In this paper we formulate the entailment graph learning problem as an Integer Linear Program, and find that this leads to an optimal solution with respect to the target function in our experiment.

3 Entailment Graph

This section presents an *entailment graph* structure, which resembles the graph in (Szpektor and Dagan, 2009).

The nodes of an entailment graph are *propositional templates*. A propositional template is a path in a dependency tree between two arguments of a common predicate[1] (Lin and Pantel, 2001; Szpektor and Dagan, 2008). Note that in a dependency parse, such a path passes through the predicate. We require that a variable appears in at least one of the argument positions, and that each sense of a polysemous predicate corresponds to a separate template (and a separate graph node): *X* $\xleftarrow{subj}$ *treat#1* $\xrightarrow{obj}$ *Y* and *X* $\xleftarrow{subj}$ *treat#1* $\xrightarrow{obj}$ *nausea* are propositional templates for the first sense of the predicate *treat*. An edge (u, v) represents the fact that template u entails template v. Note that the entailment relation transcends beyond hyponymy. For example, the template *X is diagnosed with asthma* entails the template *X suffers from asthma*, although one is not a hyponoym of the other. An example of an entailment graph is given in Figure 1, left.

Since entailment is a transitive relation, an entailment graph is *transitive*, i.e., if the edges (u, v) and (v, w) are in the graph, so is the edge (u, w). This is why we require that nodes be sense-specified, as otherwise transitivity does not hold: Possibly $a \rightarrow b$ for one sense of b, $b \rightarrow c$ for another sense of b, but $a \nrightarrow c$.

Because graph nodes represent propositions, which generally have a clear truth value, we can assume that transitivity is indeed maintained along paths of any length in an entailment graph, as entailment between each pair of nodes either occurs or doesn't occur with very high probability. We support this further in section 4.1, where we show

[1] We restrict our discussion to templates with two arguments, but generalization is straightforward.

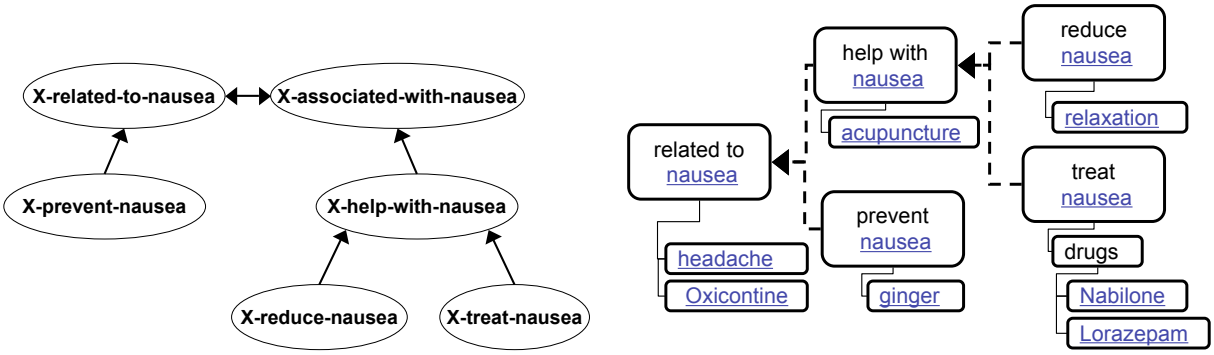

Figure 1: *Left:* An entailment graph. For clarity, edges that can be inferred by transitivity are omitted. *Right:* A hierarchical summary of propositions involving *nausea* as an argument, such as *headache is related to nausea*, *acupuncture helps with nausea*, and *Lorazepam treats nausea*.

that in our experimental setting the length of paths in the entailment graph is relatively small.

Transitivity implies that in each strong connectivity component[2] of the graph, all nodes are synonymous. Moreover, if we merge every strong connectivity component to a single node, the graph becomes a Directed Acyclic Graph (DAG), and the graph nodes can be sorted and presented hierarchically. Next, we show an application that leverages this property.

4 Motivating Application

In this section we propose an application that provides a hierarchical view of propositions extracted from a corpus, based on an entailment graph.

Organizing information in large collections has been found to be useful for effective information access (Kaki, 2005; Stoica et al., 2007). It allows for easier data exploration, and provides a compact view of the underlying content. A simple form of structural presentation is by a single hierarchy, e.g. (Hofmann, 1999). A more complex approach is hierarchical faceted metadata, where a number of concept hierarchies are created, corresponding to different facets or dimensions (Stoica et al., 2007).

Hierarchical faceted metadata categorizes *concepts* of a domain in several dimensions, but does not specify the *relations* between them. For example, in the health-care domain we might have facets for categories such as *diseases* and *symptoms*. Thus, when querying about *nausea*, one might find it is related to *vomitting* and *chicken pox*, but not that chicken pox is a *cause* of nausea, while nausea is often *accompanied* by vomitting.

We suggest that the prominent information in a text lies in the *propositions* it contains, which specify particular relations between the concepts. Propositions have been mostly presented through unstructured textual summaries or manually-constructed ontologies, which are expensive to build. We propose using the entailment graph structure, which describes entailment relations between predicates, to naturally present propositions hierarchically. That is, the entailment hierarchy can be used as an additional facet, which can improve navigation and provide a compact hierarchical summary of the propositions.

Figure 1 illustrates a scenario, on which we evaluate later our learning algorithm. Assume a user would like to retrieve information about a target concept such as *nausea*. We can extract the set of propositions where *nausea* is an argument automatically from a corprus, and learn an entailment graph over propositional templates derived from the extracted propositions, as illustrated in Figure 1, left. Then, we follow the steps in the process described in Section 3: merge synonymous nodes that are in the same strong connectivity component, and turn the resulting DAG into a predicate hierarchy, which we can then use to present the propositions (Figure 1, right). Note that in all propositional templates one argument is the target concept (nausea), and the other is a variable whose corpus instantiations can be presented according to another hierarchy (e.g. *Nabilone* and *Lorazepam* are types of *drugs*).

Moreover, new propositions are inferred from the graph by transitivity. For example, from the proposition *'relaxation reduces nausea'* we can in-

[2] A strong connectivity component is a subset of nodes in the graph where there is a path from any node to any other node.

fer the proposition *'relaxation helps with nausea'*.

4.1 Focused entailment graphs

The application presented above generates entailment graphs of a specific form: (1) Propositional templates have exactly one argument instantiated by the same entity (e.g. nausea). (2) The predicate sense is unspecified, but due to the rather small number of nodes and the instantiating argument, each predicate corresponds to a unique sense.

Generalizing this notion, we define a *focused entailment graph* to be an entailment graph where the number of nodes is relatively small (and consequently paths in the graph are short), and predicates have a single sense (so transitivity is maintained without sense specification). Section 5 presents an algorithm that given the set of nodes of a focused entailment graph learns its edges, i.e., the entailment relations between all pairs of nodes. The algorithm is evaluated in Section 6 using our proposed application. For brevity, from now on the term *entailment graph* will stand for *focused entailment graph*.

5 Learning Entailment Graph Edges

In this section we present an algorithm for learning the edges of an entailment graph given its set of nodes. The first step is preprocessing: We use a large corpus and WordNet to train an *entailment classifier* that estimates the likelihood that one propositional template entails another. Next, we can learn on the fly for any input graph: given the graph nodes, we employ a global optimization approach that determines the set of edges that maximizes the probability (or score) of the entire graph, given the edge probabilities (or scores) supplied by the entailment classifier and the graph constraints (transitivity and others).

5.1 Training an entailment classifier

We describe a procedure for learning an entailment classifier, given a corpus and a lexicographic resource (WordNet). First, we extract a large set of propositional templates from the corpus. Next, we represent each pair of propositional templates with a feature vector of various distributional similarity scores. Last, we use WordNet to automatically generate a training set and train a classifier.

Template extraction We parse the corpus with a dependency parser and extract all propositional templates from every parse tree, employing the procedure used by Lin and Pantel (2001). However, we only consider templates containing a predicate term and arguments[3]. The arguments are replaced with variables, resulting in propositional templates such as $X \xleftarrow{subj} affect \xrightarrow{obj} Y$.

Distributional similarity representation We aim to train a classifier that for an input template pair (t_1, t_2) determines whether t_1 entails t_2. A template pair is represented by a feature vector where each coordinate is a different distributional similarity score. There are a myriad of distributional similarity algorithms. We briefly describe those used in this paper, obtained through variations along the following dimensions:

Predicate representation Most algorithms measure the similarity between templates with two variables (*binary templates*) such as $X \xleftarrow{subj} affect \xrightarrow{obj} Y$ (Lin and Pantel, 2001; Bhagat et al., 2007; Yates and Etzioni, 2009). Szpketor and Dagan (2008) suggested learning over templates with one variable (*unary templates*) such as $X \xleftarrow{subj} affect$, and using them to estimate a score for binary templates.

Feature representation The features of a template are some representation of the terms that instantiated the argument variables in a corpus. Two representations are used in our experiment (see Section 6). Another variant occurs when using binary templates: a template may be represented by a pair of feature vectors, one for each variable (Lin and Pantel, 2001), or by a single vector, where features represent pairs of instantiations (Szpektor et al., 2004; Yates and Etzioni, 2009). The former variant reduces sparsity problems, while Yates and Etzioni showed the latter is more informative and performs favorably on their data.

Similarity function We consider two similarity functions: The *Lin* (2001) similarity measure, and the *Balanced Inclusion (BInc)* similarity measure (Szpektor and Dagan, 2008). The former is a symmetric measure and the latter is asymmetric. Therefore, information about the direction of entailment is provided by the BInc measure.

We then generate for any (t_1, t_2) features that are the 12 distributional similarity scores using all combinations of the dimensions. This is reminiscent of Connor and Roth (2007), who used the output of unsupervised classifiers as features for a supervised classifier in a verb disambiguation task.

[3] Via a simple heuristic, omitted due to space limitations

Training set generation Following the spirit of Snow et al. (2005), WordNet is used to automatically generate a training set of positive (entailing) and negative (non-entailing) template pairs. Let T be the set of propositional templates extracted from the corpus. For each $t_i \in T$ with two variables and a single predicate word w, we extract from WordNet the set H of direct hypernyms and synonyms of w. For every $h \in H$, we generate a new template t_j from t_i by replacing w with h. If $t_j \in T$, we consider (t_i, t_j) to be a positive example. Negative examples are generated analogously, by looking at direct co-hyponyms of w instead of hypernyms and synonyms. This follows the notion of "contrastive estimation" (Smith and Eisner, 2005), since we generate negative examples that are semantically similar to positive examples and thus focus the classifier's attention on identifying the boundary between the classes. Last, we filter training examples for which all features are zero, and sample an equal number of positive and negative examples (for which we compute similarity features), since classifiers tend to perform poorly on the minority class when trained on imbalanced data (Van Hulse et al., 2007; Nikulin, 2008).

5.2 Global learning of edges

Once the entailment classifier is trained we learn the graph edges given its nodes. This is equivalent to learning all entailment relations between all propositional template pairs for that graph.

To learn edges we consider global constraints, which allow only certain graph topologies. Since we seek a global solution under transitivity and other constraints, linear programming is a natural choice, enabling the use of state of the art optimization packages. We describe two formulations of integer linear programs that learn the edges: one maximizing a global *score* function, and another maximizing a global *probability* function.

Let I_{uv} be an indicator denoting the event that node u entails node v. Our goal is to learn the edges E over a set of nodes V. We start by formulating the constraints and then the target functions.

The first constraint is that the graph must respect transitivity. Our formulation is equivalent to the one suggested by Finkel and Manning (2008) in a coreference resolution task:

$$\forall_{u,v,w \in V} I_{uv} + I_{vw} - I_{uw} \leq 1$$

In addition, for a few pairs of nodes we have strong evidence that one does not entail the other and so we add the constraint $I_{uv} = 0$. Combined with the constraint of transitivity this implies that there must be no path from u to v. This is done in the following two scenarios: (1) When two nodes u and v are identical except for a pair of words w_u and w_v, and w_u is an antonym of w_v, or a hypernym of w_v at distance ≥ 2. (2) When two nodes u and v are transitive opposites, that is, if $u = X \xleftarrow{subj} w \xrightarrow{obj} Y$ and $v = X \xleftarrow{obj} w \xrightarrow{subj} Y$, for any word w[4].

Score-based target function We assume an entailment classifier estimating a positive score S_{uv} if it believes $I_{uv} = 1$ and a negative score otherwise (for example, an SVM classifier). We look for a graph G that maximizes the sum of scores over the edges:

$$\begin{aligned}\hat{G} &= \operatorname*{argmax}_G S(G) \\ &= \operatorname*{argmax}_G \left(\sum_{u \neq v} S_{uv} I_{uv} \right) - \lambda |E|\end{aligned}$$

where $\lambda|E|$ is a regularization term reflecting the fact that edges are sparse. Note that this constant needs to be optimized on a development set.

Probabilistic target function Let F_{uv} be the features for the pair of nodes (u, v) and $F = \cup_{u \neq v} F_{uv}$. We assume an entailment classifier estimating the probability of an edge given its features: $P_{uv} = P(I_{uv} = 1 | F_{uv})$. We look for the graph G that maximizes the posterior probability $P(G|F)$:

$$\hat{G} = \operatorname*{argmax}_G P(G|F)$$

Following Snow et al., we make two independence assumptions: First, we assume each set of features F_{uv} is independent of other sets of features given the graph G, i.e., $P(F|G) = \prod_{u \neq v} P(F_{uv}|G)$. Second, we assume the features for the pair (u, v) are generated by a distribution depending only on whether entailment holds for (u, v). Thus, $P(F_{uv}|G) = P(F_{uv}|I_{uv})$. Last, for simplicity we assume edges are independent and the prior probability of a graph is a product of the prior probabilities of the edge indicators:

[4] We note that in some rare cases transitive verbs are indeed reciprocal, as in *"X marry Y"*, but in the grand majority of cases reciprocal activities are not expressed using a transitive-verb structure.

$P(G) = \prod_{u \neq v} P(I_{uv})$. Note that although we assume edges are independent, dependency is still expressed using the transitivity constraint. We express $P(G|F)$ using the assumptions above and Bayes rule:

$$\begin{aligned} P(G|F) &\propto P(G)P(F|G) \\ &= \prod_{u \neq v} [P(I_{uv})P(F_{uv}|I_{uv})] \\ &= \prod_{u \neq v} P(I_{uv}) \frac{P(I_{uv}|F_{uv})P(F_{uv})}{P(I_{uv})} \\ &\propto \prod_{u \neq v} P(I_{uv}|F_{uv}) \\ &= \prod_{(u,v) \in E} P_{uv} \cdot \prod_{(u,v) \notin E} (1 - P_{uv}) \end{aligned}$$

Note that the prior $P(F_{uv})$ is constant with respect to the graph. Now we look for the graph that maximizes $\log P(G|F)$:

$$\begin{aligned} \hat{G} &= \operatorname*{argmax}_G \sum_{(u,v) \in E} \log P_{uv} + \sum_{(u,v) \notin E} \log(1 - P_{uv}) \\ &= \operatorname*{argmax}_G \sum_{u \neq v} [I_{uv} \cdot \log P_{uv} \\ &\qquad + (1 - I_{uv}) \cdot \log(1 - P_{uv})] \\ &= \operatorname*{argmax}_G \sum_{u \neq v} \log \frac{P_{uv}}{1 - P_{uv}} \cdot I_{uv} \end{aligned}$$

(in the last transition we omit the constant $\sum_{u \neq v} \log(1 - P_{uv})$). Importantly, while the score-based formulation contains a parameter λ that requires optimization, this probabilistic formulation is parameter free and does not utilize a development set at all.

Since the variables are binary, both formulations are integer linear programs with $O(|V|^2)$ variables and $O(|V|^3)$ transitivity constraints that can be solved using standard ILP packages.

Our work resembles Snow et al.'s in that both try to learn graph edges given a transitivity constraint. However, there are two key differences in the model and in the optimization algorithm. First, Snow et al.'s model attempts to determine the graph that maximizes the likelihood $P(F|G)$ and not the posterior $P(G|F)$. Therefore, their model contains an edge prior $P(I_{uv})$ that has to be estimated, whereas in our model it cancels out. Second, they incrementally add hyponyms to a large taxonomy (WordNet) and therefore utilize a greedy algorithm, while we simultaneously learn all edges of a rather small graph and employ integer linear programming, which is more sound theoretically, and as shown in Section 6, leads to an optimal solution. Nevertheless, Snow et al.'s model can also be formulated as a linear program with the following target function:

$$\operatorname*{argmax}_G \sum_{u \neq v} \log \frac{P_{uv} \cdot P(I_{uv} = 0)}{(1 - P_{uv}) \cdot P(I_{uv} = 1)} I_{uv}$$

Note that if the prior inverse odds $k = \frac{P(I_{uv}=0)}{P(I_{uv}=1)} = 1$, i.e., $P(I_{uv} = 1) = 0.5$, then this is equivalent to our probabilistic formulation. We implemented Snow et al's model and optimization algorithm and in Section 6.3 we compare our model and optimization algorithm to theirs.

6 Experimental Evaluation

This section presents our evaluation, which is geared for the application proposed in Section 4.

6.1 Experimental setting

A health-care corpus of 632MB was harvested from the web and parsed with the Minipar parser (Lin, 1998). The corpus contains 2,307,585 sentences and almost 50 million word tokens. We used the Unified Medical Language System (UMLS)[5] to annotate medical concepts in the corpus. The UMLS is a database that maps natural language phrases to over one million *concept identifiers* in the health-care domain (termed CUIs). We annotated all nouns and noun phrases that are in the UMLS with their possibly multiple CUIs. We extracted all propositional templates from the corpus, where both argument instantiations are medical concepts, i.e., annotated with a CUI (∼50,000 templates). When computing distributional similarity scores, a template is represented as a feature vector of the CUIs that instantiate its arguments.

To evaluate the performance of our algorithm, we constructed 23 gold standard entailment graphs. First, 23 medical concepts, representing typical topics of interest in the medical domain, were manually selected from a list of the most frequent concepts in the corpus. For each concept, nodes were defined by extracting all propositional

templates for which the target concept instantiated an argument at least $K(= 3)$ times (average number of graph nodes=22.04, std=3.66, max=26, min=13).

Ten medical students constructed the gold standard of graph edges. Each concept graph was annotated by two students. Following RTE-5 practice (Bentivogli et al., 2009), after initial annotation the two students met for a reconciliation phase. They worked to reach an agreement on differences and corrected their graphs. Inter-annotator agreement was calculated using the Kappa statistic (Siegel and Castellan, 1988) both before ($\kappa = 0.59$) and after ($\kappa = 0.9$) reconciliation. 882 edges were included in the 23 graphs out of a possible 10,364, providing a sufficiently large data set. The graphs were randomly split into a development set (11 graphs) and a test set (12 graphs)[6]. The entailment graph fragment in Figure 1 is from the gold standard.

The graphs learned by our algorithm were evaluated by two measures, one evaluating the graph directly, and the other motivated by our application: (1) F_1 of the learned edges compared to the gold standard edges (2) Our application provides a summary of propositions extracted from the corpus. Note that we infer new propositions by propagating inference transitively through the graph. Thus, we compute F_1 for the set of propositions inferred from the learned graph, compared to the set inferred based on the gold standard graph. For example, given the proposition from the corpus *'relaxation reduces nausea'* and the edge *'X reduce nausea → X help with nausea'*, we evaluate the set {*'relaxation reduces nausea', 'relaxation helps with nausea'*}. The final score for an algorithm is a macro-average over the 12 graphs of the test set.

[6]Test set concepts were: asthma, chemotherapy, diarrhea, FDA, headache, HPV, lungs, mouth, salmonella, seizure, smoking and X-ray.

6.2 Evaluated algorithms

Local algorithms We described 12 distributional similarity measures computed over our corpus (Section 5.1). For each measure we computed for each template t a list of templates most similar to t (or entailing t for directional measures). In addition, we obtained similarity lists learned by Lin and Pantel (2001), and replicated 3 similarity measures learned by Szpektor and Dagan (2008), over the RCV1 corpus[7]. For each distributional similarity measure (altogether 16 measures), we learned a graph by inserting any edge (u, v), when u is in the top K templates most similar to v. We also omitted edges for which there was strong evidence that they do not exist, as specified by the constraints in Section 5.2. Another local resource was WordNet where we inserted an edge (u, v) when v was a direct hypernym or synonym of u. For all algorithms, we added all edges inferred by transitivity.

Global algorithms We experimented with all 6 combinations of the following two dimensions: (1) Target functions: score-based, probabilistic and Snow et al.'s (2) Optimization algorithms: Snow et al.'s greedy algorithm and a standard ILP solver. A training set of 20,144 examples was automatically generated, each example represented by 16 features using the distributional similarity measures mentioned above. SVMperf (Joachims, 2005) was used to train an SVM classifier yielding S_{uv}, and the SMO classifier from WEKA (Hall et al., 2009) estimated P_{uv}. We used the *lpsolve*[8] package to solve the linear programs. In all results, the relaxation $\forall_{u,v} 0 \leq I_{uv} \leq 1$ was used, which guarantees an optimal output solution. In

[7]http://trec.nist.gov/data/reuters/reuters.html. The similarity lists were computed using: (1) Unary templates and the Lin function (2) Unary templates and the BInc function (3) Binary templates and the Lin function

Table 2: Comparing disagreements between the best local and global algorithms against the gold standard

all experiments the output solution was integer, and therefore it is optimal. Constructing graph nodes and learning its edges given an input concept took 2-3 seconds on a standard desktop.

6.3 Results and analysis

Table 1 summarizes the results of the algorithms. The left half depicts methods where the development set was needed to tune parameters, and the right half depicts methods that do not require a (manually created) development set at all. Hence, our score-based LP (*tuned-LP)*, where the parameter λ is tuned, is on the left, and the probabilistic LP (*untuned-LP*) is on the right. The row *Greedy* is achieved by using the greedy algorithm instead of *lpsolve*. The row *Local-LP* is achieved by omitting global transitivity constraints, making the algorithm completely local. We omit Snow et al.'s formulation, since the optimal prior inverse odds k was almost exactly 1, which conflates with untuned-LP.

The rows $Local_1$ and $Local_2$ present the best distributional similarity resources. Local_1 is achieved using binary templates, the *Lin* function, and a single vector with feature pairs. Local_2 is identical but employs the *BInc* function. $Local_1^*$ and $Local_2^*$ also exploit the local constraints mentioned above. Results on the left were achieved by optimizing the top-K parameter on the development set, and on the right by optimizing on the training set automatically generated from WordNet.

The global methods clearly outperform local methods: Tuned-LP outperforms significantly all local methods that require a development set both on the edges F_1 measure ($p<.05$) and on the propositions F_1 measure ($p<.01$)[9]. The untuned-LP algorithm also significantly outperforms all local methods that do not require a development set on the edges F_1 measure ($p<.05$) and on the propositions F_1 measure ($p<.01$). Omitting the global transitivity constraints decreases performance, as shown by *Local-LP*. Last, local methods are sensitive to parameter tuning and in the absence of a development set their performance dramatically deteriorates.

[9]We tested significance using the two-sided Wilcoxon rank test (Wilcoxon, 1945)

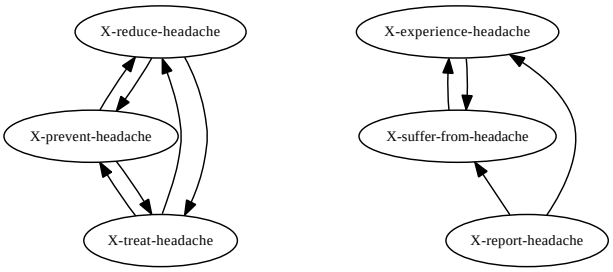

Figure 2: Subgraph of tuned-LP output for "headache"

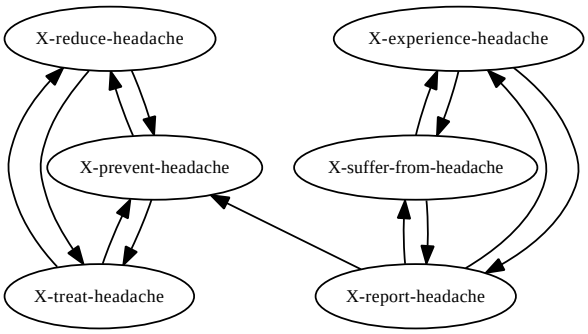

Figure 3: Subgraph of Local_1^* output for"headache"

To further establish the merits of global algorithms, we compare (Table 2) tuned-LP, the best global algorithm, with Local_1^*, the best local algorithm. The table considers all edges where the two algorithms disagree, and counts how many are in the gold standard and how many are not. Clearly, tuned-LP is superior at avoiding wrong edges (false positives). This is because tuned-LP refrains from adding edges that subsequently induce many undesirable edges through transitivity. Figures 2 and 3 illustrate this by comparing tuned-LP and Local_1^* on a subgraph of the *Headache* concept, before adding missing edges to satisfy transitivity to Local_1^* . Note that Local_1^* inserts a single wrong edge *X-report-headache* $\rightarrow$ *X-prevent-headache*, which leads to adding 8 more wrong edges. This is the type of global consideration that is addressed in an ILP formulation, but is ignored in a local approach and often overlooked when employing a greedy algorithm. Figure 2 also illustrates the utility of a local entailment graph for information presentation. Presenting information according to this subgraph distinguishes between propositions dealing with headache treatments and

propositions dealing with headache risk groups.

Comparing our use of an ILP algorithm to the greedy one reveals that tuned-LP significantly outperforms its greedy counterpart on both measures ($p<.01$). However, untuned-LP is practically equivalent to its greedy counterpart. This indicates that in this experiment the greedy algorithm provides a good approximation for the optimal solution achieved by our LP formulation.

Last, when comparing WordNet to local distributional similarity methods, we observe low recall and high precision, as expected. However, global methods achieve much higher recall than WordNet while maintaining comparable precision.

The results clearly demonstrate that a global approach improves performance on the entailment graph learning task, and the overall advantage of employing an ILP solver rather than a greedy algorithm.

7 Conclusion

This paper presented a global optimization algorithm for learning entailment relations between predicates represented as propositional templates. We modeled the problem as a graph learning problem, and searched for the best graph under a global transitivity constraint. We used Integer Linear Programming to solve the optimization problem, which is theoretically sound, and demonstrated empirically that this method outperforms local algorithms as well as a greedy optimization algorithm on the graph learning task.

Currently, we are investigating a generalization of our probabilistic formulation that includes a prior on the edges, and the relation of this prior to the regularization term introduced in our score-based formulation. In future work, we would like to learn general entailment graphs over a large number of nodes. This will introduce a challenge to our current optimization algorithm due to complexity issues, and will require careful handling of predicate ambiguity. Additionally, we will investigate novel features for the entailment classifier. This paper used distributional similarity, but other sources of information are likely to improve performance further.

Acknowledgments

Modeling Semantic Relevance for Question-Answer Pairs in Web Social Communities

Abstract

Quantifying the semantic relevance between questions and their candidate answers is essential to answer detection in social media corpora. In this paper, a deep belief network is proposed to model the semantic relevance for question-answer pairs. Observing the textual similarity between the community-driven question-answering (cQA) dataset and the forum dataset, we present a novel learning strategy to promote the performance of our method on the social community datasets without hand-annotating work. The experimental results show that our method outperforms the traditional approaches on both the cQA and the forum corpora.

1 Introduction

In natural language processing (NLP) and information retrieval (IR) fields, question answering (QA) problem has attracted much attention over the past few years. Nevertheless, most of the QA researches mainly focus on locating the exact answer to a given factoid question in the related documents. The most well known international evaluation on the factoid QA task is the Text REtrieval Conference (TREC)[1], and the annotated questions and answers released by TREC have become important resources for the researchers. However, when facing a non-factoid question such as *why*, *how*, or *what about*, however, almost no automatic QA systems work very well.

The user-generated question-answer pairs are definitely of great importance to solve the non-factoid questions. Obviously, these natural QA pairs are usually created during people's communication via Internet social media, among which we are interested in the community-driven question-answering (cQA) sites and online forums. The cQA sites (or systems) provide platforms where users can either ask questions or deliver answers, and best answers are selected manually (e.g., Baidu Zhidao[2] and Yahoo! Answers[3]). Comparing with cQA sites, online forums have more virtual society characteristics, where people hold discussions in certain domains, such as techniques, travel, sports, etc. Online forums contain a huge number of QA pairs, and much noise information is involved.

To make use of the QA pairs in cQA sites and online forums, one has to face the challenging problem of distinguishing the questions and their answers from the noise. According to our investigation, the data in the community based sites, especially for the forums, have two obvious characteristics: (a) a post usually includes a very short content, and when a person is initializing or replying a post, an informal tone tends to be used; (b) most of the posts are useless, which makes the community become a noisy environment for question-answer detection.

In this paper, a novel approach for modeling the semantic relevance for QA pairs in the social media sites is proposed. We concentrate on the following two problems:

1. How to model the semantic relationship between two short texts using simple textual features? As mentioned above, the user generated questions and their answers via social media are always short texts. The limitation of length leads to the sparsity of the word features. In addition, the word frequency is usually either 0 or 1, that is, the frequency offers little information except the occurrence of a word. Because of this situation, the traditional relevance computing methods based on word co-occurrence, such as Cosine similarity and KL-divergence, are not effective for question-

Uppsala, Sweden, 11-16 July 2010.

answer semantic modeling. Most researchers try to introduce structural features or users' behavior to improve the models performance, by contrast, the effect of textual features is not obvious.

2. How to train a model so that it has good performance on both cQA and forum datasets? So far, people have been doing QA researches on the cQA and the forum datasets separately (Ding et al., 2008; Surdeanu et al., 2008), and no one has noticed the relationship between the two kinds of data. Since both the cQA systems and the online forums are open platforms for people to communicate, the QA pairs in the cQA systems have similarity with those in the forums. In this case, it is highly valuable and desirable to propose a training strategy to improve the model's performance on both of the two kinds of datasets. In addition, it is possible to avoid the expensive and arduous hand-annotating work by introducing the method.

To solve the first problem, we present a deep belief network (DBN) to model the semantic relevance between questions and their answers. The network establishes the semantic relationship for QA pairs by minimizing the answer-to-question reconstructing error. Using only word features, our model outperforms the traditional methods on question-answer relevance calculating.

For the second problem, we make our model to learn the semantic knowledge from the solved question threads in the cQA system. Instead of mining the structure based features from cQA pages and forum threads individually, we consider the textual similarity between the two kinds of data. The semantic information learned from cQA corpus is helpful to detect answers in forums, which makes our model show good performance on social media corpora. Thanks to the labels for the best answers existing in the threads, no manual work is needed in our strategy.

The rest of this paper is organized as follows: Section 2 surveys the related work. Section 3 introduces the deep belief network for answer detection. In Section 4, the homogenous data based learning strategy is described. Experimental result is given in Section 5. Finally, conclusions and future directions are drawn in Section 6.

2 Related Work

The value of the naturally generated question-answer pairs has not been recognized until recent years. Early studies mainly focus on extracting QA pairs from frequently asked questions (FAQ) pages (Jijkoun and de Rijke, 2005; Riezler et al., 2007) or service call-center dialogues (Berger et al., 2000).

Judging whether a candidate answer is semantically related to the question in the cQA page automatically is a challenging task. A framework for predicting the quality of answers has been presented in (Jeon et al., 2006). Bernhard and Gurevych (2009) have developed a translation based method to find answers. Surdeanu et al. (2008) propose an approach to rank the answers retrieved by Yahoo! Answers. Our work is partly similar to Surdeanu et al. (2008), for we also aim to rank the candidate answers reasonably, but our ranking algorithm needs only word information, instead of the combination of different kinds of features.

Because people have considerable freedom to post on forums, there are a great number of irrelevant posts for answering questions, which makes it more difficult to detect answers in the forums. In this field, exploratory studies have been done by Feng et al. (2006) and Huang et al. (2007), who extract input-reply pairs for the discussion-bot. Ding et al.(2008) and Cong et al.(2008) have also presented outstanding research works on forum QA extraction. Ding et al. (2008) detect question contexts and answers using the conditional random fields, and a ranking algorithm based on the authority of forum users is proposed by Cong et al. (2008). Treating answer detection as a binary classification problem is an intuitive idea, thus there are some studies trying to solve it from this view (Hong and Davison, 2009; Wang et al., 2009). Especially Hong and Davison (2009) have achieved a rather high precision on the corpora with less noise, which also shows the importance of "social" features.

In order to select the answers for a given question, one has to face the problem of lexical gap. One of the problems with lexical gap embedding is to find similar questions in QA achieves (Jeon et al., 2005). Recently, the statistical machine translation (SMT) strategy has become popular. Lee et al. (2008) use translate models to bridge the lexical gap between queries and questions in QA collections. The SMT based methods are effective on modeling the semantic relationship between questions and answers and expending users' queries in answer retrieval (Riezler et al., 2007; Berger et al.,

2000; Bernhard and Gurevych, 2009). In (Surdeanu et al., 2008), the translation model is used to provide features for answer ranking.

The structural features (e.g., authorship, acknowledgement, post position, etc), also called non-textual features, play an important role in answer extraction. Such features are used in (Ding et al., 2008; Cong et al., 2008), and have significantly improved the performance. The studies of Jeon et al. (2006) and Hong et al. (2009) show that the structural features have even more contribution than the textual features. In this case, the mining of textual features tends to be ignored.

There are also some other research topics in this field. Cong et al. (2008) and Wang et al. (2009) both propose the strategies to detect questions in the social media corpus, which is proved to be a non-trivial task. The deep research on question detection has been taken by Duan et al. (2008). A graph based algorithm is presented to answer opinion questions (Li et al., 2009). In email summarization field, the QA pairs are also extracted from email contents as the main elements of email summarization (Shrestha and McKeown, 2004).

3 The Deep Belief Network for QA pairs

Due to the feature sparsity and the low word frequency of the social media corpus, it is difficult to model the semantic relevance between questions and answers using only co-occurrence features. It is clear that the semantic link exists between the question and its answers, even though they have totally different lexical representations. Thus a specially designed model may learn semantic knowledge by reconstructing a great number of questions using the information in the corresponding answers. In this section, we propose a deep belief network for modeling the semantic relationship between questions and their answers. Our model is able to map the QA data into a low-dimensional semantic-feature space, where a question is close to its answers.

3.1 The Restricted Boltzmann Machine

An ensemble of binary vectors can be modeled using a two-layer network called a "restricted Boltzmann machine" (RBM) (Hinton, 2002). The dimension reducing approach based on RBM initially shows good performance on image processing (Hinton and Salakhutdinov, 2006). Salakhutdinov and Hinton (2009) propose a deep graphical model composed of RBMs into the information retrieval field, which shows that this model is able to obtain semantic information hidden in the word-count vectors.

As shown in Figure 1, the RBM is a two-layer network. The bottom layer represents a visible vector **v** and the top layer represents a latent feature **h**. The matrix W contains the symmetric interaction terms between the visible units and the hidden units. Given an input vector **v**, the trained

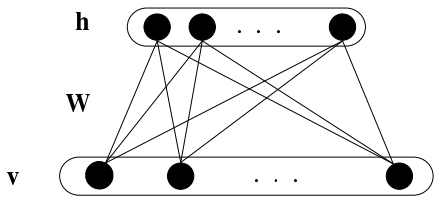

Figure 1: Restricted Boltzmann machine

RBM model provides a hidden feature **h**, which can be used to reconstruct **v** with a minimum error. The training algorithm for this paper will be described in the next subsection. The ability of the RBM suggests us to build a deep belief network based on RBM so that the semantic relevance between questions and answers can be modeled.

3.2 Pretraining a Deep Belief Network

In the social media corpora, the answers are always descriptive, containing one or several sentences. Noticing that an answer has strong semantic association with the question and involves more information than the question, we propose to train a deep belief network by reconstructing the question using its answers. The training object is to minimize the error of reconstruction, and after the pretraining process, a point that lies in a good region of parameter space can be achieved.

Firstly, the illustration of the DBN model is given in Figure 2. This model is composed of three layers, and here each layer stands for the RBM or its variant. The bottom layer is a variant form of RBM's designed for the QA pairs. This layer we design is a little different from the classical RBM's, so that the bottom layer can generate the hidden features according to the visible answer vector and reconstruct the question vector using the hidden features. The pre-training procedure of this architecture is practically convergent. In the bottom layer, the binary feature vectors based on the statistics of the word occurrence in the answers are used to compute the "hidden features" in the

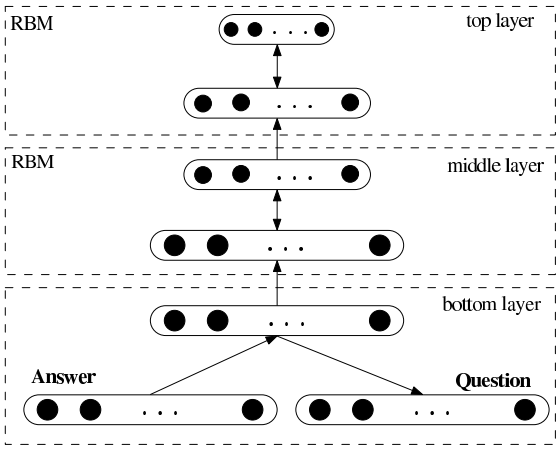

Figure 2: The Deep Belief Network for QA Pairs

hidden units. The model can reconstruct the questions using the hidden features. The processes can be modeled as follows:

$$p(h_j = 1|\mathbf{a}) = \sigma(b_j + \sum_i w_{ij} a_i) \quad (1)$$

$$p(q_i = 1|\mathbf{h}) = \sigma(b_i + \sum_j w_{ij} h_j) \quad (2)$$

where $\sigma(x) = 1/(1 + e^{-x})$, $\mathbf{a}$ denotes the visible feature vector of the answer, q_i is the *ith* element of the question vector, and $\mathbf{h}$ stands for the hidden feature vector for reconstructing the questions. w_{ij} is a symmetric interaction term between word i and hidden feature j, b_i stands for the bias of the model for word i, and b_j denotes the bias of hidden feature j.

Given the training set of answer vectors, the bottom layer generates the corresponding hidden features using Equation 1. Equation 2 is used to reconstruct the Bernoulli rates for each word in the question vectors after stochastically activating the hidden features. Then Equation 1 is taken again to make the hidden features active. We use 1-step Contrastive Divergence (Hinton, 2002) to update the parameters by performing gradient ascent:

$$\Delta w_{ij} = \epsilon(< q_i h_j >_{qData} - < q_i h_j >_{qRecon}) \quad (3)$$

where $< q_i h_j >_{qData}$ denotes the expectation of the frequency with which the word i in a question and the feature j are on together when the hidden features are driven by the question data. $< q_i h_j >_{qRecon}$ defines the corresponding expectation when the hidden features are driven by the reconstructed question data. ϵ is the learning rate.

The classical RBM structure is taken to build the middle layer and the top layer of the network. The training method for the higher two layer is similar to that of the bottom one, and we only have to make each RBM to reconstruct the input data using its hidden features. The parameter updates still obeying the rule defined by gradient ascent, which is quite similar to Equation 3. After training one layer, the $\mathbf{h}$ vectors are then sent to the higher-level layer as its "training data".

3.3 Fine-tuning the Weights

Notice that a greedy strategy is taken to train each layer individually during the pre-training procedure, it is necessary to fine-tune the weights of the entire network for optimal reconstruction. To fine-tune the weights, the network is unrolled, taking the answers as the input data to generate the corresponding questions at the output units. Using the cross-entropy error function, we can then tune the network by performing backpropagation through it. The experiment results in section 5.2 will show fine-tuning makes the network performs better for answer detection.

3.4 Best answer detection

After pre-training and fine-tuning, a deep belief network for QA pairs is established. To detect the best answer to a given question, we just have to send the vectors of the question and its candidate answers into the input units of the network and perform a level-by-level calculation to obtain the corresponding feature vectors. Then we calculate the distance between the mapped question vector and each candidate answer vector. We consider the candidate answer with the smallest distance as the best one.

4 Learning with Homogenous Data

In this section, we propose our strategy to make our DBN model to detect answers in both cQA and forum datasets, while the existing studies focus on one single dataset.

4.1 Homogenous QA Corpora from Different Sources

Our motivation of finding the homogenous question-answer corpora from different kind of social media is to guarantee the model's performance and avoid hand-annotating work.

In this paper, we get the "solved question" pages in the computer technology domain from Baidu Zhidao as the cQA corpus, and the threads of

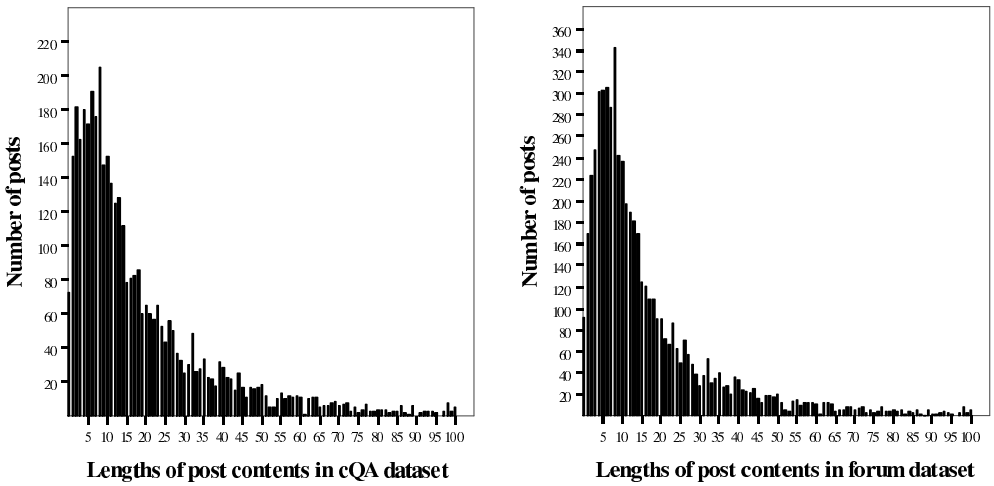

Figure 3: Comparison of the post content lengths in the cQA and the forum datasets

ComputerFansClub Forum[4] as the online forum corpus. The domains of the corpora are the same. To further explain that the two corpora are homogenous, we will give the detail comparison on text style and word distribution.

As shown in Figure 3, we have compared the post content lengths of the cQA and the forum in our corpora. For the comparison, 5,000 posts from the cQA corpus and 5,000 posts from the forum corpus are randomly selected. The left panel shows the statistical result on the Baidu Zhidao data, and the right panel shows the one on the forum data. The number i on the horizontal axis denotes the post contents whose lengths range from $10(i-1)+1$ to $10i$ bytes, and the vertical axis represents the counts of the post contents. From Figure 3 we observe that the contents of most posts in both the cQA corpus and the forum corpus are short, with the lengths not exceeding 400 bytes.

The content length reflects the text style of the posts in cQA systems and online forums. From Figure 3 it can be also seen that the distributions of the content lengths in the two figures are very similar. It shows that the contents in the two corpora are both mainly short texts.

Figure 4 shows the percentage of the concurrent words in the top-ranked content words with high frequency. In detail, we firstly rank the words by frequency in the two corpora. The words are chosen based on a professional dictionary to guarantee that they are meaningful in the computer knowledge field. The number k on the horizontal axis in Figure 4 represents the top k content words in the corpora, and the vertical axis stands for the percentage of the words shared by the two corpora in the top k words.

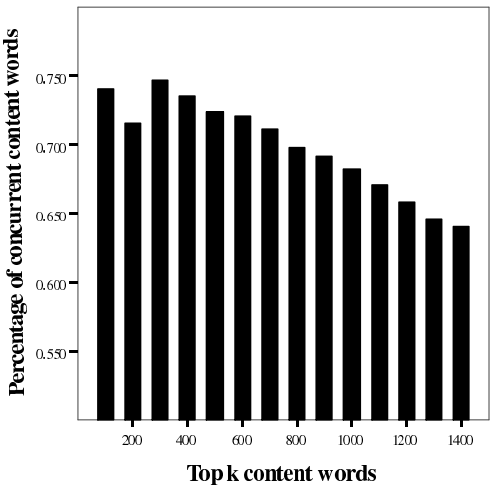

Figure 4: Distribution of concurrent content words

Figure 4 shows that a large number of meaningful words appear in both of the two corpora with high frequencies. The percentage of the concurrent words maintains above 64% in the top 1,400 words. It indicates that the word distributions of the two corpora are quite similar, although they come from different social media sites.

Because the cQA corpus and the forum corpus used in this study have homogenous characteristics for answer detecting task, a simple strategy may be used to avoid the hand-annotating work. Apparently, in every "solved question" page of Baidu Zhidao, the best answer is selected by the user who asks this question. We can easily extract the QA pairs from the cQA corpus as the training

[4]http://bbs.cfanclub.net/

set. Because the two corpora are similar, we can apply the deep belief network trained by the cQA corpus to detect answers on both the cQA data and the forum data.

4.2 Features

The task of detecting answers in social media corpora suffers from the problem of feature sparsity seriously. High-dimensional feature vectors with only several non-zero dimensions bring large time consumption to our model. Thus it is necessary to reduce the dimension of the feature vectors.

In this paper, we adopt two kinds of word features. Firstly, we consider the 1,300 most frequent words in the training set as Salakhutdinov and Hinton (2009) did. According to our statistics, the frequencies of the rest words are all less then 10, which are not statistically significant and may introduce much noise.

We take the occurrence of some function words as another kind of features. The function words are quite meaningful for judging whether a short text is an answer or not, especially for the non-factoid questions. For example, in the answers to the causation questions, the words such as *because* and *so* are more likely to appear; and the words such as *firstly*, *then*, and *should* may suggest the answers to the manner questions. We give an example for function word selection in Figure 5.

> ***Q***: 我的电脑开机一直黑屏，无法进 bios，应该怎么办？(The screen of my computer turns black after booting, and I can not enter bios, what should I do?)
> ***A***: ***可以先***拔掉硬盘，试试开机，***如果***能开机，***然后***在 bios 里把光驱设置成第一启动，重装系统吧。 (You ***may firstly*** unplug the hard disc and try to boot, ***if*** it works, ***then*** you ***should*** set your CD-Rom as the boot driver in bios and reinstall the system.)

Figure 5: An example for function word selection

For this reason, we collect 200 most frequent function words in the answers of the training set. Then for every short text, either a question or an answer, a 1,500-dimensional vector can be generated. Specifically, all the features we have adopted are binary, for they only have to denote whether the corresponding word appears in the text or not.

5 Experiments

To evaluate our question-answer semantic relevance computing method, we compare our approach with the popular methods on the answer detecting task.

5.1 Experiment Setup

Architecture of the Network: To build the deep belief network, we use a 1500-1500-1000-600 architecture, which means the three layers of the network have individually 1,500×1,500, 1,500×1,000 and 1,000×600 units. Using the network, a 1,500-dimensional binary vector is finally mapped to a 600-dimensional real-value vector.

During the pretraining stage, the bottom layer is greedily pretrained for 200 passes through the entire training set, and each of the rest two layers is greedily pretrained for 50 passes. For fine-tuning we apply the method of conjugate gradients[5], with three line searches performed in each pass. This algorithm is performed for 50 passes to fine-tune the network.

Dataset: we have crawled 20,000 pages of "solved question" from the *computer and network* category of Baidu Zhidao as the cQA corpus. Correspondingly we obtain 90,000 threads from ComputerFansClub, which is an online forum on computer knowledge. We take the forum threads as our forum corpus.

From the cQA corpus, we extract 12,600 human generated QA pairs as the training set without any manual work to label the best answers. We get the contents from another 2,000 cQA pages to form a testing set, each content of which includes one question and 4.5 candidate answers on average, with one best answer among them. To get another testing dataset, we randomly select 2,000 threads from the forum corpus. For this training set, human work are necessary to label the best answers in the posts of the threads. There are 7 posts included in each thread on average, among which one question and at least one answer exist.

Baseline: To show the performance of our method, three main popular relevance computing methods for ranking candidate answers are considered as our baselines. We will briefly introduce them:

Cosine Similarity. Given a question $\mathbf{q}$ and its candidate answer $\mathbf{a}$, their cosine similarity can be computed as follows:

$$\cos(\mathbf{q}, \mathbf{a}) = \frac{\sum_{k=1}^{n} w_{q_k} \times w_{a_k}}{\sqrt{\sum_{k=1}^{n} w_{q_k}^2} \times \sqrt{\sum_{k=1}^{n} w_{a_k}^2}} \quad (4)$$

where w_{q_k} and w_{a_k} stand for the weight of the kth word in the question and the answer respectively.

[5]Code is available at http://www.kyb.tuebingen.mpg.de/bs/people/carl/code/minimize/

The weights can be get by computing the product of term frequency (*tf*) and inverse document frequency (*idf*)

HowNet based Similarity. HowNet[6] is an electronic world knowledge system, which serves as a powerful tool for meaning computation in human language technology. Normally the similarity between two passages can be calculated by two steps: (1) matching the most semantic-similar words in each passages greedily using the API's provided by HowNet; (2) computing the weighted average similarities of the word pairs. This strategy is taken as a baseline method for computing the relevance between questions and answers.

KL-divergence Language Model. Given a question **q** and its candidate answer **a**, we can construct unigram language model M_q and unigram language model M_a. Then we compute KL-divergence between M_q and M_a as below:

$$KL(M_a||M_q) = \sum_w p(w|M_a) \log(p(w|M_a)/p(w|M_q)) \quad (5)$$

5.2 Results and Analysis

We evaluate the performance of our approach for answer detection using two metrics: Precision@1 (P@1) and Mean Reciprocal Rank (MRR). Applying the two metrics, we perform the baseline methods and our DBN based methods on the two testing set above.

Table 1 lists the results achieved on the forum data using the baseline methods and ours. The additional "Nearest Answer" stands for the method without any ranking strategies, which returns the nearest candidate answer from the question by position. To illustrate the effect of the fine-tuning for our model, we list the results of our method without fine-tuning and the results with fine-tuning.

As shown in Table 1, our deep belief network based methods outperform the baseline methods as expected. The main reason for the improvements is that the DBN based approach is able to learn semantic relationship between the words in QA pairs from the training set. Although the training set we offer to the network comes from a different source (the cQA corpus), it still provide enough knowledge to the network to perform better than the baseline methods. This phenomena indicates that the homogenous corpora for training is effective and meaningful.

Method	P@1 (%)	MRR (%)
Nearest Answer	21.25	38.72
Cosine Similarity	23.15	43.50
HowNet	22.55	41.63
KL divergence	25.30	51.40
DBN (without FT)	**41.45**	**59.64**
DBN (with FT)	**45.00**	**62.03**

Table 1: Results on Forum Dataset

We have also investigated the reasons for the unsatisfying performance of the baseline approaches. Basically, the low precision is ascribable to the forum corpus we have obtained. As mentioned in Section 1, the contents of the forum posts are short, which leads to the sparsity of the features. Besides, when users post messages in the online forums, they are accustomed to be casual and use some synonymous words interchangeably in the posts, which is believed to be a significant situation in Chinese forums especially. Because the features for QA pairs are quite sparse and the content words in the questions are usually morphologically different from the ones with the same meaning in the answers, the Cosine Similarity method become less powerful. For HowNet based approaches, there are a large number of words not included by HowNet, thus it fails to compute the similarity between questions and answers. KL-divergence suffers from the same problems with the Cosine Similarity method. Compared with the Cosine Similarity method, this approach has achieved the improvement of 9.3% in P@1, but it performs much better than the other baseline methods in MRR.

The baseline results indicate that the online forum is a complex environment with large amount of noise for answer detection. Traditional IR methods using pure textual features can hardly achieve good results. The similar baseline results for forum answer ranking are also achieved by Hong and Davison (2009), which takes some non-textual features to improve the algorithm's performance. We also notice that, however, the baseline methods have obtained better results on forum corpus (Cong et al., 2008). One possible reason is that the baseline approaches are suitable for their data, since we observe that the "nearest answer" strategy has obtained a 73.5% precision in their work.

Our model has achieved the precision of

[6]Detail information can be found in: http://www.keenage.com/

45.00% in P@1 and 62.03% in MRR for answer detecting on forum data after fine-tuning, while some related works have reported the results with the precision over 90% (Cong et al., 2008; Hong and Davison, 2009). There are mainly two reasons for this phenomena: Firstly, both of the previous works have adopt non-textual features based on the forum structure, such as *authorship*, *position* and *quotes*, etc. The non-textual (or social based) features have played a significant role in improving the algorithms' performance. Secondly, the quality of corpora influences the results of the ranking strategies significantly, and even the same algorithm may perform differently when the dataset is changed (Hong and Davison, 2009). For the experiments of this paper, large amount of noise is involved in the forum corpus and we have done nothing extra to filter it.

Table 2 shows the experimental results on the cQA dataset. In this experiment, each sample is composed of one question and its following several candidate answers. We delete the ones with only one answer to confirm there are at least two candidate answers for each question. The candidate answers are rearranged by post time, so that the real answers do not always appear next to the questions. In this group of experiment, no hand-annotating work is needed because the real answers have been labeled by cQA users.

Method	**P@1 (%)**	**MRR (%)**
Nearest Answer	36.05	56.33
Cosine Similarity	44.05	62.84
HowNet	41.10	58.75
KL divergence	43.75	63.10
DBN (without FT)	**56.20**	**70.56**
DBN (with FT)	**58.15**	**72.74**

Table 2: Results on cQA Dataset

From Table 2 we observe that all the approaches perform much better on this dataset. We attribute the improvements to the high quality QA corpus Baidu Zhidao offers: the candidate answers tend to be more formal than the ones in the forums, with less noise information included. In addition, the "Nearest Answer" strategy has reached 36.05% in P@1 on this dataset, which indicates quite a number of askers receive the real answers at the first answer post. This result has supported the idea of introducing position features. What's more, if the best answer appear immediately, the asker tends to lock down the question thread, which helps to reduce the noise information in the cQA corpus.

Despite the baseline methods' performances have been improved, our approaches still outperform them, with a 32.0% improvement in P@1 and a 15.3% improvement in MRR at least. On the cQA dataset, our model shows better performance than the previous experiment, which is expected because the training set and the testing set come from the same corpus, and the DBN model is more adaptive to the cQA data.

We have observed that, from both of the two groups of experiments, fine-tuning is effective for enhancing the performance of our model. On the forum data, the results have been improved by 8.6% in P@1 and 4.0% in MRR, and the improvements are 3.5% and 3.1% individually.

6 Conclusions

In this paper, we have proposed a deep belief network based approach to model the semantic relevance for the question answering pairs in social community corpora.

The contributions of this paper can be summarized as follows: (1) The deep belief network we present shows good performance on modeling the QA pairs' semantic relevance using only word features. As a data driven approach, our model learns semantic knowledge from large amount of QA pairs to represent the semantic relevance between questions and their answers. (2) We have studied the textual similarity between the cQA and the forum datasets for QA pair extraction, and introduce a novel learning strategy to make our method show good performance on both cQA and forum datasets. The experimental results show that our method outperforms the traditional approaches on both the cQA and the forum corpora.

Our future work will be carried out along two directions. Firstly, we will further improve the performance of our method by adopting the non-textual features. Secondly, more research will be taken to put forward other architectures of the deep networks for QA detection.

Abstract

In this paper we tackle the problem of automatic caption generation for news images. Our approach leverages the vast resource of pictures available on the web and the fact that many of them are captioned. Inspired by recent work in summarization, we propose *extractive* and *abstractive* caption generation models. They both operate over the output of a probabilistic image annotation model that preprocesses the pictures and suggests keywords to describe their content. Experimental results show that an abstractive model defined over phrases is superior to extractive methods.

1 Introduction

Recent years have witnessed an unprecedented growth in the amount of digital information available on the Internet. Flickr, one of the best known photo sharing websites, hosts more than three billion images, with approximately 2.5 million images being uploaded every day.[1] Many on-line news sites like CNN, Yahoo!, and BBC publish images with their stories and even provide photo feeds related to current events. Browsing and finding pictures in large-scale and heterogeneous collections is an important problem that has attracted much interest within information retrieval.

Many of the search engines deployed on the web retrieve images without analyzing their content, simply by matching user queries against collocated textual information. Examples include meta-data (e.g., the image's file name and format), user-annotated tags, captions, and generally text surrounding the image. As this limits the applicability of search engines (images that do not coincide with textual data cannot be retrieved), a great deal of work has focused on the development of methods that generate description words for a picture *automatically*. The literature is littered with various attempts to learn the associations between image features and words using supervised classification (Vailaya et al., 2001; Smeulders et al., 2000), instantiations of the noisy-channel model (Duygulu et al., 2002), latent variable models (Blei and Jordan, 2003; Barnard et al., 2002; Wang et al., 2009), and models inspired by information retrieval (Lavrenko et al., 2003; Feng et al., 2004).

In this paper we go one step further and generate captions for images rather than individual keywords. Although image indexing techniques based on keywords are popular and the method of choice for image retrieval engines, there are good reasons for using more linguistically meaningful descriptions. A list of keywords is often ambiguous. An image annotated with the words *blue*, *sky*, *car* could depict a blue car or a blue sky, whereas the caption "*car running under the blue sky*" would make the relations between the words explicit. Automatic caption generation could improve image retrieval by supporting longer and more targeted queries. It could also assist journalists in creating descriptions for the images associated with their articles. Beyond image retrieval, it could increase the accessibility of the web for visually impaired (blind and partially sighted) users who cannot access the content of many sites in the same ways as sighted users can (Ferres et al., 2006).

We explore the feasibility of automatic caption generation in the news domain, and create descriptions for images associated with on-line articles. Obtaining training data in this setting does not require expensive manual annotation as many articles are published together with captioned images. Inspired by recent work in summarization, we propose *extractive* and *abstractive* caption gen-

eration models. The backbone for both approaches is a probabilistic image annotation model that suggests keywords for an image. We can then simply identify (and rank) the sentences in the documents that share these keywords or create a new caption that is potentially more concise but also informative and fluent. Our abstractive model operates over image description keywords and document phrases. Their combination gives rise to many caption realizations which we select probabilistically by taking into account dependency and word order constraints. Experimental results show that the model's output compares favorably to handwritten captions and is often superior to extractive methods.

2 Related Work

Although image understanding is a popular topic within computer vision, relatively little work has focused on the interplay between visual and linguistic information. A handful of approaches generate image descriptions automatically following a two-stage architecture. The picture is first analyzed using image processing techniques into an abstract representation, which is then rendered into a natural language description with a text generation engine. A common theme across different models is domain specificity, the use of handlabeled data, and reliance on background ontological information.

For example, Héde et al. (2004) generate descriptions for images of objects shot in uniform background. Their system relies on a manually created database of objects indexed by an image signature (e.g., color and texture) and two keywords (the object's name and category). Images are first segmented into objects, their signature is retrieved from the database, and a description is generated using templates. Kojima et al. (2002, 2008) create descriptions for human activities in office scenes. They extract features of human motion and interleave them with a concept hierarchy of actions to create a case frame from which a natural language sentence is generated. Yao et al. (2009) present a general framework for generating text descriptions of image and video content based on image parsing. Specifically, images are hierarchically decomposed into their constituent visual patterns which are subsequently converted into a semantic representation using WordNet. The image parser is trained on a corpus, manually annotated with graphs representing image structure. A multi-sentence description is generated using a document planner and a surface realizer.

Within natural language processing most previous efforts have focused on generating captions to accompany complex graphical presentations (Mittal et al., 1998; Corio and Lapalme, 1999; Fasciano and Lapalme, 2000; Feiner and McKeown, 1990) or on using the captions accompanying information graphics to infer their intended message, e.g., the author's goal to convey ostensible increase or decrease of a quantity of interest (Elzer et al., 2005). Little emphasis is placed on image processing; it is assumed that the data used to create the graphics are available, and the goal is to enable users understand the information expressed in them.

The task of generating captions for news images is novel to our knowledge. Instead of relying on manual annotation or background ontological information we exploit a multimodal database of news articles, images, and their captions. The latter is admittedly noisy, yet can be easily obtained from on-line sources, and contains rich information about the entities and events depicted in the images and their relations. Similar to previous work, we also follow a two-stage approach. Using an image annotation model, we first describe the picture with keywords which are subsequently realized into a human readable sentence. The caption generation task bears some resemblance to headline generation (Dorr et al., 2003; Banko et al., 2000; Jin and Hauptmann, 2002) where the aim is to create a very short summary for a document. Importantly, we aim to create a caption that not only summarizes the document but is also a faithful to the image's content (i.e., the caption should also mention some of the objects or individuals depicted in the image). We therefore explore extractive and abstractive models that rely on visual information to drive the generation process. Our approach thus differs from most work in summarization which is solely text-based.

3 Problem Formulation

We formulate image caption generation as follows. Given an image I, and a related knowledge database κ, create a natural language description C which captures the main content of the image under κ. Specifically, in the news story scenario, we will generate a caption C for an image I and its accompanying document D. The training data thus consists of document-image-caption tu-

Thousands of Tongans have attended the funeral of King Taufa'ahau Tupou IV, who died last week at the age of 88. Representatives from 30 foreign countries watched as the king's coffin was carried by 1,000 men to the official royal burial ground.	 **King Tupou, who was 88, died a week ago.**	Contaminated Cadbury's chocolate was the most likely cause of an outbreak of salmonella poisoning, the Health Protection Agency has said. About 36 out of a total of 56 cases of the illness reported between March and July could be linked to the product.	 **Cadbury will increase its contamination testing levels.**
A Nasa satellite has documented startling changes in Arctic sea ice cover between 2004 and 2005. The extent of "perennial" ice declined by 14%, losing an area the size of Pakistan or Turkey. The last few decades have seen ice cover shrink by about 0.7% per year.	 **Satellite instruments can distinguish "old" Arctic ice from "new".**	A third of children in the UK use blogs and social network websites but two thirds of parents do not even know what they are, a survey suggests. The children's charity NCH said there was "an alarming gap" in technological knowledge between generations.	 **Children were found to be far more internet-wise than parents.**

Table 1: Each entry in the BBC News database contains a document an image, and its caption.

ples like the ones shown in Table 1. During testing, we are given a document and an associated image for which we must generate a caption.

Our experiments used the dataset created by Feng and Lapata (2008).[2] It contains 3,361 articles downloaded from the BBC News website[3] each of which is associated with a captioned news image. The latter is usually 203 pixels wide and 152 pixels high. The average caption length is 9.5 words, the average sentence length is 20.5 words, and the average document length 421.5 words. The caption vocabulary is 6,180 words and the document vocabulary is 26,795. The vocabulary shared between captions and documents is 5,921 words. The captions tend to use half as many words as the document sentences, and more than 50% of the time contain words that are not attested in the document (even though they may be attested in the collection).

Generating image captions is a challenging task even for humans, let alone computers. Journalists are given explicit instructions on how to write captions[4] and laypersons do not always agree on what a picture depicts (von Ahn and Dabbish, 2004). Along with the title, the lead, and section headings, captions are the most commonly read words in an article. A good caption must be succinct and informative, clearly identify the subject of the picture, establish the picture's relevance to the article, provide context for the picture, and ultimately draw the reader into the article. It is also worth noting that journalists often write their own captions rather than simply extract sentences from the document. In doing so they rely on general world knowledge but also expertise in current affairs that goes beyond what is described in the article or shown in the picture.

4 Image Annotation

As mentioned earlier, our approach relies on an image annotation model to provide description keywords for the picture. Our experiments made use of the probabilistic model presented in Feng and Lapata (2010). The latter is well-suited to our task as it has been developed with noisy, multimodal data sets in mind. The model is based on the assumption that images and their surrounding text are generated by mixtures of latent topics which are inferred from a concatenated representation of words and visual features.

Specifically, images are preprocessed so that they are represented by word-like units. Local image descriptors are computed using the Scale Invariant Feature Transform (SIFT) algorithm (Lowe, 1999). The general idea behind the algorithm is to first sample an image with the difference-of-Gaussians point detector at different

[2] Available from http://homepages.inf.ed.ac.uk/s677528/data/

[3] http://news.bbc.co.uk/

[4] See http://www.theslot.com/captions.html and http://www.thenewsmanual.net/ for tips on how to write good captions.

scales and locations. Importantly, this detector is, to some extent, invariant to translation, scale, rotation and illumination changes. Each detected region is represented with a SIFT descriptor which is a histogram of edge directions at different locations. Subsequently SIFT descriptors are quantized into a discrete set of visual terms via a clustering algorithm such as K-means.

The model thus works with a bag-of-words representation and treats each article-image-caption tuple as a single document d_{Mix} consisting of textual and visual words. Latent Dirichlet Allocation (LDA, Blei et al. 2003) is used to infer the latent topics assumed to have generated d_{Mix}. The basic idea underlying LDA, and topic models in general, is that each document is composed of a probability distribution over topics, where each topic represents a probability distribution over words. The document-topic and topic-word distributions are learned automatically from the data and provide information about the semantic themes covered in each document and the words associated with each semantic theme. The image annotation model takes the topic distributions into account when finding the most likely keywords for an image and its associated document.

More formally, given an image-caption-document tuple (I,C,D) the model finds the subset of keywords W_I ($W_I \subseteq W$) which appropriately describe I. Assuming that keywords are conditionally independent, and I, D are represented jointly by d_{Mix}, the model estimates:

$$\begin{aligned} W_I^* &\approx \arg\max_{W_t} \prod_{w_t \in W_t} P(w_t|d_{Mix}) \qquad (1) \\ &= \arg\max_{W_t} \prod_{w_t \in W_t} \sum_{k=1}^{K} P(w_t|z_k)P(z_k|d_{Mix}) \end{aligned}$$

W_t denotes a set of description keywords (the subscript t is used to discriminate from the visual words which are not part of the model's output), K the number of topics, $P(w_t|z_k)$ the multimodal word distributions over topics, and $P(z_k|d_{Mix})$ the estimated posterior of the topic proportions over documents. Given an unseen image-document pair and trained multimodal word distributions over topics, it is possible to infer the posterior of topic proportions over the new data by maximizing the likelihood. The model delivers a ranked list of textual words w_t, the n-best of which are used as annotations for image I.

It is important to note that the caption generation models we propose are not especially tied to the above annotation model. Any probabilistic model with broadly similar properties could serve our purpose. Examples include PLSA-based approaches to image annotation (e.g., Monay and Gatica-Perez 2007) and correspondence LDA (Blei and Jordan, 2003).

5 Extractive Caption Generation

Much work in summarization to date focuses on sentence extraction where a summary is created simply by identifying and subsequently concatenating the most important sentences in a document. Without a great deal of linguistic analysis, it is possible to create summaries for a wide range of documents, independently of style, text type, and subject matter. For our caption generation task, we need only extract a single sentence. And our guiding hypothesis is that this sentence must be maximally similar to the description keywords generated by the annotation model. We discuss below different ways of operationalizing similarity.

Word Overlap Perhaps the simplest way of measuring the similarity between image keywords and document sentences is word overlap:

$$Overlap(W_I,S_d) = \frac{|W_I \cap S_d|}{|W_I \cup S_d|} \qquad (2)$$

where W_I is the set of keywords and S_d a sentence in the document. The caption is then the sentence that has the highest overlap with the keywords.

Cosine Similarity Word overlap is admittedly a naive measure of similarity, based on lexical identity. We can overcome this by representing keywords and sentences in vector space (Salton and McGill, 1983). The latter is a word-sentence co-occurrence matrix where each row represents a word, each column a sentence, and each entry the frequency with which the word appeared within the sentence. More precisely matrix cells are weighted by their tf-idf values. The similarity of the vectors representing the keywords $\overrightarrow{W_I}$ and document sentence $\overrightarrow{S_d}$ can be quantified by measuring the cosine of their angle:

$$sim(\overrightarrow{W_I},\overrightarrow{S_d}) = \frac{\overrightarrow{W_I} \cdot \overrightarrow{S_d}}{|W_I||\overrightarrow{S_d}|} \qquad (3)$$

Probabilistic Similarity Recall that the backbone of our image annotation model is a topic model with images and documents represented as a probability distribution over latent topics. Under this framework, the similarity between an im-

age and a sentence can be broadly measured by the extent to which they share the same topic distributions (Steyvers and Griffiths, 2007). For example, we may use the KL divergence to measure the difference between the distributions p and q:

$$D(p,q) = \sum_{j=1}^{K} p_j \log_2 \frac{p_j}{q_j} \quad (4)$$

where p and q are shorthand for the image topic distribution $P_{d_{Mix}}$ and sentence topic distribution P_{S_d}, respectively. When doing inference on the document sentence, we also take its neighboring sentences into account to avoid estimating inaccurate topic proportions on short sentences.

The KL divergence is asymmetric and in many applications, it is preferable to apply a symmetric measure such as the Jensen Shannon (JS) divergence. The latter measures the "distance" between p and q through $\frac{(p+q)}{2}$, the average of p and q:

$$JS(p,q) = \frac{1}{2}\left[D(p, \frac{(p+q)}{2}) + D(q, \frac{(p+q)}{2})\right] \quad (5)$$

6 Abstractive Caption Generation

Although extractive methods yield grammatical captions and require relatively little linguistic analysis, there are a few caveats to consider. Firstly, there is often no single sentence in the document that uniquely describes the image's content. In most cases the keywords are found in the document but interspersed across multiple sentences. Secondly, the selected sentences make for long captions (sometimes longer than the average document sentence), are not concise and overall not as catchy as human-written captions. For these reasons we turn to abstractive caption generation and present models based on single words but also phrases.

Word-based Model Our first abstractive model builds on and extends a well-known probabilistic model of headline generation (Banko et al., 2000). The task is related to caption generation, the aim is to create a short, title-like headline for a given document, without however taking visual information into account. Like captions, headlines have to be catchy to attract the reader's attention.

Banko et al. (2000) propose a bag-of-words model for headline generation. It consists of content selection and surface realization components. Content selection is modeled as the probability of a word appearing in the headline given the same word appearing in the corresponding document and is independent from other words in the headline. The likelihood of different surface realizations is estimated using a bigram model. They also take the distribution of the length of the headlines into account in an attempt to bias the model towards generating concise output:

$$\begin{aligned} P(w_1, w_2, ..., w_n) = & \prod_{i=1}^{n} P(w_i \in H | w_i \in D) \\ & \cdot P(len(H) = n) \\ & \cdot \prod_{i=2}^{n} P(w_i | w_{i-1}) \end{aligned} \quad (6)$$

where w_i is a word that may appear in headline H, D the document being summarized, and $P(len(H) = n)$ a headline length distribution model.

The above model can be easily adapted to the caption generation task. Content selection is now the probability of a word appearing in the caption given the image and its associated document which we obtain from the output of our image annotation model (see Section 4). In addition we replace the bigram surface realizer with a trigram:

$$\begin{aligned} P(w_1, w_2, ..., w_n) = & \prod_{i=1}^{n} P(w_i \in C | I, D) \\ & \cdot P(len(C) = n) \\ & \cdot \prod_{i=3}^{n} P(w_i | w_{i-1}, w_{i-2}) \end{aligned} \quad (7)$$

where C is the caption, I the image, D the accompanying document, and $P(w_i \in C | I, D)$ the image annotation probability.

Despite its simplicity, the caption generation model in (7) has a major drawback. The content selection component will naturally tend to ignore function words, as they are not descriptive of the image's content. This will seriously impact the grammaticality of the generated captions, as there will be no appropriate function words to glue the content words together. One way to remedy this is to revert to a content selection model that ignores the image and simply estimates the probability of a word appearing in the caption given the same word appearing in the document. At the same time we modify our surface realization component so that it takes note of the image annotation probabilities. Specifically, we use an *adaptive* language model (Kneser et al., 1997) that modifies an

n-gram model with local unigram probabilities:

$$P(w_1,w_2,...,w_n) = \prod_{i=1}^{n} P(w_i \in C | w_i \in D) \cdot P(len(C)=n) \cdot \prod_{i=3}^{n} P_{adap}(w_i|w_{i-1},w_{i-2}) \quad (8)$$

where $P(w_i \in C|w_i \in D)$ is the probability of w_i appearing in the caption given that it appears in the document D, and $P_{adap}(w_i|w_{i-1},w_{i-2})$ the language model adapted with probabilities from our image annotation model:

$$P_{adap}(w|h) = \frac{\alpha(w)}{z(h)} P_{back}(w|h) \quad (9)$$

$$\alpha(w) \approx (\frac{P_{adap}(w)}{P_{back}(w)})^{\beta} \quad (10)$$

$$z(h) = \sum_{w} \alpha(w) \cdot P_{back}(w|h) \quad (11)$$

where $P_{back}(w|h)$ is the probability of w given the history h of preceding words (i.e., the original trigram model), $P_{adap}(w)$ the probability of w according to the image annotation model, $P_{back}(w)$ the probability of w according to the original model, and β a scaling parameter.

Phrase-based Model The model outlined in equation (8) will generate captions with function words. However, there is no guarantee that these will be compatible with their surrounding context or that the caption will be globally coherent beyond the trigram horizon. To avoid these problems, we turn our attention to phrases which are naturally associated with function words and can potentially capture long-range dependencies.

Specifically, we obtain phrases from the output of a dependency parser. A phrase is simply a head and its dependents with the exception of verbs, where we record only the head (otherwise, an entire sentence could be a phrase). For example, from the first sentence in Table 1 (first row, left document) we would extract the phrases: *thousands of Tongans*, *attended*, *the funeral*, *King Taufa'ahau Tupou IV*, *last week*, *at the age*, *died*, and so on. We only consider dependencies whose heads are nouns, verbs, and prepositions, as these constitute 80% of all dependencies attested in our caption data. We define a bag-of-phrases model for caption generation by modifying the content selection and caption length components in equation (8) as follows:

$$P(\rho_1,\rho_2,...,\rho_m) \approx \prod_{j=1}^{m} P(\rho_j \in C|\rho_j \in D) \cdot P(len(C) = \sum_{j=1}^{m} len(\rho_j)) \cdot \prod_{i=3}^{\sum_{j=1}^{m} len(\rho_j)} P_{adap}(w_i|w_{i-1},w_{i-2}) \quad (12)$$

Here, $P(\rho_j \in C|\rho_j \in D)$ models the probability of phrase ρ_j appearing in the caption given that it also appears in the document and is estimated as:

$$P(\rho_j \in C|\rho_j \in D) = \prod_{w_j \in \rho_j} P(w_j \in C|w_j \in D) \quad (13)$$

where w_j is a word in the phrase ρ_j.

One problem with the models discussed thus far is that words or phrases are independent of each other. It is up to the trigram model to enforce coarse ordering constraints. These may be sufficient when considering isolated words, but phrases are longer and their combinations are subject to structural constraints that are not captured by sequence models. We therefore attempt to take phrase *attachment* constraints into account by estimating the probability of phrase ρ_j attaching to the right of phrase ρ_i as:

$$P(\rho_j|\rho_i) = \sum_{w_i \in \rho_i} \sum_{w_j \in \rho_j} p(w_j|w_i) = \frac{1}{2} \sum_{w_i \in \rho_i} \sum_{w_j \in \rho_j} \{\frac{f(w_i,w_j)}{f(w_i,-)} + \frac{f(w_i,w_j)}{f(-,w_j)}\} \quad (14)$$

where $p(w_j|w_i)$ is the probability of a phrase containing word w_j appearing to the right of a phrase containing word w_i, $f(w_i,w_j)$ indicates the number of times w_i and w_j are adjacent, $f(w_i,-)$ is the number of times w_i appears on the left of any phrase, and $f(-,w_i)$ the number of times it appears on the right.[5]

After integrating the attachment probabilities into equation (12), the caption generation model becomes:

$$P(\rho_1,\rho_2,...,\rho_m) \approx \prod_{j=1}^{m} P(\rho_j \in C|\rho_j \in D) \cdot \prod_{j=2}^{m} P(\rho_j|\rho_{j-1}) \cdot P(len(C) = \textstyle\sum_{j=1}^{m} len(\rho_j)) \cdot \prod_{i=3}^{\sum_{j=1}^{m} len(\rho_j)} P_{adap}(w_i|w_{i-1},w_{i-2}) \quad (15)$$

[5] Equation (14) is smoothed to avoid zero probabilities.

On the one hand, the model in equation (15) takes long distance dependency constraints into account, and has some notion of syntactic structure through the use of attachment probabilities. On the other hand, it has a primitive notion of caption length estimated by $P(len(C) = \sum_{j=1}^{m} len(\rho_j))$ and will therefore generate captions of the same (phrase) length. Ideally, we would like the model to vary the length of its output depending on the chosen context. However, we leave this to future work.

Search To generate a caption it is necessary to find the sequence of words that maximizes $P(w_1, w_2, ..., w_n)$ for the word-based model (equation (8)) and $P(\rho_1, \rho_2, ..., \rho_m)$ for the phrase-based model (equation (15)). We rewrite both probabilities as the weighted sum of their log form components and use beam search to find a near-optimal sequence. Note that we can make search more efficient by reducing the size of the document D. Using one of the models from Section 5, we may rank its sentences in terms of their relevance to the image keywords and consider only the n-best ones. Alternatively, we could consider the single most relevant sentence together with its surrounding context under the assumption that neighboring sentences are about the same or similar topics.

7 Experimental Setup

In this section we discuss our experimental design for assessing the performance of the caption generation models presented above. We give details on our training procedure, parameter estimation, and present the baseline methods used for comparison with our models.

Data All our experiments were conducted on the corpus created by Feng and Lapata (2008), following their original partition of the data (2,881 image-caption-document tuples for training, 240 tuples for development and 240 for testing). Documents and captions were parsed with the Stanford parser (Klein and Manning, 2003) in order to obtain dependencies for the phrase-based abstractive model.

Model Parameters For the image annotation model we extracted 150 (on average) SIFT features which were quantized into 750 visual terms. The underlying topic model was trained with 1,000 topics using only content words (i.e., nouns, verbs, and adjectives) that appeared no less than five times in the corpus. For all models discussed here (extractive and abstractive) we report results with the 15 best annotation keywords. For the abstractive models, we used a trigram model trained with the SRI toolkit on a newswire corpus consisting of BBC and Yahoo! news documents (6.9 M words). The attachment probabilities (see equation (14)) were estimated from the same corpus. We tuned the caption length parameter on the development set using a range of $[5, 14]$ tokens for the word-based model and $[2, 5]$ phrases for the phrase-based model. Following Banko et al. (2000), we approximated the length distribution with a Gaussian. The scaling parameter β for the adaptive language model was also tuned on the development set using a range of [0.5,0.9]. We report results with β set to 0.5. For the abstractive models the beam size was set to 500 (with at least 50 states for the word-based model). For the phrase-based model, we also experimented with reducing the search scope, either by considering only the n most similar sentences to the keywords (range $[2, 10]$), or simply the single most similar sentence and its neighbors (range $[2, 5]$). The former method delivered better results with 10 sentences (and the KL divergence similarity function).

Evaluation We evaluated the performance of our models automatically, and also by eliciting human judgments. Our automatic evaluation was based on Translation Edit Rate (TER, Snover et al. 2006), a measure commonly used to evaluate the quality of machine translation output. TER is defined as the minimum number of edits a human would have to perform to change the system output so that it exactly matches a reference translation. In our case, the original captions written by the BBC journalists were used as reference:

$$\text{TER}(E, E_r) = \frac{\text{Ins} + \text{Del} + \text{Sub} + \text{Shft}}{N_r} \qquad (16)$$

where E is the hypothetical system output, E_r the reference caption, and N_r the reference length. The number of possible edits include insertions (Ins), deletions (Del), substitutions (Sub) and shifts (Shft). TER is similar to word error rate, the only difference being that it allows shifts. A shift moves a contiguous sequence to a different location within the the same system output and is counted as a single edit. The perfect TER score is 0, however note that it can be higher than 1 due to insertions. The minimum translation edit align-

JS Divergence	$1.77^{*\dagger}$	18.6
Abstract Words	$1.11^{*\dagger}$	10.0
Abstract Phrases	$1.06^{*\dagger}$	10.1

Table 2: TER results for extractive, abstractive models, and lead sentence baseline; *: sig. different from lead sentence; †: sig. different from KL and JS divergence.

ment is usually found through beam search. We used TER to compare the output of our extractive and abstractive models and also for parameter tuning (see the discussion above).

In our human evaluation study participants were presented with a document, an associated image, and its caption, and asked to rate the latter on two dimensions: grammaticality (is the sentence fluent or word salad?) and relevance (does it describe succinctly the content of the image and document?). We used a 1–7 rating scale, participants were encouraged to give high ratings to captions that were grammatical and appropriate descriptions of the image given the accompanying document. We randomly selected 12 document-image pairs from the test set and generated captions for them using the best extractive system, and two abstractive systems (word-based and phrase-based). We also included the original human-authored caption as an upper bound. We collected ratings from 23 unpaid volunteers, all self reported native English speakers. The study was conducted over the Internet.

8 Results

Table 2 reports our results on the test set using TER. We compare four extractive models based on word overlap, cosine similarity, and two probabilistic similarity measures, namely KL and JS divergence and two abstractive models based on words (see equation (8)) and phrases (see equation (15)). We also include a simple baseline that selects the first document sentence as a caption and show the average caption length (AvgLen) for each model. We examined whether performance differences among models are statistically significant, using the Wilcoxon test.

Model	Grammaticality	Relevance
KL Divergence	$6.42^{*\dagger}$	$4.10^{*\dagger}$
Abstract Words	$2.08^{\dagger}$	$3.20^{\dagger}$
Abstract Phrases	4.80^{*}	4.96^{*}
Gold Standard	$6.39^{*\dagger}$	5.55^{*}

Table 3: Mean ratings on caption output elicited by humans; *: sig. different from word-based abstractive system; †: sig. different from phrase-based abstractive system.

As can be seen the probabilistic models (KL and JS divergence) outperform word overlap and cosine similarity (all differences are statistically significant, $p < 0.01$).[6] They make use of the same topic model as the image annotation model, and are thus able to select sentences that cover common content. They are also significantly better than the lead sentence which is a competitive baseline. It is well known that news articles are written so that the lead contains the most important information in a story.[7] This is an encouraging result as it highlights the importance of the visual information for the caption generation task. In general, word overlap is the worst performing model which is not unexpected as it does not take any lexical variation into account. Cosine is slightly better but not significantly different from the lead sentence. The abstractive models obtain the best TER scores overall, however they generate shorter captions in comparison to the other models (closer to the length of the gold standard) and as a result TER treats them favorably, simply because the number of edits is less. For this reason we turn to the results of our judgment elicitation study which assesses in more detail the quality of the generated captions.

Recall that participants judge the system output on two dimensions, grammaticality and relevance. Table 3 reports mean ratings for the output of the extractive system (based on the KL divergence), the two abstractive systems, and the human-authored gold standard caption. We performed an Analysis of Variance (ANOVA) to examine the effect of system type on the generation task. Post-hot Tukey tests were carried out on the mean of the ratings shown in Table 3 (for grammaticality and relevance).

[6] We also note that mean length differences are not significant among these models.

[7] As a rule of thumb the lead should answer most or all of the five W's (who, what, when, where, why).

G:	King Tupou, who was 88, died a week ago.
KL:	Last year, thousands of Tongans took part in unprecedented demonstrations to demand greater democracy and public ownership of key national assets.
A_W:	King Toupou IV died at the age of Tongans last week.
A_P:	King Toupou IV died at the age of 88 last week.
G:	Cadbury will increase its contamination testing levels.
KL:	Contaminated Cadbury's chocolate was the most likely cause of an outbreak of salmonella poisoning, the Health Protection Agency has said.
A_W:	Purely dairy milk buttons Easter had agreed to work has caused.
A_P:	The 105g dairy milk buttons Easter egg affected by the recall.
G:	Satellite instruments can distinguish "old" Arctic ice from "new".
KL:	So a planet with less ice warms faster, potentially turning the projected impacts of global warming into reality sooner than anticipated.
A_W:	Dr less winds through ice cover all over long time when.
A_P:	The area of the Arctic covered in Arctic sea ice cover.
G:	Children were found to be far more internet-wise than parents.
KL:	That's where parents come in.
A_W:	The survey found a third of children are about mobile phones.
A_P:	The survey found a third of children in the driving seat.

Table 4: Captions written by humans (G) and generated by extractive (KL), word-based abstractive (A_W), and phrase-based extractive (A_P systems).

The word-based system yields the least grammatical output. It is significantly worse than the phrase-based abstractive system ($\alpha < 0.01$), the extractive system ($\alpha < 0.01$), and the gold standard ($\alpha < 0.01$). Unsurprisingly, the phrase-based system is significantly less grammatical than the gold standard and the extractive system, whereas the latter is perceived as equally grammatical as the gold standard (the difference in the means is not significant). With regard to relevance, the word-based system is significantly worse than the phrase-based system, the extractive system, and the gold-standard. Interestingly, the phrase-based system performs on the same level with the human gold standard (the difference in the means is not significant) and significantly better than the extractive system. Overall, the captions generated by the phrase-based system, capture the same content as the human-authored captions, even though they tend to be less grammatical. Examples of system output for the image-document pairs shown in Table 1 are given in Table 4 (the first row corresponds to the left picture (top row) in Table 1, the second row to the right picture, and so on).

9 Conclusions

We have presented extractive and abstractive models that generate image captions for news articles. A key aspect of our approach is to allow both the visual and textual modalities to influence the generation task. This is achieved through an image annotation model that characterizes pictures in terms of description keywords that are subsequently used to guide the caption generation process. Our results show that the visual information plays an important role in content selection. Simply extracting a sentence from the document often yields an inferior caption. Our experiments also show that a probabilistic abstractive model defined over phrases yields promising results. It generates captions that are more grammatical than a closely related word-based system and manages to capture the gist of the image (and document) as well as the captions written by journalists.

Future extensions are many and varied. Rather than adopting a two-stage approach, where the image processing and caption generation are carried out sequentially, a more general model should integrate the two steps in a unified framework. Indeed, an avenue for future work would be to define a phrase-based model for both image annotation and caption generation. We also believe that our approach would benefit from more detailed linguistic and non-linguistic information. For instance, we could experiment with features related to document structure such as titles, headings, and sections of articles and also exploit syntactic information more directly. The latter is currently used in the phrase-based model by taking attachment probabilities into account. We could, however, improve grammaticality more globally by generating a well-formed tree (or dependency graph).

Generating image descriptions using dependency relational patterns

Abstract

This paper presents a novel approach to automatic captioning of geo-tagged images by summarizing multiple web-documents that contain information related to an image's location. The summarizer is biased by dependency pattern models towards sentences which contain features typically provided for different scene types such as those of churches, bridges, etc. Our results show that summaries biased by dependency pattern models lead to significantly higher ROUGE scores than both n-gram language models reported in previous work and also Wikipedia baseline summaries. Summaries generated using dependency patterns also lead to more readable summaries than those generated without dependency patterns.

1 Introduction

The number of images tagged with location information on the web is growing rapidly, facilitated by the availability of GPS (Global Position System) equipped cameras and phones, as well as by the widespread use of online social sites. The majority of these images are indexed with GPS coordinates (latitude and longitude) only and/or have minimal captions. This typically small amount of textual information associated with the image is of limited usefulness for image indexing, organization and search. Therefore methods which could automatically supplement the information available for image indexing and lead to improved image retrieval would be extremely useful.

Following the general approach proposed by Aker and Gaizauskas (2009), in this paper we describe a method for automatic image captioning or caption enhancement starting with only a scene or subject type and a set of place names pertaining to an image – for example $\langle$church, $\{$St. Paul's,London$\}\rangle$. Scene type and place names can be obtained automatically given GPS coordinates and compass information using techniques such as those described in Xin et al. (2010) – that task is not the focus of this paper.

Our method applies only to images of static features of the built or natural landscape, i.e. objects with persistent geo-coordinates, such as buildings and mountains, and not to images of objects which move about in such landscapes, e.g. people, cars, clouds, etc. However, our technique is suitable not only for image captioning but in any application context that requires summary descriptions of instances of object classes, where the instance is to be characterized in terms of the features typically mentioned in describing members of the class.

Aker and Gaizauskas (2009) have argued that humans appear to have a conceptual model of what is salient regarding a certain object type (e.g. church, bridge, etc.) and that this model informs their choice of what to say when describing an instance of this type. They also experimented with representing such conceptual models using n-gram language models derived from corpora consisting of collections of descriptions of instances of specific object types (e.g. a corpus of descriptions of churches, a corpus of bridge descriptions, and so on) and reported results showing that incorporating such n-gram language models as a feature in a feature-based extractive summarizer improves the quality of automatically generated summaries.

The main weakness of n-gram language models is that they only capture very local information about short term sequences and cannot model long distance dependencies between terms. For example one common and important feature of object descriptions is the simple specification of the object type, e.g. the information that the object *London Bridge* is a *bridge* or that the *Rhine* is a *river*. If this information is expressed as in the first line of Table 1, n-gram language models are likely to

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1250–1258,
Uppsala, Sweden, 11-16 July 2010.

Table 1: Example of sentences which express the type of an object.

London Bridge is a **bridge**...
The **Rhine** (German: Rhein; Dutch: Rijn; French: Rhin; Romansh: Rain; Italian: Reno; Latin: Rhenus West Frisian Ryn) is one of the longest and most important **rivers** in Europe...

reflect it, since one would expect the tri-gram *is a bridge* to occur with high frequency in a corpus of bridge descriptions. However, if the type predication occurs with less commonly seen local context, as is the case for the object *Rhine* in the second row of Table 1 – *most important rivers* – n-gram language models may well be unable to identify it.

Intuitively, what is important in both these cases is that there is a predication whose subject is the object instance of interest and the head of whose complement is the object type: *London Bridge ... is ... bridge* and *Rhine ... is ... river*. Sentences matching such patterns are likely to be important ones to include in a summary. This intuition suggests that rather than representing object type conceptual models via corpus-derived language models as do Aker and Gaizauskas (2009), we do so instead using *corpus-derived dependency patterns*.

We pursue this idea in this paper, our hypothesis being that information that is important for describing objects of a given type will frequently be realized linguistically via expressions with the same dependency structure. We explore this hypothesis by developing a method for deriving common dependency patterns from object type corpora (Section 2) and then incorporating these patterns into an extractive summarization system (Section 3). In Section 4 we evaluate the approach both by scoring against model summaries and via a readability assessment. Since our work aims to extend the work of Aker and Gaizauskas (2009) we reproduce their experiments with n-gram language models in the current setting so as to permit accurate comparison.

Multi-document summarizers face the problem of avoiding redundancy: often, important information which must be included in the summary is repeated several times across the document set, but must be included in the summary only once. We can use the dependency pattern approach to address this problem in a novel way. The common approach to avoiding redundancy is to use a text similarity measure to block the addition of a further sentence to the summary if it is too similar to one already included. Instead, since specific dependency patterns express specific types of information we can group the patterns into groups expressing the same type of information and then, during sentence selection, ensure that sentences matching patterns from different groups are selected in order to guarantee broad, non-redundant coverage of information relevant for inclusion in the summary. We report work experimenting with this idea too.

Table 2: Object types and the number of articles in each object type corpus. Object types which are bold are covered by the evaluation image set.

2 Representing conceptual models

2.1 Object type corpora

We derive n-gram language and dependency pattern models using object type corpora made available to us by Aker and Gaizauskas. Aker and Gaizauskas (2009) define an object type corpus as a collection of texts about a specific static object type such as *church, bridge, etc.* Objects can be named locations such as *Eiffel Tower*. To refer to such names they use the term *toponym*. To build such object type corpora the authors categorized Wikipedia articles places by object type. The object type of each article was identified automatically by running *Is-A* patterns over the first five sentences of the article. The authors report 91% accuracy for their categorization process. The most populated of the categories identified (in total 107 containing articles about places around the world) are shown in Table 2.

2.2 N-gram language models

Aker and Gaizauskas (2009) experimented with uni-gram and bi-gram language models to capture the features commonly used when describing an object type and used these to bias the sentence selection of the summarizer towards the sentences that contain these features. As in Song and Croft (1999) they used their language models in a gener-

ative way, i.e. they calculate the probability that a sentence is generated based on a n-gram language model. They showed that summarizer biased with bi-gram language models produced better results than those biased with uni-gram models. We replicate the experiments of Aker and Gaizauskas and generate a bi-gram language model for each object type corpus. In later sections we use *LM* to refer to these models.

2.3 Dependency patterns

We use the same object type corpora to derive dependency patterns. Our patterns are derived from dependency trees which are obtained using the Stanford parser[1]. Each article in each object type corpus was pre-processed by sentence splitting and named entity tagging[2]. Then each sentence was parsed by the Stanford dependency parser to obtain relational patterns. As with the chain model introduced by Sudo et al. (2001) our relational patterns are concentrated on the verbs in the sentences and contain *n+1* words (the verb and *n* words in direct or indirect relation with the verb). The number *n* is experimentally set to two words.

For illustration consider the sentence shown in Table 3 that is taken from an article in the *bridge* corpus. The first two rows of the table show the original sentence and its form after named entity tagging. The next step in processing is to replace any occurrence of a string denoting the object type by the term "OBJECTTYPE" as shown in the third row of Table 3. The final two rows of the table show the output of the Stanford dependency parser and the relational patterns identified for this example. To obtain the relational patterns from the parser output we first identified the verbs in the output. For each such verb we extracted two further words being in direct or indirect relation to the current verb. Two words are directly related if they occur in the same relational term. The verb *built-4*, for instance, is directly related to *DATE-6* because they both are in the same relational term *prep-in(built-4, DATE-6)*. Two words are indirectly related if they occur in two different terms but are linked by a word that occurs in those two terms. The verb *was-3* is, for instance, indirectly related to *OBJECTTYPE-2* because they are both in different terms but linked with *built-4* that occurs in both terms. E.g. for the term *nsubjpass(built-4, OBJECTTYPE-2)* we use the verb *built* and extract patterns based on this. *OBJECTTYPE* is in direct relation to *built* and *The* is in indirect relation to *built* through *OBJECTTYPE*. So a pattern from these relations is *The OBJECTTYPE built*. The next pattern extracted from this term is *OBJECTTYPE was built*. This pattern is based on direct relations. The verb *built* is in direct relation to *OBJECTTYPE* and also to *was*. We continue this until we cover all direct relations with *built* resulting in two more patterns (*OBJECTTYPE built DATE* and *OBJECTTYPE built W*). It should be noted that we consider all direct and indirect relations while generating the patterns.

Table 3: Example sentence for dependency pattern.

Original sentence: The bridge was built in 1876 by W. W.
After NE tagging: The bridge was built in DATE by W. W.
Input to the parser: The OBJECTTYPE was built in DATE by W. W.
Output of the parser: *det(OBJECTTYPE-2, The-1), nsubjpass(built-4, OBJECTTYPE-2), auxpass(built-4, was-3), prep-in(built-4, DATE-6), nn(W-10, W-8), agent(built-4, W-10)*
Patterns: The OBJECTTYPE built, OBJECTTYPE was built, OBJECTTYPE built DATE, OBJECTTYPE built W, was built DATE, was built W

Following these steps we extracted relational patterns for each object type corpus along with the frequency of occurrence of the pattern in the entire corpus. The frequency values are used by the summarizer to score the sentences. In the following sections we will use the term *DpM* to refer to these dependency pattern models.

2.3.1 Pattern categorization

In addition to using dependency patterns as models for biasing sentence selection, we can also use them to control the kind of information to be included in the final summary (see Section 3.2). We may want to ensure that the summary contains a sentence describing the object type of the object, its location and some background information. For example, for the object *Eiffel Tower* we aim to say that it is a tower, located in Paris, designed by Gustave Eiffel, etc. To be able to do so, we categorize dependency patterns according to the type of information they express.

We manually analyzed human written descriptions about instances of different object types and recorded for each sentence in the descriptions the kind of information it contained about the object. We analyzed descriptions of 310 different objects where each object had up to four different human written descriptions (Section 4.1). We categorized the information contained in the descriptions into

[1] http://nlp.stanford.edu/software/lex-parser.shtml

[2] For performing shallow text analysis the OpenNLP tools (http://opennlp.sourceforge.net/) were used.

the following categories:

- **type**: sentences containing the "type" information of the object such as *XXX* is a *bridge*
- **year**: sentences containing information about when the object was built or in case of mountains, for instance, when it was first climbed
- **location**: sentences containing information about where the object is located
- **background**: sentences containing some specific information about the object
- **surrounding**: sentences containing information about what other objects are close to the main object
- **visiting**: sentences containing information about e.g. visiting times, etc.

We also manually assigned each dependency pattern in each corpus-derived model to one of the above categories, provided it occurred five or more times in the object type corpora. The patterns extracted for our example sentence shown in Table 3, for instance, are all categorized by *year* category because all of them contain information about the foundation date of an object.

3 Summarizer

We adopted the same overall approach to summarization used by Aker and Gaizauskas (2009) to generate the image descriptions. The summarizer is an extractive, query-based multi-document summarization system. It is given two inputs: a toponym associated with an image and a set of documents to be summarized which have been retrieved from the web using the toponym as a query. The summarizer creates image descriptions in a three step process. First, it applies shallow text analysis, including sentence detection, tokenization, lemmatization and POS-tagging to the given input documents. Then it extracts features from the document sentences. Finally, it combines the features using a linear weighting scheme to compute the final score for each sentence and to create the final summary. We modified the approach to feature extraction and the way the summarizer acquires the weights for feature combination. The following subsections describe how feature extraction/combination is done in more detail.

3.1 Feature Extraction

The original summarizer reported in Aker and Gaizauskas (2009) uses the following features to score the sentences:

- ***querySimilarity***: Sentence similarity to the query (toponym) (cosine similarity over the vector representation of the sentence and the query).
- ***centroidSimilarity***: Sentence similarity to the centroid. The centroid is composed of the 100 most frequently occurring non stop words in the document collection (cosine similarity over the vector representation of the sentence and the centroid).
- ***sentencePosition***: Position of the sentence within its document. The first sentence in the document gets the score 1 and the last one gets $\frac{1}{n}$ where *n* is the number of sentences in the document.
- ***starterSimilarity***: A sentence gets a binary score if it starts with the query term (e.g. *Westminster Abbey*, *The Westminster Abbey*, *The Westminster* or *The Abbey*) or with the object type, e.g. *The church*. We also allow gaps (up to four words) between *the* and the query to capture cases such as *The most magnificent Abbey*, etc.
- ***LMSim***[3]: The similarity of a sentence *S* to an n-gram language model *LM* (the probability that the sentence *S* is generated by *LM*).

In our experiments we extend this feature set by two dependency pattern related features: *DpMSim* and *DepCat*.

DpMSim is computed in a similar fashion to *LMSim* feature. We assign each sentence a dependency similarity score. To compute this score, we first parse the sentence on the fly with the Stanford parser and obtain the dependency patterns for the sentence. We then associate each dependency pattern of the sentence with the occurrence frequency of that pattern in the dependency pattern model (*DpM*). *DpMSim* is then computed as given in Equation 1. It is a sum of all occurrence frequencies of the dependency patterns detected in a sentence *S* that are also contained in the *DpM*.

$$DpMSim(S, DpM) = \sum_{p \in S} f_{DpM}(p) \quad (1)$$

The second feature, *DepCat*, uses dependency patterns to categorize the sentences rather than ranking them. It can be used independently from other features to categorize each sentence by one of the categories described in Section 2.3.1. To do this, we obtain the relational patterns for the current sentence, check whether for each such pattern whether it is included in the *DpM*, and, if so, we add to the sentence the category the pattern was manually associated with. It should be noted that a sentence can have more than one category. This can occur, for instance, if the sentence contains information about when *something* was built and at the same time where it is located. It is also important to mention that assigning sentences categories does not change the order in the ranked list.

We use *DepCat* to generate an automated summary by first including sentences containing the category "type", then "year" and so on until the

[3] In Aker and Gaizauskas (2009) this feature is called *modelSimilarity*.

summary length is violated. The sentences are selected according to the order in which they occur in the ranked list. From each of the first three categories ("type", "year" and "location") we take a single sentence to avoid redundancy. The same is applied to the final two categories ("surrounding" and "visiting"). Then, if length limit is not violated, we fill the summary with sentences from the "background" category until the word limit of 200 words is reached. Here the number of added sentences is not limited. Finally, we order the sentences by first adding the sentences from the first three categories to the summary, then the "background" related sentences and finally the last two sentences from the "surrounding" and "visiting" categories. However, in cases where we have not reached the summary word limit because of uncovered categories, i.e. there were not, for instance, sentences about "location", we add to the end of the summary the next top sentence from the ranked list that was not taken.

3.2 Sentence Selection

To compute the final score for each sentence Aker and Gaizauskas (2009) use a linear function with weighted features:

$$S_{score} = (\sum_{i=1}^{n} feature_i * weight_i) \qquad (2)$$

We use the same approach, but whereas the feature weights they use are experimentally set rather than learned, we learn the weights using linear regression instead. We used $\frac{2}{3}$ of the 310 images from our image set (see Section 4.1) to train the weights. The image descriptions from this data set are used as model summaries.

Our training data contains for each image a set of image descriptions taken from the *VirtualTourist* travel community web-site [4]. From this web-site we took all existing image descriptions about a particular image or object. Note that some of these descriptions about a particular object were used to derive the model summaries for that object (see Section 4.1). Assuming that model summaries contain the most relevant sentences about an object we perform ROUGE comparisons between the sentences in all the image descriptions and the model summaries, i.e. we pair each sentence from all image descriptions about a particular place with every sentence from all the model summaries for that particular object. Sentences which are exactly the same or have common parts will score higher in ROUGE than sentences which do not have anything in common. In this way, we have for each sentence from all existing image descriptions about an object a ROUGE score[5] indicating its relevance. We also ran the summarizer for each of these sentences to compute the values for the different features. This gives information about each feature's value for each sentence. Then the ROUGE scores and feature score values for every sentence were input to the linear regression algorithm to train the weights.

Given the weights, Equation 2 is used to compute the final score for each sentence. The final sentence scores are used to sort the sentences in the descending order. This sorted list is then used by the summarizer to generate the final summary as described in Aker and Gaizauskas (2009).

4 Evaluation

To evaluate our approach we used two different assessment methods: ROUGE (Lin, 2004) and manual readability. In the following we first describe the data sets used in each of these evaluations, and then we present the results of each assessment.

4.1 Data sets

For evaluation we use the image collection described in Aker and Gaizauskas (2010). The image collection contains 310 different images with manually assigned toponyms. The images cover 60 of the 107 object types identified from Wikipedia (see Table 2). For each image there are up to four short descriptions or model summaries. The model summaries were created manually based on image descriptions taken from *VirtualTourist* and contain a minimum of 190 and a maximum of 210 words. An example model summary about the *Eiffel Tower* is shown in Table 4. $\frac{2}{3}$ of this image collection was used to train the weights and the remaining $\frac{1}{3}$ (105 images) for evaluation.

To generate automatic captions for the images we automatically retrieved the top 30 related web-documents for each image using the Yahoo! search engine and the toponym associated with the image as a query. The text from these documents was extracted using an HTML parser and passed to the summarizer. The set of documents we used to generate our summaries excluded any *VirtualTourist* related sites, as these were used to generate

[4] www.virtualtourist.com

[5] We used ROUGE 1.

Table 4: Model, Wikipedia baseline and starterSimilarity+LMSim+DepCat summary for Eiffel Tower.

Model Summary	Wikipedia baseline summary	starterSimilarity+LMSim+DepCat summary
The Eiffel Tower is the most famous place in Paris. It is made of 15,000 pieces fitted together by 2,500,000 rivets. It's of 324 m (1070 ft) high structure and weighs about 7,000 tones. This world famous landmark was built in 1889 and was named after its designer, engineer Gustave Alexandre Eiffel. It is now one of the world's biggest tourist places which is visited by around 6,5 million people yearly. There are three levels to visit: Stages 1 and 2 which can be reached by either taking the steps (680 stairs) or the lift, which also has a restaurant "Altitude 95" and a Souvenir shop on the first floor. The second floor also has a restaurant "Jules Verne". Stage 3, which is at the top of the tower can only be reached by using the lift. But there were times in the history when Tour Eiffel was not at all popular, when the Parisians thought it looked ugly and wanted to pull it down. The Eiffel Tower can be reached by using the Mtro through Trocadro, Ecole Militaire, or Bir-Hakeim stops. The address is: Champ de Mars-Tour Eiffel.	The Eiffel Tower (French: Tour Eiffel, [tur efel]) is a 19th century iron lattice tower located on the Champ de Mars in Paris that has become both a global icon of France and one of the most recognizable structures in the world. The Eiffel Tower, which is the tallest building in Paris, is the single most visited paid monument in the world; millions of people ascend it every year. Named after its designer, engineer Gustave Eiffel, the tower was built as the entrance arch for the 1889 World's Fair. The tower stands at 324 m (1,063 ft) tall, about the same height as an 81-story building. It was the tallest structure in the world from its completion until 1930, when it was eclipsed by the Chrysler Building in New York City. Not including broadcast antennas, it is the second-tallest structure in France, behind the Millau Viaduct, completed in 2004. The tower has three levels for visitors. Tickets can be purchased to ascend either on stairs or lifts to the first and second levels.	The Eiffel Tower, which is the tallest building in Paris, is the single most visited paid monument in the world; millions of people ascend it every year. The tower is located on the Left Bank of the Seine River, at the northwestern extreme of the Parc du Champ de Mars, a park in front of the Ecole Militaire that used to be a military parade ground. The tower was met with much criticism from the public when it was built, with many calling it an eyesore. Counting from the ground, there are 347 steps to the first level, 674 steps to the second level, and 1,710 steps to the small platform on the top of the tower. Although it was the world's tallest structure when completed in 1889, the Eiffel Tower has since lost its standing both as the tallest lattice tower and as the tallest structure in France. The tower has two restaurants: Altitude 95, on the first floor 311ft (95m) above sea level; and the Jules Verne, an expensive gastronomical restaurant on the second floor, with a private lift.

Table 5: ROUGE scores for each single feature and Wikipedia baseline.

the model summaries.

4.2 ROUGE assessment

In the first assessment we compared the automatically generated summaries against model summaries written by humans using ROUGE (Lin, 2004). Following the Document Understanding Conference (DUC) evaluation standards we used ROUGE 2 (*R2*) and ROUGE SU4 (*RSU4*) as evaluation metrics (Dang, 2006) . ROUGE 2 gives recall scores for bi-gram overlap between the automatically generated summaries and the reference ones. ROUGE SU4 allows bi-grams to be composed of non-contiguous words, with a maximum of four words between the bi-grams.

As baselines for evaluation we used two different summary types. Firstly, we generated summaries for each image using the top-ranked non Wikipedia document retrieved in the Yahoo! search results for the given toponyms. From this document we create a baseline summary by selecting sentences from the beginning until the summary reaches a length of 200 words. As a second baseline we use the Wikipedia article for a given toponym from which we again select sentences from the beginning until the summary length limit is reached.

First, we compared the baseline summaries against the VirtualTourist model summaries. The comparison shows that the Wikipedia baseline ROUGE scores (R2 .097***, RSU4 .14***) are significantly higher than the first document ones (R2 0.042, RSU4 .079) [6]. Thus, we will focus on the Wikipedia baseline summaries to draw conclusions about our automatic summaries. Table 4 shows the Wikipedia baseline summary about the *Eiffel Tower*.

Secondly, we separately ran the summarizer over the top ten documents for each single feature and compared the automated summaries against the model ones. The results of this comparison are shown in Table 5.

Table 5 shows that the dependency model feature (*DpMSim*) contributes most to the summary quality according to the ROUGE metrics. It is also significantly better than all other feature scores except the *LMSim* feature. Compared to *LMSim* ROUGE scores the *DpMSim* feature offers only a moderate improvement. The same moderate improvement we can see between the *DpMSim* RSU4 and the *Wiki* RSU4. The lowest ROUGE scores are obtained if only sentence position (*sentecePosition*) is used.

To see how the ROUGE scores change when features are combined with each other we performed different combinations of the features, ran the summarizer for each combination and compared the automated summaries against the model ones. In the different combinations we

[6] To assess the statistical significance of ROUGE score differences between multiple summarization results we performed a pairwise Wilcoxon signed-rank test. We use the following conventions for indicating significance level in the tables: *** = $p < .0001$, ** = $p < .001$, * = $p < .05$ and no star indicates non-significance.

Table 6: ROUGE scores of feature combinations which score moderately or significantly higher than dependency pattern model (*DpMSim*) feature and Wikipedia baseline.

Recall	starterSimilarity + LMSim	starterSimilarity + LMSim + DepCat***	DpmSim	Wiki
R2	.095	**.102**	.093	.097
RSU4	.145	**.155**	.145	.14

also included the dependency pattern categorization (*DepCat*) feature explained in Section 3.1. Table 6 shows the results of feature combinations which score moderately or significantly higher than the dependency pattern model (*DpMSim*) feature score shown in Table 5.

The results showed that combining *DpMSim* with other features did not lead to higher ROUGE scores than those produced by that feature alone.

The summaries categorized by dependency patterns (*starterSimilarity+LMSim+DepCat*) achieve significantly higher ROUGE scores than the Wikipedia baseline. For both ROUGE R2 and ROUGE SU4 the significance is at level $p < .0001$. Table 4 shows a summary about the *Eiffel Tower* obtained using this *starterSimilarity+LMSim+DepCat* feature. Table 5 also shows the ROUGE scores of the feature combination *starterSimilarity* and *LMSim* used without the dependency categorization (*DepCat*) feature. It can be seen that this combination without the dependency patterns lead to lower ROUGE scores in ROUGE 2 and only moderate improvement in ROUGE SU4 if compared with Wikipedia baseline ROUGE scores.

4.3 Readability assessment

We also evaluated our summaries using a readability assessment as in DUC and TAC. DUC and TAC manually assess the quality of automatically generated summaries by asking human subjects to score each summary using five criteria – *grammaticality, redundancy, clarity, focus* and *structure* criteria. Each criterion is scored on a five point scale with high scores indicating a better result (Dang, 2005).

For this evaluation we used the same 105 images as in the ROUGE evaluation. As the ROUGE evaluation showed that the dependency pattern categorization (*DepCat*) renders the best results when used in feature combination *starterSimilarity + LMSim + DepCat*, we further investigated the contribution of dependency pattern categorization by performing a readability assessment on summaries generated using this feature combination. For comparison we also evaluated summaries which were not structured by dependency patterns (*starterSimilarity + LMSim*) and also the Wikipedia baseline summaries.

We asked four people to assess the summaries. Each person was shown all 315 summaries (105 from each summary type) in a random way and was asked to assess them according to the DUC and TAC manual assessment scheme. The results are shown in Table 7.

We see from Table 7 that using dependency patterns to categorize the sentences and produce a structured summary helps to obtain better readable summaries. Looking at the 5 and 4 scores the table shows that the dependency pattern categorized summaries (*SLMD*) have better clarity (85% of the summaries), are more coherent (74% of the summaries), contain less redundant information (83% of the summaries) and have better grammar (92% of the summaries) than the ones without dependency categorization (80%, 70%, 60%, 84%).

The scores of our automated summaries were better than the Wikipedia baseline summaries in the *grammar* feature. However, in other features the Wikipedia baseline summaries obtained better scores than our automated summaries. This comparison show that there is a gap to fill in order to obtain better readable summaries.

5 Related Work

Our approach has an advantage over related work in automatic image captioning in that it requires only GPS information associated with the image in order to generate captions. Other attempts towards automatic generation of image captions generate captions based on the immediate textual context of the image with or without consideration of image related features such as colour, shape or texture (Deschacht and Moens, 2007; Mori et al., 2000; Barnard and Forsyth, 2001; Duygulu et al., 2002; Barnard et al., 2003; Pan et al., 2004; Feng and Lapata, 2008; Satoh et al., 1999; Berg et al., 2005). However, Marsch & White (2003) argue that the content of an image and its immediate text have little semantic agreement and this can, according to Purves et al. (2008), be misleading to image retrieval. Furthermore, these approaches assume that the image has been obtained from a document. In cases where there is no document associated with the image, which is the scenario we are principally concerned with, these techniques are not applicable.

Table 7: Readability evaluation results: Each cell shows the percentage of summaries scoring the ranking score heading the column for each criterion in the row as produced by the summary method indicated by the subcolumn heading – Wikipedia baseline (W), starterSimilarity + LMSim (SLM) and starterSimilarity + LMSim + DepCat (SLMD). The numbers indicate the percentage values averaged over the four people.

Dependency patterns have been exploited in various language processing applications. In information extraction, for instance, dependency patterns have been used to extract relevant information from text resources (Yangarber et al., 2000; Sudo et al., 2001; Culotta and Sorensen, 2004; Stevenson and Greenwood, 2005; Bunescu and Mooney, 2005; Stevenson and Greenwood, 2009). However, dependency patterns have not been used extensively in summarization tasks. We are aware only of the work described in Nobata et al. (2002) who used dependency patterns in combination with other features to generate extracts in a single document summarization task. The authors found that when learning weights in a simple feature weigthing scheme, the weight assigned to dependency patterns was lower than that assigned to other features. The small contribution of the dependency patterns may have been due to the small number of documents they used to derive their dependency patterns – they gathered dependency patterns from only ten domain specific documents which are unlikely to be sufficient to capture repeated features in a domain.

6 Discussion and Conclusion

We have proposed a method by which dependency patterns extracted from corpora of descriptions of instances of particular object types can be used in a multi-document summarizer to automatically generate image descriptions. Our evaluations show that such an approach yields summaries which score more highly than an approach which uses a simpler representation of an object type model in the form of a n-gram language model.

When used as the sole feature for sentence ranking, dependency pattern models (*DpMSim*) produced summaries with higher ROUGE scores than those obtained using the features reported in Aker and Gaizauskas (2009). These dependency pattern models also achieved a modest improvement over Wikipedia baseline ROUGE SU4. Furthermore, we showed that using dependency patterns in combination with features reported in Aker and Gaizauskas to produce a structured summary led to significantly better results than Wikipedia baseline summaries as assessed by ROUGE. However, human assessed readability showed that there is still scope for improvement.

These results indicate that dependency patterns are worth investigating for object focused automated summarization tasks. Such investigations should in particular concentrate on how dependency patterns can be used to structure information within the summary, as our best results were achieved when dependency patterns were used for this purpose.

There are a number of avenues to pursue in future work. One is to explore how dependency patterns could be used to produce generative summaries and/or perform sentence trimming. Another is to investigate how dependency patterns might be automatically clustered into groups expressing similar or related facts, rather than relying on manual categorization of dependency patterns into categories such as “type”, “year”, etc. as was done here. Evaluation should be extended to investigate the utility of the automatically generated image descriptions for image retrieval. Finally, we also plan to analyze automated ways for learning information structures (e.g. what is the flow of facts to describe a location) from existing image descriptions to produce better summaries.

7 Acknowlegment

The research reported was funded by the TRIPOD project supported by the European Commission under the contract No. 045335. We would like to thank Emina Kurtic, Mesude Bicak, Edina Kurtic and Olga Nesic for participating in our manual evaluation. We also would like to thank Trevor Cohn and Mark Hepple for discussions and comments.

Incorporating Extra-linguistic Information into Reference Resolution in Collaborative Task Dialogue

Abstract

This paper proposes an approach to reference resolution in situated dialogues by exploiting extra-linguistic information. Recently, investigations of referential behaviours involved in situations in the real world have received increasing attention by researchers (Di Eugenio et al., 2000; Byron, 2005; van Deemter, 2007; Spanger et al., 2009). In order to create an accurate reference resolution model, we need to handle extra-linguistic information as well as textual information examined by existing approaches (Soon et al., 2001; Ng and Cardie, 2002, etc.). In this paper, we incorporate extra-linguistic information into an existing corpus-based reference resolution model, and investigate its effects on reference resolution problems within a corpus of Japanese dialogues. The results demonstrate that our proposed model achieves an accuracy of 79.0% for this task.

1 Introduction

The task of identifying reference relations including anaphora and coreferences within texts has received a great deal of attention in natural language processing, from both theoretical and empirical perspectives. Recently, research trends for reference resolution have drastically shifted from handcrafted rule-based approaches to corpus-based approaches, due predominately to the growing success of machine learning algorithms (such as Support Vector Machines (Vapnik, 1998)); many researchers have examined ways for introducing various linguistic clues into machine learning-based models (Ge et al., 1998; Soon et al., 2001; Ng and Cardie, 2002; Yang et al., 2003; Iida et al., 2005; Yang et al., 2005; Yang et al., 2008; Poon and Domingos, 2008, etc.). Research has continued to progress each year, focusing on tackling the problem as it is represented in the annotated data sets provided by the Message Understanding Conference (MUC)[1] and the Automatic Content Extraction (ACE)[2]. In these data sets, coreference relations are defined as a limited version of a typical coreference; this generally means that only the relations where expressions refer to the same named entities are addressed, because it makes the coreference resolution task more information extraction-oriented. In other words, the coreference task as defined by MUC and ACE is geared toward only identifying coreference relations anchored to an entity within the text.

In contrast to this research trend, investigations of referential behaviour in real world situations have continued to gain interest in the language generation community (Di Eugenio et al., 2000; Byron, 2005; van Deemter, 2007; Foster et al., 2008; Spanger et al., 2009), aiming at applications such as human-robot interaction. Spanger et al. (2009) for example constructed a corpus by recording dialogues of two participants collaboratively solving the Tangram puzzle. The corpus includes extra-lingustic information synchronised with utterances (such as operations on the puzzle pieces). They analysed the relations between referring expressions and the extra-linguistic information, and reported that the pronominal usage of referring expressions is predominant. They also revealed that the multi-modal perspective of reference should be dealt with for more realistic reference understanding. Thus, a challenging issue in reference resolution is to create a model bridging a referring expression in the text and its object in the real world. As a first step, this paper focuses on incorporating extra-linguistic information into an existing corpus-based approach, taking Spanger et al. (2009)'s REX-J corpus[3] as the data set. In our

[1] www-nlpir.nist.gov/related_projects/muc/
[2] www.itl.nist.gov/iad/mig//tests/ace/
[3] The corpus was named REX-J after their publication of

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1259–1267,
Uppsala, Sweden, 11-16 July 2010.

problem setting, a referent needs to be identified by taking into account extra-linguistic information, such as the spatiala relations of puzzle pieces and the participants' operations on them, as well as any preceding utterances in the dialogue. We particularly focus on the participants' operation of pieces and so introduce it as several features in a machine learning-based approach.

This paper is organised as follows. We first explain the corpus of collaborative work dialogues in Section 2, and then present our approach for identifying a referent given a referring expression in situated dialogues in Section 3. Section 4 shows the results of our empirical evaluation. In Section 5 we compare our work with existing work on reference resolution, and then conclude this paper and discuss future directions in Section 6.

2 REX-J corpus: a corpus of collaborative work dialogue

For investigating dialogue from the multi-modal perspective, researchers have developed data sets including extra-linguistic information, bridging objects in the world and their referring expressions. The COCONUT corpus (Di Eugenio et al., 2000) is collected from keyboard-dialogues between two participants, who are collaborating on a simple 2D design task. The setting tends to encourage simple types of expressions by the participants. The COCONUT corpus is also limited to annotations with symbolic information about objects, such as object attributes and location in discrete coordinates. Thus, in addition to the artificial nature of interaction, such as using keyboard input, this corpus only records restricted types of data.

On the other hand, though the annotated corpus by Spanger et al. (2009) focuses on a limited domain (i.e. collaborative work dialogues for solving the Tangram puzzle using a puzzle simulator on the computer), the required operations to solve the puzzle, and the situation as it is updated by a series of operations on the pieces are both recorded by the simulator. The relationship between a referring expression in a dialogue and its referent on a computer display is also annotated. For this reason, we selected the REX-J corpus for use in our empirical evaluations on reference resolution. Before explaining the details of our evaluation, we sketch out the REX-J corpus and some of its prominent statistics.

Spanger et al. (2009), which describes its construction.

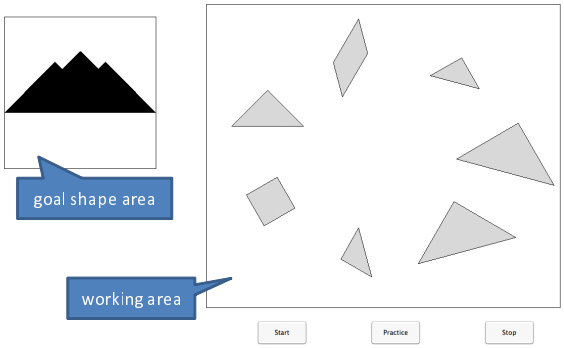

Figure 1: Screenshot of the Tangram simulator

2.1 The REX-J corpus

In the process of building the REX-J corpus, Spanger et al. (2009) recruited 12 Japanese graduate students (4 females and 8 males), and split them into 6 pairs. All pairs knew each other previously and were of the same sex and approximately the same age. Each pair was instructed to solve the Tangram puzzle. The goal of the puzzle is to construct a given shape by arranging seven pieces of simple figures as shown in Figure 1. The precise position of every piece and every action that the participants make are recorded by the Tangram simulator in which the pieces on the computer display can be moved, rotated and flipped with simple mouse operations. The piece position and the mouse actions were recorded at intervals of 10 msec. The simulator displays two areas: a goal shape area (the left side of Figure 1) and a working area (the right side of Figure 1) where pieces are shown and can be manipulated.

A different role was assigned to each participant of a pair: a *solver* and an *operator*. Given a certain goal shape, the solver thinks of the necessary arrangement of the pieces and gives instructions to the operator for how to move them. The operator manipulates the pieces with the mouse according to the solver's instructions. During this interaction, frequent uttering of referring expressions are needed to distinguish the pieces of the puzzle. This collaboration is achieved by placing a set of participants side by side, each with their own display showing the work area, and a shield screen set between them to prevent the operator from seeing the goal shape, which is visible only on the solver's screen, and to further restrict their

interaction to only speech.

2.2 Statistics

Table 1 lists the syntactic and semantic features of the referring expressions in the corpus with their respective frequencies. Note that multiple features can be used in a single expression. This list demonstrates that 'pronoun' and 'shape' features are frequently uttered in the corpus. This is because pronominal expressions are often used for pointing to a piece on a computer display. Expressions representing 'shape' frequently appear in dialogues even though they may be relatively redundant in the current utterance. From these statistics, capturing these two features can be judged as crucial as a first step toward accurate reference resolution.

3 Reference Resolution using Extra-linguistic Information

Before explaining the treatment of extra-linguistic information, let us first describe the task definition, taking the REX-J corpus as target data. In the task of reference resolution, the reference resolution model has to identify a referent (i.e. a piece on a computer display)[4]. In comparison to conventional problem settings for anaphora resolution, where the model searches for an antecedent out of a set of candidate antecedents from preceding utterances, expressions corresponding to antecedents are sometimes omitted because referring expressions are used as deixis (i.e. physically pointing to a piece on a computer display); they may also refer to a piece that has just been manipulated by an operator due to the temporal salience in a series of operations. For these reasons, even though the model checks all candidates in the preceding utterances, it may not find the antecedent of a given referring expression. However, we do know that each referent exists as a piece on the display. We can therefore establish that when a referring expression is uttered by either a solver or an operator, the model can choose one of seven pieces as a referent of the current referring expression.

3.1 Ranking model to identify referents

To investigate the impact of extra-linguistic information on reference resolution, we conduct an empirical evaluation in which a reference resolution model chooses a referent (i.e. a piece) for a given referring expression from the set of pieces illustrated on the computer display.

As a basis for our reference resolution model, we adopt an existing model for reference resolution. Recently, machine learning-based approaches to reference resolution (Soon et al., 2001; Ng and Cardie, 2002, etc.) have been developed, particularly focussing on identifying anaphoric relations in texts, and have achieved better performance than hand-crafted rule-based approaches. These models for reference resolution take into account linguistic factors, such as relative salience of candidate antecedents, which have been modeled in Centering Theory (Grosz et al., 1995) by ranking candidate antecedents appearing in the preceding discourse (Iida et al., 2003; Yang et al., 2003; Denis and Baldridge, 2008). In order to take advantage of existing models, we adopt the ranking-based approach as a basis for our reference resolution model.

In conventional ranking-based models, Yang et al. (2003) and Iida et al. (2003) decompose the ranking process into a set of pairwise comparisons of two candidate antecedents. However, recent work by Denis and Baldridge (2008) reports that appropriately constructing a model for ranking all candidates yields improved performance over those utilising pairwise ranking.

Similarly we adopt a *ranking-based* model, in which all candidate antecedents compete with one another to decide the most likely candidate antecedent. Although the work by Denis and Baldridge (2008) uses Maximum Entropy to create their ranking-based model, we adopt the Ranking SVM algorithm (Joachims, 2002), which learns a weight vector to rank candidates for a given partial ranking of each referent. Each training instance is created from the set of all referents for each referring expression. To define the partial ranking of referents, we simply rank referents referred to by a given referring expression as first place and other referents as second place.

3.2 Use of extra-linguistic information

Recent work on multi-modal reference resolution or referring expression generation (Prasov and Chai, 2008; Foster et al., 2008; Carletta et al., 2010) indicates that extra-linguistic information, such as eye-gaze and manipulation of objects, is

[4] In the current task on reference resolution, we deal only with referring expressions referring to a single piece to minimise complexity.

Table 1: Referring expressions in REX-J corpus

feature	tokens	example
demonstratives	742	
adjective	194	"*ano migigawa no sankakkei* (that triangle at the right side)"
pronoun	548	"*kore* (this)"
attribute	795	
size	223	"*tittyai sankakkei* (the small triangle)"
shape	566	"*ôkii sankakkei* (the large triangle)"
direction	6	"*ano sita muiteru dekai sankakkei* (that large triangle facing to the bottom)"
spatial relations	147	
projective	143	"*hidari no okkii sankakkei* (the small triangle on the left)"
topological	2	"*ôkii hanareteiru yatu* (the big distant one)"
overlapping	2	" *sono sita ni aru sankakkei* (the triangle underneath it)"
action-mentioning	85	"*migi ue ni doketa sankakkei* (the triangle you put away to the top right)"

one of essential clues for distinguishing deictic reference from endophoric reference.

For instance, Prasov and Chai (2008) demonstrated that integrating eye-gaze information (especially, relative fixation intensity, the amount of time spent fixating a candidate object) into the conventional dialogue history-based model improved the performance of reference resolution. Foster et al. (2008) investigated the relationship of referring expressions and the manupluation of objects on a collaborative construction task, which is similar to our Tangram task[5]. They reported about 36% of the initial mentioned referring expressions in their corpus were involved with participant's operations of objects, such as mouse manipulation.

From these background, in addition to the information about the history of the preceding discourse, which has been used in previous machine learning-based approaches, we integrate extra-linguistic information into the reference resolution model shown in Section 3.1. More precisely, we introduce the following extra-linguistic information: the information with regards to the history of a piece's movement and the mouse cursor positions, and the information of the piece currently manipulated by an operator. We next elaborate on these three kinds of features. All the features are summarised in Table 2.

3.2.1 Discourse history features

First, 'type of' features are acquired from the expressions of a given referring expression and its antecedent in the preceding discourse if the antecedent explicitly appears. These features have been examined by approaches to anaphora or coreference resolution (Soon et al., 2001; Ng and Cardie, 2002, etc.) to capture the salience of a candidate antecedent. To capture the textual aspect of dialogues for solving Tangram puzzle, we exploit the features such as a binary value indicating whether a referring expression has no antecedent in the preceding discourse and case markers following a candidate antecedent.

3.2.2 Action history features

The history of the operations may yield important clues that indicate the salience in terms of the temporal recency of a piece within a series of operations. To introduce this aspect as a set of features, we can use, for example, the time distance of a candidate referent (i.e. a piece in the Tangram puzzle) since the mouse cursor was moved over it. We call this type of feature the *action history feature*.

3.2.3 Current operation features

The recency of operations of a piece is also an important factor on reference resolution because it is directly associated with the focus of attention in terms of the cognition in a series of operations. For example, since a piece which was most recently manipulated is most salient from cognitive perspectives, it might be expected that the piece tends to be referred to by unmarked referring expressions such as pronouns. To incorporate such clues into the reference resolution model, we can use, for example, the time distance of a candidate referent since it was last manipulated in the preceding utterances. We call this type of feature the *current operation feature*.

[5]Note that the task defined in Foster et al. (2008) makes no distinction between two roles; a operator and a solver. Thus, two partipants both can mamipulate pieces on a computer display, but need to jointly construct to create a predefined goal shape.

Table 2: Feature set

(a) **Discourse history features**		
DH1 :	yes, no	a binary value indicating that P is referred to by the most recent referring expression.
DH2 :	yes, no	a binary value indicating that the time distance to the last mention of P is less than or equal to 10 sec.
DH3 :	yes, no	a binary value indicating that the time distance to the last mention of P is more than 10 sec and less than or equal to 20 sec.
DH4 :	yes, no	a binary value indicating that the time distance to the last mention of P is more than 20 sec.
DH5 :	yes, no	a binary value indicating that P has never been referred to by any mentions in the preceding utterances.
DH6 :	yes, no, N/A	a binary value indicating that the attributes of P are compatible with the attributes of R.
DH7 :	yes, no	a binary value indicating that R is followed by the case marker '*o* (accusative)'.
DH8 :	yes, no	a binary value indicating that R is followed by the case marker '*ni* (dative)'.
DH9 :	yes, no	a binary value indicating that R is a pronoun and the most recent reference to P is not a pronoun.
DH10 :	yes, no	a binary value indicating that R is not a pronoun and was most recently referred to by a pronoun.
(b) **Action history features**		
AH1 :	yes, no	a binary value indicating that the mouse cursor was over P at the beginning of uttering R.
AH2 :	yes, no	a binary value indicating that P is the last piece that the mouse cursor was over when feature AH1 is 'no'.
AH3 :	yes, no	a binary value indicating that the time distance is less than or equal to 10 sec after the mouse cursor was over P.
AH4 :	yes, no	a binary value indicating that the time distance is more than 10 sec and less than or equal to 20 sec after the mouse cursor was over P.
AH5 :	yes, no	a binary value indicating that the time distance is more than 20 sec after the mouse cursor was over P.
AH6 :	yes, no	a binary value indicating that the mouse cursor was never over P in the preceding utterances.
(c) **Current operation features**		
CO1 :	yes, no	a binary value indicating that P is being manipulated at the beginning of uttering R.
CO2 :	yes, no	a binary value indicating that P is the most recently manipulated piece when feature CO1 is 'no'.
CO3 :	yes, no	a binary value indicating that the time distance is less than or equal to 10 sec after P was most recently manipulated.
CO4 :	yes, no	a binary value indicating that the time distance is more than 10 sec and less than or equal to 20 sec after P was most recently manipulated.
CO5 :	yes, no	a binary value indicating that the time distance is more than 20 sec after P was most recently manipulated.
CO6 :	yes, no	a binary value indicating that P has never been manipulated.

P stands for a piece of the Tangram puzzle (i.e. a candidate referent of a referring expression) and R stands for the target referring expression.

4 Empirical Evaluation

In order to investigate the effect of the extra-linguistic information introduced in this paper, we conduct an empirical evaluation using the REX-J corpus.

4.1 Models

As we see in Section 2.2, the feature testing whether a referring expression is a pronoun or not is crucial because it is directly related to the 'deictic' usage of referring expressions, whereas other expressions tend to refer to an expression appearing in the preceding utterances. As described in Denis and Baldridge (2008), when the size of training instances is relatively small, the models induced by learning algorithms (e.g. SVM) should be separately created with regards to distinct features. Therefore, focusing on the difference of the pronominal usage of referring expressions, we separately create the reference resolution models; one is for identifying a referent of a given pronoun, and the other is for all other expressions. We henceforth call the former model the *pronoun model* and the latter one the *non-pronoun model* respectively. At the training phase, we use only training instances whose referring expressions are pronouns for creating the pronoun model, and all other training instances are used for the non-pronoun model. The model using one of these models depending on the referring expression to be solved is called the *separate model*.

To verify Denis and Baldridge (2008)'s premise mentioned above, we also create a model using all training instances without dividing pronouns and other. This model is called the *combined model* hereafter.

4.2 Experimental setting

We used 40 dialogues in the REX-J corpus[6], containing 2,048 referring expressions. To facilitate the experiments, we conduct 10-fold crossvalidation using 2,035 referring expressions, each of which refers to a single piece in a computer dis-

[6]Spanger et al. (2009)'s original corpus contains only 24 dialogues. In addition to this, we obtained anothor 16 dialogues by favour of the authors.

Table 3: Results on reference resolution: accuracy

model	discourse history (baseline)		+action history*		+current operation		+action history, +current operation*	
separated model (a+b)	0.664	(1352/2035)	0.790	(1608/2035)	0.685	(1394/2035)	0.780	(1587/2035)
a) pronoun model	0.648	(660/1018)	0.886	(902/1018)	0.692	(704/1018)	0.875	(891/1018)
b) non-pronoun model	0.680	(692/1017)	0.694	(706/1017)	0.678	(690/1017)	0.684	(696/1017)
combined model	0.664	(1352/2035)	0.749	(1524/2035)	0.650	(1322/2035)	0.743	(1513/2035)

'*' means the extra-lingustic features (or the combinations of them) significantly contribute to improving performance. For the significant tests, we used McNemar test with Bonferroni's correction for multiple comparisons, i.e. $\alpha/K = 0.05/4 = 0.01$.

play[7].

As a baseline model, we adopted a model only using the discourse history features. We utilised *SVM*^{rank}[8] as an implementation of the Ranking SVM algorithm, in which the parameter *c* was set as 1.0 and the remaining parameters were set to their defaults.

4.3 Results

The results of each model are shown in Table 3. First of all, by comparing the models with and without extra-linguistic information (i.e. the model using all features shown in Table 2 and the baseline model), we can see the effectiveness of extra-linguistic information. The results typically show that the former achieved better performance than the latter. In particular, it indicates that exploiting the action history features are significantly useful for reference resolution in this data set.

Second, we can also see the impact of extra-linguistic information (especially, the action history features) with regards to the pronoun and non-pronoun models. In the former case, the model with extra-linguistic information improved by about 22% compared with the baseline model. On the other hand, in the latter case, the accuracy improved by only 7% over the baseline model. The difference may be caused by the fact that pronouns are more sensitive to the usage of the action history features because pronouns are often uttered as deixis (i.e. a pronoun tends to directly refer to a piece shown in a computer display).

The results also show that the model using the discourse history and action history features achieved better performance than the model using all the features. This may be due to the duplicated definitions between the action history and current operation features. As we can see in the feature definitions of CO1 and AH1, some current operation features partially overlap with the action history features, which is effectively used in the ranking process. However, the other current operation features may have bad effects for ranking referents due to their ill-formed definitions. To shed light on this problem, we need additional investigation of the usage of features, and to refine their definitions.

Finally, the results show that the performance of the separated model is significantly better than that of the combined model[9], which indicates that separately creating models to specialise in distinct factors (i.e. whether a referring expression is a pronoun or not) is important as suggested by Denis and Baldridge (2008).

We next investigated the significance of each

Table 4: Weights of the features in each model

	pronoun model		non-pronoun model	
rank	feature	weight	feature	weight
1	AH1	0.6371	DH6	0.7060
2	AH3	0.2721	DH2	0.2271
3	DH1	0.2239	AH3	0.2035
4	DH2	0.2191	AH1	0.1839
5	CO1	0.1911	DH1	0.1573
6	DH9	0.1055	DH7	0.0669
7	AH2	0.0988	CO5	0.0433
8	CO3	0.0852	CO3	0.0393
9	DH6	0.0314	CO1	0.0324
10	CO2	0.0249	DH3	0.0177
11	DH10	0	AH4	0.0079
12	DH7	-0.0011	AH2	0.0069
13	DH3	-0.0088	CO4	0.0059
14	CO6	-0.0228	DH10	0.0059
15	CO4	-0.0308	DH9	0
16	CO5	-0.0317	CO2	-0.0167
17	DH8	-0.0371	DH8	-0.0728
18	AH6	-0.0600	CO6	-0.0885
19	AH4	-0.0761	DH4	-0.0924
20	DH5	-0.0910	AH5	-0.1042
21	DH4	-0.1193	AH6	-0.1072
22	AH5	-0.1361	DH5	-0.1524

[7]The remaining 13 instances referred to either more than one piece or a class of pieces, thus were excluded in this experiment.

[8]www.cs.cornell.edu/people/tj/svm_light/svm_rank.html

[9]For the significant tests, we used McNemar test ($\alpha = 0.05$).

Table 5: Frequencies of REs relating to on-mouse

	pronouns	others	total
# all REs	548	693	1,241
# on-mouse	452	155	607
	(82.5%)	(22.4%)	(48.9%)

'# all REs' stands for the frequency of referring expressions uttered in the corpus and '# on-mouse' is the frequency of referring expressions in the situation when a referring expression is uttered and a mouse cursor is over the piece referred to by the expression.

feature of the pronoun and non-pronoun models. We calculate the weight of feature f shown in Table 2 according to the following formula.

$$\text{weight}(f) = \sum_{x \in SVs} w_x z_x(f) \qquad (1)$$

where *SVs* is a set of the support vectors in a ranker induced by *SVM*^{rank}, w_x is the weight of the support vector x, $z_x(f)$ is the function that returns 1 if f occurs in x, respectively.

The feature weights are shown in Table 4. This demonstrates that in the pronoun model the action history features have the highest weight, while with the non-pronoun model these features are less significant. As we can see in Table 5, pronouns are strongly related to the situation where a mouse cursor is over a piece, directly causing the weights of the features associated with the 'on-mouse' situation to become higher than other features.

On the other hand, in the non-pronoun model, the discourse history features, such as DH6 and DH2, are the most significant, indicating that the compatibility of the attributes of a piece and a referring expression is more crucial than other action history and current operation features. This is compatible with the previous research concerning textual reference resolution (Mitkov, 2002).

Table 4 shows that feature AH3 (aiming at capturing the recency in terms of a series of operations) is also significant. It empirically proves that the recent operation is strongly related to the salience of reference as a kind of 'focus' by humans.

5 Related Work

There have been increasing concerns about reference resolution in dialogue. Byron and Allen (1998) and Eckert and Strube (2000) reported about 50% of pronouns had no antecedent in TRAINS93 and Switchboard corpora respectively. Strube and Müller (2003) attempted to resolve pronominal anaphora in the Switchboard corpus by porting a corpus-based anaphora resolution model focusing on written texts (e.g. Soon et al. (2001) and Ng and Cardie (2002)). They used specialised features for spoken dialogues as well as conventional features. They reported relatively worse results than with written texts. The reason is that the features in their work capture only information derived from transcripts of dialogues, while it is also essential to bridge objects and concepts in the real (or virtual) world and their expressions (especially pronouns) for recognising referential relations intrinsically.

To improve performance on reference resolution in dialogue, researchers have focused on anaphoricity determination, which is the task of judging whether an expression explicitly has an antecedent in the text (i.e. in the preceding utterances) (Müller, 2006; Müller, 2007). Their work presented implementations of pronominal reference resolution in transcribed, multi-party dialogues. Müller (2006) focused on the determination of non-referential *it*, categorising instances of *it* in the ICSI Meeting Corpus (Janin et al., 2003) into six classes in terms of their grammatical categories. They also took into account each characteristic of these types by using a refined feature set. In the work by Müller (2007), they conducted an empirical evaluation including antecedent identification as well as anaphoricity determination. They used the relative frequencies of linguistic patterns as clues to introduce specific patterns for non-referentials. They reported that their performance for detecting non-referentials was relatively high (80.0% in precision and 60.9% in recall), while the overall performance was still low (18.2% in precision and 19.1% in recall). These results indicate the need for advancing research in reference resolution in dialogue.

In contrast to the above mentioned research, our task includes the treatment of entity disambiguation (i.e. selecting a referent out of a set of pieces on a computer display) as well as conventional anaphora resolution. Although our task setting is limited to the problem of solving the Tangram puzzle, we believe it is a good starting point for incorporating real (or virtual) world entities into coventional anaphora resolution.

6 Conclusion

This paper presented the task of reference resolution bridging pieces in the real world and their referents in dialogue. We presented an implementation of a reference resolution model exploiting extra-linguistic information, such as action history and current operation features, to capture the salience of operations by a participant and the arrangement of the pieces. Through our empirical evaluation, we demonstrated that the extra-linguistic information introduced in this paper contributed to improving performance. We also analysed the effect of each feature, showing that while action history features were useful for pronominal reference, discourse history features made sense for the other references.

In order to enhance this kind of reference resolution, there are several possible future directions. First, in the current problem setting, we exclude zero-anaphora (i.e. omitted expressions refer to either an expression in the previous utterances or an object on a display deictically). However, zero-anaphora is essential for precise modeling and recognition of reference because it is also directly related with the recency of referents, either textually or situationally. Second, representing distractors in a reference resolution model is also a key. Although, this paper presents an implementation of a reference model considering only the relationship between a referring expression and its candidate referents. However, there might be cases when the occurrence of expressions or manipulated pieces intervening between a referring expression and its referent need to be taken into account. Finally, more investigation is needed for considering other extra-linguistic information, such as eye-gaze, for exploring what kinds of information is critical to recognising reference in dialogue.

Reading Between the Lines: Learning to Map High-level Instructions to Commands

Abstract

In this paper, we address the task of mapping *high-level instructions* to sequences of commands in an external environment. Processing these instructions is challenging—they posit goals to be achieved without specifying the steps required to complete them. We describe a method that fills in missing information using an automatically derived environment model that encodes states, transitions, and commands that cause these transitions to happen. We present an efficient approximate approach for learning this environment model as part of a policy-gradient reinforcement learning algorithm for text interpretation. This design enables learning for mapping high-level instructions, which previous statistical methods cannot handle.[1]

1 Introduction

In this paper, we introduce a novel method for mapping high-level instructions to commands in an external environment. These instructions specify goals to be achieved without explicitly stating all the required steps. For example, consider the first instruction in Figure 1 — "open control panel." The three GUI commands required for its successful execution are not explicitly described in the text, and need to be inferred by the user. This dependence on domain knowledge makes the automatic interpretation of high-level instructions particularly challenging.

The standard approach to this task is to start with both a manually-developed model of the environment, and rules for interpreting high-level instructions in the context of this model (Agre and Chapman, 1988; Di Eugenio and White, 1992; Di Eugenio, 1992; Webber et al., 1995). Given both the model and the rules, logic-based inference is used to automatically fill in the intermediate steps missing from the original instructions.

Our approach, in contrast, operates directly on the textual instructions in the context of the interactive environment, while requiring no additional information. By interacting with the environment and observing the resulting feedback, our method automatically learns both the mapping between the text and the commands, and the underlying model of the environment. One particularly noteworthy aspect of our solution is the interplay between the evolving mapping and the progressively acquired environment model as the system learns how to interpret the text. Recording the state transitions observed during interpretation allows the algorithm to construct a relevant model of the environment. At the same time, the environment model enables the algorithm to consider the consequences of commands before they are executed, thereby improving the accuracy of interpretation. Our method efficiently achieves both of these goals as part of a policy-gradient reinforcement learning algorithm.

We apply our method to the task of mapping software troubleshooting guides to GUI actions in the Windows environment (Branavan et al., 2009; Kushman et al., 2009). The key findings of our experiments are threefold. First, the algorithm can accurately interpret 61.5% of high-level instructions, which cannot be handled by previous statistical systems. Second, we demonstrate that explicitly modeling the environment also greatly improves the accuracy of processing low-level instructions, yielding a 14% absolute increase in performance over a competitive baseline (Branavan et al., 2009). Finally, we show the importance of constructing an environment model relevant to the language interpretation task — using textual

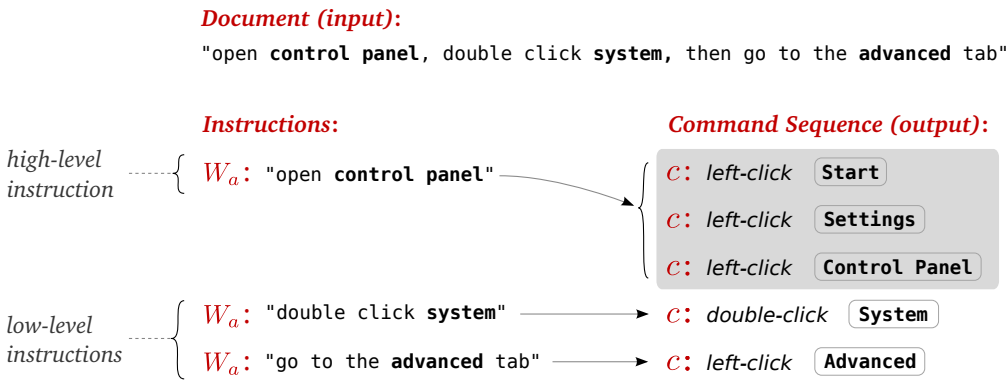

Figure 1: An example mapping of a document containing high-level instructions into a candidate sequence of five commands. The mapping process involves segmenting the document into individual instruction word spans W_a, and translating each instruction into the sequence $\vec{c}$ of one or more commands it describes. During learning, the correct output command sequence is not provided to the algorithm.

instructions enables us to bias exploration toward transitions relevant for language learning. This approach yields superior performance compared to a policy that relies on an environment model constructed via random exploration.

2 Related Work

Interpreting Instructions Our approach is most closely related to the reinforcement learning algorithm for mapping text instructions to commands developed by Branavan et al. (2009) (see Section 4 for more detail). Their method is predicated on the assumption that each command to be executed is explicitly specified in the instruction text. This assumption of a direct correspondence between the text and the environment is not unique to that paper, being inherent in other work on grounded language learning (Siskind, 2001; Oates, 2001; Yu and Ballard, 2004; Fleischman and Roy, 2005; Mooney, 2008; Liang et al., 2009; Matuszek et al., 2010). A notable exception is the approach of Eisenstein et al. (2009), which learns how an environment operates by reading text, rather than learning an explicit mapping from the text to the environment. For example, their method can learn the rules of a card game given instructions for how to play.

Many instances of work on instruction interpretation are replete with examples where instructions are formulated as high-level goals, targeted at users with relevant knowledge (Winograd, 1972; Di Eugenio, 1992; Webber et al., 1995; MacMahon et al., 2006). Not surprisingly, automatic approaches for processing such instructions have relied on hand-engineered world knowledge to reason about the preconditions and effects of environment commands. The assumption of a fully specified environment model is also common in work on semantics in the linguistics literature (Lascarides and Asher, 2004). While our approach learns to analyze instructions in a goal-directed manner, it does not require manual specification of relevant environment knowledge.

Reinforcement Learning Our work combines ideas of two traditionally disparate approaches to reinforcement learning (Sutton and Barto, 1998). The first approach, *model-based learning*, constructs a model of the environment in which the learner operates (e.g., modeling location, velocity, and acceleration in robot navigation). It then computes a policy directly from the rich information represented in the induced environment model. In the NLP literature, model-based reinforcement learning techniques are commonly used for dialog management (Singh et al., 2002; Lemon and Konstas, 2009; Schatzmann and Young, 2009). However, if the environment cannot be accurately approximated by a compact representation, these methods perform poorly (Boyan and Moore, 1995; Jong and Stone, 2007). Our instruction interpretation task falls into this latter category,[2] rendering standard model-based learning ineffective.

The second approach – model-free methods such as *policy learning* – aims to select the opti-

[2]For example, in the Windows GUI domain, clicking on the *File* menu will result in a different submenu depending on the application. Thus it is impossible to predict the effects of a previously unseen GUI command.

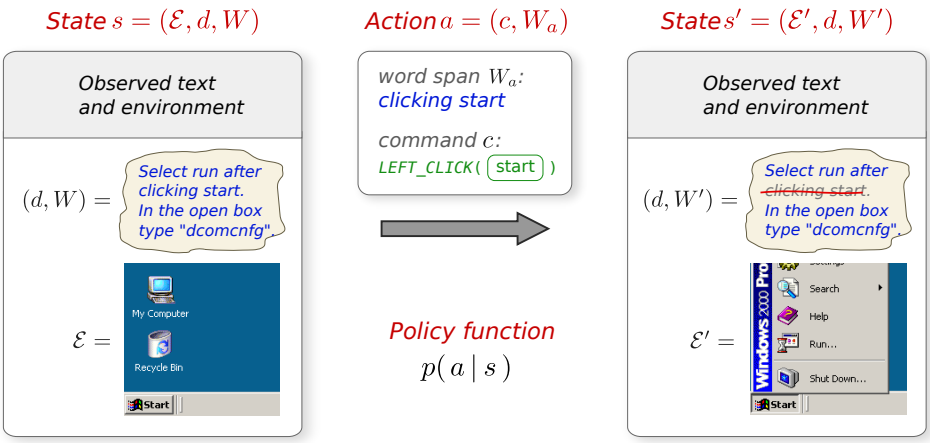

Figure 2: A single step in the instruction mapping process formalized as an MDP. State s is comprised of the state of the external environment $\mathcal{E}$, and the state of the document (d, W), where W is the list of all word spans mapped by previous actions. An action a selects a span W_a of unused words from (d, W), and maps them to an environment command c. As a consequence of a, the environment state changes to $\mathcal{E}' \sim p(\mathcal{E}'|\mathcal{E}, c)$, and the list of mapped words is updated to $W' = W \cup W_a$.

mal action at every step, without explicitly constructing a model of the environment. While policy learners can effectively operate in complex environments, they are not designed to benefit from a learned environment model. We address this limitation by expanding a policy learning algorithm to take advantage of a partial environment model estimated during learning. The approach of conditioning the policy function on future reachable states is similar in concept to the use of *post-decision state* information in the approximate dynamic programming framework (Powell, 2007).

3 Problem Formulation

Our goal is to map instructions expressed in a natural language document d into the corresponding sequence of commands $\vec{c} = \langle c_1, \ldots, c_m \rangle$ executable in an environment. As input, we are given a set of raw instruction documents, an environment, and a reward function as described below.

The *environment* is formalized as its states and transition function. An *environment state* $\mathcal{E}$ specifies the objects accessible in the environment at a given time step, along with the objects' properties. The environment state transition function $p(\mathcal{E}'|\mathcal{E}, c)$ encodes how the state changes from $\mathcal{E}$ to $\mathcal{E}'$ in response to a command c.[3] During learning, this function is not known, but samples from it can be collected by executing commands and observing the resulting environment state. A real-valued *reward function* measures how well a command sequence $\vec{c}$ achieves the task described in the document.

We posit that a document d is composed of a sequence of instructions, each of which can take one of two forms:

- *Low-level instructions*: these explicitly describe single commands.[4] E.g., "double click system" in Figure 1.
- *High-level instructions*: these correspond to a sequence of one or more environment commands, none of which are explicitly described by the instruction. E.g., "open control panel" in Figure 1.

4 Background

Our innovation takes place within a previously established general framework for the task of mapping instructions to commands (Branavan et al., 2009). This framework formalizes the mapping process as a *Markov Decision Process* (MDP) (Sutton and Barto, 1998), with actions encoding individual instruction-to-command mappings, and states representing partial interpretations of the document. In this section, we review the details of this framework.

[3] While in the general case the environment state transitions maybe stochastic, they are deterministic in the software GUI used in this work.

[4] Previous work (Branavan et al., 2009) is only able to handle low-level instructions.

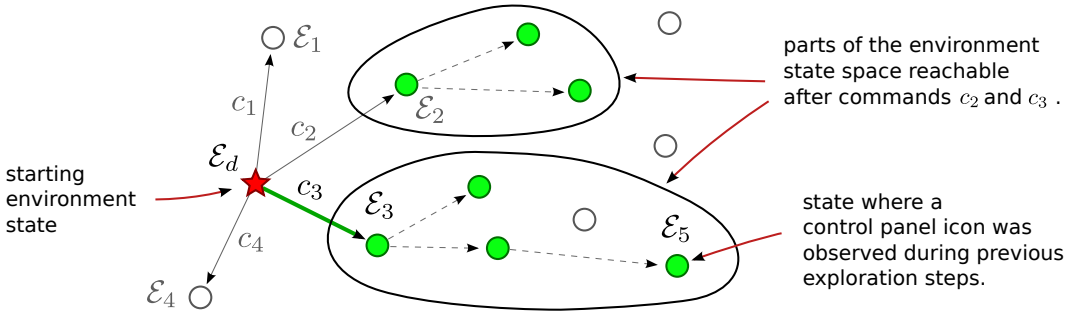

Figure 3: Using information derived from future states to interpret the high-level instruction "open control panel." $\mathcal{E}_d$ is the starting state, and c_1 through c_4 are candidate commands. Environment states are shown as circles, with previously visited environment states colored green. Dotted arrows show known state transitions. All else being equal, the information that the control panel icon was observed in state $\mathcal{E}_5$ during previous exploration steps can help to correctly select command c_3.

States and Actions A document is interpreted by incrementally constructing a sequence of actions. Each action selects a word span from the document, and maps it to one environment command. To predict actions sequentially, we track the states of the environment and the document over time as shown in Figure 2. This *mapping state* s is a tuple $(\mathcal{E}, d, W)$ where $\mathcal{E}$ is the current environment state, d is the document being interpreted, and W is the list of word spans selected by previous actions. The mapping state s is observed prior to selecting each action.

The *mapping action* a is a tuple (c, W_a) that represents the joint selection of a span of words W_a and an environment command c. Some of the candidate actions would correspond to the correct instruction mappings, e.g., (c = *double-click* system, W_a = "double click system"). Others such as (c = *left-click* system, W_a = "double click system") would be erroneous. The algorithm learns to interpret instructions by learning to construct sequences of actions that assign the correct commands to the words.

The interpretation of a document d begins at an initial mapping state $s_0 = (\mathcal{E}_d, d, \emptyset)$, $\mathcal{E}_d$ being the starting state of the environment for the document. Given a state $s = (\mathcal{E}, d, W)$, the space of possible actions $a = (c, W_a)$ is defined by enumerating sub-spans of unused words in d and candidate commands in $\mathcal{E}$.[5] The action to execute, a, is selected based on a *policy function* $p(a|s)$ by finding $\arg\max_a p(a|s)$. Performing action a in state $s = (\mathcal{E}, d, W)$ results in a new state s' according to the distribution $p(s'|s, a)$, where:

$$\begin{aligned} a &= (c, W_a), \\ \mathcal{E}' &\sim p(\mathcal{E}'|\mathcal{E}, c), \\ W' &= W \cup W_a, \\ s' &= (\mathcal{E}', d, W'). \end{aligned}$$

The process of selecting and executing actions is repeated until all the words in d have been mapped.[6]

A Log-Linear Parameterization The policy function used for action selection is defined as a log-linear distribution over actions:

$$p(a|s;\theta) = \frac{e^{\theta \cdot \phi(s,a)}}{\sum_{a'} e^{\theta \cdot \phi(s,a')}}, \quad (1)$$

where $\theta \in \mathbb{R}^n$ is a weight vector, and $\phi(s, a) \in \mathbb{R}^n$ is an n-dimensional feature function. This representation has the flexibility to incorporate a variety of features computed on the states and actions.

Reinforcement Learning Parameters of the policy function $p(a|s;\theta)$ are estimated to maximize the expected future reward for analyzing each document $d \in D$:

$$\theta = \arg\max_\theta \; E_{p(h|\theta)}\left[r(h)\right], \quad (2)$$

where $h = (s_0, a_0, \ldots, s_{m-1}, a_{m-1}, s_m)$ is a *history* that records the analysis of document d, $p(h|\theta)$ is the probability of selecting this analysis given policy parameters θ, and the reward $r(h)$ is a real valued indication of the quality of h.

[5] Here, command reordering is possible. At each step, the span of selected words W_a is not required to be adjacent to the previous selections. This reordering is used to interpret sentences such as "Select exit after opening the File menu."

[6] To account for document words that are not part of an instruction, c may be a *null* command.

5 Algorithm

We expand the scope of learning approaches for automatic document interpretation by enabling the analysis of *high-level instructions*. The main challenge in processing these instructions is that, in contrast to their low-level counterparts, they correspond to sequences of one or more commands. A simple way to enable this one-to-many mapping is to allow actions that do not consume words (i.e., $|W_a| = 0$). The sequence of actions can then be constructed incrementally using the algorithm described above. However, this change significantly complicates the interpretation problem – we need to be able to predict commands that are not directly described by any words, and allowing action sequences significantly increases the space of possibilities for each instruction. Since we cannot enumerate all possible sequences at decision time, we limit the space of possibilities by learning which sequences are likely to be relevant for the current instruction.

To motivate the approach, consider the decision problem in Figure 3, where we need to find a command sequence for the high-level instruction "open control panel." The algorithm focuses on command sequences leading to environment states where the control panel icon was previously observed. The information about such states is acquired during exploration and is stored in a *partial environment model* $q(\mathcal{E}'|\mathcal{E}, c)$.

Our goal is to map high-level instructions to command sequences by leveraging knowledge about the long-term effects of commands. We do this by integrating the partial environment model into the policy function. Specifically, we modify the log-linear policy $p(a|s; q, \theta)$ by adding *look-ahead features* $\phi(s, a, q)$ which complement the local features used in the previous model. These look-ahead features incorporate various measurements that characterize the potential of future states reachable via the selected action. Although primarily designed to analyze high-level instructions, this approach is also useful for mapping low-level instructions.

Below, we first describe how we estimate the partial environment transition model and how this model is used to compute the look-ahead features. This is followed by the details of parameter estimation for our algorithm.

5.1 Partial Environment Transition Model

To compute the look-ahead features, we first need to collect statistics about the environment transition function $p(\mathcal{E}'|\mathcal{E}, c)$. An example of an environment transition is the change caused by clicking on the "start" button. We collect this information through observation, and build a partial environment transition model $q(\mathcal{E}'|\mathcal{E}, c)$.

One possible strategy for constructing q is to observe the effects of executing random commands in the environment. In a complex environment, however, such a strategy is unlikely to produce state samples relevant to our text analysis task. Instead, we use the training documents to guide the sampling process. During training, we execute the command sequences predicted by the policy function in the environment, caching the resulting state transitions. Initially, these commands may have little connection to the actual instructions. As learning progresses and the quality of the interpretation improves, more promising parts of the environment will be observed. This process yields samples that are biased toward the content of the documents.

5.2 Look-Ahead Features

We wish to select actions that allow for the best follow-up actions, thereby finding the analysis with the highest total reward for a given document. In practice, however, we do not have information about the effects of all possible future actions. Instead, we capitalize on the state transitions observed during the sampling process described above, allowing us to incrementally build an environment model of actions and their effects.

Based on this transition information, we can estimate the usefulness of actions by considering the properties of states they can reach. For instance, some states might have very low immediate reward, indicating that they are unlikely to be part of the best analysis for the document. While the usefulness of most states is hard to determine, it correlates with various properties of the state. We encode the following properties as look-ahead features in our policy:

- The highest reward achievable by an action sequence passing through this state. This property is computed using the learned environment model, and is therefore an approximation.

- The length of the above action sequence.
- The average reward received at the environment state while interpreting any document. This property introduces a bias towards commonly visited states that frequently recur throughout multiple documents' correct interpretations.

Because we can never encounter all states and all actions, our environment model is always incomplete and these properties can only be computed based on partial information. Moreover, the predictive strength of the properties is not known in advance. Therefore we incorporate them as separate features in the model, and allow the learning process to estimate their weights. In particular, we select actions a based on the current state s and the partial environment model q, resulting in the following policy definition:

$$p(a|s;q,\theta) = \frac{e^{\theta \cdot \phi(s,a,q)}}{\sum_{a'} e^{\theta \cdot \phi(s,a',q)}}, \qquad (3)$$

where the feature representation $\phi(s,a,q)$ has been extended to be a function of q.

5.3 Parameter Estimation

The learning algorithm is provided with a set of documents $d \in D$, an environment in which to execute command sequences $\vec{c}$, and a reward function $r(h)$. The goal is to estimate two sets of parameters: 1) the parameters θ of the policy function, and 2) the partial environment transition model $q(\mathcal{E}'|\mathcal{E},c)$, which is the observed portion of the true model $p(\mathcal{E}'|\mathcal{E},c)$. These parameters are mutually dependent: θ is defined over a feature space dependent on q, and q is sampled according to the policy function parameterized by θ.

Algorithm 1 shows the procedure for joint learning of these parameters. As in standard policy gradient learning (Sutton et al., 2000), the algorithm iterates over all documents $d \in D$ (steps 1, 2), selecting and executing actions in the environment (steps 3 to 6). The resulting reward is used to update the parameters θ (steps 8, 9). In the new joint learning setting, this process also yields samples of state transitions which are used to estimate $q(\mathcal{E}'|\mathcal{E},c)$ (step 7). This updated q is then used to compute the feature functions $\phi(s,a,q)$ during the next iteration of learning (step 4). This process is repeated until the total reward on training documents converges.

Input: A document set D,
Feature function ϕ,
Reward function $r(h)$,
Number of iterations T

Initialization: Set θ to small random values.
Set q to the empty set.

1 **for** $i = 1 \cdots T$ **do**
2 **foreach** $d \in D$ **do**

Sample history $h \sim p(h|\theta)$ where $h = (s_0, a_0, \cdots, a_{n-1}, s_n)$ as follows:

Initialize environment to document specific starting state $\mathcal{E}_d$

3 **for** $t = 0 \cdots n-1$ **do**
4 Compute $\phi(a, s_t, q)$ based on latest q
5 Sample action $a_t \sim p(a|s_t;q,\theta)$
6 Execute a_t on state s_t: $s_{t+1} \sim p(s|s_t,a_t)$
7 Set $q = q \cup \{(\mathcal{E}', \mathcal{E}, c)\}$ where $\mathcal{E}'$, $\mathcal{E}$, c are the environment states and commands from s_{t+1}, s_t, and a_t
end
8 $\Delta \leftarrow$
$$\sum_t \left[\phi(s_t, a_t, q) - \sum_{a'} \phi(s_t, a', q)\, p(a'|s_t;q,\theta) \right]$$
9 $\theta \leftarrow \theta + r(h)\Delta$
end
end

Output: Estimate of parameters θ

Algorithm 1: A policy gradient algorithm that also learns a model of the environment.

This algorithm capitalizes on the synergy between θ and q. As learning proceeds, the method discovers a more complete state transition function q, which improves the accuracy of the look-ahead features, and ultimately, the quality of the resulting policy. An improved policy function in turn produces state samples that are more relevant to the document interpretation task.

6 Applying the Model

We apply our algorithm to the task of interpreting help documents to perform software related tasks (Branavan et al., 2009; Kushman et al., 2009). Specifically, we consider documents from Microsoft's Help and Support website.[7] As in prior work, we use a virtual machine set-up to allow our method to interact with a Windows 2000 environment.

Environment States and Actions In this application of our model, the environment state is the set of visible user interface (UI) objects, along

[7] http://support.microsoft.com/

with their properties (e.g., the object's label, parent window, etc). The environment commands consist of the UI commands *left-click*, *right-click*, *double-click*, and *type-into*. Each of these commands requires a UI object as a parameter, while *type-into* needs an additional parameter containing the text to be typed. On average, at each step of the interpretation process, the branching factor is 27.14 commands.

Reward Function An ideal reward function would be to verify whether the task specified by the help document was correctly completed. Since such verification is a challenging task, we rely on a noisy approximation: we assume that each sentence specifies at least one command, and that the text describing the command has words matching the label of the environment object. If a history h has at least one such command for each sentence, the environment reward function $r(h)$ returns a positive value, otherwise it returns a negative value. This environment reward function is a simplification of the one described in Branavan et al. (2009), and it performs comparably in our experiments.

Features In addition to the look-ahead features described in Section 5.2, the policy also includes the set of features used by Branavan et al. (2009). These features are functions of both the text and environment state, modeling local properties that are useful for action selection.

7 Experimental Setup

Datasets Our model is trained on the same dataset used by Branavan et al. (2009). For testing we use two datasets: the first one was used in prior work and contains only low-level instructions, while the second dataset is comprised of documents with high-level instructions. This new dataset was collected from the Microsoft Help and Support website, and has on average 1.03 high-level instructions per document. The second dataset contains 60 test documents, while the first is split into 70, 18 and 40 document for training, development and testing respectively. The combined statistics for these datasets is shown below:

Total # of documents	188
Total # of words	7448
Vocabulary size	739
Avg. actions per document	10

Reinforcement Learning Parameters Following common practice, we encourage exploration during learning with an ϵ-greedy strategy (Sutton and Barto, 1998), with ϵ set to 0.1. We also identify *dead-end* states, i.e. states with the lowest possible immediate reward, and use the induced environment model to encourage additional exploration by lowering the likelihood of actions that lead to such dead-end states.

During the early stages of learning, experience gathered in the environment model is extremely sparse, causing the look-ahead features to provide poor estimates. To speed convergence, we ignore these estimates by disabling the look-ahead features for a fixed number of initial training iterations.

Finally, to guarantee convergence, stochastic gradient ascent algorithms require a learning rate schedule. We use a modified *search-then-converge* algorithm (Darken and Moody, 1990), and tie the learning rate to the ratio of training documents that received a positive reward in the current iteration.

Baselines As a baseline, we compare our method against the results reported by Branavan et al. (2009), denoted here as BCZB09.

As an upper bound for model performance, we also evaluate our method using a reward signal that simulates a fully-supervised training regime. We define a reward function that returns positive one for histories that match the annotations, and zero otherwise. Performing policy-gradient with this function is equivalent to training a fully-supervised, stochastic gradient algorithm that optimizes conditional likelihood (Branavan et al., 2009).

Evaluation Metrics We evaluate the accuracy of the generated mapping by comparing it against manual annotations of the correct action sequences. We measure the percentage of correct actions and the percentage of documents where every action is correct. In general, the sequential nature of the interpretation task makes it difficult to achieve high action accuracy. For example, executing an incorrect action early on, often leads to an environment state from which the remaining instructions cannot be completed. When this happens, it is not possible to recover the remaining actions, causing cascading errors that significantly reduce performance.

	Low-level instruction dataset		High-level instruction dataset		
	action	document	action	high-level action	document
BCZB09	0.647	0.375	0.021	0.022	0.000
BCZB09 + annotation	$*$ 0.756	0.525	0.035	0.022	0.000
Our model	**0.793**	**0.517**	$*$ **0.419**	$*$ **0.615**	$*$ **0.283**
Our model + annotation	0.793	0.650	$*$ 0.357	0.492	0.333

Table 1: Accuracy of the mapping produced by our model, its variants, and the baseline. Values marked with $*$ are statistically significant at $p < 0.01$ compared to the value immediately above it.

8 Results

As shown in Table 1, our model outperforms the baseline on the two datasets, according to all evaluation metrics. In contrast to the baseline, our model can handle high-level instructions, accurately interpreting 62% of them in the second dataset. Every document in this set contains at least one high-level action, which on average, maps to 3.11 environment commands each. The overall action performance on this dataset, however, seems unexpectedly low at 42%. This discrepancy is explained by the fact that in this dataset, high-level instructions are often located towards the beginning of the document. If these initial challenging instructions are not processed correctly, the rest of the actions for the document cannot be interpreted.

As the performance on the first dataset indicates, the new algorithm is also beneficial for processing low-level instructions. The model outperforms the baseline by at least 14%, both in terms of the actions and the documents it can process. Not surprisingly, the best performance is achieved when the new algorithm has access to manually annotated data during training.

We also performed experiments to validate the intuition that the partial environment model must contain information relevant for the language interpretation task. To test this hypothesis, we replaced the learned environment model with one of the same size gathered by executing random commands. The model with randomly sampled environment transitions performs poorly: it can only process 4.6% of documents and 15% of actions on the dataset with high-level instructions, compared to 28.3% and 41.9% respectively for our algorithm. This result also explains why training with full supervision hurts performance on high-level instructions (see Table 1). Learning directly from annotations results in a low-quality environment model due to the relative lack of exploration, hurting the model's ability to leverage the look-ahead features.

High-level instruction
- open **device manager**

Extracted low-level instruction paraphrase
- double click **my computer**
- double click **control panel**

- double click **network and dial-up connections**

Figure 4: Examples of automatically generated paraphrases for high-level instructions. The model maps the high-level instruction into a sequence of commands, and then translates them into the corresponding low-level instructions.

Finally, to demonstrate the quality of the learned word–command alignments, we evaluate our method's ability to paraphrase from high-level instructions to low-level instructions. Here, the goal is to take each high-level instruction and construct a text description of the steps required to achieve it. We did this by finding high-level instructions where each of the commands they are associated with is also described by a low-level instruction in some other document. For example, if the text "open control panel" was mapped to the three commands in Figure 1, and each of those commands was described by a low-level instruction elsewhere, this procedure would create a paraphrase such as "click start, left click setting, and select control panel." Of the 60 high-level instructions tagged in the test set, this approach found paraphrases for 33 of them. 29 of

these paraphrases were correct, in the sense that they describe all the necessary commands. Figure 4 shows some examples of the automatically extracted paraphrases.

9 Conclusions and Future Work

In this paper, we demonstrate that knowledge about the environment can be learned and used effectively for the task of mapping instructions to actions. A key feature of this approach is the synergy between language analysis and the construction of the environment model: instruction text drives the sampling of the environment transitions, while the acquired environment model facilitates language interpretation. This design enables us to learn to map high-level instructions while also improving accuracy on low-level instructions.

To apply the above method to process a broad range of natural language documents, we need to handle several important semantic and pragmatic phenomena, such as reference, quantification, and conditional statements. These linguistic constructions are known to be challenging to learn – existing approaches commonly rely on large amounts of hand annotated data for training. An interesting avenue of future work is to explore an alternative approach which learns these phenomena by combining linguistic information with knowledge gleaned from an automatically induced environment model.

Abstract

We show how web mark-up can be used to improve unsupervised dependency parsing. Starting from raw bracketings of four common HTML tags (anchors, bold, italics and underlines), we refine approximate partial phrase boundaries to yield accurate parsing constraints. Conversion procedures fall out of our linguistic analysis of a newly available million-word hyper-text corpus. We demonstrate that derived constraints aid grammar induction by training Klein and Manning's Dependency Model with Valence (DMV) on this data set: parsing accuracy on Section 23 (all sentences) of the Wall Street Journal corpus jumps to 50.4%, beating previous state-of-the-art by more than 5%. Web-scale experiments show that the DMV, perhaps because it is unlexicalized, does not benefit from orders of magnitude more annotated but noisier data. Our model, trained on a single blog, generalizes to 53.3% accuracy out-of-domain, against the Brown corpus — nearly 10% higher than the previous published best. The fact that web mark-up strongly correlates with syntactic structure may have broad applicability in NLP.

1 Introduction

Unsupervised learning of hierarchical syntactic structure from free-form natural language text is a hard problem whose eventual solution promises to benefit applications ranging from question answering to speech recognition and machine translation. A restricted version of this problem that targets dependencies and assumes partial annotation — sentence boundaries and part-of-speech (POS) tagging — has received much attention. Klein and Manning (2004) were the first to beat a simple parsing heuristic, the right-branching baseline; today's state-of-the-art systems (Headden et al., 2009; Cohen and Smith, 2009; Spitkovsky et al., 2010a) are rooted in their Dependency Model with Valence (DMV), still trained using variants of EM.

Pereira and Schabes (1992) outlined three major problems with classic EM, applied to a related problem, constituent parsing. They extended classic inside-outside re-estimation (Baker, 1979) to respect any bracketing constraints included with a training corpus. This conditioning on partial parses addressed all three problems, leading to: (i) linguistically reasonable constituent boundaries and induced grammars more likely to agree with qualitative judgments of sentence structure, which is underdetermined by unannotated text; (ii) fewer iterations needed to reach a good grammar, countering convergence properties that sharply deteriorate with the number of non-terminal symbols, due to a proliferation of local maxima; and (iii) better (in the best case, linear) time complexity per iteration, versus running time that is ordinarily cubic in both sentence length *and* the total number of non-terminals, rendering sufficiently large grammars computationally impractical. Their algorithm sometimes found good solutions from bracketed corpora but not from raw text, supporting the view that purely unsupervised, self-organizing inference methods can miss the trees for the forest of distributional regularities. This was a promising break-through, but the problem of whence to get partial bracketings was left open.

We suggest mining partial bracketings from a cheap and abundant natural language resource: the hyper-text mark-up that annotates web-pages. For example, consider that anchor text can match linguistic constituents, such as verb phrases, exactly:

..., whereas McCain is secure on the topic, Obama <a>[VP worries about winning the pro-Israel vote].

To validate this idea, we created a new data set, novel in combining a real blog's raw HTML with tree-bank-like constituent structure parses, gener-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1278–1287,
Uppsala, Sweden, 11-16 July 2010.

ated automatically. Our linguistic analysis of the most prevalent tags (anchors, bold, italics and underlines) over its 1M$^+$ words reveals a strong connection between syntax and mark-up (all of our examples draw from this corpus), inspiring several simple techniques for automatically deriving parsing constraints. Experiments with both hard and more flexible constraints, as well as with different styles and quantities of annotated training data — the blog, web news and the web itself, confirm that mark-up-induced constraints consistently improve (otherwise unsupervised) dependency parsing.

2 Intuition and Motivating Examples

It is natural to expect hidden structure to seep through when a person annotates a sentence. As it happens, a non-trivial fraction of the world's population routinely annotates text diligently, if only partially and informally.[1] They inject hyper-links, vary font sizes, and toggle colors and styles, using mark-up technologies such as HTML and XML.

As noted, web annotations can be indicative of phrase boundaries, e.g., in a complicated sentence:

> In 1998, however, as I <a>[VP established in [NP *The New Republic*] and Bill Clinton just <a>[VP confirmed in his memoirs], Netanyahu changed his mind and ...

In doing so, mark-up sometimes offers useful cues even for low-level tokenization decisions:

> [NP [NP Libyan ruler]
> <a>[NP Mu'ammar al-Qaddafi] referred to ...

```
(NP (ADJP (NP (JJ Libyan) (NN ruler))
          (JJ Mu))
    (`` `) (NN ammar) (NNS al-Qaddafi))
```

Above, a backward quote in an Arabic name confuses the Stanford parser.[2] Yet mark-up lines up with the broken noun phrase, signals cohesion, and moreover sheds light on the internal structure of a compound. As Vadas and Curran (2007) point out, such details are frequently omitted even from manually compiled tree-banks that err on the side of flat annotations of base-NPs.

Admittedly, not all boundaries between HTML tags and syntactic constituents match up nicely:

> ..., but [S [NP the <a>*Toronto Star*][VP reports [NP this][PP in the softest possible way],[S stating only that ...]]]

Combining parsing with mark-up may not be straight-forward, but there is hope: even above, one of each nested tag's boundaries aligns; and *Toronto Star*'s neglected determiner could be forgiven, certainly within a dependency formulation.

3 A High-Level Outline of Our Approach

Our idea is to implement the DMV (Klein and Manning, 2004) — a standard unsupervised grammar inducer. But instead of learning the unannotated test set, we train with text that contains web mark-up, using various ways of converting HTML into parsing constraints. We still test on WSJ (Marcus et al., 1993), in the standard way, and also check generalization against a hidden data set — the Brown corpus (Francis and Kucera, 1979). Our parsing constraints come from a blog — a new corpus we created, the web and news (see Table 1 for corpora's sentence and token counts).

To facilitate future work, we make the final models and our manually-constructed blog data publicly available.[3] Although we are unable to share larger-scale resources, our main results should be reproducible, as both linguistic analysis and our best model rely exclusively on the blog.

Corpus	*Sentences*	*POS Tokens*
WSJ$^\infty$	49,208	1,028,347

Table 1: Sizes of corpora derived from WSJ and Brown, as well as those we collected from the web.

4 Data Sets for Evaluation and Training

The appeal of unsupervised parsing lies in its ability to learn from surface text alone; but (intrinsic) evaluation still requires parsed sentences. Following Klein and Manning (2004), we begin with reference constituent parses and compare against deterministically derived dependencies: after pruning out all empty subtrees, punctuation and terminals (tagged # and $) not pronounced where they appear, we drop all sentences with more than a prescribed number of tokens remaining and use automatic "head-percolation" rules (Collins, 1999) to convert the rest, as is standard practice.

[1] Even when (American) grammar schools lived up to their name, they only taught dependencies. This was back in the days before constituent grammars were invented.

40	0	0	0	0

Table 2: Counts of sentences, tokens and (unique) bracketings for BLOG_p, restricted to only those sentences having at least one bracketing no shorter than the length cutoff (but shorter than the sentence).

Our primary reference sets are derived from the Penn English Treebank's Wall Street Journal portion (Marcus et al., 1993): WSJ45 (sentences with fewer than 46 tokens) and Section 23 of WSJ^{∞} (all sentence lengths). We also evaluate on Brown100, similarly derived from the parsed portion of the Brown corpus (Francis and Kucera, 1979). While we use WSJ45 and WSJ15 to train baseline models, the bulk of our experiments is with web data.

4.1 A News-Style Blog: Daniel Pipes

Since there was no corpus overlaying syntactic structure with mark-up, we began constructing a new one by downloading articles[4] from a news-style blog. Although limited to a single genre — political opinion, `danielpipes.org` is clean, consistently formatted, carefully edited and larger than WSJ (see Table 1). Spanning decades, Pipes' editorials are mostly in-domain for POS taggers and tree-bank-trained parsers; his recent (internet-era) entries are thoroughly cross-referenced, conveniently providing just the mark-up we hoped to study via uncluttered (printer-friendly) HTML.[5]

After extracting moderately clean text and mark-up locations, we used MxTerminator (Reynar and Ratnaparkhi, 1997) to detect sentence boundaries. This initial automated pass begot multiple rounds of various semi-automated clean-ups that involved fixing sentence breaking, modifying parser-unfriendly tokens, converting HTML entities and non-ASCII text, correcting typos, and so on. After throwing away annotations of fractional words (e.g., *basmachi*s) and tokens (e.g., *Sesame Street*-like), we broke up all mark-up that crossed sentence boundaries (i.e., loosely speaking, replaced constructs like <u>...]\[s...</u> with <u>...</u>]\[s <u>...</u>) and discarded any tags left covering entire sentences.

We finalized two versions of the data: BLOG_t, tagged with the Stanford tagger (Toutanova and Manning, 2000; Toutanova et al., 2003),[6] and BLOG_p, parsed with Charniak's parser (Charniak, 2001; Charniak and Johnson, 2005).[7] The reason for this dichotomy was to use state-of-the-art parses to analyze the relationship between syntax and mark-up, yet to prevent jointly tagged (and non-standard `AUX[G]`) POS sequences from interfering with our (otherwise unsupervised) training.[8]

4.2 Scaled up *Quantity*: The (English) Web

We built a large (see Table 1) but messy data set, WEB — English-looking web-pages, pre-crawled by a search engine. To avoid machine-generated spam, we excluded low quality sites flagged by the indexing system. We kept only sentence-like runs of words (satisfying punctuation and capitalization constraints), POS-tagged with TnT (Brants, 2000).

4.3 Scaled up *Quality*: (English) Web News

In an effort to trade quantity for quality, we constructed a smaller, potentially cleaner data set, NEWS. We reckoned editorialized content would lead to fewer extracted non-sentences. Perhaps surprisingly, NEWS is less than an order of magnitude smaller than WEB (see Table 1); in part, this is due to less aggressive filtering — we trust sites approved by the human editors at Google News.[9] In all other respects, our pre-processing of NEWS pages was identical to our handling of WEB data.

[7] `ftp://ftp.cs.brown.edu/pub/nlparser/parser05Aug16.tar.gz`

[8] However, since many taggers are themselves trained on manually parsed corpora, such as WSJ, no parser that relies on external POS tags could be considered truly unsupervised; for a *fully* unsupervised example, see Seginer's (2007) CCL parser, available at `http://www.seggu.net/ccl/`

5 Linguistic Analysis of Mark-Up

Is there a connection between mark-up and syntactic structure? Previous work (Barr et al., 2008) has only examined search engine queries, showing that they consist predominantly of short noun phrases. If web mark-up shared a similar characteristic, it might not provide sufficiently disambiguating cues to syntactic structure: HTML tags could be too short (e.g., singletons like "click <a>here") or otherwise unhelpful in resolving truly difficult ambiguities (such as PP-attachment). We began simply by counting various basic events in BLOG_p.

	Count	*POS Sequence*	*Frac*	*Sum*

BLOG_p	+81	*more with Count* ≤ 16	1.0%	

Table 4: Top 99% of dominating non-terminals.

5.1 Surface Text Statistics

Out of 57,809 sentences, 6,047 (10.5%) are annotated (see Table 2); and 4,934 (8.5%) have multi-token bracketings. We do not distinguish HTML tags and track only unique bracketing end-points within a sentence. Of these, 6,015 are multi-token — an average per-sentence yield of 10.4%.[10]

[10] A non-trivial fraction of our corpus is older (pre-internet) unannotated articles, so this estimate may be conservative.

As expected, many of the annotated words are nouns, but there are adjectives, verbs and other parts of speech too (see Table 3). Mark-up is short, typically under five words, yet (by far) the most frequently marked sequence of POS tags is a pair.

5.2 Common Syntactic Subtrees

For three-quarters of all mark-up, the lowest dominating non-terminal is a noun phrase (see Table 4); there are also non-trace quantities of verb phrases (12.9%) and other phrases, clauses and fragments.

Of the top fifteen — *35.2%* of all — annotated productions, only one is *not* a noun phrase (see Table 5, left). Four of the fifteen lowest dominating non-terminals do *not* match the entire bracketing — all four miss the leading determiner, as we saw earlier. In such cases, we recursively split internal nodes until the bracketing aligned, as follows:

[S [NP the <a>*Toronto Star*][VP reports [NP this]
[PP in the softest possible way],[S stating ...]]]

S → NP VP → DT NNP NNP VBZ NP PP S

We can summarize productions more compactly by using a dependency framework and clipping off any dependents whose subtrees do not cross a bracketing boundary, relative to the parent. Thus,

DT NNP NNP VBZ DT IN DT JJS JJ NN

becomes DT NNP VBZ, "the <a>*Star* reports." Viewed this way, the top fifteen (now collapsed) productions cover *59.4%* of all cases and include four verb heads, in addition to a preposition and an adjective (see Table 5, right). This exposes five cases of inexact matches, three of which involve neglected determiners or adjectives to the left of the head. In fact, the only case that cannot be explained by dropped dependents is #8, where the daughters are marked but the parent is left out. Most instances contributing to this pattern are flat NPs that end with a noun, incorrectly assumed to be the head of *all* other words in the phrase, e.g.,

... [NP a 1994 *New Yorker* article] ...

As this example shows, disagreements (as well as agreements) between mark-up and machine-generated parse trees with automatically percolated heads should be taken with a grain of salt.[11]

[11] In a relatively recent study, Ravi et al. (2008) report that Charniak's re-ranking parser (Charniak and Johnson, 2005) — `reranking-parserAug06.tar.gz`, also available from `ftp://ftp.cs.brown.edu/pub/nlparser/` — attains 86.3% accuracy when trained on WSJ and tested against Brown; its nearly 5% performance loss out-of-domain is consistent with the numbers originally reported by Gildea (2001).

Table 5: Top 15 marked productions, viewed as constituents (left) and as dependencies (right), after recursively expanding any internal nodes that did not align with the bracketing (underlined). Tabulated dependencies were collapsed, dropping any dependents that fell entirely in the same region as their parent (i.e., both inside the bracketing, both to its left or both to its right), keeping only crossing attachments.

5.3 Proposed Parsing Constraints

The straight-forward approach — forcing mark-up to correspond to constituents — agrees with Charniak's parse trees only **48.0**% of the time, e.g.,

... in [NP <a> [NP an analysis] [PP of perhaps the most astonishing PC item I have yet stumbled upon]].

This number should be higher, as the vast majority of disagreements are due to tree-bank idiosyncrasies (e.g., bare NPs). Earlier examples of incomplete constituents (e.g., legitimately missing determiners) would also be fine in many linguistic theories (e.g., as N-bars). A dependency formulation is less sensitive to such stylistic differences.

We begin with the hardest possible constraint on dependencies, then slowly relax it. Every example used to demonstrate a softer constraint doubles as a counter-example against all previous versions.

• *strict* — seals mark-up into attachments, i.e., inside a bracketing, enforces exactly one external arc — into the overall head. This agrees with head-percolated trees just **35.6**% of the time, e.g.,

As author of *The Satanic Verses*, I ...

• *loose* — same as *strict*, but allows the bracketing's head word to have external dependents. This relaxation already agrees with head-percolated dependencies **87.5**% of the time, catching many (though far from all) dropped dependents, e.g.,

... the *Toronto Star* reports ...

• *sprawl* — same as *loose*, but now allows *all* words inside a bracketing to attach external dependents.[12] This boosts agreement with head-percolated trees to **95.1**%, handling new cases, e.g., where "*Toronto Star*" is embedded in longer mark-up that includes its own parent — a verb:

... the <a>*Toronto Star* reports ... ...

• *tear* — allows mark-up to fracture after all, requiring only that the external heads attaching the pieces lie to the same side of the bracketing. This propels agreement with percolated dependencies to **98.9**%, fixing previously broken PP-attachment ambiguities, e.g., a fused phrase like "Fox News in Canada" that detached a preposition from its verb:

... concession ... has raised eyebrows among those waiting [PP for <a>Fox News] [PP in Canada] .

Most of the remaining 1.1% of disagreements are due to parser errors. Nevertheless, it *is* possible for mark-up to be torn apart by external heads from *both* sides. We leave this section with a (very rare) true negative example. Below, "CSA" modifies "authority" (to its left), appositively, while "Al-Manar" modifies "television" (to its right):[13]

The French broadcasting authority, <a>CSA, banned ... Al-Manar satellite television from ...

[12] This view evokes the trapezoids of the $O(n^3)$ recognizer for split head automaton grammars (Eisner and Satta, 1999).

[13] But this is a stretch, since the comma after "CSA" renders the marked phrase ungrammatical even *out* of context.

6 Experimental Methods and Metrics

We implemented the DMV (Klein and Manning, 2004), consulting the details of (Spitkovsky et al., 2010a). Crucially, we swapped out inside-outside re-estimation in favor of Viterbi training. Not only is it better-suited to the general problem (see §7.1), but it also admits a trivial implementation of (most of) the dependency constraints we proposed.[14]

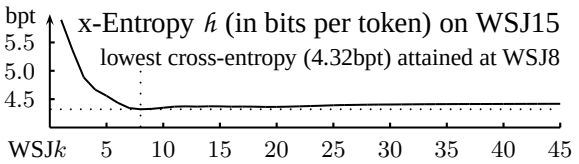

Figure 1: Sentence-level cross-entropy on WSJ15 for Ad-Hoc* initializers of WSJ$\{1, \ldots, 45\}$.

Six settings parameterized each run:

• INIT: 0 — default, uniform initialization; or 1 — a high quality initializer, pre-trained using Ad-Hoc* (Spitkovsky et al., 2010a): we chose the Laplace-smoothed model trained at WSJ15 (the "sweet spot" data gradation) but initialized off WSJ8, since that ad-hoc harmonic initializer has the best cross-entropy on WSJ15 (see Figure 1).

• GENRE: 0 — default, baseline training on WSJ; else, uses 1 — BLOG$_t$; 2 — NEWS; or 3 — WEB.

• SCOPE: 0 — default, uses all sentences up to length 45; if 1, trains using sentences up to length 15; if 2, re-trains on sentences up to length 45, starting from the solution to sentences up to length 15, as recommended by Spitkovsky et al. (2010a).

• CONSTR: if 4, *strict*; if 3, *loose*; and if 2, *sprawl*. We did not implement level 1, *tear*. Over-constrained sentences are re-attempted at successively lower levels until they become possible to parse, if necessary at the lowest (default) level 0.[15]

• TRIM: if 1, discards any sentence without a single multi-token mark-up (shorter than its length).

• ADAPT: if 1, upon convergence, initializes re-training on WSJ45 using the solution to <GENRE>, attempting domain adaptation (Lee et al., 1991).

These make for 294 meaningful combinations. We judged each one by its accuracy on WSJ45, using standard directed scoring — the fraction of correct dependencies over randomized "best" parse trees.

[14] We analyze the benefits of Viterbi training in a companion paper (Spitkovsky et al., 2010b), which dedicates more space to implementation and to the WSJ baselines used here.

[15] At level 4, X<u> Y Z</u> is over-constrained.

7 Discussion of Experimental Results

Evaluation on Section 23 of WSJ and Brown reveals that blog-training beats all published state-of-the-art numbers in every traditionally-reported length cutoff category, with news-training not far behind. Here is a mini-preview of these results, for Section 23 of WSJ10 and WSJ$^\infty$ (from Table 8):

	WSJ10	WSJ$^\infty$
(Cohen and Smith, 2009)	62.0	42.2
(Spitkovsky et al., 2010a)	57.1	45.0
NEWS-best	67.3	*50.1*
BLOG$_t$-best	**69.3**	**50.4**
(Headden et al., 2009)	*68.8*	

Table 6: Directed accuracies on Section 23 of WSJ$\{10, \infty\}$ for three recent state-of-the-art systems and our best runs (as judged against WSJ45) for NEWS and BLOG$_t$ (more details in Table 8).

Since our experimental setup involved testing nearly three hundred models simultaneously, we must take extreme care in analyzing and interpreting these results, to avoid falling prey to any looming "data-snooping" biases.[16] In a sufficiently large pool of models, where each is trained using a randomized and/or chaotic procedure (such as ours), the best may look good due to pure chance. We appealed to three separate diagnostics to convince ourselves that our best results are *not* noise.

The most radical approach would be to write off WSJ as a development set and to focus only on the results from the held-out Brown corpus. It was initially intended as a test of out-of-domain generalization, but since Brown was in no way involved in selecting the best models, it also qualifies as a blind evaluation set. We observe that our best models perform even better (and gain more — see Table 8) on Brown than on WSJ — a strong indication that our selection process has not overfitted.

Our second diagnostic is a closer look at WSJ. Since we cannot graph the full (six-dimensional) set of results, we begin with a simple linear regression, using accuracy on WSJ45 as the dependent variable. We prefer this full factorial design to the more traditional ablation studies because it allows us to account for and to incorporate every single experimental data point incurred along the

[16] In the standard statistical hypothesis testing setting, it is reasonable to expect that $p\%$ of randomly chosen hypotheses will appear significant at the $p\%$ level simply by chance. Consequently, *multiple* hypothesis testing requires re-evaluating significance levels — adjusting raw p-values, e.g., using the Holm-Bonferroni method (Holm, 1979).

Table 7: Counts of sentences, tokens and (unique) bracketings for web-based data sets; trimmed versions, restricted to only those sentences having at least one multi-token bracketing, are indicated by a prime ($'$).

way. Its output is a coarse, high-level summary of our runs, showing which factors significantly contribute to changes in error rate on WSJ45:

Parameter	*(Indicator)*	*Setting*	$\hat{\beta}$	*p-value*
INIT	1	ad-hoc @WSJ8,15	11.8	***
GENRE	1	BLOG$_t$	-3.7	0.06
	2	NEWS	-5.3	**
	3	WEB	-7.7	***
SCOPE	1	@15	-0.5	0.40
	2	@15→45	-0.4	0.53
CONSTR	2	*sprawl*	0.9	0.23
	3	*loose*	1.0	0.15
	4	*strict*	1.8	*
TRIM	1	drop unmarked	-7.4	***
ADAPT	1	WSJ re-training	1.5	**
Intercept		($R^2_{\text{Adjusted}} = 73.6\%$)	39.9	***

We use a standard convention: *** for $p < 0.001$;
** for $p < 0.01$ (very signif.); and * for $p < 0.05$ (signif.).

The default training mode (all parameters zero) is estimated to score 39.9%. A good initializer gives the biggest (double-digit) gain; both domain adaptation and constraints also make a positive impact. Throwing away unannotated data hurts, as does training out-of-domain (the blog is least bad; the web is worst). Of course, this overview should not be taken too seriously. Overly simplistic, a first order model ignores interactions between parameters. Furthermore, a least squares fit aims to capture central tendencies, whereas we are more interested in outliers — the best-performing runs.

A major imperfection of the simple regression model is that helpful factors that require an interaction to "kick in" may not, on their own, appear statistically significant. Our third diagnostic is to examine parameter settings that give rise to the best-performing models, looking out for combinations that consistently deliver superior results.

7.1 WSJ Baselines

Just two parameters apply to learning from WSJ. Five of their six combinations are state-of-the-art, demonstrating the power of Viterbi training; only the default run scores worse than 45.0%, attained by Leapfrog (Spitkovsky et al., 2010a), on WSJ45:

Settings	SCOPE=0	SCOPE=1	SCOPE=2
INIT=0	*41.3*	45.0	45.2
1	46.6	47.5	**47.6**
	@45	@15	@15→45

7.2 Blog

Simply training on BLOG$_t$ instead of WSJ hurts:

GENRE=1	SCOPE=0	SCOPE=1	SCOPE=2
INIT=0	39.6	36.9	36.9
1	46.5	46.3	46.4
	@45	@15	@15→45

The best runs use a good initializer, discard unannotated sentences, enforce the *loose* constraint on the rest, follow up with domain adaptation and benefit from re-training — GENRE=TRIM=ADAPT=1:

INIT=1	SCOPE=0	SCOPE=1	SCOPE=2
CONSTR=0	45.8	48.3	49.6
(*sprawl*) 2	46.3	49.2	49.2
(*loose*) 3	41.3	*50.2*	**50.4**
(*strict*) 4	40.7	49.9	48.7
	@45	@15	@15→45

The contrast between unconstrained learning and annotation-guided parsing is higher for the default initializer, still using trimmed data sets (just over a thousand sentences for BLOG$'_t$15 — see Table 7):

INIT=0	SCOPE=0	SCOPE=1	SCOPE=2
CONSTR=0	25.6	19.4	19.3
(*sprawl*) 2	25.2	22.7	22.5
(*loose*) 3	32.4	26.3	27.3
(*strict*) 4	36.2	38.7	40.1
	@45	@15	@15→45

Above, we see a clearer benefit to our constraints.

7.3 News

Training on WSJ is also better than using NEWS:

GENRE=2	SCOPE=0	SCOPE=1	SCOPE=2
INIT=0	40.2	38.8	38.7
1	43.4	44.0	43.8
	@45	@15	@15→45

As with the blog, the best runs use the good initializer, discard unannotated sentences, enforce the *loose* constraint and follow up with domain adaptation — GENRE=2; INIT=TRIM=ADAPT=1:

Settings	SCOPE=0	SCOPE=1	SCOPE=2
CONSTR=0	46.6	45.4	45.2
(*sprawl*) 2	46.1	44.9	44.9
(*loose*) 3	**49.5**	48.1	48.3
(*strict*) 4	37.7	36.8	37.6
	@45	@15	@15→45

With all the extra training data, the best new score is just 49.5%. On the one hand, we are disappointed by the lack of dividends to orders of magnitude more data. On the other, we are comforted that the system arrives within 1% of its best result — 50.4%, obtained with a manually cleaned up corpus — now using an auto-generated data set.

7.4 Web

The WEB-side story is more discouraging:

GENRE=3	SCOPE=0	SCOPE=1	SCOPE=2
INIT=0	38.3	35.1	35.2
1	42.8	43.6	43.4
	@45	@15	@15→45

Our best run again uses a good initializer, keeps *all* sentences, still enforces the *loose* constraint and follows up with domain adaptation, but performs worse than all well-initialized WSJ baselines, scoring only 45.9% (trained at WEB15).

We suspect that the web is just too messy for us. On top of the challenges of language identification and sentence-breaking, there is a lot of boiler-plate; furthermore, web text can be difficult for news-trained POS taggers. For example, note that the verb "sign" is twice mistagged as a noun and that "YouTube" is classified as a verb, in the top four POS sequences of web sentences:[17]

	POS Sequence	WEB *Count*
	Sample web sentence, chosen uniformly at random.	
1	DT NNS VBN	82,858,487
	All rights reserved.	
2	NNP NNP NNP	65,889,181

	Sign in to YouTube now!	
4	NN IN IN PRP$ JJ NN	31,007,471
	Sign in with your Google Account!	

[17] Further evidence: TnT tags the ubiquitous but ambiguous fragments "click here" and "print post" as noun phrases.

7.5 The State of the Art

Our best model gains more than 5% over previous state-of-the-art accuracy across all sentences of WSJ's Section 23, more than 8% on WSJ20 and rivals the oracle skyline (Spitkovsky et al., 2010a) on WSJ10; these gains generalize to Brown100, where it improves by nearly 10% (see Table 8).

We take solace in the fact that our best models agree in using *loose* constraints. Of these, the models trained with less data perform better, with the best two using trimmed data sets, echoing that "less is more" (Spitkovsky et al., 2010a), pace Halevy et al. (2009). We note that orders of magnitude more data did not improve parsing performance further and suspect a different outcome from lexicalized models: The primary benefit of additional lower-quality data is in improved coverage. But with only 35 unique POS tags, data sparsity is hardly an issue. Extra examples of lexical items help little and hurt when they are mistagged.

8 Related Work

The wealth of new annotations produced in many languages every day already fuels a number of NLP applications. Following their early and wide-spread use by search engines, in service of spam-fighting and retrieval, anchor text and link data enhanced a variety of traditional NLP techniques: cross-lingual information retrieval (Nie and Chen, 2002), translation (Lu et al., 2004), both named-entity recognition (Mihalcea and Csomai, 2007) and categorization (Watanabe et al., 2007), query segmentation (Tan and Peng, 2008), plus semantic relatedness and word-sense disambiguation (Gabrilovich and Markovitch, 2007; Yeh et al., 2009). Yet several, seemingly natural, candidate core NLP tasks — tokenization, CJK segmentation, noun-phrase chunking, and (until now) parsing — remained conspicuously uninvolved.

Approaches related to ours arise in applications that combine parsing with named-entity recognition (NER). For example, constraining a parser to respect the boundaries of known entities is standard practice not only in joint modeling of (constituent) parsing and NER (Finkel and Manning, 2009), but also in higher-level NLP tasks, such as relation extraction (Mintz et al., 2009), that couple chunking with (dependency) parsing. Although restricted to proper noun phrases, dates, times and quantities, we suspect that constituents identified by trained (supervised) NER systems would also

be helpful in constraining grammar induction.

Following Pereira and Schabes' (1992) success with partial annotations in training a model of (English) constituents generatively, their idea has been extended to discriminative estimation (Riezler et al., 2002) and also proved useful in modeling (Japanese) dependencies (Sassano, 2005). There was demand for partially bracketed corpora. Chen and Lee (1995) constructed one such corpus by learning to partition (English) POS sequences into chunks (Abney, 1991); Inui and Kotani (2001) used n-gram statistics to split (Japanese) clauses.

We combine the two intuitions, using the web to build a partially parsed corpus. Our approach could be called *lightly-supervised*, since it does not require manual annotation of a single complete parse tree. In contrast, traditional semi-supervised methods rely on fully-annotated seed corpora.[18]

9 Conclusion

We explored novel ways of training dependency parsing models, the best of which attains 50.4% accuracy on Section 23 (all sentences) of WSJ, beating all previous unsupervised state-of-the-art by more than 5%. Extra gains stem from guiding Viterbi training with web mark-up, the *loose* constraint consistently delivering best results. Our linguistic analysis of a blog reveals that web annotations can be converted into accurate parsing constraints (*loose*: 88%; *sprawl*: 95%; *tear*: 99%) that could be helpful to supervised methods, e.g., by boosting an initial parser via self-training (McClosky et al., 2006) on sentences with mark-up. Similar techniques may apply to standard word-processing annotations, such as font changes, and to certain (balanced) punctuation (Briscoe, 1994).

We make our blog data set, overlaying mark-up and syntax, publicly available. Its annotations are 75% noun phrases, 13% verb phrases, 7% simple declarative clauses and 2% prepositional phrases, with traces of other phrases, clauses and fragments. The type of mark-up, combined with POS tags, could make for valuable features in discriminative models of parsing (Ratnaparkhi, 1999).

A logical next step would be to explore the connection between syntax and mark-up for genres other than a news-style blog and for languages other than English. We are excited by the possibilities, as unsupervised parsers are on the cusp of becoming useful in their own right — recently, Davidov et al. (2009) successfully applied Seginer's (2007) fully unsupervised grammar inducer to the problems of pattern-acquisition and extraction of semantic data. If the strength of the connection between web mark-up and syntactic structure is universal across languages and genres, this fact could have broad implications for NLP, with applications extending well beyond parsing.

[18] A significant effort expended in building a tree-bank comes with the first batch of sentences (Druck et al., 2009).

Phylogenetic Grammar Induction

Taylor Berg-Kirkpatrick and **Dan Klein**
Computer Science Division
University of California, Berkeley
{tberg, klein}@cs.berkeley.edu

Abstract

We present an approach to multilingual grammar induction that exploits a phylogeny-structured model of parameter drift. Our method does not require any translated texts or token-level alignments. Instead, the phylogenetic prior couples languages at a parameter level. Joint induction in the multilingual model substantially outperforms independent learning, with larger gains both from more articulated phylogenies and as well as from increasing numbers of languages. Across eight languages, the multilingual approach gives error reductions over the standard monolingual DMV averaging 21.1% and reaching as high as 39%.

1 Introduction

Learning multiple languages together should be easier than learning them separately. For example, in the domain of syntactic parsing, a range of recent work has exploited the mutual constraint between two languages' parses of the same bitext (Kuhn, 2004; Burkett and Klein, 2008; Kuzman et al., 2009; Smith and Eisner, 2009; Snyder et al., 2009a). Moreover, Snyder et al. (2009b) in the context of unsupervised part-of-speech induction (and Bouchard-Côté et al. (2007) in the context of phonology) show that extending beyond two languages can provide increasing benefit. However, multitexts are only available for limited languages and domains. In this work, we consider unsupervised grammar induction without bitexts or multitexts. Without translation examples, multilingual constraints cannot be exploited at the sentence token level. Rather, we capture multilingual constraints at a *parameter* level, using a phylogeny-structured prior to tie together the various individual languages' learning problems. Our joint, hierarchical prior couples model parameters for different languages in a way that respects knowledge about how the languages evolved.

Aspects of this work are closely related to Cohen and Smith (2009) and Bouchard-Côté et al. (2007). Cohen and Smith (2009) present a model for jointly learning English and Chinese dependency grammars without bitexts. In their work, structurally constrained covariance in a logistic normal prior is used to couple parameters between the two languages. Our work, though also different in technical approach, differs most centrally in the extension to multiple languages and the use of a phylogeny. Bouchard-Côté et al. (2007) considers an entirely different problem, phonological reconstruction, but shares with this work both the use of a phylogenetic structure as well as the use of log-linear parameterization of local model components. Our work differs from theirs primarily in the task (syntax vs. phonology) and the variables governed by the phylogeny: in our model it is the grammar parameters that drift (in the prior) rather than individual word forms (in the likelihood model).

Specifically, we consider dependency induction in the DMV model of Klein and Manning (2004). Our data is a collection of standard dependency data sets in eight languages: English, Dutch, Danish, Swedish, Spanish, Portuguese, Slovene, and Chinese. Our focus is not the DMV model itself, which is well-studied, but rather the prior which couples the various languages' parameters. While some choices of prior structure can greatly complicate inference (Cohen and Smith, 2009), we choose a hierarchical Gaussian form for the drift term, which allows the gradient of the observed data likelihood to be easily computed using standard dynamic programming methods.

In our experiments, joint multilingual learning substantially outperforms independent monolingual learning. Using a limited phylogeny that

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1288–1297,
Uppsala, Sweden, 11-16 July 2010.

only couples languages within linguistic families reduces error by 5.6% over the monolingual baseline. Using a flat, global phylogeny gives a greater reduction, almost 10%. Finally, a more articulated phylogeny that captures both inter- and intra-family effects gives an even larger average relative error reduction of 21.1%.

2 Model

We define our model over two kinds of random variables: dependency trees and parameters. For each language ℓ in a set L, our model will generate a collection $\mathbf{t}_\ell$ of dependency trees $\mathbf{t}_\ell^i$. We assume that these dependency trees are generated by the DMV model of Klein and Manning (2004), which we write as $\mathbf{t}_\ell^i \sim \text{DMV}(\theta_\ell)$. Here, θ_ℓ is a vector of the various model parameters for language ℓ. The prior is what couples the θ_ℓ parameter vectors across languages; it is the focus of this work. We first consider the likelihood model before moving on to the prior.

2.1 Dependency Model with Valence

A dependency parse is a directed tree $\mathbf{t}$ over tokens in a sentence $\mathbf{s}$. Each edge of the tree specifies a directed dependency from a head token to a dependent, or argument token. The DMV is a generative model for trees $\mathbf{t}$, which has been widely used for dependency parse induction. The observed data likelihood, used for parameter estimation, is the marginal probability of generating the observed sentences $\mathbf{s}$, which are simply the leaves of the trees $\mathbf{t}$. Generation in the DMV model involves two types of local conditional probabilities: CONTINUE distributions that capture valence and ATTACH distributions that capture argument selection.

First, the Bernoulli CONTINUE probability distributions $P^{\text{CONTINUE}}(c|h, dir, adj; \theta_\ell)$ model the fertility of a particular head type h. The outcome $c \in \{stop, continue\}$ is conditioned on the head type h, direction dir, and adjacency adj. If a head type's continue probability is low, tokens of this type will tend to generate few arguments.

Second, the ATTACH multinomial probability distributions $P^{\text{ATTACH}}(a|h, dir; \theta_\ell)$ capture attachment preferences of heads, where a and h are both token types. We take the same approach as previous work (Klein and Manning, 2004; Cohen and Smith, 2009) and use gold part-of-speech labels as tokens. Thus, the basic observed "word" types are actually word classes.

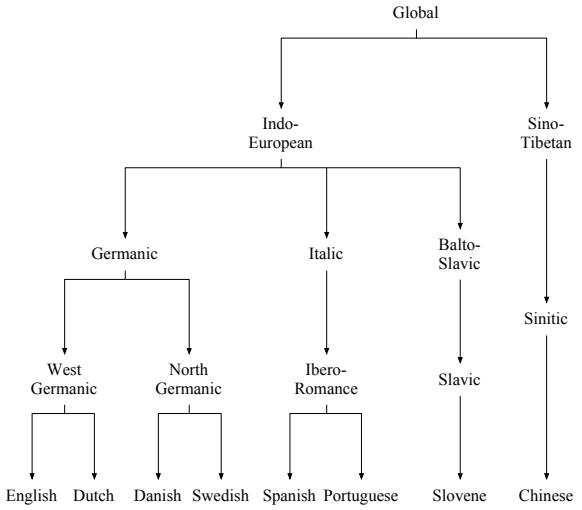

Figure 1: An example of a linguistically-plausible phylogenetic tree over the languages in our training data. Leaves correspond to (observed) modern languages, while internal nodes represent (unobserved) ancestral languages.

2.1.1 Log-Linear Parameterization

The DMV's local conditional distributions were originally given as simple multinomial distributions with one parameter per outcome. However, they can be re-parameterized to give the following log-linear form (Eisner, 2002; Bouchard-Côté et al., 2007; Berg-Kirkpatrick et al., 2010):

$$P^{\text{CONTINUE}}(c|h, dir, adj; \theta_\ell) = \frac{\exp\left[{\theta_\ell}^T \boldsymbol{f}_{\text{CONTINUE}}(c, h, dir, adj)\right]}{\sum_{c'} \exp\left[{\theta_\ell}^T \boldsymbol{f}_{\text{CONTINUE}}(c', h, dir, adj)\right]}$$

$$P^{\text{ATTACH}}(a|h, dir; \theta_\ell) = \frac{\exp\left[{\theta_\ell}^T \boldsymbol{f}_{\text{ATTACH}}(a, h, dir)\right]}{\sum_{a'} \exp\left[{\theta_\ell}^T \boldsymbol{f}_{\text{ATTACH}}(a', h, dir)\right]}$$

The parameters are weights θ_ℓ with one weight vector per language. In the case where the vector of feature functions $\boldsymbol{f}$ has an indicator for each possible conjunction of outcome and conditions, the original multinomial distributions are recovered. We refer to these full indicator features as the set of SPECIFIC features.

2.2 Phylogenetic Prior

The focus of this work is coupling each of the parameters θ_ℓ in a phylogeny-structured prior. Consider a phylogeny like the one shown in Figure 1, where each modern language ℓ in L is a leaf. We would like to say that the leaves' parameter vectors arise from a process which slowly

drifts along each branch. A convenient choice is to posit additional parameter variables θ_{ℓ^+} at internal nodes $\ell^+ \in L^+$, a set of ancestral languages, and to assume that the conditional distribution $P(\theta_\ell|\theta_{\text{par}(\ell)})$ at each branch in the phylogeny is a Gaussian centered on $\theta_{\text{par}(\ell)}$, where $\text{par}(\ell)$ is the parent of ℓ in the phylogeny and ℓ ranges over $L \cup L^+$. The variance structure of the Gaussian would then determine how much drift (and in what directions) is expected. Concretely, we assume that each drift distribution is an isotropic Gaussian with mean $\theta_{\text{par}(\ell)}$ and scalar variance σ^2. The root is centered at zero. We have thus defined a joint distribution $P(\Theta|\sigma^2)$ where $\Theta = (\theta_\ell : \ell \in L \cup L^+)$. σ^2 is a hyperparameter for this prior which could itself be re-parameterized to depend on branch length or be learned; we simply set it to a plausible constant value.

Two primary challenges remain. First, inference under arbitrary priors can become complex. However, in the simple case of our diagonal covariance Gaussians, the gradient of the observed data likelihood can be computed directly using the DMV's expected counts and maximum-likelihood estimation can be accomplished by applying standard gradient optimization methods. Second, while the choice of diagonal covariance is efficient, it causes components of θ that correspond to features occurring in only one language to be marginally independent of the parameters of all other languages. In other words, only features which fire in more than one language are coupled by the prior. In the next section, we therefore increase the overlap between languages' features by using coarse projections of parts-of-speech.

2.3 Projected Features

With diagonal covariance in the Gaussian drift terms, each parameter evolves independently of the others. Therefore, our prior will be most informative when features activate in multiple languages. In phonology, it is useful to map phonemes to the International Phonetic Alphabet (IPA) in order to have a language-independent parameterization. We introduce a similarly neutral representation here by projecting language-specific parts-of-speech to a coarse, shared inventory.

Indeed, we assume that each language has a distinct tagset, and so the basic configurational features will be language specific. For example, when an English VBZ takes a left argument headed by a NNS, a feature will activate specific to VBZ-NNS-LEFT. That feature will be used in the log-linear attachment probability for English. However, because that feature does not show up in any other language, it is not usefully controlled by the prior. Therefore, we also include coarser features which activate on more abstract, cross-linguistic configurations. In the same example, a feature will fire indicating a coarse, direction-free NOUN-VERB attachment. This feature will now occur in multiple languages and will contribute to each of those languages' attachment models. Although such cross-lingual features will have different weight parameters in each language, those weights will covary, being correlated by the prior.

SPECIFIC:	Activate for only one conjunction of outcome and conditions: $\mathbb{1}(c = \cdot, h = \cdot, dir = \cdot, adj = \cdot)$
SHARED:	Activate for heads from multiple languages using cross-lingual POS projection $\pi(\cdot)$: $\mathbb{1}(c = \cdot, \pi(h) = \cdot, dir = \cdot, adj = \cdot)$

CONTINUE distribution feature templates.

SPECIFIC:	Activate for only one conjunction of outcome and conditions: $\mathbb{1}(a = \cdot, h = \cdot, dir = \cdot)$
SHARED:	Activate for heads and arguments from multiple languages using cross-lingual POS projection $\pi(\cdot)$: $\mathbb{1}(\pi(a) = \cdot, \pi(h) = \cdot, dir = \cdot)$ $\mathbb{1}(\pi(a) = \cdot, h = \cdot, dir = \cdot)$ $\mathbb{1}(a = \cdot, \pi(h) = \cdot, dir = \cdot)$

ATTACH distribution feature templates.

Table 1: Feature templates for CONTINUE and ATTACH conditional distributions.

The coarse features are defined via a projection π from language-specific part-of-speech labels to coarser, cross-lingual word classes, and hence we refer to them as SHARED features. For each corpus used in this paper, we use the tagging annotation guidelines to manually define a fixed mapping from the corpus tagset to the following coarse tagset: noun, verb, adjective, adverb, conjunction, preposition, determiner, interjection, numeral, and pronoun. Parts-of-speech for which this coarse mapping is ambiguous or impossible are not mapped, and do not have corresponding SHARED features.

We summarize the feature templates for the CONTINUE and ATTACH conditional distributions in Table 1. Variants of all feature templates that ignore direction and/or adjacency are included. In practice, we found it beneficial for all language-

independent features to ignore direction.

Again, only the coarse features occur in multiple languages, so all phylogenetic influence is through those. Nonetheless, the effect of the phylogeny turns out to be quite strong.

2.4 Learning

We now turn to learning with the phylogenetic prior. Since the prior couples parameters across languages, this learning problem requires parameters for all languages be estimated jointly. We seek to find $\Theta = (\theta_\ell : \ell \in L \cup L^+)$ which optimizes $\log P(\Theta|\mathbf{s})$, where $\mathbf{s}$ aggregates the observed leaves of all the dependency trees in all the languages. This can be written as

$$\log P(\Theta) + \log P(\mathbf{s}|\Theta) - \log P(\mathbf{s})$$

The third term is a constant and can be ignored. The first term can be written as

$$\log P(\Theta) = \sum_{\ell \in L \cup L^+} \frac{1}{2\sigma^2} \|\theta_\ell - \theta_{\mathrm{par}(\ell)}\|_2^2 + C$$

where C is a constant. The form of $\log P(\Theta)$ immediately shows how parameters are penalized for being different across languages, more so for languages that are near each other in the phylogeny. The second term

$$\log P(\mathbf{s}|\Theta) = \sum_{\ell \in L} \log P(\mathbf{s}_\ell|\theta_\ell)$$

is a sum of observed data likelihoods under the standard DMV models for each language, computable by dynamic programming (Klein and Manning, 2004). Together, this yields the following objective function:

$$l(\Theta) = \textstyle\sum_{\ell \in L \cup L^+} \frac{1}{2\sigma^2} \|\theta_\ell - \theta_{\mathrm{par}(\ell)}\|_2^2 + \sum_{\ell \in L} \log P(\mathbf{s}_\ell|\theta_\ell)$$

which can be optimized using gradient methods or (MAP) EM. Here we used L-BFGS (Liu et al., 1989). This requires computation of the gradient of the observed data likelihood $\log P(\mathbf{s}_\ell|\theta_\ell)$ which is given by:

$$\nabla \log P(\mathbf{s}_\ell|\theta_\ell) = \mathbb{E}_{\mathbf{t}_\ell|\mathbf{s}_\ell}\left[\nabla \log P(\mathbf{s}_\ell, \mathbf{t}_\ell|\theta_\ell)\right] =$$

$$\begin{bmatrix} \sum_{c,h,dir,adj} e_{c,h,dir,adj}(\mathbf{s}_\ell;\theta_\ell) \cdot \Big[\boldsymbol{f}_{\text{CONTINUE}}(c,h,dir,adj) - \\ \quad \sum_{c'} P^{\text{CONTINUE}}(c'|h,dir,adj;\theta_\ell)\boldsymbol{f}_{\text{CONTINUE}}(c',h,dir,adj)\Big] \\ \\ \sum_{a,h,dir} e_{a,h,dir}(\mathbf{s}_\ell;\theta_\ell) \cdot \Big[\boldsymbol{f}_{\text{ATTACH}}(a,h,dir) - \\ \quad \sum_{a'} P^{\text{ATTACH}}(a'|h,dir;\theta_\ell)\boldsymbol{f}_{\text{ATTACH}}(a',h,dir)\Big] \end{bmatrix}$$

The expected gradient of the log joint likelihood of sentences and parses is equal to the gradient of the log marginal likelihood of just sentences, or the observed data likelihood (Salakhutdinov et al., 2003). $e_{a,h,dir}(\mathbf{s}_\ell;\theta_\ell)$ is the expected count of the number of times head h is attached to a in direction dir given the observed sentences $\mathbf{s}_\ell$ and DMV parameters θ_ℓ. $e_{c,h,dir,adj}(\mathbf{s}_\ell;\theta_\ell)$ is defined similarly. Note that these are the same expected counts required to perform EM on the DMV, and are computable by dynamic programming.

The computation time is dominated by the computation of each sentence's posterior expected counts, which are independent given the parameters, so the time required per iteration is essentially the same whether training all languages jointly or independently. In practice, the total number of iterations was also similar.

3 Experimental Setup

3.1 Data

We ran experiments with the following languages: English, Dutch, Danish, Swedish, Spanish, Portuguese, Slovene, and Chinese. For all languages but English and Chinese, we used corpora from the 2006 CoNLL-X Shared Task dependency parsing data set (Buchholz and Marsi, 2006). We used the shared task training set to both train and test our models. These corpora provide hand-labeled part-of-speech tags (except for Dutch, which is automatically tagged) and provide dependency parses, which are either themselves hand-labeled or have been converted from hand-labeled parses of other kinds. For English and Chinese we use sections 2-21 of the Penn Treebank (PTB) (Marcus et al., 1993) and sections 1-270 of the Chinese Treebank (CTB) (Xue et al., 2002) respectively. Similarly, these sections were used for both training and testing. The English and Chinese data sets have hand-labeled constituency parses and part-of-speech tags, but no dependency parses. We used the Bikel Chinese head finder (Bikel and Chiang, 2000) and the Collins English head finder (Collins, 1999) to transform the gold constituency parses into gold dependency parses. None of the corpora are bitexts. For all languages, we ran experiments on all sentences of length 10 or less after punctuation has been removed.

When constructing phylogenies over the languages we made use of their linguistic classifications. English and Dutch are part of the West Ger-

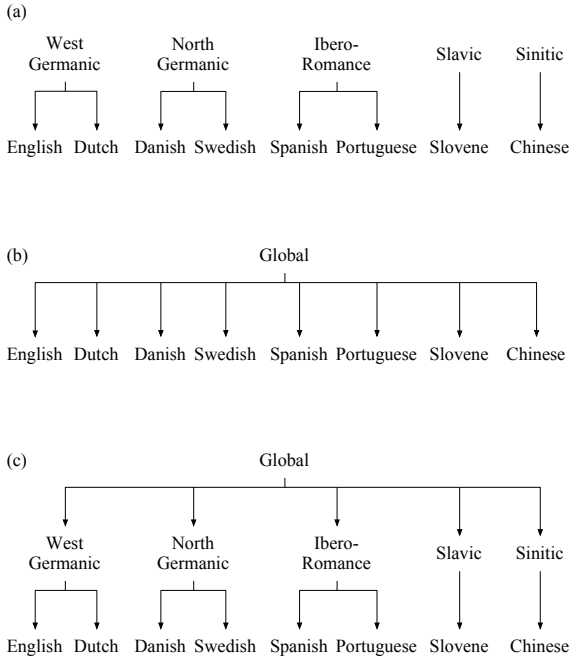

Figure 2: (a) Phylogeny for FAMILIES model. (b) Phylogeny for GLOBAL model. (c) Phylogeny for LINGUISTIC model.

manic family of languages, whereas Danish and Swedish are part of the North Germanic family. Spanish and Portuguese are both part of the Ibero-Romance family. Slovene is part of the Slavic family. Finally, Chinese is in the Sinitic family, and is not an Indo-European language like the others. We interchangeably speak of a language family and the ancestral node corresponding to that family's root language in a phylogeny.

3.2 Models Compared

We evaluated three phylogenetic priors, each with a different phylogenetic structure. We compare with two monolingual baselines, as well as an all-pairs multilingual model that does not have a phylogenetic interpretation, but which provides very similar capacity for parameter coupling.

3.2.1 Phylogenetic Models

The first phylogenetic model uses the shallow phylogeny shown in Figure 2(a), in which only languages within the same family have a shared parent node. We refer to this structure as FAMILIES. Under this prior, the learning task decouples into independent subtasks for each family, but no regularities across families can be captured.

The family-level model misses the constraints between distant languages. Figure 2(b) shows another simple configuration, wherein all languages share a common parent node in the prior, meaning that global regularities that are consistent across all languages can be captured. We refer to this structure as GLOBAL.

While the global model couples the parameters for all eight languages, it does so without sensitivity to the articulated structure of their descent. Figure 2(c) shows a more nuanced prior structure, LINGUISTIC, which groups languages first by family and then under a global node. This structure allows global regularities as well as regularities within families to be learned.

3.2.2 Parameterization and ALLPAIRS Model

Daumé III (2007) and Finkel and Manning (2009) consider a formally similar Gaussian hierarchy for domain adaptation. As pointed out in Finkel and Manning (2009), there is a simple equivalence between hierarchical regularization as described here and the addition of new tied features in a "flat" model with zero-meaned Gaussian regularization on all parameters. In particular, instead of parameterizing the objective in Section 2.4 in terms of multiple sets of weights, one at each node in the phylogeny (the *hierarchical parameterization*, described in Section 2.4), it is equivalent to parameterize this same objective in terms of a single set of weights on a larger of group features (the *flat parameterization*). This larger group of features contains a duplicate set of the features discussed in Section 2.3 for each node in the phylogeny, each of which is active only on the languages that are its descendants. A linear transformation between parameterizations gives equivalence. See Finkel and Manning (2009) for details.

In the flat parameterization, it seems equally reasonable to simply tie all pairs of languages by adding duplicate sets of features for each pair. This gives the ALLPAIRS setting, which we also compare to the tree-structured phylogenetic models above.

3.3 Baselines

To evaluate the impact of multilingual constraint, we compared against two monolingual baselines. The first baseline is the standard DMV with only SPECIFIC features, which yields the standard multinomial DMV (*weak baseline*). To facilitate comparison to past work, we used no prior for this monolingual model. The second baseline is the DMV with added SHARED features. This model includes a simple isotropic Gaussian prior on pa-

Table 2: Directed dependency accuracy of monolingual and multilingual models, and relative error reduction over the monolingual baseline with SHARED features macro-averaged over languages. Multilingual models outperformed monolingual models in general, with larger gains from increasing numbers of languages. Additionally, more nuanced phylogenetic structures outperformed cruder ones.

rameters. This second baseline is the more direct comparison to the multilingual experiments here (*strong baseline*).

3.4 Evaluation

For each setting, we evaluated the directed dependency accuracy of the minimum Bayes risk (MBR) dependency parses produced by our models under maximum (posterior) likelihood parameter estimates. We computed accuracies separately for each language in each condition. In addition, for multilingual models, we computed the relative error reduction over the strong monolingual baseline, macro-averaged over languages.

3.5 Training

Our implementation used the flat parameterization described in Section 3.2.2 for both the phylogenetic and ALLPAIRS models. We originally did this in order to facilitate comparison with the non-phylogenetic ALLPAIRS model, which has no equivalent hierarchical parameterization. In practice, optimizing with the hierarchical parameterization also seemed to underperform.[1]

All models were trained by directly optimizing the observed data likelihood using L-BFGS (Liu et al., 1989). Berg-Kirkpatrick et al. (2010) suggest that directly optimizing the observed data likelihood may offer improvements over the more standard expectation-maximization (EM) optimization procedure for models such as the DMV, especially when the model is parameterized using features. We stopped training after 200 iterations in all cases. This fixed stopping criterion seemed to be adequate in all experiments, but presumably there is a potential gain to be had in fine tuning. To initialize, we used the harmonic initializer presented in Klein and Manning (2004). This type of initialization is deterministic, and thus we did not perform random restarts.

We found that for all models $\sigma^2 = 0.2$ gave reasonable results, and we used this setting in all experiments. For most models, we found that varying σ^2 in a reasonable range did not substantially affect accuracy. For some models, the directed accuracy was less flat with respect to σ^2. In these less-stable cases, there seemed to be an interaction between the variance and the choice between head conventions. For example, for some settings of σ^2, but not others, the model would learn that determiners head noun phrases. In particular, we observed that even when direct accuracy did fluctuate, undirected accuracy remained more stable.

[1] We noticed that the weights of features shared across languages had larger magnitude early in the optimization procedure when using the flat parameterization compared to using the hierarchical parameterization, perhaps indicating that cross-lingual influences had a larger effect on learning in its initial stages.

4 Results

Table 2 shows the overall results. In all cases, methods which coupled the languages in some way outperformed the independent baselines that considered each language independently.

4.1 Bilingual Models

The weakest of the coupled models was FAMILIES, which had an average relative error reduction of 5.6% over the strong baseline. In this case, most of the average improvement came from a single family: Spanish and Portuguese. The limited improvement of the family-level prior compared to other phylogenies suggests that there are important multilingual interactions that do not happen within families. Table 2 also reports the maximum accuracy achieved for each language when it was paired with another language (same family or otherwise) and trained together with a single common parent. These results appear in the column headed by BESTPAIR, and show the best accuracy for the language on that row over all possible pairings with other languages. When pairs of languages were trained together in isolation, the largest benefit was seen for languages with small training corpora, not necessarily languages with common ancestry. In our setup, Spanish, Slovene, and Chinese have substantially smaller training corpora than the rest of the languages considered. Otherwise, the patterns are not particularly clear; combined with subsequent results, it seems that pairwise constraint is fairly limited.

4.2 Multilingual Models

Models that coupled multiple languages performed better in general than models that only considered pairs of languages. The GLOBAL model, which couples all languages, if crudely, yielded an average relative error reduction of 9.9%. This improvement comes as the number of languages able to exert mutual constraint increases. For example, Dutch and Danish had large improvements, over and above any improvements these two languages gained when trained with a single additional language. Beyond the simplistic GLOBAL phylogeny, the more nuanced LINGUISTIC model gave large improvements for English, Swedish, and Portuguese. Indeed, the LINGUISTIC model is the only model we evaluated that gave improvements for *all* the languages we considered.

It is reasonable to worry that the improvements from these multilingual models might be partially due to having more total training data in the multilingual setting. However, we found that halving the amount of data used to train the English, Dutch, and Swedish (the languages with the most training data) monolingual models did not substantially affect their performance, suggesting that for languages with several thousand sentences or more, the increase in statistical support due to additional monolingual data was not an important effect (the DMV is a relatively low-capacity model in any case).

4.3 Comparison of Phylogenies

Recall the structures of the three phylogenies presented in Figure 2. These phylogenies differ in the correlations they can represent. The GLOBAL phylogeny captures only "universals," while FAMILIES captures only correlations between languages that are known to be similar. The LINGUISTIC model captures both of these effects simultaneously by using a two layer hierarchy. Notably, the improvement due to the LINGUISTIC model is more than the sum of the improvements due to the GLOBAL and FAMILIES models.

4.4 Phylogenetic vs. ALLPAIRS

The phylogeny is capable of allowing appropriate influence to pass between languages at multiple levels. We compare these results to the ALLPAIRS model in order to see whether limitation to a tree structure is helpful. The ALLPAIRS model achieved an average relative error reduction of 17.1%, certainly outperforming both the simple phylogenetic models. However, the rich phylogeny of the LINGUISTIC model, which incorporates linguistic constraints, outperformed the freer ALLPAIRS model. A large portion of this improvement came from English, a language for which the LINGUISTIC model greatly outperformed all other models evaluated. We found that the improved English analyses produced by the LINGUISTIC model were more consistent with this model's analyses of other languages. This consistency was not present for the English analyses produced by other models. We explore consistency in more detail in Section 5.

4.5 Comparison to Related Work

The likelihood models for both the strong monolingual baseline and the various multilingual mod-

els are the same, both expanding upon the standard DMV by adding coarse SHARED features. These coarse features, even in a monolingual setting, improved performance slightly over the weak baseline, perhaps by encouraging consistent treatment of the different finer-grained variants of parts-of-speech (Berg-Kirkpatrick et al., 2010).[2] The only difference between the multilingual systems and the strong baseline is whether or not cross-language influence is allowed through the prior.

While this progression of model structure is similar to that explored in Cohen and Smith (2009), Cohen and Smith saw their largest improvements from tying together parameters for the varieties of coarse parts-of-speech monolinugally, and then only moderate improvements from allowing cross-linguistic influence on top of monolingual sharing. When Cohen and Smith compared their best shared logistic-normal bilingual models to monolingual counter-parts for the languages they investigate (Chinese and English), they reported a relative error reduction of 5.3%. In comparison, with the LINGUISTIC model, we saw a much larger 16.9% relative error reduction over our strong baseline for these languages. Evaluating our LINGUISTIC model on the same test sets as (Cohen and Smith, 2009), sentences of length 10 or less in section 23 of PTB and sections 271-300 of CTB, we achieved an accuracy of 56.6 for Chinese and 60.3 for English. The best models of Cohen and Smith (2009) achieved accuracies of 52.0 and 62.0 respectively on these same test sets.

Our results indicate that the majority of our model's power beyond that of the standard DMV is derived from multilingual, and in particular, more-than-bilingual, interaction. These are, to the best of our knowledge, the first results of this kind for grammar induction without bitext.

5 Analysis

By examining the proposed parses we found that the LINGUISTIC and ALLPAIRS models produced analyses that were more consistent across languages than those of the other models. We also observed that the most common errors can be summarized succinctly by looking at attachment counts between coarse parts-of-speech. Figure 3 shows matrix representations of dependency counts. The area of a square is proportional to the number of order-collapsed dependencies where the column label is the head and the row label is the argument in the parses from each system. For ease of comprehension, we use the cross-lingual projections and only show counts for selected interesting classes.

Comparing Figure 3(c), which shows dependency counts proposed by the LINGUISTIC model, to Figure 3(a), which shows the same for the strong monolingual baseline, suggests that the analyses proposed by the LINGUISTIC model are more consistent across languages than are the analyses proposed by the monolingual model. For example, the monolingual learners are divided as to whether determiners or nouns head noun phrases. There is also confusion about which labels head whole sentences. Dutch has the problem that verbs modify pronouns more often than pronouns modify verbs, and pronouns are predicted to head sentences as often as verbs are. Spanish has some confusion about conjunctions, hypothesizing that verbs often attach to conjunctions, and conjunctions frequently head sentences. More subtly, the monolingual analyses are inconsistent in the way they head prepositional phrases. In the monolingual Portuguese hypotheses, prepositions modify nouns more often than nouns modify prepositions. In English, nouns modify prepositions, and prepositions modify verbs. Both the Dutch and Spanish models are ambivalent about the attachment of prepositions.

As has often been observed in other contexts (Liang et al., 2008), promoting agreement can improve accuracy in unsupervised learning. Not only are the analyses proposed by the LINGUISTIC model more consistent, they are also more in accordance with the gold analyses. Under the LINGUISTIC model, Dutch now attaches pronouns to verbs, and thus looks more like English, its sister in the phylogenetic tree. The LINGUISTIC model has also chosen consistent analyses for prepositional phrases and noun phrases, calling prepositions and nouns the heads of each, respectively. The problem of conjunctions heading Spanish sentences has also been corrected.

Figure 3(b) shows dependency counts for the GLOBAL multilingual model. Unsurprisingly, the analyses proposed under global constraint appear somewhat more consistent than those proposed under no multi-lingual constraint (now three lan-

[2] Coarse features that only tie nouns and verbs are explored in Berg-Kirkpatrick et al. (2010). We found that these were very effective for English and Chinese, but gave worse performance for other languages.

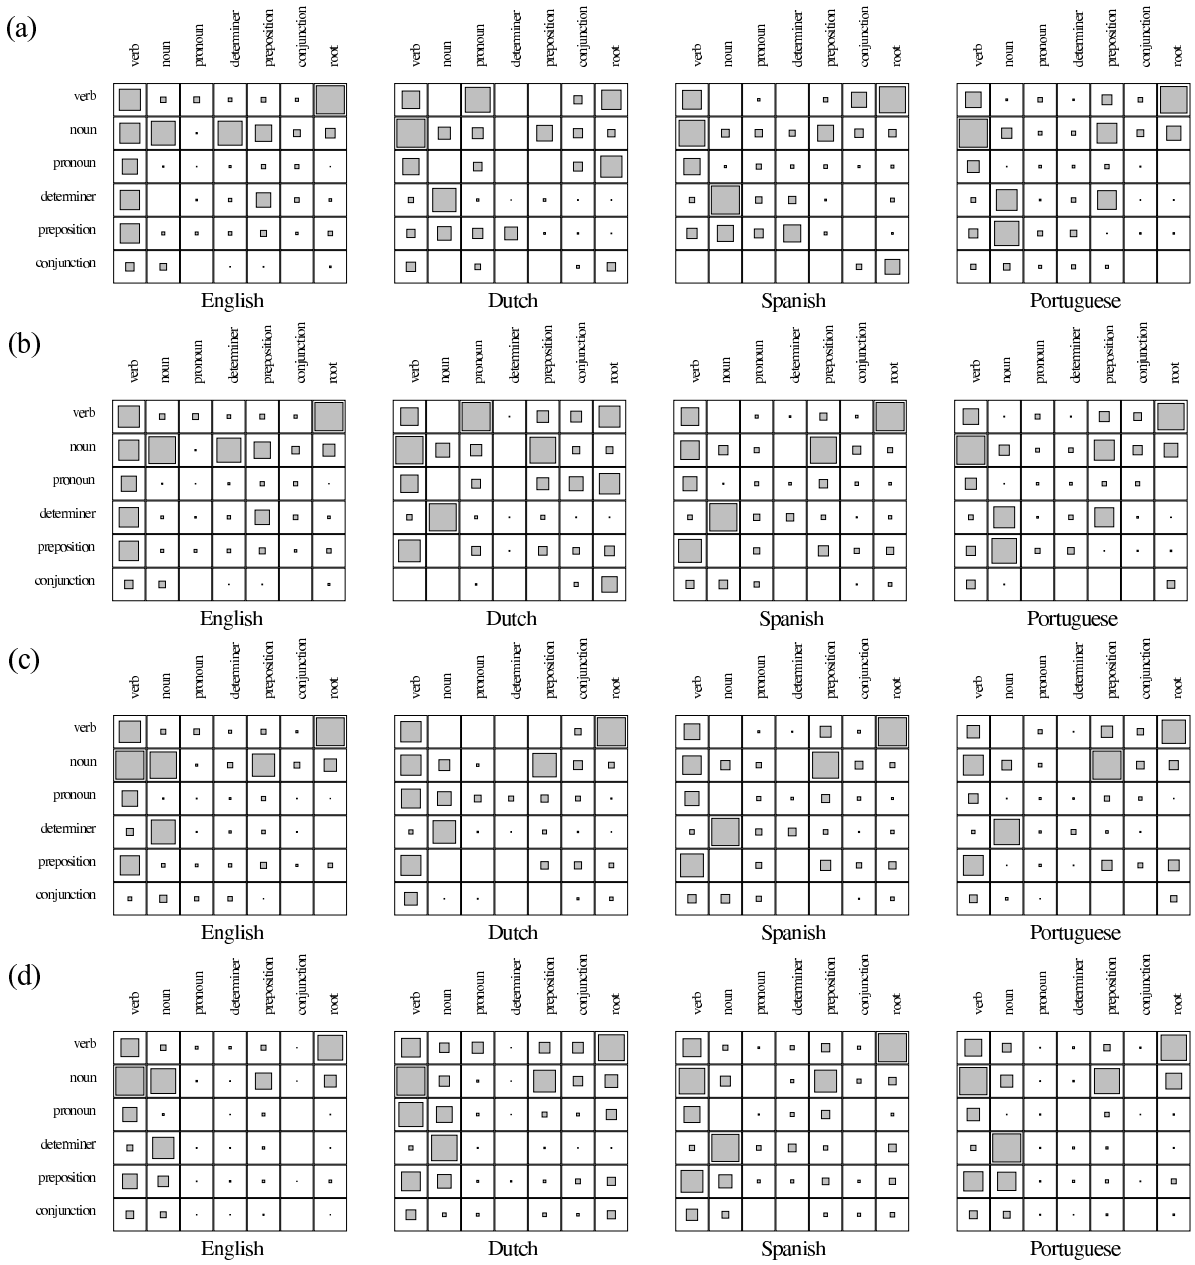

Figure 3: Dependency counts in proposed parses. Row label modifies column label. (a) Monolingual baseline with SHARED features. (b) GLOBAL model. (c) LINGUISTIC model. (d) Dependency counts in hand-labeled parses. Analyses proposed by monolingual baseline show significant inconsistencies across languages. Analyses proposed by LINGUISTIC model are more consistent across languages than those proposed by either the monolingual baseline or the GLOBAL model.

guages agree that prepositional phrases are headed by prepositions), but not as consistent as those proposed by the LINGUISTIC model.

Finally, Figure 3(d) shows dependency counts in the hand-labeled dependency parses. It appears that even the very consistent LINGUISTIC parses do not capture the non-determinism of prepositional phrase attachment to both nouns and verbs.

6 Conclusion

Even without translated texts, multilingual constraints expressed in the form of a phylogenetic prior on parameters can give substantial gains in grammar induction accuracy over treating languages in isolation. Additionally, articulated phylogenies that are sensitive to evolutionary structure can outperform not only limited flatter priors but also unconstrained all-pairs interactions.

Abstract

We present a novel fully unsupervised algorithm for POS induction from plain text, motivated by the cognitive notion of prototypes. The algorithm first identifies *landmark* clusters of words, serving as the cores of the induced POS categories. The rest of the words are subsequently mapped to these clusters. We utilize morphological and distributional representations computed in a fully unsupervised manner. We evaluate our algorithm on English and German, achieving the best reported results for this task.

1 Introduction

Part-of-speech (POS) tagging is a fundamental NLP task, used by a wide variety of applications. However, there is no single standard POS tagging scheme, even for English. Schemes vary significantly across corpora and even more so across languages, creating difficulties in using POS tags across domains and for multi-lingual systems (Jiang et al., 2009). Automatic induction of POS tags from plain text can greatly alleviate this problem, as well as eliminate the efforts incurred by manual annotations. It is also a problem of great theoretical interest. Consequently, POS induction is a vibrant research area (see Section 2).

In this paper we present an algorithm based on the theory of prototypes (Taylor, 2003), which posits that some members in cognitive categories are more central than others. These practically define the category, while the membership of other elements is based on their association with the central members. Our algorithm first clusters words based on a fine morphological representation. It then clusters the most frequent words, defining *landmark* clusters which constitute the cores of the categories. Finally, it maps the rest of the words to these categories. The last two stages utilize a distributional representation that has been shown to be effective for unsupervised parsing (Seginer, 2007).

We evaluated the algorithm in both English and German, using four different mapping-based and information theoretic clustering evaluation measures. The results obtained are generally better than all existing POS induction algorithms.

Section 2 reviews related work. Sections 3 and 4 detail the algorithm. Sections 5, 6 and 7 describe the evaluation, experimental setup and results.

2 Related Work

Unsupervised and semi-supervised POS tagging have been tackled using a variety of methods. Schütze (1995) applied latent semantic analysis. The best reported results (when taking into account all evaluation measures, see Section 5) are given by (Clark, 2003), which combines distributional and morphological information with the likelihood function of the Brown algorithm (Brown et al., 1992). Clark's tagger is very sensitive to its initialization. Reichart et al. (2010b) propose a method to identify the high quality runs of this algorithm. In this paper, we show that our algorithm outperforms not only Clark's mean performance, but often its best among 100 runs. Most research views the task as a sequential labeling problem, using HMMs (Merialdo, 1994; Banko and Moore, 2004; Wang and Schuurmans, 2005) and discriminative models (Smith and Eisner, 2005; Haghighi and Klein, 2006). Several

Uppsala, Sweden, 11-16 July 2010.

techniques were proposed to improve the HMM model. A Bayesian approach was employed by (Goldwater and Griffiths, 2007; Johnson, 2007; Gao and Johnson, 2008). Van Gael et al. (2009) used the infinite HMM with non-parametric priors. Graça et al. (2009) biased the model to induce a small number of possible tags for each word.

The idea of utilizing seeds and expanding them to less reliable data has been used in several papers. Haghighi and Klein (2006) use POS 'prototypes' that are manually provided and tailored to a particular POS tag set of a corpus. Freitag (2004) and Biemann (2006) induce an initial clustering and use it to train an HMM model. Dasgupta and Ng (2007) generate morphological clusters and use them to bootstrap a distributional model. Goldberg et al. (2008) use linguistic considerations for choosing a good starting point for the EM algorithm. Zhao and Marcus (2009) expand a partial dictionary and use it to learn disambiguation rules. Their evaluation is only at the type level and only for half of the words. Ravi and Knight (2009) use a dictionary and an MDL-inspired modification to the EM algorithm.

Many of these works use a dictionary providing allowable tags for each or some of the words. While this scenario might reduce human annotation efforts, it does not induce a tagging scheme but remains tied to an existing one. It is further criticized in (Goldwater and Griffiths, 2007).

Morphological representation. Many POS induction models utilize morphology to some extent. Some use simplistic representations of terminal letter sequences (e.g., (Smith and Eisner, 2005; Haghighi and Klein, 2006)). Clark (2003) models the entire letter sequence as an HMM and uses it to define a morphological prior. Dasgupta and Ng (2007) use the output of the *Morfessor* segmentation algorithm for their morphological representation. *Morfessor* (Creutz and Lagus, 2005), which we use here as well, is an unsupervised algorithm that segments words and classifies each segment as being a stem or an affix. It has been tested on several languages with strong results.

Our work has several unique aspects. First, our clustering method discovers prototypes in a fully unsupervised manner, mapping the rest of the words according to their association with the prototypes. Second, we use a distributional representation which has been shown to be effective for unsupervised parsing (Seginer, 2007). Third, we use a morphological representation based on signatures, which are sets of affixes that represent a family of words sharing an inflectional or derivational morphology (Goldsmith, 2001).

3 Distributional Algorithm

Our algorithm is given a plain text corpus and optionally a desired number of clusters k. Its output is a partitioning of words into clusters. The algorithm utilizes two representations, distributional and morphological. Although eventually the latter is used before the former, for clarity of presentation we begin by detailing the base distributional algorithm. In the next section we describe the morphological representation and its integration into the base algorithm.

Overview. The algorithm consists of two main stages: landmark clusters discovery, and word mapping. For the former, we first compute a distributional representation for each word. We then cluster the coordinates corresponding to high frequency words. Finally, we define *landmark clusters*. In the word mapping stage we map each word to the most similar landmark cluster.

The rationale behind using only the high frequency words in the first stage is twofold. First, prototypical members of a category are frequent (Taylor, 2003), and therefore we can expect the salient POS tags to be represented in this small subset. Second, higher frequency implies more reliable statistics. Since this stage determines the cores of all resulting clusters, it should be as accurate as possible.

Distributional representation. We use a simplified form of the elegant representation of lexical entries used by the Seginer unsupervised parser (Seginer, 2007). Since a POS tag reflects the grammatical role of the word and since this representation is effective to parsing, we were motivated to apply it to the present task.

Let W be the set of word types in the corpus. The right context entry of a word $x \in W$ is a pair of mappings $r\_int_x : W \rightarrow [0,1]$ and $r\_adj_x : W \rightarrow [0,1]$. For each $w \in W$, $r\_adj_x(w)$ is an adjacency score of w to x, reflecting w's tendency to appear on the right hand side of x.

For each $w \in W$, $r\_int_x(w)$ is an interchangeability score of x with w, reflecting the tendency of w to appear to the left of words that tend to appear to the right of x. This can be viewed as a

similarity measure between words with respect to their right context. The higher the scores the more the words tend to be adjacent/interchangeable.

Left context parameters l_int_x and l_adj_x are defined analogously.

There are important subtleties in these definitions. First, for two words $x, w \in W$, $r\_adj_x(w)$ is generally different from $l\_adj_w(x)$. For example, if w is a high frequency word and x is a low frequency word, it is likely that w appears many times to the right of x, yielding a high $r\_adj_x(w)$, but that x appears only a few times to the left of w yielding a low $l\_adj_w(x)$. Second, from the definition of $r\_int_x(w)$ and $r\_int_w(x)$, it is clear that they need not be equal.

These functions are computed incrementally by a bootstrapping process. We initialize all mappings to be identically 0. We iterate over the words in the training corpus. For every word instance x, we take the word immediately to its right y and update x's right context using y's left context:

$$\forall w \in W: \quad r\_int_x(w) \mathrel{+}= \frac{l\_adj_y(w)}{N(y)}$$

$$\forall w \in W: \quad r\_adj_x(w) \mathrel{+}= \begin{cases} 1 & w = y \\ \frac{l\_int_y(w)}{N(y)} & w \neq y \end{cases}$$

The division by $N(y)$ (the number of times y appears in the corpus before the update) is done in order not to give a disproportional weight to high frequency words. Also, $r\_int_x(w)$ and $r\_adj_x(w)$ might become larger than 1. We therefore normalize them after all updates are performed by the number of occurrences of x in the corpus.

We update l_int_x and l_adj_x analogously using the word z immediately to the left of x. The updates of the left and right functions are done in parallel.

We define the distributional representation of a word type x to be a $4|W| + 2$ dimensional vector v_x. Each word w yields four coordinates, one for each direction (left/right) and one for each mapping type (int/adj). Two additional coordinates represent the frequency in which the word appears to the left and to the right of a stopping punctuation. Of the $4|W|$ coordinates corresponding to words, we allow only $2n$ to be non-zero: the n top scoring among the right side coordinates (those of r_int_x and r_adj_x), and the n top scoring among the left side coordinates (those of l_int_x and l_adj_x). We used $n = 50$.

The distance between two words is defined to be one minus the cosine of the angle between their representation vectors.

Coordinate clustering. Each of our landmark clusters will correspond to a set of high frequency words (HFWs). The number of HFWs is much larger than the number of expected POS tags. Hence we should cluster HFWs. Our algorithm does that by unifying some of the non-zero coordinates corresponding to HFWs in the distributional representation defined above.

We extract the words that appear more than N times per million[1] and apply the following procedure I times (5 in our experiments).

We run average link clustering with a threshold α (AVGLINK$_\alpha$, (Jain et al., 1999)) on these words, in each iteration initializing every HFW to have its own cluster. AVGLINK$_\alpha$ means running the average link algorithm until the two closest clusters have a distance larger than α. We then use the induced clustering to update the distributional representation, by collapsing all coordinates corresponding to words appearing in the same cluster into a single coordinate whose value is the sum of the collapsed coordinates' values. In order to produce a conservative (fine) clustering, we used a relatively low α value of 0.25.

Note that the AVGLINK$_\alpha$ initialization in each of the I iterations assigns each HFW to a separate cluster. The iterations differ in the distributional representation of the HFWs, resulting from the previous iterations.

In our English experiments, this process reduced the dimension of the HFWs set (the number of coordinates that are non-zero in at least one of the HFWs) from 14365 to 10722. The average number of non-zero coordinates per word decreased from 102 to 55.

Since all eventual POS categories correspond to clusters produced at this stage, to reduce noise we delete clusters of less than five elements.

Landmark detection. We define landmark clusters using the clustering obtained in the final iteration of the coordinate clustering stage. However, the number of clusters might be greater than the desired number k, which is an optional parameter of the algorithm. In this case we select a subset of k clusters that best covers the HFW space. We use the following heuristic. We start from the most frequent cluster, and greedily select the clus-

[1] We used $N = 100$, yielding 1242 words for English and 613 words for German.

ter farthest from the clusters already selected. The distance between two clusters is defined to be the average distance between their members. A cluster's distance from a set of clusters is defined to be its minimal distance from the clusters in the set. The final set of clusters $\{L_1, ..., L_k\}$ and their members are referred to as *landmark clusters* and *prototypes*, respectively.

Mapping all words. Each word $w \in W$ is assigned the cluster L_i that contains its nearest prototype:

$$d(w, L_i) = min_{x \in L_i}\{1 - cos(v_w, v_x)\}$$
$$Map(w) = argmin_{L_i}\{d(w, L_i)\}$$

Words that appear less than 5 times are considered as *unknown words*. We consider two schemes for handling unknown words. One randomly maps each such word to a cluster, using a probability proportional to the number of unique known words already assigned to that cluster. However, when the number k of landmark clusters is relatively large, it is beneficial to assign all unknown words to a separate new cluster (after running the algorithm with $k - 1$). In our experiments, we use the first option when k is below some threshold (we used 15), otherwise we use the second.

4 Morphological Model

The morphological model generates another word clustering, based on the notion of a signature. This clustering is integrated with the distributional model as described below.

4.1 Morphological Representation

We use the *Morfessor* (Creutz and Lagus, 2005) word segmentation algorithm. First, all words in the corpus are segmented. Then, for each stem, the set of all affixes with which it appears (its *signature*, (Goldsmith, 2001)) is collected. The morphological representation of a word type is then defined to be its stem's signature in conjunction with its specific affixes[2] (See Figure 1).

We now collect all words having the same representation. For instance, if the words *joined* and *painted* are found to have the same signature, they would share the same cluster since both have the affix '_ed'. The word *joins* does not share the same cluster with them since it has a different affix, '_s'. This results in coarse-grained clusters exclusively defined according to morphology.

[2] A word may contain more than a single affix.

Types	join	joins	joined	joining
Stem	join	join	join	join
Affixes	ϕ	_s	_ed	_ing
Signature	{ϕ,_ed,_s,_ing}			

Figure 1: An example for a morphological representation, defined to be the conjunction of its affix(es) with the stem's signature.

In addition, we incorporate capitalization information into the model, by constraining all words that appear capitalized in more than half of their instances to belong to a separate cluster, regardless of their morphological representation. The motivation for doing so is practical: capitalization is used in many languages to mark grammatical categories. For instance, in English capitalization marks the category of proper names and in German it marks the noun category . We report English results both with and without this modification.

Words that contain non-alphanumeric characters are represented as the sequence of the non-alphanumeric characters they include, e.g., 'vis-à-vis' is represented as *("-", "-")*. We do not assign a morphological representation to words including more than one stem (like *weatherman*), to words that have a null affix (i.e., where the word is identical to its stem) and to words whose stem is not shared by any other word (signature of size 1). Words that were not assigned a morphological representation are included as singletons in the morphological clustering.

4.2 Distributional-Morphological Algorithm

We detail the modifications made to our base distributional algorithm given the morphological clustering defined above.

Coordinate clustering and landmarks. We constrain AVGLINK$_\alpha$ to begin by forming links between words appearing in the same morphological cluster. Only when the distance between the two closest clusters gets above α we remove this constraint and proceed as before. This is equivalent to performing AVGLINK$_\alpha$ separately within each morphological cluster and then using the result as an initial condition for an AVGLINK$_\alpha$ coordinate clustering. The modified algorithm in this stage is otherwise identical to the distributional algorithm.

Word mapping. In this stage words that are not prototypes are mapped to one of the landmark

clusters. A reasonable strategy would be to map all words sharing a morphological cluster as a single unit. However, these clusters are too coarse-grained. We therefore begin by partitioning the morphological clusters into sub-clusters according to their distributional behavior. We do so by applying AVGLINK$_\beta$ (the same as AVGLINK$_\alpha$ but with a different parameter) to each morphological cluster. Since our goal is cluster *refinement*, we use a β that is considerably higher than α (0.9).

We then find the closest prototype to each such sub-cluster (averaging the distance across all of the latter's members) and map it as a single unit to the cluster containing that prototype.

5 Clustering Evaluation

We evaluate the clustering produced by our algorithm using an external quality measure: we take a corpus tagged by gold standard tags, tag it using the induced tags, and compare the two taggings. There is no single accepted measure quantifying the similarity between two taggings. In order to be as thorough as possible, we report results using four known measures, two mapping-based measures and two information theoretic ones.

Mapping-based measures. The induced clusters have arbitrary names. We define two mapping schemes between them and the gold clusters. After the induced clusters are mapped, we can compute a derived accuracy. The **Many-to-1** measure finds the mapping between the gold standard clusters and the induced clusters which maximizes accuracy, allowing several induced clusters to be mapped to the same gold standard cluster. The **1-to-1** measure finds the mapping between the induced and gold standard clusters which maximizes accuracy such that no two induced clusters are mapped to the same gold cluster. Computing this mapping is equivalent to finding the maximal weighted matching in a bipartite graph, whose weights are given by the intersection sizes between matched classes/clusters. As in (Reichart and Rappoport, 2008), we use the Kuhn-Munkres algorithm (Kuhn, 1955; Munkres, 1957) to solve this problem.

Information theoretic measures. These are based on the observation that a good clustering reduces the uncertainty of the gold tag given the induced cluster, and vice-versa. Several such measures exist; we use **V** (Rosenberg and Hirschberg, 2007) and **NVI** (Reichart and Rappoport, 2009), **VI**'s (Meila, 2007) normalized version.

6 Experimental Setup

Since a goal of unsupervised POS tagging is inducing an annotation scheme, comparison to an existing scheme is problematic. To address this problem we compare to three different schemes in two languages. In addition, the two English schemes we compare with were designed to tag corpora contained in our training set, and have been widely and successfully used with these corpora by a large number of applications.

Our algorithm was run with the exact same parameters on both languages: $N = 100$ (high frequency threshold), $n = 50$ (the parameter that determines the effective number of coordinates), $\alpha = 0.25$ (cluster separation during landmark cluster generation), $\beta = 0.9$ (cluster separation during refinement of morphological clusters).

The algorithm we compare with in most detail is (Clark, 2003), which reports the best current results for this problem (see Section 7). Since Clark's algorithm is sensitive to its initialization, we ran it a 100 times and report its average and standard deviation in each of the four measures. In addition, we report the percentile in which our result falls with respect to these 100 runs.

Punctuation marks are very frequent in corpora and are easy to cluster. As a result, including them in the evaluation greatly inflates the scores. For this reason we do not assign a cluster to punctuation marks and we report results using this policy, which we recommend for future work. However, to be able to directly compare with previous work, we also report results for the full POS tag set. We do so by assigning a singleton cluster to each punctuation mark (in addition to the k required clusters). This simple heuristic yields very high performance on punctuation, scoring (when all other words are assumed perfect tagging) 99.6% (99.1%) 1-to-1 accuracy when evaluated against the English fine (coarse) POS tag sets, and 97.2% when evaluated against the German POS tag set.

For English, we trained our model on the 39832 sentences which constitute sections 2-21 of the PTB-WSJ and on the 500K sentences from the NYT section of the NANC newswire corpus (Graff, 1995). We report results on the WSJ part of our data, which includes 950028 words tokens in 44389 types. Of the tokens, 832629 (87.6%)

Table 1: Top: English. Bottom: German. Results are reported for our model (Prototype Tagger), Clark's average score (μ), Clark's standard deviation (σ) and the fraction of Clark's results that scored worse than our model (%). For the mapping based measures, results are accuracy percentage. For $V \in [0,1]$, higher is better. For high quality output, $NVI \in [0,1]$ as well, and lower is better. In each entry, the top number indicates the score when including punctuation and the bottom number the score when excluding it. In English, our results are always better than Clark's. In German, they are almost always better.

are not punctuation. The percentage of unknown words (those appearing less than five times) is 1.6%. There are 45 clusters in this annotation scheme, 34 of which are not punctuation.

We ran each algorithm both with k=13 and k=34 (the number of desired clusters). We compare the output to two annotation schemes: the fine grained PTB WSJ scheme, and the coarse grained tags defined in (Smith and Eisner, 2005). The output of the k=13 run is evaluated both against the coarse POS tag annotation (the *'Coarse k=13'* scenario) and against the full PTB-WSJ annotation scheme (the *'Fine k=13'* scenario). The k=34 run is evaluated against the full PTB-WSJ annotation scheme (the *'Fine k=34'* scenario).

The POS cluster frequency distribution tends to be skewed: each of the 13 most frequent clusters in the PTB-WSJ cover more than 2.5% of the tokens (excluding punctuation) and together 86.3% of them. We therefore chose k=13, since it is both the number of coarse POS tags (excluding punctuation) as well as the number of frequent POS tags in the PTB-WSJ annotation scheme. We chose k=34 in order to evaluate against the full 34 tags PTB-WSJ annotation scheme (excluding punctuation) using the same number of clusters.

For German, we trained our model on the 20296 sentences of the NEGRA corpus (Brants, 1997) and on the first 450K sentences of the DeWAC corpus (Baroni et al., 2009). DeWAC is a corpus extracted by web crawling and is therefore out of domain. We report results on the NEGRA part, which includes 346320 word tokens of 49402 types. Of the tokens, 289268 (83.5%) are not punctuation. The percentage of unknown words (those appearing less than five times) is 8.1%. There are 62 clusters in this annotation scheme, 51 of which are not punctuation.

We ran the algorithms with k=17 and k=26. k=26 was chosen since it is the number of clusters that cover each more than 0.5% of the NEGRA tokens, and in total cover 96% of the (non-punctuation) tokens. In order to test our algorithm in another scenario, we conducted experiments with k=17 as well, which covers 89.9% of the tokens. All outputs are compared against NEGRA's gold standard scheme.

We do not report results for k=51 (where the number of gold clusters is the same as the number of induced clusters), since our algorithm produced only 42 clusters in the landmark detection stage. We could of course have modified the parameters to allow our algorithm to produce 51 clusters. However, we wanted to use the exact same parameters as those used for the English experiments to minimize the issue of parameter tuning.

In addition to the comparisons described above, we present results of experiments (in the 'Fine

	B	B+M	B+C	F(I=1)	F

Table 4: Comparison of our algorithms with the recent fully unsupervised POS taggers for which results are reported. The models differ in the annotation scheme, the corpus size and the number of induced clusters (k) that they used. HK: (Haghighi and Klein, 2006), 193K tokens, fine tags, k=45. GG: (Goldwater and Griffiths, 2007), 24K tokens, coarse tags, k=17. J : (Johnson, 2007), 1.17M tokens, fine tags, k=25–50. GJ: (Gao and Johnson, 2008), 1.17M tokens, fine tags, k=50. VG: (Van Gael et al., 2009), 1.17M tokens, fine tags, k=47–192. GGTP-45: (Graça et al., 2009), 1.17M tokens, fine tags, k=45. GGTP-17: (Graça et al., 2009), 1.17M tokens, coarse tags, k=17. Lower VI values indicate better clustering. VI is computed using e as the base of the logarithm. Our algorithm gives the best results.

k=13' scenario) that quantify the contribution of each component of the algorithm. We ran the base distributional algorithm, a variant which uses only capitalization information (i.e., has only one non-singleton morphological class, that of words appearing capitalized in most of their instances) and a variant which uses no capitalization information, defining the morphological clusters according to the morphological representation alone.

7 Results

Table 1 presents results for the English and German experiments. For English, our algorithm obtains better results than Clark's in all measures and scenarios. It is without exception better than the average score of Clark's and in most cases better than the maximal Clark score obtained in 100 runs.

A significant difference between our algorithm and Clark's is that the latter, like most algorithms which addressed the task, induces the clustering

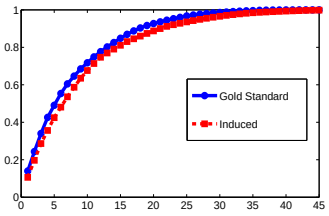

Figure 2: POS class frequency distribution for our model and the gold standard, in the 'Fine k=34' scenario. The distributions are similar.

by maximizing a non-convex function. These functions have many local maxima and the specific solution to which algorithms that maximize them converge strongly depends on their (random) initialization. Therefore, their output's quality often significantly diverges from the average. This issue is discussed in depth in (Reichart et al., 2010b). Our algorithm is deterministic[3].

For German, in the k=26 scenario our algorithm outperforms Clark's, often outperforming even its maximum in 100 runs. In the k=17 scenario, our algorithm obtains a higher score than Clark with probability 0.4 to 0.78, depending on the measure and scenario. Clark's average score is slightly better in the Many-to-1 measure, while our algorithm performs somewhat better than Clark's average in the 1-to-1 and NVI measures.

The DeWAC corpus from which we extracted statistics for the German experiments is out of domain with respect to NEGRA. The corresponding corpus in English, NANC, is a newswire corpus and therefore clearly in-domain with respect to WSJ. This is reflected by the percentage of unknown words, which was much higher in German than in English (8.1% and 1.6%), lowering results.

Table 2 shows the effect of each of our algorithm's components. Each component provides an improvement over the base distributional algorithm. The full coordinate clustering stage (several iterations, F) considerably improves the score over a single iteration (F(I=1)). Capitalization information increases the score more than the morphological information, which might stem from the granularity of the POS tag set with respect to names. This analysis is supported by similar experiments we made in the 'Coarse k=13' scenario (not shown in tables here). There, the decrease in performance was only of 1%–2% in the mapping

[3]The fluctuations inflicted on our algorithm by the random mapping of unknown words are of less than 0.1% .

	Excluding Punctuation				Including Punctuation				Perfect Punctuation

based measures and 3.5% in the V measure.

Finally, Table 4 presents reported results for all recent algorithms we are aware of that tackled the task of unsupervised POS induction from plain text. Results for our algorithm's and Clark's are reported for the 'Fine, k=34' scenario. The settings of the various experiments vary in terms of the exact annotation scheme used (coarse or fine grained) and the size of the test set. However, the score differences are sufficiently large to justify the claim that our algorithm is currently the best performing algorithm on the PTB-WSJ corpus for POS induction from plain text[4].

Since previous works provided results only for the scenario in which punctuation is included, the reported results are not directly comparable. In order to quantify the effect various punctuation schemes have on the results, we evaluated the *'iHMM: PY-fixed'* model (Van Gael et al., 2009) and ours when punctuation is excluded, included or perfectly tagged[5]. The results (Table 3) indicate that most probably even after an appropriate correction for punctuation, our model remains the best performing one.

8 Discussion

In this work we presented a novel unsupervised algorithm for POS induction from plain text. The algorithm first generates relatively accurate clusters of high frequency words, which are subsequently used to bootstrap the entire clustering. The distributional and morphological representations that we use are novel for this task.

We experimented on two languages with mapping and information theoretic clustering evaluation measures. Our algorithm obtains the best reported results on the English PTB-WSJ corpus. In addition, our results are almost always better than Clark's on the German NEGRA corpus.

We have also performed a manual error analysis, which showed that our algorithm performs much better on closed classes than on open classes. In order to asses this quantitatively, let us define a random variable for each of the gold clusters, which receives a value corresponding to each induced cluster with probability proportional to their intersection size. For each gold cluster, we compute the entropy of this variable. In addition, we greedily map each induced cluster to a gold cluster and compute the ratio between their intersection size and the size of the gold cluster (mapping accuracy).

We experimented in the 'Fine k=34' scenario. The clusters that obtained the best scores were (brackets indicate mapping accuracy and entropy for each of these clusters) coordinating conjunctions (95%, 0.32), prepositions (94%, 0.32), determiners (94%, 0.44) and modals (93%, 0.45). These are all closed classes.

The classes on which our algorithm performed worst consist of open classes, mostly verb types: past tense verbs (47%, 2.2), past participle verbs (44%, 2.32) and the morphologically unmarked non-3rd person singular present verbs (32%, 2.86). Another class with low performance is the proper nouns (37%, 2.9). The errors there are mostly of three types: confusions between common and proper nouns (sometimes due to ambiguity), unknown words which were put in the unknown words cluster, and abbreviations which were given a separate class by our algorithm. Finally, the algorithm's performance on the heterogeneous adverbs class (19%, 3.73) is the lowest.

Clark's algorithm exhibits[6] a similar pattern with respect to open and closed classes. While his algorithm performs considerably better on adverbs (15% mapping accuracy difference and 0.71 entropy difference), our algorithm scores considerably better on prepositions (17%, 0.77), superlative adjectives (38%, 1.37) and plural proper names (45%, 1.26).

[4] Graça et al. (2009) report very good results for 17 tags in the M-1 measure. However, their 1-1 results are quite poor, and results for the common IT measures were not reported. Their results for 45 tags are considerably lower.

[5] We thank the authors for sending us their data.

[6] Using average mapping accuracy and entropy over the 100 runs.

Naturally, this analysis might reflect the arbitrary nature of a manually design POS tag set rather than deficiencies in automatic POS induction algorithms. In future work we intend to analyze the output of such algorithms in order to improve POS tag sets.

Our algorithm and Clark's are monosemous (i.e., they assign each word exactly one tag), while most other algorithms are polysemous. In order to assess the performance loss caused by the monosemous nature of our algorithm, we took the M-1 greedy mapping computed for the entire dataset and used it to compute accuracy over the monosemous and polysemous words separately. Results are reported for the English 'Fine k=34' scenario (without punctuation). We define a word to be monosemous if more than 95% of its tokens are assigned the same gold standard tag. For English, there are approximately 255K polysemous tokens and 578K monosemous ones. As expected, our algorithm is much more accurate on the monosemous tokens, achieving 76.6% accuracy, compared to 47.1% on the polysemous tokens.

The evaluation in this paper is done at the token level. Type level evaluation, reflecting the algorithm's ability to detect the set of possible POS tags for each word type, is important as well. It could be expected that a monosemous algorithm such as ours would perform poorly in a type level evaluation. In (Reichart et al., 2010a) we discuss type level evaluation at depth and propose type level evaluation measures applicable to the POS induction problem. In that paper we compare the performance of our Prototype Tagger with leading unsupervised POS tagging algorithms (Clark, 2003; Goldwater and Griffiths, 2007; Gao and Johnson, 2008; Van Gael et al., 2009). Our algorithm obtained the best results in 4 of the 6 measures in a margin of 4–6%, and was second best in the other two measures. Our results were better than Clark's (the only other monosemous algorithm evaluated there) on all measures in a margin of 5–21%. The fact that our monosemous algorithm was better than good polysemous algorithms in a type level evaluation can be explained by the prototypical nature of the POS phenomenon (a longer discussion is given in (Reichart et al., 2010a)). However, the quality upper bound for monosemous algorithms is obviously much lower than that for polysemous algorithms, and we expect polysemous algorithms to outperform monosemous algorithms in the future in both type level and token level evaluations.

The skewed (Zipfian) distribution of POS class frequencies in corpora is a problem for many POS induction algorithms, which by default tend to induce a clustering having a balanced distribution. Explicit modifications to these algorithms were introduced in order to bias their model to produce such a distribution (see (Clark, 2003; Johnson, 2007; Reichart et al., 2010b)). An appealing property of our model is its ability to induce a skewed distribution without being explicitly tuned to do so, as seen in Figure 2.

Abstract

We present a novel framework for automated extraction and approximation of numerical object attributes such as height and weight from the Web. Given an object-attribute pair, we discover and analyze attribute information for a set of comparable objects in order to infer the desired value. This allows us to approximate the desired numerical values even when no exact values can be found in the text.

Our framework makes use of relation defining patterns and WordNet similarity information. First, we obtain from the Web and WordNet a list of terms similar to the given object. Then we retrieve attribute values for each term in this list, and information that allows us to compare different objects in the list and to infer the attribute value range. Finally, we combine the retrieved data for all terms from the list to select or approximate the requested value.

We evaluate our method using automated question answering, WordNet enrichment, and comparison with answers given in Wikipedia and by leading search engines. In all of these, our framework provides a significant improvement.

1 Introduction

Information on various numerical properties of physical objects, such as length, width and weight is fundamental in question answering frameworks and for answering search engine queries. While in some cases manual annotation of objects with numerical properties is possible, it is a hard and labor intensive task, and is impractical for dealing with the vast amount of objects of interest. Hence, there is a need for automated semantic acquisition algorithms targeting such properties.

In addition to answering direct questions, the ability to make a crude comparison or estimation of object attributes is important as well. For example, it allows to disambiguate relationships between objects such as *X part-of Y* or *X inside Y*. Thus, a coarse approximation of the height of a house and a window is sufficient to decide that in the 'house window' nominal compound, 'window' is very likely to be a part of house and not vice versa. Such relationship information can, in turn, help summarization, machine translation or textual entailment tasks.

Due to the importance of relationship and attribute acquisition in NLP, numerous methods were proposed for extraction of various lexical relationships and attributes from text. Some of these methods can be successfully used for extracting numerical attributes. However, numerical attribute extraction is substantially different in two aspects, verification and approximation.

First, unlike most general lexical attributes, numerical attribute values are comparable. It usually makes no sense to compare the names of two actors, but it is meaningful to compare their ages. The ability to compare values of different objects allows to improve attribute extraction precision by verifying consistency with attributes of other similar objects. For example, suppose that for Toyota Corolla width we found two different values, 1.695m and 27cm. The second value can be either an extraction error or a length of a toy car. Extracting and looking at width values for different car brands and for 'cars' in general we find:

- Boundaries: Maximal car width is 2.195m, minimal is 88cm.
- Average: Estimated avg. car width is 1.7m.
- Direct/indirect comparisons: Toyota Corolla is wider than Toyota Corona.
- Distribution: Car width is distributed normally around the average.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1308–1317,
Uppsala, Sweden, 11-16 July 2010.

Usage of all this knowledge allows us to select the correct value of 1.695m and reject other values. Thus we can increase the precision of value extraction by finding and analyzing an entire group of comparable objects.

Second, while it is usually meaningless and impossible to approximate general lexical attribute values like an actor's name, numerical attributes can be estimated *even if they are not explicitly mentioned in the text.*

In general, attribute extraction frameworks usually attempt to discover a single correct value (e.g., capital city of a country) or a set of distinct correct values (e.g., actors of a movie). So there is essentially nothing to do when there is no explicit information present in the text for a given object and an attribute. In contrast, in numerical attribute extraction it is possible to provide an approximation even when no explicit information is present in the text, by using values of comparable objects for which information is provided.

In this paper we present a pattern-based framework that takes advantage of the properties of similar objects to improve extraction precision and allow approximation of requested numerical object properties. Our framework comprises three main stages. First, given an object name we utilize WordNet and pattern-based extraction to find a list of similar objects and their category labels. Second, we utilize a predefined set of lexical patterns in order to extract attribute values of these objects and available comparison/boundary information. Finally, we analyze the obtained information and select or approximate the attribute value for the given (object, attribute) pair.

We performed a thorough evaluation using three different applications: Question Answering (QA), WordNet (WN) enrichment, and comparison with Wikipedia and answers provided by leading search engines. QA evaluation was based on a designed dataset of 1250 questions on size, height, width, weight, and depth, for which we created a gold standard and compared against it automatically[1].

For WN enrichment evaluation, our framework discovered size and weight values for 300 WN physical objects, and the quality of results was evaluated by human judges. For interactive search, we compared our results to information obtained through Wikipedia, Google and Wolfram Alpha. Utilization of information about comparable objects provided a significant boost to numerical attribute extraction quality, and allowed a meaningful approximation of missing attribute values.

Section 2 discusses related work, Section 3 details the algorithmic framework, Section 4 describes the experimental setup, and Section 5 presents our results.

2 Related work

Numerous methods have been developed for extraction of diverse semantic relationships from text. While several studies propose relationship identification methods using distributional analysis of feature vectors (Turney, 2005), the majority of the proposed open-domain relations extraction frameworks utilize lexical patterns connecting a pair of related terms. (Hearst, 1992) manually designed lexico-syntactic patterns for extracting hypernymy relations. (Berland and Charniak, 1999; Girju et al, 2006) proposed a set of patterns for meronymy relations. Davidov and Rappoport (2008a) used pattern clusters to disambiguate nominal compound relations. Extensive frameworks were proposed for iterative discovery of any pre-specified (e.g., (Riloff and Jones, 1999; Chklovski and Pantel, 2004)) and unspecified (e.g., (Banko et al., 2007; Rosenfeld and Feldman, 2007; Davidov and Rappoport, 2008b)) relation types.

The majority of the above methods utilize the following basic strategy. Given (or discovering automatically) a set of patterns or relationship-representing term pairs, these methods mine the web for these patterns and pairs, iteratively obtaining more instances. The proposed strategies generally include some weighting/frequency/context-based algorithms (e.g. (Pantel and Pennacchiotti, 2006)) to reduce noise. Some of the methods are suitable for retrieval of numerical attributes. However, most of them do not exploit the numerical nature of the attribute data.

Our research is related to a sub-domain of question answering (Prager, 2006), since one of the applications of our framework is answering questions on numerical values. The majority of the proposed QA frameworks rely on pattern-based relationship acquisition (Ravichandran and Hovy, 2009). However, most QA studies focus on different types of problems than our paper, including question classification, paraphrasing, etc.

[1]This dataset is available in the authors' websites for the research community.

Several recent studies directly target the acquisition of numerical attributes from the Web and attempt to deal with ambiguity and noise of the retrieved attribute values. (Aramaki et al., 2007) utilize a small set of patterns to extract physical object sizes and use the averages of the obtained values for a noun compound classification task. (Banerjee et al, 2009) developed a method for dealing with quantity consensus queries (QCQs) where there is uncertainty about the answer quantity (e.g. "driving time from Paris to Nice"). They utilize a textual snippet feature and snippet quantity in order to select and rank intervals of the requested values. This approach is particularly useful when it is possible to obtain a substantial amount of a desired attribute values for the requested query. (Moriceau, 2006) proposed a rule-based system which analyzes the variation of the extracted numerical attribute values using information in the textual context of these values.

A significant body of recent research deals with extraction of various data from web tables and lists (e.g., (Cafarella et al., 2008; Crestan and Pantel, 2010)). While in the current research we do not utilize this type of information, incorporation of the numerical data extracted from semi-structured web pages can be extremely beneficial for our framework.

All of the above numerical attribute extraction systems utilize only direct information available in the discovered object-attribute co-occurrences and their contexts. However, as we show, indirect information available for comparable objects can contribute significantly to the selection of the obtained values. Using such indirect information is particularly important when only a modest amount of values can be obtained for the desired object. Also, since the above studies utilize only explicitly available information they were unable to approximate object values in cases where no explicit information was found.

3 The Attribute Mining Framework

Our algorithm is given an object and an attribute. In the WN enrichment scenario, it is also given the object's synset. The algorithm comprises three main stages: (1) mining for similar objects and determination of a class label; (2) mining for attribute values and comparison statements; (3) processing the results.

3.1 Similar objects and class label

To verify and estimate attribute values for the given object we utilize similar objects (co-hyponyms) and the object's class label (hypernym). In the WN enrichment scenario we can easily obtain these, since we get the object's synset as input. However, in Question Answering (QA) scenarios we do not have such information. To obtain it we employ a strategy which uses WordNet along with pattern-based web mining.

Our web mining part follows common pattern-based retrieval practice (Davidov et al., 2007). We utilize Yahoo! Boss API to perform search engine queries. For an object name Obj we query the Web using a small set of pre-defined co-hyponymy patterns like *"as * and/or [Obj]"*[2]. In the WN enrichment scenario, we can add the WN class label to each query in order to restrict results to the desired word sense. In the QA scenario, if we are given the full question and not just the (object, attribute) pair we can add terms appearing in the question and having a strong PMI with the object (this can be estimated using any fixed corpus). However, this is not essential.

We then extract new terms from the retrieved web snippets and use these terms iteratively to retrieve more terms from the Web. For example, when searching for an object 'Toyota', we execute a search engine query *["as * and Toyota"]* and we might retrieve a text snippet containing *"... as Honda and Toyota ... "*. We then extract from this snippet the additional word 'Honda' and use it for iterative retrieval of additional similar terms. We attempt to avoid runaway feedback loop by requiring each newly detected term to co-appear with the original term in at least a single co-hyponymy pattern.

WN class labels are used later for the retrieval of boundary values, and here for expansion of the similar object set. In the WN enrichment scenario, we already have the class label of the object. In the QA scenario, we automatically find class labels as follows. We compute for each WN subtree a coverage value, the number of retrieved terms found in the subtree divided by the number of subtree terms, and select the subtree having the highest coverage. In all scenarios, we add all terms found in this subtree to the retrieved term list. If no WN subtree with significant (> 0.1) coverage is found,

[2] "*" means a search engine wildcard. Square brackets indicate filled slots and are not part of the query.

we retrieve a set of category labels from the Web using hypernymy detection patterns like *"* such as [Obj]"* (Hearst, 1992). If several label candidates were found, we select the most frequent.

Note that we perform this stage only once for each object and do not need to repeat it for different attribute types.

3.2 Querying for values, bounds and comparison data

Now we would like to extract the attribute values for the given object and its similar objects. We will also extract bounds and comparison information in order to verify the extracted values and to approximate the missing ones.

To allow us to extract attribute-specific information, we provided the system with a seed set of extraction patterns for each attribute type. There are three kinds of patterns: value extraction, bounds and comparison patterns. We used up to 10 patterns of each kind. These patterns are the only attribute-specific resource in our framework.

Value extraction. The first pattern group, P_{values}, allows extraction of the attribute values from the Web. All seed patterns of this group contain a measurement unit name, attribute name, and some additional anchoring words, e.g., *'Obj is * [height unit] tall'* or *'Obj width is * [width unit]'*. As in Section 3.1, we execute search engine queries and collect a set of numerical values for each pattern. We extend this group iteratively from the given seed as commonly done in pattern-based acquisition methods. To do this we re-query the Web with the obtained (object, attribute value, attribute name) triplets (e.g., *'[Toyota width 1.695m]'*). We then extract new patterns from the retrieved search engine snippets and re-query the Web with the new patterns to obtain more attribute values.

We provided the framework with unit names and with an appropriate conversion table which allows to convert between different measurement systems and scales. The provided names include common abbreviations like *cm/centimeter*. All value acquisition patterns include unit names, so we know the units of each extracted value. At the end of the value extraction stage, we convert all values to a single unit format for comparison.

Boundary extraction. The second group, $P_{boundary}$, consists of boundary-detection patterns like *'the widest [label] is * [width unit]'*. These patterns incorporate the class labels discovered in the previous stage. They allow us to find maximal and minimal values for the object category defined by labels. If we get several lower bounds and several upper bounds, we select the highest upper bound and the lowest lower bound.

Extraction of comparison information. The third group, $P_{compare}$, consists of comparison patterns. They allow to compare objects directly even when no attribute values are mentioned. This group includes attribute equality patterns such as *'[Object1] has the same width as [Object2]'*, and attribute inequality ones such as *'[Object1] is wider than [Object2]'*. We execute search queries for each of these patterns, and extract a set of ordered term pairs, keeping track of the relationships encoded by the pairs.

We use these pairs to build a directed graph (Widdows and Dorow, 2002; Davidov and Rappoport, 2006) in which nodes are objects (not necessarily with assigned values) and edges correspond to extracted co-appearances of objects inside the comparison patterns. The directions of edges are determined by the comparison sign. If two objects co-appear inside an equality pattern we put a bidirectional edge between them.

3.3 Processing the collected data

As a result of the information collection stage, for each object and attribute type we get:

- A set of attribute values for the requested object.
- A set of objects similar or comparable to the requested object, some of them annotated with one or many attribute values.
- Upper and lowed bounds on attribute values for the given object category.
- A comparison graph connecting some of the retrieved objects by comparison edges.

Obviously, some of these components may be missing or noisy. Now we combine these information sources to select a single attribute value for the requested object or to approximate this value. First we apply bounds, removing out-of-range values, then we use comparisons to remove inconsistent comparisons. Finally we examine the remaining values and the comparison graph.

Processing bounds. First we verify that indeed most ($\geq 50\%$) of the retrieved values fit the retrieved bounds. If the lower and/or upper bound

contradicts more than half of the data, we reject the bound. Otherwise we remove all values which do not satisfy one or both of the accepted bounds. If no bounds are found or if we disable the bound retrieval (see Section 4.1), we assign the maximal and minimal observed values as bounds.

Since our goal is to obtain a value for the single requested object, if at the end of this stage we remain with a single value, no further processing is needed. However, if we obtain a set of values or no values at all, we have to utilize comparison data to select one of the retrieved values or to approximate the value in case we do not have an exact answer.

Processing comparisons. First we simplify the comparison graph. We drop all graph components that are not connected (when viewing the graph as undirected) to the desired object.

Now we refine the graph. Note that each graph node may have a single value, many assigned values, or no assigned values. We define *assigned nodes* as nodes that have at least one value. For each directed edge $E(A \rightarrow B)$, if both A and B are assigned nodes, we check if $Avg(A) \leq Avg(B)$[3]. If the average values violate the equation, we gradually remove up to half of the highest values for A and up to half of the lowest values for B till the equation is satisfied. If this cannot be done, we drop the edge. We repeat this process until every edge that connects two assigned nodes satisfies the inequality.

Selecting an exact attribute value. The goal now is to select an attribute value for the given object. During the first stage it is possible that we directly extract from the text a set of values for the requested object. The bounds processing step rejects some of these values, and the comparisons step may reject some more. If we still have several values remaining, we choose the most frequent value based on the number of web snippets retrieved during the value acquisition stage. If there are several values with the same frequency we select the median of these values.

Approximating the attribute value. In the case when we do not have any values remaining after the bounds processing step, the object node will remain unassigned after construction of the comparison graph, and we would like to estimate its value. Here we present an algorithm which allows us to set the values of all unassigned nodes, including the node of the requested object.

In the algorithm below we treat all node groups connected by bidirectional (equality) edges as a same-value group, i.e., if a value is assigned to one node in the group, the same value is immediately assigned to the rest of the nodes in the same group.

We start with some preprocessing. We create dummy lower and upper bound nodes L and U with corresponding upper/lower bound values obtained during the previous stage. These dummy nodes will be used when we encounter a graph which ends with one or more nodes with no available numerical information. We then connect them to the graph as follows: (1) if A has no incoming edges, we add an edge $L \rightarrow A$; (2) if A has no outgoing edges, we add an edge $A \rightarrow U$.

We define a *legal unassigned path* as a directed path $A_0 \rightarrow A_1 \rightarrow \ldots \rightarrow A_n \rightarrow A_{n+1}$ where A_0 and A_{n+1} are assigned satisfying $Avg(A_0) \leq Avg(A_{n+1})$ and $A_1 \ldots A_n$ are unassigned. We would like to use dummy bound nodes only in cases when no other information is available. Hence we consider paths $L \rightarrow \ldots \rightarrow U$ connecting both bounds are illegal. First we assign values for all unassigned nodes that belong to a single legal unassigned path, using a simple linear combination:
$Val(A_i)_{i \in (1 \ldots n)} =$

$$\frac{n+1-i}{n+1} Avg(A_0) + \frac{i}{n+1} Avg(A_{n+1})$$

Then, for all unassigned nodes that belong to multiple legal unassigned paths, we compute node value as above for each path separately and assign to the node the average of the computed values.

Finally we assign the average of all extracted values within bounds to all the remaining unassigned nodes. Note that if we have no comparison information and no value information for the requested object, the requested object will receive the average of the extracted values of the whole set of the retrieved comparable objects and the comparison step will be essentially empty.

4 Experimental Setup

We performed automated question answering (QA) evaluation, human-based WN enrichment evaluation, and human-based comparison of our results to data available through Wikipedia and to the top results of leading search engines.

[3] Avg. is of values of an object, without similar objects.

4.1 Experimental conditions

In order to test the main system components, we ran our framework under five different conditions:

- **FULL:** All system components were used.
- **DIRECT:** Only direct pattern-based acquisition of attribute values (Section 3.2, value extraction) for the given object was used, as done in most general-purpose attribute acquisition systems. If several values were extracted, the most common value was used as an answer.
- **NOCB:** No boundary and no comparison data were collected and processed ($P_{compare}$ and P_{bounds} were empty). We only collected and processed a set of values for the similar objects.
- **NOB:** As in **FULL** but no boundary data was collected and processed (P_{bounds} was empty).
- **NOC:** As in **FULL** but no comparison data was collected and processed ($P_{compare}$ was empty).

4.2 Automated QA Evaluation

We created two QA datasets, Web and TREC based.

Web-based QA dataset. We created QA datasets for size, height, width, weight, and depth attributes. For each attribute we extracted from the Web 250 questions in the following way. First, we collected several thousand questions, querying for the following patterns: "How long/tall/wide/heavy/deep/high is","What is the size/width/height/depth/weight of". Then we manually filtered out non-questions and heavily context-specific questions, e.g., *"what is the width of the triangle"*. Next, we retained only a single question for each entity by removing duplicates.

For each of the extracted questions we manually assigned a gold standard answer using trusted resources including books and reliable Web data. For some questions, the exact answer is the only possible one (e.g., the height of a person), while for others it is only the center of a distribution (e.g., the weight of a coffee cup). Questions with no trusted and exact answers were eliminated. From the remaining questions we randomly selected 250 questions for each attribute.

TREC-based QA dataset. As a small complementary dataset we used relevant questions from the TREC Question Answering Track 1999-2007. From 4355 questions found in this set we collected 55 (17 size, 2 weight, 3 width, 3 depth and 30 height) questions.

Examples. Some example questions from our datasets are (correct answers are in parentheses): How tall is Michelle Obama? (180cm); How tall is the tallest penguin? (122cm); What is the height of a tennis net? (92cm); What is the depth of the Nile river? (1000cm = 10 meters); How heavy is a cup of coffee? (360gr); How heavy is a giraffe? (1360000gr = 1360kg); What is the width of a DNA molecule? (2e-7cm); What is the width of a cow? (65cm).

Evaluation protocol. Evaluation against the datasets was done automatically. For each question and each condition our framework returned a numerical value marked as either an exact answer or as an approximation. In cases where no data was found for an approximation (no similar objects with values were found), our framework returned no answer.

We computed precision[4], comparing results to the gold standard. Approximate answers are considered to be correct if the approximation is within 10% of the gold standard value. While a choice of 10% may be too strict for some applications and too generous for others, it still allows to estimate the quality of our framework.

4.3 WN enrichment evaluation

We manually selected 300 WN entities from about 1000 randomly selected objects below the object tree in WN, by filtering out entities that clearly do not possess any of the addressed numerical attributes.

Evaluation was done using human subjects. It is difficult to do an automated evaluation, since the nature of the data is different from that of the QA dataset. Most of the questions asked over the Web target named entities like specific car brands, places and actors. There is usually little or no variability in attribute values of such objects, and the major source of extraction errors is name ambiguity of the requested objects.

WordNet physical objects, in contrast, are much less specific and their attributes such as size and

[4]Due to the nature of the task recall/f-score measures are redundant here

weight rarely have a single correct value, but usually possess an acceptable numerical range. For example, the majority of the selected objects like 'apple' are too general to assign an exact size. Also, it is unclear how to define acceptable values and an approximation range. Crudeness of desired approximation depends both on potential applications and on object type. Some objects show much greater variability in size (and hence a greater range of acceptable approximations) than others. This property of the dataset makes it difficult to provide a meaningful gold standard for the evaluation. Hence in order to estimate the quality of our results we turn to an evaluation based on human judges.

In this evaluation we use only *approximate* retrieved values, keeping out the small amount of returned *exact* values[5].

We have mixed (Object, Attribute name, Attribute value) triplets obtained through each of the conditions, and asked human subjects to assign these to one of the following categories:

- The attribute value is reasonable for the given object.
- The value is a very crude approximation of the given object attribute.
- The value is incorrect or clearly misleading.
- The object is not familiar enough to me so I cannot answer the question.

Each evaluator was provided with a random sample of 40 triplets. In addition we mixed in 5 manually created clearly correct triplets and 5 clearly incorrect ones. We used five subjects, and the agreement (inter-annotator Kappa) on shared evaluated triplets was 0.72.

4.4 Comparisons to search engine output

Recently there has been a significant improvement both in the quality of search engine results and in the creation of manual well-organized and annotated databases such as Wikipedia.

Google and Yahoo! queries frequently provide attribute values in the top snippets or in search result web pages. Many Wikipedia articles include infoboxes with well-organized attribute values. Recently, the Wolfram Alpha computational knowledge engine presented the computation of attribute values from a given query text.

[5]So our results are in fact higher than shown.

Hence it is important to test how well our framework can complement the manual extraction of attributes from resources such as Wikipedia and top Google snippets. In order to test this, we randomly selected 100 object-attribute pairs from our Web QA and WordNet datasets and used human subjects to test the following:

1. **Go1**: Querying Google for *[object-name attribute-name]* gives in some of the first three snippets a correct value or a good approximation value[6] for this pair.
2. **Go2**: Querying Google for *[object-name attribute-name]* and following the first three links gives a correct value or a good approximation value.
3. **Wi**: There is a Wikipedia page for the given object and it contains an appropriate attribute value or an approximation in an infobox.
4. **Wf**: A Wolfram Alpha query for *[object-name attribute-name]* retrieves a correct value or a good approximation value

5 Results

5.1 QA results

We applied our framework to the above QA datasets. Table 1 shows the precision and the percentage of approximations and exact answers.

Looking at %Exact+%Approx, we can see that for all datasets only 1-9% of the questions remain unanswered, while correct exact answers are found for 65%/87% of the questions for Web/TREC (% Exact and Prec(Exact) in the table). Thus approximation allows us to answer 13-24% of the requested values which are either simply missing from the retrieved text or cannot be detected using the current pattern-based framework. Comparing performance of FULL to DIRECT, we see that our framework not only allows an approximation when no exact answer can be found, but also significantly increases the precision of exact answers using the comparison and the boundary information. It is also apparent that both boundary and comparison features are needed to achieve good performance and that using both of them achieves substantially better results than each of them separately.

[6]As defi ned in the human subject questionnaire.

	FULL	DIRECT	NOCB	NOB	NOC
Web QA					
Size					
%Exact	80	82	82	82	80

%Approx	13	-	9	9	13
Prec(Appr)	**57**	-	20	40	57

Table 1: Precision and amount of exact and approximate answers for QA datasets.

Comparing results for different question types we can see substantial performance differences between the attribute types. Thus depth shows much better overall results than width. This is likely due to a lesser difficulty of depth questions or to a more exact nature of available depth information compared to width or size.

5.2 WN enrichment

As shown in Table 2, for the majority of examined WN objects, the algorithm returned an approximate value, and only for 13-15% of the objects (vs. 70-80% in QA data) the algorithm could retrieve exact answers.

Note that the common pattern-based acquisition framework, presented as the DIRECT condition, could only extract attribute values for 15% of the objects since it does not allow approximations and may only extract values from the text where they explicitly appear.

	FULL	DIRECT	NOCB	NOB	NOC
Size					
%Exact	15.3	18.0	18.0	18.0	15.3
%Approx	80.3	-	38.2	20.0	23.6
Weight					
%Exact	11.8	12.5	12.5	12.5	11.8
%Approx	71.7	-	38.2	20.0	23.6

Table 2: Percentage of exact and approximate values for the WordNet enrichment dataset.

	FULL	NOCB	NOB	NOC
Size				
%Correct	73	21	49	28
%Crude	15	54	31	49
%Incorrect	8	21	16	19
Weight				
%Correct	64	24	46	38
%Crude	24	45	30	41
%Incorrect	6	25	18	15

Table 3: Human evaluation of approximations for the WN enrichment dataset (the percentages are averaged over the human subjects).

Table 3 shows human evaluation results. We see that the majority of approximate values were clearly accepted by human subjects, and only 6-8% were found to be incorrect. We also observe that both boundary and comparison data significantly improve the approximation results. Note that DIRECT is missing from this table since no approximations are possible in this condition.

Some examples for WN objects and approximate values discovered by the algorithm are: Sandfish, 15gr; skull, 1100gr; pilot, 80.25kg. The latter value is amusing due to the high variability of the value. However, even this value is valuable, as a sanity check measure for automated inference systems and for various NLP tasks (e.g., 'pilot jacket' likely refers to a jacket used by pilots and not vice versa).

5.3 Comparison with search engines and Wikipedia

Table 4 shows results for the above datasets in comparison to the proportion of correct results and the approximations returned by our framework under the FULL condition (correct exact values and approximations are taken together).

We can see that our framework, due to its approximation capability, currently shows significantly greater coverage than manual extraction of data from Wikipedia infoboxes or from the first

WordNet	87	24	27	18	5

Table 4: Comparison of our attribute extraction framework to manual extraction using Wikipedia and search engines.

search engine results.

6 Conclusion

We presented a novel framework which allows an automated extraction and approximation of numerical attributes from the Web, even when no explicit attribute values can be found in the text for the given object. Our framework retrieves similarity, boundary and comparison information for objects similar to the desired object, and combines this information to approximate the desired attribute.

While in this study we explored only several specific numerical attributes like size and weight, our framework can be easily augmented to work with any other consistent and comparable attribute type. The only change required for incorporation of a new attribute type is the development of attribute-specific $P_{boundary}$, P_{values}, and $P_{compare}$ pattern groups; the rest of the system remains unchanged.

In our evaluation we showed that our framework achieves good results and significantly outperforms the baseline commonly used for general lexical attribute retrieval[7].

While there is a growing justification to rely on extensive manually created resources such as Wikipedia, we have shown that in our case automated numerical attribute acquisition could be a preferable option and provides excellent coverage in comparison to handcrafted resources or manual examination of the leading search engine results. Hence a promising direction would be to use our approach in combination with Wikipedia data and with additional manually created attribute rich sources such as Web tables, to achieve the best possible performance and coverage.

We would also like to explore the incorporation of approximate discovered numerical attribute data into existing NLP tasks such as noun compound classification and textual entailment.

[7]It should be noted, however, that in our DIRECT baseline we used a basic pattern-based retrieval strategy; more sophisticated strategies for value selection might bring better results.

Learning Word-Class Lattices for Definition and Hypernym Extraction

Roberto Navigli and **Paola Velardi**
Dipartimento di Informatica
Sapienza Università di Roma
{navigli,velardi}@di.uniroma1.it

Abstract

Definition extraction is the task of automatically identifying definitional sentences within texts. The task has proven useful in many research areas including ontology learning, relation extraction and question answering. However, current approaches – mostly focused on lexico-syntactic patterns – suffer from both low recall and precision, as definitional sentences occur in highly variable syntactic structures. In this paper, we propose Word-Class Lattices (WCLs), a generalization of word lattices that we use to model textual definitions. Lattices are learned from a dataset of definitions from Wikipedia. Our method is applied to the task of definition and hypernym extraction and compares favorably to other pattern generalization methods proposed in the literature.

1 Introduction

Textual definitions constitute a fundamental source to look up when the meaning of a term is sought. Definitions are usually collected in dictionaries and domain glossaries for consultation purposes. However, manually constructing and updating glossaries requires the cooperative effort of a team of domain experts. Further, in the presence of new words or usages, and – even worse – new domains, such resources are of no help. Nonetheless, terms are attested in texts and some (usually few) of the sentences in which a term occurs are typically definitional, that is they provide a formal explanation for the term of interest. While it is not feasible to manually search texts for definitions, this task can be automatized by means of Machine Learning (ML) and Natural Language Processing (NLP) techniques.

Automatic definition extraction is useful not only in the construction of glossaries, but also in many other NLP tasks. In ontology learning, definitions are used to create and enrich concepts with textual information (Gangemi et al., 2003), and extract taxonomic and non-taxonomic relations (Snow et al., 2004; Navigli and Velardi, 2006; Navigli, 2009a). Definitions are also harvested in Question Answering to deal with "what is" questions (Cui et al., 2007; Saggion, 2004). In eLearning, they are used to help students assimilate knowledge (Westerhout and Monachesi, 2007), etc.

Much of the current literature focuses on the use of lexico-syntactic patterns, inspired by Hearst's (1992) seminal work. However, these methods suffer both from low recall and precision, as definitional sentences occur in highly variable syntactic structures, and because the most frequent definitional pattern – X is a Y – is inherently very noisy.

In this paper we propose a generalized form of word lattices, called Word-Class Lattices (WCLs), as an alternative to lexico-syntactic pattern learning. A lattice is a directed acyclic graph (DAG), a subclass of non-deterministic finite state automata (NFA). The lattice structure has the purpose of preserving the salient differences among distinct sequences, while eliminating redundant information. In computational linguistics, lattices have been used to model in a compact way many sequences of symbols, each representing an alternative hypothesis. Lattice-based methods differ in the types of nodes (words, phonemes, concepts), the interpretation of links (representing either a sequential or hierarchical ordering between nodes), their means of creation, and the scoring method used to extract the best consensus output from the lattice (Schroeder et al., 2009). In speech processing, phoneme or word lattices (Campbell et al., 2007; Mathias and Byrne, 2006; Collins et al., 2004) are used as an interface between speech recognition and understanding. Lat-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1318–1327,
Uppsala, Sweden, 11-16 July 2010.

tices are adopted also in Chinese word segmentation (Jiang et al., 2008), decompounding in German (Dyer, 2009), and to represent classes of translation models in machine translation (Dyer et al., 2008; Schroeder et al., 2009). In more complex text processing tasks, such as information retrieval, information extraction and summarization, the use of word lattices has been postulated but is considered unrealistic because of the dimension of the hypothesis space.

To reduce this problem, concept lattices have been proposed (Carpineto and Romano, 2005; Klein, 2008; Zhong et al., 2008). Here links represent hierarchical relations, rather than the sequential order of symbols like in word/phoneme lattices, and nodes are clusters of salient words aggregated using synonymy, similarity, or subtrees of a thesaurus. However, salient word selection and aggregation is non-obvious and furthermore it falls into word sense disambiguation, a notoriously AI-hard problem (Navigli, 2009b).

In definition extraction, the variability of patterns is higher than for "traditional" applications of lattices, such as translation and speech, however not as high as in unconstrained sentences. The methodology that we propose to align patterns is based on the use of star (wildcard *) characters to facilitate sentence clustering. Each cluster of sentences is then generalized to a lattice of word classes (each class being either a frequent word or a part of speech). A key feature of our approach is its inherent ability to both identify definitions and extract hypernyms. The method is tested on an annotated corpus of Wikipedia sentences and a large Web corpus, in order to demonstrate the independence of the method from the annotated dataset. WCLs are shown to generalize over lexico-syntactic patterns, and outperform well-known approaches to definition and hypernym extraction.

The paper is organized as follows: Section 2 discusses related work, WCLs are introduced in Section 3 and illustrated by means of an example in Section 4, experiments are presented in Section 5. We conclude the paper in Section 6.

2 Related Work

Definition Extraction. A great deal of work is concerned with definition extraction in several languages (Klavans and Muresan, 2001; Storrer and Wellinghoff, 2006; Gaudio and Branco, 2007; Iftene et al., 2007; Westerhout and Monachesi, 2007; Przepiórkowski et al., 2007; Degórski et al., 2008). The majority of these approaches use symbolic methods that depend on lexico-syntactic patterns or features, which are manually crafted or semi-automatically learned (Zhang and Jiang, 2009; Hovy et al., 2003; Fahmi and Bouma, 2006; Westerhout, 2009). Patterns are either very simple sequences of words (e.g. "refers to", "is defined as", "is a") or more complex sequences of words, parts of speech and chunks. A fully automated method is instead proposed by Borg et al. (2009): they use genetic programming to learn simple features to distinguish between definitions and non-definitions, and then they apply a genetic algorithm to learn individual weights of features. However, rules are learned for only one category of patterns, namely "is" patterns. As we already remarked, most methods suffer from both low recall and precision, because definitional sentences occur in highly variable and potentially noisy syntactic structures. Higher performance (around 60-70% F_1-measure) is obtained only for specific domains (e.g., an ICT corpus) and patterns (Borg et al., 2009).

Only few papers try to cope with the generality of patterns and domains in real-world corpora (like the Web). In the GlossExtractor web-based system (Velardi et al., 2008), to improve precision while keeping pattern generality, candidates are pruned using more refined stylistic patterns and lexical filters. Cui et al. (2007) propose the use of probabilistic lexico-semantic patterns, called *soft patterns*, for definitional question answering in the TREC contest[1]. The authors describe two soft matching models: one is based on an n-gram language model (with the Expectation Maximization algorithm used to estimate the model parameter), the other on Profile Hidden Markov Models (PHMM). Soft patterns generalize over lexico-syntactic "hard" patterns in that they allow a partial matching by calculating a generative degree of match probability between the test instance and the set of training instances. Thanks to its generalization power, this method is the most closely related to our work, however the task of definitional question answering to which it is applied is slightly different from that of definition extraction, so a direct performance comparison is not possi-

[1]Text REtrieval Conferences: `http://trec.nist.gov`

ble[2]. In fact, the TREC evaluation datasets cannot be considered true definitions, but rather text fragments providing some relevant fact about a target term. For example, sentences like: "Bollywood is a Bombay-based film industry" and "700 or more films produced by India with 200 or more from Bollywood" are both "vital" answers for the question "Bollywood", according to TREC classification, but the second sentence is not a definition.

Hypernym Extraction. The literature on hypernym extraction offers a higher variability of methods, from simple lexical patterns (Hearst, 1992; Oakes, 2005) to statistical and machine learning techniques (Agirre et al., 2000; Caraballo, 1999; Dolan et al., 1993; Sanfilippo and Poznański, 1992; Ritter et al., 2009). One of the highest-coverage methods is proposed by Snow et al. (2004). They first search sentences that contain two terms which are known to be in a taxonomic relation (term pairs are taken from WordNet (Miller et al., 1990)); then they parse the sentences, and automatically extract patterns from the parse trees. Finally, they train a hypernym classifer based on these features. Lexico-syntactic patterns are generated for each sentence relating a term to its hypernym, and a dependency parser is used to represent them.

3 Word-Class Lattices

3.1 Preliminaries

Notion of definition. In our work, we rely on a formal notion of textual definition. Specifically, given a definition, e.g.: "In computer science, a closure is a first-class function with free variables that are bound in the lexical environment", we assume that it contains the following fields (Storrer and Wellinghoff, 2006):

- The DEFINIENDUM field (DF): this part of the definition includes the *definiendum* (that is, the word being defined) and its modifiers (e.g., "In computer science, a closure");
- The DEFINITOR field (VF): it includes the verb phrase used to introduce the definition (e.g., "is");
- The DEFINIENS field (GF): it includes the genus phrase (usually including the hypernym, e.g., "a first-class function");
- The REST field (RF): it includes additional clauses that further specify the *differentia* of the definiendum with respect to its genus (e.g., "with free variables that are bound in the lexical environment").

Further examples of definitional sentences annotated with the above fields are shown in Table 1. For each sentence, the definiendum (that is, the word being defined) and its hypernym are marked in bold and italic, respectively. Given the lexico-syntactic nature of the definition extraction models we experiment with, training and test sentences are part-of-speech tagged with the TreeTagger system, a part-of-speech tagger available for many languages (Schmid, 1995).

Word Classes and Generalized Sentences. We now introduce our notion of word class, on which our learning model is based. Let $\mathcal{T}$ be the set of training sentences, manually bracketed with the DF, VF, GF and RF fields. We first determine the set F of words in $\mathcal{T}$ whose frequency is above a threshold θ (e.g., *the*, *a*, *is*, *of*, *refer*, etc.). In our training sentences, we replace the term being defined with ⟨TARGET⟩, thus this frequent token is also included in F.

We use the set of frequent words F to generalize words to "word classes". We define a word class as either a word itself or its part of speech. Given a sentence $s = w_1, w_2, \ldots, w_{|s|}$, where w_i is the i-th word of s, we generalize its words w_i to word classes ω_i as follows:

$$\omega_i = \begin{cases} w_i & \text{if } w_i \in F \\ POS(w_i) & \text{otherwise} \end{cases}$$

that is, a word w_i is left unchanged if it occurs frequently in the training corpus (i.e., $w_i \in F$) or is transformed to its part of speech ($POS(w_i)$) otherwise. As a result, we obtain a generalized sentence $s' = \omega_1, \omega_2, \ldots, \omega_{|s|}$. For instance, given the first sentence in Table 1, we obtain the corresponding generalized sentence: "In NN, a ⟨TARGET⟩ is a JJ NN", where NN and JJ indicate the noun and adjective classes, respectively.

3.2 Algorithm

We now describe our learning algorithm based on Word-Class Lattices. The algorithm consists of three steps:

[2] In the paper, a 55% recall and 34% precision is achieved with the best experiment on TREC-13 data. Furthermore, the classifier of Cui et al. (2007) is based on soft patterns but also on a bag-of-word relevance heuristic. However, the relative influence of the two methods on the final performance is not discussed.

[In arts, a **chiaroscuro**]$_{\text{DF}}$ [is]$_{\text{VF}}$ [a monochrome *picture*]$_{\text{GF}}$.
[In mathematics, a **graph**]$_{\text{DF}}$ [is]$_{\text{VF}}$ [a *data structure*]$_{\text{GF}}$ [that consists of ...]$_{\text{REST}}$.
[In computer science, a **pixel**]$_{\text{DF}}$ [is]$_{\text{VF}}$ [a *dot*]$_{\text{GF}}$ [that is part of a computer image]$_{\text{REST}}$.

Table 1: Example definitions (defined terms are marked in bold face, their hypernyms in italic).

- **Star patterns:** each sentence in the training set is pre-processed and generalized to a star pattern. For instance, "In arts, a chiaroscuro is a monochrome picture" is transformed to "In *, a ⟨TARGET⟩ is a *" (Section 3.2.1);
- **Sentence clustering:** the training sentences are then clustered based on the star patterns to which they belong (Section 3.2.2);
- **Word-Class Lattice construction:** for each sentence cluster, a WCL is created by means of a greedy alignment algorithm (Section 3.2.3).

We present two variants of our WCL model, dealing either globally with the entire sentence or separately with its definition fields (Section 3.2.4). The WCL models can then be used to classify any input sentence of interest (Section 3.2.5).

3.2.1 Star Patterns

Let $\mathcal{T}$ be the set of training sentences. In this step, we associate a star pattern $\sigma(s)$ with each sentence $s \in \mathcal{T}$. To do so, let $s \in \mathcal{T}$ be a sentence such that $s = w_1, w_2, \ldots, w_{|s|}$, where w_i is its i-th word. Given the set F of most frequent words in $\mathcal{T}$ (cf. Section 3.1), the star pattern $\sigma(s)$ associated with s is obtained by replacing with * all the words $w_i \notin F$, that is all the tokens that are non-frequent words. For instance, given the sentence "In arts, a chiaroscuro is a monochrome picture", the corresponding star pattern is "In *, a ⟨TARGET⟩ is a *", where ⟨TARGET⟩ is the defined term.

Note that, here and in what follows, we discard the sentence fragments tagged with the REST field, which is used only to delimit the core part of definitional sentences.

3.2.2 Sentence Clustering

In the second step, we cluster the sentences in our training set $\mathcal{T}$ based on their star patterns. Formally, let $\Sigma = (\sigma_1, \ldots, \sigma_m)$ be the set of star patterns associated with the sentences in $\mathcal{T}$. We create a clustering $\mathcal{C} = (C_1, \ldots, C_m)$ such that $C_i = \{s \in \mathcal{T} : \sigma(s) = \sigma_i\}$, that is C_i contains all the sentences whose star pattern is σ_i.

As an example, assume σ_3 = "In *, a ⟨TARGET⟩ is a *". The sentences reported in Table 1 are all grouped into cluster C_3. We note that each cluster C_i contains sentences whose degree of variability is generally much lower than for any pair of sentences in $\mathcal{T}$ belonging to two different clusters.

3.2.3 Word-Class Lattice Construction

Finally, the third step consists of the construction of a Word-Class Lattice for each sentence cluster. Given such a cluster $C_i \in \mathcal{C}$, we apply a greedy algorithm that iteratively constructs the WCL.

Let $C_i = \{s_1, s_2, \ldots, s_{|C_i|}\}$ and consider its first sentence $s_1 = w_1^1, w_2^1, \ldots, w_{|s_1|}^1$ (w_i^j denotes the i-th token of the j-th sentence). We first produce the corresponding generalized sentence $s'_1 = \omega_1^1, \omega_2^1, \ldots, \omega_{|s_1|}^1$ (cf. Section 3.1). We then create a directed graph $G = (V, E)$ such that $V = \{\omega_1^1, \ldots, \omega_{|s_1|}^1\}$ and $E = \{(\omega_1^1, \omega_2^1), (\omega_2^1, \omega_3^1), \ldots, (\omega_{|s_1|-1}^1, \omega_{|s_1|}^1)\}$. Next, for the subsequent sentences in C_i, that is, for each $j = 2, \ldots, |C_i|$, we determine the alignment between the sentence s_j and each sentence $s_k \in C_i$ such that $k < j$ based on the following dynamic programming formulation (Cormen et al., 1990, pp. 314–319):

$$M_{a,b} = \max \{M_{a-1,b-1} + S_{a,b}, M_{a,b-1}, M_{a-1,b}\}$$

where $a \in \{1, \ldots, |s_k|\}$ and $b \in \{1, \ldots, |s_j|\}$, $S_{a,b}$ is a score of the matching between the a-th token of s_k and the b-th token of s_j, and $M_{0,0}$, $M_{0,b}$ and $M_{a,0}$ are initially set to 0 for all a and b.

The matching score $S_{a,b}$ is calculated on the generalized sentences s'_k of s_k and s'_j of s_j as follows:

$$S_{a,b} = \begin{cases} 1 & \text{if } \omega_a^k = \omega_b^j \\ 0 & \text{otherwise} \end{cases}$$

where ω_a^k and ω_b^j are the a-th and b-th word classes of s'_k and s'_j, respectively. In other words, the matching score equals 1 if the a-th and the b-th tokens of the two original sentences have the same word class.

Finally, the alignment score between s_k and s_j is given by $M_{|s_k|,|s_j|}$, which calculates the mini-

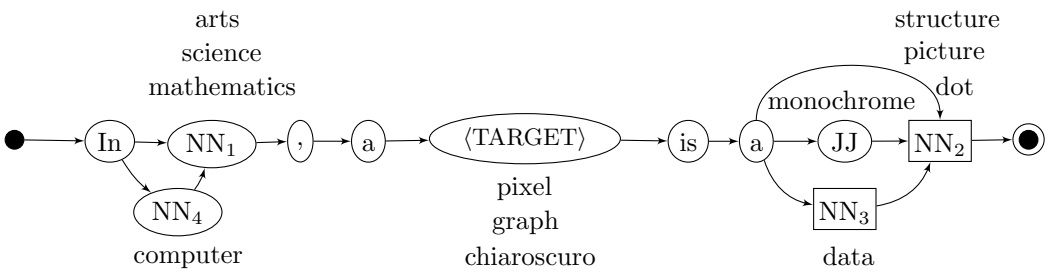

Figure 1: The Word-Class Lattice for the sentences in Table 1. The support of each word class is reported beside the corresponding node.

mal number of misalignments between the two token sequences. We repeat this calculation for each sentence s_k ($k = 1, \ldots, j-1$) and choose the one that maximizes its alignment score with s_j. We then use the best alignment to add s_j to the graph G. Such alignment is obtained by means of backtracking from $M_{|s_k|,|s_j|}$ to $M_{0,0}$. We add to the set of vertices V the tokens of the generalized sentence s'_j for which there is no alignment to s'_k and we add to E the edges (ω^j_1, ω^j_2), $\ldots, (\omega^j_{|s_j|-1}, \omega^j_{|s_j|})$. Furthermore, in the final lattice, nodes associated with the hypernym words in the learning sentences are marked as hypernyms in order to be able to determine the hypernym of a test sentence at classification time.

3.2.4 Variants of the WCL Model

So far, we have assumed that our WCL model learns lattices from the training sentences in their entirety (we call this model WCL-1). We now propose a second model that learns separate WCLs for each field of the definition, namely: the DEFINIENDUM (DF), DEFINITOR (VF) and DEFINIENS (GF) fields (see Section 3.1). We refer to this latter model as WCL-3. Rather than applying the WCL algorithm to the entire sentence, the very same method is applied to the sentence fragments tagged with one of the three definition fields. The reason for introducing the WCL-3 model is that, while definitional patterns are highly variable, DF, VF and GF individually exhibit a lower variability, thus WCL-3 should improve the generalization power.

3.2.5 Classification

Once the learning process is over, a set of WCLs is produced. Given a test sentence s, the classification phase for the WCL-1 model consists of determining whether it exists a lattice that matches s. In the case of WCL-3, we consider any combination of DEFINIENDUM, DEFINITOR and DEFINIENS lattices. While WCL-1 is applied as a yes-no classifier as there is a single WCL that can possibly match the input sentence, WCL-3 selects, if any, the combination of the three WCLs that best fits the sentence. In fact, choosing the most appropriate combination of lattices impacts the performance of hypernym extraction. The best combination of WCLs is selected by maximizing the following confidence score:

$$score(s, l_{\text{DF}}, l_{\text{VF}}, l_{\text{GF}}) = \textit{coverage} \cdot log(\textit{support})$$

where s is the candidate sentence, l_{DF}, l_{VF} and l_{GF} are three lattices one for each definition field, *coverage* is the fraction of words of the input sentence covered by the three lattices, and *support* is the sum of the number of sentences in the star patterns corresponding to the three lattices.

Finally, when a sentence is classified as a definition, its hypernym is extracted by selecting the words in the input sentence that are marked as "hypernyms" in the WCL-1 lattice (or in the WCL-3 GF lattice).

4 Example

As an example, consider the definitions in Table 1. As illustrated in Section 3.2.2, their star pattern is "In *, a ⟨TARGET⟩ is a *". The corresponding WCL is built as follows: the first part-of-speech tagged sentence, "In/IN arts/NN , a/DT ⟨TARGET⟩/NN is/VBZ a/DT monochrome/JJ *picture*/NN", is considered. The corresponding generalized sentence is "In NN , a ⟨TARGET⟩ is a JJ NN". The initially empty graph is thus populated with one node for each word class and one edge for each pair of consecutive tokens, as shown in Figure 1 (the central sequence of nodes in the graph). Note that we draw the hypernym token $\boxed{\text{NN}_2}$ with a rectangle shape. We also add to the

graph a start node • and an end node ⊙, and connect them to the corresponding initial and final sentence tokens. Next, the second sentence, "In mathematics, a graph is a data structure that consists of...", is aligned to the first sentence. The alignment of the generalized sentence is perfect, apart from the $\boxed{\text{NN}_3}$ node corresponding to "data". The node is added to the graph together with the edges a$\rightarrow\boxed{\text{NN}_3}$ and $\boxed{\text{NN}_3}\rightarrow\boxed{\text{NN}_2}$. Finally, the third sentence in Table 1, "In computer science, a pixel is a dot that is part of a computer image", is generalized as "In NN NN , a ⟨TARGET⟩ is a NN". Thus, a new node NN_4 is added, corresponding to "computer" and new edges are added: In$\rightarrow\text{NN}_4$ and $\text{NN}_4\rightarrow\text{NN}_1$. Figure 1 shows the resulting WCL-1 lattice.

5 Experiments

5.1 Experimental Setup

Datasets. We conducted experiments on two different datasets:

- A corpus of 4,619 Wikipedia sentences, that contains 1,908 definitional and 2,711 non-definitional sentences. The former were obtained from a random selection of the first sentences of Wikipedia articles[3]. The defined terms belong to different Wikipedia domain categories[4], so as to capture a representative and cross-domain sample of lexical and syntactic patterns for definitions. These sentences were manually annotated with DEFINIENDUM, DEFINITOR, DEFINIENS and REST fields by an expert annotator, who also marked the hypernyms. The associated set of negative examples ("syntactically plausible" false definitions) was obtained by extracting from the same Wikipedia articles sentences in which the page title occurs.
- A subset of the ukWaC Web corpus (Ferraresi et al., 2008), a large corpus of the English language constructed by crawling the `.uk` domain of the Web. The subset includes over 300,000 sentences in which occur any of 239 terms selected from the terminology of four different domains (COMPUTER SCIENCE, ASTRONOMY, CARDIOLOGY, AVIATION).

The reason for using the ukWaC corpus is that, unlike the "clean" Wikipedia dataset, in which relatively simple patterns can achieve good results, ukWaC represents a real-world test, with many complex cases. For example, there are sentences that should be classified as definitional according to Section 3.1 but are rather uninformative, like "**dynamic programming** was the *brainchild* of an american mathematician", as well as informative sentences that are not definitional (e.g., they do not have a hypernym), like "**cubism** was characterised by muted colours and fragmented images". Even more frequently, the dataset includes sentences which are not definitions but have a definitional pattern ("A Pacific Northwest tribe's **saga** refers to a young woman who [..]"), or sentences with very complex definitional patterns ("**white body cells** are the body's clean up *squad*" and "**joule** is also an *expression of electric energy*"). These cases can be correctly handled only with fine-grained patterns. Additional details on the corpus and a more thorough linguistic analysis of complex cases can be found in Navigli et al. (2010).

Systems. For definition extraction, we experiment with the following systems:

- **WCL-1** and **WCL-3**: these two classifiers are based on our Word-Class Lattice model. WCL-1 learns from the training set a lattice for each cluster of sentences, whereas WCL-3 identifies clusters (and lattices) separately for each sentence field (DEFINIENDUM, DEFINITOR and DEFINIENS) and classifies a sentence as a definition if any combination from the three sets of lattices matches (cf. Section 3.2.4, the best combination is selected).
- **Star patterns**: a simple classifier based on the patterns learned as a result of step 1 of our WCL learning algorithm (cf. Section 3.2.1): a sentence is classified as a definition if it matches any of the star patterns in the model.
- **Bigrams**: an implementation of the bigram classifier for soft pattern matching proposed by Cui et al. (2007). The classifier selects as definitions all the sentences whose probability is above a specific threshold. The probability is calculated as a mixture of bigram and

[3] The first sentence of Wikipedia entries is, in the large majority of cases, a definition of the page title.

Table 3: Performance on the ukWaC dataset († Recall is estimated).

unigram probabilities, with Laplace smoothing on the latter. We use the very same settings of Cui et al. (2007), including threshold values. While the authors propose a second soft-pattern approach based on Profile HMM (cf. Section 2), their results do not show significant improvements over the bigram language model.

For hypernym extraction, we compared WCL-1 and WCL-3 with **Hearst's patterns**, a system that extracts hypernyms from sentences based on the lexico-syntactic patterns specified in Hearst's seminal work (1992). These include (hypernym in italic): "such *NP* as {NP ,} {(or | and)} NP", "NP {, NP} {,} or other *NP*", "*NP* {,} including { NP ,} {or | and} NP", "*NP* {,} especially { NP ,} {or | and} NP", and variants thereof. However, it should be noted that hypernym extraction methods in the literature do not extract hypernyms from definitional sentences, like we do, but rather from specific patterns like "X such as Y". Therefore a direct comparison with these methods is not possible. Nonetheless, we decided to implement Hearst's patterns for the sake of completeness. We could not replicate the more refined approach by Snow et al. (2004) because it requires the annotation of a possibly very large dataset of sentence fragments. In any case Snow et al. (2004) reported the following performance figures on a corpus of dimension and complexity comparable with ukWaC: the recall-precision graph indicates precision 85% at recall 10% and precision 25% at recall of 30% for the hypernym classifier. A variant of the classifier that includes evidence from coordinate terms (terms with a common ancestor in a taxonomy) obtains an increased precision of 35% at recall 30%. We see no reasons why these figures should vary dramatically on the ukWaC.

Finally, we compare all systems with the **random baseline**, that classifies a sentence as a definition with probability $\frac{1}{2}$.

Measures. To assess the performance of our systems, we calculated the following measures:

- **precision** – the number of definitional sentences correctly retrieved by the system over the number of sentences marked by the system as definitional.
- **recall** – the number of definitional sentences correctly retrieved by the system over the number of definitional sentences in the dataset.
- the **F_1-measure** – a harmonic mean of precision (P) and recall (R) given by $\frac{2PR}{P+R}$.
- **accuracy** – the number of correctly classified sentences (either as definitional or non-definitional) over the total number of sentences in the dataset.

5.2 Results and Discussion

Definition Extraction. In Table 2 we report the results of definition extraction systems on the Wikipedia dataset. Given this dataset is also used for training, experiments are performed with 10-fold cross validation. The results show very high precision for WCL-1, WCL-3 (around 99%) and star patterns (86%). As expected, bigrams and star patterns exhibit a higher recall (82% and 66%, respectively). The lower recall of WCL-1 is due to its limited ability to generalize compared to WCL-3 and the other methods. In terms of F_1-measure, star patterns and WCL-3 achieve 75%, and are thus the best systems. Similar performance is observed when we also account for negative sentences – that is we calculate accuracy (with WCL-3 performing better). All the systems perform significantly better than the random baseline.

From our Wikipedia corpus, we learned over 1,000 lattices (and star patterns). Using WCL-3, we learned 381 DF, 252 VF and 395 GF lattices, that then we used to extract definitions from

Algorithm	Full	Substring
WCL-1	**42.75**	77.00
WCL-3	40.73	**78.58**

Table 4: Precision in hypernym extraction on the Wikipedia dataset

Algorithm	Full		Substring	
WCL-1	86.19	(206)	**96.23**	(230)
WCL-3	**89.27**	(383)	**96.27**	(413)
Hearst	65.26	(62)	88.42	(84)

Table 5: Precision in hypernym extraction on the ukWaC dataset (number of hypernyms in parentheses).

the ukWaC dataset. To calculate precision on this dataset, we manually validated the definitions output by each system. However, given the large size of the test set, recall could only be estimated. To this end, we manually analyzed 50,000 sentences and identified 99 definitions, against which recall was calculated. The results are shown in Table 3. On the ukWaC dataset, WCL-3 performs best, obtaining 94.87% precision and 56.57% recall (we did not calculate F_1, as recall is estimated). Interestingly, star patterns obtain only 44% precision and around 63% recall. Bigrams achieve even lower performance, namely 46.60% precision, 45.45% recall. The reason for such bad performance on ukWaC is due to the very different nature of the two datasets: for example, in Wikipedia most "is a" sentences are definitional, whereas this property is not verified in the real world (that is, on the Web, of which ukWaC is a sample). Also, while WCL does not need any parameter tuning[5], the same does not hold for bigrams[6], whose probability threshold and mixture weights need to be best tuned on the task at hand.

Hypernym Extraction. For hypernym extraction, we tested WCL-1, WCL-3 and Hearst's patterns. Precision results are reported in Tables 4 and 5 for the two datasets, respectively. The Substring column refers to the case in which the captured hypernym is a substring of what the annotator considered to be the correct hypernym. Notice that this is a complex matter, because often the selection of a hypernym depends on semantic and contextual issues. For example, "**Fluoroscopy** is an *imaging method*" and "the **Mosaic** was an interesting *project*" have precisely the same genus pattern, but (probably depending on the vagueness of the noun in the first sentence, and of the adjective in the second) the annotator selected respectively *imaging method* and *project* as hypernyms. For the above reasons it is difficult to achieve high performance in capturing the correct hypernym (e.g. 40.73% with WCL-3 on Wikipedia). However, our performance of identifying a substring of the correct hypernym is much higher (around 78.58%). In Table 4 we do not report the precision of Hearst's patterns, as only one hypernym was found, due to the inherently low coverage of the method.

On the ukWaC dataset, the hypernyms returned by the three systems were manually validated and precision was calculated. Both WCL-1 and WCL-3 obtained a very high precision (86-89% and 96% in identifying the exact hypernym and a substring of it, respectively). Both WCL models are thus equally robust in identifying hypernyms, whereas WCL-1 suffers from a lack of generalization in definition extraction (cf. Tables 2 and 3). Also, given that the ukWaC dataset contains sentences in which any of 239 domain terms occur, WCL-3 extracts on average 1.6 and 1.7 full and substring hypernyms per term, respectively. Hearst's patterns also obtain high precision, especially when substrings are taken into account. However, the number of hypernyms returned by this method is much lower, due to the specificity of the patterns (62 vs. 383 hypernyms returned by WCL-3).

6 Conclusions

In this paper, we have presented a lattice-based approach to definition and hypernym extraction. The novelty of our approach is:

1. The use of a lattice structure to generalize over lexico-syntactic definitional patterns;
2. The ability of the system to jointly identify definitions and extract hypernyms;
3. The generality of the method, which applies to generic Web documents in any domain and style, and needs no parameter tuning;

[5]WCL has only one threshold value θ to be set for determining frequent words (cf. Section 3.1). However, no tuning was made for choosing the best value of θ.

[6]We had to re-tune the system parameters on ukWaC, since with the original settings of Cui et al. (2007) performance was much lower.

4. The high performance as compared with the best-known methods for both definition and hypernym extraction. Our approach outperforms the other systems particularly where the task is more complex, as in real-world documents (i.e., the ukWaC corpus).

Even though definitional patterns are learned from a manually annotated dataset, the dimension and heterogeneity of the training dataset ensures that training needs not to be repeated for specific domains[7], as demonstrated by the cross-domain evaluation on the ukWaC corpus.

The datasets used in our experiments are available from `http://lcl.uniroma1.it/wcl`. We also plan to release our system to the research community. In the near future, we aim to apply the output of our classifiers to the task of automated taxonomy building, and to test the WCL approach on other information extraction tasks, like hypernym extraction from generic sentence fragments, as in Snow et al. (2004).

On Learning Subtypes of the Part-Whole Relation: Do Not Mix your Seeds

Abstract

An important relation in information extraction is the part-whole relation. Ontological studies mention several types of this relation. In this paper, we show that the traditional practice of initializing minimally-supervised algorithms with a single set that mixes seeds of different types fails to capture the wide variety of part-whole patterns and tuples. The results obtained with mixed seeds ultimately converge to one of the part-whole relation types. We also demonstrate that all the different types of part-whole relations can still be discovered, regardless of the type characterized by the initializing seeds. We performed our experiments with a state-of-the-art information extraction algorithm.

1 Introduction

A fundamental semantic relation in many disciplines such as linguistics, cognitive science, and conceptual modelling is the part-whole relation, which exists between parts and the wholes they compise (Winston et al., 1987; Gerstl and Pribbenow, 1995). Different types of part-whole relations, classified in various taxonomies, are mentioned in literature (Winston et al., 1987; Odell, 1994; Gerstl and Pribbenow, 1995; Keet and Artale, 2008). The taxonomy of Keet and Artale (2008), for instance, distinguishes part-whole relations based on their transitivity, and on the semantic classes of entities they sub-categorize. Part-whole relations are also crucial for many information extraction (IE) tasks (Girju et al., 2006). Annotated corpora and semantic dictionaries used in IE, such as the ACE corpus[1] and WordNet (Fellbaum, 1998), include examples of part-whole relations. Also, previous relation extraction work, such as Berland and Charniak (1999) and Girju et al. (2006), have specifically targeted the discovery of part-whole relations from text. Furthermore, part-whole relations are de-facto benchmarks for evaluating the performance of general relation extraction systems (Pantel and Pennacchiotti, 2006; Beamer et al., 2008; Pyysalo et al., 2009). However, these relation extraction efforts have overlooked the ontological distinctions between the different types of part-whole relations. They assume the existence of a single relation, subsuming the different part-whole relation types.

In this paper, we show that enforcing the ontological distinctions between the different types of part-whole relations enable information extraction systems to capture a wider variety of both generic and specialised part-whole lexico-syntactic patterns and tuples. Specifically, we address 3 major questions.

1. Is information extraction (IE) harder when learning the individual types of part-whole relations? That is, we determine whether the performance of state-of-the-art IE systems in learning the individual part-whole relation types increases (due to more coherency in the relations' linguistic realizations) or drops (due to fewer examples), compared to the traditional practice of considering a single part-whole relation.

2. Are the patterns and tuples discovered when focusing on a specific part-whole relation type confined to that particular type? That is, we investgate whether IE systems discover examples representative of the different types by targetting one particular part-whole relation type.

3. Are more distinct examples discovered when IE systems learn the individual part-whole relation types? That is, we determine whether

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1328–1336,
Uppsala, Sweden, 11-16 July 2010.

a wider variety of unique patterns and tuples are extracted when IE systems target the different types of part-whole relations instead of considering a single part-whole relation that subsumes all the different types.

To answer these questions, we bootstrapped a minimally-supervised relation extraction algorithm, based on Espresso (Pantel and Pennacchiotti, 2006), with different seed-sets for the various types of part-whole relations, and analyzed the harvested tuples and patterns.

2 Previous Work

Investigations on the part-whole relations span across many disciplines, such as conceptual modeling (Artale et al., 1996; Keet, 2006; Keet and Artale, 2008), which focus on the ontological aspects, and linguistics and cognitive sciences, which focus on natural language semantics. Several linguistically-motivated taxonomies (Odell, 1994; Gerstl and Pribbenow, 1995), based on the work of Winston et al. (1987), have been proposed to clarify the semantics of the different part-whole relations types across these various disciplines. Keet and Artale (2008) developed a formal taxonomy, distinguishing transitive *mereological* part-whole relations from intransitive *meronymic* ones. Meronymic relations identified are: 1) *member-of*, between a physical object (or role) and an aggregation, e.g. *player-team*, 2) *constituted-of*, between a physical object and an amount of matter e.g. *clay-statue*, 3) *sub-quantity-of*, between amounts of matter or units, e.g. *oxygen-water* or *m-km*, and 4)*participates-in*, between an entity and a process e.g. *enzyme-reaction*. Mereological relations are: 1)*involved-in*, between a phase and a process, e.g. *chewing-eating*, 2) *located-in*, between an entity and its 2-dimensional region, e.g. *city-region*, 3)*contained-in*, between an entity and its 3-dimensional region, e.g.*tool-trunk*, and 4)*structural part-of*, between integrals and their (functional) components, e.g. *engine-car*. This taxonomy further discriminates between part-whole relation types by enforcing semantical selectional restrictions, in the form of DOLCE ontology (Gangemi et al., 2002) classes, on their entities.

In NLP, information extraction (IE) techniques, for discovering part-whole relations from text have also been developed. Berland and Charniak (1999) use manually-crafted patterns, similar to Hearst (1992), and on initial "seeds" denoting "whole" objects (e.g. building) to harvest possible "part" objects (e.g. room) from the North Americal News Corpus (NANC) of 1 million words. They rank their results with measures like log-likelihood (Dunning, 1993), and report a maximum accuracy of 70% over their top-20 results. In the supervised approaches in Girju et al. (2003) and Girju et al. (2006), lexical patterns expressing part-whole relations between WordNet concept pairs are manually extracted from 20,000 sentences of the L.A Times and SemCor corpora (Miller et al., 1993), and used to generate a training corpus, with manually-annotated positive and negative examples of part-whole relations. Classification rules, induced over the training data, achieve a precision of 80.95% and recall of 75.91% in predicting whether an unseen pattern encode a part-whole relation. Van Hage et al. (2006) acquire 503 part-whole pairs from dedicated thesauri (e.g. AGROVOC[2]) to learn 91 reliable part-whole patterns. They substituted the patterns' "part" arguments with known entities to formulate web-search queries. Corresponding "whole" entities were then discovered from documents in the query results with a precision of 74%. The part-whole relation is also a benchmark to evaluate the performance of general information extraction systems. The Espresso algorithm (Pantel and Pennacchiotti, 2006) achieves a precision of 80% in learning part-whole relations from the Acquaint (TREC-9) corpus of nearly 6M words. Despite the reasonable performance of the above IE systems in discovering part-whole relations, they overlook the ontological distinctions between the different relation types. For example, Girju et al. (2003) and Girju et al. (2006) assume a single part-whole relation, encompassing all the different types mentioned in the taxonomy of Winston et al. (1987). Similarly, the minimally-supervised Espresso algorithm (Pantel and Pennacchiotti, 2006) is initialized with a single set that mixes seeds of heterogeneous types, such as *leader-panel* and *oxygen-water*, which respectively correspond to the *member-of* and *sub-quantity-of* relations in the taxonomy of Keet and Artale (2008).

3 Methodology

Our aim is to compare the relations harvested when a minimally-supervised IE algorithm is initialized with separate sets of seeds for each type of part-whole relation, and when it is initialized following the traditional practice of a single set that mixes seeds of the different types. To distinguish between types of part-whole relations, we commit to the taxonomy of Keet and Artale (2008) (Keet's taxonomy), which uses sound ontological formalisms to unambiguously discrimate the relation types. Also, this taxonomy classifies the various part-whole relations introduced in literature, including ontologically-motivated mereological relations and linguistically-motivated meronymic ones. We adopt a 3-step approach to address our questions from section 1.

1. Define prototypical seeds (part-whole tuples) as follows:
   - (Separate) sets of seeds for each type of part-whole relation in Keet's taxonomy.
   - A single set that mixes seeds denoting all the different part-whole relations types.
2. Part-whole relations extraction from a corpus by initializing a minimally-supervised IE algorithm with the seed-sets
3. Evaluation of the harvested relations to determine performance gain/loss, types of part-whole relations extracted, and distinct and unique patterns and tuples discovered.

The corpora and IE algorithm we used, and the seed-sets construction are described below. Results are presented in the next section.

3.1 Corpora

We used the English and Dutch Wikipedia texts since their broad-coverage and size ensures that they include sufficient lexical realizations of the different types of part-whole relations. Wikipedia has also been targeted by recent IE efforts (Nguyen et al., 2007; Wu and Weld, 2007). However, while they exploited the structured features (e.g. infoboxes), we only consider the unstructured texts. The English corpus size is approximately 470M words ($\sim$ 80% of the August 2007 dump), while for Dutch, we use the full text collection (February 2008 dump) of approximately 110M words. We parsed the English and Dutch corpora respectively with the Stanford[3] (Klein and Manning, 2003) and the Alpino[4] (van Noord, 2006) parsers, and formalized the relations between terms (entities) as dependency paths. A dependency path is the shortest path of lexico-syntactic elements, i.e. shortest lexico-syntactic pattern, connecting entities (proper and common nouns) in their parse-trees. Such a formalization has been successfully employed in previous IE tasks (see Stevenson and Greenwood (2009) for an overview). Compared to traditional surface-pattern representations, used by Pantel and Pennacchiotti (2006), dependency paths abstract from surface texts to capture long range dependencies between terms. They also alleviate the manual authoring of large numbers of surface patterns. In our formalization, we substitute entities in the dependency paths with generic placeholders PART and WHOLE. Below, we show two dependency paths (1-b) and (2-b), respectively derived from English and Dutch Wikipedia sentences (1-a) and (2-a), and denoting the relations between *sample-song*, and *alkaloïde-plant*.

(1) a. The song "Mao Tse Tung Said" by Alabama 3 contains samples of a speech by Jim Jones
    b. WHOLE+nsubj ← contains → dobj+PART

(2) a. Alle delen van de planten bevatten alkaloïden en zijn daarmee giftig (*All parts of the plants contain alkaloids and therefore are poisonous*)
    b. WHOLE+obj1+van+mod+deel+su ← bevat→ obj1+PART

In our experiments, we only consider those entity pairs (tuples), patterns, and co-occuring pairs-patterns with a minimum frequency of 10 in the English corpus, and 5 in the Dutch corpus. Statistics on the number of tuples and patterns preserved after applying the frequency cut-off are given in Table 1.

3.2 Information Extraction Algorithm

As IE algorithm for extracting part-whole relations from our texts, we relied on *Espresso*, a minimally-supervised algorithm, as described by Pantel and Pennacchiotti (2006). They show

[3] http://nlp.stanford.edu/software/lex-parser.shtml

[4] http://www.let.rug.nl/~vannoord/alp/Alpino

	English	Dutch
words	470.0	110.0
pairs	328.0	28.8
unique pairs	6.7	1.4
patterns	238.0	54.0
unique patterns	2.0	0.9

Table 1: Corpus Statistics in millions

that the algorithm achieves state-of-the-art performance when initialized with relatively small seed-sets over the Acquaint corpus ($\sim$ 6M words). Recall is improved with web search queries as additional source of information.

Espresso extracts surface patterns connecting the seeds (tuples) in a corpus. The reliability of a pattern p, $r(p)$, given a set of input tuples I, is computed using (3), as its average strength of association with each tuple,i, weighted by each tuple's reliability, $r_\iota(i)$.

$$r_\pi(p) = \frac{\sum_{i \in I} \left(\frac{pmi(i,p)}{\max_{pmi}} \times r_\iota(i) \right)}{|I|} \quad (3)$$

In this equation, $pmi(i,p)$ is the pointwise mutual information score (Church and Hanks, 1990) between a pattern, p (e.g. *consist-of*), and a tuple, i (e.g. *engine-car*), and max_{pmi} is the maximum PMI score between all patterns and tuples. The reliability of the initializing seeds is set to 1.

The top-k most reliable patterns are selected to find new tuples. The reliability of each tuple i, $r_\iota(i)$ is computed according to (4), where P is the set of harvested patterns. The top-m most reliable tuples are used to infer new patterns.

$$r_\iota(i) = \frac{\sum_{i \in I} \left(\frac{pmi(i,p)}{\max_{pmi}} \times r_\pi(p) \right)}{|P|} \quad (4)$$

The recursive discovery of patterns from tuples and vice-versa is repeated until a threshold number of patterns and/or tuples have been extracted. In our implementation, we maintain the core of the original Espresso algorithm, which pertains to estimating the reliability of patterns and tuples.

Pantel and Pennacchiotti (2006) mention that their method is independent of the way patterns are formulated. Thus, instead of relying on surface patterns, we use dependency paths (as described above). Another difference is that while Pantel and Pennacchiotti (2006) complement their small corpus with documents retrieved from the web, we only rely on patterns extracted from our (much larger) corpora. Finally, we did not apply the discounting factor suggested in Pantel and Pennacchiotti (2006) to correct for the fact that PMI overestimates the importance of low-frequency events. Instead, as explained above, we applied a general frequency cut-off.[5]

3.3 Seed Selection

Initially,we selected seeds from WordNet (Fellbaum, 1998) (for English) and EuroWordNet (Vossen, 1998) (for Dutch) to initialize the IE algorithm. However, we found that these pairs, such as *acinos-mother of thyme* or *radarscherm-radarapparatuur (radar screen - radar equipment*, hardly co-occured with reasonable frequency in Wikipedia sentences, hindering pattern extraction. We therefore adopted the following strategy.

We searched our corpora for archetypal patterns, e.g. *contain* , which characterize all the different types of part-whole relations. The tuples sub-categorized by these patterns in the English texts were automatically[6] typed to appropriate DOLCE ontology[7] classes, corresponding to those employed by Keet and Artale for constraining the entity pairs participating in different types of part-whole relations. The types of part-whole relations instantiated by the tuples could then be determined based on their ontological classes. Separate sets of 20 tuples, with each set corresponding to a specific relation type in the taxonomy of Keet and Artale (Keet's taxonomy), were then created. For example, the English Wikipedia tuple $t1$ =*actor-cast* was used as a seed to discover *member-of* part-whole relations since both its elements were typed to the SOCIAL OBJECT class of the DOLCE ontology, and according to Keet's taxonomy, they instantiate a *member-of* relation. Seeds for extracting relations from the Dutch corpus were defined in a similar way, except that we manually determined their ontological classes based on the class glossary of DOLCE.

Below, we only report on the *member-of* and *sub-quantity-of* meronymic relations, and on the *located-in*, *contained-in* and *structural part-of* mereological relations. We were unable to find sufficient seeds for the *constituted-of* meronymic

[5] We experimented with the suggested discounting factor for PMI, but were not able to improve over the accuracy scores reported later.

Table 2: Seeds used for learning part-whole relations (*contained-in, located-in, member-of, structural part-of, sub-quantity-of*).

relations (e.g. *clay-statue*). Also, we did not experiment with the *participates-in* and *involved-in* relations since their lexical realizations in our corpora are sparse, and they contain at least one verbal argument, whereas we only targeted patterns connecting nomimals. Sample seeds, their corpus frequency, and the part-whole relation type they instantiate from the English (EN) and Dutch (NL) corpora are illustrated in Table 2. Besides the five specialized seed-sets of 20 prototypical tuples for the aforementioned relations, we also defined a *general* set of mixed seeds, which combines four seeds from each of the specialized sets.

4 Experiments and Evaluation

We initialized our IE algorithm with the seed-sets to extract part-whole relations from our corpora. The same parameters as Pantel and Pennacchiotti (2006) were used. That is, the 10 most reliable patterns inferred from the initial seeds are bootstrapped to induce 100 part-whole tuples. In each subsequent iteration, we learn one additional pattern and 100 additional tuples. We evaluated our results after 5 iterations since the performance in later iterations was almost constant. The results are discussed next.

	meronomic		mereological			
	memb	subq	cont	struc	locat	gen
EN	0.67	0.74	0.70	0.82	0.75	0.80
NL	0.68	0.60	0.60	0.60	0.70	0.71

Table 3: Precision for seed-sets representing specific types of part-whole relations (*member-of, sub-quantity-of, contained-in, structural part-of* and *located-in*), and for the *general* set composed of all types.

4.1 Precision of Extracted Relations

Two human judges manually evaluated the tuples extracted from the English and Dutch corpora per seed-set in each iteration of our algorithm. Tuples that unambiguously instantiated part-whole relations were considered *true positives*. Those that did not were considered *false positives*. Ambiguous tuples were discarded. The precision of the tuples discovered by the different seed-sets in the last iteration of our algorithm are in Table 3.

These results reveal that the precision of harvested tuples varies depending on the part-whole relation type that the initializing seeds denote. Mereological seeds (*cont, struct, locat* sets) outperformed their meronymic counterparts (*memb, subq*) in extracting relations with higher precision from the English texts. This could be attributed to their formal ontological grounding, making them less ambiguous than the linguistically-motivated meronymic relations (Keet, 2006; Keet and Artale, 2008). The precision variations were less discernible for tuples extracted from the Dutch corpus, although the best precision was still achieved with mereological *located-in* seeds. We also noticed that the precision of tuples extracted from both the English and Dutch corpora by the general set of mixed seeds was as high as the maximum precision obtained by the individual sets of specialized seeds over these two corpora, i.e. 0.80 (*general* seeds) vs. 0.82 (*structural part-of* seeds) for English, and 0.71 (*general* seeds) vs. 0.70 (*located-in* seeds) for Dutch. Based on these findings, we address our first question, and conclude that 1) the type of relation instantiated by the initializing seeds affects the performance of IE algorithms, with mereological seeds being in general more fertile than their meronymic counterparts, and generating higher-precision tuples; 2) the precision achieved when initializing IE algorithms with a general set, which mixes

seeds of heterogeneous part-whole relation types, is comparable to the best results obtained with individual sets of specialized seeds, denoting specific part-whole relations. An evaluation of the patterns and tuples extracted indicated considerable precision drop between successive iterations of our algorithm. This appears to be due to *semantic drift* (McIntosh and Curran, 2009), where highly-ambiguous patterns promote incorrect tuples , which in turn, compound the precision loss.

4.2 Types of Extracted Relations

Initializing our algorithm with seeds of a particular type always led to the discovery of tuples characterizing other types of part-whole relations in the English corpus. This can be explained by prototypical patterns, e.g. "include", generated regardless of the seeds' types, and which are highy correlated with, and hence, trigger tuples denoting other part-whole relation types. An almost similar observation was made for the Dutch corpus, except that tuples instantiating the *member-of* relation could only be learnt using initial seeds of that particular type (i.e. *member-of*). Upon inspecting our results, it was found that this phenomenon was due to the distinct and specific patterns, such as "treedt toe tot" ("become member of"), which linguistically realize the *member-of* relations in the Dutch corpus. Thus, initializing our IE algorithm with seeds that instantiate relations other than *member-of* fails to detect these unique patterns, and fails to subsequently discover part-whole tuples describing the *member-of* relations. Our findings are illustrated in Table 4, where each cell lists a tuple of a particular type (column), which was harvested from seeds of a given type (row). These results answer our second question.

4.3 Distinct Patterns and Tuples

We address our third question by comparing the output of our algorithm to determine whether the results obtained by initializing with the individual specialized seeds were (dis)similar and/or distinct. Each result set consisted of maximally 520 tuples (including 20 initializing seeds) and 15 lexico-syntactic patterns, obtained after five iterations.

Tuples extracted from the English corpus using the *member-of* and *contained-in* seed-sets exhibited a high degree of similarity, with 465 common tuples discovered by both sets. These identical tuples were also assigned the same ranks (reliability) in the results generated by the *member-of* and *contained-in* seeds, with a Spearman rank correlation of 0.82 between their respective outputs. This convergence was also reflected in the fact that the *member-of* and *contained-in* seeds generated around 80% of common patterns. These patterns were mostly prototypical ones indicative of part-whole relations, such as WHOLE+nsubj ← include → dobj+PART ("include") and their cognates involving passive forms and relative clauses. However, the specialized seeds also generated distinct patterns, like "joined as" and "released with" for the *member-of* and *contained-in* seeds respectively.

The most distinct tuples and patterns were harvested with the *sub-quantity-of*, *structural part-of*, and *located-in* seeds. Negative Spearman correlation scores were obtained when comparing the results of these three sets among themselves, and with the results of the *member-of* and *contained-in* seeds, indicating insignificant similarity and overlap. Examining the patterns harvested by the *sub-quantity-of*, *structural part-of*, and *located-in* seeds revealed a high prominence of specialized and unique patterns, which specifically characterize these relations. Examples of such patterns include "made with", "released with" and "found in", which lexically realize the *sub-quantity-of*, *structural part-of*, and *located-in* relations respectively.

For the Dutch corpus, the seeds that generated the most similar tuples were those corresponding to the *sub-quantity-of*, *contained-in*, and *structural part-of* relations, with 490 common tuples discovered, and a Spearman rank correlation in the range of 0.89-0.93 between their respective outputs. As expected, these seeds also led to the discovery of a substantial number of common and prototypical part-whole patterns. Examples include "bevat" ("contain"), "omvat" ("comprise"), and their variants. The most distinct results were harvested by the *located-in* and *member-of* seeds, with negative Spearman correlation scores between the output tuples indicating hardly any overlap. We also found out that the patterns harvested by the *located-in* and *member-of* seeds characteristically pertained to these relations. Example of such patterns include "ligt in" ("lie in"), "is gelegen in" ("is located in"), and "treedt toe tot" ("become member of"), respectively describing the *located-in* and *member-of* relations.

Thus, we observed that 1) tuples harvested from

Table 4: Sample tuples found per relation type.

both the English and Dutch corpora by seeds instantiating a single particular type of part-whole relation highly correlated with tuples discovered by at least one other type of seeds (*member-of* and *contained-in* for English, and *sub-quantity-of*, *contained-in* and *structural part-of* for Dutch); 2) some part-whole relations are manifested by a wide variety of specialized patterns (*sub-quantity-of*, *structural part-of*, and *located-in* for English, and *located-in* and *member-of* for Dutch).

Finally, instead of a single set that mixes seeds of different types, we created five such *general* sets by picking four different seeds from each of the specialized sets, and used them to initialize our algorithm. When examining the results of each of the five *general* sets, we found out that they were unstable, and always correlated with the output of a different specialized set.

Based on these findings, we believe that the traditional practice of initializing IE algorithms with *general* sets that mix seeds denoting different part-whole relation types leads to inherently unstable results. As we have shown, the relations extracted by combining seeds of heterogeneous types almost always converge to one specific part-whole relation type, which cannot be conclusively predicted. Furthermore, *general* seeds are unable to capture the specific and distinct patterns that lexically realize the individual types of part-whole relations.

5 Conclusions

In this paper, we have investigated the effect of ontologically-motivated distinctions in part-whole relations on IE systems that learn instances of these relations from text.

We have shown that learning from specialized seeds-sets, denoting specific types of the part-whole relations, results in precision that is as high as or higher than the precision achieved with a general set that mixes seeds of different types. By comparing the outputs generated by different seed-sets, we observed that the tuples learnt with seeds denoting a specific part-whole relation type are not confined to that particular type. In most case, we are still able to discover tuples across all the different types of part-whole relations, regardless of the type instantiated by the initializing seeds. Most importantly, we demonstrated that IE algorithms initialized with general sets of mixed seeds harvest results that tend to converge towards a specific type of part-whole relation. Conversely, when starting with seeds representing a specific type, it is likely to discover tuples and patterns that are completely distinct from those found by a mixed seed-set.

Our results also illustrate that the outputs of IE algorithms are heavily influenced by the initializing seeds, concurring with the findings of McIntosh and Curran (2009). We believe that our results show a drastic form of this phenomenon: given a set of mixed seeds, denoting heterogeneous relations, the harvested tuples may converge towards any of the relations instantiated by the seeds. Predicting the convergent relation is in usual cases impossible, and may depend on factors pertaining to corpus characteristics. This instability strongly suggests that seeds instantiating different types of relations should not be mixed, partic-

ularly when learning part-whole relations, which are characterized by many subtypes. Seeds should be defined such that they represent an ontologically well-defined class, for which one may hope to find a coherent set of extraction patterns.

Understanding the Semantic Structure of Noun Phrase Queries

Abstract

Determining the semantic intent of web queries not only involves identifying their semantic class, which is a primary focus of previous works, but also understanding their semantic structure. In this work, we formally define the semantic structure of noun phrase queries as comprised of *intent heads* and *intent modifiers*. We present methods that automatically identify these constituents as well as their semantic roles based on Markov and semi-Markov conditional random fields. We show that the use of semantic features and syntactic features significantly contribute to improving the understanding performance.

1 Introduction

Web queries can be considered as implicit questions or commands, in that they are performed either to find information on the web or to initiate interaction with web services. Web users, however, rarely express their intent in full language. For example, to find out "what are the movies of 2010 in which johnny depp stars", a user may simply query "johnny depp movies 2010". Today's search engines, generally speaking, are based on matching such keywords against web documents and ranking relevant results using sophisticated features and algorithms.

As search engine technologies evolve, it is increasingly believed that search will be shifting away from "ten blue links" toward understanding intent and serving objects. This trend has been largely driven by an increasing amount of structured and semi-structured data made available to search engines, such as relational databases and semantically annotated web documents. Searching over such data sources, in many cases, can offer more relevant and essential results compared with merely returning web pages that contain query keywords. Table 1 shows a simplified view of a structured data source, where each row represents a movie object. Consider the query "johnny depp movies 2010". It is possible to retrieve a set of movie objects from Table 1 that satisfy the constraints *Year = 2010* and *Cast* $\ni$ *Johnny Depp*. This would deliver direct answers to the query rather than having the user sort through list of keyword results.

In no small part, the success of such an approach relies on robust understanding of query intent. Most previous works in this area focus on query intent classification (Shen et al., 2006; Li et al., 2008b; Arguello et al., 2009). Indeed, the intent class information is crucial in determining if a query can be answered by any structured data sources and, if so, by which one. In this work, we go one step further and study the semantic structure of a query, *i.e.*, individual constituents of a query and their semantic roles. In particular, we focus on *noun phrase* queries. A key contribution of this work is that we formally define query semantic structure as comprised of *intent heads* (IH) and *intent modifiers* (IM), *e.g.*,

$$[_{\text{IM:}\textit{Title}}\ \text{alice in wonderland}]\ [_{\text{IM:}\textit{Year}}\ 2010]\ [_{\text{IH}}\ \text{cast}]$$

It is determined that "cast" is an IH of the above query, representing the essential information the user intends to obtain. Furthermore, there are two IMs, "alice in wonderland" and "2010", serving as filters of the information the user receives.

Identifying the semantic structure of queries can be beneficial to information retrieval. Knowing the semantic role of each query constituent, we

can reformulate the query into a structured form or reweight different query constituents for structured data retrieval (Robertson et al., 2004; Kim et al., 2009; Paparizos et al., 2009). Alternatively, the knowledge of IHs, IMs and semantic labels of IMs may be used as additional evidence in a learning to rank framework (Burges et al., 2005).

A second contribution of this work is to present methods that automatically extract the semantic structure of noun phrase queries, *i.e.*, IHs, IMs and the semantic labels of IMs. In particular, we investigate the use of transition, lexical, semantic and syntactic features. The semantic features can be constructed from structured data sources or by mining query logs, while the syntactic features can be obtained by readily-available syntactic analysis tools. We compare the roles of these features in two discriminative models, Markov and semi-Markov conditional random fields. The second model is especially interesting to us since in our task it is beneficial to use features that measure segment-level characteristics. Finally, we evaluate our proposed models and features on manually-annotated query sets from three domains, while our techniques are general enough to be applied to many other domains.

2 Related Works

2.1 Query intent understanding

As mentioned in the introduction, previous works on query intent understanding have largely focused on classification, *i.e.*, automatically mapping queries into semantic classes (Shen et al., 2006; Li et al., 2008b; Arguello et al., 2009). There are relatively few published works on understanding the semantic structure of web queries. The most relevant ones are on the problem of query tagging, *i.e.*, assigning semantic labels to query terms (Li et al., 2009; Manshadi and Li, 2009). For example, in "canon powershot sd850 camera silver", the word "canon" should be tagged as *Brand*. In particular, Li et al. leveraged click-through data and a database to automatically derive training data for learning a CRF-based tagger. Manshadi and Li developed a hybrid, generative grammar model for a similar task. Both works are closely related to one aspect of our work, which is to assign semantic labels to IMs. A key difference is that they do not conceptually distinguish between IHs and IMs.

On the other hand, there have been a series of research studies related to IH identification (Pasca and Durme, 2007; Pasca and Durme, 2008). Their methods aim at extracting attribute names, such as *cost* and *side effect* for the concept *Drug*, from documents and query logs in a weakly-supervised learning framework. When used in the context of web queries, attribute names usually serve as IHs. In fact, one immediate application of their research is to understand web queries that request factual information of some concepts, *e.g.* "asiprin cost" and "aspirin side effect". Their framework, however, does not consider the identification and categorization of IMs (attribute values).

2.2 Question answering

Query intent understanding is analogous to question understanding for *question answering* (QA) systems. Many web queries can be viewed as the keyword-based counterparts of natural language questions. For example, the query "california national" and "national parks califorina" both imply the question "What are the national parks in California?". In particular, a number of works investigated the importance of *head noun* extraction in understanding *what-type* questions (Metzler and Croft, 2005; Li et al., 2008a). To extract head nouns, they applied syntax-based rules using the information obtained from part-of-speech (POS) tagging and deep parsing. As questions posed in natural language tend to have strong syntactic structures, such an approach was demonstrated to be accurate in identifying head nouns.

In identifying IHs in noun phrase queries, however, direct syntactic analysis is unlikely to be as effective. This is because syntactic structures are in general less pronounced in web queries. In this

work, we propose to use POS tagging and parsing outputs as features, in addition to other features, in extracting the semantic structure of web queries.

2.3 Information extraction

Finally, there exist large bodies of work on information extraction using models based on Markov and semi-Markov CRFs (Lafferty et al., 2001; Sarawagi and Cohen, 2004), and in particular for the task of named entity recognition (McCallum and Li, 2003).

The problem studied in this work is concerned with identifying more generic "semantic roles" of the constituents in noun phrase queries. While some IM categories belong to named entities such as IM:*Director* for the intent class *Movie*, there can be semantic labels that are not named entities such as IH and IM:*Genre* (again for *Movie*).

3 Query Semantic Structure

Unlike database query languages such as SQL, web queries are usually formulated as sequences of words without explicit structures. This makes web queries difficult to interpret by computers. For example, should the query "aspirin side effect" be interpreted as "the side effect of aspirin" or "the aspirin of side effect"? Before trying to build models that can automatically makes such decisions, we first need to understand what constitute the semantic structure of a noun phrase query.

3.1 Definition

We let $\mathcal{C}$ denote a set of query intent classes that represent semantic concepts such as *Movie*, *Product* and *Drug*. The query constituents introduced below are all defined w.r.t. the intent class of a query, $c \in \mathcal{C}$, which is assumed to be known.

Intent head

An *intent head* (IH) is a query segment that corresponds to an **attribute name** of an intent class. For example, the IH of the query "alice in wonderland 2010 cast" is "cast", which is an attribute name of *Movie*. By issuing the query, the user intends to find out the values of the IH (*i.e.*, cast). A query can have multiple IHs, *e.g.*, "movie avatar director and cast". More importantly, there can be queries without an explicit IH. For example, "movie avatar" does not contain any segment that corresponds to an attribute name of *Movie*. Such a query, however, does have an implicit intent which is to obtain general information about the movie.

Intent modifier

In contrast, an *intent modifier* (IM) is a query segment that corresponds to an **attribute value** (of some attribute name). The role of IMs is to imposing constraints on the attributes of an intent class. For example, there are two constraints implied in the query "alice in wonderland 2010 cast": (1) the *Title* of the movie is "alice in wonderland"; and (2) the *Year* of the movie is "2010". Interestingly, the user does not explicitly specify the attribute names, *i.e.*, *Title* and *Year*, in this query. Such information, however, can be inferred given domain knowledge. In fact, one important goal of this work is to identify the semantic labels of IMs, *i.e.*, the attribute names they implicitly refer to. We use $\mathcal{A}_c$ to denote the set of IM semantic labels for the intent class c.

Other

Additionally, there can be query segments that do not play any semantic roles, which we refer to as Other.

3.2 Syntactic analysis

The notion of IHs and IMs in this work is closely related to that of linguistic *head nouns* and *modifiers* for noun phrases. In many cases, the IHs of noun phrase queries are exactly the head nouns in the linguistic sense. Exceptions mostly occur in queries without explicit IHs, *e.g.*, "movie avatar" in which the head noun "avatar" serves as an IM instead. Due to the strong resemblance, it is interesting to see if IHs can be identified by extracting linguistic head nouns from queries based on syntactic analysis. To this end, we apply the following heuristics for head noun extraction. We first run a POS-tagger and a chunker jointly on each query, where the POS-tagger/chunker is based on an HMM system trained on English Penn Treebank (Gao et al., 2001). We then mark the right most NP chunk before any prepositional phrase or adjective clause, and apply the NP head rules (Collins, 1999) to the marked NP chunk.

The main problem with this approach, however, is that a readily-available POS tagger or chunker is usually trained on natural language sentences and thus is unlikely to produce accurate results on web queries. As shown in (Barr et al., 2008), the lexical category distribution of web queries is dramatically different from that of natural languages. For example, prepositions and subordinating conjunctions, which are strong indicators of the syntactic

structure in natural languages, are often missing in web queries. Moreover, unlike most natural languages that follow the linear-order principle, web queries can have relatively free word orders (although some orders may occur more often than others statistically). These factors make it difficult to produce reliable syntactic analysis outputs. Consequently, the head nouns and hence the IHs extracted therefrom are likely to be error-prone, as will be shown by our experiments in Section 6.3.

Although a POS tagger and a chunker may not work well on queries, their output can be used as features for learning statistical models for semantic structure extraction, which we introduce next.

4 Models

This section presents two statistical models for semantic understanding of noun phrase queries. Assuming that the intent class $c \in \mathcal{C}$ of a query is known, we cast the problem of extracting the semantic structure of the query into a joint segmentation/classification problem. At a high level, we would like to identify query segments that correspond to IHs, IMs and Others. Furthermore, for each IM segment, we would like to assign a semantic label, denoted by IM:a, $a \in \mathcal{A}_c$, indicating which attribute name it refers to. In other words, our label set consists of $\mathcal{Y} = \{\text{IH}, \{\text{IM:}a\}_{a \in \mathcal{A}_c}, \text{Other}\}$.

Formally, we let $\mathbf{x} = (x_1, x_2, \ldots, x_M)$ denote an input query of length M. To avoid confusion, we use i to represent the index of a word token and j to represent the index of a segment in the following text. Our goal is to obtain

$$\mathbf{s}^* = \operatorname*{argmax}_{\mathbf{s}} p(\mathbf{s}|c, \mathbf{x}) \tag{1}$$

where $\mathbf{s} = (s_1, s_2, \ldots, s_N)$ denotes a query segmentation as well as a classification of all segments. Each segment s_j is represented by a tuple (u_j, v_j, y_j). Here u_j and v_j are the indices of the starting and ending word tokens respectively; $y_j \in \mathcal{Y}$ is a label indicating the semantic role of s. We further augment the segment sequence with two special segments: *Start* and *End*, represented by s_0 and s_{N+1} respectively. For notional simplicity, we assume that the intent class is given and use $p(\mathbf{s}|\mathbf{x})$ as a shorthand for $p(\mathbf{s}|c, \mathbf{x})$, but keep in mind that the label space and hence the parameter space is class-dependent. Now we introduce two methods of modeling $p(\mathbf{s}|\mathbf{x})$.

4.1 CRFs

One natural approach to extracting the semantic structure of queries is to use linear-chain CRFs (Lafferty et al., 2001). They model the conditional probability of a label sequence given the input, where the labels, denoted as $\mathbf{y} = (y_1, y_2, \ldots, y_M)$, $y_i \in \mathcal{Y}$, have a one-to-one correspondence with the word tokens in the input.

Using linear-chain CRFs, we aim to find the label sequence that maximizes

$$p_\lambda(\mathbf{y}|\mathbf{x}) = \frac{1}{Z_\lambda(\mathbf{x})} \exp\left\{\sum_{i=1}^{M+1} \lambda \cdot f(y_{i-1}, y_i, \mathbf{x}, i)\right\}. \tag{2}$$

The partition function $Z_\lambda(\mathbf{x})$ is a normalization factor. λ is a weight vector and $f(y_{i-1}, y_i, \mathbf{x})$ is a vector of feature functions referred to as a feature vector. The features used in CRFs will be described in Section 5.

Given manually-labeled queries, we estimate λ that maximizes the conditional likelihood of training data while regularizing model parameters. The learned model is then used to predict the label sequence $\mathbf{y}$ for future input sequences $\mathbf{x}$. To obtain $\mathbf{s}$ in Equation (1), we simply concatenate the maximum number of consecutive word tokens that have the same label and treat the resulting sequence as a segment. By doing this, we implicitly assume that there are no two adjacent segments with the same label in the true segment sequence. Although this assumption is not always correct in practice, we consider it a reasonable approximation given what we empirically observed in our training data.

4.2 Semi-Markov CRFs

In contrast to standard CRFs, semi-Markov CRFs directly model the segmentation of an input sequence as well as a classification of the segments (Sarawagi and Cohen, 2004), *i.e.*,

$$p(\mathbf{s}|\mathbf{x}) = \frac{1}{Z_\lambda(\mathbf{x})} \exp \sum_{j=1}^{N+1} \lambda \cdot f(s_{j-1}, s_j, \mathbf{x}) \tag{3}$$

In this case, the features $f(s_{j-1}, s_j, \mathbf{x})$ are defined on segments instead of on word tokens. More precisely, they are of the function form $f(y_{j-1}, y_j, \mathbf{x}, u_j, v_j)$. It is easy to see that by imposing a constraint $u_i = v_i$, the model is reduced to standard linear-chain CRFs. Semi-Markov CRFs make Markov assumptions at the segment level, thereby naturally offering means to

CRF features		
A1: Transition	$\delta(y_{i-1} = a)\delta(y_i = b)$	transiting from state a to b
A2: Lexical	$\delta(x_i = w)\delta(y_i = b)$	current word is w
A3: Semantic	$\delta(x_i \in \mathcal{W}_\mathcal{L})\delta(y_i = b)$	current word occurs in lexicon $\mathcal{L}$

B7: Syntactic	$\delta(\text{Chunk}(\mathbf{x}_{u_j:v_j}) = c)\delta(y_j = b)$	Current segment is a chunk with phrase type c

Table 2: A summary of feature types in CRFs and segmental CRFs for query understanding. We assume that the state label is b in all features and omit this in the feature descriptions.

incorporate segment-level features, as will be presented in Section 5.

5 Features

In this work, we explore the use of transition, lexical, semantic and syntactic features in Markov and semi-Markov CRFs. The mathematical expression of these features are summarized in Table 2 with details described as follows.

5.1 Transition features

Transition features, *i.e.*, A1 and B1 in Table 2, capture state transition patterns between adjacent word tokens in CRFs, and between adjacent segments in semi-Markov CRFs. We only use first-order transition features in this work.

5.2 Lexical features

In CRFs, a lexical feature (A2) is implemented as a binary function that indicates whether a specific word co-occurs with a state label. The set of words to be considered in this work are those observed in the training data. We can also generalize this type of features from words to n-grams. In other words, instead of inspecting the word identity at the current position, we inspect the n-gram identity by applying a window of length n centered at the current position.

Since feature functions are defined on segments in semi-Markov CRFs, we create B2 that indicates whether the phrase in a hypothesized query segment co-occurs with a state label. Here the set of phrase identities are extracted from the query segments in the training data. Furthermore, we create another type of lexical feature, B3, which is activated when a specific word occurs in a hypothesized query segment. The use of B3 would favor unseen words being included in adjacent segments rather than to be isolated as separate segments.

5.3 Semantic features

Models relying on lexical features may require very large amounts of training data to produce accurate prediction performance, as the feature space is in general large and sparse. To make our model generalize better, we create semantic features based on what we call *lexicons*. A lexicon, denoted as $\mathcal{L}$, is a cluster of semantically-related words/phrases. For example, a cluster of movie titles or director names can be such a lexicon. Before describing how such lexicons are generated for our task, we first introduce the forms of the semantic features assuming the availability of the lexicons.

We let $\mathcal{L}$ denote a lexicon, and $\mathcal{W}_\mathcal{L}$ denote the set of n-grams extracted from $\mathcal{L}$. For CRFs, we create a binary function that indicates whether *any* n-gram in $\mathcal{W}_\mathcal{L}$ co-occurs with a state label, with $n = 1, 2$ for A3, A4 respectively. For both A3 and A4, the number of such semantic features is equal to the number of lexicons multiplied by the number of state labels.

The same source of semantic knowledge can be conveniently incorporated in semi-Markov CRFs. One set of semantic features (B4) inspect whether the phrase of a hypothesized query segment matches *any* element in a given lexicon. A second set of semantic features (B5) relax the exact match constraints made by B4, and take as the feature value the maximum "similarity" between the query segment and *all* lexicon elements. The fol-

lowing similarity function is used in this work ,

$$s(\mathbf{x}_{u_j:v_j}, l) = 1 - \text{Lev}(\mathbf{x}_{u_j:v_j}, l)/|l| \quad (4)$$

where Lev represents the Levenshtein distance. Notice that we normalize the Levenshtein distance by the length of the lexicon element, as we empirically found it performing better compared with normalizing by the length of the segment. In computing the maximum similarity, we first retrieve a set of lexicon elements with a positive *tf-idf* cosine distance with the segment; we then evaluate Equation (4) for each retrieved element and find the one with the maximum similarity score.

Lexicon generation

To create the semantic features described above, we generate two types of lexicons leveraging databases and query logs for each intent class.

The first type of lexicon is an IH lexicon comprised of a list of attribute names for the intent class, *e.g.*, "box office" and "review" for the intent class *Movie*. One easy way of composing such a list is by aggregating the column names in the corresponding database such as Table 1. However, this approach may result in low coverage on IHs for some domains. Moreover, many database column names, such as *Title*, are unlikely to appear as IHs in queries. Inspired by Pasca and Van Durme (2007), we apply a bootstrapping algorithm that automatically learns attribute names for an intent class from query logs. The key difference from their work is that we create templates that consist of semantic labels at the segment level from training data. For example, "alice in wonderland 2010 cast" is labeled as "IM:*Title* IM:*Year* IH", and thus "IM:*Title* + IM:*Year* + #" is used as a template. We select the most frequent templates (top 2 in this work) from training data and use them to discover new IH phrases from the query log.

Secondly, we have a set IM lexicons, each comprised of a list of attribute values of an attribute name in $\mathcal{A}_c$. We exploit internal resources to generate such lexicons. For example, the lexicon for IM:*Title* (in *Movie*) is a list of movie titles generated by aggregating the values in the *Title* column of a movie database. Similarly, the lexicon for IM:*Employee* (in *Job*) is a list of employee names extracted from a job listing database. Note that a substantial amount of research effort has been dedicated to automatic lexicon acquisition from the Web (Pantel and Pennacchiotti, 2006; Pennacchiotti and Pantel, 2009). These techniques can be used in expanding the semantic lexicons for IMs when database resources are not available. But we do not use such techniques in our work since the lexicons extracted from databases in general have good precision and coverage.

5.4 Syntactic features

As mentioned in Section 3.2, web queries often lack syntactic cues and do not necessarily follow the linear order principle. Consequently, applying syntactic analysis such as POS tagging or chunking using models trained on natural language corpora is unlikely to give accurate results on web queries, as supported by our experimental evidence in Section 6.3. It may be beneficial, however, to use syntactic analysis results as additional evidence in learning.

To this end, we generate a sequence of POS tags for a given query, and use the co-occurrence of POS tag identities and state labels as syntactic features (A5) for CRFs.

For semi-Markov CRFs, we instead examine the POS tag sequence of the corresponding phrase in a query segment. Again their identities are combined with state labels to create syntactic features B6. Furthermore, since it is natural to incorporate segment-level features in semi-Markov CRFs, we can directly use the output of a syntactic chunker. To be precise, if a query segment is determined by the chunker to be a chunk, we use the indicator of the phrase type of the chunk (*e.g.*, NP, PP) combined with a state label as the feature, denoted by B7 in the Table. Such features are not activated if a query segment is determined not to be a chunk.

6 Evaluation

6.1 Data

To evaluate our proposed models and features, we collected queries from three domains, *Movie*, *Job* and *National Park*, and had them manually annotated. The annotation was given on both segmentation of the queries and classification of the segments according to the label sets defined in Table 3. There are 1000/496 samples in the training/test set for the *Movie* domain, 600/366 for the *Job* domain and 491/185 for the *National Park* domain. In evaluation, we report the test-set performance in each domain as well as the average performance (weighted by their respectively test-set size) over all domains.

Movie		Job		National Park	
IH	trailer, box office	IH	listing, salary	IH	lodging, calendar
IM:*Award*	oscar best picture	IM:*Category*	engineering	IM:*Category*	national forest
IM:*Cast*	johnny depp	IM:*City*	las vegas	IM:*City*	page
IM:*Character*	michael corleone	IM:*County*	orange	IM:*Country*	us
IM:*Category*	tv series	IM:*Employer*	walmart	IM:*Name*	yosemite
IM:*Country*	american	IM:*Level*	entry level	IM:*POI*	volcano
IM:*Director*	steven spielberg	IM:*Salary*	high-paying	IM:*Rating*	best
IM:*Genre*	action	IM:*State*	florida	IM:*State*	flordia
IM:*Rating*	best	IM:*Type*	full time		
IM:*Title*	the godfather				
Other	the, in, that	Other	the, in, that	Other	the, in, that

Table 3: Label sets and their respective query segment examples for the intent class *Movie*, *Job* and *National Park*.

6.2 Metrics

There are two evaluation metrics used in our work: segment F1 and sentence accuracy (Acc). The first metric is computed based on precision and recall at the segment level. Specifically, let us assume that the true segment sequence of a query is $\mathbf{s} = (s_1, s_2, \ldots, s_N)$, and the decoded segment sequence is $\mathbf{s}' = (s'_1, s'_2, \ldots, s'_K)$. We say that s'_k is a true positive if $s'_k \in \mathbf{s}$. The precision and recall, then, are measured as the total number of true positives divided by the total number of decoded and true segments respectively. We report the F1-measure which is computed as $2 \cdot \text{prec} \cdot \text{recall}/(\text{prec} + \text{recall})$.

Secondly, a sentence is correct if all decoded segments are true positives. Sentence accuracy is measured by the total number of correct sentences divided by the total number of sentences.

6.3 Results

We start with models that incorporate first-order transition features which are standard for both Markov and semi-Markov CRFs. We then experiment with lexical features, semantic features and syntactic features for both models. Table 4 and Table 5 give a summarization of all experimental results.

Lexical features

The first experiment we did is to evaluate the performance of lexical features (combined with transition features). This involves the use of A2 in Table 2 for CRFs, and B2 and B3 for semi-Markov CRFs. Note that adding B3, *i.e.,* indicators of whether a query segment contains a word identity, gave an absolute 7.0%/3.2% gain in sentence accuracy and segment F1 on average, as shown in the row B1-B3 in Table 5. For both A2 and B3, we also tried extending the features based on word IDs to those based on n-gram IDs, where $n = 1, 2, 3$. This greatly increased the number of lexical features but did not improve learning performance, most likely due to the limited amounts of training data coupled with the sparsity of such features. In general, lexical features do not generalize well to the test data, which accounts for the relatively poor performance of both models.

Semantic features

We created IM lexicons from three in-house databases on *Movie*, *Job* and *National Parks*. Some lexicons, *e.g.*, IM:*State*, are shared across domains. Regarding IH lexicons, we applied the bootstrapping algorithm described in Section 5.3 to a 1-month query log of *Bing*. We selected the most frequent 57 and 131 phrases to form the IH lexicons for *Movie* and *National Park* respectively. We do not have an IH lexicon for *Job* as the attribute names in that domain are much fewer and are well covered by training set examples.

We implemented A3 and A4 for CRFs, which are based on the n-gram sets created from lexicons; and B4 and B5 for semi-Markov CRFs, which are based on exact and fuzzy match with lexicon items. As shown in Table 4 and 5, drastic increases in sentence accuracies and F1-measures were observed for both models.

Syntactic features

As shown in the row A1-A5 in Table 4, combined with all other features, the syntactic features (A5) built upon POS tags boosted the CRF model performance. Table 6 listed the most dominant positive and negative features based on POS tags for *Movie* (features for the other two domains are not reported due to space limit). We can see that many of these features make intuitive sense. For

	Movie		Job		National Park		Average	
Features	Acc	F1	Acc	F1	Acc	F1	Acc	F1
A1,A2: Tran + Lex	59.9	75.8	65.6	84.7	61.6	75.6	62.1	78.9
A1-A3: Tran + Lex + Sem	67.9	80.2	70.8	87.4	70.5	80.8	69.4	82.8
A1-A4: Tran + Lex + Sem	72.4	83.5	72.4	89.7	71.1	82.3	72.2	85.0
A1-A5: Tran + Lex + Sem + Syn	74.4	84.8	75.1	89.4	75.1	85.4	74.8	86.5
A2-A5: Lex + Sem + Syn	64.9	78.8	68.1	81.1	64.8	83.7	65.4	81.0

Table 4: Sentence accuracy (Acc) and segment F1 (F1) using CRFs with different features.

	Movie		Job		National Park		Average	
Features	Acc	F1	Acc	F1	Acc	F1	Acc	F1
B1,B2: Tran + Lex	53.4	71.6	59.6	83.8	60.0	77.3	56.7	76.9
B1-B3: Tran + Lex	61.3	77.7	65.9	85.9	66.0	80.7	63.7	80.1
B1-B4: Tran + Lex + Sem	73.8	83.6	76.0	89.7	74.6	85.3	74.7	86.1
B1-B5: Tran + Lex + Sem	75.0	84.3	76.5	89.7	76.8	86.8	75.8	86.6
B1-B6: Tran + Lex + Sem + Syn	75.8	84.3	76.2	89.7	76.8	87.2	**76.1**	**86.7**
B1-B5,B7: Tran + Lex + Sem + Syn	75.6	84.1	76.0	89.3	76.8	86.8	75.9	86.4
B2-B6:Lex + Sem + Syn	72.0	82.0	73.2	87.9	76.5	89.3	73.8	85.6

Table 5: Sentence accuracy (Acc) and segment F1 (F1) using semi-Markov CRFs with different features.

example, IN (preposition or subordinating conjunction) is a strong indicator of Other, while TO and IM:*Date* usually do not co-occur. Some features, however, may appear less "correct". This is largely due to the inaccurate output of the POS tagger. For example, a large number of actor names were mis-tagged as RB, resulting in a high positive weight of the feature (RB, IM:*Cast*).

Positive	Negative
(IN, Other),	(TO, IM:*Date*)
(VBD, Other)	(IN, IM:*Cast*)
(CD, IM:*Date*)	(CD, IH)
(RB, IM:*Cast*)	(IN, IM:*Character*)

Table 6: Syntactic features with the largest positive/negative weights in the CRF model for *Movie*

Similarly, we added segment-level POS tag features (B6) to semi-Markov CRFs, which lead to the best overall results as shown by the highlighted numbers in Table 5. Again many of the dominant features are consistent with our intuition. For example, the most positive feature for *Movie* is (CD JJS, IM:*Rating*) (*e.g.* 100 best). When syntactic features based on chunking results (B7) are used instead of B6, the performance is not as good.

Transition features

In addition, it is interesting to see the importance of transition features in both models. Since web queries do not generally follow the linear order principle, is it helpful to incorporate transition features in learning? To answer this question, we dropped the transition features from the best systems, corresponding to the last rows in Table 4 and 5. This resulted in substantial degradations in performance. One intuitive explanation is that although web queries are relatively "order-free", statistically speaking, some orders are much more likely to occur than others. This makes it beneficial to use transition features.

Comparison to syntactic analysis

Finally, we conduct a simple experiment by using the heuristics described in Section 3.2 in extracting IHs from queries. The precision and recall of IHs averaged over all 3 domains are 50.4% and 32.8% respectively. The precision and recall numbers from our best model-based system, *i.e.*, B1-B6 in Table 5, are 89.9% and 84.6% respectively, which are significantly better than those based on pure syntactic analysis.

7 Conclusions

In this work, we make the first attempt to define the semantic structure of noun phrase queries. We propose statistical methods to automatically extract IHs, IMs and the semantic labels of IMs using a variety of features. Experiments show the effectiveness of semantic features and syntactic features in both Markov and semi-Markov CRF models. In the future, it would be useful to explore other approaches to automatic lexicon discovery to improve the quality or to increase the coverage of both IH and IM lexicons, and to systematically evaluate their impact on query understanding performance.

The author would like to thank Hisami Suzuki and Jianfeng Gao for useful discussions.

Multilingual Pseudo-Relevance Feedback: Performance Study of Assisting Languages

Manoj K. Chinnakotla Karthik Raman Pushpak Bhattacharyya

Mumbai, India
{manoj,karthikr,pb}@cse.iitb.ac.in

Abstract

In a previous work of ours Chinnakotla et al. (2010) we introduced a novel framework for Pseudo-Relevance Feedback (PRF) called *MultiPRF*. Given a query in one language called *Source*, we used English as the *Assisting Language* to improve the performance of PRF for the source language. MulitiPRF showed remarkable improvement over plain Model Based Feedback (MBF) uniformly for 4 languages, *viz., French, German, Hungarian* and *Finnish* with *English* as the assisting language. This fact inspired us to study the effect of *any source-assistant* pair on MultiPRF performance from out of a set of languages with widely different characteristics, *viz., Dutch, English, Finnish, French, German* and *Spanish*. Carrying this further, we looked into the effect of using *two assisting languages together* on PRF.

The present paper is a report of these investigations, their results and conclusions drawn therefrom. While performance improvement on MultiPRF is observed whatever the assisting language and whatever the source, observations are mixed when two assisting languages are used simultaneously. Interestingly, the performance improvement is more pronounced when the source and assisting languages are *closely related*, e.g., French and Spanish.

1 Introduction

The central problem of Information Retrieval (IR) is to satisfy the user's information need, which is typically expressed through a short (typically 2-3 words) and often ambiguous query. The problem of matching the user's query to the documents is rendered difficult by natural language phenomena like *morphological variations*, *polysemy* and *synonymy*. Relevance Feedback (RF) tries to overcome these problems by eliciting user feedback on the relevance of documents obtained from the initial ranking and then uses it to automatically refine the query. Since user input is hard to obtain, Pseudo-Relevance Feedback (PRF) (Buckley et al., 1994; Xu and Croft, 2000; Mitra et al., 1998) is used as an alternative, wherein RF is performed by *assuming* the top k documents from the initial retrieval as being *relevant* to the query. Based on the above assumption, the terms in the feedback document set are analyzed to choose the most distinguishing set of terms that characterize the feedback documents and as a result the relevance of a document. Query refinement is done by adding the terms obtained through PRF, along with their weights, to the actual query.

Although PRF has been shown to improve retrieval, it suffers from the following drawbacks: (a) the type of term associations obtained for query expansion is restricted to co-occurrence based relationships in the feedback documents, and thus other types of term associations such as lexical and semantic relations (morphological variants, synonyms) are not explicitly captured, and (b) due to the inherent assumption in PRF, *i.e.*, relevance of top k documents, performance is sensitive to that of the initial retrieval algorithm and as a result is not robust.

Multilingual Pseudo-Relevance Feedback (MultiPRF) (Chinnakotla et al., 2010) is a novel framework for PRF to overcome both the above limitations of PRF. It does so by taking the help of a different language called the *assisting language*. In MultiPRF, given a query in source language L_1, the query is automatically translated into the assisting language L_2 and PRF performed in the assisting language. The resultant terms are translated back into L_1 using a probabilistic bi-lingual dictionary. The translated feedback

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1346–1356,
Uppsala, Sweden, 11-16 July 2010.

model, is then combined with the original feedback model of L_1 to obtain the final model which is used to re-rank the corpus. MulitiPRF showed remarkable improvement on standard CLEF collections over plain Model Based Feedback (MBF) uniformly for 4 languages, *viz., French, German, Hungarian* and *Finnish* with *English* as the assisting language. This fact inspired us to study the effect of *any source-assistant* pair on PRF performance from out of a set of languages with widely different characteristics, *viz., Dutch, English, Finnish, French, German* and *Spanish*. Carrying this further, we looked into the effect of using *two assisting languages together* on PRF.

The present paper is a report of these investigations, their results and conclusions drawn therefrom. While performance improvement on PRF is observed whatever the assisting language and whatever the source, observations are mixed when two assisting languages are used simultaneously. Interestingly, the performance improvement is more pronounced when the source and assisting languages are *closely related*, e.g., French and Spanish.

The paper is organized as follows: Section 2, discusses the related work. Section 3, explains the Language Modeling (LM) based PRF approach. Section 4, describes the MultiPRF approach. Section 5 discusses the experimental set up. Section 6 presents the results, and studies the effect of varying the assisting language and incorporates multiple assisting languages. Finally, Section 7 concludes the paper by summarizing and outlining future work.

2 Related Work

PRF has been successfully applied in various IR frameworks like vector space models, probabilistic IR and language modeling (Buckley et al., 1994; Jones et al., 2000; Lavrenko and Croft, 2001; Zhai and Lafferty, 2001). Several approaches have been proposed to improve the performance and robustness of PRF. Some of the representative techniques are (i) Refining the feedback document set (Mitra et al., 1998; Sakai et al., 2005), (ii) Refining the terms obtained through PRF by selecting good expansion terms (Cao et al., 2008) and (iii) Using selective query expansion (Amati et al., 2004; Cronen-Townsend et al., 2004) and (iv) Varying the importance of documents in the feedback set (Tao and Zhai, 2006). Another direction of work, often reported in the TREC Robust Track, is to use a large external collection like Wikipedia or the Web as a source of expansion terms (Xu et al., 2009; Voorhees, 2006). The intuition behind the above approach is that if the query does not have many relevant documents in the collection then any improvements in the modeling of PRF is bound to perform poorly due to query drift.

Several approaches have been proposed for including different types of lexically and semantically related terms during query expansion. Voorhees (1994) use Wordnet for query expansion and report negative results. Recently, random walk models (Lafferty and Zhai, 2001; Collins-Thompson and Callan, 2005) have been used to learn a rich set of term level associations by combining evidence from various kinds of information sources like WordNet, Web *etc*. Metzler and Croft (2007) propose a feature based approach called *latent concept expansion* to model term dependencies.

All the above mentioned approaches use the resources available *within* the language to improve the performance of PRF. However, we make use of a *second language* to improve the performance of PRF. Our proposed approach is especially attractive in the case of resource-constrained languages where the original retrieval is bad due to poor coverage of the collection and/or inherent complexity of query processing (for example *term conflation*) in those languages.

Jourlin et al. (1999) use parallel blind relevance feedback, *i.e.* they use blind relevance feedback on a larger, more reliable parallel corpus, to improve retrieval performance on imperfect transcriptions of speech. Another related idea is by Xu et al. (2002), where a statistical thesaurus is learned using the probabilistic bilingual dictionaries of Arabic to English and English to Arabic. Meij et al. (2009) tries to expand a query in a different language using language models for domain-specific retrieval, but in a very different setting. Since our method uses a corpus in the assisting language from a similar time period, it can be likened to the work by Talvensaari et al. (2007) who used comparable corpora for Cross-Lingual Information Retrieval (CLIR). Other work pertaining to document alignment in comparable corpora, such as Braschler and Schäuble (1998), Lavrenko et al. (2002), also share certain common themes with our approach. Recent work by Gao et al.

(2008) uses English to improve the performance over a subset of Chinese queries whose translations in English are unambiguous. They use inter-document similarities across languages to improve the ranking performance. However, cross language document similarity measurement is in itself known to be an hard problem and the scale of their experimentation is quite small.

3 PRF in the LM Framework

The Language Modeling (LM) Framework allows PRF to be modelled in a principled manner. In the LM approach, documents and queries are modeled using multinomial distribution over words called *document language model* $P(w|D)$ and *query language model* $P(w|\Theta_Q)$ respectively. For a given query, the document language models are ranked based on their proximity to the query language model, measured using KL-Divergence.

$$KL(\Theta_Q||D) = \sum_w P(w|\Theta_Q) \cdot log \frac{P(w|\Theta_Q)}{P(w|D)}$$

Since the query length is short, it is difficult to estimate Θ_Q accurately using the query alone. In PRF, the top *k* documents obtained through the initial ranking algorithm are assumed to be relevant and used as feedback for improving the estimation of Θ_Q. The feedback documents contain both relevant and noisy terms from which the feedback language model is inferred based on a Generative Mixture Model (Zhai and Lafferty, 2001).

Let $D_F = \{d_1, d_2, \ldots, d_k\}$ be the top k documents retrieved using the initial ranking algorithm. Zhai and Lafferty (Zhai and Lafferty, 2001) model the feedback document set D_F as a mixture of two distributions: (a) the *feedback language model* and (b) the *collection model* $P(w|C)$. The feedback language model is inferred using the EM Algorithm (Dempster et al., 1977), which iteratively accumulates probability mass on the most *distinguishing* terms, *i.e.* terms which are more frequent in the feedback document set than in the entire collection. To maintain query focus the final converged feedback model, Θ_F is interpolated with the initial query model Θ_Q to obtain the final query model Θ_{Final}.

$$\Theta_{Final} = (1 - \alpha) \cdot \Theta_Q + \alpha \cdot \Theta_F$$

Θ_{Final} is used to re-rank the corpus using the KL-Divergence ranking function to obtain the final ranked list of documents. Henceforth, we refer to the above technique as *Model Based Feedback (MBF)*.

4 Multilingual PRF (MultiPRF)

The schematic of the MultiPRF approach is shown in Figure 1. Given a query Q in the source language L_1, we automatically translate the query into the assisting language L_2. We then rank the documents in the L_2 collection using the query likelihood ranking function (John Lafferty and Chengxiang Zhai, 2003). Using the top k documents, we estimate the feedback model using MBF as described in the previous section. Similarly, we also estimate a feedback model using the original query and the top k documents retrieved from the initial ranking in L_1. Let the resultant feedback models be $\Theta^F_{L_2}$ and $\Theta^F_{L_1}$ respectively. The feedback model estimated in the assisting language $\Theta^F_{L_2}$ is translated back into language L_1 using a probabilistic bi-lingual dictionary $t(f|e)$ from $L_2 \rightarrow L_1$ as follows:

$$P(f|\Theta^{Trans}_{L_1}) = \sum_{\forall\ e \text{ in } L_2} t(f|e) \cdot P(e|\Theta^F_{L_2}) \quad (1)$$

The probabilistic bi-lingual dictionary $t(f|e)$ is

Source Term	Top Aligned Terms in Target
French	**English**
américain	american, us, united, state, america
nation	nation, un, united, state, country
eťude	study, research, assess, investigate, survey
German	**English**
flugzeug	aircraft, plane, aeroplane, air, flight
spiele	play, game, stake, role, player
verhältnis	relationship, relate, balance, proportion

Table 3: Top Translation Alternatives for some sample words in Probabilistic Bi-Lingual Dictionary

learned from a parallel sentence-aligned corpora in $L_1 - L_2$ based on word level alignments. Tiedemann (Tiedemann, 2001) has shown that the translation alternatives found using word alignments could be used to infer various morphological and semantic relations between terms. In Table 3, we show the top translation alternatives for some sample words. For example, the French word *américain* (american) brings different variants of the translation like *american, america, us, united, state, america* which are lexically and semantically related. Hence, the probabilistic bi-lingual dictionary acts as a rich source of morphologically and semantically related feedback terms. Thus, during this step, of translating the feedback model as given in Equation 1, the translation model adds related terms in L_1 which have their source as the term from feedback model $\Theta^F_{L_2}$. The final MultiPRF model is obtained by interpolating the above translated feedback model with the original query model and the feedback model of language L_1 as given below:

$$\Theta^{Multi}_{L_1} = (1 - \beta - \gamma) \cdot \Theta_Q + \beta \cdot \Theta^F_{L_1} + \gamma \cdot \Theta^{Trans}_{L_1} \quad (2)$$

Since we want to retain the query focus during back translation the feedback model in L_2 is interpolated with the translated query before translation of the L_2 feedback model. The parameters β and γ control the relative importance of the original query model, feedback model of L_1 and the translated feedback model obtained from L_1 and are tuned based on the choice of L_1 and L_2.

5 Experimental Setup

We evaluate the performance of our system using the standard CLEF evaluation data in six languages, widely varying in their familial relationships - Dutch, German, English, French, Spanish and Finnish using more than 600 topics. The details of the collections and their corresponding topics used for MultiPRF are given in Table 1. Note that, in each experiment, we choose assisting collections such that the topics in the source language are covered in the assisting collection so as to get meaningful feedback terms. In all the topics, we only use the *title* field. We ignore the topics which have no relevant documents as the true performance on those topics cannot be evaluated.

We demonstrate the performance of MultiPRF approach with French, German and Finnish as source languages and Dutch, English and Spanish as the assisting language. We later vary the assisting language, for each source language and study the effects. We use the Terrier IR platform (Ounis et al., 2005) for indexing the documents. We perform standard tokenization, stop word removal and stemming. We use the Porter Stemmer for English and the stemmers available through the Snowball package for other languages. Other than these, we do not perform any language-specific processing on the languages. In case of French,

Table 4: Results comparing the performance of MultiPRF over baseline MBF on CLEF collections with English (EN), Spanish (ES) and Dutch (NL) as assisting languages. Results marked as ‡ indicate that the improvement was found to be statistically significant over the baseline at 90% confidence level ($\alpha = 0.01$) when tested using a paired two-tailed t-test.

since some function words like *l'*, *d' etc.,* occur as prefixes to a word, we strip them off during indexing and query processing, since it significantly improves the baseline performance. We use standard evaluation measures like *MAP*, *P@5* and *P@10* for evaluation. Additionally, for assessing robustness, we use the Geometric Mean Average Precision (GMAP) metric (Robertson, 2006) which is also used in the TREC Robust Track (Voorhees, 2006). The probabilistic bi-lingual dictionary used in MultiPRF was learnt automatically by running GIZA++: a word alignment tool (Och and Ney, 2003) on a parallel sentence aligned corpora. For all the above language pairs we used the *Europarl Corpus* (Philipp, 2005). We use Google Translate as the query translation system as it has been shown to perform well for the task (Wu et al., 2008). We use the MBF approach explained in Section 3 as a baseline for comparison. We use two-stage Dirichlet smoothing with the optimal parameters tuned based on the collection (Zhai and Lafferty, 2004). We tune the parameters of MBF, specifically λ and α, and choose the values which give the optimal performance on a given collection. We uniformly choose the top ten documents for feedback. Table 4 gives the overall results.

6 Results and Discussion

In Table 4, we see the performance of the MultiPRF approach for three assisting languages, and how it compares with the baseline MBF methods. We find MultiPRF to consistently outperform the baseline value on all metrics, namely MAP (where significant improvements range from 4.4% to 7.1%); P@5 (significant improvements range from 4.9% to 39.5% and P@10 (where MultiPRF has significant gains varying from 4% to 22.8%). Additionally we also find MultiPRF to be more robust than the baseline, as indicated by the GMAP score, where improvements vary from 4.2% to 730%. Furthermore we notice these trends hold across different assisting languages, with Spanish and Dutch outperforming English as the assisting language on some of the French and German collections. On performing a more detailed study of the results we identify the main reason for improvements in our approach is the ability to obtain good feedback terms in the assisting language coupled with the introduction of lexically and semantically related terms during the back-translation step.

In Table 5, we see some examples, which illustrates the feedback terms brought by the MultiPRF method. As can be seen by these example, the gains achieved by MultiPRF are primarily due to one of three reasons: (a) Good Feedback in Assisting Language: If the feedback model in the assisting language contains good terms, then the back-translation process will introduce the corresponding feedback terms in the source language, thus leading to improved performance. As an example of this phenomena, consider the French Query *"Maladie de Creutzfeldt-Jakob"*. In this case the original feedback model also performs

Table 5: Qualitative comparison of feedback terms given by MultiPRF and MBF on representative queries where positive and negative results were observed in French and German collections.

quite strongly with a MAP score of 0.507. Although there is no significant topic drift in this case, there are not many relevant terms apart from the query terms. However the same query performs very well in English with all the documents in the feedback set of the English corpus being relevant, thus resulting in informative feedback terms such as {*bovin, scientif, recherch*}. (b) Finding Synonyms/Morphological Variations: Another situation in which MultiPRF leads to large improvements is when it finds semantically/lexically related terms to the query terms which the original feedback model was unable to. For example, consider the French query *"Ingénierie g´n´tique"*. While the feedback model was unable to find any of the synonyms of the query terms, due to their lack of co-occurence with the query terms, the MultiPRF model was able to get these terms, which are introduced primarily during the back-translation process. Thus terms like {*genetic, gen, engineering*}, which are synonyms of the query words, are found thus resulting in improved performance. (c) Combination of Above Factors: Sometimes a combination of the above two factors causes improvements in the performance as in the German query *"Ölkatastrophein Sibirien"*. For this query, MultiPRF finds good feedback terms such as {*russisch, russland*} while also obtaining semantically related terms such as {*olverschmutz, erdol, olunfall*}.

Although all of the previously described examples had good quality translations of the query in the assisting language, as mentioned in (Chinnakotla et al., 2010), the MultiPRF approach is robust to suboptimal translation quality as well. To see how MultiPRF leads to improvements even with errors in query translation consider the German Query *"Siegerinnen von Wimbledon"*. When this is translated to English, the term "Lady" is dropped, this causes only "Wimbledon Champions" to remain. As can be observed, this causes terms like *sampras* to come up in the MultiPRF model. However, while the MultiPRF model has some terms pertaining to Men's Winners of Wimbledon as well, the original feedback model suffers from severe topic drift, with irrelevant terms such as {*telefonbuch, telekom*} also amongst the top terms. Thus we notice that despite the error in query translation MultiPRF still manages to correct the drift of the original feedback model, while also introducing relevant terms such as {*verfecht, steffi, martina, novotna, navratilova*} as well. Thus as shown in (Chinnakotla et al., 2010), having a better query translation system can only lead to better performance. We also perform a detailed error analysis and found three main reasons for MultiPRF failing: (i) Inaccuracies in query translation (including the presence of out-of-vocabulary terms). This is seen in the German Query *AI in Lateinamerika*, which wrongly translates to *Avian Flu in Latin America* in Spanish thus affecting performance. (ii) Poor retrieval in Assisting Language. Consider the French query *Les droits de l'enfant*, for which due to topic drift in English, MultiPRF performance reduces. (iii) In a few rare cases inaccuracy in the back transla-

Figure 2: Results showing the sensitivity of MultiPRF performance to parameters β and γ for French, German and Finnish.

tion affects performance as well.

6.1 Parameter Sensitivity Analysis

The MultiPRF parameters β and γ in Equation 2 control the relative importance assigned to the original feedback model in source language L_1, the translated feedback model obtained from assisting language L_2 and the original query terms. We varied the β and γ parameters for French, German and Finnish collections with English, Dutch and Spanish as assisting languages and studied its effect on MAP of MultiPRF. The results are shown in Figure 2. The results show that, in all the three collections, the optimal value of the parameters almost remains the same and lies in the range of 0.4-0.48. Due to the above reason, we arbitrarily choose the parameters in the above range and do not use any technique to learn these parameters.

6.2 Effect of Assisting Language Choice

In this section, we discuss the effect of varying the assisting language. Besides, we also study the inter and intra familial behaviour of source-assisting language pairs. In order to ensure that the results are comparable across languages, we indexed the collections from the years 2002, 2003 and use common topics from the topic range 91-200 that have relevant documents across all the six languages. The number of such common topics were 67. For each source language, we use the other languages as assisting collections and study the performance of MultiPRF. Since query translation quality varies across language pairs, we analyze the behaviour of MultiPRF in the following two scenarios: (a) Using ideal query translation (b) Using Google Translate for query translation. In ideal query translation setup, in order to eliminate its effect, we skip the query translation step and use the corresponding original topics for each target language instead. The results for both the above scenarios are given in Tables 6 and 7.

From the results, we firstly observe that besides English, other languages such as French, Spanish, German and Dutch act as good assisting languages and help in improving performance over monolingual MBF. We also observe that the best assisting language varies with the source language. However, the crucial factors of the assisting language which influence the performance of MultiPRF are: (a) *Monolingual PRF Performance:* The main motivation for using a different language was to get good feedback terms, especially in case of queries which fail in the source language. Hence, an assisting language in which the monolingual feedback performance itself is poor, is unlikely to give any performance gains. This observation is evident in case of Finnish, which has the lowest Monolingual MBF performance. The results show that Finnish is the least helpful of assisting languages, with performance similar to those of the baselines. We also observe that the three best performing assistant languages, i.e. English, French and Spanish, have the highest monolingual performances as well, thus further validating the claim. One possible reason for this is the relative

Table 6: Results showing the performance of MultiPRF with different source and assisting languages using Google Translate for query translation step. The intra-familial affinity could be observed from the elements close to the diagonal.

ease of processing in these languages. (b) *Familial Similarity Between Languages:* We observe that the performance of MultiPRF is good if the assisting language is from the same language family. Birch et al. (2008) show that the language family is a strong predictor of machine translation performance. Hence, the query translation and back translation quality improves if the source and assisting languages belong to the same family. For example, in the Germanic family, the source-assisting language pairs German-English, Dutch-English, Dutch-German and German-Dutch show good performance. Similarly, in Romance family, the performance of French-Spanish confirms this behaviour. In some cases, we observe that MultiPRF scores decent improvements even when the assisting language does not belong to the same language family as witnessed in French-English and English-French. This is primarily due to their strong monolingual MBF performance.

6.3 Effect of Language Family on Back Translation Performance

As already mentioned, the performance of MultiPRF is good if the source and assisting languages belong to the same family. In this section, we verify the above intuition by studying the impact of language family on back translation performance. The experiment designed is as follows: Given a query in source language L_1, the ideal translation in assisting language L_2 is used to compute the query model in L_2 using only the query terms. Then, without performing PRF the query model is directly back translated from L_2 into L_1 and finally documents are re-ranked using this translated feedback model. Since the automatic query translation and PRF steps have been eliminated, the only factor which influences the MultiPRF performance is the back-translation step. This means that the source-assisting language pairs for which the back-translation is good will score a higher performance. The results of the above experiment is shown in Table 8. For each source language, the best performing assisting languages have been highlighted.

Source Lang.	Assisting Language							
	FR	ES	DE	NL	EN	FI	MBF	MPRF
French	-	**0.3686**	0.3113	0.3366	**0.4338**	0.3011	0.4342	0.4535
Spanish	**0.3647**	-	0.3440	0.3476	**0.3954**	0.3036	0.5000	0.4892
German	0.2729	0.2736	-	**0.2951**	0.2107	0.2266	0.4229	0.4576
Dutch	0.2663	0.2836	**0.2902**	-	0.2757	0.2372	0.3968	0.3989

Table 8: Effect of Language Family on Back Translation Performance measured through MultiPRF MAP. 100 Topics from years 2001 and 2002 were used for all languages.

The results show that the performance of closely related languages like French-Spanish and German-Dutch is more when compared to other source-assistant language pairs. This shows that in case of closely related languages, the back-translation step succeeds in adding good terms which are relevant like morphological variants, synonyms and other semantically related terms. Hence, familial closeness of the assisting language helps in boosting the MultiPRF performance. An exception to this trend is English as assisting lan-

guage which shows good performance across both families.

6.4 Multiple Assisting Languages

So far, we have only considered a single assisting language. However, a natural extension to the method which comes to mind, is using multiple assisting languages. In other words, combining the evidence from all the feedback models of more than one assisting language, to get a feedback model which is better than that obtained using a single assisting language. To check how this simple extension works, we performed experiments using a pair of assisting languages. In these experiments for a given source language (from amongst the 6 previously mentioned languages) we tried using all pairs of assisting languages (for each source language, we have 10 pairs possible). To obtain the final model, we simply interpolate all the feedback models with the initial query model, in a similar manner as done in MultiPRF. The results for these experiments are given in Table 9. As we see, out of the 60 possible combinations of source language and assisting language pairs, we obtain improvements of greater than 3% in 16 cases. Here the improvements are with respect to the best model amongst the two MultiPRF models corresponding to each of the two assisting languages, with the same source language. Thus we observe that a simple linear interpolation of models is not the best way of combining evidence from multiple assisting languages. We also observe than when German or Spanish are used as one of the two assisting languages, they are most likely to lead to improvements. A more detailed study of this observation needs to be done to explain this.

Source Language	Assisting Language Pairs with Improvement >3%
English	FR-DE (4.5%), FR-ES (4.8%), DE-NL (+3.1%)
French	EN-DE (4.1%), DE-ES (3.4%), NL-FI (4.8%)
German	None
Spanish	None
Dutch	EN-DE (3.9%), DE-FR (4.1%), FR-ES (3.8%), DE-ES (3.9%)
Finnish	EN-ES (3.2%), FR-DE (4.6%), FR-ES (6.4%), DE-ES (11.2%), DE-NL (4.4%), ES-NL (5.9%)
Total - 16	EN – 3 Pairs; FR – 6 Pairs; DE – 10 Pairs; ES - 8 Pairs; NL – 4 Pairs; FI – 1 Pair

Table 9: Summary of MultiPRF Results with Two Assisting Languages. The improvements described above are with respect to maximum MultiPRF MAP obtained using either L_1 or L_2 alone as assisting language.

7 Conclusion and Future Work

We studied the effect of different *source-assistant* pairs and multiple assisting languages on the performance of MultiPRF. Experiments across a wide range of language pairs with varied degree of familial relationships show that MultiPRF improves performance in most cases with the performance improvement being more pronounced when the source and assisting languages are *closely related*. We also notice that the results are mixed when two assisting languages are used simultaneously. As part of future work, we plan to vary the model interpolation parameters dynamically to improve the performance in case of multiple assisting languages.

Wikipedia as Sense Inventory to Improve Diversity in Web Search Results

Abstract

Is it possible to use sense inventories to improve Web search results diversity for one word queries? To answer this question, we focus on two broad-coverage lexical resources of a different nature: WordNet, as a de-facto standard used in Word Sense Disambiguation experiments; and Wikipedia, as a large coverage, updated encyclopaedic resource which may have a better coverage of relevant senses in Web pages.

Our results indicate that (i) Wikipedia has a much better coverage of search results, (ii) the distribution of senses in search results can be estimated using the internal graph structure of the Wikipedia and the relative number of visits received by each sense in Wikipedia, and (iii) associating Web pages to Wikipedia senses with simple and efficient algorithms, we can produce modified rankings that cover 70% more Wikipedia senses than the original search engine rankings.

1 Motivation

The application of Word Sense Disambiguation (WSD) to Information Retrieval (IR) has been subject of a significant research effort in the recent past. The essential idea is that, by indexing and matching word senses (or even meanings) , the retrieval process could better handle polysemy and synonymy problems (Sanderson, 2000). In practice, however, there are two main difficulties: (i) for long queries, IR models implicitly perform disambiguation, and thus there is little room for improvement. This is the case with most standard IR benchmarks, such as TREC (trec.nist.gov) or CLEF (www.clef-campaign.org) ad-hoc collections; (ii) for very short queries, disambiguation may not be possible or even desirable. This is often the case with one word and even two word queries in Web search engines.

In Web search, there are at least three ways of coping with ambiguity:

- Promoting diversity in the search results (Clarke et al., 2008): given the query "*oasis*", the search engine may try to include representatives for different senses of the word (such as the Oasis band, the Organization for the Advancement of Structured Information Standards, the online fashion store, etc.) among the top results. Search engines are supposed to handle diversity as one of the multiple factors that influence the ranking.

- Presenting the results as a set of (labelled) clusters rather than as a ranked list (Carpineto et al., 2009).

- Complementing search results with search suggestions (e.g. "*oasis band*", "*oasis fashion store*") that serve to refine the query in the intended way (Anick, 2003).

All of them rely on the ability of the search engine to cluster search results, detecting topic similarities. In all of them, disambiguation is implicit, a side effect of the process but not its explicit target. Clustering may detect that documents about the Oasis band and the Oasis fashion store deal with unrelated topics, but it may as well detect a group of documents discussing why one of the Oasis band members is leaving the band, and another group of documents about Oasis band lyrics; both are different aspects of the broad topic Oasis band. A perfect hierarchical clustering should distinguish between the different Oasis senses at a first level, and then discover different topics within each of the senses.

Is it possible to use sense inventories to improve search results for one word queries? To answer

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1357–1366,
Uppsala, Sweden, 11-16 July 2010.

this question, we will focus on two broad-coverage lexical resources of a different nature: WordNet (Miller et al., 1990), as a de-facto standard used in Word Sense Disambiguation experiments and many other Natural Language Processing research fields; and Wikipedia (www.wikipedia.org), as a large coverage and updated encyclopedic resource which may have a better coverage of relevant senses in Web pages.

Our hypothesis is that, under appropriate conditions, any of the above mechanisms (clustering, search suggestions, diversity) might benefit from an explicit disambiguation (classification of pages in the top search results) using a wide-coverage sense inventory. Our research is focused on four relevant aspects of the problem:

1. Coverage: Are Wikipedia/Wordnet senses representative of search results? Otherwise, trying to make a disambiguation in terms of a fixed sense inventory would be meaningless.

2. If the answer to (1) is positive, the reverse question is also interesting: can we estimate search results diversity using our sense inventories?

3. Sense frequencies: knowing sense frequencies in (search results) Web pages is crucial to have a usable sense inventory. Is it possible to estimate Web sense frequencies from currently available information?

4. Classification: The association of Web pages to word senses must be done with some unsupervised algorithm, because it is not possible to hand-tag training material for every possible query word. Can this classification be done accurately? Can it be effective to promote diversity in search results?

In order to provide an initial answer to these questions, we have built a corpus consisting of 40 nouns and 100 Google search results per noun, manually annotated with the most appropriate Wordnet and Wikipedia senses. Section 2 describes how this corpus has been created, and in Section 3 we discuss WordNet and Wikipedia coverage of search results according to our testbed. As this initial results clearly discard Wordnet as a sense inventory for the task, the rest of the paper mainly focuses on Wikipedia. In Section 4 we estimate search results diversity from our testbed, finding that the use of Wikipedia could substantially improve diversity in the top results. In Section 5 we use the Wikipedia internal link structure and the number of visits per page to estimate relative frequencies for Wikipedia senses, obtaining an estimation which is highly correlated with actual data in our testbed. Finally, in Section 6 we discuss a few strategies to classify Web pages into word senses, and apply the best classifier to enhance diversity in search results. The paper concludes with a discussion of related work (Section 7) and an overall discussion of our results in Section 8.

2 Test Set

2.1 Set of Words

The most crucial step in building our test set is choosing the set of words to be considered. We are looking for words which are susceptible to form a one-word query for a Web search engine, and therefore we should focus on nouns which are used to denote one or more named entities. At the same time we want to have some degree of comparability with previous research on Word Sense Disambiguation, which points to noun sets used in Senseval/SemEval evaluation campaigns[1]. Our budget for corpus annotation was enough for two persons-month, which limited us to handle 40 nouns (usually enough to establish statistically significant differences between WSD algorithms, although obviously limited to reach solid figures about the general behaviour of words in the Web).

With these arguments in mind, we decided to choose: (i) 15 nouns from the Senseval-3 lexical sample dataset, which have been previously employed by (Mihalcea, 2007) in a related experiment (see Section 7); (ii) 25 additional words which satisfy two conditions: they are all ambiguous, and they are all names for music bands in one of their senses (not necessarily the most salient). The Senseval set is: {*argument, arm, atmosphere, bank, degree, difference, disc, image, paper, party, performance, plan, shelter, sort, source*}. The bands set is {*amazon, apple, camel, cell, columbia, cream, foreigner, fox, genesis, jaguar, oasis, pioneer, police, puma, rainbow, shell, skin, sun, tesla, thunder, total, traffic, trapeze, triumph, yes*}.

For each noun, we looked up all its possible senses in WordNet 3.0 and in Wikipedia (using

[1] http://senseval.org

Table 1: Coverage of Search Results: Wikipedia vs. WordNet

	Wikipedia		WordNet	
	# senses available/used	# documents assigned to some sense	# senses available/used	# documents assigned to some sense
Senseval set	242/100	877 (59%)	92/52	696 (46%)
Bands set	640/174	1358 (54%)	78/39	599 (24%)
Total	882/274	2235 (56%)	170/91	1295 (32%)

Wikipedia disambiguation pages). Wikipedia has an average of 22 senses per noun (25.2 in the Bands set and 16.1 in the Senseval set), and Wordnet a much smaller figure, 4.5 (3.12 for the Bands set and 6.13 for the Senseval set). For a conventional dictionary, a higher ambiguity might indicate an excess of granularity; for an encyclopaedic resource such as Wikipedia, however, it is just an indication of larger coverage. Wikipedia entries for *camel* which are not in WordNet, for instance, include the Apache Camel routing and mediation engine, the British rock band, the brand of cigarettes, the river in Cornwall, and the World World War I fighter biplane.

2.2 Set of Documents

We retrieved the 150 first ranked documents for each noun, by submitting the nouns as queries to a Web search engine (Google). Then, for each document, we stored both the snippet (small description of the contents of retrieved document) and the whole HTML document. This collection of documents contain an implicit new inventory of senses, based on Web search, as documents retrieved by a noun query are associated with some sense of the noun. Given that every document in the top Web search results is supposed to be highly relevant for the query word, we assume a "one sense per document" scenario, although we allow annotators to assign more than one sense per document. In general this assumption turned out to be correct except in a few exceptional cases (such as Wikipedia disambiguation pages): only nine documents received more than one WordNet sense, and 44 (1.1% of all annotated pages) received more than one Wikipedia sense.

2.3 Manual Annotation

We implemented an annotation interface which stored all documents and a short description for every Wordnet and Wikipedia sense. The annotators had to decide, for every document, whether there was one or more appropriate senses in each of the dictionaries. They were instructed to provide annotations for 100 documents per name; if an URL in the list was corrupt or not available, it had to be discarded. We provided 150 documents per name to ensure that the figure of 100 usable documents per name could be reached without problems.

Each judge provided annotations for the 4,000 documents in the final data set. In a second round, they met and discussed their independent annotations together, reaching a consensus judgement for every document.

3 Coverage of Web Search Results: Wikipedia vs Wordnet

Table 1 shows how Wikipedia and Wordnet cover the senses in search results. We report each noun subset separately (*Senseval* and *bands* subsets) as well as aggregated figures.

The most relevant fact is that, unsurprisingly, Wikipedia senses cover much more search results (56%) than Wordnet (32%). If we focus on the top ten results, in the bands subset (which should be more representative of plausible web queries) Wikipedia covers 68% of the top ten documents. This is an indication that it can indeed be useful for promoting diversity or help clustering search results: even if 32% of the top ten documents are not covered by Wikipedia, it is still a representative source of senses in the top search results.

We have manually examined all documents in the top ten results that are not covered by Wikipedia: a majority of the missing senses consists of names of (generally not well-known) companies (45%) and products or services (26%); the other frequent type (12%) of non annotated document is disambiguation pages (from Wikipedia and also from other dictionaries).

It is also interesting to examine the degree of overlap between Wikipedia and Wordnet senses. Being two different types of lexical resource, they might have some degree of complementarity. Table 2 shows, however, that this is not the case: most of the (annotated) documents either fit Wikipedia senses (26%) or both Wikipedia and Wordnet (29%), and just 3% fit Wordnet only.

Table 2: Overlap between Wikipedia and Wordnet in Search Results

	# documents annotated with			
	Wikipedia & Wordnet	Wikipedia only	Wordnet only	none
Senseval set	607 (40%)	270 (18%)	89 (6%)	534 (36%)
Bands set	572 (23%)	786 (31%)	27 (1%)	1115 (45%)
Total	1179 (29%)	1056 (26%)	116 (3%)	1649 (41%)

Therefore, Wikipedia seems to extend the coverage of Wordnet rather than providing complementary sense information. If we wanted to extend the coverage of Wikipedia, the best strategy seems to be to consider lists of companies, products and services, rather than complementing Wikipedia with additional sense inventories.

4 Diversity in Google Search Results

Once we know that Wikipedia senses are a representative subset of actual Web senses (covering more than half of the documents retrieved by the search engine), we can test how well search results respect diversity in terms of this subset of senses.

Table 3 displays the number of different senses found at different depths in the search results rank, and the average proportion of total senses that they represent. These results suggest that diversity is not a major priority for ranking results: the top ten results only cover, in average, 3 Wikipedia senses (while the average number of senses listed in Wikipedia is 22). When considering the first 100 documents, this number grows up to 6.85 senses per noun.

Another relevant figure is the frequency of the most frequent sense for each word: in average, 63% of the pages in search results belong to the most frequent sense of the query word. This is roughly comparable with most frequent sense figures in standard annotated corpora such as Semcor (Miller et al., 1993) and the Senseval/Semeval data sets, which suggests that diversity may not play a major role in the current Google ranking algorithm.

Of course this result must be taken with care, because variability between words is high and unpredictable, and we are using only 40 nouns for our experiment. But what we have is a positive indication that Wikipedia could be used to improve diversity or cluster search results: potentially the first top ten results could cover 6.15 different senses in average (see Section 6.5), which would be a substantial growth.

5 Sense Frequency Estimators for Wikipedia

Wikipedia disambiguation pages contain no systematic information about the relative importance of senses for a given word. Such information, however, is crucial in a lexicon, because sense distributions tend to be skewed, and knowing them can help disambiguation algorithms.

We have attempted to use two estimators of expected sense distribution:

- Internal relevance of a word sense, measured as incoming links for the URL of a given sense in Wikipedia.
- External relevance of a word sense, measured as the number of visits for the URL of a given sense (as reported in http://stats.grok.se).

The number of internal incoming links is expected to be relatively stable for Wikipedia articles. As for the number of visits, we performed a comparison of the number of visits received by the bands noun subset in May, June and July 2009, finding a stable-enough scenario with one notorious exception: the number of visits to the noun Tesla raised dramatically in July, because July 10 was the anniversary of the birth of Nicola Tesla, and a special Google logo directed users to the Wikipedia page for the scientist.

We have measured correlation between the relative frequencies derived from these two indicators and the actual relative frequencies in our testbed. Therefore, for each noun w and for each sense w_i, we consider three values: (i) proportion of documents retrieved for w which are manually assigned to each sense w_i; (ii) inlinks(w_i): relative amount of incoming links to each sense w_i; and (iii) visits(w_i): relative number of visits to the URL for each sense w_i.

We have measured the correlation between these three values using a linear regression correlation coefficient, which gives a correlation value of .54 for the number of visits and of .71 for the number of incoming links. Both estimators seem

Table 3: Diversity in Search Results according to Wikipedia

	average # senses in search results			average coverage of Wikipedia senses		
	Bands set	Senseval set	Total	Bands set	Senseval set	Total
First 10 docs	2.88	3.2	3.00	.21	.21	.21
First 25	4.44	4.8	4.58	.28	.33	.30
First 50	5.56	5.47	5.53	.33	.36	.34
First 75	6.56	6.33	6.48	.37	.43	.39
First 100	6.96	6.67	6.85	.38	.45	.41

to be positively correlated with real relative frequencies in our testbed, with a strong preference for the number of links.

We have experimented with weighted combinations of both indicators, using weights of the form $(k, 1-k), k \in \{0, 0.1, 0.2 \ldots 1\}$, reaching a maximal correlation of .73 for the following weights:

$$\text{freq}(w_i) = 0.9 * \text{inlinks}(w_i) + 0.1 * \text{visits}(w_i) \quad (1)$$

This weighted estimator provides a slight advantage over the use of incoming links only (.73 vs .71). Overall, we have an estimator which has a strong correlation with the distribution of senses in our testbed. In the next section we will test its utility for disambiguation purposes.

6 Association of Wikipedia Senses to Web Pages

We want to test whether the information provided by Wikipedia can be used to classify search results accurately. Note that we do not want to consider approaches that involve a manual creation of training material, because they can't be used in practice.

Given a Web page p returned by the search engine for the query w, and the set of senses $w_1 \ldots w_n$ listed in Wikipedia, the task is to assign the best candidate sense to p. We consider two different techniques:

- A basic Information Retrieval approach, where the documents and the Wikipedia pages are represented using a Vector Space Model (VSM) and compared with a standard cosine measure. This is a basic approach which, if successful, can be used efficiently to classify search results.

- An approach based on a state-of-the-art supervised WSD system, extracting training examples automatically from Wikipedia content.

We also compute two baselines:

- A random assignment of senses (precision is computed as the inverse of the number of senses, for every test case).

- A most frequent sense heuristic which uses our estimation of sense frequencies and assigns the same sense (the most frequent) to all documents.

Both are naive baselines, but it must be noted that the most frequent sense heuristic is usually hard to beat for unsupervised WSD algorithms in most standard data sets.

We now describe each of the two main approaches in detail.

6.1 VSM Approach

For each word sense, we represent its Wikipedia page in a (unigram) vector space model, assigning standard tf*idf weights to the words in the document. idf weights are computed in two different ways:

1. Experiment **VSM** computes inverse document frequencies in the collection of retrieved documents (for the word being considered).

2. Experiment **VSM-GT** uses the statistics provided by the Google Terabyte collection (Brants and Franz, 2006), i.e. it replaces the collection of documents with statistics from a representative snapshot of the Web.

3. Experiment **VSM-mixed** combines statistics from the collection and from the Google Terabyte collection, following (Chen et al., 2009).

The document p is represented in the same vector space as the Wikipedia senses, and it is compared with each of the candidate senses w_i via the cosine similarity metric (we have experimented

with other similarity metrics such as χ^2, but differences are irrelevant). The sense with the highest similarity to p is assigned to the document. In case of ties (which are rare), we pick the first sense in the Wikipedia disambiguation page (which in practice is like a random decision, because senses in disambiguation pages do not seem to be ordered according to any clear criteria).

We have also tested a variant of this approach which uses the estimation of sense frequencies presented above: once the similarities are computed, we consider those cases where two or more senses have a similar score (in particular, all senses with a score greater or equal than 80% of the highest score). In that cases, instead of using the small similarity differences to select a sense, we pick up the one which has the largest frequency according to our estimator. We have applied this strategy to the best performing system, VSM-GT, resulting in experiment **VSM-GT+freq**.

6.2 WSD Approach

We have used TiMBL (Daelemans et al., 2001), a state-of-the-art supervised WSD system which uses Memory-Based Learning. The key, in this case, is how to extract learning examples from the Wikipedia automatically. For each word sense, we basically have three sources of examples: (i) occurrences of the word in the Wikipedia page for the word sense; (ii) occurrences of the word in Wikipedia pages pointing to the page for the word sense; (iii) occurrences of the word in external pages linked in the Wikipedia page for the word sense.

After an initial manual inspection, we decided to discard external pages for being too noisy, and we focused on the first two options. We tried three alternatives:

- **TiMBL-core** uses only the examples found in the page for the sense being trained.
- **TiMBL-inlinks** uses the examples found in Wikipedia pages pointing to the sense being trained.
- **TiMBL-all** uses both sources of examples.

In order to classify a page p with respect to the senses for a word w, we first disambiguate all occurrences of w in the page p. Then we choose the sense which appears most frequently in the page according to TiMBL results. In case of ties we pick up the first sense listed in the Wikipedia disambiguation page.

We have also experimented with a variant of the approach that uses our estimation of sense frequencies, similarly to what we did with the VSM approach. In this case, (i) when there is a tie between two or more senses (which is much more likely than in the VSM approach), we pick up the sense with the highest frequency according to our estimator; and (ii) when no sense reaches 30% of the cases in the page to be disambiguated, we also resort to the most frequent sense heuristic (among the candidates for the page). This experiment is called TiMBL-core+freq (we discarded "inlinks" and "all" versions because they were clearly worse than "core").

6.3 Classification Results

Table 4 shows classification results. The accuracy of systems is reported as precision, i.e. the number of pages correctly classified divided by the total number of predictions. This is approximately the same as recall (correctly classified pages divided by total number of pages) for our systems, because the algorithms provide an answer for every page containing text (actual coverage is 94% because some pages only contain text as part of an image file such as photographs and logotypes).

Table 4: Classification Results

Experiment	Precision
random	.19
most frequent sense (estimation)	.46
TiMBL-core	.60
TiMBL-inlinks	.50
TiMBL-all	.58
TiMBL-core+freq	**.67**
VSM	.67
VSM-GT	.68
VSM-mixed	.67
VSM-GT+freq	**.69**

All systems are significantly better than the random and most frequent sense baselines (using $p < 0.05$ for a standard t-test). Overall, both approaches (using TiMBL WSD machinery and using VSM) lead to similar results (.67 vs. .69), which would make VSM preferable because it is a simpler and more efficient approach. Taking a

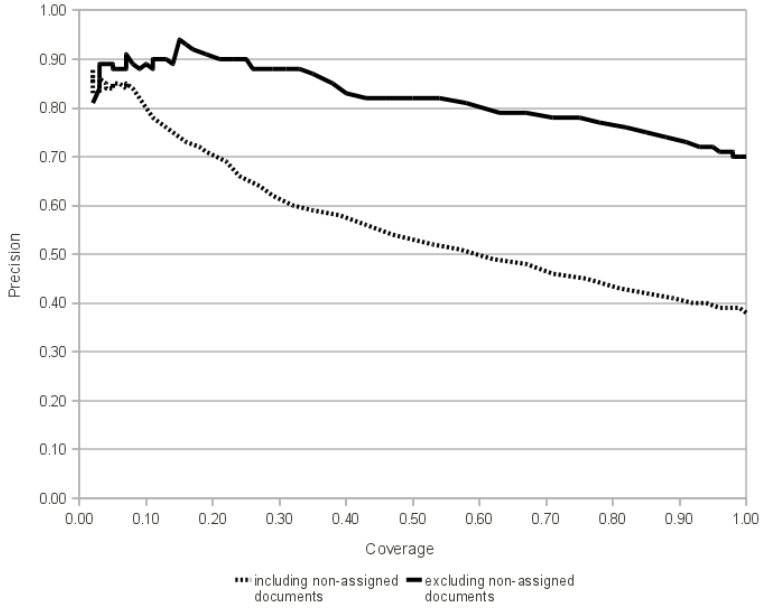

Figure 1: Precision/Coverage curves for VSM-GT+freq classification algorithm

closer look at the results with TiMBL, there are a couple of interesting facts:

- There is a substantial difference between using only examples taken from the Wikipedia Web page for the sense being trained (TiMBL-core, .60) and using examples from the Wikipedia pages pointing to that page (TiMBL-inlinks, .50). Examples taken from related pages (even if the relationship is close as in this case) seem to be too noisy for the task. This result is compatible with findings in (Santamaría et al., 2003) using the Open Directory Project to extract examples automatically.

- Our estimation of sense frequencies turns out to be very helpful for cases where our TiMBL-based algorithm cannot provide an answer: precision rises from .60 (TiMBL-core) to .67 (TiMBL-core+freq). The difference is statistically significant ($p < 0.05$) according to the t-test.

As for the experiments with VSM, the variations tested do not provide substantial improvements to the baseline (which is .67). Using idf frequencies obtained from the Google Terabyte corpus (instead of frequencies obtained from the set of retrieved documents) provides only a small improvement (VSM-GT, .68), and adding the estimation of sense frequencies gives another small improvement (.69). Comparing the baseline VSM with the optimal setting (VSM-GT+freq), the difference is small (.67 vs .69) but relatively robust ($p = 0.066$ according to the t-test).

Remarkably, the use of frequency estimations is very helpful for the WSD approach but not for the SVM one, and they both end up with similar performance figures; this might indicate that using frequency estimations is only helpful up to certain precision ceiling.

6.4 Precision/Coverage Trade-off

All the above experiments are done at maximal coverage, i.e., all systems assign a sense for every document in the test collection (at least for every document with textual content). But it is possible to enhance search results diversity without annotating every document (in fact, not every document can be assigned to a Wikipedia sense, as we have discussed in Section 3). Thus, it is useful to investigate which is the precision/coverage trade-off in our dataset. We have experimented with the best performing system (VSM-GT+freq), introducing a similarity threshold: assignment of a document to a sense is only done if the similarity of the document to the Wikipedia page for the sense exceeds the similarity threshold.

We have computed precision and coverage for every threshold in the range $[0.00 - 0.90]$ (beyond 0.90 coverage was null) and represented the results in Figure 1 (solid line). The graph shows that we

can classify around 20% of the documents with a precision above .90, and around 60% of the documents with a precision of .80.

Note that we are reporting disambiguation results using a conventional WSD test set, i.e., one in which every test case (every document) has been manually assigned to some Wikipedia sense. But in our Web Search scenario, 44% of the documents were not assigned to any Wikipedia sense: in practice, our classification algorithm would have to cope with all this noise as well. Figure 1 (dotted line) shows how the precision/coverage curve is affected when the algorithm attempts to disambiguate all documents retrieved by Google, whether they can in fact be assigned to a Wikipedia sense or not. At a coverage of 20%, precision drops approximately from .90 to .70, and at a coverage of 60% it drops from .80 to .50. We now address the question of whether this performance is good enough to improve search results diversity in practice.

6.5 Using Classification to Promote Diversity

We now want to estimate how the reported classification accuracy may perform in practice to enhance diversity in search results. In order to provide an initial answer to this question, we have re-ranked the documents for the 40 nouns in our testbed, using our best classifier (VSM-GT+freq) and making a list of the top-ten documents with the primary criterion of maximising the number of senses represented in the set, and the secondary criterion of maximising the similarity scores of the documents to their assigned senses. The algorithm proceeds as follows: we fill each position in the rank (starting at rank 1), with the document which has the highest similarity to some of the senses which are not yet represented in the rank; once all senses are represented, we start choosing a second representative for each sense, following the same criterion. The process goes on until the first ten documents are selected.

We have also produced a number of alternative rankings for comparison purposes:

- **clustering (centroids)**: this method applies Hierarchical Agglomerative Clustering – which proved to be the most competitive clustering algorithm in a similar task (Artiles et al., 2009) – to the set of search results, forcing the algorithm to create ten clusters. The centroid of each cluster is then selected as one of the top ten documents in the new rank.

- **clustering (top ranked)**: Applies the same clustering algorithm, but this time the top ranked document (in the original Google rank) of each cluster is selected.

- **random**: Randomly selects ten documents from the set of retrieved results.

- **upper bound**: This is the maximal diversity that can be obtained in our testbed. Note that coverage is not 100%, because some words have more than ten meanings in Wikipedia and we are only considering the top ten documents.

Table 5: Enhancement of Search Results Diversity

rank@10	# senses	coverage
Original rank	2.80	49%
Wikipedia	**4.75**	**77%**
clustering (centroids)	2.50	42%
clustering (top ranked)	2.80	46%
random	2.45	43%
upper bound	6.15	97%

All experiments have been applied on the full set of documents in the testbed, including those which could not be annotated with any Wikipedia sense. Coverage is computed as the ratio of senses that appear in the top ten results compared to the number of senses that appear in all search results.

Results are presented in Table 5. Note that diversity in the top ten documents increases from an average of 2.80 Wikipedia senses represented in the original search engine rank, to 4.75 in the modified rank (being 6.15 the upper bound), with the coverage of senses going from 49% to 77%. With a simple VSM algorithm, the coverage of Wikipedia senses in the top ten results is 70% larger than in the original ranking.

Using Wikipedia to enhance diversity seems to work much better than clustering: both strategies to select a representative from each cluster are unable to improve the diversity of the original ranking. Note, however, that our evaluation has a bias towards using Wikipedia, because only Wikipedia senses are considered to estimate diversity.

Of course our results do not imply that the Wikipedia modified rank is better than the original

Google rank: there are many other factors that influence the final ranking provided by a search engine. What our results indicate is that, with simple and efficient algorithms, Wikipedia can be used as a reference to improve search results diversity for one-word queries.

7 Related Work

Web search results clustering and diversity in search results are topics that receive an increasing attention from the research community. Diversity is used both to represent sub-themes in a broad topic, or to consider alternative interpretations for ambiguous queries (Agrawal et al., 2009), which is our interest here. Standard IR test collections do not usually consider ambiguous queries, and are thus inappropriate to test systems that promote diversity (Sanderson, 2008); it is only recently that appropriate test collections are being built, such as (Paramita et al., 2009) for image search and (Artiles et al., 2009) for person name search. We see our testbed as complementary to these ones, and expect that it can contribute to foster research on search results diversity.

To our knowledge, Wikipedia has not explicitly been used before to promote diversity in search results; but in (Gollapudi and Sharma, 2009), it is used as a gold standard to evaluate diversification algorithms: given a query with a Wikipedia disambiguation page, an algorithm is evaluated as promoting diversity when different documents in the search results are semantically similar to different Wikipedia pages (describing the alternative senses of the query). Although semantic similarity is measured automatically in this work, our results confirm that this evaluation strategy is sound, because Wikipedia senses are indeed representative of search results.

(Clough et al., 2009) analyses query diversity in a Microsoft Live Search, using click entropy and query reformulation as diversity indicators. It was found that at least 9.5% - 16.2% of queries could benefit from diversification, although no correlation was found between the number of senses of a word in Wikipedia and the indicators used to discover diverse queries. This result does not discard, however, that queries where applying diversity is useful cannot benefit from Wikipedia as a sense inventory.

In the context of clustering, (Carmel et al., 2009) successfully employ Wikipedia to enhance automatic cluster labeling, finding that Wikipedia labels agree with manual labels associated by humans to a cluster, much more than with significant terms that are extracted directly from the text. In a similar line, both (Gabrilovich and Markovitch, 2007) and (Syed et al., 2008) provide evidence suggesting that categories of Wikipedia articles can successfully describe common concepts in documents.

In the field of Natural Language Processing, there has been successful attempts to connect Wikipedia entries to Wordnet senses: (Ruiz-Casado et al., 2005) reports an algorithm that provides an accuracy of 84%. (Mihalcea, 2007) uses internal Wikipedia hyperlinks to derive sense-tagged examples. But instead of using Wikipedia directly as sense inventory, Mihalcea then manually maps Wikipedia senses into Wordnet senses (claiming that, at the time of writing the paper, Wikipedia did not consistently report ambiguity in disambiguation pages) and shows that a WSD system based on acquired sense-tagged examples reaches an accuracy well beyond an (informed) most frequent sense heuristic.

8 Conclusions

We have investigated whether generic lexical resources can be used to promote diversity in Web search results for one-word, ambiguous queries. We have compared WordNet and Wikipedia and arrived to a number of conclusions: (i) unsurprisingly, Wikipedia has a much better coverage of senses in search results, and is therefore more appropriate for the task; (ii) the distribution of senses in search results can be estimated using the internal graph structure of the Wikipedia and the relative number of visits received by each sense in Wikipedia, and (iii) associating Web pages to Wikipedia senses with simple and efficient algorithms, we can produce modified rankings that cover 70% more Wikipedia senses than the original search engine rankings.

We expect that the testbed created for this research will complement the - currently short - set of benchmarking test sets to explore search results diversity and query ambiguity. Our testbed is publicly available for research purposes at http://nlp.uned.es.

Our results endorse further investigation on the use of Wikipedia to organize search results. Some limitations of our research, however, must be

noted: (i) the nature of our testbed (with every search result manually annotated in terms of two sense inventories) makes it too small to extract solid conclusions on Web searches (ii) our work does not involve any study of diversity from the point of view of Web users (i.e. when a Web query addresses many different use needs in practice); research in (Clough et al., 2009) suggests that word ambiguity in Wikipedia might not be related with diversity of search needs; (iii) we have tested our classifiers with a simple re-ordering of search results to test how much diversity can be improved, but a search results ranking depends on many other factors, some of them more crucial than diversity; it remains to be tested how can we use document/Wikipedia associations to improve search results clustering (for instance, providing seeds for the clustering process) and to provide search suggestions.

A Unified Graph Model for Sentence-based Opinion Retrieval

Binyang Li, Lanjun Zhou, Shi Feng, Kam-Fai Wong

{byli, ljzhou, sfeng, kfwong}@se.cuhk.edu.hk

Abstract

There is a growing research interest in opinion retrieval as on-line users' opinions are becoming more and more popular in business, social networks, etc. Practically speaking, the goal of opinion retrieval is to retrieve documents, which entail opinions or comments, relevant to a target subject specified by the user's query. A fundamental challenge in opinion retrieval is information representation. Existing research focuses on document-based approaches and documents are represented by *bag-of-word*. However, due to loss of contextual information, this representation fails to capture the associative information between an opinion and its corresponding target. It cannot distinguish different degrees of a sentiment word when associated with different targets. This in turn seriously affects opinion retrieval performance. In this paper, we propose a sentence-based approach based on a new information representation, namely topic-sentiment word pair, to capture intra-sentence contextual information between an opinion and its target. Additionally, we consider inter-sentence information to capture the relationships among the opinions on the same topic. Finally, the two types of information are combined in a unified graph-based model, which can effectively rank the documents. Compared with existing approaches, experimental results on the COAE08 dataset showed that our graph-based model achieved significant improvement.

1 Introduction

In recent years, there is a growing interest in sharing personal opinions on the Web, such as product reviews, economic analysis, political polls, etc. These opinions cannot only help independent users make decisions, but also obtain valuable feedbacks (Pang et al., 2008). Opinion oriented research, including sentiment classification, opinion extraction, opinion question answering, and opinion summarization, etc. are receiving growing attention (Wilson, et al., 2005; Liu et al., 2005; Oard et al., 2006). However, most existing works concentrate on analyzing opinions expressed in the documents, and none on how to represent the information needs required to retrieve opinionated documents. In this paper, we focus on opinion retrieval, whose goal is to find a set of documents containing not only the query keyword(s) but also the relevant opinions. This requirement brings about the challenge on how to represent information needs for effective opinion retrieval.

In order to solve the above problem, previous work adopts a 2-stage approach. In the first stage, relevant documents are determined and ranked by a score, i.e. *tf-idf* value. In the second stage, an opinion score is generated for each relevant document (Macdonald and Ounis, 2007; Oard et al., 2006). The opinion score can be acquired by either machine learning-based sentiment classifiers, such as SVM (Zhang and Yu, 2007), or a sentiment lexicons with weighted scores from training documents (Amati et al., 2007; Hannah et al., 2007; Na et al., 2009). Finally, an overall score combining the two is computed by using a score function, e.g. linear combination, to re-rank the retrieved documents.

Retrieval in the 2-stage approach is based on document and document is represented by *bag-of-word*. This representation, however, can only ensure that there is at least one opinion in each relevant document, but it cannot determine the relevance pairing of individual opinion to its target. In general, by simply representing a document in *bag-of-word*, contextual information i.e. the corresponding target of an opinion, is neglected. This may result in possible mismatch between an opinion and a target and in turn affects opinion retrieval performance. By the same token, the effect to documents consisting of mul-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1367–1375,
Uppsala, Sweden, 11-16 July 2010.

tiple topics, which is common in blogs and on-line reviews, is also significant. In this setting, even if a document is regarded opinionated, it cannot ensure that all opinions in the document are indeed relevant to the target concerned. Therefore, we argue that existing information representation i.e. *bag-of-word*, cannot satisfy the information needs for opinion retrieval.

In this paper, we propose to handle opinion retrieval in the granularity of sentence. It is observed that a complete opinion is always expressed in one sentence, and the relevant target of the opinion is mostly the one found in it. Therefore, it is crucial to maintain the associative information between an opinion and its target within a sentence. We define the notion of a topic-sentiment word pair, which is composed of a topic term (i.e. the target) and a sentiment word (i.e. opinion) of a sentence. Word pairs can maintain intra-sentence contextual information to express the potential relevant opinions. In addition, inter-sentence contextual information is also captured by word pairs to represent the relationship among opinions on the same topic. In practice, the inter-sentence information reflects the degree of a word pair. Finally, we combine both intra-sentence and inter-sentence contextual information to construct a unified undirected graph to achieve effective opinion retrieval.

The rest of the paper is organized as follows. In Section 2, we describe the motivation of our approach. Section 3 presents a novel unified graph-based model for opinion retrieval. We evaluated our model and the results are presented in Section 4. We review related works on opinion retrieval in Section 5. Finally, in Section 6, the paper is concluded and future work is suggested.

2 Motivation

In this section, we start from briefly describing the objective of opinion retrieval. We then illustrate the limitations of current opinion retrieval approaches, and analyze the motivation of our method.

2.1 Formal Description of Problem

Opinion retrieval was first presented in the TREC 2006 Blog track, and the objective is to retrieve documents that express an opinion about a given target. The opinion target can be a "traditional" named entity (e.g. a name of person, location, or organization, etc.), a concept (e.g. a type of technology), or an event (e.g. presidential election). The topic of the document is not required to be the same as the target, but an opinion about the target has to be presented in the document or one of the comments to the document (Macdonald and Ounis, 2006). Therefore, in this paper we regard the information needs for opinion retrieval as *relevant opinion*.

2.2 Motivation of Our Approach

In traditional information retrieval (IR) *bag-of-word* representation is the most common way to express information needs. However, in opinion retrieval, information need target at *relevant opinion*, and this renders *bag-of-word* representation ineffective.

Consider the example in Figure 1. There are three sentences *A*, *B*, and *C* in a document d_i. Now given an opinion-oriented query Q related to '*Avatar'*. According to the conventional 2-stage opinion retrieval approach, d_i is represented by a *bag-of-word*. Among the words, there is a topic term *Avatar* (t_1) occurring twice, i.e. *Avatar in A* and *Avatar in C*, and two sentiment words *comfortable* (o_1) and *favorite* (o_2) (refer to Figure 2 (a)). In order to rank this document, an overall score of the document d_i is computed by a simple combination of the relevant score ($Score_{\text{rel}}$) and the opinion score ($Score_{\text{op}}$), e.g. equal weighted linear combination, as follows.

$$Score_{\text{doc}} = Score_{\text{rel}} + \quad Score_{\text{op}}$$

For simplicity, we let $Score_{\text{rel}} = tf_{\text{Q}} \times idf_{\text{Q}}$, and $Score_{\text{op}}$ be computed by using lexicon-based method: $Score_{\text{op}} = weight_{\text{comfortable}} + weight_{\text{favorite}}$.

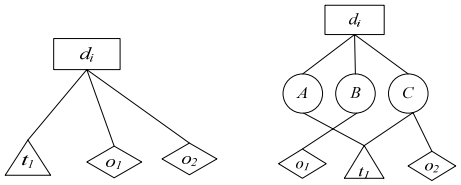
> A. 阿凡达明日将在中国上映。
> Tomorrow, Avatar will be shown in China.
> B. 我预订到了IMAX影院中最舒服的位子。
> I've reserved a comfortable seat in IMAX.
> C. 阿凡达是我最喜欢的一部 3D 电影。
> Avatar is my favorite 3D movie.

Figure 1: A retrieved document d_i on the target '*Avatar'*.

Although *bag-of-word* representation achieves good performance in retrieving relevant documents, our study shows that it cannot satisfy the information needs for retrieval of *relevant opinion*. It suffers from the following limitations:

(1) It cannot maintain contextual information; thus, an opinion may not be related to the target of the retrieved document is neglected. In this example, only the opinion *favorite* (o_2) on *Avatar in C* is the *relevant opinion*. But due to loss of contextual information between the opinion and its corresponding target, *Avatar in A* and *com-*

fortable (o_1) are also regarded as *relevant opinion* mistakenly, creating a false positive. In reality *comfortable* (o_1) describes "the seats in IMAX", which is an irrelevant opinion, and sentence *A* is a factual statement rather than an opinion statement.



(a) (b)

Figure 2: Two kinds of information representation of opinion retrieval. (t_1='*Avatar*' o_1= '*comfortable*', o_2='*favorite*')

(1) Current approaches cannot capture the relationship among opinions about the same topic. Suppose there is another document including sentence *C* which expresses the same opinion on *Avatar*. Existing information representation simply does not cater for the two identical opinions from different documents. In addition, if many documents contain opinions on *Avatar*, the relationship among them is not clearly represented by existing approaches.

In this paper, we process opinion retrieval in the granularity of sentence as we observe that a complete opinion always exists within a sentence (refer to Figure 2 (b)). To represent a *relevant opinion*, we define the notion of topic-sentiment word pair, which consists of a topic term and a sentiment word. A word pair maintains the associative information between the two words, and enables systems to draw up the relationship among all the sentences with the same opinion on an identical target. This relationship information can identify all documents with sentences including the sentiment words and to determine the contributions of such words to the target (topic term). Furthermore, based on word pairs, we designed a unified graph-based method for opinion retrieval (see later in Section 3).

3 Graph-based model

3.1 Basic Idea

Different from existing approaches which simply make use of document relevance to reflect the relevance of opinions embedded in them, our approach concerns more on identifying the relevance of individual opinions. Intuitively, we believed that the more *relevant opinions* appear in a document, the more relevant is that document for subsequent opinion analysis operations. Further, since the lexical scope of an opinion does not usually go beyond a sentence, we propose to handle opinion retrieval in the granularity of sentence.

Without loss of generality, we assume that there is a document set $\mathcal{D} = \{d_1, d_2, d_3, \cdots, d_n\}$, and a specific query $\mathcal{Q} = \{q_1, q_2, q_3, \cdots, q_z\}$, where $q_1, q_2, q_3, \cdots, q_z$ are query keywords. Opinion retrieval aims at retrieving documents from $\mathcal{D}$ with *relevant opinion* about the query $\mathcal{Q}$. In addition, we construct a sentiment word lexicon V_o and a topic term lexicon V_t (see Section 4). To maintain the associative information between the target and the opinion, we consider the document set as a *bag of sentences*, and define a sentence set as $\mathcal{S} = \{s_1, s_2, s_3, \cdots, s_N\}$. For each sentence, we capture the intra-sentence information through the topic-sentiment word pair.

Definition 1. topic-sentiment word pair p_{ij} consists of two elements, one is from V_t, and the other one is from V_o.

$$p_{ij} = \{< t_i, o_j > | t_i \in V_t, o_j \in V_o)\}.$$

The topic term from V_t determines relevance by the query term matching, and the sentiment word from V_o is used to express an opinion. We use the word pair to maintain the associative information between the topic term and the opinion word (also referred to as sentiment word). The word pair is used to identify a *relevant opinion* in a sentence. In Figure 2 (b), t_1, i.e. *Avatar in C*, is a topic term relevant to the query, and o_2 ('*favorite*') is supposed to be an opinion; and the word pair < t_1, o_2> indicates sentence *C* contains a *relevant opinion*. Similarly, we map each sentence in word pairs by the following rule, and express the intra-sentence information using word pairs.

For each sentiment word of a sentence, we choose the topic term with minimum distance as the other element of the word pair:

$$s_l \rightarrow \{< t_i, o_j > | t_i = \min Dist(t_i, o_j) \text{ for each } o_j\}$$

According to the mapping rule, although a sentence may give rise to a number of word pairs, only the pair with the minimum word distance is selected. We do not take into consideration of the other words in a sentence as *relevant opinions* are generally formed in close proximity. A sentence is regarded non-opinionated unless it contains at least one word pair.

In practice, not all word pairs carry equal weights to express a *relevant opinion* as the contribution of an opinion word differs from different target topics, and vice versa. For example, the word pair < t_1, o_2> should be more probable as a *relevant opinion* than < t_1, o_1>. To consider

that, inter-sentence contextual information is explored. This is achieved by assigning a weight to each word pair to measure their associative degrees to different queries. We believe that the more a word pair appears the higher should be the weight between the opinion and the target in the context.

We will describe how to utilize intra-sentence contextual information to express *relevant opinion*, and inter-sentence information to measure the degree of each word pair through a graph-based model in the following section.

3.2 HITS Model

We propose an opinion retrieval model based on HITS, a popular graph ranking algorithm (Kleinberg, 1999). By considering both intra-sentence information and inter-sentence information, we can determine the weight of a word pair and rank the documents.

HITS algorithm distinguishes hubs and authorities in objects. A hub object has links to many authorities. An authority object, which has high-quality content, would have many hubs linking to it. The hub scores and authority scores are computed in an iterative way. Our proposed opinion retrieval model contains two layers. The upper level contains all the topic-sentiment word pairs $p_{ij} = \{< t_i, o_j > | t_i \in V_t, o_j \in V_o)\}$. The lower level contains all the documents to be retrieved. Figure 3 gives the bipartite graph representation of the HITS model.

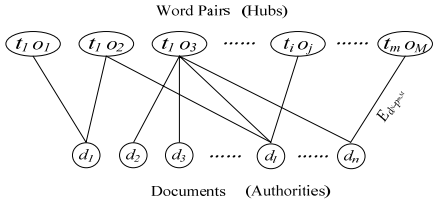


Figure 3: Bipartite link graph.

For our purpose, the word pairs layer is considered as hubs and the documents layer authorities. If a word pair occurs in one sentence of a document, there will be an edge between them. In Figure 3, we can see that the word pair that has links to many documents can be assigned a high weight to denote a strong associative degree between the topic term and a sentiment word, and it likely expresses a *relevant opinion*. On the other hand, if a document has links to many word pairs, the document is with many *relevant opinions*, and it will result in high ranking.

Formally, the representation for the bipartite graph is denoted as $G =< H_p, A_d, E_{dp} >$, where $H_p = \{p_{ij}\}$ is the set of all pairs of topic words and sentiment words, which appear in one sentence. $A_d = \{d_k\}$ is the set of documents. $E_{dp} = \{e_{ij}^k | p_{ij} \in H_p, d_k \in A_d\}$ corresponds to the connection between documents and topic-sentiment word pairs. Each edge e_{ij}^k is associated with a weight $w_{ij}^k \in [0,1]$ denoting the contribution of p_{ij} to the document d_k. The weight w_{ij}^k is computed by the contribution of word pair p_{ij} in all sentences of d_k as follows:

$$w_{ij}^k = \frac{1}{|d_k|} \sum_{p_{ij} \in s_l \in d_k} [\lambda \cdot rel(t_i, s_l) + (1-\lambda) opn(o_j, s_l)] \quad (1)$$

- $|d_k|$ is the number of sentences in d_k;
- λ is introduced as the trade-off parameter to balance the $rel(t_i, s_l)$ and $opn(o_j, s_l)$;
- $rel(t_i, s_l)$ is computed to judge the relevance of t_i in s_l which belongs to d_k;

$$rel(t_i, s_l) = tf_{t_i, s_l} \times isf_{t_i} \quad (2)$$

where tf_{t_i,s_l} is the number of t_i appears in s_l, and

$$isf_{t_i} = \log\left(\frac{N+1}{0.5+sf_{t_i}}\right) \quad (3)$$

where sf_{t_i} is the number of sentences that the word t_i appears in.

- $opn(o_j, s_l)$ is the contribution of o_j in s_l which belongs to d_k.

$$opn(o_j, s_l) = \frac{tf_{o_j, s_l}}{tf_{o_j, s_l} + 0.5 + (1.5 \times \frac{len(s_l)}{asl})} \quad (4)$$

where asl is the average number of sentences in d_k; tf_{t_i,o_j} is the number of o_j appears in s_l (Allan et al., 2003; Otterbacher et al., 2005).

It is found that the contribution of a sentiment word o_j will not decrease even if it appears in all the sentences. Therefore in Equation 4, we just use the length of a sentence instead of isf_{o_j} to normalize long sentences which would likely contain more sentiment words.

The authority score $AuthScore^{(T+1)}(d_k)$ of document d_k and a hub score $HubScore^{(T+1)}(p_{ij})$ of p_{ij} at the $(T+1)^{\text{th}}$ iteration are computed based on the hub scores and authority scores in the T^{th} iteration as follows.

$$AuthScore^{(T+1)}(d_k) = \sum_{p_{ij} \in H_p} w_{ij}^k \times HubScore^T(p_{ij}) \quad (5)$$

$$HubScore^{(T+1)}(p_{ij}) = \sum_{d_k \in A_d} w_{ij}^k \times AuthScore^T(d_k) \quad (6)$$

We let $L = (L_{i,j})_{|H_p| \times |A_d|}$ denote the adjacency matrix.

$$\vec{a}^{(T+1)} = L\vec{h}^{(T)} \quad (7)$$

$$\vec{h}^{(T+1)} = L^T\vec{a}^{(T)} \quad (8)$$

where $\vec{a}^{(T)} = [AuthScore^T(d_k)]_{|A_d| \times 1}$ is the vector of authority scores for documents at the T^{th} iteration and $\vec{h}^{(T)} = [HubScore^T(p_{ij})]_{|H_p| \times 1}$ is the vector of hub scores for the word pairs at T^{th} iteration. In order to ensure convergence of the iterative form, $\vec{a}$ and $\vec{h}$ are normalized in each iteration cycle.

For computation of the final scores, the initial scores of all documents are set to $\frac{1}{\sqrt{n}}$, and topic-sentiment word pairs are set to $\frac{1}{\sqrt{m \times M}}$. The above iterative steps are then used to compute the new scores until convergence. Usually the convergence of the iteration algorithm is achieved when the difference between the scores computed at two successive iterations for any nodes falls below a given threshold (Wan et al., 2008; Li et al., 2009; Erkan and Radev, 2004). In our model, we use the hub scores to denote the associative degree of each word pair and the authority scores as the total scores. The documents are then ranked based on the total scores.

4 Experiment

We performed the experiments on the Chinese benchmark dataset to verify our proposed approach for opinion retrieval. We first tested the effect of the parameter λ of our model. To demonstrate the effectiveness of our opinion retrieval model, we compared its performance with the same of other approaches. In addition, we studied each individual query to investigate the influence of query to our model. Furthermore, we showed the top-5 highest weight word pairs of 5 queries to further demonstrate the effect of word pair.

4.1 Experiment Setup

4.1.1 Benchmark Datasets

Our experiments are based on the Chinese benchmark dataset, COAE08 (Zhao et al., 2008). COAE dataset is the benchmark data set for the opinion retrieval track in the Chinese Opinion Analysis Evaluation (COAE) workshop, consisting of blogs and reviews. 20 queries are provided in COAE08. In our experiment, we created relevance judgments through pooling method, where documents are ranked at different levels: irrelevant, relevant but without opinion, and relevant with opinion. Since polarity is not considered, all relevant documents with opinion are classified into the same level.

4.1.2 Sentiment Lexicon

In our experiment, the sentiment lexicon is composed by the following resources (Xu et al., 2007):

(1) *The Lexicon of Chinese Positive Words,* which consists of 5,054 positive words and the *Lexicon of Chinese Negative Words*, which consists of 3,493 negative words;

(2) The opinion word lexicon provided by National Taiwan University which consists of 2,812 positive words and 8,276 negative words;

(3) Sentiment word lexicon and comment word lexicon from *Hownet*. It contains 1836 positive sentiment words, 3,730 positive comments, 1,254 negative sentiment words and 3,116 negative comment words.

The different graphemes corresponding to Traditional Chinese and Simplified Chinese are both considered so that the sentiment lexicons from different sources are applicable to process Simplified Chinese text. The lexicon was manually verified.

4.1.3 Topic Term Collection

In order to acquire the collection of topic terms, we adopt two expansion methods, dictionary-based method and pseudo relevance feedback method.

The dictionary-based method utilizes Wikipedia (Popescu and Etzioni, 2005) to find an entry page for a phrase or a single term in a query. If such an entry exists, all titles of the entry page are extracted as synonyms of the query concept. For example, if we search “绿坝” (Green Tsunami, a firewall) in Wikipedia, it is re-directed to an entry page titled “花季护航” (Youth Escort). This term is then added as a synonym of “绿坝” (Green Tsunami) in the query. Synonyms are treated the same as the original query terms in a retrieval process. The content words in the entry page are ranked by their frequencies in the page. The top-*k* terms are returned as potential expanded topic terms.

The second query expansion method is a web-based method. It is similar to the pseudo relevance feedback expansion but using web documents as the document collection. The query is submitted to a web search engine, such as Google, which returns a ranked list of documents. In the top-*n* documents, the top-*m* topic terms which are highly correlated to the query terms are returned.

4.2 Performance Evaluation

4.2.1 Parameter Tuning

We first studied how the parameter λ (see Equation 1) influenced the mean average precision (MAP) in our model. The result is given in Figure 4.

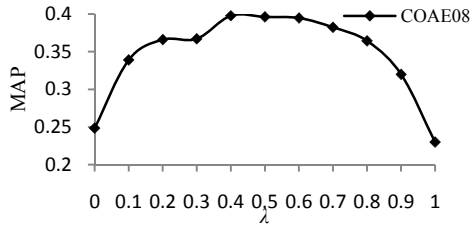

Figure 4: Performance of MAP with varying λ.

Best MAP performance was achieved in COAE08 evaluation, when λ was set between 0.4 and 0.6. Therefore, in the following experiments, we set $\lambda = 0.4$.

4.2.2 Opinion Retrieval Model Comparison

To demonstrate the effectiveness of our proposed model, we compared it with the following models using different evaluation metrics:

(1) IR: We adopted a classical information retrieval model, and further assumed that all retrieved documents contained *relevant opinions*.

(2) Doc: The 2-stage document-based opinion retrieval model was adopted. The model used sentiment lexicon-based method for opinion identification and a conventional information retrieval method for relevance detection.

(3) ROSC: This was the model which achieved the best run in TREC Blog 07. It employed machine learning method to identify opinions for each sentence, and to determine the target topic by a *NEAR* operator.

(4) ROCC: This model was similar to ROSC, but it considered the factor of sentence and regarded the count of relevant opinionated sentence to be the opinion score (Zhang and Yu, 2007). In our experiment, we treated this model as the evaluation baseline.

(5) GORM: our proposed graph-based opinion retrieval model.

Approach	COAE08			
	Evaluation metrics			
Run id	MAP	R-pre	bPref	P@10
IR	0.2797	0.3545	0.2474	0.4868
Doc	0.3316	0.3690	0.3030	0.6696
ROSC	0.3762	0.4321	0.4162	0.7089
Baseline	0.3774	0.4411	0.4198	0.6931
GORM	**0.3978**	**0.4835**	**0.4265**	**0.7309**

Table 1: Comparison of different approaches on COAE08 dataset, and the best is highlighted.

Most of the above models were originally designed for opinion retrieval in English, and re-designed them to handle Chinese opinionated documents. We incorporated our own Chinese sentiment lexicon for this purpose. In our experiments, in addition to MAP, other metrics such as R-precision (R-prec), binary Preference (bPref) and Precision at 10 documents (P@10) were also used. The evaluation results based on these metrics are shown in Table 1.

Table 1 summarized the results obtained. We found that GORM achieved the best performance in all the evaluation metrics. Our baseline, ROSC and GORM which were sentence-based approaches achieved better performance than the document-based approaches by 20% in average. Moreover, our GORM approach did not use machine learning techniques, but it could still achieve outstanding performance.

To study GORM influenced by different queries, the MAP from median average precision on individual topic was shown in Figure 5.

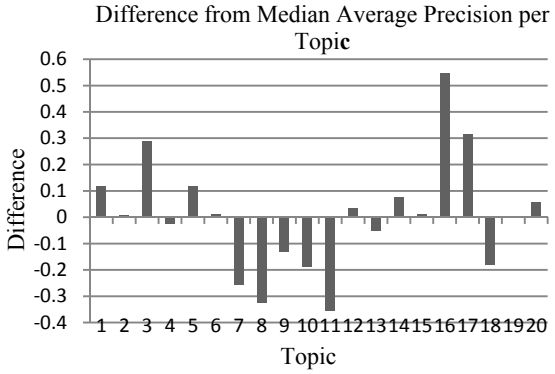

Figure 5: Difference of MAP from Median on COAE08 dataset. (MAP of Median is 0.3724)

As shown in Figure 5, the MAP performance was very low on topic 8 and topic 11. Topic 8, i.e. '成龙' (Jackie Chan), it was influenced by topic 7, i.e. '李连杰' (Jet Lee) as there were a number of similar relevant targets for the two topics, and therefore many word pairs ended up the same. As a result, documents belonging to topic 7 and topic 8 could not be differentiated, and they both performed badly. In order to solve this problem, we extracted the topic term with highest relevant weight in the sentence to form word pairs so that it reduce the impact on the topic terms in common. 24% and 30% improvement were achieved, respectively.

As to topic 11, i.e. '指环王' (Lord of King), there were only 8 relevant documents without any opinion and 14 documents with *relevant opinions*. As a result, the graph constructed by insufficient documents worked ineffectively.

Except for the above queries, GORM performed well in most of the others. To further investigate the effect of word pair, we summarized the top-5 word pairs with highest weight of 5 queries in Table 2.

Top-5 MAP				
陈凯歌 Chen Kaige	国六条 Six States	宏观调控 Macro-regulation	周星驰 Stephen Chow	Vista Vista
<陈凯歌 支持> Chen Kaige Support	<房价 上涨> Room rate Rise	<经济 平稳> Economics Steady	<电影 喜欢> Movie Like	<价格 贵> Price Expensive
<陈凯歌 最佳> Chen Kaige Best	<调控 加强> Regulate Strengthen	<价格 上涨> Price Rise	<周星驰 喜欢> Stephen Chow Like	<微软 喜欢> Microsoft Like
<《无极》 骂> Limitless Revile	<中央 加强> CCP Strengthen	<发展 平稳> Development Steady	<主角 最佳> Protagonist Best	<Vista 推荐> Vista Recommend
<影片 优秀> Movie Excellent	<房价 平稳> Room rate Steady	<消费 上涨> Consume Rise	<喜剧 好> Comedy Good	<问题 重要> Problem Vital
<阵容 强大的> Cast Strong	<住房 保障> Housing Security	<社会 保障> Social Security	<作品 精彩> Works Splendid	<性能 不> Performance No

Table 2: Top-5 highest weight word pairs for 5 queries in COAE08 dataset.

Table 2 showed that most word pairs could represent the *relevant opinions* about the corresponding queries. This showed that inter-sentence information was very helpful to identify the associative degree of a word pair. Furthermore, since word pairs can indicate relevant opinions effectively, it is worth further study on how they could be applied to other opinion oriented applications, e.g. opinion summarization, opinion prediction, etc.

5 Related Work

Our research focuses on *relevant opinion* rather than on relevant document retrieval. We, therefore, review related works in opinion identification research. Furthermore, we do not support the conventional 2-stage opinion retrieval approach. We conducted literature review on unified opinion retrieval models and related work in this area is presented in the section.

5.1 Lexicon-based Opinion Identification

Different from traditional IR, opinion retrieval focuses on the opinion nature of documents. During the last three years, NTICR and TREC evaluations have shown that sentiment lexicon-based methods led to good performance in opinion identification.

A lightweight lexicon-based statistical approach was proposed by Hannah et al. (2007). In this method, the distribution of terms in relevant opinionated documents was compared to their distribution in relevant fact-based documents to calculate an opinion weight. These weights were used to compute opinion scores for each retrieved document. A weighted dictionary was generated from previous TREC relevance data (Amati et al., 2007). This dictionary was submitted as a query to a search engine to get an initial query-independent opinion score of all retrieved documents. Similarly, a pseudo opinionated word composed of all opinion words was first created, and then used to estimate the opinion score of a document (Na et al., 2009). This method was shown to be very effective in TREC evaluations (Lee et al., 2008). More recently, Huang and Croft (2009) proposed an effective relevance model, which integrated both query-independent and query-dependent sentiment words into a mixture model.

In our approach, we also adopt sentiment lexicon-based method for opinion identification. Unlike the above methods, we generate a weight to a sentiment word for each target (associated topic term) rather than assign a unified weight or an equal weight to the sentiment word for the whole topics. Besides, in our model no training data is required. We just utilize the structure of our graph to generate a weight to reflect the associative degree between the two elements of a word pair in different context.

5.2 Unified Opinion Retrieval Model

In addition to conventional 2-stage approach, there has been some research on unified opinion retrieval models.

Eguchi and Lavrenko proposed an opinion retrieval model in the framework of generative language modeling (Eguchi and Lavrenko, 2006). They modeled a collection of natural language documents or statements, each of which consisted of some topic-bearing and some sentiment-bearing words. The sentiment was either represented by a group of predefined seed words, or extracted from a training sentiment corpus. This model was shown to be effective on the MPQA corpus.

Mei et al. tried to build a fine-grained opinion retrieval system for consumer products (Mei et al., 2007). The opinion score for a product was a mixture of several facets. Due to the difficulty in

associating sentiment with products and facets, the system was only tested using small scale text collections.

Zhang and Ye proposed a generative model to unify topic relevance and opinion generation (Zhang and Ye, 2008). This model led to satisfactory performance, but an intensive computation load was inevitable during retrieval, since for each possible candidate document, an opinion score was summed up from the generative probability of thousands of sentiment words.

Huang and Croft proposed a unified opinion retrieval model according to the Kullback-Leibler divergence between the two probability distributions of opinion relevance model and document model (Huang and Croft, 2009). They divided the sentiment words into query-dependent and query-independent by utilizing several sentiment expansion techniques, and integrated them into a mixed model. However, in this model, the contribution of a sentiment word was its corresponding incremental mean average precision value. This method required that large amount of training data and manual labeling.

Different from the above opinion retrieval approaches, our proposed graph-based model processes opinion retrieval in the granularity of sentence. Instead of *bag-of-word*, the sentence is split into word pairs which can maintain the contextual information. On the one hand, word pair can identify the *relevant opinion* according to intra-sentence contextual information. On the other hand, it can measure the degree of a *relevant opinion* by considering the inter-sentence contextual information.

6 Conclusion and Future Work

In this work we focus on the problem of opinion retrieval. Different from existing approaches, which regard document relevance as the key indicator of opinion relevance, we propose to explore the relevance of individual opinion. To do that, opinion retrieval is performed in the granularity of sentence. We define the notion of word pair, which can not only maintain the association between the opinion and the corresponding target in the sentence, but it can also build up the relationship among sentences through the same word pair. Furthermore, we convert the relationships between word pairs and sentences into a unified graph, and use the HITS algorithm to achieve document ranking for opinion retrieval. Finally, we compare our approach with existing methods. Experimental results show that our proposed model performs well on COAE08 dataset.

The novelty of our work lies in using word pairs to represent the information needs for opinion retrieval. On the one hand, word pairs can identify the *relevant opinion* according to intra-sentence contextual information. On the other hand, word pairs can measure the degree of a *relevant opinion* by taking inter-sentence contextual information into consideration. With the help of word pairs, the information needs for opinion retrieval can be represented appropriately.

In the future, more research is required in the following directions:

(1) Since word pairs can indicate relevant opinions effectively, it is worth further study on how they could be applied to other opinion oriented applications, e.g. opinion summarization, opinion prediction, etc.

(2) The characteristics of blogs will be taken into consideration, i.e., the post time, which could be helpful to create a more time sensitivity graph to filter out fake opinions.

(3) Opinion holder is another important role of an opinion, and the identification of opinion holder is a main task in NTCIR. It would be interesting to study opinion holders, e.g. its seniority, for opinion retrieval.

Generating Fine-Grained Reviews of Songs From Album Reviews

Swati Tata and **Barbara Di Eugenio**
Computer Science Department
University of Illinois, Chicago, IL, USA
{stata2 | bdieugen}@uic.edu

Abstract

Music Recommendation Systems often recommend individual songs, as opposed to entire albums. The challenge is to generate reviews for each song, since only full album reviews are available on-line. We developed a summarizer that combines information extraction and generation techniques to produce summaries of reviews of individual songs. We present an intrinsic evaluation of the extraction components, and of the informativeness of the summaries; and a user study of the impact of the song review summaries on users' decision making processes. Users were able to make quicker and more informed decisions when presented with the summary as compared to the full album review.

1 Introduction

In recent years, the personal music collection of many individuals has significantly grown due to the availability of portable devices like MP3 players and of internet services. Music listeners are now looking for techniques to help them manage their music collections and explore songs they may not even know they have (Clema, 2006). Currently, most of those electronic devices follow a Universal Plug and Play (UPNP) protocol (UPN, 2008), and can be used in a simple network, on which the songs listened to can be monitored. Our interest is in developing a Music Recommendation System (Music RS) for such a network.

Commercial web-sites such as Amazon (www.amazon.com) and Barnes and Nobles (www.bnn.com) have deployed Product Recommendation Systems (Product RS) to help customers choose from large catalogues of products. Most Product RSs include reviews from customers who bought or tried the product. As the number of reviews available for each individual product increases, RSs may overwhelm the user if they make all those reviews available. Additionally, in some reviews only few sentences actually describe the recommended product, hence, the interest in opinion mining and in summarizing those reviews.

A Music RS could be developed along the lines of Product RSs. However, Music RSs recommend individual tracks, not full albums, e.g. see www.itunes.com. Summarizing reviews becomes more complex: available data consists of album reviews, not individual song reviews (www.amazon.com, www.epinions.com). Comments about a given song are fragmented all over an album review. Though some web-sites like www.last.fm allow users to comment on individual songs, the comments are too short (a few words such as "awesome song") to be counted as a full review.

In this paper, after presenting related work and contrasting it to our goals in Section 2, we discuss our prototype Music RS in Section 3. We devote Section 4 to our summarizer, that extracts comments on individual tracks from album reviews and produces a summary of those comments for each individual track recommended to the user. In Section 5, we report two types of evaluation: an intrinsic evaluation of the extraction components, and of the coverage of the summary; an extrinsic evaluation via a between-subject study. We found that users make quicker and more informed decisions when presented with the song review summaries as opposed to the full album review.

2 Related Work

Over the last decade, summarization has become a hot topic for research. Quite a few systems were developed for different tasks, including multi-document summarization (Barzilay and McKeown, 2005; Soubbotin and Soubbotin, 2005; Nastase, 2008).

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1376–1385,
Uppsala, Sweden, 11-16 July 2010.

What's not to get? Yes, **Maxwell**, and **Octopus** are a bit silly! ...
.....
"Something" and **"Here Comes The Sun"** are two of George's best songs ever (and **"Something"** may be the single greatest love song ever). **"Oh Darling"** is a bluesy masterpiece with Paul screaming.....
.....
"Come Together" contains a great riff, but he ended up getting sued over the lyrics by Chuck Berry.....

Figure 1: A sample review for the album "Abbey Road"

Whereas summarizing customer reviews can be seen as multi-document summarization, an added necessary step is to first extract the most important features customers focus on. Hence, summarizing customer reviews has mostly been studied as a combination of machine learning and NLP techniques (Hu and Liu, 2004; Gamon et al., 2005). For example, (Hu and Liu, 2004) use associative mining techniques to identify features that frequently occur in reviews taken from `www.epinions.com` and `www.amazon.com`. Then, features are paired to the nearest words that express some opinion on that feature. Most work on product reviews focuses on identifying sentences and polarity of opinion terms, not on generating a coherent summary from the extracted features, which is the main goal of our research. Exceptions are (Carenini et al., 2006; Higashinaka et al., 2006), whose focus was on extracting domain specific ontologies in order to structure summarization of customer reviews.

Summarizing reviews on objects different from products, such as restaurants (Nguyen et al., 2007), or movies (Zhuang et al., 2006), has also been tackled, although not as extensively. We are aware of only one piece of work that focuses on music reviews (Downie and Hu, 2006). This study is mainly concerned with identifying descriptive patterns in positive or negative reviews but not on summarizing the reviews.

2.1 Summarizing song reviews is different

As mentioned earlier, using album reviews for song summarization poses new challenges:
a) Comments on features of a song are embedded and fragmented within the album reviews, as shown in Figure 1. It is necessary to correctly map features to songs.
b) Each song needs to be identified each time it is referred to in the review. Titles are often abbreviated, and in different ways, even in the same review – e.g. see *Octopus* for *Octopus's Garden* in Figure 1. Additionally, song titles need not be noun phrases and hence NP extraction algorithms miss many occurrences, as was shown by preliminary experiments we ran.
c) Reviewers focus on both inherent features such as lyrics, genre and instruments, but also on people (artist, lyricist, producer etc.), unlike in product reviews where manufacturer/designer are rarely mentioned. This variety of features makes it harder to generate a coherent summary.

3 SongRecommend: Prototype Music RS

Figure 2 shows the interface of our prototype Music RS. It is a simple interface dictated by our focus on the summarization process (but it was informed by a small pilot study). Moving from window to window and from top to bottom:
a) The top leftmost window shows different devices on which the user listens to songs. These devices are monitored with a UPNP control point. Based on the messages received by the control point, the user activities, including the metadata of the song, are logged.
b) Once the user chooses a certain song on one of the devices (see second window on top), we display more information about the song (third top window); we also identify related songs from the internet, including: other songs from the same album, popular songs of the artist and popular songs of related artists, as obtained from Yahoo Music.
c) The top 25 recommendations are shown in the fourth top window. We use the SimpleKMeans Clustering (Mitchell, 1997) to identify and rank the top twenty-five songs which belong to the same cluster and are closest to the given song. Closeness between two songs in a cluster is measured as the number of attributes (album, artist etc) of the songs that match.
d) When the user clicks on *More Info* for one of the recommended songs, the pop-up, bottom window is displayed, which contains the summary of the reviews for the specific song.

4 Extraction and Summarization

Our summarization framework consists of the five tasks illustrated in Figure 3. The first two tasks pertain to information extraction, the last three to repackaging the information and generating a co-

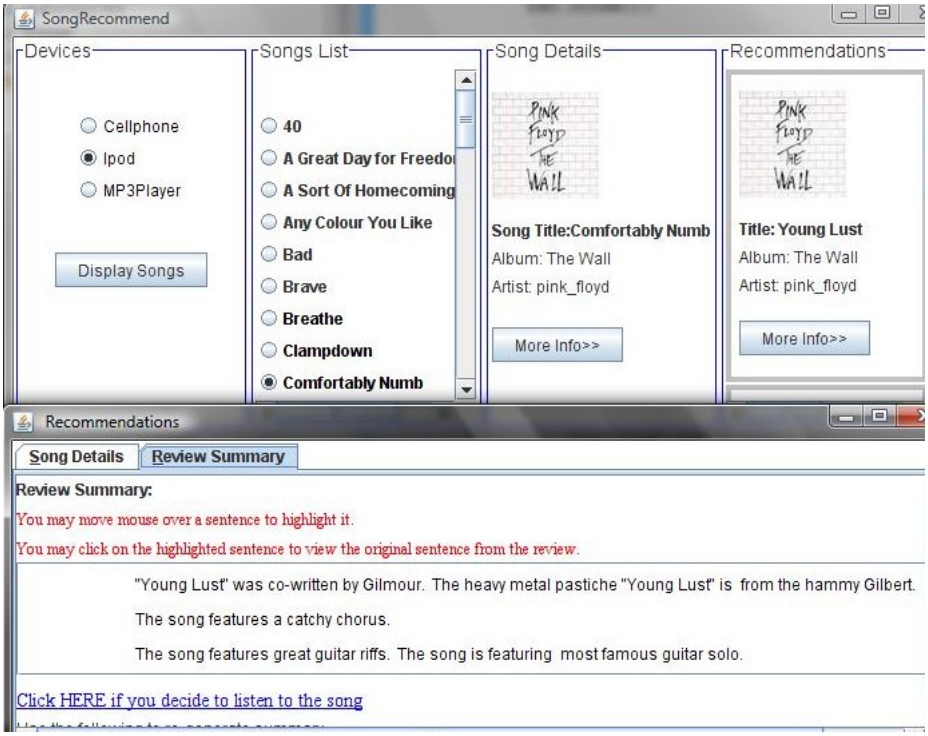

Figure 2: SongRecommend Interface

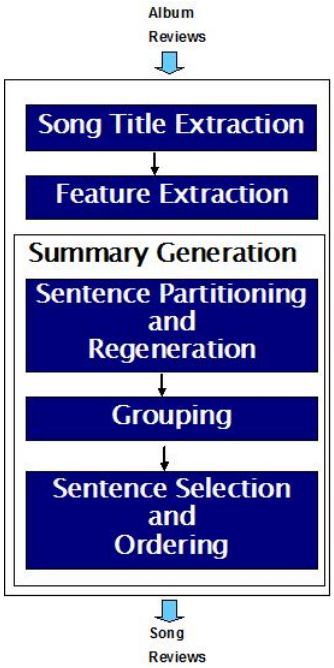

Figure 3: Summarization Pipeline

herent summary. Whereas the techniques we use for each individual step are state-of-the-art, our approach is innovative in that it integrates them into an effective end-to-end system. Its effectiveness is shown by the promising results obtained both via the intrinsic evaluation, and the user study. Our framework can be applied to any domain where reviews of individual components need to be summarized from reviews of collections, such as reviews of different hotels and restaurants in a city.

Our corpus was opportunistically collected from `www.amazon.com` and `www.epinions.com`. It consists of 1350 album reviews across 27 albums (50 reviews per album). 50 randomly chosen reviews were used for development. Reviews have noise, since the writing is informal. We did not clean it, for example we did not correct spelling mistakes. This corpus was annotated for song titles and song features. Feature annotation consists of marking a phrase as a feature and matching it with the song to which the feature is attributed. Note that we have no a priori inventory of features; what counts as features of songs emerged from the annotation, since annotators were asked to annotate for noun phrases which contain "any song related term or terms spoken in the context of a song". Further, they were given about 5 positive and 5 negative

What's not to get? Yes, <**song id=3**>**Maxwell**</**song**>, and <**song id=5**>**Octopus**</**song**> are a bit silly! ...
.....
.....
<**song id=2**>**"Something"**</**song**> and <**song id=7**>**"Here Comes The Sun"**</**song**> are two of <**feature id=(2,7)**>**George's**</**feature**> best songs ever (and <**song id=2**>**"Something"**</**song**> may be
.....
<**song id=4**>**"Oh Darling"**</**song**> is a <**feature id=4**>**bluesy masterpiece**</**feature**> with <**feature id=4**>**Paul**</**feature**> screaming.....
.....
<**song id=1**>**"Come Together"**</**song**> contains a great <**feature id=1**>**riff**</**feature**>, but ...

Figure 4: A sample annotated review

examples of features. Figure 4 shows annotations for the excerpt in Figure 1. For example in Figure 4, *George, Paul, bluesy masterpiece* and *riff* have been marked as features. Ten randomly chosen reviews were doubly annotated for song titles and features. The Kappa co-efficient of agreement on both was excellent (**0.9**), hence the rest of the corpus was annotated by one annotator only. The two annotators were considered to be in agreement on a feature if they marked the same head of phrase **and** attributed it to the same song.

We will now turn to describing the component tasks. The algorithms are described in full in (Tata, 2010).

4.1 Title Extraction

Song identification is the first step towards summarization of reviews. We identify a string of words as the title of a song to be extracted from an album review if it (1) includes some or all the words in the title of a track of that album, and (2) this string occurs in the right context. Constraint (2) is necessary because the string of words corresponding to the title may appear in the lyrics of the song or anywhere else in the review. The string *Maxwell's Silver Hammer* counts as a title only in sentence (a) below; the second sentence is a verse in the lyrics:

a. Then, the wild and weird "Maxwell's Silver Hammer."

b. Bang, Bang, maxwell's silver hammer cam down on her head.

Similar to Named Entity Recognition (Schedl et al., 2007), our approach to song title extraction is based on *n-grams*. We proceed album by album. Given the reviews for an album and the list of songs in that album, first, we build a lexicon of all the words in the song titles. We also segment the reviews into sentences via sentence boundary detection. All 1,2,3,4-grams for each sentence (the upper-bound 4 was determined experimentally) in the review are generated. First, n-grams that contain at least one word with an edit distance greater than one from a word in the lexicon are filtered out. Second, if higher and lower order n-grams overlap at the same position in the same sentence, lower order n-grams are filtered out. Third, the n-grams are merged if they occur sequentially in a sentence. Fourth, the n-grams are further filtered to include only those where (i) the n-gram is within quotation marks; and/or (ii) the first character of each word in the n-gram is upper case. This filters n-grams such as those shown in sentence (b) above. All the n-grams remaining at this point are potential song titles. Finally, for each n-gram, we retrieve the set of IDs for each of its words and intersect those sets. This intersection always resulted in one single song ID, since song titles in each album differ by at least one content word. Recall that the algorithm is run on reviews for each album separately.

4.2 Feature Extraction

Once the song titles are identified in the album review, sentences with song titles are used as anchors to (1) identify *segments* of texts that talk about a specific song, and then (2) extract the feature(s) that the pertinent text segment discusses.

The first step roughly corresponds to identifying the flow of topics in a review. The second step corresponds to identifying the properties of each song. Both steps would greatly benefit from reference resolution, but current algorithms still have a low accuracy. We devised an approach that combines text tiling (Hearst, 1994) and domain heuristics. The text tiling algorithm divides the text into coherent discourse units, to describe the sub-topic structure of the given text. We found the relatively coarse segments the text tiling algorithm provides sufficient to identify different topics.

An album review is first divided into segments using the text tiling algorithm. Let $[seg_1, seg_2, ..., seg_k]$ be the segments obtained. The segments that contain potential features of a song are identified using the following heuristics:

Step 1: Include seg_i if it contains a song title.

These segments are more likely to contain features of songs as they are composed of the sentences surrounding the song title.

Step 2: Include seg_{i+1} if seg_i is included and seg_{i+1} contains one or more *feature terms*.

Since we have no a priori inventory of features (the feature annotation will be used for evaluation, not for development), we use WordNet (Fellbaum, 1998) to identify *feature terms*: i.e., those nouns whose synonyms, direct hypernym or direct hyponym, or the definitions of any of those, contain the terms "music" or "song", or any form of these words like "musical", "songs" etc, for at least one sense of the noun. Feature terms exclude the words "music", "song", the artist/band/album name as they are likely to occur across album reviews. All feature terms in the final set of segments selected by the heuristics are taken to be features of the song described by that segment.

4.3 Sentence Partitioning and Regeneration

After extracting the sentences containing the features, the next step is to divide the sentences into two or more "sub-sentences", if necessary. For example, *"McCartney's bouncy bass-line is especially wonderful, and George comes in with an excellent, minimal guitar solo."* discusses both features *bass* and *guitar*. Only a portion of the sentence describes the *guitar*. This sentence can thus be divided into two individual sentences. Removing parts of sentences that describe another feature, will have no effect on the summary as a whole as the portions that are removed will be present in the group of sentences that describe the other feature.

To derive n sentences, each concerning a single feature f, from the original sentence that covered n features, we need to:

1. Identify portions of sentences relevant to each feature f (partitioning)
2. Regenerate each portion as an independent sentence, which we call f-sentence.

To identify portions of the sentence relevant to the single feature f, we use the Stanford Typed Dependency Parser (Klein and Manning, 2002; de Marnee and Manning, 2008). Typed Dependencies describe grammatical relationships between pairs of words in a sentence. Starting from the feature term f in question, we collect all the nouns, adjectives and verbs that are directly related to it in the sentence. These nouns, adjectives and verbs become the components of the new f-sentence. Next, we need to adjust their number and forms. This is a natural language generation task, specifically, sentence realization.

1. **"Maxwell"** is a bit silly.
2. **"Octopus"** is a bit silly.
3. **"Something"** is George's best song.
4. **"Here Comes The Sun"** is George's best song.
5. **"Something"** may be the single greatest love song.
6. **"Oh! Darling"** is a bluesy masterpiece.
7. **"Come Together"** contains a great riff.

Figure 5: f-sentences corresponding to Figure 1

We use YAG (McRoy et al., 2003), a template based sentence realizer. *clause* is the main template used to generate a sentence. Slots in a template can in turn be templates. The grammatical relationships obtained from the Typed Dependency Parser such as *subject* and *object* identify the slots and the template the slots follows; the words in the relationship fill the slot. We use a morphological tool (Minnen et al., 2000) to obtain the base form from the original verb or noun, so that YAG can generate grammatical sentences. Figure 5 shows the regenerated review from Figure 1.

YAG regenerates as many f-sentences from the original sentence, as many features were contained in it. By the end of this step, for each feature f of a certain song s_i, we have generated a set of f-sentences. This set also contains every original sentence that only covered the single feature f.

4.4 Grouping

f-sentences are further grouped, by sub-feature and by polarity. As concerns sub-feature grouping, consider the following f-sentences for the feature *guitar*:

a. *George comes in with an excellent, minimal guitar solo.*

b. *McCartney laid down the guitar lead for this track.*

c. *Identical lead guitar provide the rhythmic basis for this song.*

The first sentence talks about the *guitar solo*, the second and the third about the *lead guitar*. This step will create two subgroups, with sentence *a* in one group and sentences *b* and *c* in another. We

Let $[f_x\text{-}s_1, f_x\text{-}s_2, ...f_x\text{-}s_n]$ be the set of sentences for feature f_x and song S_y

Step 1: *Find the longest common n-gram (LCN) between f_x-s_i and f_x-s_j for all $i \neq j$: LCN(f_x-s_i, f_x-s_j)*

Step 2: *If LCN(f_x-s_i, f_x-s_j) contains the feature term and is not the feature term alone, f_x-s_i and f_x-s_j are in the same group.*

Step 3: *For any f_x-s_i, if LCN(f_x-s_i, f_x-s_j) for all i and j, is the feature term, then f_x-s_i belongs to the default group for the feature.*

Figure 6: Grouping sentences by sub-features

Example: *The lyrics are the best*
Adjectives in the sentence: *best*

Senti-wordnet Scores of *best*:
Sense 1 (frequency=2):
positive = 0.625, negative =0 , objective = 0.375

Sense 2 (frequency=1):
positive = 0.75, negative = 0, objective = 0.25

Polarity Scores Calculation:
positive(best) = $\frac{2*0.625+1*0.75}{(2+1)}$ = 0.67
negative(best) = $\frac{2*0+1*0}{(2+1)}$ = 0
objective(best) = $\frac{2*0.375+1*0.25}{(2+1)}$ = 0.33

Since the sentence contains only the adjective *best*, its polarity is positive, from:
Max (positive(best), negative(best), objective(best))

Figure 7: Polarity Calculation

identify subgroups via common n-grams between f-sentences, and make sure that only n-grams that are related to feature f are identified at this stage, as detailed in Figure 6. When the procedure described in Figure 6 is applied to the three sentences above, it identifies *guitar* as the longest pertinent LCN between *a* and *b*, and between *a* and *c*; and *guitar lead* between *b* and *c* (we do not take into account linear order within n-grams, hence *guitar lead* and *lead guitar* are considered identical). Step 2 in Figure 6 will group *b* and *c* together since *guitar lead* properly contains the feature term *guitar*. In Step 3, sentence *a* is sentence f_x-s_i such that its LCN with all other sentences (*b* and *c*) contains only the feature term; hence, sentence *a* is left on its own. Note that Steps 2 and 3 ensure that, among all the possible LNCs between pair of sentences, we only consider the ones containing the feature in question.

As concerns polarity grouping, different reviews may express different opinions regarding a particular feature. To generate a coherent summary that mentions conflicting opinions, we need to subdivide f-sentences according to polarity.

We use SentiWordNet (Esuli and Sebastiani, 2006), an extension of WordNet where each sense of a word is augmented with the probability of that sense being positive, negative or neutral. The overall sentence score is based on the scores of the adjectives contained in the sentence.

Since there are a number of senses for each word, an adjective a_i in a sentence is scored as the normalized weighted scores of each sense of the adjective. For each a_i, we compute three scores, positive, as shown in Formula 1, negative and objective, which are computed analogously:

$$pos(a_i) = \frac{freq_1 * pos_1 + ... + freq_n * pos_n}{(freq_1 + ... + freq_n)} \quad (1)$$

a_i is the i^{th} adjective, $freq_j$ is the frequency of the j^{th} sense of a_i as given by Wordnet, and pos_j is the positive score of the j^{th} sense of a_i, as given by SentiWordnet. Figure 7 shows an example of calculating the polarity of a sentence.

For an f-sentence, three scores will be computed, as the sum of the corresponding scores (positive, negative, objective) of all the adjectives in the sentence. The polarity of the sentence is determined by the maximum of these three scores.

4.5 Selection and Ordering

Finally, the generation of a coherent summary involves selection of the sentences to be included, and ordering them in a coherent fashion. This step has in input groups of f-sentences, where each group pertains to the feature f, one of its subfeatures, and one polarity type (positive, negative, objective). We need to select one sentence from each subgroup to make sure that all essential concepts are included in the summary. Note that if there are contrasting opinions on one feature or subfeatures, one sentence per polarity will be extracted, resulting in potentially inconsistent opinions on that feature to be included in the review (we did not observe this happening frequently, and even if it did, it did not appear to confuse our users).

Recall that at this point, most f-sentences have been regenerated from portions of original sen-

tences (see Section 4.3). Each f-sentence in a subgroup is assigned a score which is equivalent to the number of features in the original sentence from which the f-sentence was obtained. The sentence which has the lowest score in each subgroup is chosen as the representative for that subgroup. If multiple sentences have the lowest score, one sentence is selected randomly. Our assumption is that among the original sentences, a sentence that talks about one feature only is likely to express a stronger opinion about that feature than a sentence in which other features are present.

We order the sentences by exploiting a music ontology (Giasson and Raimond, 2007). We have extended this ontology to include few additional concepts that correspond to features identified in our corpus. Also, we extended each of the classes by adding the domain to which it belongs. We identified a total of 20 different domains for all the features. For example, *[saxophone,drums]* belongs to the domain *Instrument*, and *[tone, vocals]* belong to the domain *Sound*. We also identified the priority order in which each of these domains should appear in the final summary. The ordering of the domains is such that first we present the general features of the song (e.g. *Song*) domain, then present more specific domains (e.g. *Sound, Instrument*). $f-$sentences of a single domain form one paragraph in the final summary. However, features domains that are considered as sub-domains of another domain are included in the same paragraph, but are ordered next to the features of the parent domain. The complete list of domains is described in (Tata, 2010). f-sentences are grouped and ordered according to the domain of the features. Figure 8 shows a sample summary when the extracted sentences are ordered via this method.

> "The Song That Jane Likes" is cute. The song has some nice riffs by Leroi Moore. "The Song That Jane Likes" is also amazing funk number.
>
> The lyrics are sweet and loving.
>
> The song carries a light-hearted tone. It has a catchy tune. The song features some nice accents.
>
> "The Song That Jane Likes" is beautiful song with great rhythm. The funky beat will surely make a move.
>
> It is a heavily acoustic guitar-based song.

Figure 8: Sample summary

5 Evaluation

In this section we report three evaluations, two intrinsic and one extrinsic: evaluation of the song title and feature extraction steps; evaluation of the informativeness of summaries; and a user study to judge how summaries affect decision making.

5.1 Song Title and Feature Extraction

The song title extraction and feature extraction algorithms (Sections 4.1 and 4.2) were manually evaluated on 100 reviews randomly taken from the corpus (2 or 3 from each album). This relatively small number is due to the need to conduct the evaluation manually. The 100 reviews contained 1304 occurrences of song titles and 898 occurrences of song features, as previously annotated.

1294 occurrences of song titles were correctly identified; additionally, 123 spurious occurrences were also identified. This results in a precision of 91.3%, and recall of 98%. The 10 occurrences that were not identified contained either abbreviations like *Dr.* for *Doctor* or spelling mistakes (recall that we don't clean up mistakes).

Of the 898 occurrences of song features, 853 were correctly identified by our feature extraction algorithm, with an additional 41 spurious occurrences. This results in a precision of 95.4% and a recall of 94.9%. Note that a feature (NP) is considered as correctly identified, if its head noun is annotated in a review for the song with correct ID.

As a baseline comparison, we implemented the feature extraction algorithm from (Hu and Liu, 2004). We compared their algorithm to ours on 10 randomly chosen reviews from our corpus, for a total of about 500 sentences. Its accuracy (40.8% precision, and 64.5% recall) is much lower than ours, and than their original results on product reviews (72% precision, and 80% recall).

5.2 Informativeness of the summaries

To evaluate the information captured in the summary, we randomly selected 5 or 6 songs from 10 albums, and generated the corresponding 52 summaries, one per song – this corresponds to a test set of about 500 album reviews (each album has about 50 reviews). Most summary evaluation schemes, for example the Pyramid method (Harnly et al., 2005), make use of reference summaries written by humans. We approximate those gold-standard reference summaries with 2 or 3 critic reviews per album taken from `www.pitchfork.`

com, www.rollingstone.com and www.allmusic.com.

First, we manually annotated both critic reviews and the automatically generated summaries for song titles and song features. 302, i.e., 91.2% of the features identified in the critic reviews are also identified in the summaries (recall that a feature is considered as identified, if the head-noun of the NP is identified by both the critic review and the summary, and attributed to the same song). 64 additional features were identified, for a recall of 82%. It is not surprising that additional features may appear in the summaries: even if only one of the 50 album reviews talks about that feature, it is included in the summary. Potentially, a threshold on frequency of feature mention could increase recall, but we found out that even a threshold of two significantly affects precision.

In a second evaluation, we used our Feature Extraction algorithm to extract features from the critic reviews, for each song whose summary needs to be evaluated. This is an indirect evaluation of that algorithm, in that it shows it is not affected by somewhat different data, since the critic reviews are more formally written. 375, or 95% of the features identified in the critic reviews are also identified in the summaries. 55 additional features were additionally identified, for a recall of 87.5%. These values are comparable, even if slightly higher, to the precision and recall of the manual annotation described above.

5.3 Between-Subject User Study

Our intrinsic evaluation gives satisfactory results. However, we believe the ultimate measure of such a summarization algorithm is an end-to-end evaluation to ascertain whether it affects user behavior, and how. We conducted a between-subject user study, where users were presented with two different versions of our Music RS. For each of the recommended songs, the baseline version provides *only* whole album reviews, the experimental version provides the automatically generated song feature summary, as shown in Figure 2. The interface for the baseline version is similar, but the summary in the bottom window is replaced by the corresponding album review. The presented review is the one among the 50 reviews for that album whose length is closest to the average length of album reviews in the corpus (478 words).

Each user was presented with 5 songs in succession, with 3 recommendations each (only the top 3 recommendations were presented among the available 25, see Section 3). Users were asked to select at least one recommendation for each song, namely, to click on the url where they can listen to the song. They were also asked to base their selection on the information provided by the interface. The first song was a test song for users to get acquainted with the system. We collected comprehensive timed logs of the user actions, including clicks, when windows are open and closed, etc. After using the system, users were administered a brief questionnaire which included questions on a 5-point Likert Scale. 18 users interacted with the baseline version and 21 users with the experimental version (five additional subjects were run but their log data was not properly saved). All users were students at our University, and most of them, graduate students (no differences were found due to gender, previous knowledge of music, or education level).

Our main measure is time on task, the total time taken to select the recommendations from song 2 to song 5 – this excludes the time spent listening to the songs. A t-test showed that users in the experimental version take less time to make their decision when compared to baseline subjects ($p = 0.019$, $t = 2.510$). This is a positive result, because decreasing time to selection is important, given that music collections can include millions of songs. However, time-on-task basically represents the time it takes users to peruse the review or summary, and the number of words in the summaries is significantly lower than the number of words in the reviews ($p < 0.001$, $t = 16.517$).

Hence, we also analyzed the influence of summaries on decision making, to see if they have any effects beyond cutting down on the number of words to read. Our assumption is that the default choice is to choose the first recommendation. Users in the baseline condition picked the first recommendation as often as the other two recommendations combined; users in the experimental condition picked the second and third recommendations more often than the first, and the difference between the two conditions is significant ($\chi^2 = 8.74$, $df = 1$, $p = 0.003$). If we examine behavior song by song, this holds true especially for song 3 ($\chi^2 = 12.3$, $df = 1$, $p < 0.001$) and song 4 ($\chi^2 = 5.08$, $df = 1$, $p = 0.024$). We speculate that users in the experimental condition

are more discriminatory in their choices, because important features of the recommended songs are evident in the summaries, but are buried in the album reviews. For example, for Song 3, only one of the 20 sentences in the album review is about the first recommended song, and is not very positive. Negative opinions are much more evident in the review summaries.

The questionnaires included three common questions between the two conditions. The experimental subjects gave a more positive assessment of the length of the summary than the baseline subjects ($p = 0.003$, $t = -3.248$, $df = 31.928$). There were no significant differences on the other two questions, feeling overwhelmed by the information provided; and whether the review/summary helped them to quickly make their selection.

A multiple Linear Regression with, as predictors, the number of words the user read before making the selection and the questions, and time on task as dependent variable, revealed only one, not surprising, correlation: the number of words the user read correlates with time on task ($R^2 = 0.277$, $\beta = 0.509$, $p = 0.004$).

Users in the experimental version were also asked to rate the grammaticality and coherence of the summary. The average rating was 3.33 for grammaticality, and 3.14 for coherence. Whereas these numbers in isolation are not too telling, they are at least suggestive that users did not find these summaries badly written. We found no significant correlations between grammaticality and coherence of summaries, and time on task.

6 Discussion and Conclusions

Most summarization research on customer reviews focuses on obtaining features of the products, but not much work has been done on presenting them as a coherent summary. In this paper, we described a system that uses information extraction and summarization techniques in order to generate summaries of individual songs from multiple album reviews. Whereas the techniques we have used are state-of-the-art, the contribution of our work is integrating them in an effective end-to-end system. We first evaluated it intrinsically as concerns information extraction, and the informativeness of the summaries. Perhaps more importantly, we also ran an extrinsic evaluation in the context of our prototype Music RS. Users made quicker decisions and their choice of recommendations was more varied when presented with song review summaries than with album reviews. Our framework can be applied to any domain where reviews of individual components need to be summarized from reviews of collections, such as travel reviews that cover many cities in a country, or different restaurants in a city.

Abstract

Most sentiment analysis approaches use as baseline a support vector machines (SVM) classifier with binary unigram weights. In this paper, we explore whether more sophisticated feature weighting schemes from Information Retrieval can enhance classification accuracy. We show that variants of the classic $tf.idf$ scheme adapted to sentiment analysis provide significant increases in accuracy, especially when using a sublinear function for term frequency weights and document frequency smoothing. The techniques are tested on a wide selection of data sets and produce the best accuracy to our knowledge.

1 Introduction

The increase of user-generated content on the web in the form of reviews, blogs, social networks, tweets, fora, etc. has resulted in an environment where everyone can publicly express their opinion about events, products or people. This wealth of information is potentially of vital importance to institutions and companies, providing them with ways to research their consumers, manage their reputations and identify new opportunities. Wright (2009) claims that "for many businesses, online opinion has turned into a kind of virtual currency that can make or break a product in the marketplace".

Sentiment analysis, also known as opinion mining, provides mechanisms and techniques through which this vast amount of information can be processed and harnessed. Research in the field has mainly, but not exclusively, focused in two subproblems: detecting whether a segment of text, either a whole document or a sentence, is subjective or objective, i.e. contains an expression of opinion, and detecting the overall polarity of the text, i.e. positive or negative.

Most of the work in sentiment analysis has focused on supervised learning techniques (Sebastiani, 2002), although there are some notable exceptions (Turney, 2002; Lin and He, 2009). Previous research has shown that in general the performance of the former tend to be superior to that of the latter (Mullen and Collier, 2004; Lin and He, 2009). One of the main issues for supervised approaches has been the representation of documents. Usually a *bag of words* representation is adopted, according to which a document is modeled as an unordered collection of the words that it contains. Early research by Pang et al. (2002) in sentiment analysis showed that a binary unigram-based representation of documents, according to which a document is modeled only by the presence or absence of words, provides the best baseline classification accuracy in sentiment analysis in comparison to other more intricate representations using bigrams, adjectives, etc.

Later research has focused on extending the document representation with more complex features such as structural or syntactic information (Wilson et al., 2005), favorability measures from diverse sources (Mullen and Collier, 2004), implicit syntactic indicators (Greene and Resnik, 2009), stylistic and syntactic feature selection (Abbasi et al., 2008), "annotator rationales" (Zaidan et al., 2007) and others, but no systematic study has been presented exploring the benefits of employing more sophisticated models for assigning weights to word features.

In this paper, we examine whether term weighting functions adopted from Information Retrieval (IR) based on the standard $tf.idf$ formula and adapted to the particular setting of sentiment analysis can help classification accuracy. We demonstrate that variants of the original $tf.idf$ weighting scheme provide significant increases in classification performance. The advantages of the approach are that it is intuitive, computationally efficient

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1386–1395,
Uppsala, Sweden, 11-16 July 2010.

and doesn't require additional human annotation or external sources. Experiments conducted on a number of publicly available data sets improve on the previous state-of-the art.

The next section provides an overview of relevant work in sentiment analysis. In section 3 we provide a brief overview of the original $tf.idf$ weighting scheme along with a number of variants and show how they can be applied to a classification scenario. Section 4 describes the corpora that were used to test the proposed weighting schemes and section 5 discusses the results. Finally, we conclude and propose future work in section 6.

2 Prior Work

Sentiment analysis has been a popular research topic in recent years. Most of the work has focused on analyzing the content of movie or general product reviews, but there are also applications to other domains such as debates (Thomas et al., 2006; Lin et al., 2006), news (Devitt and Ahmad, 2007) and blogs (Ounis et al., 2008; Mishne, 2005). The book of Pang and Lee (2008) presents a thorough overview of the research in the field. This section presents the most relevant work.

Pang et al. (2002) conducted early polarity classification of reviews using supervised approaches. They employed Support Vector Machines (SVMs), Naive Bayes and Maximum Entropy classifiers using a diverse set of features, such as unigrams, bigrams, binary and term frequency feature weights and others. They concluded that sentiment classification is more difficult that standard topic-based classification and that using a SVM classifier with binary unigram-based features produces the best results.

A subsequent innovation was the detection and removal of the objective parts of documents and the application of a polarity classifier on the rest (Pang and Lee, 2004). This exploited text coherence with adjacent text spans which were assumed to belong to the same subjectivity or objectivity class. Documents were represented as graphs with sentences as nodes and association scores between them as edges. Two additional nodes represented the subjective and objective poles. The weights between the nodes were calculated using three different, heuristic decaying functions. Finding a partition that minimized a cost function separated the objective from the subjective sentences. They reported a statistically significant improvement over a Naive Bayes baseline using the whole text but only slight increase compared to using a SVM classifier on the entire document.

Mullen and Collier (2004) used SVMs and expanded the feature set for representing documents with favorability measures from a variety of diverse sources. They introduced features based on Osgood's Theory of Semantic Differentiation (Osgood, 1967) using WordNet to derive the values of potency, activity and evaluative of adjectives and Turney's semantic orientation (Turney, 2002). Their results showed that using a *hybrid* SVM classifier, that uses as features the distance of documents from the separating hyperplane, with all the above features produces the best results.

Whitelaw et al. (2005) added fine-grained semantic distinctions in the feature set. Their approach was based on a lexicon created in a semi-supervised fashion and then manually refined It consists of 1329 adjectives and their modifiers categorized under several taxonomies of appraisal attributes based on Martin and White's Appraisal Theory (2005). They combined the produced appraisal groups with unigram-based document representations as features to a Support Vector Machine classifier (Witten and Frank, 1999), resulting in significant increases in accuracy.

Zaidan et al. (2007) introduced "annotator rationales", i.e. words or phrases that explain the polarity of the document according to human annotators. By deleting rationale text spans from the original documents they created several *contrast* documents and constrained the SVM classifier to classify them less confidently than the originals. Using the largest training set size, their approach significantly increased the accuracy on a standard data set (see section 4).

Prabowo and Thelwall (2009) proposed a *hybrid* classification process by combining in sequence several ruled-based classifiers with a SVM classifier. The former were based on the General Inquirer lexicon (Wilson et al., 2005), the MontyLingua part-of-speech tagger (Liu, 2004) and co-occurrence statistics of words with a set of predefined reference words. Their experiments showed that combining multiple classifiers can result in better effectiveness than any individual classifier, especially when sufficient training data isn't available.

In contrast to machine learning approaches that require labeled corpora for training, Lin and

He (2009) proposed an unsupervised probabilistic modeling framework, based on Latent Dirichlet Allocation (LDA). The approach assumes that documents are a mixture of topics, i.e. probability distribution of words, according to which each document is generated through an hierarchical process and adds an extra sentiment layer to accommodate the opinionated nature (positive or negative) of the document. Their best attained performance, using a filtered subjectivity lexicon and removing objective sentences in a manner similar to Pang and Lee (2004), is only slightly lower than that of a fully-supervised approach.

3 A study of non-binary weights

We use the terms "features", "words" and "terms" interchangeably in this paper, since we mainly focus on unigrams. The approach nonetheless can easily be extended to higher order n-grams. Each document D therefore is represented as a bag-of-words feature vector: $D = \{w_1, w_2, ..., w_{|V|}\}$ where $|V|$ is the size of the vocabulary (i.e. the number of unique words) and w_i, $i = 1, \ldots, |V|$ is the weight of term i in document D.

Despite the significant attention that sentiment analysis has received in recent years, the best accuracy without using complex features (Mullen and Collier, 2004; Whitelaw et al., 2005) or additional human annotations (Zaidan et al., 2007) is achieved by employing a binary weighting scheme (Pang et al., 2002), where $w_i = 1, \text{if } tf_i > 0$ and $w_i = 0, \text{if } tf_i = 0$, where tf_i is the number of times that term i appears in document D (henceforth *raw term frequency*) and utilizing a SVM classifier. It is of particular interest that using tf_i in the document representation usually results in decreased accuracy, a result that appears to be in contrast with topic classification (Mccallum and Nigam, 1998; Pang et al., 2002).

In this paper, we also utilize SVMs but our study is centered on whether more sophisticated than binary or raw term frequency weighting functions can improve classification accuracy. We base our approach on the classic $tf.idf$ weighting scheme from Information Retrieval (IR) and adapt it to the domain of sentiment classification.

3.1 The classic tf.idf weighting schemes

The classic $tf.idf$ formula assigns weight w_i to term i in document D as:

$$w_i = tf_i \cdot idf_i = tf_i \cdot log\frac{N}{df_i} \quad (1)$$

where tf_i is the number of times term i occurs in D, idf_i is the *inverse document frequency* of term i, N is the total number of documents and df_i is the number of documents that contain term i.

The utilization of tf_i in classification is rather straightforward and intuitive but, as previously discussed, usually results in decreased accuracy in sentiment analysis. On the other hand, using idf to assign weights to features is less intuitive, since it only provides information about the general distribution of term i amongst documents of all classes, without providing any additional evidence of class preference. The utilization of idf in information retrieval is based on its ability to distinguish between content-bearing words (words with some semantical meaning) and simple function words, but this behavior is at least ambiguous in classification.

Table 1: SMART notation for *term frequency* variants. $max_t(tf)$ is the maximum frequency of any term in the document and avg_dl is the average number of terms in all the documents. For ease of reference, we also include the BM25 tf scheme. The k_1 and b parameters of BM25 are set to their default values of 1.2 and 0.95 respectively (Jones et al., 2000).

Notation	Term frequency
n (natural)	tf
l (logarithm)	$1 + log(tf)$
a (augmented)	$0.5 + \frac{0.5 \cdot tf}{max_t(tf)}$
b (boolean)	$\begin{cases} 1, & tf > 0 \\ 0, & otherwise \end{cases}$
L (log ave)	$\frac{1+log(tf)}{1+log(avg\_dl)}$
o (BM25)	$\frac{(k_1+1) \cdot tf}{k_1\left((1-b)+b \cdot \frac{dl}{avg\_dl}\right)+tf}$

3.2 Delta tf.idf

Martineau and Finin (2009) provide a solution to the above issue of idf utilization in a classification scenario by localizing the estimation of idf to the documents of one or the other class and subtracting the two values. Therefore, the weight of term

Table 2: SMART notation for *inverse document frequency* variants. For ease of reference we also include the BM25 idf factor and also present the extensions of the original formulations with their Δ variants.

Notation	Inverse Document Frequency
n (no)	1
t (idf)	$log\frac{N}{df}$
p (prob idf)	$log\frac{N-df}{df}$
k (BM25 idf)	$log\frac{N-df+0.5}{df+0.5}$
$\Delta(t)$ (Delta idf)	$log\frac{N_1 \cdot df_2}{N_2 \cdot df_1}$
$\Delta(t')$ (Delta smoothed idf)	$log\frac{N_1 \cdot df_2+0.5}{N_2 \cdot df_1+0.5}$
$\Delta(p)$ (Delta prob idf)	$log\frac{(N_1-df_1)\cdot df_2}{df_1 \cdot (N_2-df_2)}$
$\Delta(p')$ (Delta smoothed prob idf)	$log\frac{(N_1-df_1)\cdot df_2+0.5}{(N_2-df_2)\cdot df_1+0.5}$
$\Delta(k)$ (Delta BM25 idf)	$log\frac{(N_1-df_1+0.5)\cdot df_2+0.5}{(N_2-df_2+0.5)\cdot df_1+0.5}$

i in document D is estimated as:

$$\begin{aligned} w_i &= tf_i \cdot log_2(\frac{N_1}{df_{i,1}}) - tf_i \cdot log_2(\frac{N_2}{df_{i,2}}) \\ &= tf_i \cdot log_2(\frac{N_1 \cdot df_{i,2}}{df_{i,1} \cdot N_2}) \end{aligned} \quad (2)$$

where N_j is the total number of training documents in class c_j and $df_{i,j}$ is the number of training documents in class c_j that contain term i. The above weighting scheme was appropriately named $Delta\, tf.idf$.

The produced results (Martineau and Finin, 2009) show that the approach produces better results than the simple tf or binary weighting scheme. Nonetheless, the approach doesn't take into consideration a number of tested notions from IR, such as the non-linearity of term frequency to document relevancy (e.g. Robertson et al. (2004)) according to which, the probability of a document being relevant to a query term is typically sublinear in relation to the number of times a query term appears in the document. Additionally, their approach doesn't provide any sort of smoothing for the $df_{i,j}$ factor and is therefore susceptible to errors in corpora where a term occurs in documents of only one or the other class and therefore $df_{i,j} = 0$.

3.3 SMART and BM25 tf.idf variants

The SMART retrieval system by Salton (1971) is a retrieval system based on the vector space model (Salton and McGill, 1986). Salton and Buckley (1987) provide a number of variants of the $tf.idf$ weighting approach and present the *SMART notation scheme*, according to which each weighting function is defined by triples of letters; the first one denotes the term frequency factor, the second one corresponds to the inverse document frequency function and the last one declares the normalization that is being applied. The upper rows of tables 1, 2 and 3 present the three most commonly used weighting functions for each factor respectively. For example, a binary document representation would be equivalent to $SMART.bnn$[1] or more simply bnn, while a simple raw term frequency based would be notated as nnn or nnc with cosine normalization.

Table 3: SMART normalization.

Notation	Normalization
n (none)	1
c (cosine)	$\frac{1}{\sqrt{w_1^2+w_2^2+...+w_n^2}}$

Significant research has been done in IR on diverse weighting functions and not all versions of SMART notations are consistent (Manning et al., 2008). Zobel and Moffat (1998) provide an exhaustive study but in this paper, due to space constraints, we will follow the concise notation presented by Singhal et al. (1995).

The BM25 weighting scheme (Robertson et al., 1994; Robertson et al., 1996) is a probabilistic model for information retrieval and is one of the most popular and effective algorithms used in information retrieval. For ease of reference, we incorporate the BM25 tf and idf factors into the SMART annotation scheme (last row of table 1 and 4^{th} row of table 2), therefore the weight w_i of term i in document D according to the BM25 scheme is notated as $SMART.okn$ or okn.

Most of the tf weighting functions in SMART and the BM25 model take into consideration the non-linearity of document relevance to term fre-

[1]Typically, a weighting function in the SMART system is defined as a pair of triples, i.e. $ddd.qqq$ where the first triple corresponds to the document representation and the second to the query representation. In the context that the SMART annotation is used here, we will use the prefix $SMART$ for the first part and a triple for the document representation in the second part, i.e. $SMART.ddd$, or more simply ddd.

quency and thus employ tf factors that scale sublinearly in relation to term frequency. Additionally, the BM25 tf variant also incorporates a scaling for the length of the document, taking into consideration that longer documents will by definition have more term occurences[2]. Effective weighting functions is a very active research area in information retrieval and it is outside the scope of this paper to provide an in-depth analysis but significant research can be found in Salton and McGill (1986), Robertson et al. (2004), Manning et al. (2008) or Armstrong et al. (2009) for a more recent study.

3.4 Introducing SMART and BM25 Delta tf.idf variants

We apply the idea of localizing the estimation of idf values to documents of one class but employ more sophisticated term weighting functions adapted from the SMART retrieval system and the BM25 probabilistic model. The resulting idf weighting functions are presented in the lower part of table 2. We extend the original SMART annotation scheme by adding Delta (Δ) variants of the original idf functions and additionally introduce smoothed Delta variants of the *idf* and the *prob idf* factors for completeness and comparative reasons, noted by their *accented* counterparts. For example, the weight of term i in document D according to the $o\Delta(k)n$ weighting scheme where we employ the BM25 tf weighting function and utilize the difference of class-based BM25 idf values would be calculated as:

$$\begin{aligned} w_i &= \frac{(k_1+1)\cdot tf_i}{K+tf_i}\cdot log(\frac{N_1-df_{i,1}+0.5}{df_{i,1}+0.5}) \\ &- \frac{(k_1+1)\cdot tf_i}{K+tf_i}\cdot log(\frac{N_2-df_{i,2}+0.5}{df_{i,2}+0.5}) \\ &= \frac{(k_1+1)\cdot tf_i}{K+tf_i} \\ &\cdot \quad log\left(\frac{(N_1-df_{i,1}+0.5)\cdot(df_{i,2}+0.5)}{(N_2-df_{i,2}+0.5)\cdot(df_{i,1}+0.5)}\right) \end{aligned}$$

where K is defined as $k_1\left((1-b)+b\cdot\frac{dl}{avg\_dl}\right)$. However, we used a minor variation of the above formulation for all the final *accented* weighting functions in which the smoothing factor is added to the product of df_i with N_i (or its variation for $\Delta(p')$ and $\Delta(k)$), rather than to the df_i alone as the above formulation would imply (see table 2). The above variation was made for two reasons: firstly, when the df_i's are larger than 1 then the smoothing factor influences the final idf value only in a minor way in the revised formulation, since it is added only after the multiplication of the df_i with N_i (or its variation). Secondly, when $df_i = 0$, then the smoothing factor correctly adds only a small mass, avoiding a potential division by zero, where otherwise it would add a much greater mass, because it would be multiplied by N_i.

According to this annotation scheme therefore, the original approach by Martineau and Finin (2009) can be represented as $n\Delta(t)n$.

We hypothesize that the utilization of sophisticated term weighting functions that have proved effective in information retrieval, thus providing an indication that they appropriately model the distinctive power of terms to documents and the smoothed, localized estimation of idf values will prove beneficial in sentiment classification.

Table 4: Reported accuracies on the Movie Review data set. Only the best reported accuracy for each approach is presented, measured by 10-fold cross validation. The list is not exhaustive and because of differences in training/testing data splits the results are not directly comparable. It is produced here only for reference.

Approach	Acc.
SVM with unigrams & binary weights (Pang et al., 2002), reported at (Pang and Lee, 2004)	87.15%
Hybrid SVM with Turney/Osgood Lemmas (Mullen and Collier, 2004)	86%
SVM with min-cuts (Pang and Lee, 2004)	87.2%
SVM with appraisal groups (Whitelaw et al., 2005)	90.2%
SVM with log likehood ratio feature selection (Aue and Gamon, 2005)	90.45%
SVM with annotator rationales (Zaidan et al., 2007)	92.2%
LDA with filtered lexicon, subjectivity detection (Lin and He, 2009)	84.6%

The approach is straightforward, intuitive, computationally efficient, doesn't require additional human effort and takes into consideration standardized and tested notions from IR. The results presented in section 5 show that a number

[2]We deliberately didn't extract the normalization component from the BM25 tf variant, as that would unnecessarily complicate the notation.

of weighting functions solidly outperform other state-of-the-art approaches. In the next section, we present the corpora that were used to study the effectiveness of different weighting schemes.

4 Experimental setup

We have experimented with a number of publicly available data sets.

The movie review dataset by Pang et al. (2002) has been used extensively in the past by a number of researchers (see Table 4), presenting the opportunity to compare the produced results with previous approaches. The dataset comprises 2,000 movie reviews, equally divided between positive and negative, extracted from the Internet Movie Database[3] archive of the *rec.arts.movies.reviews* newsgroup. In order to avoid reviewer bias, only 20 reviews per author were kept, resulting in a total of 312 reviewers[4]. The best attained accuracies by previous research on the specific data are presented in table 4. We do not claim that those results are directly comparable to ours, because of potential subtle differences in tokenization, classifier implementations etc, but we present them here for reference.

The Multi-Domain Sentiment data set (MDSD) by Blitzer et al. (2007) contains Amazon reviews for four different product types: books, electronics, DVDs and kitchen appliances. Reviews with ratings of 3 or higher, on a 5-scale system, were labeled as positive and reviews with a rating less than 3 as negative. The data set contains 1,000 positive and 1,000 negative reviews for each product category for a total of 8,000 reviews. Typically, the data set is used for domain adaptation applications but in our setting we only split the reviews between positive and negative[5].

Lastly, we present results from the BLOGS06 (Macdonald and Ounis, 2006) collection that is comprised of an uncompressed 148GB crawl of approximately 100,000 blogs and their respective RSS feeds. The collection has been used for 3 consecutive years by the Text REtrieval Conferences (TREC)[6]. Participants of the conference are provided with the task of finding documents (i.e. web pages) expressing an opinion about specific entities X, which may be people, companies, films etc. The results are given to human assessors who then judge the content of the webpages (i.e. blog post and comments) and assign each webpage a score: "1" if the document contains relevant, factual information about the entity but no expression of opinion, "2" if the document contains an explicit negative opinion towards the entity and "4" is the document contains an explicit positive opinion towards the entity. We used the produced assessments from all 3 years of the conference in our data set, resulting in 150 different entity searches and, after duplicate removal, 7,930 negative documents (i.e. having an assessment of "2") and 9,968 positive documents (i.e. having an assessment of "4"), which were used as the "gold standard" [7]. Documents are annotated at the document-level, rather than at the post level, making this data set somewhat noisy. Additionally, the data set is particularly large compared to the other ones, making classification especially challenging and interesting. More information about all data sets can be found at table 5.

We have kept the pre-processing of the documents to a minimum. Thus, we have lower-cased all words and removed all punctuation but we have not removed stop words or applied stemming. We have also refrained from removing words with low or high occurrence. Additionally, for the BLOGS06 data set, we have removed all html formatting.

We utilize the implementation of a support vector classifier from the *LIBLINEAR* library (Fan et al., 2008). We use a linear kernel and default parameters. All results are based on leave-one out cross validation accuracy. The reason for this choice of cross-validation setting, instead of the most standard ten-fold, is that all of the proposed approaches that use some form of idf utilize the training documents for extracting document frequency statistics, therefore more information is available to them in this experimental setting.

Because of the high number of possible combinations between tf and idf variants ($6 \cdot 9 \cdot 2 = 108$) and due to space constraints we only present results from a subset of the most representative combinations. Generally, we'll use the cosine normalized variants of unsmoothed delta weighting schemes, since they perform better than their un-

normalized counterparts. We'll avoid using normalization for the smoothed versions, in order to focus our attention on the results of smoothing, rather than normalization.

5 Results

Results for the Movie Reviews, Multi-Domain Sentiment Dataset and BLOGS06 corpora are reported in figures 1, 2 and 3 respectively.

On the Movie Review data set, the results reconfirm that using binary features (bnc) is better than raw term frequency (nnc) (83.40%) features. For reference, in this setting the unnormalized vector using the raw tf approach (nnn) performs similar to the normalized (nnc) (83.40% vs. 83.60%), the former not present in the graph. Nonetheless, using any scaled tf weighting function (anc or onc) performs as well as the binary approach (87.90% and 87.50% respectively). Of interest is the fact that although the BM25 tf algorithm has proved much more successful in IR, the same doesn't apply in this setting and its accuracy is similar to the simpler *augmented tf* approach.

Incorporating un-localized variants of idf (middle graph section) produces only small increases in accuracy. Smoothing also doesn't provide any particular advantage, e.g. btc (88.20%) vs. $bt'c$ (88.45%), since no zero idf values are present. Again, using more sophisticated tf functions provides an advantage over raw tf, e.g. $nt'c$ attains an accuracy of 86.6% in comparison to $at'c$'s 88.25%, although the simpler $at'c$ is again as effective than the BM25 tf ($ot'c$), which performs at 88%. The actual idf weighting function is of some importance, e.g. $ot'c$ (88%) vs. okc (87.65%) and akc (88%) vs. $at'c$ (88.25%), with simpler idf factors performing similarly, although slightly better than BM25.

Introducing smoothed, localized variants of idf and scaled or binary tf weighting schemes produces significant advantages. In this setting, smoothing plays a role, e.g. $n\Delta(t)c$[8] (91.60%) vs. $n\Delta(t')n$ (95.80%) and $a\Delta(p)c$ (92.80%) vs. $a\Delta(p')n$ (96.55%), since we can expect zero class-based estimations of idf values, supporting our initial hypothesis on its importance. Additionally, using *augmented*, BM25 or binary tf weights is always better than raw term frequency, providing further support on the advantages of using sublinear tf weighting functions[9]. In this setting, the best accuracy of 96.90% is attained using BM25 tf weights with the BM25 delta idf variant, although binary or *augmented* tf weights using

[8]The original *Delta tf.idf* by Martineau and Finin (2009) has a limitation of utilizing features with $df > 2$. In our experiments it performed similarly to $n\Delta(t)n$ (90.60%) but still lower than the $cosine$ normalized variant $n\Delta(t)c$ included in the graph (91.60%).

[9]Although not present in the graph, for completeness reasons it should be noted that $l\Delta(s)n$ and $L\Delta(s)n$ also perform very well, both reaching accuracies of approx. 96%.

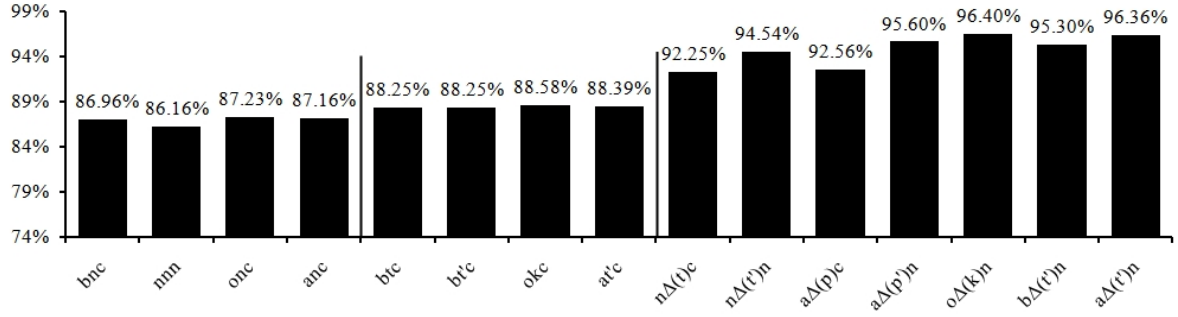

Figure 2: Reported accuracy on the Multi-Domain Sentiment data set.

delta idf perform similarly (96.50% and 96.60% respectively). The results indicate that the tf and the idf factor themselves aren't of significant importance, as long as the former are scaled and the latter smoothed in some manner. For example, $a\Delta(p')n$ vs. $a\Delta(t')n$ perform quite similarly.

The results from the Multi-Domain Sentiment data set (figure 2) largely agree with the findings on the Movie Review data set, providing a strong indication that the approach isn't limited to a specific domain. Binary weights outperform *raw term frequency* weights and perform similarly with scaled tf's. Non-localized variants of idf weights do provide a small advantage in this data set although the actual idf variant isn't important, e.g. btc, $bt'c$, and okc all perform similarly. The utilized tf variant also isn't important, e.g. $at'c$ (88.39%) vs. $bt'c$ (88.25%).

We focus our attention on the $delta\ idf$ variants which provide the more interesting results. The importance of smoothing becomes apparent when comparing the accuracy of $a\Delta(p)c$ and its smoothed variant $a\Delta(p')n$ (92.56% vs. 95.6%). Apart from that, all smoothed $delta\ idf$ variants perform very well in this data set, including somewhat surprisingly, $n\Delta(t')n$ which uses raw tf (94.54%). Considering that the average tf per document is approx. 1.9 in the Movie Review data set and 1.1 in the MDSD, the results can be attributed to the fact that words tend to typically appear only once per document in the latter, therefore minimizing the difference of the weights attributed by different tf functions[10]. The best attained accuracy is 96.40% but as the MDSD has mainly been used for domain adaptation applications, there is no clear baseline to compare it with.

[10]For reference, the average tf per document in the BLOGS06 data set is 2.4.

Lastly, we present results on the BLOGS06 dataset in figure 3. As previously noted, this data set is particularly noisy, because it has been annotated at the document-level rather than the post-level and as a result, the differences aren't as profound as in the previous corpora, although they do follow the same patterns. Focusing on the delta idf variants, the importance of smoothing becomes apparent, e.g. $a\Delta(p)c$ vs. $a\Delta(p')n$ and $n\Delta(t)c$ vs. $n\Delta(t')n$. Additionally, because of the fact that documents tend to be more verbose in this data set, the scaled tf variants also perform better than the simple *raw tf* ones, $n\Delta(t')n$ vs. $a\Delta(t')n$. Lastly, as previously, the smoothed localized idf variants perform better than their unsmoothed counterparts, e.g. $n\Delta(t)n$ vs. $n\Delta(t')n$ and $a\Delta(p)c$ vs. $a\Delta(p')n$.

6 Conclusions

In this paper, we presented a study of document representations for sentiment analysis using term weighting functions adopted from information retrieval and adapted to classification. The proposed weighting schemes were tested on a number of publicly available datasets and a number of them repeatedly demonstrated significant increases in accuracy compared to other state-of-the-art approaches. We demonstrated that for accurate classification it is important to use term weighting functions that scale sublinearly in relation to the number of times a term occurs in a document and that document frequency smoothing is a significant factor.

In the future we plan to test the proposed weighting functions in other domains such as topic classification and additionally extend the approach to accommodate multi-class classification.

Supervised Noun Phrase Coreference Research: The First Fifteen Years

Vincent Ng

vince@hlt.utdallas.edu

Abstract

The research focus of computational coreference resolution has exhibited a shift from heuristic approaches to machine learning approaches in the past decade. This paper surveys the major milestones in supervised coreference research since its inception fifteen years ago.

1 Introduction

Noun phrase (NP) coreference resolution, the task of determining which NPs in a text or dialogue refer to the same real-world entity, has been at the core of natural language processing (NLP) since the 1960s. NP coreference is related to the task of anaphora resolution, whose goal is to identify an antecedent for an *anaphoric* NP (i.e., an NP that depends on another NP, specifically its antecedent, for its interpretation) [see van Deemter and Kibble (2000) for a detailed discussion of the difference between the two tasks]. Despite its simple task definition, coreference is generally considered a difficult NLP task, typically involving the use of sophisticated knowledge sources and inference procedures (Charniak, 1972). Computational theories of discourse, in particular *focusing* (see Grosz (1977) and Sidner (1979)) and *centering* (Grosz et al. (1983; 1995)), have heavily influenced coreference research in the 1970s and 1980s, leading to the development of numerous *centering algorithms* (see Walker et al. (1998)).

The focus of coreference research underwent a gradual shift from heuristic approaches to machine learning approaches in the 1990s. This shift can be attributed in part to the advent of the statistical NLP era, and in part to the public availability of annotated coreference corpora produced as part of the MUC-6 (1995) and MUC-7 (1998) conferences. Learning-based coreference research has remained vibrant since then, with results regularly published not only in general NLP conferences, but also in specialized conferences (e.g., the biennial Discourse Anaphora and Anaphor Resolution Colloquium (DAARC)) and workshops (e.g., the series of Bergen Workshop on Anaphora Resolution (WAR)). Being inherently a *clustering* task, coreference has also received a lot of attention in the machine learning community.

Fifteen years have passed since the first paper on learning-based coreference resolution was published (Connolly et al., 1994). Our goal in this paper is to provide NLP researchers with a survey of the major milestones in *supervised* coreference research, focusing on the computational models, the linguistic features, the annotated corpora, and the evaluation metrics that were developed in the past fifteen years. Note that several leading coreference researchers have published books (e.g., Mitkov (2002)), written survey articles (e.g., Mitkov (1999), Strube (2009)), and delivered tutorials (e.g., Strube (2002), Ponzetto and Poesio (2009)) that provide a broad overview of coreference research. This survey paper aims to *complement*, rather than supersede, these previously published materials. In particular, while existing survey papers discuss learning-based coreference research primarily in the context of the influential mention-pair model, we additionally survey recently proposed learning-based coreference models, which attempt to address the weaknesses of the mention-pair model. Due to space limitations, however, we will restrict our discussion to the most commonly investigated kind of coreference relation: the *identity* relation for NPs, excluding coreference among clauses and bridging references (e.g., part/whole and set/subset relations).

2 Annotated Corpora

The widespread popularity of machine learning approaches to coreference resolution can be attributed in part to the public availability of an-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1396–1411,
Uppsala, Sweden, 11-16 July 2010.

notated coreference corpora. The MUC-6 and MUC-7 corpora, though relatively small (60 documents each) and homogeneous w.r.t. document type (newswire articles only), have been extensively used for training and evaluating coreference models. Equally popular are the corpora produced by the Automatic Content Extraction (ACE[1]) evaluations in the past decade: while the earlier ACE corpora (e.g., ACE-2) consist of solely English newswire and broadcast news articles, the later ones (e.g., ACE 2005) have also included Chinese and Arabic documents taken from additional sources such as broadcast conversations, webblog, usenet, and conversational telephone speech.

Coreference annotations are also publicly available in treebanks. These include (1) the English Penn Treebank (Marcus et al., 1993), which is labeled with coreference links as part of the OntoNotes project (Hovy et al., 2006); (2) the Tübingen Treebank (Telljohann et al., 2004), which is a collection of German news articles consisting of 27,125 sentences; (3) the Prague Dependency Treebank (Hajič et al., 2006), which consists of 3168 news articles taken from the Czech National Corpus; (4) the NAIST Text Corpus (Iida et al., 2007b), which consists of 287 Japanese news articles; (5) the AnCora Corpus (Recasens and Martí, 2009), which consists of Spanish and Catalan journalist texts; and (6) the GENIA corpus (Ohta et al., 2002), which contains 2000 MEDLINE abstracts.

Other publicly available coreference corpora of interest include two annotated by Ruslan Mitkov's research group: (1) a 55,000-word corpus in the domain of security/terrorism (Hasler et al., 2006); and (2) training data released as part of the 2007 Anaphora Resolution Exercise (Orăsan et al., 2008), a coreference resolution shared task. There are also two that consist of spoken dialogues: the TRAINS93 corpus (Heeman and Allen, 1995) and the Switchboard data set (Calhoun et al., in press).

Additional coreference data will be available in the near future. For instance, the SemEval-2010 shared task on Coreference Resolution in Multiple Languages (Recasens et al., 2009) has promised to release coreference data in six languages. In addition, Massimo Poesio and his colleagues are leading an annotation project that aims to collect large amounts of coreference data for English via a Web Collaboration game called Phrase Detectives[2].

3 Learning-Based Coreference Models

In this section, we examine three important classes of coreference models that were developed in the past fifteen years, namely, the mention-pair model, the entity-mention model, and ranking models.

3.1 Mention-Pair Model

The mention-pair model is a classifier that determines whether two NPs are coreferent. It was first proposed by Aone and Bennett (1995) and McCarthy and Lehnert (1995), and is one of the most influential learning-based coreference models. Despite its popularity, this binary classification approach to coreference is somewhat undesirable: the transitivity property inherent in the coreference relation cannot be enforced, as it is possible for the model to determine that A and B are coreferent, B and C are coreferent, but A and C are not coreferent. Hence, a separate clustering mechanism is needed to coordinate the pairwise classification decisions made by the model and construct a coreference partition.

Another issue that surrounds the acquisition of the mention-pair model concerns the way training instances are created. Specifically, to determine whether a pair of NPs is coreferent or not, the mention-pair model needs to be trained on a data set where each instance represents two NPs and possesses a class value that indicates whether the two NPs are coreferent. Hence, a natural way to assemble a training set is to create one instance from each pair of NPs appearing in a training document. However, this instance creation method is rarely employed: as most NP pairs in a text are not coreferent, this method yields a training set with a skewed class distribution, where the negative instances significantly outnumber the positives.

As a result, in practical implementations of the mention-pair model, one needs to specify not only the *learning algorithm* for training the model and the *linguistic features* for representing an instance, but also the *training instance creation method* for reducing class skewness and the *clustering algorithm* for constructing a coreference partition.

3.1.1 Creating Training Instances

As noted above, the primary purpose of training instance creation is to reduce class skewness. Many heuristic instance creation methods have been proposed, among which Soon et al.'s (1999; 2001) is arguably the most popular choice. Given

an anaphoric noun phrase[3], NP_k, Soon et al.'s method creates a *positive instance* between NP_k and its closest preceding antecedent, NP_j, and a *negative instance* by pairing NP_k with each of the intervening NPs, $\text{NP}_{j+1}, \ldots, \text{NP}_{k-1}$.

With an eye towards improving the precision of a coreference resolver, Ng and Cardie (2002c) propose an instance creation method that involves a single modification to Soon et al.'s method: if NP_k is non-pronominal, a positive instance should be formed between NP_k and its closest preceding *non-pronominal* antecedent instead. This modification is motivated by the observation that it is not easy for a human, let alone a machine learner, to learn from a positive instance where the antecedent of a non-pronominal NP is a pronoun.

To further reduce class skewness, some researchers employ a filtering mechanism on top of an instance creation method, thereby disallowing the creation of training instances from NP pairs that are unlikely to be coreferent, such as NP pairs that violate gender and number agreement (e.g., Strube et al. (2002), Yang et al. (2003)).

While many instance creation methods are heuristic in nature (see Uryupina (2004) and Hoste and Daelemans (2005)), some are learning-based. For example, motivated by the fact that some coreference relations are harder to identify than the others (see Harabagiu et al. (2001)), Ng and Cardie (2002a) present a method for mining easy positive instances, in an attempt to avoid the inclusion of hard training instances that may complicate the acquisition of an accurate coreference model.

3.1.2 Training a Coreference Classifier

Once a training set is created, we can train a coreference model using an off-the-shelf learning algorithm. Decision tree induction systems (e.g., C5 (Quinlan, 1993)) are the first and one of the most widely used learning algorithms by coreference researchers, although rule learners (e.g., RIPPER (Cohen, 1995)) and memory-based learners (e.g., TiMBL (Daelemans and Van den Bosch, 2005)) are also popular choices, especially in early applications of machine learning to coreference resolution. In recent years, statistical learners such as maximum entropy models (Berger et al., 1996), voted perceptrons (Freund and Schapire, 1999), and support vector machines (Joachims, 1999) have been increasingly used, in part due to their ability to provide a confidence value (e.g., in the form of a probability) associated with a classification, and in part due to the fact that they can be easily adapted to train recently proposed ranking-based coreference models (see Section 3.3).

3.1.3 Generating an NP Partition

After training, we can apply the resulting model to a test text, using a clustering algorithm to coordinate the pairwise classification decisions and impose an NP partition. Below we describe some commonly used coreference clustering algorithms.

Despite their simplicity, *closest-first clustering* (Soon et al., 2001) and *best-first clustering* (Ng and Cardie, 2002c) are arguably the most widely used coreference clustering algorithms. The closest-first clustering algorithm selects as the antecedent for an NP, NP_k, the closest preceding noun phrase that is classified as coreferent with it.[4] However, if no such preceding noun phrase exists, no antecedent is selected for NP_k. The *best-first* clustering algorithm aims to improve the precision of closest-first clustering, specifically by selecting as the antecedent of NP_k the *most probable* preceding NP that is classified as coreferent with it.

One criticism of the closest-first and best-first clustering algorithms is that they are too greedy. In particular, clusters are formed based on a small subset of the pairwise decisions made by the model. Moreover, positive pairwise decisions are unjustifiably favored over their negative counterparts. For example, three NPs are likely to end up in the same cluster in the resulting partition even if there is strong evidence that A and C are not coreferent, as long as the other two pairs (i.e., (A,B) and (B,C)) are classified as positive.

Several algorithms that address one or both of these problems have been used for coreference clustering. *Correlation clustering* (Bansal et al., 2002), which produces a partition that respects as many pairwise decisions as possible, is used by McCallum and Wellner (2004), Zelenko et al. (2004), and Finley and Joachims (2005). *Graph partitioning algorithms* are applied on a weighted, undirected graph where a vertex corresponds to an NP and an edge is weighted by the pairwise coreference scores between two NPs (e.g., McCallum and Wellner (2004), Nicolae and Nico-

[3] In this paper, we use the term *anaphoric* to describe any NP that is part of a coreference chain but is not the head of the chain. Hence, proper names can be anaphoric under this overloaded definition, but linguistically, they are not.

[4] If a probabilistic model is used, we can define a threshold above which a pair of NPs is considered coreferent.

lae (2006)). The *Dempster-Shafer rule* (Dempster, 1968), which combines the positive and negative pairwise decisions to score a partition, is used by Kehler (1997) and Bean and Riloff (2004) to identify the most probable NP partition.

Some clustering algorithms bear a closer resemblance to the way a human creates coreference clusters. In these algorithms, not only are the NPs in a text processed in a left-to-right manner, the later coreference decisions are dependent on the earlier ones (Cardie and Wagstaff, 1999; Klenner and Ailloud, 2008).[5] For example, to resolve an NP, NP_k, Cardie and Wagstaff's algorithm considers each preceding NP, NP_j, as a candidate antecedent in a right-to-left order. If NP_k and NP_j are likely to be coreferent, the algorithm imposes an additional check that NP_k does not violate any constraint on coreference (e.g., gender agreement) with any NP in the cluster containing NP_j before positing that the two NPs are coreferent.

Luo et al.'s (2004) Bell-tree-based algorithm is another clustering algorithm where the later coreference decisions are dependent on the earlier ones. A Bell tree provides an elegant way of organizing the space of NP partitions. Informally, a node in the ith level of a Bell tree corresponds to an ith-order *partial* partition (i.e., a partition of the first i NPs of the given document), and the ith level of the tree contains *all* possible ith-order partial partitions. Hence, a leaf node contains a *complete* partition of the NPs, and the goal is to search for the leaf node that contains the most probable partition. The search starts at the root, and a partitioning of the NPs is incrementally constructed as we move down the tree. Specifically, based on the coreference decisions it has made in the first $i-1$ levels of the tree, the algorithm determines at the ith level whether the ith NP should start a new cluster, or to which preceding *cluster* it should be assigned.

While many coreference clustering algorithms have been developed, there have only been a few attempts to compare their effectiveness. For example, Ng and Cardie (2002c) report that best-first clustering is better than closest-first clustering. Nicolae and Nicolae (2006) show that best-first clustering performs similarly to Bell-tree-based clustering, but neither of these algorithms performs as well as their proposed minimum-cut-based graph partitioning algorithm.

[5] When applying closest-first and best-first clustering, Soon et al. (2001) and Ng and Cardie (2002c) also process the NPs in a sequential manner, but since the later decisions are not dependent on the earlier ones, the order in which the NPs are processed does not affect their clustering results.

3.1.4 Determining NP Anaphoricity

While coreference clustering algorithms attempt to resolve *each* NP encountered in a document, only a subset of the NPs are *anaphoric* and therefore need to be resolved. Hence, knowledge of the anaphoricity of an NP can potentially improve the precision of a coreference resolver.

Traditionally, the task of anaphoricity determination has been tackled independently of coreference resolution using a variety of techniques. For example, pleonastic *it* has been identified using heuristic approaches (e.g., Paice and Husk (1987), Lappin and Leass (1994), Kennedy and Boguraev (1996)), supervised approaches (e.g., Evans (2001), Müller (2006), Versley et al. (2008a)), and distributional methods (e.g., Bergsma et al. (2008)); and non-anaphoric definite descriptions have been identified using rule-based techniques (e.g., Vieira and Poesio (2000)) and unsupervised techniques (e.g., Bean and Riloff (1999)).

Recently, anaphoricity determination has been evaluated in the context of coreference resolution, with results showing that training an anaphoricity classifier to identify and filter non-anaphoric NPs prior to coreference resolution can improve a learning-based resolver (e.g., Ng and Cardie (2002b), Uryupina (2003), Poesio et al. (2004b)). Compared to earlier work on anaphoricity determination, recently proposed approaches are more "global" in nature, taking into account the pairwise decisions made by the mention-pair model when making anaphoricity decisions. Examples of such approaches have exploited techniques including integer linear programming (ILP) (Denis and Baldridge, 2007a), label propagation (Zhou and Kong, 2009), and minimum cuts (Ng, 2009).

3.1.5 Combining Classification & Clustering

From a learning perspective, a two-step approach to coreference — classification and clustering — is undesirable. Since the classification model is trained independently of the clustering algorithm, improvements in classification accuracy do not guarantee corresponding improvements in clustering-level accuracy. That is, overall performance on the coreference task might not improve.

To address this problem, McCallum and Wellner (2004) and Finley and Joachims (2005) eliminate the classification step entirely, treating coref-

erence as a *supervised clustering* task where a similarity metric is learned to directly maximize clustering accuracy. Klenner (2007) and Finkel and Manning (2008) use ILP to ensure that the pairwise classification decisions satisfy transitivity.[6]

3.1.6 Weaknesses of the Mention-Pair Model

While many of the aforementioned algorithms for clustering and anaphoricity determination have been shown to improve coreference performance, the underlying model with which they are used in combination — the mention-pair model — remains fundamentally weak. The model has two commonly-cited weaknesses. First, since each candidate antecedent for an anaphoric NP to be resolved is considered independently of the others, the model only determines how good a candidate antecedent is relative to the anaphoric NP, but not how good a candidate antecedent is relative to other candidates. In other words, it fails to answer the question of which candidate antecedent is most probable. Second, it has limitations in its expressiveness: the information extracted from the two NPs alone may not be sufficient for making an informed coreference decision, especially if the candidate antecedent is a pronoun (which is semantically empty) or a mention that lacks descriptive information such as gender (e.g., "Clinton"). Below we discuss how these weaknesses are addressed by the entity-mention model and ranking models.

3.2 Entity-Mention Model

The entity-mention model addresses the expressiveness problem with the mention-pair model. To motivate the entity-mention model, consider an example taken from McCallum and Wellner (2003), where a document consists of three NPs: "Mr. Clinton," "Clinton," and "she." The mention-pair model may determine that "Mr. Clinton" and "Clinton" are coreferent using string-matching features, and that "Clinton" and "she" are coreferent based on proximity and lack of evidence for gender and number disagreement. However, these two pairwise decisions together with transitivity imply that "Mr. Clinton" and "she" will end up in the same cluster, which is incorrect due to gender mismatch. This kind of error arises in part because the later coreference decisions are not dependent on the earlier ones. In particular, had the model taken into consideration that "Mr. Clinton" and "Clinton" were in the same cluster, it probably would not have posited that "she" and "Clinton" are coreferent. The aforementioned Cardie and Wagstaff algorithm attempts to address this problem in a *heuristic* manner. It would be desirable to *learn* a model that can classify whether an NP to be resolved is coreferent with a preceding, possibly partially-formed, cluster. This model is commonly known as the entity-mention model.

Since the entity-mention model aims to classify whether an NP is coreferent with a preceding cluster, each of its training instances (1) corresponds to an NP, NP_k, and a preceding cluster, C_j, and (2) is labeled with either POSITIVE or NEGATIVE, depending on whether NP_k should be assigned to C_j. Consequently, we can represent each instance by a set of *cluster-level* features (i.e., features that are defined over an arbitrary subset of the NPs in C_j). A cluster-level feature can be computed from a feature employed by the mention-pair model by applying a logical predicate. For example, given the NUMBER AGREEMENT feature, which determines whether two NPs agree in number, we can apply the ALL predicate to create a cluster-level feature, which has the value YES if NP_k agrees in number with *all* of the NPs in C_j and NO otherwise. Other commonly-used logical predicates for creating cluster-level features include relaxed versions of the ALL predicate, such as MOST, which is true if NP_k agrees in number with more than half of the NPs in C_j, and ANY, which is true as long as NP_k agrees in number with just one of the NPs in C_j. The ability of the entity-mention model to employ cluster-level features makes it more expressive than its mention-pair counterpart.

Despite its improved expressiveness, the entity-mention model has not yielded particularly encouraging results. For example, Luo et al. (2004) apply the ANY predicate to generate cluster-level features for their entity-mention model, which does not perform as well as the mention-pair model. Yang et al. (2004b; 2008a) also investigate the entity-mention model, which produces results that are only marginally better than those of the mention-pair model. However, it appears that they are not fully exploiting the expressiveness of the entity-mention model, as cluster-level features only comprise a small fraction of their features.

Variants of the entity-mention model have been investigated. For example, Culotta et al. (2007) present a first-order logic model that determines

[6] Recently, however, Klenner and Ailloud (2009) have become less optimistic about ILP approaches to coreference.

the probability that an arbitrary set of NPs are all co-referring. Their model resembles the entity-mention model in that it enables the use of cluster-level features. Daumé III and Marcu (2005) propose an online learning model for constructing coreference chains in an incremental fashion, allowing later coreference decisions to be made by exploiting cluster-level features that are computed over the coreference chains created thus far.

3.3 Ranking Models

While the entity-mention model addresses the expressiveness problem with the mention-pair model, it does not address the other problem: failure to identify the most probable candidate antecedent. Ranking models, on the other hand, allow us to determine which candidate antecedent is most probable given an NP to be resolved. Ranking is arguably a more natural reformulation of coreference resolution than classification, as a ranker allows all candidate antecedents to be considered *simultaneously* and therefore directly captures the competition among them. Another desirable consequence is that there exists a natural resolution strategy for a ranking approach: an anaphoric NP is resolved to the candidate antecedent that has the highest rank. This contrasts with classification-based approaches, where many clustering algorithms have been employed to coordinate the pairwise classification decisions, and it is still not clear which of them is the best.

The notion of ranking candidate antecedents can be traced back to centering algorithms, many of which use grammatical roles to rank forward-looking centers (see Walker et al. (1998)). Ranking is first applied to learning-based coreference resolution by Connolly et al. (1994; 1997), where a model is trained to rank two candidate antecedents. Each training instance corresponds to the NP to be resolved, NP_k, as well as two candidate antecedents, NP_i and NP_j, one of which is an antecedent of NP_k and the other is not. Its class value indicates which of the two candidates is better. This model is referred to as the *tournament* model by Iida et al. (2003) and the *twin-candidate* model by Yang et al. (2003; 2008b). To resolve an NP during testing, one way is to apply the model to each pair of its candidate antecedents, and the candidate that is classified as better the largest number of times is selected as its antecedent.

Advances in machine learning have made it possible to train a *mention ranker* that ranks *all* of the candidate antecedents simultaneously. While mention rankers have consistently outperformed the mention-pair model (Versley, 2006; Denis and Baldridge, 2007b), they are not more expressive than the mention-pair model, as they are unable to exploit cluster-level features, unlike the entity-mention model. To enable rankers to employ cluster-level features, Rahman and Ng (2009) propose the cluster-ranking model, which ranks preceding *clusters*, rather than candidate antecedents, for an NP to be resolved. Cluster rankers therefore address both weaknesses of the mention-pair model, and have been shown to improve mention rankers. Cluster rankers are conceptually similar to Lappin and Leass's (1994) heuristic pronoun resolver, which resolves an anaphoric pronoun to the most salient preceding cluster.

An important issue with ranking models that we have eluded so far concerns the identification of non-anaphoric NPs. As a ranker simply imposes a ranking on candidate antecedents or preceding clusters, it cannot determine whether an NP is anaphoric (and hence should be resolved). To address this problem, Denis and Baldridge (2008) apply an independently trained anaphoricity classifier to identify non-anaphoric NPs prior to ranking, and Rahman and Ng (2009) propose a model that jointly learns coreference and anaphoricity.

4 Knowledge Sources

Another thread of supervised coreference research concerns the development of linguistic features. Below we give an overview of these features.

String-matching features can be computed robustly and typically contribute a lot to the performance of a coreference system. Besides simple string-matching operations such as exact string match, substring match, and head noun match for different kinds of NPs (see Daumé III and Marcu (2005)), slightly more sophisticated string-matching facilities have been attempted, including minimum edit distance (Strube et al., 2002) and longest common subsequence (Castaño et al., 2002). Yang et al. (2004a) treat the two NPs involved as two bags of words, and compute their similarity using metrics commonly-used in information retrieval, such as the dot product, with each word weighted by their TF-IDF value.

Syntactic features are computed based on a syntactic parse tree. Ge et al. (1998) implement

a *Hobbs distance* feature, which encodes the rank assigned to a candidate antecedent for a pronoun by Hobbs's (1978) seminal syntax-based pronoun resolution algorithm. Luo and Zitouni (2005) extract features from a parse tree for implementing Binding Constraints (Chomsky, 1988). Given an automatically parsed corpus, Bergsma and Lin (2006) extract from each parse tree a dependency path, which is represented as a sequence of nodes and dependency labels connecting a pronoun and a candidate antecedent, and collect statistical information from these paths to determine the likelihood that a pronoun and a candidate antecedent connected by a given path are coreferent. Rather than deriving features from parse trees, Iida et al. (2006) and Yang et al. (2006) employ these trees directly as *structured* features for pronoun resolution. Specifically, Yang et al. define tree kernels for efficiently computing the similarity between two parse trees, and Iida et al. use a boosting-based algorithm to compute the usefulness of a subtree.

Grammatical features encode the grammatical properties of one or both NPs involved in an instance. For example, Ng and Cardie's (2002c) resolver employs 34 grammatical features. Some features determine NP type (e.g., are both NPs definite or pronouns?). Some determine the grammatical role of one or both of the NPs. Some encode traditional linguistic (hard) constraints on coreference. For example, coreferent NPs have to agree in number and gender and cannot span one another (e.g., "Google" and "Google employees"). There are also features that encode general linguistic preferences either for or against coreference. For example, an indefinite NP (that is not in apposition to an anaphoric NP) is not likely to be coreferent with any NP that precedes it.

There has been an increasing amount of work on investigating **semantic features** for coreference resolution. One of the earliest kinds of semantic knowledge employed for coreference resolution is perhaps selectional preference (Dagan and Itai, 1990; Kehler et al., 2004b; Yang et al., 2005; Haghighi and Klein, 2009): given a pronoun to be resolved, its governing verb, and its grammatical role, we prefer a candidate antecedent that can be governed by the same verb and be in the same role. Semantic knowledge has also been extracted from WordNet and unannotated corpora for computing the semantic compatibility/similarity between two common nouns (Harabagiu et al., 2001; Versley, 2007) as well as the semantic class of a noun (Ng, 2007a; Huang et al., 2009). One difficulty with deriving knowledge from WordNet is that one has to determine which sense of a given word to use. Some researchers simply use the first sense (Soon et al., 2001) or all possible senses (Ponzetto and Strube, 2006a), while others overcome this problem with word sense disambiguation (Nicolae and Nicolae, 2006). Knowledge has also been mined from Wikipedia for measuring the semantic relatedness of two NPs, NP_j and NP_k (Ponzetto and Strube (2006a; 2007)), such as: whether $\text{NP}_{j/k}$ appears in the first paragraph of the Wiki page that has $\text{NP}_{k/j}$ as the title or in the list of categories to which this page belongs, and the degree of overlap between the two pages that have the two NPs as their titles (see Poesio et al. (2007) for other uses of encyclopedic knowledge for coreference resolution). Contextual roles (Bean and Riloff, 2004), semantic relations (Ji et al., 2005), semantic roles (Ponzetto and Strube, 2006b; Kong et al., 2009), and animacy (Orăsan and Evans, 2007) have also been exploited to improve coreference resolution.

Lexico-syntactic *patterns* have been used to capture the semantic relatedness between two NPs and hence the likelihood that they are coreferent. For instance, given the pattern *X is a Y* (which is highly indicative that *X* and *Y* are coreferent), we can instantiate it with a pair of NPs and search for the instantiated pattern in a large corpus or the Web (Daumé III and Marcu, 2005; Haghighi and Klein, 2009). The more frequently the pattern occurs, the more likely they are coreferent. This technique has been applied to resolve different kinds of anaphoric references, including *other*-anaphora (Modjeska et al., 2003; Markert and Nissim, 2005) and bridging references (Poesio et al., 2004a). While these patterns are typically hand-crafted (e.g., Garera and Yarowsky (2006)), they can also be learned from an annotated corpus (Yang and Su, 2007) or bootstrapped from an unannotated corpus (Bean and Riloff, 2004).

Despite the large amount of work on discourse-based anaphora resolution in the 1970s and 1980s (see Hirst (1981)), learning-based resolvers have only exploited shallow **discourse-based features**, which primarily involve characterizing the salience of a candidate antecedent by measuring its distance from the anaphoric NP to be resolved or determining whether it is in a prominent grammatical role (e.g., subject). A notable exception

is Iida et al. (2009), who train a ranker to rank the candidate antecedents for an anaphoric pronoun by their salience. It is worth noting that Tetreault (2005) has employed Grosz and Sidner's (1986) discourse theory and Veins Theory (Ide and Cristea, 2000) to identify and remove candidate antecedents that are not referentially accessible to an anaphoric pronoun in his heuristic pronoun resolvers. It would be interesting to incorporate this idea into a learning-based resolver.

There are also features that do not fall into any of the preceding categories. For example, a memorization feature is a word pair composed of the head nouns of the two NPs involved in an instance (Bengtson and Roth, 2008). Memorization features have been used as binary-valued features indicating the presence or absence of their words (Luo et al., 2004) or as probabilistic features indicating the probability that the two heads are coreferent according to the training data (Ng, 2007b). An anaphoricity feature indicates whether an NP to be resolved is anaphoric, and is typically computed using an anaphoricity classifier (Ng, 2004), hand-crafted patterns (Daumé III and Marcu, 2005), and automatically acquired patterns (Bean and Riloff, 1999). Finally, the outputs of rule-based pronoun and coreference resolvers have also been used as features for learning-based coreference resolution (Ng and Cardie, 2002c).

For an empirical evaluation of the contribution of a subset of these features to the mention-pair model, see Bengtson and Roth (2008).

5 Evaluation Issues

Two important issues surround the evaluation of a coreference resolver. First, how do we obtain the set of NPs that a resolver will partition? Second, how do we score the partition it produces?

5.1 Extracting Candidate Noun Phrases

To obtain the set of NPs to be partitioned by a resolver, three methods are typically used. In the first method, the NPs are extracted automatically from a syntactic parser. The second method involves extracting the NPs directly from the gold standard. In the third method, a *mention detector* is first trained on the gold-standard NPs in the training texts, and is then applied to automatically extract *system mentions* in a test text.[7] Note that these three extraction methods typically produce different numbers of NPs: the NPs extracted from a parser tend to significantly outnumber the system mentions, which in turn outnumber the gold NPs. The reasons are two-fold. First, in some coreference corpora (e.g., MUC-6 and MUC-7), the NPs that are not part of any coreference chain are not annotated. Second, in corpora such as those produced by the ACE evaluations, only the NPs that belong to one of the ACE entity types (e.g., PERSON, ORGANIZATION, LOCATION) are annotated.

Owing in large part to the difference in the number of NPs extracted by these three methods, a coreference resolver can produce substantially different results when applied to the resulting three sets of NPs, with gold NPs yielding the best results and NPs extracted from a parser yielding the worst (Nicolae and Nicolae, 2006). While researchers who evaluate their resolvers on gold NPs point out that the results can more accurately reflect the performance of their coreference algorithm, Stoyanov et al. (2009) argue that such evaluations are unrealistic, as NP extraction is an integral part of an end-to-end fully-automatic resolver.

Whichever NP extraction method is employed, it is clear that the use of gold NPs can considerably simplify the coreference task, and hence resolvers employing different extraction methods should *not* be compared against each other.

5.2 Scoring a Coreference Partition

The MUC scorer (Vilain et al., 1995) is the first program developed for scoring coreference partitions. It has two often-cited weaknesses. As a *link-based* measure, it does not reward correctly identified singleton clusters since there is no coreference link in these clusters. Also, it tends to underpenalize partitions with overly large clusters.

To address these problems, two coreference scoring programs have been developed: B^3 (Bagga and Baldwin, 1998) and CEAF (Luo, 2005). Note that both scorers have only been defined for the case where the key partition has the same set of NPs as the response partition. To apply these scorers to automatically extracted NPs, different methods have been proposed (see Rahman and Ng (2009) and Stoyanov et al. (2009)).

Since coreference is a clustering task, any general-purpose method for evaluating a response partition against a key partition (e.g., Kappa (Carletta, 1996)) can be used for coreference scor-

[7] An exception is Daumé III and Marcu (2005), whose model jointly learns to extract NPs and perform coreference.

ing (see Popescu-Belis et al. (2004)). In practice, these general-purpose methods are typically used to provide scores that complement those obtained via the three coreference scorers discussed above. It is worth mentioning that there is a trend towards evaluating a resolver against multiple scorers, which can indirectly help to counteract the bias inherent in a particular scorer. For further discussion on evaluation issues, see Byron (2001).

6 Concluding Remarks

While we have focused our discussion on supervised approaches, coreference researchers have also attempted to reduce a resolver's reliance on annotated data by combining a small amount of labeled data and a large amount of unlabeled data using general-purpose semi-supervised learning algorithms such as co-training (Müller et al., 2002), self-training (Kehler et al., 2004a), and EM (Cherry and Bergsma, 2005; Ng, 2008). Interestingly, recent results indicate that unsupervised approaches to coreference resolution (e.g., Haghighi and Klein (2007; 2010), Poon and Domingos (2008)) rival their supervised counterparts, casting doubts on whether supervised resolvers are making effective use of the available labeled data.

Another issue that we have not focused on but which is becoming increasingly important is multilinguality. While many of the techniques discussed in this paper were originally developed for English, they have been applied to learn coreference models for other languages, such as Chinese (e.g., Converse (2006)), Japanese (e.g., Iida (2007)), Arabic (e.g., Luo and Zitouni (2005)), Dutch (e.g., Hoste (2005)), German (e.g., Wunsch (2010)), Swedish (e.g., Nilsson (2010)), and Czech (e.g., Nguỵ et al. (2009)). In addition, researchers have developed approaches that are targeted at handling certain kinds of anaphora present in non-English languages, such as zero anaphora (e.g., Iida et al. (2007a), Zhao and Ng (2007)).

As Mitkov (2001) puts it, coreference resolution is a "difficult, but not intractable problem," and we have been making "slow, but steady progress" on improving machine learning approaches to the problem in the past fifteen years. To ensure further progress, researchers should compare their results against a baseline that is stronger than the commonly-used Soon et al. (2001) system, which relies on a weak model (i.e., the mention-pair model) and a small set of linguistic features. As recent systems are becoming more sophisticated, we suggest that researchers make their systems publicly available in order to facilitate performance comparisons. Publicly available coreference systems currently include JavaRAP (Qiu et al., 2004), GuiTaR (Poesio and Kabadjov, 2004), BART (Versley et al., 2008b), CoRTex (Denis and Baldridge, 2008), the Illinois Coreference Package (Bengtson and Roth, 2008), CherryPicker (Rahman and Ng, 2009), Reconcile (Stoyanov et al., 2010), and Charniak and Elsner's (2009) pronoun resolver.

We conclude with a discussion of two questions regarding supervised coreference research. First, *what is the state of the art?* This is not an easy question, as researchers have been evaluating their resolvers on different corpora using different evaluation metrics and preprocessing tools. In particular, preprocessing tools can have a large impact on the performance of a resolver (Barbu and Mitkov, 2001). Worse still, assumptions about whether gold or automatically extracted NPs are used are sometimes not explicitly stated, potentially causing results to be interpreted incorrectly. To our knowledge, however, the best results on the MUC-6 and MUC-7 data sets using automatically extracted NPs are reported by Yang et al. (2003) (71.3 MUC F-score) and Ng and Cardie (2002c) (63.4 MUC F-score), respectively;[8] and the best results on the ACE data sets using gold NPs can be found in Luo (2007) (88.4 ACE-value).

Second, *what lessons can we learn from fifteen years of learning-based coreference research?* The mention-pair model is weak because it makes coreference decisions based on local information (i.e., information extracted from two NPs). Expressive models (e.g., those that can exploit cluster-level features) generally offer better performance, and so are models that are "global" in nature. Global coreference models may refer to any kind of models that can exploit non-local information, including models that can consider multiple candidate antecedents simultaneously (e.g., ranking models), models that allow joint learning for coreference resolution and related tasks (e.g., anaphoricity determination), models that can directly optimize clustering-level (rather than classification) accuracy, and models that can coordinate with other components of a resolver, such as training instance creation and clustering.

[8] These results by no means suggest that no progress has been made since 2003: most of the recently proposed coreference models were evaluated on the ACE data sets.

Acknowledgments

Abstract

This paper examines how a new class of nonparametric Bayesian models can be effectively applied to an open-domain event coreference task. Designed with the purpose of clustering complex linguistic objects, these models consider a potentially infinite number of features and categorical outcomes. The evaluation performed for solving both within- and cross-document event coreference shows significant improvements of the models when compared against two baselines for this task.

1 Introduction

The event coreference task consists of finding clusters of event mentions that refer to the same event. Although it has not been extensively studied in comparison with the related problem of entity coreference resolution, solving event coreference has already proved its usefulness in various applications such as topic detection and tracking (Allan et al., 1998), information extraction (Humphreys et al., 1997), question answering (Narayanan and Harabagiu, 2004), textual entailment (Haghighi et al., 2005), and contradiction detection (de Marneffe et al., 2008).

Previous approaches for solving event coreference relied on supervised learning methods that explore various linguistic properties in order to decide if a pair of event mentions is coreferential or not (Humphreys et al., 1997; Bagga and Baldwin, 1999; Ahn, 2006; Chen and Ji, 2009). In spite of being successful for a particular labeled corpus, these pairwise models are dependent on the domain or language that they are trained on. Moreover, since event coreference resolution is a complex task that involves exploring a rich set of linguistic features, annotating a large corpus with event coreference information for a new language or domain of interest requires a substantial amount of manual effort. Also, since these models are dependent on local pairwise decisions, they are unable to capture a global event distribution at topic or document collection level.

To address these limitations and to provide a more flexible representation for modeling observable data with rich properties, we present two novel, fully generative, nonparametric Bayesian models for unsupervised within- and cross-document event coreference resolution. The first model extends the *hierarchical Dirichlet process* (Teh et al., 2006) to take into account additional properties associated with observable objects (i.e., event mentions). The second model overcomes some of the limitations of the first model. It uses the *infinite factorial hidden Markov model* (Van Gael et al., 2008b) coupled to the *infinite hidden Markov model* (Beal et al., 2002) in order to (1) consider a potentially infinite number of features associated with observable objects, (2) perform an automatic selection of the most salient features, and (3) capture the structural dependencies of observable objects at the discourse level. Furthermore, both models are designed to account for a potentially infinite number of categorical outcomes (i.e., events). These models provide additional details and experimental results to our preliminary work on unsupervised event coreference resolution (Bejan et al., 2009).

2 Event Coreference

The problem of determining if two events are identical was originally studied in philosophy. One relevant theory on event identity was proposed by Davidson (1969) who argued that two events are identical if they have the same causes and effects. Later on, a different theory was proposed by Quine (1985) who considered that each event refers to a physical object (which is well defined in space and time), and therefore, two events are identical

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1412–1422,
Uppsala, Sweden, 11-16 July 2010.

if they have the same spatiotemporal location. In (Davidson, 1985), Davidson abandoned his suggestion to embrace the Quinean theory on event identity (Malpas, 2009).

2.1 An Example

In accordance with the Quinean theory, we consider that two event mentions are coreferential if they have the same *event properties* and share the same *event participants*. For instance, the sentences from Example 1 encode event mentions that refer to several individuated events. These sentences are extracted from a newly annotated corpus with event coreference information (see Section 4). In this corpus, we organize documents that describe the same seminal event into topics. In particular, the topics shown in this example describe the seminal event of buying ATI by AMD (topic 43) and the seminal event of buying EDS by HP (topic 44).

Although all the event mentions of interest emphasized in boldface in Example 1 evoke the same generic event *buy*, they refer to three individuated events: $e_1 = \{em_1, em_2\}$, $e_2 = \{em_{3-6}, em_8\}$, and $e_3 = \{em_7\}$. For example, em_1(*buy*) and em_3(*buy*) correspond to different individuated events since they have a different AGENT ([BUYER(em_1)=*AMD*] $\neq$ [BUYER(em_3)=*HP*]). This organization of event mentions leads to the idea of creating an event hierarchy which has on the first level, *event mentions*, on the second level, *individuated events*, and on the third level, *generic events*. In particular, the event hierarchy corresponding to the event mentions annotated in our example is illustrated in Figure 1.

Solving the event coreference problem poses many interesting challenges. For instance, in order to solve the coreference chain of event mentions that refer to the event e_2, we need to take into account the following issues: (i) a coreference chain can encode both within- and cross-document coreference information; (ii) two mentions from the same chain can have different word classes (e.g., em_3(*buy*)–verb, em_4(*purchase*)–noun); (iii) not all the mentions from the same chain are synonymous (e.g., em_3(*buy*) and em_8(*acquire*)), although a semantic relation might exist between them (e.g., in WordNet (Fellbaum, 1998), the genus of *buy* is *acquire*); (iv) partial (or all) properties and participants of an event mention can be omitted in text (e.g., em_4(*purchase*)). In Section 5, we discuss additional aspects of the event coreference problem that are not revealed in Example 1.

2.2 Linguistic Features

The events representing coreference clusters of event mentions are characterized by a large set of linguistic features. To compute an accurate event distribution for event coreference resolution, we associate the following categories of linguistic features with each annotated event mention.

Lexical Features (LF) We capture the lexical context of an event mention by extracting the following features: the head word (HW), the lemmatized head word (HL), the lemmatized left and right words surrounding the mention (LHL,RHL), and the HL features corresponding to the left and right mentions (LHE,RHE). For instance, the lexical features extracted for the event mention em_7(*bought*) from our example are HW:*bought*, HL:*buy*, LHL:*it*, RHL:*Compaq*, LHE:*acquisition*, and RHE:*acquire*.

Class Features (CF) These features aim to group mentions into several types of classes: the part-of-speech of the HW feature (POS), the word class of the HW feature (HWC), and the event class of the mention (EC). The HWC feature can take one of the following values: VERB, NOUN, ADJEC-

TIVE, and OTHER. As values for the EC feature, we consider the seven event classes defined in the TimeML specification language (Pustejovsky et al., 2003a): OCCURRENCE, PERCEPTION, REPORTING, ASPECTUAL, STATE, I_ACTION, and I_STATE. In order to extract the event classes corresponding to the event mentions from a given dataset, we employed the event extractor described in (Bejan, 2007). This extractor is trained on the TimeBank corpus (Pustejovsky et al., 2003b), which is a TimeML resource encoding temporal elements such as events, time expressions, and temporal relations.

WordNet Features (WF) In our efforts to create clusters of event mention attributes as close as possible to the true attribute clusters of the individuated events, we build two sets of word clusters using the entire lexical information from the WordNet database. After creating these sets of clusters, we then associate each event mention with only one cluster from each set. The first set uses the transitive closure of the WordNet SYNONYMOUS relation to form clusters with all the words from WordNet (WNS). For instance, the verbs *buy* and *purchase* correspond to the same cluster ID because there exist a chain of SYNONYMOUS relations between them in WordNet. The second set considers as grouping criteria the categorization of words from the WordNet lexicographer's files (WNL). In addition, for each word that is not covered in WordNet, we create a new cluster ID in each set of clusters.

Semantic Features (SF) To extract features that characterize participants and properties of event mentions, we use the semantic parser described in (Bejan and Hathaway, 2007). One category of semantic features that we identify for event mentions is the *predicate argument structures* encoded in PropBank annotations (Palmer et al., 2005). In PropBank, the predicate argument structures are represented by events expressed as verbs in text and by the semantic roles, or *predicate arguments*, associated with these events. For example, ARG0 annotates a specific type of semantic role which represents the AGENT, DOER, or ACTOR of a specific event. Another argument is ARG1, which plays the role of the PATIENT, THEME, or EXPERIENCER of an event. In particular, the predicate arguments associated to the event mention em_8(*bought*) from Example 1 are ARG0:[*it*], ARG1:[*Compaq Computer Corp.*], ARG3:[*for $19 billion*], and ARG-TMP:[*in 2002*].

Event mentions are not only expressed as verbs in text, but also as nouns and adjectives. Therefore, for a better coverage of semantic features, we also employ the semantic annotations encoded in the FrameNet corpus (Baker et al., 1998). FrameNet annotates word expressions capable of evoking conceptual structures, or *semantic frames*, which describe specific situations, objects, or events (Fillmore, 1982). The semantic roles associated with a word in FrameNet, or *frame elements*, are locally defined for the semantic frame evoked by the word. In general, the words annotated in FrameNet are expressed as verbs, nouns, and adjectives.

To preserve the consistency of semantic role features, we align frame elements to predicate arguments by running the PropBank semantic parser on the manual annotations from FrameNet; conversely, we also run the FrameNet parser on the manual annotations from PropBank. Moreover, to obtain a better alignment of semantic roles, we run both parsers on a large amount of unlabeled text. The result of this process is a map with all frame elements statistically aligned to all predicate arguments. For instance, in 99.7% of the cases the frame element BUYER of the semantic frame COMMERCE BUY is mapped to ARG0, and in the remaining 0.3% of the cases to ARG1. Additionally, we use this map to create a more general semantic feature which assigns to each predicate argument a frame element label. In particular, the features for em_8(*acquire*) are FEA0:BUYER, FEA1:GOODS, FEA3:MONEY, and FEATMP:TIME.

Two additional semantic features used in our experiments are: (1) the semantic frame (FR) evoked by every mention;[1] and (2) the WNS feature applied to the head word of every semantic role (e.g., WSA0, WSA1).

Feature Combinations (FC) We also explore various combinations of the features presented above. Examples include HW+HWC, HL+FR, FR+ARG1, LHL+RHL, etc.

It is worth noting that there exist event mentions for which not all the features can be extracted. For example, the LHE and RHE features are missing for the first and last event mentions in a document, respectively. Also, many semantic roles can be absent for an event mention in a given context.

[1] The reason for extracting this feature is given by the fact that, in general, frames are able to capture properties of generic events (Lowe et al., 1997).

3 Nonparametric Bayesian Models

As input for our models, we consider a collection of I documents, where each document i has J_i event mentions. For features, we make the distinction between *feature types* and *feature values* (e.g., POS is a feature type and has values such as NN and VB). Each event mention is characterized by L feature types, FT, and each feature type is represented by a finite vocabulary of feature values, fv. Thus, we can represent the observable properties of an event mention as a vector of L feature type – feature value pairs $\langle(\text{FT}_1 : fv_{1i}), \ldots, (\text{FT}_L : fv_{Li})\rangle$, where each feature value index i ranges in the feature value space associated with a feature type.

3.1 A Finite Feature Model

We present an extension of the *hierarchical Dirichlet process* (HDP) model which is able to represent each observable object (i.e., event mention) by a finite number of feature types L. Our HDP extension is also inspired from the Bayesian model proposed by Haghighi and Klein (2007). However, their model is strictly customized for entity coreference resolution, and therefore, extending it to include additional features for each observable object is a challenging task (Ng, 2008; Poon and Domingos, 2008).

In the HDP model, a *Dirichlet process* (DP) (Ferguson, 1973) is associated with each document, and each mixture component (i.e., event) is shared across documents. To describe its extension, we consider $\mathbf{Z}$ the set of indicator random variables for indices of events, ϕ_z the set of parameters associated with an event z, $\boldsymbol{\phi}$ a notation for all model parameters, and $\mathbf{X}$ a notation for all random variables that represent observable features.[2] Given a document collection annotated with event mentions, the goal is to find the best assignment of event indices $\mathbf{Z}^*$, which maximize the posterior probability $P(\mathbf{Z}|\mathbf{X})$. In a Bayesian approach, this probability is computed by integrating out all model parameters:

$$P(\mathbf{Z}|\mathbf{X}) = \int P(\mathbf{Z}, \phi|\mathbf{X})d\phi = \int P(\mathbf{Z}|\mathbf{X}, \phi)P(\phi|\mathbf{X})d\phi$$

Our HDP extension is depicted graphically in Figure 2(a). Similar to the HDP model, the distribution over events associated with each document, $\boldsymbol{\beta}$, is generated by a Dirichlet process with a concentration parameter $\alpha > 0$. Since this setting enables a clustering of event mentions at the document level, it is desirable that events be shared across documents and the number of events K be inferred from data. To ensure this flexibility, a global nonparametric DP prior with a hyperparameter γ and a global base measure H can be considered for $\boldsymbol{\beta}$ (Teh et al., 2006). The global distribution drawn from this DP prior, denoted as $\boldsymbol{\beta}_0$ in Figure 2(a), encodes the event mixing weights. Thus, same global events are used for each document, but each event has a document specific distribution β_i that is drawn from a DP prior centered on the global weights $\boldsymbol{\beta}_0$.

To infer the true posterior probability of $P(\mathbf{Z}|\mathbf{X})$, we follow (Teh et al., 2006) and use the *Gibbs sampling algorithm* (Geman and Geman, 1984) based on the direct assignment sampling scheme. In this sampling scheme, the parameters $\boldsymbol{\beta}$ and $\boldsymbol{\phi}$ are integrated out analytically. Moreover, to reduce the complexity of computing $P(\mathbf{Z}|\mathbf{X})$, we make the naïve Bayes assumption that the feature variables $\mathbf{X}$ are conditionally independent given $\mathbf{Z}$. This allows us to factorize the joint distribution of feature variables $\mathbf{X}$ conditioned on $\mathbf{Z}$ into product of marginals. Thus, by Bayes rule, the formula for sampling an event index for mention j from document i, $Z_{i,j}$, is:[3]

$$P(Z_{i,j} \mid \mathbf{Z}^{-i,j}, \mathbf{X}) \propto P(Z_{i,j} \mid \mathbf{Z}^{-i,j}) \prod_{X \in \mathbf{X}} P(X_{i,j} | \mathbf{Z}, \mathbf{X}^{-i,j})$$

where $X_{i,j}$ represents the feature value of a feature type corresponding to the event mention j from the document i.

In the process of generating an event mention, an event index z is first sampled by using a mechanism that facilitates sampling from a prior for infinite mixture models called the *Chinese restaurant franchise* (CRF) representation, as reported in (Teh et al., 2006):

$$P(Z_{i,j} = z \mid \mathbf{Z}^{-i,j}, \beta_0) \propto \begin{cases} \alpha\beta_0^u, & \text{if } z = z_{new} \\ n_z + \alpha\beta_0^z, & \text{otherwise} \end{cases}$$

Here, n_z is the number of event mentions with event index z, z_{new} is a new event index not used already in $\mathbf{Z}^{-i,j}$, β_0^z are the global mixing proportions associated with the K events, and β_0^u is the weight for the unknown mixture component.

Next, to generate a feature value x (with the feature type X) of the event mention, the event z is

[2] In this subsection, the feature term is used in context of a feature type.

[3] $\mathbf{Z}^{-i,j}$ represents a notation for $\mathbf{Z} - \{Z_{i,j}\}$.

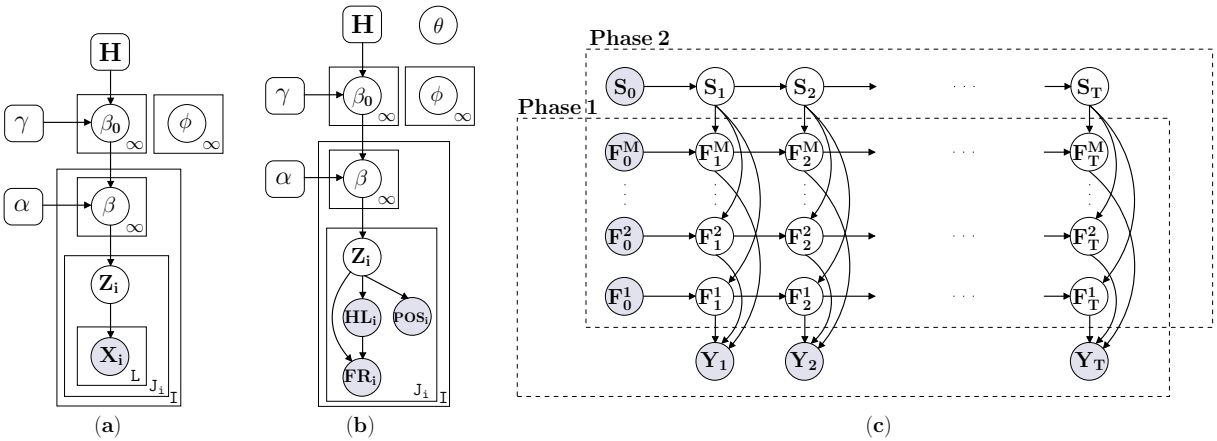

Figure 2: Graphical representation of our models: nodes correspond to random variables; shaded nodes denote observable variables; a rectangle captures the replication of the structure it contains, where the number of replications is indicated in the bottom-right corner. The model in (a) illustrates a flat representation of a limited number of features in a generalized framework (henceforth, HDP$_{flat}$). The model in (b) captures a simple example of structured network topology of three feature variables (henceforth, HDP$_{struct}$). The dependencies involving parameters ϕ and θ in these models are omitted for clarity. The model from (c) shows the representation of the iFHMM-iHMM model as well as the main phases of its generative process.

associated with a multinomial emission distribution over the feature values of X having the parameters $\boldsymbol{\phi} = \langle \phi^x_Z \rangle$. We assume that this emission distribution is drawn from a symmetric Dirichlet distribution with concentration λ_X:

$$P(X_{i,j} = x \mid \mathbf{Z}, \mathbf{X}^{-i,j}) \propto n_{x,z} + \lambda_X$$

where $X_{i,j}$ is the feature type of the mention j from the document i, and $n_{x,z}$ is the number of times the feature value x has been associated with the event index z in $(\mathbf{Z}, \mathbf{X}^{-i,j})$. We also apply the Lidstone's smoothing method to this distribution. In cases when only a feature type is considered (e.g., $\mathbf{X} = \langle HL \rangle$), the HDP$_{flat}$ model is identical with the original HDP model. We denote this one feature model by HDP$_{1f}$.

When dependencies between feature variables exist (e.g., in our case, frame elements are dependent on the semantic frames that define them, and frames are dependent on the words that evoke them), various global distributions are involved for computing $P(\mathbf{Z}|\mathbf{X})$. For the model depicted in Figure 2(b), for instance, the posterior probability is given by:

$$P(Z_{i,j}) P(FR_{i,j} \,|\, HL_{i,j}, \boldsymbol{\theta}) \prod_{X \in \mathbf{X}} P(X_{i,j} \,|\, \mathbf{Z})$$

In this formula, $P(FR_{i,j}|HL_{i,j}, \boldsymbol{\theta})$ is a global distribution parameterized by $\boldsymbol{\theta}$, and X is a feature variable from the set $\mathbf{X} = \langle HL, POS, FR \rangle$. For the sake of clarity, we omit the conditioning components of $\mathbf{Z}$, $\mathbf{HL}$, $\mathbf{FR}$, and $\mathbf{POS}$.

3.2 An Infinite Feature Model

To relax some of the restrictions of the first model, we devise an approach that combines the *infinite factorial hidden Markov model* (iFHMM) with the *infinite hidden Markov model* (iHMM) to form the iFHMM-iHMM model.

The iFHMM framework uses the *Markov Indian buffet process* (mIBP) (Van Gael et al., 2008b) in order to represent each object as a sparse subset of a potentially unbounded set of latent features (Griffiths and Ghahramani, 2006; Ghahramani et al., 2007; Van Gael et al., 2008a).[4] Specifically, the mIBP defines a distribution over an unbounded set of binary Markov chains, where each chain can be associated with a binary latent feature that evolves over time according to Markov dynamics. Therefore, if we denote by M the total number of feature chains and by T the number of observable components, the mIBP defines a probability distribution over a binary matrix $\mathbf{F}$ with T rows, which correspond to observations, and an unbounded number of columns M, which correspond to features. An observation y_t contains a subset from the unbounded set of features $\{f^1, f^2, \ldots, f^M\}$ that is represented in the matrix by a binary vector $\mathbf{F_t} = \langle F_t^1, F_t^2, \ldots, F_t^M \rangle$, where $F_t^i = 1$ indicates that f^i is associated with y_t. In other words, $\mathbf{F}$ decomposes the observations and represents them as feature factors, which can then be associated with hidden variables in an iFHMM model as depicted in Figure 2(c).

[4] In this subsection, a feature will be represented by a (feature type:feature value) pair.

Although the iFHMM allows a more flexible representation of the latent structure by letting the number of parallel Markov chains M be learned from data, it cannot be used as a framework where the number of clustering components K is infinite. On the other hand, the iHMM represents a nonparametric extension of the *hidden Markov model* (HMM) (Rabiner, 1989) that allows performing inference on an infinite number of states K. To further increase the representational power for modeling discrete time series data, we propose a nonparametric extension that combines the best of the two models, and lets the parameters M and K be learned from data.

As shown in Figure 2(c), each step in the new iHMM-iFHMM generative process is performed in two phases: (i) the latent feature variables from the iFHMM framework are sampled using the mIBP mechanism; and (ii) the features sampled so far, which become observable during this second phase, are used in an adapted version of the *beam sampling algorithm* (Van Gael et al., 2008a) to infer the clustering components (i.e., latent events).

In the first phase, the stochastic process for sampling features in $\mathbf{F}$ is defined as follows. The first component samples a number of $\mathsf{Poisson}(\alpha')$ features. In general, depending on the value that was sampled in the previous step $(t-1)$, a feature f^m is sampled for the t^{th} component according to the $P(F_t^m = 1 \mid F_{t-1}^m = 1)$ and $P(F_t^m = 1 \mid F_{t-1}^m = 0)$ probabilities.[5] After all features are sampled for the t^{th} component, a number of $\mathsf{Poisson}(\alpha'/t)$ new features are assigned for this component, and M gets incremented accordingly.

To describe the adapted beam sampler, which is employed in the second phase of the generative process, we introduce additional notations. We denote by $(s_1, \ldots, s_T)$ the sequence of hidden states corresponding to the sequence of event mentions $(y_1, \ldots, y_T)$, where each state s_t belongs to one of the K events, $s_t \in \{1, \ldots, K\}$, and each mention y_t is represented by a sequence of latent features $\langle F_t^1, F_t^2, \ldots, F_t^M \rangle$. One element of the transition probability $\boldsymbol{\pi}$ is defined as $\pi_{ij} = P(s_t = j \mid s_{t-1} = i)$, and a mention y_t is generated according to a likelihood model $\mathcal{F}$ that is parameterized by a state-dependent parameter ϕ_{s_t} $(y_t \mid s_t \sim \mathcal{F}(\phi_{s_t}))$. The observation parameters $\boldsymbol{\phi}$ are drawn independently from an identical prior base distribution H.

The beam sampling algorithm combines the ideas of slice sampling and dynamic programming for an efficient sampling of state trajectories. Since in time series models the transition probabilities have independent priors (Beal et al., 2002), Van Gael and colleagues (2008a) also used the HDP mechanism to allow couplings across transitions. For sampling the whole hidden state trajectory $\mathbf{s}$, this algorithm employs a forward filtering-backward sampling technique.

In the forward step of our adapted beam sampler, for each mention y_t, we sample features using the mIBP mechanism and the auxiliary variable $u_t \sim \mathsf{Uniform}(0, \pi_{s_{t-1}s_t})$. As explained in (Van Gael et al., 2008a), the auxiliary variables $\mathbf{u}$ are used to filter only those trajectories $\mathbf{s}$ for which $\pi_{s_{t-1}s_t} \geq u_t$ for all t. Also, in this step, we compute the probabilities $P(s_t \mid y_{1:t}, u_{1:t})$ for all t:

$$P(s_t|y_{1:t},u_{1:t}) \propto P(y_t|s_t) \sum_{s_{t-1}:u_t<\pi_{s_{t-1}s_t}} P(s_{t-1}|y_{1:t-1},u_{1:t-1})$$

Here, the dependencies involving parameters $\boldsymbol{\pi}$ and $\boldsymbol{\phi}$ are omitted for clarity.

In the backward step, we first sample the event for the last state s_T directly from $P(s_T \mid y_{1:T}, u_{1:T})$ and then, for all $t : T-1 \ldots 1$, we sample each state s_t given s_{t+1} by using the formula $P(s_t \mid s_{t+1}, y_{1:T}, u_{1:T}) \propto P(s_t \mid y_{1:t}, u_{1:t}) P(s_{t+1} \mid s_t, u_{t+1})$. To sample the emission distribution $\boldsymbol{\phi}$ efficiently, and to ensure that each mention is characterized by a finite set of representative features, we set the base distribution H to be conjugate with the data distribution $\mathcal{F}$ in a Dirichlet-multinomial model with the multinomial parameters $(o_1, \ldots, o_K)$ defined as:

$$o_k = \sum_{t=1}^{T} \sum_{f^m \in B_t} n_{mk}$$

In this formula, n_{mk} counts how many times the feature f^m was sampled for the event k, and B_t stores a finite set of features for y_t.

The mechanism for building a finite set of representative features for the mention y_t is based on *slice sampling* (Neal, 2003). Letting q_m be the number of times the feature f^m was sampled in the mIBP, and v_t an auxiliary variable for y_t such that $v_t \sim \mathsf{Uniform}(1, \max\{q_m : F_t^m = 1\})$, we define the finite feature set B_t for the observation y_t as $B_t = \{f^m : F_t^m = 1 \wedge q_m \geq v_t\}$. The finiteness of this feature set is based on the observation that, in the generative process of the mIBP, only a finite set

[5] Technical details for computing these probabilities are described in (Van Gael et al., 2008b).

of features are sampled for a component. We denote this model as iFHMM-iHMM$_{uniform}$. Also, it is worth mentioning that, by using this type of sampling, only the most representative features of y_t get selected in B_t.

Furthermore, we explore the mechanism for selecting a finite set of features associated with an observation by: (1) considering all the observation's features whose corresponding feature counter $q_m \geq 1$ ($unfiltered$); (2) selecting only the higher half of the feature distribution consisting of the observation's features that were sampled at least once in the mIBP model ($median$); and (3) sampling v_t from a discrete distribution of the observation's features that were sampled at least once in the mIBP ($discrete$).

4 Experiments

Datasets One dataset we employed is the automatic content extraction (ACE) (ACE-Event, 2005). However, the utilization of the ACE corpus for the task of solving event coreference is limited because this resource provides only within-document event coreference annotations using a restricted set of event types such as LIFE, BUSINESS, CONFLICT, and JUSTICE. Therefore, as a second dataset, we created the **EventCorefBank** (ECB) corpus[6] to increase the diversity of event types and to be able to evaluate our models for both within- and cross-document event coreference resolution. One important step in the creation process of this corpus consists in finding sets of related documents that describe the same seminal event such that the annotation of coreferential event mentions across documents is possible. For this purpose, we selected from the GoogleNews archive[7] various topics whose description contains keywords such as *commercial transaction*, *attack*, *death*, *sports*, *terrorist act*, *election*, *arrest*, *natural disaster*, etc. The entire annotation process for creating the ECB resource is described in (Bejan and Harabagiu, 2008). Table 1 lists several basic statistics extracted from these two corpora.

Evaluation For a more realistic approach, we not only trained the models on the manually annotated event mentions (i.e., true mentions), but also on all the possible mentions encoded in the two datasets. To extract all event mentions, we ran the event identifier described in (Bejan, 2007). The mentions extracted by this system (i.e., system mentions) were able to cover all the true mentions from both datasets. As shown in Table 1, we extracted from ACE and ECB corpora 45289 and 21175 system mentions, respectively.

	ACE	ECB
Number of topics	–	43
Number of documents	745	482
Number of within-topic events	–	339
Number of cross-document events	–	208
Number of within-document events	4946	1302
Number of true mentions	6553	1744
Number of system mentions	45289	21175
Number of distinct feature values	391798	237197

Table 1: Statistics of the ACE and ECB corpora.

We report results in terms of recall (R), precision (P), and F-score (F) by employing the *mention*-based B^3 metric (Bagga and Baldwin, 1998), the *entity*-based CEAF metric (Luo, 2005), and the pairwise F1 (PW) metric. All the results are averaged over 5 runs of the generative models. In the evaluation process, we considered only the true mentions of the ACE test dataset, and the event mentions of the test sets derived from a 5-fold cross validation scheme on the ECB dataset. For evaluating the cross-document coreference annotations, we adopted the same approach as described in (Bagga and Baldwin, 1999) by merging all the documents from the same topic into a meta-document and then scoring this document as performed for within-document evaluation. For both corpora, we considered a set of 132 feature types, where each feature type consists on average of 3900 distinct feature values.

Baselines We consider two baselines for event coreference resolution (rows 1&2 in Tables 2&3). One baseline groups each event mention by its event class (BL$_{eclass}$). Therefore, for this baseline, we cluster mentions according to their corresponding EC feature value. Similarly, the second baseline uses as grouping criteria for event mentions their corresponding WNS feature value (BL$_{syn}$).

HDP Extensions Due to memory limitations, we evaluated the HDP models on a restricted set of manually selected feature types. In general, the HDP$_{1f}$ model with the feature type HL, which plays the role of a baseline for the HDP$_{flat}$ and HDP$_{struct}$ models, outperforms both baselines on the ACE and ECB datasets. For the HDP$_{flat}$ models (rows 4–7 in Tables 2&3), we classified the experiments according to the set of feature types described in Section 2. Our experiments reveal that the best configuration of features for this model

Table 3: Results for WD coreference resolution on ACE.

consists of a combination of feature types from all the categories of features (row 7). For the HDP$_{struct}$ experiments, we considered the set of features of the best HDP$_{flat}$ experiment as well as the dependencies between HL, FR, and FEA. Overall, we can assert that HDP$_{flat}$ achieved the best performance results on the ACE test dataset (Table 3), whereas HDP$_{struct}$ proved to be more effective on the ECB dataset (Table 2). Moreover, the results of the HDP$_{flat}$ and HDP$_{struct}$ models show an F-score increase by 4-10% over HDP$_{1f}$, and therefore, the results prove that the HDP extension provides a more flexible representation for clustering objects with rich properties.

We also plot the evolution of our generative processes. For instance, Figure 3(a) shows that the HDP$_{flat}$ model corresponding to row 7 in Table 3 converges in 350 iteration steps to a posterior distribution over event mentions from ACE with around 2000 latent events. Additionally, our experiments with different values of the λ parameter for the Lidstone's smoothing method indicate that this smoothing method is useful for improving the performance of the HDP models. However, we could not find a λ value in our experiments that brings a major improvement over the non-smoothed HDP models. Figure3(b) shows the performances of HDP$_{struct}$ on ECB with various λ values.[8] The HDP results from Tables 2&3 correspond to a λ value of 10^{-4} and 10^{-2} for HDP$_{flat}$ and HDP$_{struct}$, respectively.

iFHMM-iHMM In spite of the fact that the iFHMM-iHMM model employs automatic feature selection, its results remain competitive against the results of the HDP models, where the feature types were manually tuned. When comparing the strategies for filtering feature values in this framework, we could not find a distinct separation between the results obtained by the $unfiltered$, $discrete$, $median$, and $uniform$ models. As observed from Tables 2&3, most of the iFHMM-iHMM results fall in between the HDP$_{flat}$ and HDP$_{struct}$ results. The results were obtained by automatically selecting only up to 1.5% of distinct feature values. Figure 3(c) shows the percents of features employed by this model for various values of the parameter α' that controls the number of sampled features. The best results (also listed in Tables 2&3) were obtained for $\alpha' = 10$ (0.05%) on ACE and $\alpha' = 150$ (0.91%) on ECB.

To show the usefulness of the sampling schemes considered for this model, we also compare in Table 4 the results obtained by an iFHMM-iHMM model that considers all the feature values associated with an observable object (iFHMM-iHMM$_{all}$) against the iFHMM-iHMM models that employ the mIBP sampling scheme together with the $unfiltered$, $discrete$, $median$, and $uniform$ filtering schemes. Because of the memory limitation constraints, we performed the experiments listed in Table 4 by selecting only a subset from

[8] A configuration $\lambda = 0$ in the Lidstone's smoothing method is equivalent with a non-smoothed version of the model on which it is applied.

Table 4: Feature non-sampling vs. feature sampling in the iFHMM-iHMM model.

the feature types which proved to be salient in the HDP experiments. As listed in Table 4, all the iFHMM-iHMM models that used a feature sampling scheme significantly outperform the iFHMM-iHMM$_{all}$ model; this proves that all the sampling schemes considered in the iFHMM-iHMM framework are able to successfully filter out noisy and redundant feature values.

The closest comparison to prior work is the supervised approach described in (Chen and Ji, 2009) that achieved a 92.2% B^3 F-measure on the ACE corpus. However, for this result, ground truth event mentions as well as a manually tuned coreference threshold were employed.

5 Error Analysis

One frequent error occurs when a more complex form of semantic inference is needed to find a correspondence between two event mentions of the same individuated event. For instance, since all properties and participants of em_3(*deal*) are omitted in our example and no common features exist between em_3(*buy*) and em_1(*buy*) to indicate a similarity between these mentions, they will most probably be assigned to different clusters. This example also suggests the need for a better modeling of the discourse salience for event mentions.

Another common error is made when matching the semantic roles corresponding to coreferential event mentions. Although we simulated entity coreference by using various semantic features, the task of matching participants of coreferential event mentions is not completely solved. This is because, in many coreferential cases, partonomic relations between semantic roles need to be inferred.[9] Examples of such relations extracted from ECB are *Israeli forces* $\xrightarrow{\text{PART OF}}$ *Israel*, *an Indian warship* $\xrightarrow{\text{PART OF}}$ *the Indian navy*, *his cell* $\xrightarrow{\text{PART OF}}$ *Sicilian jail*. Similarly for event properties, many coreferential examples do not specify a clear location and time interval (e.g., *Jabaliya refugee camp* $\xrightarrow{\text{PART OF}}$ *Gaza*, *Tuesday* $\xrightarrow{\text{PART OF}}$ *this week*). In future work, we plan to build relevant clusters using partonomies and taxonomies such as the WordNet hierarchies built from MERONYMY/HOLONYMY and HYPERNYMY/HYPONYMY relations, respectively.[10]

6 Conclusion

We have presented two novel, nonparametric Bayesian models that are designed to solve complex problems that require clustering objects characterized by a rich set of properties. Our experiments for event coreference resolution proved that these models are able to solve real data applications in which the feature and cluster numbers are treated as free parameters, and the selection of feature values is performed automatically.

[9] This observation was also reported in (Hasler and Orasan, 2009). [10] This task is not trivial since, if applying the transitive closure on these relations, all words will end up being part from the same cluster with *entity* for instance.

Abstract

This paper explores the effect that different corpus configurations have on the performance of a coreference resolution system, as measured by MUC, B^3, and CEAF. By varying separately three parameters (language, annotation scheme, and preprocessing information) and applying the same coreference resolution system, the strong bonds between system and corpus are demonstrated. The experiments reveal problems in coreference resolution evaluation relating to task definition, coding schemes, and features. They also expose systematic biases in the coreference evaluation metrics. We show that system comparison is only possible when corpus parameters are in exact agreement.

1 Introduction

The task of coreference resolution, which aims to automatically identify the expressions in a text that refer to the same discourse entity, has been an increasing research topic in NLP ever since MUC-6 made available the first coreferentially annotated corpus in 1995. Most research has centered around the rules by which mentions are allowed to corefer, the features characterizing mention pairs, the algorithms for building coreference chains, and coreference evaluation methods. The surprisingly important role played by different aspects of the corpus, however, is an issue to which little attention has been paid. We demonstrate the extent to which a system will be evaluated as performing differently depending on parameters such as the corpus language, the way coreference relations are defined in the corresponding coding scheme, and the nature and source of preprocessing information.

This paper unpacks these issues by running the same system—a prototype entity-based architecture called CISTELL—on different corpus configurations, varying three parameters. First, we show how much language-specific issues affect performance when trained and tested on English and Spanish. Second, we demonstrate the extent to which the specific annotation scheme (used on the same corpus) makes evaluated performance vary. Third, we compare the performance using gold-standard preprocessing information with that using automatic preprocessing tools.

Throughout, we apply the three principal coreference evaluation measures in use today: MUC, B^3, and CEAF. We highlight the systematic preferences of each measure to reward different configurations. This raises the difficult question of why one should use one or another evaluation measure, and how one should interpret their differences in reporting changes of performance score due to 'secondary' factors like preprocessing information.

To this end, we employ three corpora: ACE (Doddington et al., 2004), OntoNotes (Pradhan et al., 2007), and AnCora (Recasens and Martí, 2009). In order to isolate the three parameters as far as possible, we benefit from a 100k-word portion (from the TDT collection) that is common to both ACE and OntoNotes. We apply the same coreference resolution system in all cases. The results show that a system's score is not informative by itself, as different corpora or corpus parameters lead to different scores. Our goal is not to achieve the best performance to date, but rather to expose various issues raised by the choices of corpus preparation and evaluation measure and to shed light on the definition, methods, evaluation, and complexities of the coreference resolution task.

The paper is organized as follows. Section 2 sets our work in context and provides the motivations for undertaking this study. Section 3 presents the architecture of CISTELL, the system used in the experimental evaluation. In Sections 4, 5,

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1423–1432,
Uppsala, Sweden, 11-16 July 2010.

and 6, we describe the experiments on three different datasets and discuss the results. We conclude in Section 7.

2 Background

The bulk of research on automatic coreference resolution to date has been done for English and used two different types of corpus: MUC (Hirschman and Chinchor, 1997) and ACE (Doddington et al., 2004). A variety of learning-based systems have been trained and tested on the former (Soon et al., 2001; Uryupina, 2006), on the latter (Culotta et al., 2007; Bengtson and Roth, 2008; Denis and Baldridge, 2009), or on both (Finkel and Manning, 2008; Haghighi and Klein, 2009). Testing on both is needed given that the two annotation schemes differ in some aspects. For example, only ACE includes singletons (mentions that do not corefer) and ACE is restricted to seven semantic types.[1] Also, despite a critical discussion in the MUC task definition (van Deemter and Kibble, 2000), the ACE scheme continues to treat nominal predicates and appositive phrases as coreferential.

A third coreferentially annotated corpus—the largest for English—is OntoNotes (Pradhan et al., 2007; Hovy et al., 2006). Unlike ACE, it is not application-oriented, so coreference relations between all types of NPs are annotated. The identity relation is kept apart from the attributive relation, and it also contains gold-standard morphological, syntactic and semantic information.

Since the MUC and ACE corpora are annotated with only coreference information,[2] existing systems first preprocess the data using automatic tools (POS taggers, parsers, etc.) to obtain the information needed for coreference resolution. However, given that the output from automatic tools is far from perfect, it is hard to determine the level of performance of a coreference module acting on gold-standard preprocessing information. OntoNotes makes it possible to separate the coreference resolution problem from other tasks.

Our study adds to the previously reported evidence by Stoyanov et al. (2009) that differences in corpora and in the task definitions need to be taken into account when comparing coreference resolution systems. We provide new insights as the current analysis differs in four ways. First, Stoyanov et al. (2009) report on differences between MUC and ACE, while we contrast ACE and OntoNotes. Given that ACE and OntoNotes include some of the same texts but annotated according to their respective guidelines, we can better isolate the effect of differences as well as add the additional dimension of gold preprocessing. Second, we evaluate not only with the MUC and B^3 scoring metrics, but also with CEAF. Third, all our experiments use true mentions[3] to avoid effects due to spurious system mentions. Finally, including different baselines and variations of the resolution model allows us to reveal biases of the metrics.

Coreference resolution systems have been tested on languages other than English only within the ACE program (Luo and Zitouni, 2005), probably due to the fact that coreferentially annotated corpora for other languages are scarce. Thus there has been no discussion of the extent to which systems are portable across languages. This paper studies the case of English and Spanish.[4]

Several coreference systems have been developed in the past (Culotta et al., 2007; Finkel and Manning, 2008; Poon and Domingos, 2008; Haghighi and Klein, 2009; Ng, 2009). It is not our aim to compete with them. Rather, we conduct three experiments under a specific setup for comparison purposes. To this end, we use a different, neutral, system, and a dataset that is small and different from official ACE test sets despite the fact that it prevents our results from being compared directly with other systems.

3 Experimental Setup

3.1 System Description

The system architecture used in our experiments, CISTELL, is based on the incrementality of discourse. As a discourse evolves, it constructs a model that is updated with the new information gradually provided. A key element in this model are the entities the discourse is about, as they form the discourse backbone, especially those that are mentioned multiple times. Most entities, however, are only mentioned once. Consider the growth of the entity *Mount Popocatépetl* in (1).[5]

[1] The ACE-2004/05 semantic types are person, organization, geo-political entity, location, facility, vehicle, weapon.

[2] ACE also specifies entity types and relations.

[3] The adjective *true* contrasts with *system* and refers to the gold standard.

[4] Multilinguality is one of the focuses of SemEval-2010 Task 1 (Recasens et al., 2010).

[5] Following the ACE terminology, we use the term *mention* for an instance of reference to an object, and *entity* for a collection of mentions referring to the same object. Entities

(1) We have an update tonight on [this, the volcano in Mexico, they call El Popo]$_{m3}$ ... As the sun rises over [Mt. Popo]$_{m7}$ tonight, the only hint of the fire storm inside, whiffs of smoke, but just a few hours earlier, [the volcano]$_{m11}$ exploding spewing rock and red-hot lava. [The fourth largest mountain in North America, nearly 18,000 feet high]$_{m15}$, erupting this week with [its]$_{m20}$ most violent outburst in 1,200 years.

Mentions can be pronouns ($m20$), they can be a (shortened) string repetition using either the name ($m7$) or the type ($m11$), or they can add new information about the entity: $m15$ provides the supertype and informs the reader about the height of the volcano and its ranking position.

In CISTELL,[6] discourse entities are conceived as 'baskets': they are empty at the beginning of the discourse, but keep growing as new attributes (e.g., name, type, location) are predicated about them. Baskets are filled with this information, which can appear within a mention or elsewhere in the sentence. The ever-growing amount of information in a basket allows richer comparisons to new mentions encountered in the text.

CISTELL follows the learning-based coreference architecture in which the task is split into classification and clustering (Soon et al., 2001; Bengtson and Roth, 2008) but combines them simultaneously. Clustering is identified with basket-growing, the core process, and a pairwise classifier is called every time CISTELL considers whether a basket must be clustered into a (growing) basket, which might contain one or more mentions. We use a memory-based learning classifier trained with TiMBL (Daelemans and Bosch, 2005). Basket-growing is done in four different ways, explained next.

3.2 Baselines and Models

In each experiment, we compute three baselines (1, 2, 3), and run CISTELL under four different models (4, 5, 6, 7).

1. ALL SINGLETONS. No coreference link is ever created. We include this baseline given the high number of singletons in the datasets, since some evaluation measures are affected by large numbers of singletons.
2. HEAD MATCH. All non-pronominal NPs that have the same head are clustered into the same entity.
3. HEAD MATCH + PRON. Like HEAD MATCH, plus allowing personal and possessive pronouns to link to the closest noun with which they agree in gender and number.
4. STRONG MATCH. Each mention (e.g., m_{11}) is paired with previous mentions starting from the beginning of the document (m_1–m_{11}, m_2–m_{11}, etc.).[7] When a pair (e.g., m_3–m_{11}) is classified as coreferent, additional pairwise checks are performed with all the mentions contained in the (growing) entity basket (e.g., m_7–m_{11}). Only if *all* the pairs are classified as coreferent is the mention under consideration attached to the existing growing entity. Otherwise, the search continues.[8]
5. SUPER STRONG MATCH. Similar to STRONG MATCH but with a threshold. Coreference pairwise classifications are only accepted when TiMBL distance is smaller than 0.09.[9]
6. BEST MATCH. Similar to STRONG MATCH but following Ng and Cardie (2002)'s best link approach. Thus, the mention under analysis is linked to the *most confident* mention among the previous ones, using TiMBL's confidence score.
7. WEAK MATCH. A simplified version of STRONG MATCH: not all mentions in the growing entity need to be classified as coreferent with the mention under analysis. A single positive pairwise decision suffices for the mention to be clustered into that entity.[10]

3.3 Features

We follow Soon et al. (2001), Ng and Cardie (2002) and Luo et al. (2004) to generate most of the 29 features we use for the pairwise model. These include features that capture information from different linguistic levels: textual strings (head match, substring match, distance, frequency), morphology (mention type, coordination, possessive phrase, gender match, number match), syntax (nominal predicate, apposition, relative clause, grammatical function), and semantic match (named-entity type, is-a type, supertype).

containing one single mention are referred to as *singletons*.

[6] 'Cistell' is the Catalan word for 'basket.'

[7] The opposite search direction was also tried but gave worse results.

[8] Taking the first mention classified as coreferent follows Soon et al. (2001)'s first-link approach.

[9] In TiMBL, being a memory-based learner, the closer the distance to an instance, the more confident the decision. We chose 0.09 because it appeared to offer the best results.

[10] STRONG and WEAK MATCH are similar to Luo et al. (2004)'s entity-mention and mention-pair models.

For Spanish, we use 34 features as a few variations are needed for language-specific issues such as zero subjects (Recasens and Hovy, 2009).

3.4 Evaluation

Since they sometimes provide quite different results, we evaluate using three coreference measures, as there is no agreement on a standard.

- MUC (Vilain et al., 1995). It computes the number of links common between the true and system partitions. Recall (R) and precision (P) result from dividing it by the minimum number of links required to specify the true and the system partitions, respectively.
- B^3 (Bagga and Baldwin, 1998). R and P are computed for each mention and averaged at the end. For each mention, the number of common mentions between the true and the system entity is divided by the number of mentions in the true entity or in the system entity to obtain R and P, respectively.
- CEAF (Luo, 2005). It finds the best one-to-one alignment between true and system entities. Using true mentions and the ϕ_3 similarity function, R and P are the same and correspond to the number of common mentions between the aligned entities divided by the total number of mentions.

4 Parameter 1: Language

The first experiment compared the performance of a coreference resolution system on a Germanic and a Romance language—English and Spanish—to explore to what extent language-specific issues such as zero subjects[11] or grammatical gender might influence a system.

Although OntoNotes and AnCora are two different corpora, they are very similar in those aspects that matter most for the study's purpose: they both include a substantial amount of texts belonging to the same genre (news) and manually annotated from the morphological to the semantic levels (POS tags, syntactic constituents, NEs, WordNet synsets, and coreference relations). More importantly, very similar coreference annotation guidelines make AnCora the ideal Spanish counterpart to OntoNotes.

[11]Most Romance languages are pro-drop allowing zero subject pronouns, which can be inferred from the verb.

Datasets Two datasets of similar size were selected from AnCora and OntoNotes in order to rule out corpus size as an explanation of any difference in performance. Corpus statistics about the distribution of mentions and entities are shown in Tables 1 and 2. Given that this paper is focused on coreference between NPs, the number of mentions only includes NPs. Both AnCora and OntoNotes annotate only multi-mention entities (i.e., those containing two or more coreferent mentions), so singleton entities are assumed to correspond to NPs with no coreference annotation.

Apart from a larger number of mentions in Spanish (Table 1), the two datasets look very similar in the distribution of singletons and multi-mention entities: about 85% and 15%, respectively. Multi-mention entities have an average of 3.9 mentions per entity in AnCora and 3.5 in OntoNotes. The distribution of mention types (Table 2), however, differs in two important respects: AnCora has a smaller number of personal pronouns as Spanish typically uses zero subjects, and it has a smaller number of bare NPs as the definite article accompanies more NPs than in English.

Results and Discussion Table 3 presents CISTELL's results for each dataset. They make evident problems with the evaluation metrics, namely the fact that the generated rankings are contradictory (Denis and Baldridge, 2009). They are consistent across the two corpora though: MUC rewards WEAK MATCH the most, B^3 rewards HEAD MATCH the most, and CEAF is divided between SUPER STRONG MATCH and BEST MATCH.

These preferences seem to reveal weaknesses of the scoring methods that make them biased towards a type of output. The model preferred by MUC is one that clusters many mentions together, thus getting a large number of correct coreference links (notice the high R for WEAK MATCH), but

	AnCora	OntoNotes

Table 3: CISTELL results varying the corpus language.

also many spurious links that are not duly penalized. The resulting output is not very desirable.[12] In contrast, B^3 is more P-oriented and scores conservative outputs like HEAD MATCH and BEST MATCH first, even if R is low. CEAF achieves a better compromise between P and R, as corroborated by the quality of the output.

The baselines and the system runs perform very similarly in the two corpora, but slightly better for English. It seems that language-specific issues do not result in significant differences—at least for English and Spanish—once the feature set has been appropriately adapted, e.g., including features about zero subjects or removing those about possessive phrases. Comparing the feature ranks, we find that the features that work best for each language largely overlap and are language independent, like head match, is-a match, and whether the mentions are pronominal.

5 Parameter 2: Annotation Scheme

In the second experiment, we used the 100k-word portion (from the TDT collection) shared by the OntoNotes and ACE corpora (330 OntoNotes documents occurred as 22 ACE-2003 documents, 185 ACE-2004 documents, and 123 ACE-2005 documents). CISTELL was trained on the same texts in both corpora and applied to the remainder. The three measures were then applied to each result.

Datasets Since the two annotation schemes differ significantly, we made the results comparable by mapping the ACE entities (the simpler scheme) onto the information contained in OntoNotes.[13] The mapping allowed us to focus exclusively on the differences expressed on both corpora: the types of mentions that were annotated, the definition of identity of reference, etc.

Table 4 presents the statistics for the OntoNotes dataset merged with the ACE entities. The mapping was not straightforward due to several problems: there was no match for some mentions due to syntactic or spelling reasons (e.g., *El Popo* in OntoNotes vs. *Ell Popo* in ACE). ACE mentions for which there was no parse tree node in the OntoNotes gold-standard tree were omitted, as creating a new node could have damaged the tree.

Given that only seven entity types are annotated in ACE, the number of OntoNotes mentions is al-

[12] Due to space constraints, the actual output cannot be shown here. We are happy to send it to interested requesters.

[13] Both ACE entities and types were mapped onto the OntoNotes dataset.

Table 5: CISTELL results varying the annotation scheme on gold-standard data.

most twice as large as the number of ACE mentions. Unlike OntoNotes, ACE mentions include premodifiers (e.g., *state* in *state lines*), national adjectives (e.g., *Iraqi*) and relative pronouns (e.g., *who, that*). Also, given that ACE entities correspond to types that are usually coreferred (e.g., people, organizations, etc.), singletons only represent 61% of all entities, while they are 85% in OntoNotes. The average entity size is 4 in ACE and 3.5 in OntoNotes.

A second major difference is the definition of coreference relations, illustrated here:

(2) [This] was [an all-white, all-Christian community that all the sudden was taken over ... by different groups].

(3) [[Mayor] John Hyman] has a simple answer.

(4) [Postville] now has 22 different nationalities ... For those who prefer [the old Postville], Mayor John Hyman has a simple answer.

In ACE, nominal predicates corefer with their subject (2), and appositive phrases corefer with the noun they are modifying (3). In contrast, they do not fall under the identity relation in OntoNotes, which follows the linguistic understanding of coreference according to which nominal predicates and appositives express properties of an entity rather than refer to a second (coreferent) entity (van Deemter and Kibble, 2000). Finally, the two schemes frequently disagree on borderline cases in which coreference turns out to be especially complex (4). As a result, some features will behave differently, e.g., the appositive feature has the opposite effect in the two datasets.

Results and Discussion From the differences pointed out above, the results shown in Table 5 might be surprising at first. Given that OntoNotes is not restricted to any semantic type and is based on a more sophisticated definition of coreference, one would not expect a system to perform better on it than on ACE. The explanation is given by the ALL SINGLETONS baseline, which is 73–84% for OntoNotes and only 51–68% for ACE. The fact that OntoNotes contains a much larger number of singletons—as Table 4 shows—results in an initial boost of performance (except with the MUC score, which ignores singletons). In contrast, the score improvement achieved by HEAD MATCH is much more noticeable on ACE than on OntoNotes, which indicates that many of its coreferent mentions share the same head.

The systematic biases of the measures that were observed in Table 3 appear again in the case of

MUC and B^3. CEAF is divided between BEST MATCH and STRONG MATCH. The higher value of the MUC score for ACE is another indication of its tendency to reward correct links much more than to penalize spurious ones (ACE has a larger proportion of multi-mention entities).

The feature rankings obtained for each dataset generally coincide as to which features are ranked best (namely NE match, is-a match, and head match), but differ in their particular ordering.

It is also possible to compare the OntoNotes results in Tables 3 and 5, the only difference being that the first training set was three times larger. Contrary to expectation, the model trained on a larger dataset performs just slightly better. The fact that more training data does not necessarily lead to an increase in performance conforms to the observation that there appear to be few general rules (e.g., head match) that systematically govern coreference relationships; rather, coreference appeals to individual unique phenomena appearing in each context, and thus after a point adding more training data does not add much new generalizable information. Pragmatic information (discourse structure, world knowledge, etc.) is probably the key, if ever there is a way to encode it.

6 Parameter 3: Preprocessing

The goal of the third experiment was to determine how much the source and nature of preprocessing information matters. Since it is often stated that coreference resolution depends on many levels of analysis, we again compared the two corpora, which differ in the amount and correctness of such information. However, in this experiment, entity mapping was applied in the opposite direction: the OntoNotes entities were mapped onto the automatically preprocessed ACE dataset. This exposes the shortcomings of automated preprocessing in ACE for identifying all the mentions identified and linked in OntoNotes.

Datasets The ACE data was morphologically annotated with a tokenizer based on manual rules adapted from the one used in CoNLL (Tjong Kim Sang and De Meulder, 2003), with TnT 2.2, a trigram POS tagger based on Markov models (Brants, 2000), and with the built-in WordNet lemmatizer (Fellbaum, 1998). Syntactic chunks were obtained from YamCha 1.33, an SVM-based NP-chunker (Kudoh and Matsumoto, 2000), and parse trees from Malt Parser 0.4, an SVM-based parser (Hall et al., 2007).

Although the number of words in Tables 4 and 6 should in principle be the same, the latter contains fewer words as it lacks the null elements (traces, ellipsed material, etc.) manually annotated in OntoNotes. Missing parse tree nodes in the automatically parsed data account for the considerably lower number of OntoNotes mentions (approx. 5,700 fewer mentions).[14] However, the proportions of singleton:multi-mention entities as well as the average entity size do not vary.

Results and Discussion The ACE scores for the automatically preprocessed models in Table 7 are about 3% lower than those based on OntoNotes gold-standard data in Table 5, providing evidence for the advantage offered by gold-standard preprocessing information. In contrast, the similar—if not higher—scores of OntoNotes can be attributed to the use of the annotated ACE entity types. The fact that these are annotated not only for proper nouns (as predicted by an automatic NER) but also for pronouns and full NPs is a very helpful feature for a coreference resolution system.

Again, the scoring metrics exhibit similar biases, but note that CEAF prefers HEAD MATCH + PRON in the case of ACE, which is indicative of the noise brought by automatic preprocessing.

A further insight is offered from comparing the feature rankings with gold-standard syntax to that with automatic preprocessing. Since we are evaluating now on the ACE data, the NE match feature is also ranked first for OntoNotes. Head and is-a match are still ranked among the best, yet syntactic features are not. Instead, features like NP type have moved further up. This reranking probably indicates that if there is noise in the syntactic information due to automatic tools, then morphological and syntactic features switch their positions.

Given that the noise brought by automatic preprocessing can be harmful, we tried leaving out the grammatical function feature. Indeed, the results increased about 2–3%, STRONG MATCH scoring the highest. This points out that conclusions drawn from automatically preprocessed data about the kind of knowledge relevant for coreference resolution might be mistaken. Using the most successful basic features can lead to the best results when only automatic preprocessing is available.

[14] In order to make the set of mentions as similar as possible to the set in Section 5, OntoNotes singletons were mapped from the ones detected in the gold-standard treebank.

Table 7: CISTELL results varying the annotation scheme on automatically preprocessed data.

7 Conclusion

Regarding evaluation, the results clearly expose the systematic tendencies of the evaluation measures. The way each measure is computed makes it biased towards a specific model: MUC is generally too lenient with spurious links, B^3 scores too high in the presence of a large number of singletons, and CEAF does not agree with either of them. It is a cause for concern that they provide contradictory indications about the core of coreference, namely the resolution models—for example, the model ranked highest by B^3 in Table 7 is ranked *lowest* by MUC. We always assume evaluation measures provide a 'true' reflection of our approximation to a gold standard in order to guide research in system development and tuning.

Further support to our claims comes from the results of SemEval-2010 Task 1 (Recasens et al., 2010). The performance of the six participating systems shows similar problems with the evaluation metrics, and the singleton baseline was hard to beat even by the highest-performing systems.

Since the measures imply different conclusions about the nature of the corpora and the preprocessing information applied, should we use them now to constrain the ways our corpora are created in the first place, and what preprocessing we include or omit? Doing so would seem like circular reasoning: it invalidates the notion of the existence of a true and independent gold standard. But if apparently incidental aspects of the corpora can have such effects—effects rated quite differently by the various measures—then we have no fixed ground to stand on.

The worrisome fact that there is currently no clearly preferred and 'correct' evaluation measure for coreference resolution means that we cannot draw definite conclusions about coreference resolution systems at this time, unless they are compared on exactly the same corpus, preprocessed under the same conditions, and all three measures agree in their rankings.

Acknowledgments

We thank Dr. M. Antònia Martí for her generosity in allowing the first author to visit ISI to work with the second. Special thanks to Edgar Gonzàlez for his kind help with conversion issues.

Abstract

Tree-to-string systems (and their forest-based extensions) have gained steady popularity thanks to their simplicity and efficiency, but there is a major limitation: they are unable to guarantee the grammaticality of the output, which is explicitly modeled in string-to-tree systems via target-side syntax. We thus propose to combine the advantages of both, and present a novel constituency-to-dependency translation model, which uses constituency forests on the source side to direct the translation, and dependency trees on the target side (as a language model) to ensure grammaticality. Medium-scale experiments show an absolute and statistically significant improvement of +0.7 BLEU points over a state-of-the-art forest-based tree-to-string system even with fewer rules. This is also the first time that a tree-to-tree model can surpass tree-to-string counterparts.

1 Introduction

Linguistically syntax-based statistical machine translation models have made promising progress in recent years. By incorporating the syntactic annotations of parse trees from *both* or *either* side(s) of the bitext, they are believed better than phrase-based counterparts in reorderings. Depending on the type of input, these models can be broadly divided into two categories (see Table 1): the *string-based* systems whose input is a string to be simultaneously parsed and translated by a synchronous grammar, and the *tree-based* systems whose input is already a parse tree to be directly converted into a target tree or string. When we also take into account the type of output (tree or string), the *tree-based* systems can be divided into *tree-to-string* and *tree-to-tree* efforts.

tree on	*examples (partial)*	*fast*	*gram.*	BLEU
source	Liu06, Huang06	+	-	+
target	Galley06, Shen08	-	+	+
both	Ding05, Liu09	+	+	-
both	**our work**	+	+	+

Table 1: A classification and comparison of linguistically syntax-based SMT systems, where *gram.* denotes grammaticality of the output.

On one hand, tree-to-string systems (Liu et al., 2006; Huang et al., 2006) have gained significant popularity, especially after incorporating packed forests (Mi et al., 2008; Mi and Huang, 2008; Liu et al., 2009; Zhang et al., 2009). Compared with their string-based counterparts, tree-based systems are much faster in decoding (linear time vs. cubic time, see (Huang et al., 2006)), do not require a binary-branching grammar as in string-based models (Zhang et al., 2006; Huang et al., 2009), and can have separate grammars for parsing and translation (Huang et al., 2006). However, they have a major limitation that they do not have a principled mechanism to guarantee grammaticality on the target side, since there is no linguistic tree structure of the output.

On the other hand, string-to-tree systems explicitly model the grammaticality of the output by using target syntactic trees. Both string-to-constituency system (e.g., (Galley et al., 2006; Marcu et al., 2006)) and string-to-dependency model (Shen et al., 2008) have achieved significant improvements over the state-of-the-art formally syntax-based system Hiero (Chiang, 2007). However, those systems also have some limitations that they run slowly (in cubic time) (Huang et al., 2006), and do not utilize the useful syntactic information on the source side.

We thus combine the advantages of both tree-to-string and string-to-tree approaches, and propose

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1433–1442,
Uppsala, Sweden, 11-16 July 2010.

a novel constituency-to-dependency model, which uses constituency forests on the source side to direct translation, and dependency trees on the target side to guarantee grammaticality of the output. In contrast to conventional tree-to-tree approaches (Ding and Palmer, 2005; Quirk et al., 2005; Xiong et al., 2007; Zhang et al., 2007; Liu et al., 2009), which only make use of a single type of trees, our model is able to combine two types of trees, outperforming both phrase-based and tree-to-string systems. Current tree-to-tree models (Xiong et al., 2007; Zhang et al., 2007; Liu et al., 2009) still have not outperformed the phrase-based system Moses (Koehn et al., 2007) significantly even with the help of forests.[1]

Our new constituency-to-dependency model (Section 2) extracts rules from word-aligned pairs of source constituency forests and target dependency trees (Section 3), and translates source constituency forests into target dependency trees with a set of features (Section 4). Medium data experiments (Section 5) show a statistically significant improvement of +0.7 BLEU points over a state-of-the-art forest-based tree-to-string system even with less translation rules, this is also the first time that a tree-to-tree model can surpass tree-to-string counterparts.

2 Model

Figure 1 shows a word-aligned source constituency forest F_c and target dependency tree D_e, our constituency to dependency translation model can be formalized as:

$$\begin{aligned} \mathrm{P}(F_c, D_e) &= \sum_{C_c \in F_c} \mathrm{P}(C_c, D_e) \\ &= \sum_{C_c \in F_c} \sum_{o \in O} \mathrm{P}(O) \\ &= \sum_{C_c \in F_c} \sum_{o \in O} \prod_{r \in o} \mathrm{P}(r), \end{aligned} \quad (1)$$

where C_c is a constituency tree in F_c, o is a derivation that translates C_c to D_e, O is the set of derivation, r is a constituency to dependency translation rule.

[1] According to the reports of Liu et al. (2009), their forest-based constituency-to-constituency system achieves a comparable performance against Moses (Koehn et al., 2007), but a significant improvement of +3.6 BLEU points over the 1-best tree-based constituency-to-constituency system.

2.1 Constituency Forests on the Source Side

A constituency forest (in Figure 1 left) is a compact representation of all the derivations (i.e., parse trees) for a given sentence under a context-free grammar (Billot and Lang, 1989).

More formally, following Huang (2008), such a constituency forest is a pair $F_c = G^f = \langle V^f, H^f \rangle$, where V^f is the set of **nodes**, and H^f the set of **hyperedges**. For a given source sentence $c_{1:m} = c_1 \dots c_m$, each node $v^f \in V^f$ is in the form of $X_{i,j}$, which denotes the recognition of nonterminal X spanning the substring from positions i through j (that is, $c_{i+1} \dots c_j$). Each hyperedge $h^f \in H^f$ is a pair $\langle tails(h^f), head(h^f) \rangle$, where $head(h^f) \in V^f$ is the **consequent node** in the deductive step, and $tails(h^f) \in (V^f)^*$ is the list of **antecedent nodes**. For example, the hyperedge h_0^f in Figure 1 for deduction (*)

$$\frac{\mathrm{NPB}_{0,1} \quad \mathrm{CC}_{1,2} \quad \mathrm{NPB}_{2,3}}{\mathrm{NP}_{0,3}}, \quad (*)$$

is notated:

$$\langle (\mathrm{NPB}_{0,1},\ \mathrm{CC}_{1,2},\ \mathrm{NPB}_{2,3}),\ \ \mathrm{NP}_{0,3} \rangle.$$

where

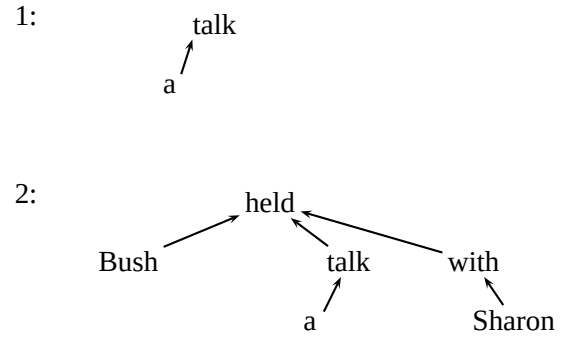
$$head(h_0^f) = \{\mathrm{NP}_{0,3}\},$$
and
$$tails(h_0^f) = \{\mathrm{NPB}_{0,1}, \mathrm{CC}_{1,2}, \mathrm{NPB}_{2,3}\}.$$

The solid line in Figure 1 shows the best parse tree, while the dashed one shows the second best tree. Note that common sub-derivations like those for the verb $\mathrm{VPB}_{3,5}$ are shared, which allows the forest to represent exponentially many parses in a compact structure.

We also denote $IN(v^f)$ to be the set of **incoming hyperedges** of node v^f, which represents the different ways of deriving v^f. Take node $\mathrm{IP}_{0,5}$ in Figure 1 for example, $IN(\mathrm{IP}_{0,5}) = \{h_1^f, h_2^f\}$. There is also a distinguished **root node** TOP in each forest, denoting the goal item in parsing, which is simply $\mathrm{S}_{0,m}$ where S is the start symbol and m is the sentence length.

2.2 Dependency Trees on the Target Side

A dependency tree for a sentence represents each word and its syntactic dependents through directed arcs, as shown in the following examples. The main advantage of a dependency tree is that it can explore the long distance dependency.



We use the lexicon dependency grammar (Hellwig, 2006) to express a projective dependency tree. Take the dependency trees above for example, they will be expressed:

1: (a) talk

2: (Bush) held ((a) talk) (with (Sharon))

where the lexicons in brackets represent the dependencies, while the lexicon out the brackets is the head.

More formally, a dependency tree is also a pair $D_e = G^d = \langle V^d, H^d \rangle$. For a given target sentence $e_{1:n} = e_1 \dots e_n$, each node $v^d \in V^d$ is a word e_i ($1 \leqslant i \leqslant n$), each hyperedge $h^d \in H^d$ is a directed arc $\langle v_i^d, v_j^d \rangle$ from node v_i^d to its head node v_j^d. Following the formalization of the constituency forest scenario, we denote a pair $\langle tails(h^d), head(h^d) \rangle$ to be a hyperedge h^d, where $head(h^d)$ is the head node, $tails(h^d)$ is the node where h^d leaves from.

We also denote $L_l(v^d)$ and $L_r(v^d)$ to be the left and right children sequence of node v^d from the nearest to the farthest respectively. Take the node $v_2^d =$ "held" for example:

$$L_l(v_2^d) = \{\text{Bush}\},$$
$$L_r(v_2^d) = \{\text{talk, with}\}.$$

2.3 Hypergraph

Actually, both the constituency forest and the dependency tree can be formalized as a **hypergraph** G, a pair $\langle V, H \rangle$. We use G^f and G^d to distinguish them. For simplicity, we also use F_c and D_e to denote a constituency forest and a dependency tree respectively. Specifically, the size of $tails(h^d)$ of a hyperedge h^d in a dependency tree is a constant one.

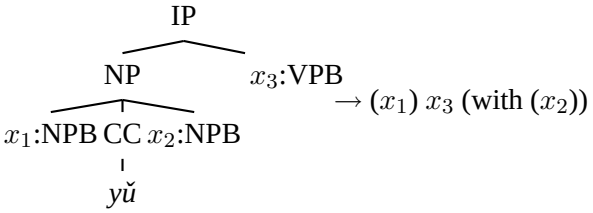


Figure 2: Example of the rule r_1. The Chinese conjunction *yǔ* "and" is translated into English preposition "with".

3 Rule Extraction

We extract constituency to dependency rules from word-aligned source constituency forest and target dependency tree pairs (Figure 1). We mainly extend the tree-to-string rule extraction algorithm of Mi and Huang (2008) to our scenario. In this section, we first formalize the constituency to string translation rule (Section 3.1). Then we present the restrictions for dependency structures as well formed fragments (Section 3.2). Finally, we describe our rule extraction algorithm (Section 3.3), fractional counts computation and probabilities estimation (Section 3.4).

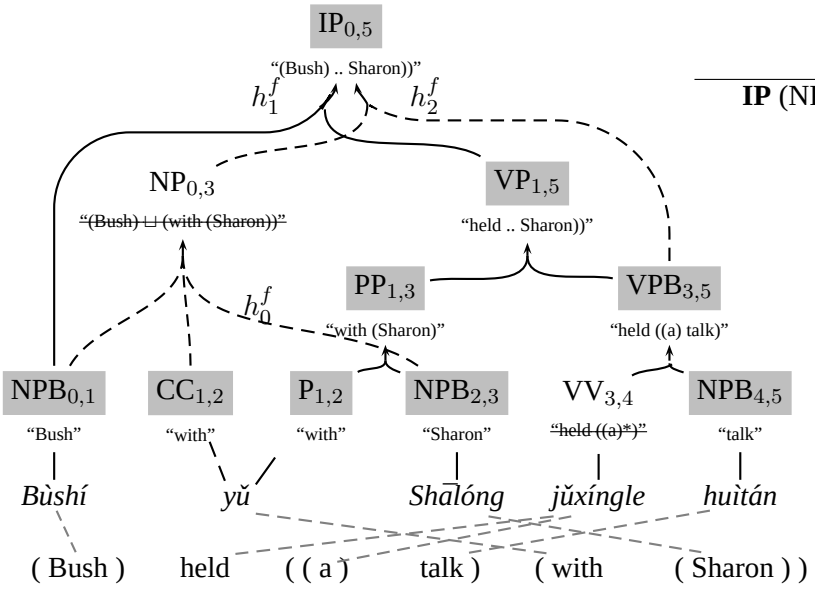
3.1 Constituency to Dependency Rule

More formally, a **constituency to dependency translation rule** r is a tuple $\langle lhs(r), rhs(r), \phi(r) \rangle$, where $lhs(r)$ is the source side tree fragment, whose internal nodes are labeled by nonterminal symbols (like NP and VP), and whose frontier nodes are labeled by source language words c_i (like "*yǔ*") or variables from a set $\mathcal{X} = \{x_1, x_2, \dots\}$; $rhs(r)$ is expressed in the target language dependency structure with words e_j (like "with") and variables from the set $\mathcal{X}$; and $\phi(r)$ is a mapping from $\mathcal{X}$ to nonterminals. Each variable $x_i \in \mathcal{X}$ occurs *exactly once* in $lhs(r)$ and *exactly once* in $rhs(r)$. For example, the rule r_1 in Figure 2,

$lhs(r_1) =$ IP(NP(x_1 CC(*yǔ*) x_2) x_3),
$rhs(r_1) = (x_1)\ x_3\ (\text{with}\ (x_2))$,
$\phi(r_1) = \{x_1 \mapsto \text{NPB}, x_2 \mapsto \text{NPB}, x_3 \mapsto \text{VPB}\}$.

3.2 Well Formed Dependency Fragment

Following Shen et al. (2008), we also restrict $rhs(r)$ to be **well formed** dependency fragment. The main difference between us is that we use more flexible restrictions. Given a dependency



Minimal rules extracted

IP (NP(x_1:NPB x_2:CC x_3:NPB) x_4:VPB) → (x_1) x_4 (x_2 (x_3))

IP (x_1:NPB x_2:VP) → (x_1) x_2

VP (x_1:PP x_2:VPB) → x_2 (x_1)

PP (x_1:P x_2:NPB) → x_1 (x_2)

VPB (VV(*jǔxíngle*)) x_1:NPB) → held ((a) x_1)

NPB (*Bùshí*) → Bush

NPB (*huìtán*) → talk

CC (*yǔ*) → with

P (*yǔ*) → with

NPB (*Shālóng*) → Sharon

Figure 1: Forest-based constituency to dependency rule extraction.

fragment $d_{i:j}$ composed by the words from i to j, two kinds of well formed structures are defined as follows:

Fixed on one node v^d_{one}, **fixed** for short, if it meets the following conditions:

- the head of v^d_{one} is out of $[i, j]$, i.e.: $\forall h^d$, if $tails(h^d) = v^d_{one} \Rightarrow head(h^d) \notin e_{i:j}$.
- the heads of other nodes except v^d_{one} are in $[i, j]$, i.e.: $\forall k \in [i, j]$ and $v^d_k \neq v^d_{one}, \forall h^d$ if $tails(h^d) = v^d_k \Rightarrow head(h^d) \in e_{i:j}$.

Floating with multi nodes M, **floating** for short, if it meets the following conditions:

- all nodes in M have a same head node, i.e.: $\exists x \notin [i, j], \forall h^d$ if $tails(h^d) \in M \Rightarrow head(h^d) = v^h_x$.
- the heads of other nodes not in M are in $[i, j]$, i.e.: $\forall k \in [i, j]$ and $v^d_k \notin M, \forall h^d$ if $tails(h^d) = v^d_k \Rightarrow head(h^d) \in e_{i:j}$.

Take the " (Bush) held ((a) talk))(with (Sharon)) " for example: partial fixed examples are " (Bush) held " and " held ((a) talk)"; while the partial floating examples are " (talk) (with (Sharon)) " and " ((a) talk) (with (Sharon)) ". Please note that the floating structure " (talk) (with (Sharon)) " can not be allowed in Shen et al. (2008)'s model.

The dependency structure " held ((a))" is not a well formed structure, since the head of word "a" is out of scope of this structure.

3.3 Rule Extraction Algorithm

The algorithm shown in this Section is mainly extended from the forest-based tree-to-string extraction algorithm (Mi and Huang, 2008). We extract rules from word-aligned source constituency forest and target dependency tree pairs (see Figure 1) in three steps:

(1) frontier set computation,

(2) fragmentation,

(3) composition.

The **frontier set** (Galley et al., 2004) is the potential points to "cut" the forest and dependency tree pair into fragments, each of which will form a **minimal rule** (Galley et al., 2006).

However, not every fragment can be used for rule extraction, since it may or may not respect to the restrictions, such as word alignments and well formed dependency structures. So we say a fragment is **extractable** if it respects to all restrictions. The root node of every extractable tree fragment corresponds to a **faithful structure** on the target side, in which case there is a "translational equivalence" between the subtree rooted at the node and the corresponding target structure. For example, in Figure 1, every node in the forest is annotated with its corresponding English structure. The $NP_{0,3}$ node maps to a non-contiguous structure "(Bush) ⊔ (with (Sharon))", the $VV_{3,4}$ node maps to a contiguous but non-faithful structure "held ((a) *)".

Algorithm 1 Forest-based constituency to dependency rule extraction.

Input: Source constituency forest F_c, target dependency tree D_e, and alignment a
Output: Minimal rule set $\mathcal{R}$

1: $fs \leftarrow$ FRONTIER(F_c, D_e, a) ▷ compute frontier set
2: **for** each $v^f \in fs$ **do**
3: $open \leftarrow \{\langle \varnothing, \{v^f\}\rangle\}$ ▷ initial queue of growing fragments
4: **while** $open \neq \varnothing$ **do**
5: $\langle hs, exps\rangle \leftarrow open.pop()$ ▷ extract a fragment
6: **if** $exps = \varnothing$ **then** ▷ nothing to expand?
7: generate a rule r using fragment hs ▷ generate a rule
8: $\mathcal{R}$.append(r)
9: **else** ▷ incomplete: further expand
10: $v' \leftarrow exps$.pop() ▷ a non-frontier node
11: **for** each $h^f \in IN(v')$ **do**
12: $newexps \leftarrow exps \cup (tails(h^f) \setminus fs)$ ▷ expand
13: $open$.append($\langle hs \cup \{h^f\}, newexps\rangle$)

Following Mi and Huang (2008), given a source target sentence pair $\langle c_{1:m}, e_{1:n}\rangle$ with an alignment a, the **span** of node v^f on source forest is the set of target words aligned to leaf nodes under v^f:

$$span(v^f) \triangleq \{e_i \in e_{1:n} \mid \exists c_j \in yield(v^f), (c_j, e_i) \in a\}.$$

where the $yield(v^f)$ is all the leaf nodes under v^f. For each $span(v^f)$, we also denote $dep(v^f)$ to be its corresponding dependency structure, which represents the dependency structure of all the words in $span(v^f)$. Take the $span(\text{PP}_{1,3})$ ={with, Sharon} for example, the corresponding $dep(\text{PP}_{1,3})$ is "with (Sharon)". A $dep(v^f)$ is **faithful structure** to node v^f if it meets the following restrictions:

- all words in $span(v^f)$ form a continuous substring $e_{i:j}$,
- every word in $span(v^f)$ is *only* aligned to leaf nodes of v^f, i.e.: $\forall e_i \in span(v^f), (c_j, e_i) \in a \Rightarrow c_j \in yield(v^f)$,
- $dep(v^f)$ is a well formed dependency structure.

For example, node $\text{VV}_{3,4}$ has a non-faithful structure (crossed out in Figure 1), since its $dep(\text{VV}_{3,4} =$ " held ((a) *)" is not a well formed structure, where the head of word "a" lies in the outside of its words covered. Nodes with faithful structure form the **frontier set** (shaded nodes in Figure 1) which serve as potential cut points for rule extraction.

Given the frontier set, fragmentation step is to "cut" the forest at all frontier nodes and form tree fragments, each of which forms a rule with variables matching the frontier descendant nodes. For example, the forest in Figure 1 is cut into 10 pieces, each of which corresponds to a minimal rule listed on the right.

Our rule extraction algorithm is formalized in Algorithm 1. After we compute the frontier set *fs* (line 1). We visit each frontier node $v^f \in fs$ on the source constituency forest F_c, and keep a queue $open$ of growing fragments rooted at v^f. We keep expanding incomplete fragments from $open$, and extract a rule if a complete fragment is found (line 7). Each fragment *hs* in $open$ is associated with a list of *expansion sites* ($exps$ in line 5) being the subset of leaf nodes of the current fragment that are *not* in the frontier set. So each fragment along hyperedge h is associated with

$$exps = tails(h^f) \setminus fs.$$

A fragment is complete if its expansion sites is empty (line 6), otherwise we pop one expansion node v' to grow and spin-off new fragments by following hyperedges of v', adding new expansion sites (lines 11-13), until all active fragments are complete and $open$ queue is empty (line 4).

After we get all the minimal rules, we glue them together to form **composed rule**s following Galley et al. (2006). For example, the composed rule r_1 in Figure 2 is glued by the following two minimal rules:

IP (NP(x_1:NPB x_2:CC x_3:NPB) x_4:VPB) $\rightarrow$ (x_1) x_4 (x_2 (x_3)) r_2

CC (*yǔ*) $\rightarrow$ with r_3

where x_2:CC in r_2 is replaced with r_3 accordingly.

3.4 Fractional Counts and Rule Probabilities

Following Mi and Huang (2008), we penalize a rule r by the posterior probability of the corresponding constituent tree fragment $lhs(r)$, which can be computed in an Inside-Outside fashion, being the product of the outside probability of its root node, the inside probabilities of its leaf nodes, and the probabilities of hyperedges involved in the fragment.

$$\begin{aligned}\alpha\beta(lhs(r)) =& \alpha(root(r)) \\ & \cdot \prod_{h^f \in lhs(r)} \mathrm{P}(h^f) \\ & \cdot \prod_{v^f \in leaves(lhs(r))} \beta(v^f)\end{aligned} \quad (2)$$

where $root$(r) is the root of the rule r, $\alpha(v)$ and $\beta(v)$ are the outside and inside probabilities of node v, and $leaves(lhs(r))$ returns the leaf nodes of a tree fragment lhs(r).

We use fractional counts to compute three conditional probabilities for each rule, which will be used in the next section:

$$\mathrm{P}(r \mid lhs(r)) = \frac{c(r)}{\sum_{r':lhs(r')=lhs(r)} c(r')}, \quad (3)$$

$$\mathrm{P}(r \mid rhs(r)) = \frac{c(r)}{\sum_{r':rhs(r')=rhs(r)} c(r')}, \quad (4)$$

$$\mathrm{P}(r \mid root(r)) = \frac{c(r)}{\sum_{r':root(r')=root(r)} c(r')}. \quad (5)$$

4 Decoding

Given a source forest F_c, the decoder searches for the best derivation o^* among the set of all possible derivations O, each of which forms a source side constituent tree $T_c(o)$, a target side string $e(o)$, and a target side dependency tree $D_e(o)$:

$$\begin{aligned}o^* = \arg\max_{T_c \in F_c, o \in O} & \lambda_1 \log \mathrm{P}(o \mid T_c) \\ & + \lambda_2 \log \mathrm{P}_{\mathrm{lm}}(e(o)) \\ & + \lambda_3 \log \mathrm{P}_{\mathrm{DLM_w}}(D_e(o)) \\ & + \lambda_4 \log \mathrm{P}_{\mathrm{DLM_p}}(D_e(o)) \\ & + \lambda_5 \log \mathrm{P}(T_c(o)) \\ & + \lambda_6 ill(o) + \lambda_7 |o| + \lambda_8 |e(o)|,\end{aligned} \quad (6)$$

where the first two terms are translation and language model probabilities, $e(o)$ is the target string (English sentence) for derivation o, the third and forth items are the dependency language model probabilities on the target side computed with words and POS tags separately, $D_e(o)$ is the target dependency tree of o, the fifth one is the parsing probability of the source side tree $T_c(o) \in F_c$, the $ill(o)$ is the penalty for the number of ill-formed dependency structures in o, and the last two terms are derivation and translation length penalties, respectively. The conditional probability $\mathrm{P}(o \mid T_c)$ is decomposes into the product of rule probabilities:

$$\mathrm{P}(o \mid T_c) = \prod_{r \in o} \mathrm{P}(r), \quad (7)$$

where each $\mathrm{P}(r)$ is the product of five probabilities:

$$\begin{aligned}\mathrm{P}(r) =& \mathrm{P}(r \mid lhs(r))^{\lambda_9} \cdot \mathrm{P}(r \mid rhs(r))^{\lambda_{10}} \\ & \cdot \mathrm{P}(r \mid root(lhs(r)))^{\lambda_{11}} \\ & \cdot \mathrm{P}_{\mathrm{lex}}(lhs(r) \mid rhs(r))^{\lambda_{12}} \\ & \cdot \mathrm{P}_{\mathrm{lex}}(rhs(r) \mid lhs(r))^{\lambda_{13}},\end{aligned} \quad (8)$$

where the first three are conditional probabilities based on fractional counts of rules defined in Section 3.4, and the last two are lexical probabilities. When computing the lexical translation probabilities described in (Koehn et al., 2003), we only take into accout the terminals in a rule. If there is no terminal, we set the lexical probability to 1.

The decoding algorithm works in a bottom-up search fashion by traversing each node in forest F_c. We first use pattern-matching algorithm of Mi et al. (2008) to convert F_c into a **translation forest**, each hyperedge of which is associated with a constituency to dependency translation rule. However, pattern-matching failure[2] at a node v^f will

[2]Pattern-matching failure at a node v^f means there is no translation rule can be matched at v^f or no translation hyperedge can be constructed at v^f.

cut the derivation path and lead to translation failure. To tackle this problem, we construct a **pseudo translation rule** for each parse hyperedge $h^f \in IN(v^f)$ by mapping the CFG rule into a target dependency tree using the head rules of Magerman (1995). Take the hyperedge h_0^f in Figure1 for example, the corresponding pseudo translation rule is:

NP(x_1:NPB x_2:CC x_3:NPB) $\rightarrow$ (x_1) (x_2) x_3,

since the x_3:NPB is the head word of the CFG rule: NP $\rightarrow$ NPB CC NPB.

After the translation forest is constructed, we traverse each node in translation forest also in bottom-up fashion. For each node, we use the **cube pruning** technique (Chiang, 2007; Huang and Chiang, 2007) to produce partial hypotheses and compute all the feature scores including the dependency language model score (Section 4.1). If all the nodes are visited, we trace back along the 1-best derivation at goal item $S_{0,m}$ and build a target side dependency tree. For k-best search after getting 1-best derivation, we use the lazy Algorithm 3 of Huang and Chiang (2005) that works backwards from the root node, incrementally computing the second, third, through the kth best alternatives.

4.1 Dependency Language Model Computing

We compute the score of a dependency language model for a dependency tree D_e in the same way proposed by Shen et al. (2008). For each nonterminal node $v_h^d = e_h$ in D_e and its children sequences $L_l = e_{l_1}, e_{l_2}...e_{l_i}$ and $L_r = e_{r_1}, e_{r_2}...e_{r_j}$, the probability of a trigram is computed as follows:

$$\mathrm{P}(L_l, L_r \mid e_h\S) = \mathrm{P}(L_l \mid e_h\S) \cdot \mathrm{P}(L_r \mid e_h\S), \quad (9)$$

where the $\mathrm{P}(L_l \mid e_h\S)$ is decomposed to be:

$$\begin{aligned} \mathrm{P}(L_l \mid e_h\S) = & \mathrm{P}(e_{l_l} \mid e_h\S) \\ & \cdot \mathrm{P}(e_{l_2} \mid e_{l_1}, e_h\S) \\ & ... \\ & \cdot \mathrm{P}(e_{l_n} \mid e_{l_{n-1}}, e_{l_{n-2}}). \end{aligned} \quad (10)$$

We use the suffix "§" to distinguish the head word and child words in the dependency language model.

In order to alleviate the problem of data sparse, we also compute a dependency language model for POS tages over a dependency tree. We store the POS tag information on the target side for each constituency-to-dependency rule. So we will also generate a POS taged dependency tree simultaneously at the decoding time. We calculate this dependency language model by simply replacing each e_i in equation 9 with its tag $t(e_i)$.

5 Experiments

5.1 Data Preparation

Our training corpus consists of 239K sentence pairs with about 6.9M/8.9M words in Chinese/English, respectively. We first word-align them by GIZA++ (Och and Ney, 2000) with refinement option "grow-diag-and" (Koehn et al., 2003), and then parse the Chinese sentences using the parser of Xiong et al. (2005) into parse forests, which are pruned into relatively small forests with a pruning threshold 3. We also parse the English sentences using the parser of Charniak (2000) into 1-best constituency trees, which will be converted into dependency trees using Magerman (1995)'s head rules. We also store the POS tag information for each word in dependency trees, and compute two different dependency language models for words and POS tags in dependency tree separately. Finally, we apply translation rule extraction algorithm described in Section 3. We use SRI Language Modeling Toolkit (Stolcke, 2002) to train a 4-gram language model with Kneser-Ney smoothing on the first 1/3 of the Xinhua portion of Gigaword corpus. At the decoding step, we again parse the input sentences into forests and prune them with a threshold 10, which will direct the translation (Section 4).

We use the 2002 NIST MT Evaluation test set as our development set and the 2005 NIST MT Evaluation test set as our test set. We evaluate the translation quality using the BLEU-4 metric (Papineni et al., 2002), which is calculated by the script mteval-v11b.pl with its default setting which is case-insensitive matching of n-grams. We use the standard minimum error-rate training (Och, 2003) to tune the feature weights to maximize the system's BLEU score on development set.

5.2 Results

Table 2 shows the results on the test set. Our baseline system is a state-of-the-art forest-based constituency-to-string model (Mi et al., 2008), or *forest c2s* for short, which translates a source forest into a target string by pattern-matching the

constituency-to-string (*c2s*) rules and the bilingual phrases (*s2s*). The baseline system extracts 31.9M *c2s* rules, 77.9M *s2s* rules respectively and achieves a BLEU score of 34.17 on the test set[3].

At first, we investigate the influence of different rule sets on the performance of baseline system. We first restrict the target side of translation rules to be well-formed structures, and we extract 13.8M constituency-to-dependency (*c2d*) rules, which is 43% of *c2s* rules. We also extract 9.0M string-to-dependency (*s2d*) rules, which is only 11.6% of *s2s* rules. Then we convert *c2d* and *s2d* rules to *c2s* and *s2s* rules separately by removing the target-dependency structures and feed them into the baseline system. As shown in the third line in the column of BLEU score, the performance drops 1.7 BLEU points over baseline system due to the poorer rule coverage. However, when we further use all *s2s* rules instead of *s2d* rules in our next experiment, it achieves a BLEU score of 34.03, which is very similar to the baseline system. Those results suggest that restrictions on *c2s* rules won't hurt the performance, but restrictions on *s2s* will hurt the translation quality badly. So we should utilize all the *s2s* rules in order to preserve a good coverage of translation rule set.

The last two lines in Table 2 show the results of our new forest-based constituency-to-dependency model (*forest c2d* for short). When we only use *c2d* and *s2d* rules, our system achieves a BLEU score of 33.25, which is lower than the baseline system in the first line. But, with the same rule set, our model still outperform the result in the second line. This suggests that using dependency language model really improves the translation quality by less than 1 BLEU point.

In order to utilize all the *s2s* rules and increase the rule coverage, we parse the target strings of the *s2s* rules into dependency fragments, and construct the *pseudo s2d* rules (*s2s-dep*). Then we use *c2d* and *s2s-dep* rules to direct the translation. With the help of the dependency language model, our new model achieves a significant improvement of +0.7 BLEU points over the *forest c2s* baseline system ($p < 0.05$, using the *sign-test* suggested by Collins et al. (2005)). For the first time, a tree-to-tree model can surpass tree-to-string counterparts significantly even with fewer rules.

[3]According to the reports of Liu et al. (2009), with a more larger training corpus (FBIS plus 30K) but *no* name entity translations (+1 BLEU points if it is used), their forest-based constituency-to-constituency model achieves a BLEU score of 30.6, which is similar to Moses (Koehn et al., 2007). So our baseline system is much better than the BLEU score (30.6+1) of the constituency-to-constituency system and Moses.

System	Rule Set		BLEU
	Type	#	
forest c2s	c2s	31.9M	34.17
	s2s	77.9M	
	c2d	13.8M	32.48(↓1.7)
	s2d	9.0M	
	c2d	13.8M	34.03(↓0.1)
	s2s	77.9M	
forest c2d	c2d	13.8M	33.25(↓0.9)
	s2d	9.0M	
	c2d	13.8M	34.88(↑0.7)
	s2s-dep	77.9M	

Table 2: Statistics of different types of rules extracted on training corpus and the BLEU scores on the test set.

6 Related Work

The concept of packed forest has been used in machine translation for several years. For example, Huang and Chiang (2007) use forest to characterize the search space of decoding with integrated language models. Mi et al. (2008) and Mi and Huang (2008) use forest to direct translation and extract rules rather than 1-best tree in order to weaken the influence of parsing errors, this is also the first time to use forest directly in machine translation. Following this direction, Liu et al. (2009) and Zhang et al. (2009) apply forest into tree-to-tree (Zhang et al., 2007) and tree-sequence-to-string models(Liu et al., 2007) respectively. Different from Liu et al. (2009), we apply forest into a new constituency tree to dependency tree translation model rather than constituency tree-to-tree model.

Shen et al. (2008) present a string-to-dependency model. They define the well-formed dependency structures to reduce the size of translation rule set, and integrate a dependency language model in decoding step to exploit long distance word relations. This model shows a significant improvement over the state-of-the-art hierarchical phrase-based system (Chiang, 2005). Compared with this work, we put fewer restrictions on the definition of well-formed dependency structures in order to extract more rules; the

other difference is that we can also extract more expressive constituency to dependency rules, since the source side of our rule can encode multi-level reordering and contain more variables being larger than two; furthermore, our rules can be pattern-matched at high level, which is more reasonable than using glue rules in Shen et al. (2008)'s scenario; finally, the most important one is that our model runs very faster.

Liu et al. (2009) propose a forest-based constituency-to-constituency model, they put more emphasize on how to utilize parse forest to increase the tree-to-tree rule coverage. By contrast, we only use 1-best dependency trees on the target side to explore long distance relations and extract translation rules. Theoretically, we can extract more rules since dependency tree has the best inter-lingual phrasal cohesion properties (Fox, 2002).

7 Conclusion and Future Work

In this paper, we presented a novel forest-based constituency-to-dependency translation model, which combines the advantages of both tree-to-string and string-to-tree systems, runs fast and guarantees grammaticality of the output. To learn the constituency-to-dependency translation rules, we first identify the frontier set for all the nodes in the constituency forest on the source side. Then we fragment them and extract minimal rules. Finally, we glue them together to be composed rules. At the decoding step, we first parse the input sentence into a constituency forest. Then we convert it into a translation forest by patter-matching the constituency to string rules. Finally, we traverse the translation forest in a bottom-up fashion and translate it into a target dependency tree by incorporating string-based and dependency-based language models. Using all constituency-to-dependency translation rules and bilingual phrases, our model achieves +0.7 points improvement in BLEU score significantly over a state-of-the-art forest-based tree-to-string system. This is also the first time that a tree-to-tree model can surpass tree-to-string counterparts.

In the future, we will do more experiments on rule coverage to compare the constituency-to-constituency model with our model. Furthermore, we will replace 1-best dependency trees on the target side with dependency forests to further increase the rule coverage.

Learning to Translate with Source and Target Syntax

Abstract

Statistical translation models that try to capture the recursive structure of language have been widely adopted over the last few years. These models make use of varying amounts of information from linguistic theory: some use none at all, some use information about the grammar of the target language, some use information about the grammar of the source language. But progress has been slower on translation models that are able to learn the relationship between the grammars of both the source and target language. We discuss the reasons why this has been a challenge, review existing attempts to meet this challenge, and show how some old and new ideas can be combined into a simple approach that uses both source and target syntax for significant improvements in translation accuracy.

1 Introduction

Statistical translation models that use synchronous context-free grammars (SCFGs) or related formalisms to try to capture the recursive structure of language have been widely adopted over the last few years. The simplest of these (Chiang, 2005) make no use of information from syntactic theories or syntactic annotations, whereas others have successfully incorporated syntactic information on the target side (Galley et al., 2004; Galley et al., 2006) or the source side (Liu et al., 2006; Huang et al., 2006). The next obvious step is toward models that make full use of syntactic information on both sides. But the natural generalization to this setting has been found to underperform phrase-based models (Liu et al., 2009; Ambati and Lavie, 2008), and researchers have begun to explore solutions (Zhang et al., 2008; Liu et al., 2009).

In this paper, we explore the reasons why tree-to-tree translation has been challenging, and how source syntax and target syntax might be used together. Drawing on previous successful attempts to relax syntactic constraints during grammar extraction in various ways (Zhang et al., 2008; Liu et al., 2009; Zollmann and Venugopal, 2006), we compare several methods for extracting a synchronous grammar from tree-to-tree data. One confounding factor in such a comparison is that some methods generate many new syntactic categories, making it more difficult to satisfy syntactic constraints at decoding time. We therefore propose to move these constraints from the formalism into the model, implemented as features in the hierarchical phrase-based model Hiero (Chiang, 2005). This augmented model is able to learn from data whether to rely on syntax or not, or to revert back to monotone phrase-based translation.

In experiments on Chinese-English and Arabic-English translation, we find that when both source and target syntax are made available to the model in an unobtrusive way, the model chooses to build structures that are more syntactically well-formed and yield significantly better translations than a nonsyntactic hierarchical phrase-based model.

2 Grammar extraction

A *synchronous tree-substitution grammar* (STSG) is a set of rules or *elementary tree pairs* (γ, α), where:

- γ is a tree whose interior labels are source-language nonterminal symbols and whose frontier labels are source-language nonterminal symbols or terminal symbols (words). The nonterminal-labeled frontier nodes are called *substitution nodes*, conventionally marked with an arrow ($\downarrow$).
- α is a tree of the same form except with

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1443–1452,
Uppsala, Sweden, 11-16 July 2010.

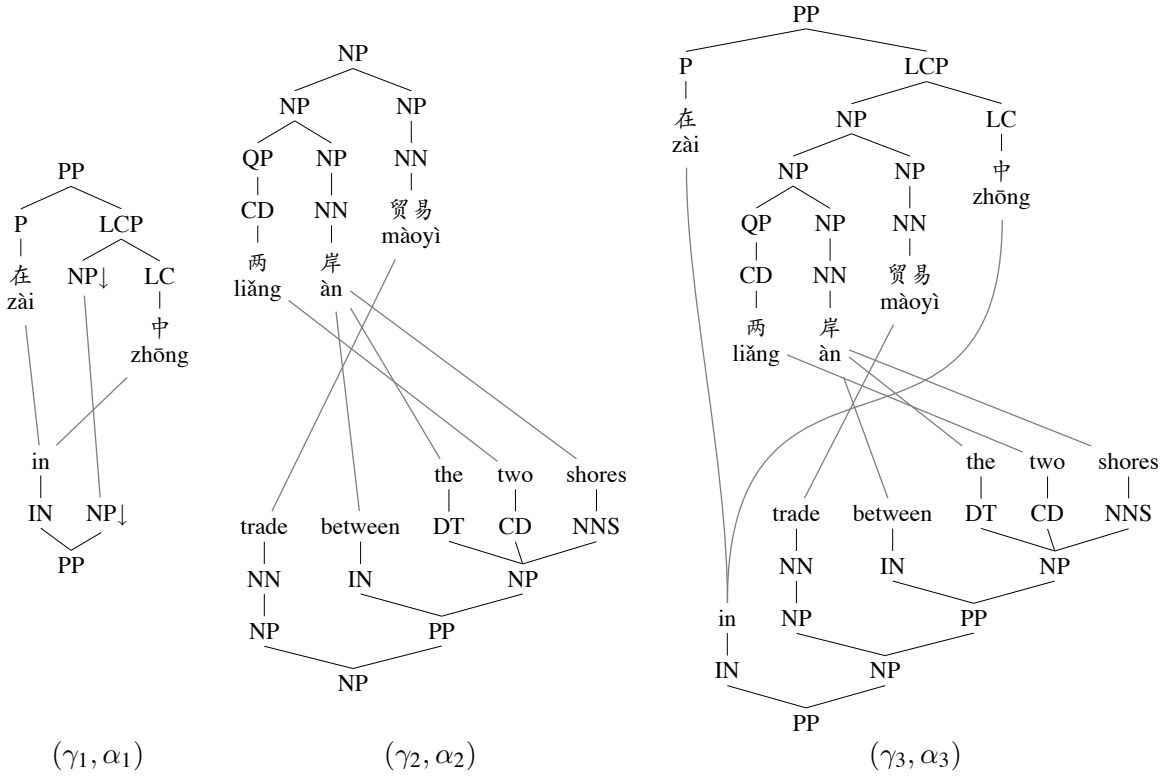

Figure 1: Synchronous tree substitution. Rule (γ_2, α_2) is substituted into rule (γ_1, α_1) to yield (γ_3, α_3).

target-language instead of source-language symbols.

- The substitution nodes of γ are aligned bijectively with those of α.
- The terminal-labeled frontier nodes of γ are aligned (many-to-many) with those of α.

In the *substitution* operation, an aligned pair of substitution nodes is rewritten with an elementary tree pair. The labels of the substitution nodes must match the root labels of the elementary trees with which they are rewritten (but we will relax this constraint below). See Figure 1 for examples of elementary tree pairs and substitution.

2.1 Exact tree-to-tree extraction

The use of STSGs for translation was proposed in the Data-Oriented Parsing literature (Poutsma, 2000; Hearne and Way, 2003) and by Eisner (2003). Both of these proposals are more ambitious about handling spurious ambiguity than approaches derived from phrase-based translation usually have been (the former uses random sampling to sum over equivalent derivations during decoding, and the latter uses dynamic programming to sum over equivalent derivations during training). If we take a more typical approach, which generalizes that of Galley et al. (2004; 2006) and is similar to Stat-XFER (Lavie et al., 2008), we obtain the following grammar extraction method, which we call *exact* tree-to-tree extraction.

	human	automatic
string-to-string	198,445	142,820
max nested	78,361	64,578
tree-to-string	60,939 (78%)	48,235 (75%)
string-to-tree	59,274 (76%)	46,548 (72%)
tree-to-tree	53,084 (68%)	39,049 (60%)

Table 1: Analysis of phrases extracted from Chinese-English newswire data with human and automatic word alignments and parses. As tree constraints are added, the number of phrase pairs drops. Errors in automatic annotations also decrease the number of phrase pairs. Percentages are relative to the maximum number of nested phrase pairs.

Given a pair of source- and target-language parse trees with a word alignment between their leaves, identify all the *phrase pairs* $(\bar{f}, \bar{e})$, i.e., those substring pairs that respect the word align-

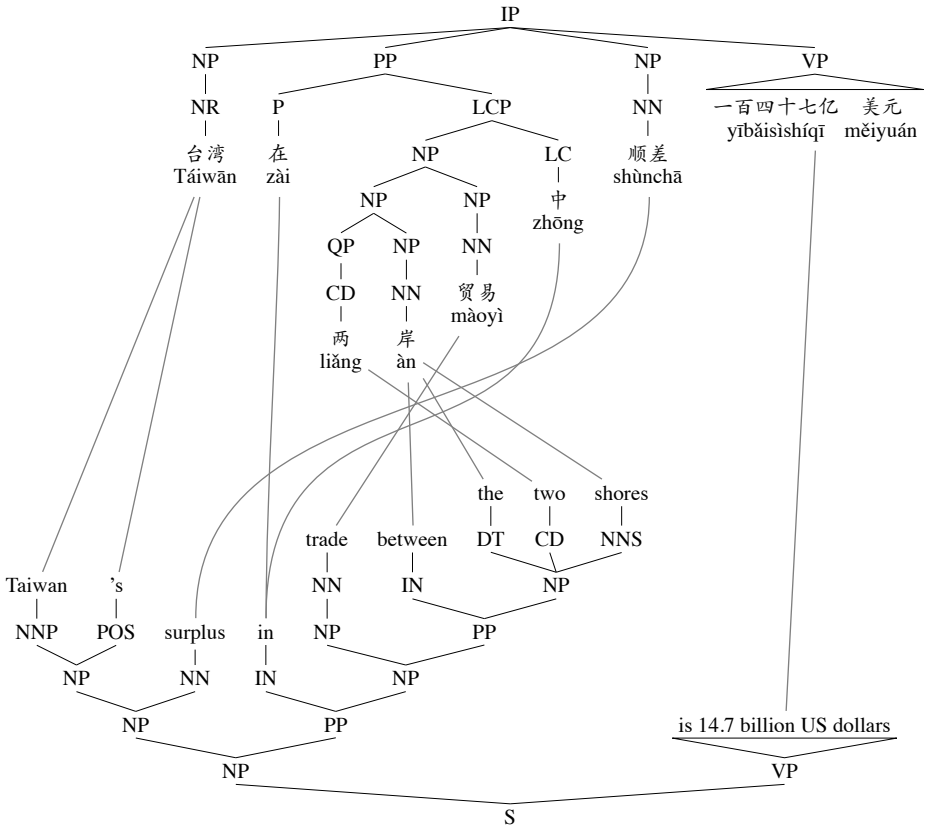

Figure 2: Example Chinese-English sentence pair with human-annotated parse trees and word alignments.

ment in the sense that at least one word in $\bar{f}$ is aligned to a word in $\bar{e}$, and no word in $\bar{f}$ is aligned to a word outside of $\bar{e}$, or vice versa. Then the extracted grammar is the smallest STSG G satisfying:

- If (γ, α) is a pair of subtrees of a training example and the frontiers of γ and α form a phrase pair, then (γ, α) is a rule in G.
- If $(\gamma_2, \alpha_2) \in G$, $(\gamma_3, \alpha_3) \in G$, and (γ_1, α_1) is an elementary tree pair such that substituting (γ_2, α_2) into (γ_1, α_1) results in (γ_3, α_3), then (γ_1, α_1) is a rule in G.

For example, consider the training example in Figure 2, from which the elementary tree pairs shown in Figure 1 can be extracted. The elementary tree pairs (γ_2, α_2) and (γ_3, α_3) are rules in G because their yields are phrase pairs, and (γ_1, α_1) results from subtracting (γ_2, α_2) from (γ_3, α_3).

2.2 Fuzzy tree-to-tree extraction

Exact tree-to-tree translation requires that translation rules deal with syntactic constituents on both the source and target side, which reduces the number of eligible phrases. Table 1 shows an analysis of phrases extracted from human word-aligned and parsed data and automatically word-aligned and parsed data.[1] The first line shows the number of phrase-pair occurrences that are extracted in the absence of syntactic constraints,[2] and the second line shows the maximum number of *nested* phrase-pair occurrences, which is the most that exact syntax-based extraction can achieve. Whereas tree-to-string extraction and string-to-tree extraction permit 70–80% of the maximum possible number of phrase pairs, tree-to-tree extraction only permits 60–70%.

Why does this happen? We can see that moving from human annotations to automatic annotations decreases not only the absolute number of phrase pairs, but the percentage of phrases that pass the syntactic filters. Wellington et al. (2006), in a more systematic study, find that, of sentences where the tree-to-tree constraint blocks rule extraction, the majority are due to parser errors. To address this problem, Liu et al. (2009) extract rules from pairs

[1] The first 2000 sentences from the GALE Phase 4 Chinese Parallel Word Alignment and Tagging Part 1 (LDC2009E83) and the Chinese News Translation Text Part 1 (LDC2005T06), respectively.

[2] Only counting phrases that have no unaligned words at their endpoints.

of packed forests instead of pairs of trees. Since a packed forest is much more likely to include the correct tree, it is less likely that parser errors will cause good rules to be filtered out.

However, even on human-annotated data, tree-to-tree extraction misses many rules, and many such rules would seem to be useful. For example, in Figure 2, the whole English phrase "Taiwan's. . .shores" is an NP, but its Chinese counterpart is not a constituent. Furthermore, neither "surplus. . .shores" nor its Chinese counterpart are constituents. But both rules are arguably useful for translation. Wellington et al. therefore argue that in order to extract as many rules as possible, a more powerful formalism than synchronous CFG/TSG is required: for example, generalized multitext grammar (Melamed et al., 2004), which is equivalent to synchronous set-local multicomponent CFG/TSG (Weir, 1988).

But the problem illustrated in Figure 2 does not reflect a very deep fact about syntax or cross-lingual divergences, but rather choices in annotation style that interact badly with the exact tree-to-tree extraction heuristic. On the Chinese side, the IP is too flat (because 台湾/Táiwān has been analyzed as a topic), whereas the more articulated structure

(1) [NP Táiwān [NP [PP zaì . . .] shùnchā]]

would also be quite reasonable. On the English side, the high attachment of the PP disagrees with the corresponding Chinese structure, but low attachment also seems reasonable:

(2) [NP [NP Taiwan's] [NP surplus in trade. . .]]

Thus even in the gold-standard parse trees, phrase structure can be underspecified (like the flat IP above) or uncertain (like the PP attachment above).

For this reason, some approaches work with a more flexible notion of constituency. *Synchronous tree-sequence–substitution grammar (STSSG)* allows either side of a rule to comprise a sequence of trees instead of a single tree (Zhang et al., 2008). In the substitution operation, a sequence of sister substitution nodes is rewritten with a tree sequence of equal length (see Figure 3a). This extra flexibility effectively makes the analysis (1) available to us.

Any STSSG can be converted into an equivalent STSG via the creation of virtual nodes (see Figure 3b): for every elementary tree sequence with roots $X_1, \ldots, X_n$, create a new root node with a

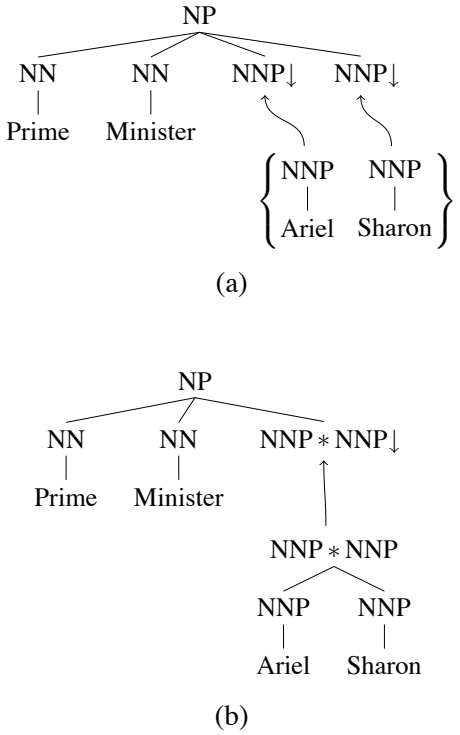

Figure 3: (a) Example tree-sequence substitution grammar and (b) its equivalent SAMT-style tree-substitution grammar.

complex label $X_1 * \cdots * X_n$ immediately dominating the old roots, and replace every sequence of substitution sites $X_1, \ldots, X_n$ with a single substitution site $X_1 * \cdots * X_n$. This is essentially what *syntax-augmented MT (SAMT)* does, in the string-to-tree setting (Zollmann and Venugopal, 2006). In addition, SAMT drops the requirement that the X_i are sisters, and uses categories X / Y (an X missing a Y on the right) and $Y \setminus X$ (an X missing a Y on the left) in the style of categorial grammar (Bar-Hillel, 1953). Under this flexible notion of constituency, both (1) and (2) become available, albeit with more complicated categories.

Both STSSG and SAMT are examples of what we might call *fuzzy tree-to-tree extraction*. We follow this approach here as well: as in STSSG, we work on tree-to-tree data, and we use the complex categories of SAMT. Moreover, we allow the product categories $X_1 * \cdots * X_n$ to be of any length n, and we allow the slash categories to take any number of arguments on either side. Thus every phrase can be assigned a (possibly very complex) syntactic category, so that fuzzy tree-to-tree extraction does not lose any rules relative to string-to-string extraction.

On the other hand, if several rules are extracted

that differ only in their nonterminal labels, only the most-frequent rule is kept, and its count is the total count of all the rules. This means that there is a one-to-one correspondence between the rules extracted by fuzzy tree-to-tree extraction and hierarchical string-to-string extraction.

2.3 Nesting phrases

Fuzzy tree-to-tree extraction (like string-to-string extraction) generates many times more rules than exact tree-to-tree extraction does. In Figure 2, we observed that the flat structure of the Chinese IP prevented exact tree-to-tree extraction from extracting a rule containing just part of the IP, for example:

(3) [PP zaì ...] [NP shùnchā]

(4) [NP Táiwān] [PP zaì ...] [NP shùnchā]

(5) [PP zaì ...] [NP shùnchā] [VP ... měiyuán]

Fuzzy tree-to-tree extraction allows any of these to be the source side of a rule. We might think of it as effectively restructuring the trees by inserting nodes with complex labels. However, it is not possible to represent this restructuring with a single tree (see Figure 4). More formally, let us say that two phrases $w_i \cdots w_{j-1}$ and $w_{i'} \cdots w_{j'-1}$ *nest* if $i \leq i' < j' \leq j$ or $i' \leq i < j < j'$; otherwise, they *cross*. The two Chinese phrases (4) and (5) cross, and therefore cannot both be constituents in the same tree. In other words, exact tree-to-tree extraction commits to a single structural analysis but fuzzy tree-to-tree extraction pursues many restructured analyses at once.

We can strike a compromise by continuing to allow SAMT-style complex categories, but committing to a single analysis by requiring all phrases to nest. To do this, we use a simple heuristic. Iterate through all the phrase pairs $(\bar{f}, \bar{e})$ in the following order:

1. sort by whether $\bar{f}$ and $\bar{e}$ can be assigned a simple syntactic category (both, then one, then neither); if there is a tie,
2. sort by how many syntactic constituents $\bar{f}$ and $\bar{e}$ cross (low to high); if there is a tie,
3. give priority to $(\bar{f}, \bar{e})$ if neither $\bar{f}$ nor $\bar{e}$ begins or ends with punctuation; if there is a tie, finally
4. sort by the position of $\bar{f}$ in the source-side string (right to left).

For each phrase pair, accept it if it does not cross any previously accepted phrase pair; otherwise, reject it.

Because this heuristic produces a set of nesting phrases, we can represent them all in a single restructured tree. In Figure 4, this heuristic chooses structure (a) because the English-side counterpart of IP/VP has the simple category NP.

3 Decoding

In decoding, the rules extracted during training must be reassembled to form a derivation whose source side matches the input sentence. In the exact tree-to-tree approach, whenever substitution is performed, the root labels of the substituted trees must match the labels of the substitution nodes—call this the *matching constraint*. Because this constraint must be satisfied on both the source and target side, it can become difficult to generalize well from training examples to new input sentences.

Venugopal et al. (2009), in the string-to-tree setting, attempt to soften the data-fragmentation effect of the matching constraint: instead of trying to find the single derivation with the highest probability, they sum over derivations that differ only in their nonterminal labels and try to find the single derivation-class with the highest probability. Still, only derivations that satisfy the matching constraint are included in the summation.

But in some cases we may want to soften the matching constraint itself. Some syntactic categories are similar enough to be considered compatible: for example, if a rule rooted in VBD (past-tense verb) could substitute into a site labeled VBZ (present-tense verb), it might still generate correct output. This is all the more true with the addition of SAMT-style categories: for example, if a rule rooted in ADVP $*$ VP could substitute into a site labeled VP, it would very likely generate correct output.

Since we want syntactic information to help the model make good translation choices, not to rule out potentially correct choices, we can change the way the information is used during decoding: we allow any rule to substitute into any site, but let the model learn which substitutions are better than others. To do this, we add the following features to the model:

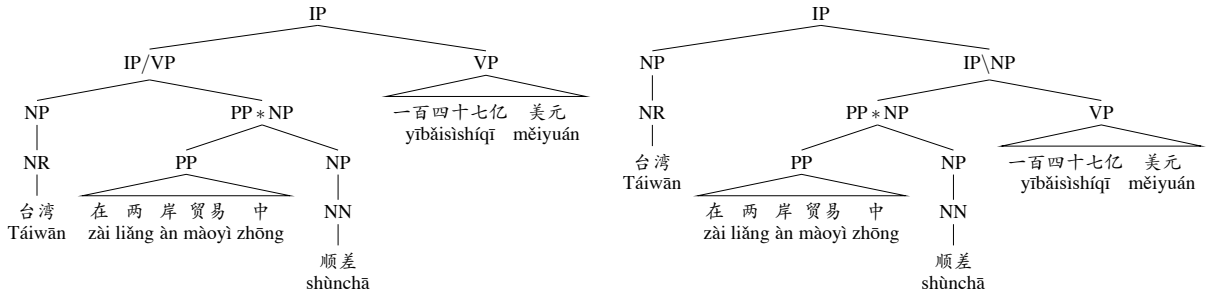

Figure 4: Fuzzy tree-to-tree extraction effectively restructures the Chinese tree from Figure 2 in two ways but does not commit to either one.

- $match^f$ counts the number of substitutions where the label of the source side of the substitution site matches the root label of the source side of the rule, and $\neg match^f$ counts those where the labels do not match.

- $subst^f_{X \rightarrow Y}$ counts the number of substitutions where the label of the source side of the substitution site is X and the root label of the source side of the rule is Y.

- $match^e$, $\neg match^e$, and $subst^e_{X \rightarrow Y}$ do the same for the target side.

- $root_{X,X'}$ counts the number of rules whose root label on the source side is X and whose root label on the target side is X'.[3]

For example, in the derivation of Figure 1, the following features would fire:

$$\begin{aligned} match^f &= 1 \\ subst^f_{\text{NP} \rightarrow \text{NP}} &= 1 \\ match^e &= 1 \\ subst^e_{\text{NP} \rightarrow \text{NP}} &= 1 \\ root_{\text{NP,NP}} &= 1 \end{aligned}$$

The decoding algorithm then operates as in hierarchical phrase-based translation. The decoder has to store in each hypothesis the source and target root labels of the partial derivation, but these labels are used for calculating feature vectors only and not for checking well-formedness of derivations. This additional state does increase the search space of the decoder, but we did not change any pruning settings.

[3]Thanks to Adam Pauls for suggesting this feature class.

4 Experiments

To compare the methods described above with hierarchical string-to-string translation, we ran experiments on both Chinese-English and Arabic-English translation.

4.1 Setup

The sizes of the parallel texts used are shown in Table 2. We word-aligned the Chinese-English parallel text using GIZA++ followed by link deletion (Fossum et al., 2008), and the Arabic-English parallel text using a combination of GIZA++ and LEAF (Fraser and Marcu, 2007). We parsed the source sides of both parallel texts using the Berkeley parser (Petrov et al., 2006), trained on the Chinese Treebank 6 and Arabic Treebank parts 1–3, and the English sides using a reimplementation of the Collins parser (Collins, 1997).

For string-to-string extraction, we used the same constraints as in previous work (Chiang, 2007), with differences shown in Table 2. Rules with nonterminals were extracted from a subset of the data (labeled "Core" in Table 2), and rules without nonterminals were extracted from the full parallel text. Fuzzy tree-to-tree extraction was performed using analogous constraints. For exact tree-to-tree extraction, we used simpler settings: no limit on initial phrase size or unaligned words, and a maximum of 7 frontier nodes on the source side.

All systems used the glue rule (Chiang, 2005), which allows the decoder, working bottom-up, to stop building hierarchical structure and instead concatenate partial translations without any reordering. The model attaches a weight to the glue rule so that it can learn from data whether to build shallow or rich structures, but for efficiency's sake the decoder has a hard limit, called the *distortion*

		Chi-Eng	Ara-Eng
Core	training words	32+38M	28+34M
	initial phrase size	10	15
	final rule size	6	6
	nonterminals	2	2
	loose source	0	∞
	loose target	0	2
Full	training words	240+260M	190+220M
	final rule size	6	6
	nonterminals	0	0
	loose source	∞	∞
	loose target	1	2

Table 2: Rule extraction settings used for experiments. "Loose source/target" is the maximum number of unaligned source/target words at the endpoints of a phrase.

limit, above which the glue rule must be used.

We trained two 5-gram language models: one on the combined English halves of the bitexts, and one on two billion words of English. These were smoothed using modified Kneser-Ney (Chen and Goodman, 1998) and stored using randomized data structures similar to those of Talbot and Brants (2008).

The base feature set for all systems was similar to the expanded set recently used for Hiero (Chiang et al., 2009), but with bigram features (source and target word) instead of trigram features (source and target word and neighboring source word). For all systems but the baselines, the features described in Section 3 were added. The systems were trained using MIRA (Crammer and Singer, 2003; Chiang et al., 2009) on a tuning set of about 3000 sentences of newswire from NIST MT evaluation data and GALE development data, disjoint from the training data. We optimized feature weights on 90% of this and held out the other 10% to determine when to stop.

4.2 Results

Table 3 shows the scores on our development sets and test sets, which are about 3000 and 2000 sentences, respectively, of newswire drawn from NIST MT evaluation data and GALE development data and disjoint from the tuning data.

For Chinese, we first tried increasing the distortion limit from 10 words to 20. This limit controls how deeply nested the tree structures built by the decoder are, and we want to see whether adding syntactic information leads to more complex structures. This change by itself led to an increase in the BLEU score. We then compared against two systems using tree-to-tree grammars. Using exact tree-to-tree extraction, we got a much smaller grammar, but decreased accuracy on all but the Chinese-English test set, where there was no significant change. But with fuzzy tree-to-tree extraction, we obtained an improvement of +0.6 on both Chinese-English sets, and +0.7/+0.8 on the Arabic-English sets.

Applying the heuristic for nesting phrases reduced the grammar sizes dramatically (by a factor of 2.4 for Chinese and 4.2 for Arabic) but, interestingly, had almost no effect on translation quality: a slight decrease in BLEU on the Arabic-English development set and no significant difference on the other sets. This suggests that the strength of fuzzy tree-to-tree extraction lies in its ability to break up flat structures and to reconcile the source and target trees with each other, rather than multiple restructurings of the training trees.

4.3 Rule usage

We then took a closer look at the behavior of the string-to-string and fuzzy tree-to-tree grammars (without the nesting heuristic). Because the rules of these grammars are in one-to-one correspondence, we can analyze the string-to-string system's derivations as though they had syntactic categories. First, Table 4 shows that the system using the tree-to-tree grammar used the glue rule much less and performed more matching substitutions. That is, in order to minimize errors on the tuning set, the model learned to build syntactically richer and more well-formed derivations.

Tables 5 and 6 show how the new syntax features affected particular substitutions. In general we see a shift towards more matching substitutions; correct placement of punctuation is particularly emphasized. Several changes appear to have to do with definiteness of NPs: on the English side, adding the syntax features encourages matching substitutions of type DT \ NP-C (anarthrous NP), but discourages DT \ NP-C and NN from substituting into NP-C and vice versa. For example, a translation with the rewriting NP-C $\rightarrow$ DT \ NP-C begins with "24th meeting of the Standing Committee. . .," but the system using the fuzzy tree-to-tree grammar changes this to "The 24th meeting of the Standing Committee. . . ."

The *root* features had a less noticeable effect on

	+ nesting	10	190M	66k	49.2	49.8

Table 3: On both the Chinese-English and Arabic-English translation tasks, fuzzy tree-to-tree extraction outperforms exact tree-to-tree extraction and string-to-string extraction. Brackets indicate statistically insignificant differences ($p \geq 0.05$).

rule choice; one interesting change was that the frequency of rules with Chinese root VP / IP and English root VP / S-C increased from 0.2% to 0.7%: apparently the model learned that it is good to use rules that pair Chinese and English verbs that subcategorize for sentential complements.

5 Conclusion

Though exact tree-to-tree translation tends to hamper translation quality by imposing too many constraints during both grammar extraction and decoding, we have shown that using both source and target syntax improves translation accuracy when the model is given the opportunity to learn from data how strongly to apply syntactic constraints. Indeed, we have found that the model learns on its own to choose syntactically richer and more well-formed structures, demonstrating that source- and target-side syntax can be used together profitably as long as they are not allowed to overconstrain the translation model.

Discriminative Modeling of Extraction Sets for Machine Translation

John DeNero and **Dan Klein**
Computer Science Division
University of California, Berkeley
{denero,klein}@cs.berkeley.edu

Abstract

We present a discriminative model that directly predicts which set of phrasal translation rules should be extracted from a sentence pair. Our model scores *extraction sets*: nested collections of all the overlapping phrase pairs consistent with an underlying word alignment. Extraction set models provide two principle advantages over word-factored alignment models. First, we can incorporate features on phrase pairs, in addition to word links. Second, we can optimize for an extraction-based loss function that relates directly to the end task of generating translations. Our model gives improvements in alignment quality relative to state-of-the-art unsupervised and supervised baselines, as well as providing up to a 1.4 improvement in BLEU score in Chinese-to-English translation experiments.

1 Introduction

In the last decade, the field of statistical machine translation has shifted from generating sentences word by word to systems that recycle whole fragments of training examples, expressed as *translation rules*. This general paradigm was first pursued using contiguous phrases (Och et al., 1999; Koehn et al., 2003), and has since been generalized to a wide variety of hierarchical and syntactic formalisms. The training stage of statistical systems focuses primarily on discovering translation rules in parallel corpora.

Most systems discover translation rules via a two-stage pipeline: a parallel corpus is aligned at the word level, and then a second procedure extracts fragment-level rules from word-aligned sentence pairs. This paper offers a model-based alternative to phrasal rule extraction, which merges this two-stage pipeline into a single step. We present a discriminative model that directly predicts which set of phrasal translation rules should be extracted from a sentence pair. Our model predicts *extraction sets*: combinatorial objects that include the set of all overlapping phrasal translation rules consistent with an underlying word-level alignment. This approach provides additional discriminative power relative to word aligners because extraction sets are scored based on the phrasal rules they contain in addition to word-to-word alignment links. Moreover, the structure of our model directly reflects the purpose of alignment models in general, which is to discover translation rules.

We address several challenges to training and applying an extraction set model. First, we would like to leverage existing word-level alignment resources. To do so, we define a deterministic mapping from word alignments to extraction sets, inspired by existing extraction procedures. In our mapping, *possible* alignment links have a precise interpretation that dictates what phrasal translation rules can be extracted from a sentence pair. This mapping allows us to train with existing annotated data sets and use the predictions from word-level aligners as features in our extraction set model.

Second, our model solves a structured prediction problem, and the choice of loss function during training affects model performance. We optimize for a phrase-level F-measure in order to focus learning on the task of predicting phrasal rules rather than word alignment links.

Third, our discriminative approach requires that we perform inference in the space of extraction sets. Our model does not factor over disjoint word-to-word links or minimal phrase pairs, and so existing inference procedures do not directly apply. However, we show that the dynamic program for a block ITG aligner can be augmented to score extraction sets that are indexed by underlying ITG word alignments (Wu, 1997). We also describe a

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1453–1463,
Uppsala, Sweden, 11-16 July 2010.

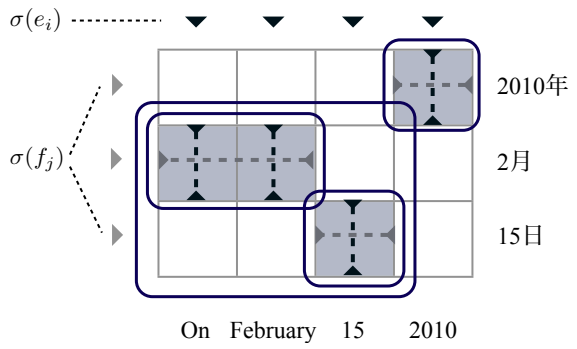

Figure 1: A word alignment $\mathcal{A}$ (shaded grid cells) defines projections $\sigma(e_i)$ and $\sigma(f_j)$, shown as dotted lines for each word in each sentence. The extraction set $R_3(\mathcal{A})$ includes all bispans licensed by these projections, shown as rounded rectangles.

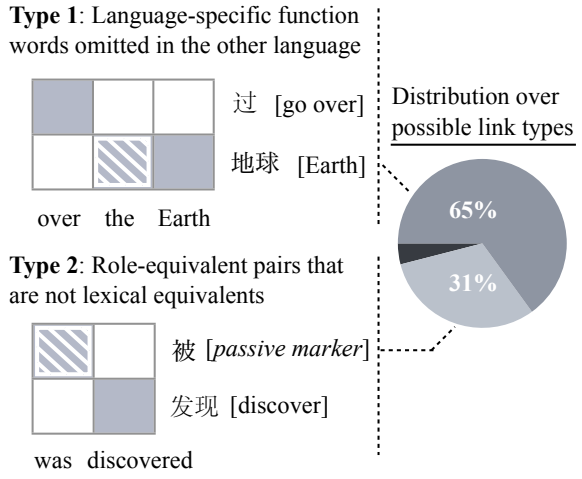

Figure 2: Examples of two types of possible alignment links (striped). These types account for 96% of the possible alignment links in our data set.

coarse-to-fine inference approach that allows us to scale our method to long sentences.

Our extraction set model outperforms both unsupervised and supervised word aligners at predicting word alignments and extraction sets. We also demonstrate that extraction sets are useful for end-to-end machine translation. Our model improves translation quality relative to state-of-the-art Chinese-to-English baselines across two publicly available systems, providing total BLEU improvements of 1.2 in Moses, a phrase-based system, and 1.4 in a Joshua, a hierarchical system (Koehn et al., 2007; Li et al., 2009)

2 Extraction Set Models

The input to our model is an unaligned sentence pair, and the output is an extraction set of phrasal translation rules. Word-level alignments are generated as a byproduct of inference. We first specify the relationship between word alignments and extraction sets, then define our model.

2.1 Extraction Sets from Word Alignments

Rule extraction is a standard concept in machine translation: word alignment constellations license particular sets of overlapping rules, from which subsets are selected according to limits on phrase length (Koehn et al., 2003), number of gaps (Chiang, 2007), count of internal tree nodes (Galley et al., 2006), etc. In this paper, we focus on phrasal rule extraction (i.e., phrase pair extraction), upon which most other extraction procedures are based.

Given a sentence pair $(\mathbf{e}, \mathbf{f})$, phrasal rule extraction defines a mapping from a set of word-to-word alignment links $\mathcal{A} = \{(i, j)\}$ to an *extraction set* of bispans $R_n(\mathcal{A}) = \{[g, h) \Leftrightarrow [k, \ell)\}$, where each bispan links target span $[g, h)$ to source span $[k, \ell)$.[1] The maximum phrase length n ensures that $\max(h - g, \ell - k) \leq n$.

We can describe this mapping via word-to-phrase projections, as illustrated in Figure 1. Let word e_i project to the phrasal span $\sigma(e_i)$, where

$$\sigma(e_i) = \left[\min_{j \in J_i} j \ , \ \max_{j \in J_i} j + 1 \right) \qquad (1)$$
$$J_i = \{j : (i, j) \in \mathcal{A}\}$$

and likewise each word f_j projects to a span of $\mathbf{e}$. Then, $R_n(\mathcal{A})$ includes a bispan $[g, h) \Leftrightarrow [k, \ell)$ iff

$$\sigma(e_i) \subseteq [k, \ell) \qquad \forall i \in [g, h)$$
$$\sigma(f_j) \subseteq [g, h) \qquad \forall j \in [k, \ell)$$

That is, every word in one of the phrasal spans must project within the other. This mapping is deterministic, and so we can interpret a word-level alignment $\mathcal{A}$ as also specifying the phrasal rules that should be extracted from a sentence pair.

2.2 Possible and Null Alignment Links

We have not yet accounted for two special cases in annotated corpora: *possible* alignments and *null* alignments. To analyze these annotations, we consider a particular data set: a hand-aligned portion

[1] We use the fencepost indexing scheme used commonly for parsing. Words are 0-indexed. Spans are inclusive on the lower bound and exclusive on the upper bound. For example, the span $[0, 2)$ includes the first two words of a sentence.

of the NIST MT02 Chinese-to-English test set, which has been used in previous alignment experiments (Ayan et al., 2005; DeNero and Klein, 2007; Haghighi et al., 2009).

Possible links account for 22% of all alignment links in these data, and we found that most of these links fall into two categories. First, possible links are used to align function words that have no equivalent in the other language, but colocate with aligned content words, such as English determiners. Second, they are used to mark pairs of words or short phrases that are not lexical equivalents, but which play equivalent roles in each sentence. Figure 2 shows examples of these two use cases, along with their corpus frequencies.[2]

On the other hand, null alignments are used sparingly in our annotated data. More than 90% of words participate in some alignment link. The unaligned words typically express content in one sentence that is absent in its translation.

Figure 3 illustrates how we interpret possible and null links in our projection. Possible links are typically not included in extraction procedures because most aligners predict only sure links. However, we see a natural interpretation for possible links in rule extraction: they license phrasal rules that both include and exclude them. We exclude null alignments from extracted phrases because they often indicate a mismatch in content.

We achieve these effects by redefining the projection operator σ. Let $\mathcal{A}^{(s)}$ be the subset of $\mathcal{A}$ that are *sure* links, then let the index set J_i used for projection σ in Equation 1 be

$$J_i = \begin{cases} \{j : (i,j) \in \mathcal{A}^{(s)}\} & \text{if } \exists j : (i,j) \in \mathcal{A}^{(s)} \\ \{-1, |\mathbf{f}|\} & \text{if } \nexists j : (i,j) \in \mathcal{A} \\ \{j : (i,j) \in \mathcal{A}\} & \text{otherwise} \end{cases}$$

Here, J_i is a set of integers, and $\sigma(e_i)$ for null aligned e_i will be $[-1, |\mathbf{f}| + 1)$ by Equation 1.

Of course, the characteristics of our aligned corpus may not hold for other annotated corpora or other language pairs. However, we hope that the overall effectiveness of our modeling approach will influence future annotation efforts to build corpora that are consistent with this interpretation.

2.3 A Linear Model of Extraction Sets

We now define a linear model that scores extraction sets. We restrict our model to score only *coherent* extraction sets $R_n(\mathcal{A})$, those that are licensed by an underlying word alignment $\mathcal{A}$ with sure alignments $\mathcal{A}^{(s)} \subseteq \mathcal{A}$. Conditioned on a sentence pair $(\mathbf{e}, \mathbf{f})$ and maximum phrase length n, we score extraction sets via a feature vector $\phi(\mathcal{A}^{(s)}, R_n(\mathcal{A}))$ that includes features on sure links $(i,j) \in \mathcal{A}^{(s)}$ and features on the bispans in $R_n(\mathcal{A})$ that link $[g,h)$ in $\mathbf{e}$ to $[k,\ell)$ in $\mathbf{f}$:

$$\phi(\mathcal{A}^{(s)}, R_n(\mathcal{A})) = \sum_{(i,j)\in\mathcal{A}^{(s)}} \phi_a(i,j) + \sum_{[g,h)\Leftrightarrow[k,\ell)\in R_n(\mathcal{A})} \phi_b(g,h,k,\ell)$$

Because the projection operator $R_n(\cdot)$ is a deterministic function, we can abbreviate $\phi(\mathcal{A}^{(s)}, R_n(\mathcal{A}))$ as $\phi(\mathcal{A})$ without loss of information, although we emphasize that $\mathcal{A}$ is a set of sure and possible alignments, and $\phi(\mathcal{A})$ does not decompose as a sum of vectors on individual word-level alignment links. Our model is parameterized by a weight vector θ, which scores an extraction set $R_n(\mathcal{A})$ as $\theta \cdot \phi(\mathcal{A})$.

To further limit the space of extraction sets we are willing to consider, we restrict $\mathcal{A}$ to block inverse transduction grammar (ITG) alignments, a space that allows many-to-many alignments through phrasal terminal productions, but otherwise enforces at-most-one-to-one phrase matchings with ITG reordering patterns (Cherry and Lin, 2007; Zhang et al., 2008). The ITG constraint

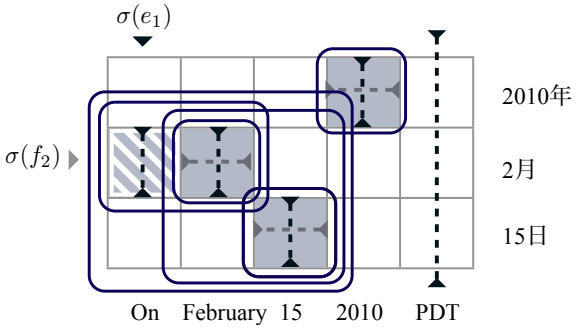

Figure 3: Possible links constrain the word-to-phrase projection of otherwise unaligned words, which in turn license overlapping phrases. In this example, $\sigma(f_2) = [1,2)$ does not include the possible link at $(1,0)$ because of the sure link at $(1,1)$, but $\sigma(e_1) = [1,2)$ does use the possible link because it would otherwise be unaligned. The word "PDT" is null aligned, and so its projection $\sigma(e_4) = [-1,4)$ extends beyond the bounds of the sentence, excluding "PDT" from all phrase pairs.

[2]We collected corpus frequencies of possible alignment link types ourselves on a sample of the hand-aligned data set.

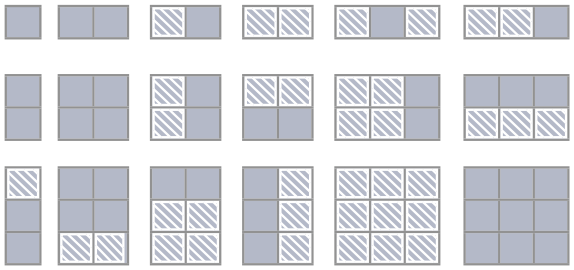

Figure 4: Above, we show a representative subset of the block alignment patterns that serve as terminal productions of the ITG that restricts the output space of our model. These terminal productions cover up to $n = 3$ words in each sentence and include a mixture of sure (filled) and possible (striped) word-level alignment links.

is more computationally convenient than arbitrarily ordered phrase matchings (Wu, 1997; DeNero and Klein, 2008). However, the space of block ITG alignments is expressive enough to include the vast majority of patterns observed in hand-annotated parallel corpora (Haghighi et al., 2009).

In summary, our model scores all $R_n(\mathcal{A})$ for $\mathcal{A} \in \text{ITG}(\mathbf{e}, \mathbf{f})$ where $\mathcal{A}$ can include block terminals of size up to n. In our experiments, $n = 3$. Unlike previous work, we allow possible alignment links to appear in the block terminals, as depicted in Figure 4.

3 Model Estimation

We estimate the weights θ of our extraction set model discriminatively using the margin-infused relaxed algorithm (MIRA) of Crammer and Singer (2003)—a large-margin, perceptron-style, online learning algorithm. MIRA has been used successfully in MT to estimate both alignment models (Haghighi et al., 2009) and translation models (Chiang et al., 2008).

For each training example, MIRA requires that we find the alignment $\mathcal{A}_m$ corresponding to the highest scoring extraction set $R_n(\mathcal{A}_m)$ under the current model,

$$\mathcal{A}_m = \arg\max_{\mathcal{A} \in \text{ITG}(\mathbf{e},\mathbf{f})} \theta \cdot \phi(\mathcal{A}) \qquad (2)$$

Section 4 describes our approach to solving this search problem for model inference.

MIRA updates away from $R_n(A_m)$ and toward a gold extraction set $R_n(A_g)$. Some hand-annotated alignments are outside of the block ITG model class. Hence, we update toward the extraction set for a pseudo-gold alignment $\mathcal{A}_g \in \text{ITG}(\mathbf{e}, \mathbf{f})$ with minimal distance from the true reference alignment $\mathcal{A}_t$.

$$\mathcal{A}_g = \arg\min_{\mathcal{A} \in \text{ITG}(\mathbf{e},\mathbf{f})} |\mathcal{A} \cup \mathcal{A}_t - \mathcal{A} \cap \mathcal{A}_t| \quad (3)$$

Inference details appear in Section 4.3.

Given $\mathcal{A}_g$ and $\mathcal{A}_m$, we update the model parameters away from $\mathcal{A}_m$ and toward $\mathcal{A}_g$.

$$\theta \leftarrow \theta + \tau \cdot (\phi(\mathcal{A}_g) - \phi(\mathcal{A}_m))$$

where τ is the minimal step size that will ensure we prefer $\mathcal{A}_g$ to $\mathcal{A}_m$ by a margin greater than the loss $L(\mathcal{A}_m; \mathcal{A}_g)$, capped at some maximum update size C to provide regularization. We use $C = 0.01$ in experiments. The step size is a closed form function of the loss and feature vectors: $\tau =$

$$\min\left(C, \frac{L(\mathcal{A}_m; \mathcal{A}_g) - \theta \cdot (\phi(\mathcal{A}_g) - \phi(\mathcal{A}_m))}{||\phi(\mathcal{A}_g) - \phi(\mathcal{A}_m)||_2^2}\right)$$

We train the model for 30 iterations over the training set, shuffling the order each time, and we average the weight vectors observed after each iteration to estimate our final model.

3.1 Extraction Set Loss Function

In order to focus learning on predicting the right bispans, we use an extraction-level loss $L(\mathcal{A}_m; \mathcal{A}_g)$: an F-measure of the overlap between bispans in $R_n(\mathcal{A}_m)$ and $R_n(\mathcal{A}_g)$. This measure has been proposed previously to evaluate alignment systems (Ayan and Dorr, 2006). Based on preliminary translation results during development, we chose bispan F_5 as our loss:

$$\text{Pr}(\mathcal{A}_m) = |R_n(\mathcal{A}_m) \cap R_n(\mathcal{A}_g)|/|R_n(\mathcal{A}_m)|$$
$$\text{Rc}(\mathcal{A}_m) = |R_n(\mathcal{A}_m) \cap R_n(\mathcal{A}_g)|/|R_n(\mathcal{A}_g)|$$
$$\text{F}_5(\mathcal{A}_m; \mathcal{A}_g) = \frac{(1+5^2) \cdot \text{Pr}(\mathcal{A}_m) \cdot \text{Rc}(\mathcal{A}_m)}{5^2 \cdot \text{Pr}(\mathcal{A}_m) + \text{Rc}(\mathcal{A}_m)}$$
$$L(\mathcal{A}_m; \mathcal{A}_g) = 1 - \text{F}_5(\mathcal{A}_m; \mathcal{A}_g)$$

F_5 favors recall over precision. Previous alignment work has shown improvements from adjusting the F-measure parameter (Fraser and Marcu, 2006). In particular, Lacoste-Julien et al. (2006) also chose a recall-biased objective.

Optimizing for a bispan F-measure penalizes alignment mistakes in proportion to their rule extraction consequences. That is, adding a word link that prevents the extraction of many correct phrasal rules, or which licenses many incorrect rules, is strongly discouraged by this loss.

3.2 Features on Extraction Sets

The discriminative power of our model is driven by the features on sure word alignment links $\phi_a(i, j)$ and bispans $\phi_b(g, h, k, \ell)$. In both cases, the most important features come from the predictions of unsupervised models trained on large parallel corpora, which provide frequency and co-occurrence information.

To score word-to-word links, we use the posterior predictions of a jointly trained HMM alignment model (Liang et al., 2006). The remaining features include a dictionary feature, an identical word feature, an absolute position distortion feature, and features for numbers and punctuation.

To score phrasal translation rules in an extraction set, we use a mixture of feature types. Extraction set models allow us to incorporate the same phrasal relative frequency statistics that drive phrase-based translation performance (Koehn et al., 2003). To implement these frequency features, we extract a phrase table from the alignment predictions of a jointly trained unsupervised HMM model using Moses (Koehn et al., 2007), and score bispans using the resulting features. We also include indicator features on lexical templates for the 50 most common words in each language, as in Haghighi et al. (2009). We include indicators for the number of words and Chinese characters in rules. One useful indicator feature exploits the fact that capitalized terms in English tend to align to Chinese words with three or more characters. On 1-by-n or n-by-1 phrasal rules, we include indicator features of fertility for common words.[3]

We also include monolingual phrase features that expose useful information to the model. For instance, English bigrams beginning with "the" are often extractable phrases. English trigrams with a hyphen as the second word are typically extractable, meaning that the first and third words align to consecutive Chinese words. When any conjugation of the word "to be" is followed by a verb, indicating passive voice or progressive tense, the two words tend to align together.

Our feature set also includes bias features on phrasal rules and links, which control the number of null-aligned words and number of rules licensed. In total, our final model includes 4,249 individual features, dominated by various instantiations of lexical templates.

[3]Limiting lexicalized features to common words helps prevent overfitting.

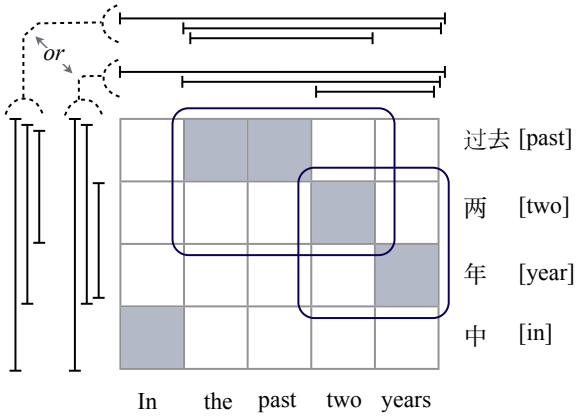

Figure 5: Both possible ITG decompositions of this example alignment will split one of the two highlighted bispans across constituents.

4 Model Inference

Equation 2 asks for the highest scoring extraction set under our model, $R_n(\mathcal{A}_m)$, which we also require at test time. Although we have restricted $\mathcal{A}_m \in \text{ITG}(\mathbf{e}, \mathbf{f})$, our extraction set model does not factor over ITG productions, and so the dynamic program for a vanilla block ITG will not suffice to find $R_n(\mathcal{A}_m)$. To see this, consider the extraction set in Figure 5. An ITG decomposition of the underlying alignment imposes a hierarchical bracketing on each sentence, and some bispan in the extraction set for this alignment will cross any such bracketing. Hence, the score of some licensed bispan will be non-local to the ITG decomposition.

4.1 A Dynamic Program for Extraction Sets

If we treat the maximum phrase length n as a fixed constant, then we can define a dynamic program to search the space of extraction sets. An ITG derivation for some alignment $\mathcal{A}$ decomposes into two sub-derivations for $\mathcal{A}_L$ and $\mathcal{A}_R$.[4] The model score of $\mathcal{A}$, which scores extraction set $R_n(\mathcal{A})$, decomposes over $\mathcal{A}_L$ and $\mathcal{A}_R$, along with any phrasal bispans licensed by adjoining $\mathcal{A}_L$ and $\mathcal{A}_R$.

$$\theta \cdot \phi(\mathcal{A}) = \theta \cdot \phi(\mathcal{A}_L) + \theta \cdot \phi(\mathcal{A}_R) + I(\mathcal{A}_L, \mathcal{A}_R)$$

where $I(\mathcal{A}_L, \mathcal{A}_R)$ is $\theta \cdot \sum \phi(g, h, k, l)$ summed over licensed bispans $[g, h) \Leftrightarrow [k, \ell)$ that overlap the boundary between $\mathcal{A}_L$ and $\mathcal{A}_R$.[5]

[4]We abuse notation in conflating an alignment $\mathcal{A}$ with its derivation. All derivations of the same alignment receive the same score, and we only compute the max, not the sum.

[5]We focus on the case of adjoining two aligned bispans. Our algorithm easily extends to include null alignments, but we focus on the non-null setting for simplicity.

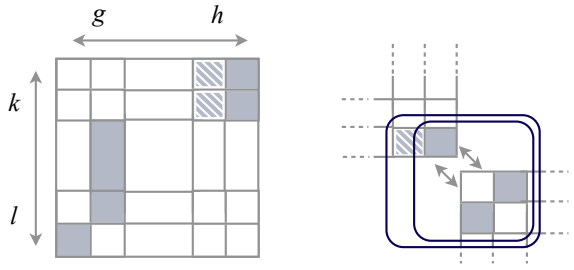

Figure 6: Augmenting the ITG grammar states with the alignment configuration in an $n-1$ deep perimeter of the bispan allows us to score all overlapping phrasal rules introduced by adjoining two bispans. The state must encode whether a sure link appears in each edge column or row, but the specific location of edge links is not required.

In order to compute $I(\mathcal{A}_L, \mathcal{A}_R)$, we need certain information about the alignment configurations of $\mathcal{A}_L$ and $\mathcal{A}_R$ where they adjoin at a corner. The state must represent (a) the specific alignment links in the $n-1$ deep corner of each $\mathcal{A}$, and (b) whether any sure alignments appear in the rows or columns extending from those corners.[6] With this information, we can infer the bispans licensed by adjoining $\mathcal{A}_L$ and $\mathcal{A}_R$, as in Figure 6.

Applying our score recurrence yields a polynomial-time dynamic program. This dynamic program is an instance of ITG bitext parsing, where the grammar uses symbols to encode the alignment contexts described above. This context-as-symbol augmentation of the grammar is similar in character to augmenting symbols with lexical items to score language models during hierarchical decoding (Chiang, 2007).

4.2 Coarse-to-Fine Inference and Pruning

Exhaustive inference under an ITG requires $O(k^6)$ time in sentence length k, and is prohibitively slow when there is no sparsity in the grammar. Maintaining the context necessary to score non-local bispans further increases running time. That is, ITG inference is organized around search states associated with a grammar symbol and a bispan; augmenting grammar symbols also augments this state space.

To parse quickly, we prune away search states using predictions from the more efficient HMM alignment model (Ney and Vogel, 1996). We discard all states corresponding to bispans that are incompatible with 3 or more alignment links under an intersected HMM—a proven approach to pruning the space of ITG alignments (Zhang and Gildea, 2006; Haghighi et al., 2009). Pruning in this way reduces the search space dramatically, but only rarely prohibits correct alignments. The oracle alignment error rate for the block ITG model class is 1.4%; the oracle alignment error rate for this pruned subset of ITG is 2.0%.

To take advantage of the sparsity that results from pruning, we use an agenda-based parser that orders search states from small to large, where we define the size of a bispan as the total number of words contained within it. For each size, we maintain a separate agenda. Only when the agenda for size k is exhausted does the parser proceed to process the agenda for size $k+1$.

We also employ coarse-to-fine search to speed up inference (Charniak and Caraballo, 1998). In the coarse pass, we search over the space of ITG alignments, but score only features on alignment links and bispans that are local to terminal blocks. This simplification eliminates the need to augment grammar symbols, and so we can exhaustively explore the (pruned) space. We then compute outside scores for bispans under a max-sum semiring (Goodman, 1996). In the fine pass with the full extraction set model, we impose a maximum size of 10,000 for each agenda. We order states on agendas by the sum of their inside score under the full model and the outside score computed in the coarse pass, pruning all states not within the fixed agenda beam size.

Search states that are popped off agendas are indexed by their corner locations for fast look-up when constructing new states. For each corner and size combination, built states are maintained in sorted order according to their inside score. This ordering allows us to stop combining states early when the results are falling off the agenda beams. Similar search and beaming strategies appear in many decoders for machine translation (Huang and Chiang, 2007; Koehn and Haddow, 2009; Moore and Quirk, 2007).

4.3 Finding Pseudo-Gold ITG Alignments

Equation 3 asks for the block ITG alignment $\mathcal{A}_g$ that is closest to a reference alignment $\mathcal{A}_t$, which may not lie in ITG(**e**,**f**). We search for

[6] The number of configuration states does not depend on the size of $\mathcal{A}$ because corners have fixed size, and because the position of links within rows or columns is not needed.

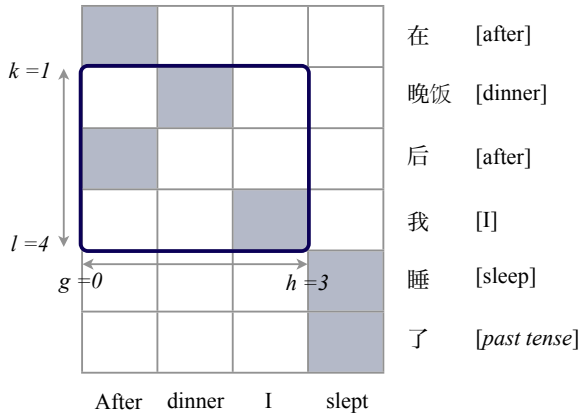

Figure 7: A* search for pseudo-gold ITG alignments uses an admissible heuristic for bispans that counts the number of gold links outside of $[k, \ell)$ but within $[g, h)$. Above, the heuristic is 1, which is also the minimal number of alignment errors that an ITG alignment will incur using this bispan.

$\mathcal{A}_g$ using A* bitext parsing (Klein and Manning, 2003). Search states, which correspond to bispans $[g, h) \Leftrightarrow [k, \ell)$, are scored by the number of errors within the bispan plus the number of $(i, j) \in A_t$ such that $j \in [k, \ell)$ but $i \notin [g, h)$ (recall errors). As an admissible heuristic for the future cost of a bispan $[g, h) \Leftrightarrow [k, \ell)$, we count the number of $(i, j) \in \mathcal{A}_t$ such that $i \in [g, h)$ but $j \notin [k, \ell)$, as depicted in Figure 7. These links will become recall errors eventually. A* search with this heuristic makes no errors, and the time required to compute pseudo-gold alignments is negligible.

5 Relationship to Previous Work

Our model is certainly not the first alignment approach to include structures larger than words. Model-based phrase-to-phrase alignment was proposed early in the history of phrase-based translation as a method for training translation models (Marcu and Wong, 2002). A variety of unsupervised models refined this initial work with priors (DeNero et al., 2008; Blunsom et al., 2009) and inference constraints (DeNero et al., 2006; Birch et al., 2006; Cherry and Lin, 2007; Zhang et al., 2008). These models fundamentally differ from ours in that they stipulate a segmentation of the sentence pair into phrases, and only align the minimal phrases in that segmentation. Our model scores the larger overlapping phrases that result from composing these minimal phrases.

Discriminative alignment is also a well-explored area. Most work has focused on predicting word alignments via partial matching inference algorithms (Melamed, 2000; Taskar et al., 2005; Moore, 2005; Lacoste-Julien et al., 2006). Work in semi-supervised estimation has also contributed evidence that hand-annotations are useful for training alignment models (Fraser and Marcu, 2006; Fraser and Marcu, 2007). The ITG grammar formalism, the corresponding word alignment class, and inference procedures for the class have also been explored extensively (Wu, 1997; Zhang and Gildea, 2005; Cherry and Lin, 2007; Zhang et al., 2008). At the intersection of these lines of work, discriminative ITG models have also been proposed, including one-to-one alignment models (Cherry and Lin, 2006) and block models (Haghighi et al., 2009). Our model directly extends this research agenda with first-class possible links, overlapping phrasal rule features, and an extraction-level loss function.

Kääriäinen (2009) trains a *translation* model discriminatively using features on overlapping phrase pairs. That work differs from ours in that it uses fixed word alignments and focuses on translation model estimation, while we focus on alignment and translate using standard relative frequency estimators.

Deng and Zhou (2009) present an alignment combination technique that uses phrasal features. Our approach differs in two ways. First, their approach is tightly coupled to the input alignments, while we perform a full search over the space of ITG alignments. Also, their approach uses greedy search, while our search is optimal aside from pruning and beaming. Despite these differences, their strong results reinforce our claim that phrase-level information is useful for alignment.

6 Experiments

We evaluate our extraction set model by the bispans it predicts, the word alignments it generates, and the translations generated by two end-to-end systems. Table 1 compares the five systems described below, including three baselines. All supervised aligners were optimized for bispan F_5.

Unsupervised Baseline: GIZA++. We trained GIZA++ (Och and Ney, 2003) using the default parameters included with the Moses training script (Koehn et al., 2007). The designated regimen concludes by Viterbi aligning under Model 4 in both directions. We combined these alignments with

the *grow-diag* heuristic (Koehn et al., 2003).

Unsupervised Baseline: Joint HMM. We trained and combined two HMM alignment models (Ney and Vogel, 1996) using the Berkeley Aligner.[7] We initialized the HMM model parameters with jointly trained Model 1 parameters (Liang et al., 2006), combined word-to-word posteriors by averaging (soft union), and decoded with the competitive thresholding heuristic of DeNero and Klein (2007), yielding a state-of-the-art unsupervised baseline.

Supervised Baseline: Block ITG. We discriminatively trained a block ITG aligner with only sure links, using block terminal productions up to 3 words by 3 words in size. This supervised baseline is a reimplementation of the MIRA-trained model of Haghighi et al. (2009). We use the same features and parser implementation for this model as we do for our extraction set model to ensure a clean comparison. To remain within the alignment class, MIRA updates this model toward a pseudo-gold alignment with only sure links. This model does not score any overlapping bispans.

Extraction Set Coarse Pass. We add possible links to the output of the block ITG model by adding the mixed terminal block productions described in Section 2.3. This model scores overlapping phrasal rules contained within terminal blocks that result from including or excluding possible links. However, this model does not score bispans that cross bracketing of ITG derivations.

Full Extraction Set Model. Our full model includes possible links and features on extraction sets for phrasal bispans with a maximum size of 3. Model inference is performed using the coarse-to-fine scheme described in Section 4.2.

6.1 Data

In this paper, we focus exclusively on Chinese-to-English translation. We performed our discriminative training and alignment evaluations using a hand-aligned portion of the NIST MT02 test set, which consists of 150 training and 191 test sentences (Ayan and Dorr, 2006). We trained the baseline HMM on 11.3 million words of FBIS newswire data, a comparable dataset to those used in previous alignment evaluations on our test set (DeNero and Klein, 2007; Haghighi et al., 2009).

[7] http://code.google.com/p/berkeleyaligner

Our end-to-end translation experiments were tuned and evaluated on sentences up to length 40 from the NIST MT04 and MT05 test sets. For these experiments, we trained on a 22.1 million word parallel corpus consisting of sentences up to length 40 of newswire data from the GALE program, subsampled from a larger data set to promote overlap with the tune and test sets. This corpus also includes a bilingual dictionary. To improve performance, we retrained our aligner on a retokenized version of the hand-annotated data to match the tokenization of our corpus.[8] We trained a language model with Kneser-Ney smoothing on 262 million words of newswire using SRILM (Stolcke, 2002).

6.2 Word and Phrase Alignment

The first panel of Table 1 gives a word-level evaluation of all five aligners. We use the alignment error rate (AER) measure: precision is the fraction of sure links in the system output that are sure or possible in the reference, and recall is the fraction of sure links in the reference that the system outputs as sure. For this evaluation, possible links produced by our extraction set models are ignored. The full extraction set model performs the best by a small margin, although it was not tuned for word alignment.

The second panel gives a phrasal rule-level evaluation, which measures the degree to which these aligners matched the extraction sets of hand-annotated alignments, $R_3(\mathcal{A}_t)$.[9] To compete fairly, all models were evaluated on the full extraction sets induced by the word alignments they predicted. Again, the extraction set model outperformed the baselines, particularly on the F_5 measure for which these systems were trained.

Our coarse pass extraction set model performed nearly as well as the full model. We believe these models perform similarly for two reasons. First, most of the information needed to predict an extraction set can be inferred from word links and phrasal rules contained within ITG terminal productions. Second, the coarse-to-fine inference may be constraining the full phrasal model to predict similar output to the coarse model. This similarity persists in translation experiments.

[8] All alignment results are reported under the annotated data set's original tokenization.

[9] While pseudo-gold approximations to the annotation were used for training, the evaluation is always performed relative to the original human annotation.

		Word			Bispan				BLEU	
		Pr	Rc	AER	Pr	Rc	F_1	F_5	Joshua	Moses
Baseline models	GIZA++	72.5	71.8	27.8	69.4	45.4	54.9	46.0	33.8	32.6
	Joint HMM	84.0	76.9	19.6	69.5	59.5	64.1	59.9	34.5	33.2
	Block ITG	83.4	83.8	16.4	**75.8**	62.3	68.4	62.8	34.7	33.6
Extraction set models	Coarse Pass	82.2	**84.2**	16.9	70.0	72.9	71.4	72.8	35.7	34.2
	Full Model	**84.7**	84.0	**15.6**	69.0	**74.2**	**71.6**	**74.0**	**35.9**	**34.4**

Table 1: Experimental results demonstrate that the full extraction set model outperforms supervised and unsupervised baselines in evaluations of word alignment quality, extraction set quality, and translation. In *word* and *bispan* evaluations, GIZA++ did not have access to a dictionary while all other methods did. In the *BLEU* evaluation, all systems used a bilingual dictionary included in the training corpus. The *BLEU* evaluation of supervised systems also included rule counts from the Joint HMM to compensate for parse failures.

6.3 Translation Experiments

We evaluate the alignments predicted by our model using two publicly available, open-source, state-of-the-art translation systems. Moses is a phrase-based system with lexicalized reordering (Koehn et al., 2007). Joshua (Li et al., 2009) is an implementation of Hiero (Chiang, 2007) using a suffix-array-based grammar extraction approach (Lopez, 2007).

Both of these systems take word alignments as input, and neither of these systems accepts possible links in the alignments they consume. To interface with our extraction set models, we produced three sets of sure-only alignments from our model predictions: one that omitted possible links, one that converted all possible links to sure links, and one that includes each possible link with 0.5 probability. These three sets were aggregated and rules were extracted from all three.

The training set we used for MT experiments is quite heterogenous and noisy compared to our alignment test sets, and the supervised aligners did not handle certain sentence pairs in our parallel corpus well. In some cases, pruning based on consistency with the HMM caused parse failures, which in turn caused training sentences to be skipped. To account for these issues, we added counts of phrasal rules extracted from the baseline HMM to the counts produced by supervised aligners.

In Moses, our extraction set model predicts the set of phrases extracted by the system, and so the estimation techniques for the alignment model and translation model both share a common underlying representation: extraction sets. Empirically, we observe a BLEU score improvement of 1.2 over the best unsupervised baseline and 0.8 over the block ITG supervised baseline (Papineni et al., 2002).

In Joshua, hierarchical rule extraction is based upon phrasal rule extraction, but abstracts away sub-phrases to create a grammar. Hence, the extraction sets we predict are closely linked to the representation that this system uses to translate. The extraction model again outperformed both unsupervised and supervised baselines, by 1.4 BLEU and 1.2 BLEU respectively.

7 Conclusion

Our extraction set model serves to coordinate the alignment and translation model components of a statistical translation system by unifying their representations. Moreover, our model provides an effective alternative to phrase alignment models that choose a particular phrase segmentation; instead, we predict many overlapping phrases, both large and small, that are mutually consistent. In future work, we look forward to developing extraction set models for richer formalisms, including hierarchical grammars.

Detecting Experiences from Weblogs

Abstract

Weblogs are a source of human activity knowledge comprising valuable information such as facts, opinions and personal experiences. In this paper, we propose a method for mining personal experiences from a large set of weblogs. We define experience as knowledge embedded in a collection of activities or events which an individual or group has actually undergone. Based on an observation that experience-revealing sentences have a certain linguistic style, we formulate the problem of detecting experience as a classification task using various features including tense, mood, aspect, modality, experiencer, and verb classes. We also present an activity verb lexicon construction method based on theories of lexical semantics. Our results demonstrate that the activity verb lexicon plays a pivotal role among selected features in the classification performance and shows that our proposed method outperforms the baseline significantly.

1 Introduction

In traditional philosophy, human beings are known to acquire knowledge mainly by reasoning and experience. Reasoning allows us to draw a conclusion based on evidence, but people tend to believe it firmly when they experience or observe it in the physical world. Despite the fact that direct experiences play a crucial role in making a firm decision and solving a problem, people often resort to indirect experiences by reading written materials or asking around. Among many sources people resort to, the Web has become the largest one for human experiences, especially with the proliferation of weblogs.

While Web documents contain various types of information including facts, encyclopedic knowledge, opinions, and experiences in general, personal experiences tend to be found in weblogs more often than other web documents like news articles, home pages, and scientific papers. As such, we have begun to see some research efforts in mining experience-related attributes such as time, location, topic, and experiencer, and their relations from weblogs (Inui et al., 2008; Kurashima et al., 2009).

Mined experiences can be of practical use in wide application areas. For example, a collection of experiences from the people who visited a resort area would help planning what to do and how to do things correctly without having to spend time sifting through a variety of resources or rely on commercially-oriented sources. Another example would be a public service department gleaning information about how a park is being used at a specific location and time.

Experiences can be recorded around a frame like "who did what, when, where, and why" although opinions and emotions can be also linked. Therefore attributes such as location, time, and activity and their relations must be extracted by devising a method for selecting experience-containing sentences based on verbs that have a particular linguistics case frame or belong to a "do" class (Kurashima et al., 2009). However, this kind of method may extract the following sentences as containing an experience:

[1] If Jason arrives on time, I'll buy him a drink.
[2] Probably, she will laugh and dance in his funeral.
[3] Can anyone explain what is going on here?
[4] Don't play soccer on the roads!

None of the sentences contain actual experiences because hypotheses, questions, and orders have not actually happened in the real world. For experience mining, it is important to ensure a sentence mentions an event or passes a factuality test to contain experience (Inui et al., 2008).

In this paper, we focus on the problem of detecting experiences from weblogs. We formulate

Uppsala, Sweden, 11-16 July 2010.

Class	Examples
State	like, know, believe
Activity	run, swim, walk
Achievement	recognize, realize
Accomplishment	paint (a picture), build (a house)

Table 1. Vendler class examples

the problem as a classification task using various linguistic features including tense, mood, aspect, modality, experiencer, and verb classes.

Based on our observation that experience-revealing sentences tend to have a certain linguistic style (Jijkoun et al., 2010), we investigate on the roles of various features. The ability to detect experience-revealing sentences should be a precursor for ensuring the quality of extracting various elements of actual experiences.

Another issue addressed in this paper is automatic construction of a lexicon for verbs related to activities and events. While there have been well-known studies about classifying verbs based on aspectual features (Vendler, 1967), thematic roles and selectional restrictions (Fillmore, 1968; Somers, 1987; Kipper et al., 2008), valence alternations and intuitions (Levin, 1993) and conceptual structures (Fillmore and Baker, 2001), we found that none of the existing lexical resources such as Framenet (Baker et al., 2003) and Verbnet (Kipper et al., 2008) are sufficient for identifying experience-revealing verbs. We introduce a method for constructing an activity/event verb lexicon based on Vendler's theory and statistics obtained by utilizing a web search engine.

We define *experience* as knowledge embedded in a collection of activities or events which an individual or group has actually undergone[1]. It can be subjective as in opinions as well as objective, but our focus in this article lies in objective knowledge. The following sentences contain objective experiences:

[5] I ran with my wife 3 times a week until we moved to Washington, D.C.
[6] Jane and I hopped on a bus into the city centre.
[7] We went to a restaurant near the central park.

Whereas sentences like the following contain subjective knowledge:

[8] I like your new style. You're beautiful!
[9] The food was great, the interior too.

Subject knowledge has been studied extensively for various functions such as identification, polarity detection, and holder extraction under the names of opinion mining and sentiment analysis (Pang and Lee, 2008).

In summary, our contribution lies in three aspects: 1) conception of experience detection, which is a precursor for experience mining, and specific related tasks that can be tackled with a high performance machine learning based solution; 2) examination and identification of salient linguistic features for experience detection; 3) a novel lexicon construction method with identification of key features to be used for verb classification.

The remainder of the paper is organized as follows. Section 2 presents our lexicon construction method with experiments. Section 3 describes the experience detection method, including experimental setup, evaluation, and results. In Section 4, we discuss related work, before we close with conclusion and future work in Section 5.

2 Lexicon Construction

Since our definition of experience is based on activities and events, it is critical to determine whether a sentence contains a predicate describing an activity or an event. To this end, it is quite conceivable that a lexicon containing activity / event verbs would play a key role. Given that our ultimate goal is to extract experiences from a large amount of weblogs, we opt for increased coverage by automatically constructing a lexicon rather than high precision obtainable by manually crafted lexicon.

Based on the theory of Vendler (1967), we classify a given verb or a verb phrase into one of the two categories: *activity* and *state*. We consider all the verbs and verb phrases in WordNet (Fellbaum, 1998) which is the largest electronic lexical database. In addition to the linguistic schemata features based on Vendler's theory, we used thematic role features and an external knowledge feature.

2.1 Background

Vendler (1967) proposes that verb meanings can be categorized into four basic classes, *states, activities, achievements*, and *accomplishments,* depending on interactions between the verbs and their aspectual and temporal modifiers. Table 1 shows some examples for the classes.

Vendler (1967) and Dowty (1979) introduce linguistic schemata that serve as evidence for the classes.

[1] http://en.wikipedia.org/wiki/Experience_(disambiguation)

Linguistic Schemata	*bs*	*prs*	*prp*	*pts*	*ptp*
No schema	■	■	■	■	■
Progressive			■		
Force	■				
Persuade	■				
Stop			■		
For	■	■	■	■	■
Carefully	■	■	■	■	■

Table 2. Query matrix. The "■" indicates that the query is applied. *No Schema* indicates that no schema is applied when the word itself is a query. *bs, prs, prp, pts, ptp* correspond to base form, present simple (3rd person singular), present participle, past simple and past participle, respectfully.

Below are the six schemata we chose because they can be tested automatically: *progressive*, *force*, *persuade*, *stop*, *for,* and *carefully* (An asterisk denotes that the statement is awkward).

- *States* cannot occur in *progressive* tense:
  John is running.
  John is liking.*
- *States* cannot occur as complements of *force* and *persuade*:
  John forced harry to run.
  John forced harry to know.*
  John persuaded harry to know.*
- *Achievements* cannot occur as complements of *stop*:
  John stopped running.
  John stopped realizing.*
- *Achievements* cannot occur with time adverbial *for*:
  John ran for an hour.
  John realized for an hour.*
- *State* and *achievement* cannot occur with adverb *carefully*:
  John runs carefully.
  John knows carefully.*

The schemata are not perfect because verbs can shift classes due to various contextual factors such as arguments and senses. However, a verb certainly has its fundamental class that is its most *natural* category at least in its dominant use.

The four classes can further be grouped into two genuses: a genus of processes going on in time and the other that refers to non-processes. *Activity* and *accomplishment* belong to the former whereas *state* and *achievement* belong to the latter. As can be seen in table 1, *states* are rather immanent operations and *achievements* are those occur in a single moment or operations related to perception level. On the other hand, *activity* and *accomplishment* are processes (transeunt operations) in traditional philosophy. We henceforth call the first genus *activity* and the latter *state.* Our aim is to classify verbs into the two genuses.

2.2 Features based on Linguistic Schemata

We developed a relatively simple computational testing method for the schemata. Assuming that an awkward expression like, "John is liking something" won't occur frequently, for example, we generated a co-occurrence based test for the first linguistic schema using the Web as a corpus. By issuing a search query, *((be OR am OR is OR was OR were OR been) and ? ing)* where '?' represents the verb at hand, to a search engine, we can get an estimate about how the verb is likely to belong to *state*. A test can be generated for each of the schemata in a similar way.

For completeness, we considered all the verb forms (i.e., 3rd person singular present, present participle, simple past, past participle) available. However, some of the patterns cannot be applied to some forms. For example, other forms except the base form cannot come as a complement of *force* (e.g., force to runs.*). Therefore, we created a query matrix which represents all query patterns we have applied, in table 2.

Based on the query matrix in table 2, we issued queries for all the verbs and verb phrases from WordNet to a search engine. We used the Google news archive search for two reasons. First, since news articles are written rather formally compared to weblogs and other web pages, the statistics obtained for a test would be more reliable. Second, Google provides an advanced option to retrieve snippets containing the query word. Normally, a snippet is composed of 3~5 sentences.

The basic statistics we consider are *hit count*, *candidate sentence count* and *correct sentence count* which we use the notations $H_{ij}(w)$, $S_{ij}(w)$, and $C_{ij}(w)$, respectfully, where w is a word, i the linguistic schema and j the verb form from the query matrix in table 2. $H_{ij}(w)$ was directly gathered from the Google search engine. $S_{ij}(w)$ is the number of sentences containing the word w in the search result snippets. $C_{ij}(w)$ is the number of correct sentences matching the query pattern among the candidate sentences. For example, the *progressive* schema for a verb "build" can retrieve the following sentences.

[10] …, New-York, is building one of the largest …
[11] Is building an artifact?

"Building" in the first example is a progressive verb, but the one in second is a noun, which does not satisfy the linguistic schema. For a POS and grammatical check of a candidate sentence, we used the Stanford POS tagger (Toutanova et al., 2003) and Stanford dependency parser (Klein and Manning, 2003).

For each linguistic schema, we derived three features: *Absolute hit ratio*, *Relative hit ratio* and *Valid ratio* for which we use the notations $A_i(w)$, $R_i(w)$ and $V_i(w)$, respectfully, where w is a word and i a linguistic schema. The index j for summations represents the j-th verb form. They are computed as follows.

$$A_i(w) = \frac{\sum_j H_{ij}(w)}{H_i(*)}$$

$$R_i(w) = \frac{\sum_j H_{ij}(w)}{\sum_j H_{No\,Scheme}(w)} \quad (1)$$

$$V_i(w) = \frac{\sum_j C_{ij}(w)}{\sum_j S_{ij}(w)}$$

Absolute hit ratio is computes the extent to which the target word w occurs with the i-th schema over all occurrences of the schema. The denominator is the *hit count* of wild card "*" matching any single word with the schema pattern from Google (e.g., $H_I(*)$, the progressive test *hit count* is 3.82×10^8). *Relative hit ratio* computes the extent to which the target word w occurs with the i-th schema over all occurrences of the word. The denominator is the sum of all verb forms. *Valid ratio* means the fraction of correct sentences among candidate sentences. The weight of a linguistic schema increases as the *valid ratio* gets high. With the three different ratios, $A_i(w)$, $R_i(w)$ and $V_i(w)$, for each test, we can generate a total of 18 features.

2.3 Features based on case frames

Since the hit count via Google API sometimes returns unreliable results (e.g., when the query becomes too long in case of long verb phrases), we also consider additional features. While our initial observation indicated that the existing lexical resources would not be sufficient for our goal, it occurred to us that the linguistic theory behind them would be worth exploring as generating additional features for categorizing verbs for the two classes. Consider the following examples:

[12] John(D) believed(V) the story(O).
[13] John(A) hit(V) him(O) with a bat(I).

The subject of a state verb is dative (D) as in [12] whereas the subject for an action verb takes the agent (A) role. In addition, a verb with the instrument (I) role tends to be an action verb. From these observations, we can use the distribution of cases (thematic roles) for a verb in a corpus. Activity verbs are expected to have high frequency of agent and instrument roles than state verbs. Although a verb may have more than one case frame, it is possible to determine which thematic roles used more dominantly.

We utilize two major resources of lexical semantics, Verbnet (Kipper et al., 2008) based on the theory of Levin (1993), and Framenet (Baker et al., 2003), which is based on Fillmore (1968). Levin (1993) demonstrated that syntactic alternations can be the basis for groupings of verbs semantically and accord reasonably well with linguistic intuitions. Verbnet provides 274 verb classes with 23 thematic roles covering 3,769 verbs based on their alternation behaviors with thematic roles annotated. Framenet defines 978 semantic frames with 7,124 unique semantic roles, covering 11,583 words including verbs, nouns, adverbs, etc.

Using Verbnet alone does not suit our needs because it has a relatively small number of example sentences. Framenet contains a much larger number of examples but the vast number of semantic roles presents a problem. In order to get meaningful distributions for a manageable number of thematic roles, we used Semlink (Loper et al., 2007) that provides a mapping between Framenet and Verbnet and uses a total of 23 thematic roles of Verbnet for the annotated corpora of the two resources. By the mapping, we obtained distributions of the thematic roles for 2,868 unique verbs that exist in both of the resources. For example, the verb "construct" has high frequencies with *agent*, *material* and *product* roles.

2.4 Features based on how-to instructions

Ryu et al. (2010) presented a method for extracting action steps for how-to goals from eHow[2] a website containing a large number of how-to instructions. The authors attempted to extract actions comprising a verb and some ingredients like an object entity from the documents based on syntactic patterns and a CRF based model.

Since each extracted action has its probability, we can use the value as a feature for state / activity verb classification. However, a verb may appear in different contexts and can have multiple

[2] http://www.ehow.com

Feature	ME		SVM	
	Prec.	*Recall*	*Prec.*	*Recall*
All 43	68%	50%	83%	75%
Top 30	72%	52%	83%	75%
Top 20	83%	76%	85%	77%
Top 10	89%	88%	91%	78%

Table 3. Classification Performance

Class	Examples
Activity	act, battle, build, carry, chase, drive, hike, jump, kick, sky dive, tap dance, walk, …
State	admire, believe, know, like, love, …

Table 4. Classified Examples

probability values. To generate a single value for a verb, we combine multiple probability values using the following sigmoid function:

$$E(w) = \frac{1}{1+e^{-t}} \qquad t = \sum_{d \in D_w} P_d(w) \tag{2}$$

Evidence of a word w being an action in eHow is denoted as $E(w)$ where variable t is the sum of individual action probability values in D_w the set of documents from which the word w has been extracted as an action. The higher probability a word gets and the more frequent the word has been extracted as an action, the more evidence we get.

2.5 Classification

For training, we selected 80 seed verbs from Dowty's list (1979) which are representative verbs for each Vendler (1967) class. The selection was based on the lack of word sense ambiguity.

One of our classifiers is based on Maximum Entropy (ME) models that implement the intuition that the best model will be the one that is consistent with the set of constraints imposed by the evidence, but otherwise is as uniform as possible (Berger et al., 1996). ME models are widely used in natural language processing tasks for its flexibility to incorporate a diverse range of features. The other one is based on Support Vector Machine (Chang and Lin, 2001) which is the state-of-the-art algorithm for many classification tasks. We used RBF kernel with the default settings (Hsu et al., 2009) because it is been known to show moderate performance using multiple feature compositions.

The features we considered are a total of 42 real values: 18 from linguistic schemata, 23 thematic role distributions, and one from eHow. In order to examine which features are discriminative for the classification, we used two well known feature selection methods, Chi-square and information gain.

2.6 Results

Table 3 shows the classification performance values for different feature selection methods. The evaluation was done on the training data with 10-fold cross validation.

Note that the precision and recall are macro-averaged values across the two classes, *activity* and *state.* The most discriminative features were *absolute ratio* and *relative ratio* in conjunction with the *force, stop, progressive,* and *persuade* schemata, the role distribution of *experiencer*, and the eHow evidence.

It is noteworthy that eHow evidence and the distribution of *experiencer* got into the top 10. Other thematic roles did not perform well because of the data sparseness. Only a few roles (e.g., experience, agent, topic, location) among the 23 had frequency values other than 0 for many verbs. Data sparseness affected the linguistic schemata as well. Many of the verbs had zero hit counts for the *for* and *carefully* schemata. It is also interesting that the validity ratio $V_i(w)$ was not shown to be a good feature-generating statistic.

We finally trained our model with the top 10 features and classified all WordNet verbs and verb phrases. For actual construction of the lexicon, 11,416 verbs and verb phrases were classified into the two classes roughly equally. We randomly sampled 200 items and examined how accurately the classification was done. A total of 164 items were correctly classified, resulting in 82% accuracy. Some examples from the classification are shown in table 4.

A further analysis of the results show that most of the errors occurred with domain-specific verbs (e.g., *ablactate*, *alkalify*, and *transaminate* in chemistry) and multi-word verb phrases (e.g., *turn a nice dime; keep one's shoulder to the wheel*). Since many features are computed based on Web resources, rare verbs cannot be classified correctly when their hit rations are very low. The domain-specific words rarely appear in Framenet or e-how, either.

3 Experience Detection

As mentioned earlier, experience-revealing sentences tend to have a certain linguistic style.

Having converted the problem of experience detection for sentences to a classification task, we focus on the extent to which various linguistic features contribute to the performance of the binary classifier for sentences. We also explain the experimental setting for evaluation, including the classifier and the test corpus.

3.1 Linguistic features

In addition to the verb class feature available in the verb lexicon constructed automatically, we used tense, mood, aspect, modality, and experiencer features.

Verb class: The feature comes directly from the lexicon since a verb has been classified into a state or activity verb. The predicate part of the sentence to be classified for experience is looked up in the lexicon without sense disambiguation.

Tense: The tense of a sentence is important since an experience-revealing sentence tends to use past and present tense. Future tenses are not experiences in most cases. We use POS tagging (Toutanova et al., 2003) for tense determination, but since the Penn tagset provides no future tenses, they are determined by exploiting modal verbs such as "will" and future expressions such "going to".

Mood: It is one of distinctive forms that are used to signal the modal status of a sentence. We consider three mood categories: indicative, imperative and subjunctive. We determine the mood of a sentence by a small set of heuristic rules using the order of POS occurrences and punctuation marks.

Aspect: It defines the temporal flow of a verb in the activity or state. Two categories are used: *progressive* and *perfective*. This feature is determined by the POS of the predicate in a sentence.

Modality: In linguistics, modals are expressions broadly associated with notions of possibility. While modality can be classified at a fine level (e.g., epistemic and deontic), we simply determine whether or not a sentence includes a modal marker that is involved in the main predicate of the sentence. In other words, this binary feature is determined based on the existence of a model verb like "can", "shall", "must", and "may" or a phrase like "have to" or "need to". The dependency parser is used to ensure a modal marker is indeed associated with the main predicate.

Experiencer: A sentence can or cannot be treated as containing an experience depending on the subject or experiencer of the verb (note that this is different from the experiencer role in a case frame). Consider the following sentences:

[14] The stranger messed up the entire garden.
[15] His presence messed up the whole situation.

The first sentence is considered an experience since the subject is a person. However, the second sentence with the same verb is not, because the subject is a non-animate abstract concept. That is, a non-animate noun can hardly constitute an experience. In order to make a distinction, we use the dependency parser and a named-entity recognizer (Finkel et al., 2005) that can recognize person pronouns and person names.

3.2 Classification

To train our classifier, we first crawled weblogs from Wordpress[3], one of the most popular blog sites in use today. Worpress provides an interface to search blog posts with queries. In selecting experience-containing blog pots, we used location names such as Central Park, SOHO, Seoul and general place names such as airport, subway station, and restaurant because blog posts with some places are expected to describe experiences rather than facts or thoughts.

We crawled 6,000 blog posts. After deleting non-English and multi-media blog posts for which we could not obtain any meaningful text data, the number became 5,326. We randomly sampled 1,000 sentences[4] and asked three annotators to judge whether or not individual sentences are considered containing an experience based on our definition. For maximum accuracy, we decided to use only those sentences all the three annotators agreed, resulting in a total of 568 sentences.

While we tested several classifiers, we chose to use two different classifiers based on SVM and Logistic Regression for the final experimental results because they showed the best performance.

3.3 Results

For comparison purposes, we take the method of Kurashima et al. (2005) as our baseline because the method was used in subsequent studies (Kurashima et al., 2006; Kurashima et al., 2009) where experience attributes are extracted. We briefly describe the method and present how we implemented it.

The method first extracts all verbs and their dependent phrasal unit from candidate sentences.

[3] http://wordpress.com
[4] It was due to the limited human resources, but when we increased the number at a later stage, the performance increase was almost negligible.

Feature	Logistic Regression		SVM

Table 6. Experience Detection Performance without Individual Features

The candidate goes through three filters before it is treated as experience-containing sentence. First, the candidates that do not have an objective case (Fillmore, 1968) are eliminated because their definition of experience as "action + object". This was done by identifying the object-indicating particle (case marker) in Japanese. Next, the candidates belonging to "become" and "be" statements based on Japanese verb types are filtered out. Finally, the candidate sentences including a verb that indicates a movement are eliminated because the main interest was to identify an activity in a place.

Although their definition of experience is somewhat different from ours (i.e., "action + object"), they used the method to generate candidate sentences from which various experience attributes are extracted. From this perspective, the method functioned like our experience detection. Put differently, the definition and the method by which it is determined were much cruder than the one we are using, which seems close to our general understanding.[5]

The three filtering steps were implemented as follows. We used the dependency parser for extracting objective cases using the *direct object* relation. The second step, however, could not be applied because there is no grammatical distinction among "do, be, become" statements in English. We had to alter this step by adopting the approach of Inui et al. (2008). The authors propose a lexicon of experience expression by collecting hyponyms from a hierarchically structured dictionary. We collected all hyponyms of words "do" and "act", from WordNet (Fellbaum, 1998). Lastly, we removed all the verbs that are under the hierarchy of "move" from WordNet.

We not only compared our results with the baseline in terms of precision and recall but also evaluated individual features for their importance in experience detection (classification). The evaluation was conducted with 10-fold cross validation. The results are shown in table 5.

The performance, especially precision, of the baseline is much lower than those of the others. The method devised for Japanese doesn't seem suitable for English. It seems that the linguistic styles shown in experience expressions are different from each other. In addition, the lexicon we constructed for the baseline (i.e., using the WordNet) contains more errors than our activity lexicon for activity verbs. Some hyponyms of an activity verb may not be activity verbs. (e.g., "appear" is a hyponym of "do").

There is almost no difference between the Logistic Regression and SVM classifiers for our methods although SVM was inferior for the baseline. The performance for the best case with all the features included is very promising, closed to 92% precision and recall. Among the features, the lexicon, i.e., verb classes, gave the best result when each is used alone, followed by *modality*, *tense*, and *mood*. *Aspect* was the worst but close to the baseline. This result is very encouraging for the automatic lexicon construction work because the lexicon plays a pivotal role in the overall performance.

In order to see the effect of including individual features in the feature set, precision and recall were measured after eliminating a particular feature from the full set. The results are shown in table 6. Although the absence of the lexicon feature hurt the performance most badly, still the performance was reasonably high (roughly 84 % in precision and recall for the Logistic Regression case). Similar to table 5, the aspect and experience features were the least contributors as the performance drops are almost negligible.

[5] This is based on our observation that the three annotators found their task of identifying experience sentences not difficulty, resulting in a high degree of agreements.

4 Related Work

Experience mining in its entirety is a relatively new area where various natural language processing and text mining techniques can play a significant role. While opinion mining or sentiment analysis, which can be considered an important part of experience mining, has been studied quite extensively (see Pang and Lee's excellent survey (2008)), another sub-area, factuality analysis, begins to gain some popularity (Inui et al., 2008; Saurí, 2008). Very few studies have focused explicitly on extracting various entities that constitute experiences (Kurashima et al., 2009) or detecting experience-containing parts of text although many NLP research areas such as named entity recognition and verb classification are strongly related. The previous work on experience detection relies on a handcrafted lexicon.

There have been a number of studies for verb classification (Fillmore, 1968; Vendler, 1967; Somers, 1982; Levin, 1993; Fillmore and Baker, 2001; Kipper et al., 2008) that are essential for construction of an activity verb lexicon, which in turn is important for experience detection. Most similar to our work was done by Siegel and McKeown (2000), who attempted to categorize verbs into state or event classes based on 14 tests similar to those of Vendler's. They attempted to compute co-occurrence statistics from a corpus. The *event* class, however, includes *activity*, *accomplishment*, and *achievement*. Similarly, Zacrone and Lenci (2008) attempted to categorize verbs in Italian into the four Vendler classes using the Vendler tests by using a tagged corpus. They focused on existence of arguments such as subject and object that should co-occur with the linguistic features in the tests.

The main difference between the previous work and ours lies in the goal and scope of the work. Since our work is specifically geared toward domain-independent experience detection, we attempted to maximize the coverage by using all the verbs in WordNet, as opposed to the verbs appearing in a particular domain-specific corpus (e.g., medicine domain) as done in the previous work. Another difference is that while we are not limited to a particular domain, we did not use extensive human-annotated corpus other than using the 80 seed verbs and existing lexical resources.

5 Conclusion and Future Work

We defined experience detection as an essential task for experience mining, which is restated as determining whether individual sentences contain experience or not. Viewing the task as a classification problem, we focused on identification and examination of various linguistic features such as verb class, tense, aspect, mood, modality, and experience, all of which were computed automatically. For verb classes, in particular, we devised a method for classifying all the verbs and verb phrases in WordNet into the *activity* and *state* classes. The experimental results show that verb and verb phrase classification method is reasonably accurate with 91% precision and 78% recall with manually constructed gold standard consisting of 80 verbs and 82% accuracy for a random sample of all the WordNet entries. For experience detection, the performance was very promising, closed to 92% in precision and recall when all the features were used. Among the features, the verb classes, or the lexicon we constructed, contributed the most.

In order to increase the coverage even further and reduce the errors in lexicon construction, i.e., verb classification, caused by data sparseness, we need to devise a different method, perhaps using domain specific resources.

Given that experience mining is a relatively new research area, there are many areas to explore. In addition to refinements of our work, our next step is to develop a method for representing and extracting actual experiences from experience-revealing sentences. Furthermore, considering that only 13% of the blog data we processed contain experiences, an interesting extension is to apply the methodology to extract other types of knowledge such as facts, which are not necessarily experiences.

Abstract

Graph-based semi-supervised learning (SSL) algorithms have been successfully used to extract class-instance pairs from large unstructured and structured text collections. However, a careful comparison of different graph-based SSL algorithms on that task has been lacking. We compare three graph-based SSL algorithms for class-instance acquisition on a variety of graphs constructed from different domains. We find that the recently proposed MAD algorithm is the most effective. We also show that class-instance extraction can be significantly improved by adding semantic information in the form of instance-attribute edges derived from an independently developed knowledge base. All of our code and data will be made publicly available to encourage reproducible research in this area.

1 Introduction

Traditionally, named-entity recognition (NER) has focused on a small number of broad classes such as person, location, organization. However, those classes are too coarse to support important applications such as sense disambiguation, semantic matching, and textual inference in Web search. For those tasks, we need a much larger inventory of specific classes and accurate classification of terms into those classes. While supervised learning methods perform well for traditional NER, they are impractical for fine-grained classification because sufficient labeled data to train classifiers for all the classes is unavailable and would be very expensive to obtain.

To overcome these difficulties, seed-based information extraction methods have been developed over the years (Hearst, 1992; Riloff and Jones, 1999; Etzioni et al., 2005; Talukdar et al., 2006; Van Durme and Paşca, 2008). Starting with a few seed instances for some classes, these methods, through analysis of unstructured text, extract new instances of the same class. This line of work has evolved to incorporate ideas from graph-based semi-supervised learning in extraction from semi-structured text (Wang and Cohen, 2007), and in combining extractions from free text and from structured sources (Talukdar et al., 2008). The benefits of combining multiple sources have also been demonstrated recently (Pennacchiotti and Pantel, 2009).

We make the following contributions:

- Even though graph-based SSL algorithms have achieved early success in class-instance acquisition, there is no study comparing different graph-based SSL methods on this task. We address this gap with a series of experiments comparing three graph-based SSL algorithms (Section 2) on graphs constructed from several sources (Metaweb Technologies, 2009; Banko et al., 2007).
- We investigate whether semantic information in the form of instance-attribute edges derived from an independent knowledge base (Suchanek et al., 2007) can improve class-instance acquisition. The intuition behind this is that instances that share attributes are more likely to belong to the same class. We demonstrate that instance-attribute edges significantly improve the accuracy of class-instance extraction. In addition, useful class-attribute relationships are learned as a by-product of this process.
- In contrast to previous studies involving pro-

prietary datasets (Van Durme and Paşca, 2008; Talukdar et al., 2008; Pennacchiotti and Pantel, 2009), all of our experiments use publicly available datasets and we plan to release our code[1].

In Section 2, we review three graph-based SSL algorithms that are compared for the class-instance acquisition task in Section 3. In Section 3.6, we show how additional instance-attribute based semantic constraints can be used to improve class-instance acquisition performance. We summarize the results and outline future work in Section 4.

2 Graph-based SSL

We now review the three graph-based SSL algorithms for class inference over graphs that we have evaluated.

2.1 Notation

All the algorithms compute a soft assignment of labels to the nodes of a graph $G = (V, E, W)$, where V is the set of nodes with $|V| = n$, E is the set of edges, and W is an edge weight matrix. Out of the $n = n_l + n_u$ nodes in G, n_l nodes are labeled, while the remaining n_u nodes are unlabeled. If edge $(u, v) \notin E$, $W_{uv} = 0$. The (unnormalized) Laplacian, L, of G is given by $L = D - W$, where D is an $n \times n$ diagonal degree matrix with $D_{uu} = \sum_v W_{uv}$. Let S be an $n \times n$ diagonal matrix with $S_{uu} = 1$ iff node $u \in V$ is labeled. That is, S identifies the labeled nodes in the graph. C is the set of labels, with $|C| = m$ representing the total number of labels. Y is the $n \times m$ matrix storing training label information, if any. $\hat{Y}$ is an $n \times m$ matrix of soft label assignments, with $\hat{Y}_{vl}$ representing the score of label l on node v. A graph-based SSL computes $\hat{Y}$ from $\{G, SY\}$.

2.2 Label Propagation (LP-ZGL)

The label propagation method presented by Zhu et al. (2003), which we shall refer to as LP-ZGL in this paper, is one of the first graph-based SSL methods. The objective minimized by LP-ZGL is:

$$\min_{\hat{Y}} \sum_{l \in C} \hat{Y}_l^\top L \hat{Y}_l, \text{ s.t. } SY_l = S\hat{Y}_l \quad (1)$$

where $\hat{Y}_l$ of size $n \times 1$ is the l^{th} column of $\hat{Y}$. The constraint $SY = S\hat{Y}$ makes sure that the supervised labels are not changed during inference. The above objective can be rewritten as:

$$\sum_{l \in C} \hat{Y}_l^\top L \hat{Y}_l = \sum_{u,v \in V, l \in C} W_{uv} (\hat{Y}_{ul} - \hat{Y}_{vl})^2$$

From this, we observe that LP-ZGL penalizes any label assignment where two nodes connected by a highly weighted edge are assigned different labels. In other words, LP-ZGL prefers *smooth* labelings over the graph. This property is also shared by the two algorithms we shall review next. LP-ZGL has been the basis for much subsequent work in the graph-based SSL area, and is still one of the most effective graph-based SSL algorithms.

2.3 Adsorption

Adsorption (Baluja et al., 2008) is a graph-based SSL algorithm which has been used for open-domain class-instance acquisition (Talukdar et al., 2008). Adsorption is an iterative algorithm, where label estimates on node v in the $(t+1)^{\text{th}}$ iteration are updated using estimates from the t^{th} iteration:

$$\hat{Y}_v^{(t+1)} \leftarrow p_v^{inj} \times Y_v + p_v^{cont} \times B_v^{(t)} + p_v^{abnd} \times \mathbf{r} \quad (2)$$

where,

$$B_v^{(t)} = \sum_u \frac{W_{uv}}{\sum_{u'} W_{u'v}} \hat{Y}_u^{(t)}$$

In (2), $p_v^{inj}, p_v^{cont}, \text{and } p_v^{abnd}$ are three probabilities defined on each node $v \in V$ by Adsorption; and $\mathbf{r}$ is a vector used by Adsorption to express label uncertainty at a node. On each node v, the three probabilities sum to one, i.e., $p_v^{inj} + p_v^{cont} + p_v^{abnd} = 1$, and they are based on the random-walk interpretation of the Adsorption algorithm (Talukdar et al., 2008). The main idea of Adsorption is to control label propagation more tightly by limiting the amount of information that passes through a node. For instance, Adsorption can reduce the importance of a high-degree node v during the label inference process by increasing p_v^{abnd} on that node. For more details on these, please refer to Section 2 of (Talukdar and Crammer, 2009). In contrast to LP-ZGL, Adsorption allows labels on labeled (seed) nodes to change, which is desirable in case of noisy input labels.

[1] http://www.talukdar.net/datasets/class_inst/

2.4 Modified Adsorption (MAD)

Talukdar and Crammer (2009) introduced a modification of Adsorption called MAD, which shares Adsorption's desirable properties but can be expressed as an unconstrained optimization problem:

$$\min_{\hat{Y}} \quad \sum_{l \in C} \Big[\mu_1 \left(Y_l - \hat{Y}_l \right)^\top S \left(Y_l - \hat{Y}_l \right) + \mu_2 \hat{Y}_l^\top L' \hat{Y}_l + \mu_3 \left\| \hat{Y}_l - R_l \right\|^2 \Big] \quad (3)$$

where μ_1, μ_2, and μ_3 are hyperparameters; L' is the Laplacian of an undirected graph derived from G, but with revised edge weights; and R is an $n \times m$ matrix of per-node label prior, if any, with R_l representing the l^{th} column of R. As in Adsorption, MAD allows labels on seed nodes to change. In case of MAD, the three random-walk probabilities, p_v^{inj}, p_v^{cont}, and p_v^{abnd}, defined by Adsorption on each node are folded inside the matrices S, L', and R, respectively. The optimization problem in (3) can be solved with an efficient iterative algorithm described in detail by Talukdar and Crammer (2009).

These three algorithms are all easily parallelizable in a MapReduce framework (Talukdar et al., 2008; Rao and Yarowsky, 2009), which makes them suitable for SSL on large datasets. Additionally, all three algorithms have similar space and time complexity.

3 Experiments

We now compare the experimental performance of the three graph-based SSL algorithms reviewed in the previous section, using graphs constructed from a variety of sources described below. Following previous work (Talukdar et al., 2008), we use Mean Reciprocal Rank (MRR) as the evaluation metric in all experiments:

$$\text{MRR} = \frac{1}{|Q|} \sum_{v \in Q} \frac{1}{r_v} \quad (4)$$

where $Q \subseteq V$ is the set of test nodes, and r_v is the rank of the gold label among the labels assigned to node v. Higher MRR reflects better performance. We used iterative implementations of the graph-based SSL algorithms, and the number of iterations was treated as a hyperparameter which was tuned, along with other hyperparameters, on separate held-out sets, as detailed in a longer version of this paper. Statistics of the graphs used during experiments in this section are presented in Table 1.

3.1 Freebase-1 Graph with Pantel Classes

Table ID: people-person

...	...	...
Isaac Newton	Lincolnshire	Male
Bob Dylan	Duluth	Male
Johnny Cash	Kingsland	Male
...	...	...

Table ID: film-music_contributor

Name	Film_Music_Credits
...	...
Bob Dylan	No Direction Home
...	...

Figure 1: Examples of two tables from Freebase, one table is from the *people* domain while the other is from the *film* domain.

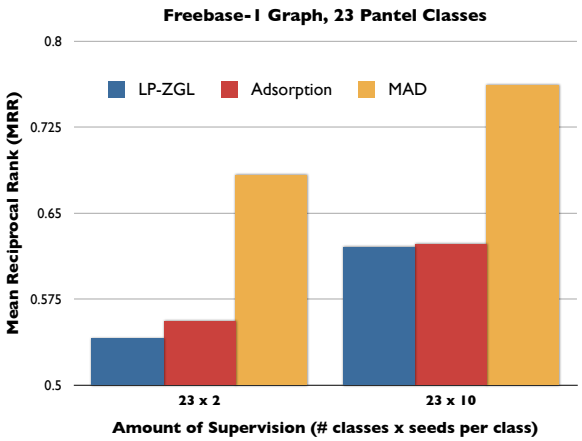

Figure 3: Comparison of three graph transduction methods on a graph constructed from the Freebase dataset (see Section 3.1), with 23 classes. All results are averaged over 4 random trials. In each group, MAD is the rightmost bar.

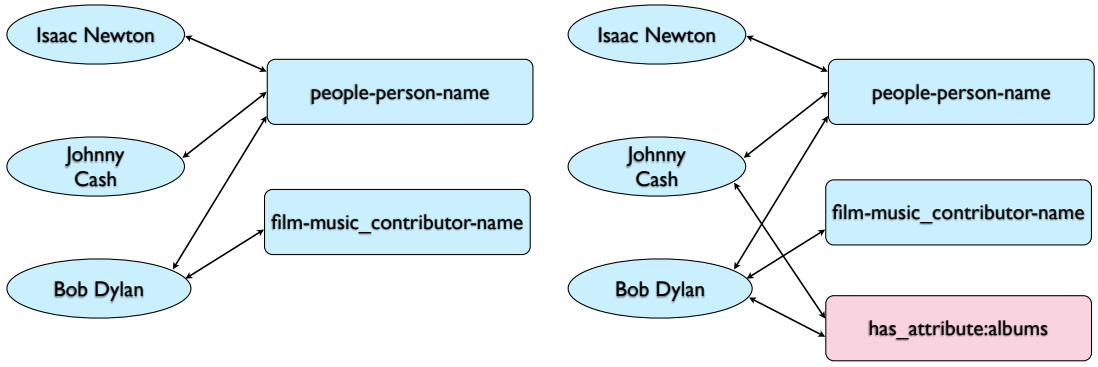
Freebase (Metaweb Technologies, 2009)[2] is a large collaborative knowledge base. The knowledge base harvests information from many open data sets (for instance Wikipedia and MusicBrainz), as well as from user contributions. For our current purposes, we can think of the Freebase

[2] http://www.freebase.com/

Graph	Vertices	Edges	Avg. Deg.	Min. Deg.	Max. Deg.
Freebase-1 (Section 3.1)	32970	957076	29.03	1	13222
Freebase-2 (Section 3.2)	301638	2310002	7.66	1	137553
TextRunner (Section 3.3)	175818	529557	3.01	1	2738
YAGO (Section 3.6)	142704	777906	5.45	0	74389
TextRunner + YAGO (Section 3.6)	237967	1307463	5.49	1	74389

Table 1: Statistics of various graphs used in experiments in Section 3. Some of the test instances in the YAGO graph, added for fair comparison with the TextRunner graph in Section 3.6, had no attributes in YAGO KB, and hence these instance nodes had degree 0 in the YAGO graph.



(a) (b)

Figure 2: (a) Example of a section of the graph constructed from the two tables in Figure 1. Rectangular nodes are properties, oval nodes are entities or cell values. (b) The graph in part (a) augmented with an attribute node, *has_attribue:albums*, along with the edges incident on it. This results is additional constraints for the nodes *Johnny Cash* and *Bob Dylan* to have similar labels (see Section 3.6).

dataset as a collection of relational tables, where each table is assigned a unique ID. A table consists of one or more *properties* (column names) and their corresponding *cell values* (column entries). Examples of two Freebase tables are shown in Figure 1. In this figure, *Gender* is a property in the table *people-person*, and *Male* is a corresponding cell value. We use the following process to convert the Freebase data tables into a single graph:

- Create a node for each unique cell value
- Create a node for each unique property name, where unique property name is obtained by prefixing the unique table ID to the property name. For example, in Figure 1, *people-person-gender* is a unique property name.
- Add an edge of weight 1.0 from cell-value node v to unique property node p, iff value v is present in the column corresponding to property p. Similarly, add an edge in the reverse direction.

By applying this graph construction process on the first column of the two tables in Figure 1, we end up with the graph shown in Figure 2 (a). We note that even though the resulting graph consists of edges connecting nodes of different types: cell value nodes to property nodes; the graph-based SSL methods (Section 2) can still be applied on such graphs as a cell value node and a property node connected by an edge should be assigned same or similar class labels. In other words, the label smoothness assumption (see Section 2.2) holds on such graphs.

We applied the same graph construction process on a subset of the Freebase dataset consisting of topics from 18 randomly selected domains: *astronomy, automotive, biology, book, business,*

chemistry, comic_books, computer, film, food, geography, location, people, religion, spaceflight, tennis, travel, and wine. The topics in this subset were further filtered so that only cell-value nodes with frequency 10 or more were retained. We call the resulting graph Freebase-1 (see Table 1).

Pantel et al. (2009) have made available a set of gold class-instance pairs derived from Wikipedia, which is downloadable from `http://ow.ly/13B57`. From this set, we selected all classes which had more than 10 instances overlapping with the Freebase graph constructed above. This resulted in 23 classes, which along with their overlapping instances were used as the gold standard set for the experiments in this section.

Experimental results with 2 and 10 seeds (labeled nodes) per class are shown in Figure 3. From the figure, we see that that LP-ZGL and Adsorption performed comparably on this dataset, with MAD significantly outperforming both methods.

3.2 Freebase-2 Graph with WordNet Classes

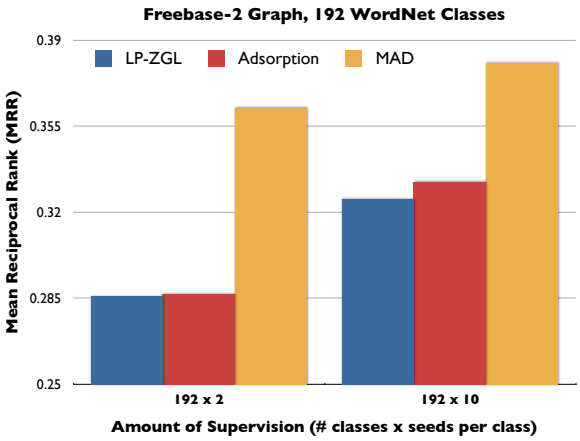


Figure 4: Comparison of graph transduction methods on a graph constructed from the Freebase dataset (see Section 3.2). All results are averaged over 10 random trials. In each group, MAD is the rightmost bar.

To evaluate how the algorithms scale up, we construct a larger graph from the same 18 domains as in Section 3.1, and using the same graph construction process. We shall call the resulting graph Freebase-2 (see Table 1). In order to scale up the number of classes, we selected all Wordnet (WN) classes, available in the YAGO KB (Suchanek et al., 2007), that had more than 100 instances overlapping with the larger Freebase graph constructed above. This resulted in 192 WN classes which we use for the experiments in this section. The reason behind imposing such frequency constraints during class selection is to make sure that each class is left with a sufficient number of instances during testing.

Experimental results comparing LP-ZGL, Adsorption, and MAD with 2 and 10 seeds per class are shown in Figure 4. A total of 292k test nodes were used for testing in the 10 seeds per class condition, showing that these methods can be applied to large datasets. Once again, we observe MAD outperforming both LP-ZGL and Adsorption. It is interesting to note that MAD with 2 seeds per class outperforms LP-ZGL and adsorption even with 10 seeds per class.

3.3 TextRunner Graph with WordNet Classes

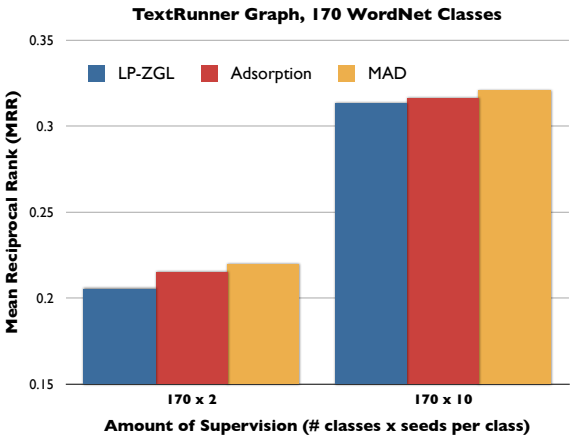

Figure 5: Comparison of graph transduction methods on a graph constructed from the hypernym tuples extracted by the TextRunner system (Banko et al., 2007) (see Section 3.3). All results are averaged over 10 random trials. In each group, MAD is the rightmost bar.

In contrast to graph construction from structured tables as in Sections 3.1, 3.2, in this section we use hypernym tuples extracted by TextRunner (Banko et al., 2007), an open domain IE system, to construct the graph. Example of a hypernym tuple extracted by TextRunner is *(http, protocol, 0.92)*, where 0.92 is the extraction confidence. To convert such a tuple into a graph, we create a node for the instance (*http*) and a node for the class (*protocol*), and then connect the nodes with two

directed edges in both directions, with the extraction confidence (*0.92*) as edge weights. The graph created with this process from TextRunner output is called the TextRunner Graph (see Table 1). As in Section 3.2, we use WordNet class-instance pairs as the gold set. In this case, we considered all WordNet classes, once again from YAGO KB (Suchanek et al., 2007), which had more than 50 instances overlapping with the constructed graph. This resulted in 170 WordNet classes being used for the experiments in this section.

Experimental results with 2 and 10 seeds per class are shown in Figure 5. The three methods are comparable in this setting, with MAD achieving the highest overall MRR.

3.4 Discussion

If we correlate the graph statistics in Table 1 with the results of sections 3.1, 3.2, and 3.3, we see that MAD is most effective for graphs with high average degree, that is, graphs where nodes tend to connect to many other nodes. For instance, the Freebase-1 graph has a high average degree of 29.03, with a corresponding large advantage for MAD over the other methods. Even though this might seem mysterious at first, it becomes clearer if we look at the objectives minimized by different algorithms. We find that the objective minimized by LP-ZGL (Equation 1) is *under-regularized*, i.e., its model parameters ($\hat{Y}$) are not constrained enough, compared to MAD (Equation 3, specifically the third term), resulting in overfitting in case of highly connected graphs. In contrast, MAD is able to avoid such overfitting because of its minimization of a well regularized objective (Equation 3). Based on this, we suggest that average degree, an easily computable structural property of the graph, may be a useful indicator in choosing which graph-based SSL algorithm should be applied on a given graph.

Unlike MAD, Adsorption does not optimize any well defined objective (Talukdar and Crammer, 2009), and hence any analysis along the lines described above is not possible. The heuristic choices made in Adsorption may have lead to its sub-optimal performance compared to MAD; we leave it as a topic for future investigation.

3.5 Effect of Per-Node Class Sparsity

For all the experiments in Sections 3.1, 3.2, and 3.6, each node was allowed to have a maximum of 15 classes during inference. After each update

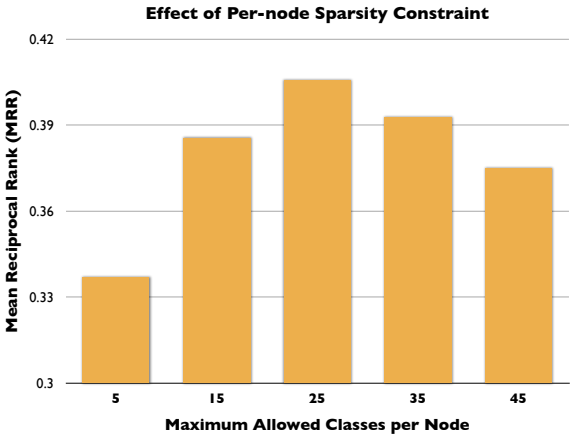

Figure 6: Effect of per node class sparsity (maximum number of classes allowed per node) during MAD inference in the experimental setting of Figure 4 (one random split).

on a node, all classes except for the top scoring 15 classes were discarded. Without such sparsity constraints, a node in a connected graph will end up acquiring all the labels injected into the graph. This is undesirable for two reasons: (1) for experiments involving a large numbers of classes (as in the previous section and in the general case of open domain IE), this increases the space requirement and also slows down inference; (2) a particular node is unlikely to belong to a large number of classes. In order to estimate the effect of such sparsity constraints, we varied the number of classes allowed per node from 5 to 45 on the graph and experimental setup of Figure 4, with 10 seeds per class. The results for MAD inference over the development split are shown in Figure 6. We observe that performance can vary significantly as the maximum number of classes allowed per node is changed, with the performance peaking at 25. This suggests that sparsity constraints during graph based SSL may have a crucial role to play, a question that needs further investigation.

3.6 TextRunner Graph with additional Semantic Constraints from YAGO

Recently, the problem of instance-attribute extraction has started to receive attention (Probst et al., 2007; Bellare et al., 2007; Pasca and Durme, 2007). An example of an instance-attribute pair is (*Bob Dylan*, *albums*). Given a set of seed instance-attribute pairs, these methods attempt to extract more instance-attribute pairs automatically

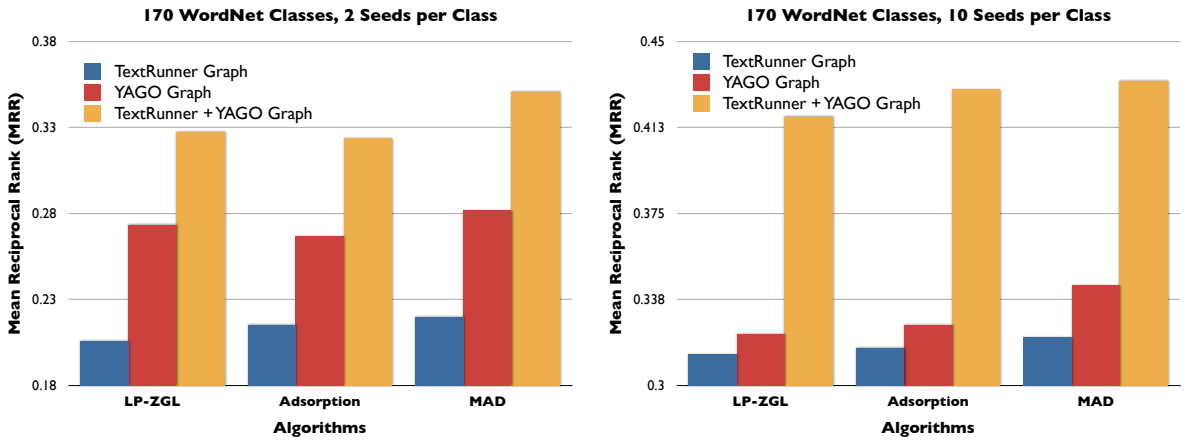

Figure 7: Comparison of class-instance acquisition performance on the three different graphs described in Section 3.6. All results are averaged over 10 random trials. Addition of YAGO attributes to the TextRunner graph significantly improves performance.

YAGO Attribute	**Top-2 WordNet Classes Assigned by MAD** (example instances for each class are shown in brackets)
has_currency	**wordnet_country_108544813 (Burma, Afghanistan)** wordnet_region_108630039 (Aosta Valley, Southern Flinders Ranges)
works_at	**wordnet_scientist_110560637 (Aage Niels Bohr, Adi Shamir)** wordnet_person_100007846 (Catherine Cornelius, Jamie White)
has_capital	**wordnet_state_108654360 (Agusan del Norte, Bali)** wordnet_region_108630039 (Aosta Valley, Southern Flinders Ranges)
born_in	**wordnet_boxer_109870208 (George Chuvalo, Fernando Montiel)** wordnet_chancellor_109906986 (Godon Brown, Bill Bryson)
has_isbn	**wordnet_book_106410904 (Past Imperfect, Berlin Diary)** wordnet_magazine_106595351 (Railway Age, Investors Chronicle)

Table 2: Top 2 (out of 170) WordNet classes assigned by MAD on 5 randomly chosen YAGO attribute nodes (out of 80) in the TextRunner + YAGO graph used in Figure 7 (see Section 3.6), with 10 seeds per class used. A few example instances of each WordNet class is shown within brackets. Top ranked class for each attribute is shown in bold.

from various sources. In this section, we explore whether class-instance assignment can be improved by incorporating new semantic constraints derived from (instance, attribute) pairs. In particular, we experiment with the following type of constraint: two instances with a common attribute are likely to belong to the same class. For example, in Figure 2 (b), instances *Johnny Cash* and *Bob Dylan* are more likely to belong to the same class as they have a common attribute, *albums*. Because of the *smooth* labeling bias of graph-based SSL methods (see Section 2.2), such constraints are naturally captured by the methods reviewed in Section 2. All that is necessary is the introduction of bidirectional (instance, attribute) edges to the graph, as shown in Figure 2 (b).

In Figure 7, we compare class-instance acquisition performance of the three graph-based SSL methods (Section 2) on the following three graphs (also see Table 1):

TextRunner Graph: Graph constructed from the hypernym tuples extracted by TextRunner, as in Figure 5 (Section 3.3), with 175k vertices and 529k edges.

YAGO Graph: Graph constructed from the (instance, attribute) pairs obtained from the YAGO KB (Suchanek et al., 2007), with 142k nodes and 777k edges.

TextRunner + YAGO Graph: Union of the

two graphs above, with 237k nodes and 1.3m edges.

In all experimental conditions with 2 and 10 seeds per class in Figure 7, we observe that the three methods consistently achieved the best performance on the TextRunner + YAGO graph. This suggests that addition of attribute based semantic constraints from YAGO to the TextRunner graph results in a better connected graph which in turn results in better inference by the graph-based SSL algorithms, compared to using either of the sources, i.e., TextRunner output or YAGO attributes, in isolation. This further illustrates the advantage of aggregating information across sources (Talukdar et al., 2008; Pennacchiotti and Pantel, 2009). However, we are the first, to the best of our knowledge, to demonstrate the effectiveness of attributes in class-instance acquisition. We note that this work is similar in spirit to the recent work by Carlson et al. (2010) which also demonstrates the benefits of additional constraints in SSL.

Because of the label propagation behavior, graph-based SSL algorithms assign classes to all nodes reachable in the graph from at least one of the labeled instance nodes. This allows us to check the classes assigned to nodes corresponding to YAGO attributes in the TextRunner + YAGO graph, as shown in Table 2. Even though the experiments were designed for class-instance acquisition, it is encouraging to see that the graph-based SSL algorithm (MAD in Table 2) is able to learn class-attribute relationships, an important by-product that has been the focus of recent studies (Reisinger and Pasca, 2009). For example, the algorithm is able to learn that *works_at* is an attribute of the WordNet class *wordnet_scientist_110560637*, and thereby its instances (e.g. *Aage Niels Bohr, Adi Shamir*).

4 Conclusion

We have started a systematic experimental comparison of graph-based SSL algorithms for class-instance acquisition on a variety of graphs constructed from different domains. We found that MAD, a recently proposed graph-based SSL algorithm, is consistently the most effective across the various experimental conditions. We also showed that class-instance acquisition performance can be significantly improved by incorporating additional semantic constraints in the class-instance acquisition process, which for the experiments in this paper were derived from instance-attribute pairs available in an independently developed knowledge base. All the data used in these experiments was drawn from publicly available datasets and we plan to release our code[3] to foster reproducible research in this area. Topics for future work include the incorporation of other kinds of semantic constraint for improved class-instance acquisition, further investigation into per-node sparsity constraints in graph-based SSL, and moving beyond bipartite graph constructions.

Acknowledgments

We thank William Cohen for valuable discussions, and Jennifer Gillenwater, Alex Kulesza, and Gregory Malecha for detailed comments on a draft of this paper. We are also very grateful to the authors of (Banko et al., 2007), Oren Etzioni and Stephen Soderland in particular, for providing TextRunner output. This work was supported in part by NSF IIS-0447972 and DARPA HRO1107-1-0029.

Learning Arguments and Supertypes of Semantic Relations using Recursive Patterns

Abstract

A challenging problem in open information extraction and text mining is the learning of the selectional restrictions of semantic relations. We propose a minimally supervised bootstrapping algorithm that uses a single seed and a recursive lexico-syntactic pattern to learn the arguments and the supertypes of a diverse set of semantic relations from the Web. We evaluate the performance of our algorithm on multiple semantic relations expressed using "verb", "noun", and "verb prep" lexico-syntactic patterns. Human-based evaluation shows that the accuracy of the harvested information is about 90%. We also compare our results with existing knowledge base to outline the similarities and differences of the granularity and diversity of the harvested knowledge.

1 Introduction

Building and maintaining knowledge-rich resources is of great importance to information extraction, question answering, and textual entailment. Given the endless amount of data we have at our disposal, many efforts have focused on mining knowledge from structured or unstructured text, including ground facts (Etzioni et al., 2005), semantic lexicons (Thelen and Riloff, 2002), encyclopedic knowledge (Suchanek et al., 2007), and concept lists (Katz et al., 2003). Researchers have also successfully harvested relations between entities, such as is-a (Hearst, 1992; Pasca, 2004) and part-of (Girju et al., 2003). The kinds of knowledge learned are generally of two kinds: ground instance facts (*New York is-a city*, *Rome is the capital of Italy*) and general relational types (*city is-a location*, *engines are part-of cars*).

A variety of NLP tasks involving inference or entailment (Zanzotto et al., 2006), including QA (Katz and Lin, 2003) and MT (Mt et al., 1988), require a slightly different form of knowledge, derived from many more relations. This knowledge is usually used to support inference and is expressed as selectional restrictions (Wilks, 1975) (namely, the types of arguments that may fill a given relation, such as *person live-in city* and *airline fly-to location*). Selectional restrictions constrain the possible fillers of a relation, and hence the possible contexts in which the patterns expressing that relation can participate in, thereby enabling sense disambiguation of both the fillers and the expression itself.

To acquire this knowledge two common approaches are employed: clustering and patterns. While clustering has the advantage of being fully unsupervised, it may or may not produce the types and granularity desired by a user. In contrast pattern-based approaches are more precise, but they typically require a handful to dozens of seeds and lexico-syntactic patterns to initiate the learning process. In a closed domain these approaches are both very promising, but when tackling an unbounded number of relations they are unrealistic. The quality of clustering decreases as the domain becomes more continuously varied and diverse, and it has proven difficult to create collections of effective patterns and high-yield seeds manually.

In addition, the output of most harvesting systems is a flat list of lexical semantic expressions such as *"New York is-a city"* and *"virus causes flu"*. However, using this knowledge in inference requires it to be formulated appropriately and organized in a semantic repository. (Pennacchiotti and Pantel, 2006) proposed an algorithm for automatically ontologizing semantic relations into WordNet. However, despite its high precision entries, WordNet's limited coverage makes it impossible for relations whose arguments are not present in WordNet to be incorporated. One would like a procedure that dynamically organizes and extends

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1482–1491,
Uppsala, Sweden, 11-16 July 2010.

its semantic repository in order to be able to accommodate all newly-harvested information, and thereby become a global semantic repository.

Given these considerations, we address in this paper the following question: *How can the selectional restrictions of semantic relations be learned automatically from the Web with minimal effort using lexico-syntactic recursive patterns?*

The contributions of the paper are as follows:

- A novel representation of semantic relations using recursive lexico-syntactic patterns.
- An automatic procedure to learn the selectional restrictions (arguments and supertypes) of semantic relations from Web data.
- An exhaustive human-based evaluation of the harvested knowledge.
- A comparison of the results with some large existing knowledge bases.

The rest of the paper is organized as follows. In the next section, we review related work. Section 3 addresses the representation of semantic relations using recursive patterns. Section 4 describes the bootstrapping mechanism that learns the selectional restrictions of the relations. Section 5 describes data collection. Section 6 discusses the obtained results. Finally, we conclude in Section 7.

2 Related Work

A substantial body of work has been done in attempts to harvest bits of semantic information, including: semantic lexicons (Riloff and Shepherd, 1997), concept lists (Lin and Pantel, 2002), is-a relations (Hearst, 1992; Etzioni et al., 2005; Pasca, 2004; Kozareva et al., 2008), part-of relations (Girju et al., 2003), and others. Knowledge has been harvested with varying success both from structured text such as Wikipedia's infoboxes (Suchanek et al., 2007) or unstructured text such as the Web (Pennacchiotti and Pantel, 2006; Yates et al., 2007). A variety of techniques have been employed, including clustering (Lin and Pantel, 2002), co-occurrence statistics (Roark and Charniak, 1998), syntactic dependencies (Pantel and Ravichandran, 2004), and lexico-syntactic patterns (Riloff and Jones, 1999; Fleischman and Hovy, 2002; Thelen and Riloff, 2002).

When research focuses on a particular relation, careful attention is paid to the pattern(s) that express it in various ways (as in most of the work above, notably (Riloff and Jones, 1999)). But it has proven a difficult task to manually find effectively different variations and alternative patterns for each relation. In contrast, when research focuses on *any* relation, as in TextRunner (Yates et al., 2007), there is no standardized manner for re-using the pattern learned. TextRunner scans sentences to obtain relation-independent lexico-syntactic patterns to extract triples of the form (*John*, *fly to*, *Prague*). The middle string denotes some (unspecified) semantic relation while the first and third denote the learned arguments of this relation. But TextRunner does not seek specific semantic relations, and does not re-use the patterns it harvests with different arguments in order to extend their yields.

Clearly, it is important to be able to specify both the actual semantic relation sought *and* use its textual expression(s) in a controlled manner for maximal benefit.

The objective of our research is to combine the strengths of the two approaches, and, in addition, to provide even richer information by automatically mapping each harvested argument to its supertype(s) (i.e., its semantic concepts). For instance, given the relation *destination* and the pattern *X flies to Y*, automatically determining that *John, Prague*) and (*John, conference*) are two valid filler instance pairs, that (*RyanAir, Prague*) is another, as well as that *person* and *airline* are supertypes of the first argument and *city* and *event* of the second. This information provides the selectional restrictions of the given semantic relation, indicating that living things like people can fly to cities and events, while non-living things like airlines fly mainly to cities. This is a significant improvement over systems that output a flat list of lexical semantic knowledge (Thelen and Riloff, 2002; Yates et al., 2007; Suchanek et al., 2007).

Knowing the sectional restrictions of a semantic relation supports inference in many applications, for example enabling more accurate information extraction. (Igo and Riloff, 2009) report that patterns like "*attack on* $\langle NP \rangle$" can learn undesirable words due to idiomatic expressions and parsing errors. Over time this becomes problematic for the bootstrapping process and leads to significant deterioration in performance. (Thelen and Riloff, 2002) address this problem by learning multiple semantic categories simultaneously, relying on the often unrealistic assumption that a word cannot belong to more than one semantic category. How-

ever, if we have at our disposal a repository of semantic relations with their selectional restrictions, the problem addressed in (Igo and Riloff, 2009) can be alleviated.

In order to obtain selectional restriction classes, (Pennacchiotti and Pantel, 2006) made an attempt to ontologize the harvested arguments of *is-a*, *part-of*, and *cause* relations. They mapped each argument of the relation into WordNet and identified the senses for which the relation holds. Unfortunately, despite its very high precision entries, WordNet is known to have limited coverage, which makes it impossible for algorithms to map the content of a relation whose arguments are not present in WordNet. To surmount this limitation, we do not use WordNet, but employ a different method of obtaining superclasses of a filler term: the inverse doubly-anchored patterns DAP^{-1} (Hovy et al., 2009), which, given two arguments, harvests its supertypes from the source corpus. (Hovy et al., 2009) show that DAP^{-1} is reliable and it enriches WordNet with additional hyponyms and hypernyms.

3 Recursive Patterns

A singly-anchored pattern contains one example of the seed term (the anchor) and one open position for the term to be learned. Most researchers use singly-anchored patterns to harvest semantic relations. Unfortunately, these patterns run out of steam very quickly. To surmount this obstacle, a handful of seeds is generally used, and helps to guarantee diversity in the extraction of new lexico-syntactic patterns (Riloff and Jones, 1999; Snow et al., 2005; Etzioni et al., 2005).

Some algorithms require ten seeds (Riloff and Jones, 1999; Igo and Riloff, 2009), while others use a variation of 5, 10, to even 25 seeds (Talukdar et al., 2008). Seeds may be chosen at random (Davidov et al., 2007; Kozareva et al., 2008), by picking the most frequent terms of the desired class (Igo and Riloff, 2009), or by asking humans (Pantel et al., 2009). As (Pantel et al., 2009) show, picking seeds that yield high numbers of different terms is difficult. Thus, when dealing with unbounded sets of relations (Banko and Etzioni, 2008), providing many seeds becomes unrealistic.

Interestingly, recent work reports a class of patterns that use only one seed to learn as much information with only one seed. (Kozareva et al., 2008; Hovy et al., 2009) introduce the so-called doubly-anchored pattern (DAP) that has two anchor seed positions "⟨*type*⟩ *such as* ⟨*seed*⟩ *and* *", plus one open position for the terms to be learned. Learned terms can then be replaced into the seed position automatically, creating a recursive procedure that is reportedly much more accurate and has much higher final yield. (Kozareva et al., 2008; Hovy et al., 2009) have successfully applied DAP for the learning of hyponyms and hypernyms of *is-a* relations and report improvements over (Etzioni et al., 2005) and (Pasca, 2004).

Surprisingly, this work was limited to the semantic relation *is-a*. No other study has described the use or effect of recursive patterns for different semantic relations. Therefore, going beyond (Kozareva et al., 2008; Hovy et al., 2009), we here introduce recursive patterns other than DAP that use only one seed to harvest the arguments and supertypes of a wide variety of relations.

(Banko and Etzioni, 2008) show that semantic relations can be expressed using a handful of relation-independent lexico-syntactic patterns. Practically, we can turn *any* of these patterns into recursive form by giving as input only one of the arguments and leaving the other one as an open slot, allowing the learned arguments to replace the initial seed argument directly. For example, for the relation "*fly to*", the following recursive patterns can be built: "* *and* ⟨*seed*⟩ *fly to* *", "⟨*seed*⟩ *and* * *fly to* *", "* *fly to* ⟨*seed*⟩ *and* *", "* *fly to* * *and* ⟨*seed*⟩", "⟨*seed*⟩ *fly to* *" or "* *fly to* ⟨*seed*⟩", where ⟨*seed*⟩ is an example like *John* or *Ryanair*, and (∗) indicates the position on which the arguments are learned. Conjunctions like *and*, *or* are useful because they express list constructions and extract arguments similar to the *seed*. Potentially, one can explore all recursive pattern variations when learning a relation and compare their yield, however this study is beyond the scope of this paper.

We are particularly interested in the usage of recursive patterns for the learning of semantic relations not only because it is a novel method, but also because recursive patterns of the DAP fashion are known to: (1) learn concepts with high precision compared to singly-anchored patterns (Kozareva et al., 2008), (2) use only one seed instance for the discovery of new previously unknown terms, and (3) harvest knowledge with minimal supervision.

4 Bootstrapping Recursive Patterns

4.1 Problem Formulation

The main goal of our research is:

> **Task Definition**: Given a seed and a semantic relation expressed using a recursive lexico-syntactic pattern, learn in bootstrapping fashion the selectional restrictions (i.e., the arguments and supertypes) of the semantic relation from an unstructured corpus such as the Web.

Figure 1 shows an example of the task and the types of information learned by our algorithm.

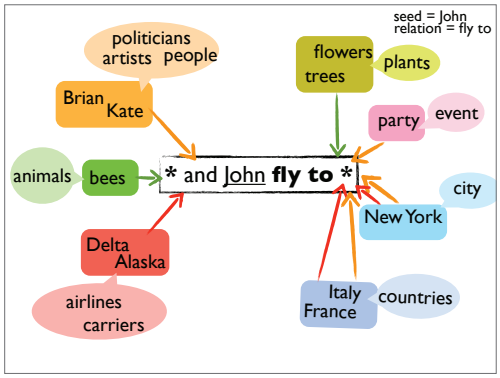

Figure 1: *Bootstrapping Recursive Patterns.*

Given a seed *John* and a semantic relation *fly to* expressed using the recursive pattern "* *and John fly to* *", our algorithm learns the left side arguments {*Brian, Kate, bees, Delta, Alaska*} and the right side arguments {*flowers, trees, party, New York, Italy, France*}. For each argument, the algorithm harvests supertypes such as {*people, artists, politicians, airlines, city, countries, plants, event*} among others. The colored links between the right and left side concepts denote the selectional restrictions of the relation. For instance, *people* fly to *events* and *countries*, but never to *trees* or *flowers*.

4.2 System Architecture

We propose a minimally supervised bootstrapping algorithm based on the framework adopted in (Kozareva et al., 2008; Hovy et al., 2009). The algorithm has two phases: *argument* harvesting and *supertype* harvesting. The final output is a ranked list of interlinked concepts which captures the selectional restrictions of the relation.

4.2.1 Argument Harvesting

In the argument extraction phase, the first bootstrapping iteration is initiated with a seed Y and a recursive pattern "X^* *and* Y *verb+prep|verb|noun* Z^*", where X^* and Z^* are the placeholders for the arguments to be learned. The pattern is submitted to Yahoo! as a web query and all unique snippets matching the query are retrieved. The newly learned and previously unexplored arguments on the X^* position are used as seeds in the subsequent iteration. The arguments on the Z^* position are stored at each iteration, but never used as seeds since the recursivity is created using the terms on X and Y. The bootstrapping process is implemented as an exhaustive breadth-first algorithm which terminates when all arguments are explored.

We noticed that despite the specific lexico-syntactic structure of the patterns, erroneous information can be acquired due to part-of-speech tagging errors or flawed facts on the Web. The challenge is to identify and separate the erroneous from the true arguments. We incorporate the harvested arguments on X and Y positions in a directed graph $G = (V, E)$, where each vertex $v \in V$ is a candidate argument and each edge $(u, v) \in E$ indicates that the argument v is generated by the argument u. An edge has weight w corresponding to the number of times the pair (u, v) is extracted from different snippets. A node u is ranked by $u = \frac{\sum_{\forall(u,v)\in E} w(u,v) + \sum_{\forall(v,u)\in E} w(v,u)}{|V|-1}$ which represents the weighted sum of the outgoing and incoming edges normalized by the total number of nodes in the graph. Intuitively, our confidence in a correct argument u increases when the argument (1) discovers and (2) is discovered by many different arguments.

Similarly, to rank the arguments standing on the Z position, we build a bipartite graph $G' = (V', E')$ that has two types of vertices. One set of vertices represents the arguments found on the Y position in the recursive pattern. We will call these V_y. The second set of vertices represents the arguments learned on the Z position. We will call these V_z. We create an edge $e'(u', v') \in E'$ between $u' \in V_y$ and $v' \in V_z$ when the argument on the Z position represented by v' was harvested by the argument on the Y position represented by u'. The weight w' of the edge indicates the number of times an argument on the Y position found Z. Vertex v' is ranked as $v' = \frac{\sum_{\forall(u',v')\in E'} w(u',v')}{|V'|-1}$. In a very large corpus, like the Web, we assume that a correct argument Z is the one that is frequently discovered by various arguments Y.

4.2.2 Supertype Harvesting

In the supertype extraction phase, we take all <X,Y> argument pairs collected during the argument harvesting stage and instantiate them in the inverse DAP^{-1} pattern *"* such as X and Y"*. The query is sent to Yahoo! as a web query and all 1000 snippets matching the pattern are retrieved. For each <X,Y> pair, the terms on the (*) position are extracted and considered as candidate supertypes.

To avoid the inclusion of erroneous supertypes, again we build a bipartite graph $G'' = (V'', E'')$. The set of vertices V_{sup} represents the supertypes, while the set of vertices V_p corresponds to the $\langle$X,Y$\rangle$ pair that produced the supertype. An edge $e''(u'', v'') \in E''$, where $u'' \in V_p$ and $v'' \in V_{sup}$ shows that the pair $\langle$X,Y$\rangle$ denoted as u'' harvested the supertype represented by v''.

For example, imagine that the argument *X**= *Ryanair* was harvested in the previous phase by the recursive pattern *"X* and EasyJet fly to Z*"*. Then the pair $\langle$*Ryanair,EasyJet*$\rangle$ forms a new Web query *"* such as Ryanair and EasyJet"* which learns the supertypes *"airlines"* and *"carriers"*. The bipartite graph has two vertices v''_1 and v''_2 for the supertypes *"airlines"* and *"carriers"*, one vertex u''_3 for the argument pair $\langle$*Ryanair, EasyJet*$\rangle$, and two edges $e''_1(u''_3, v''_1)$ and $e''_2(u''_3, v''_1)$. A vertex $v'' \in V_{sup}$ is ranked by v''=$\frac{\sum_{\forall(u'',v'')\in E''} w(u'',v'')}{|V''|-1}$. Intuitively, a supertype which is discovered multiple times by various argument pairs is ranked highly.

However, it might happen that a highly ranked supertype actually does not satisfy the selectional restrictions of the semantic relation. To avoid such situations, we further instantiate each supertype concept in the original pattern[1]. For example, *"aircompanies fly to *"* and *"carriers fly to *"*. If the candidate supertype produces many web hits for the query, then this suggests that the term is a relevant supertype.

Unfortunately, to learn the supertypes of the Z arguments, currently we have to form all possible combinations among the top 150 highly ranked concepts, because these arguments have not been learned through pairing. For each pair of Z arguments, we repeat the same procedure as described above.

[1]Except for the *"dress"* and *"person"* relations, where the targeted arguments are adjectives, and the supertypes are nouns.

5 Semantic Relations

So far, we have described the mechanism that learns from one seed and a recursive pattern the selectional restrictions of any semantic relation. Now, we are interested in evaluating the performance of our algorithm. A natural question that arises is: *"How many patterns are there?"*. (Banko and Etzioni, 2008) found that 95% of the semantic relations can be expressed using eight lexico-syntactic patterns. Space prevents us from describing all of them, therefore we focus on the three most frequent patterns which capture a large diversity of semantic relations. The relative frequency of these patterns is 37.80% for "verbs", 22.80% for "noun prep", and 16.00% for "verb prep".

5.1 Data Collection

Table 1 shows the lexico-syntactic pattern and the initial seed we used to express each semantic relation. To collect data, we ran our knowledge harvesting algorithm until complete exhaustion. For each query submitted to Yahoo!, we retrieved the top 1000 web snippets and kept only the unique ones. In total, we collected 30GB raw data which was part-of-speech tagged and used for the argument and supertype extraction. Table 1 shows the obtained results.

recursive pattern	seed	X arg	Z arg	#iter
X and Y **work for** Z	Charlie	2949	3396	20
X and Y **fly to** Z	EasyJet	772	1176	19
X and Y **go to** Z	Rita	18406	27721	13
X and Y **work in** Z	John	4142	4918	13
X and Y **work on** Z	Mary	4126	5186	7
X and Y **work at** Z	Scott	1084	1186	14
X and Y **live in** Z	Harry	8886	19698	15
X and Y **live at** Z	Donald	1102	1175	15
X and Y **live with** Z	Peter	1344	834	11
X and Y **cause** Z	virus	12790	52744	19
X and Y **celebrate**	Jim	6033	–	12
X and Y **drink**	Sam	1810	–	13
X and Y **dress**	nice	1838	–	8
X and Y **person**	scared	2984	–	17

Table 1: *Total Number of Harvested Arguments.*

An interesting characteristic of the recursive patterns is the speed of leaning which can be measured in terms of the number of unique arguments acquired during each bootstrapping iteration. Figure 2 shows the bootstrapping process for the *"cause"* and *"dress"* relations. Although both relations differ in terms of the total number of iterations and harvested items, the overall behavior of the learning curves is similar. Learning starts of very slowly and as bootstrapping progresses a

rapid growth is observed until a saturation point is reached.

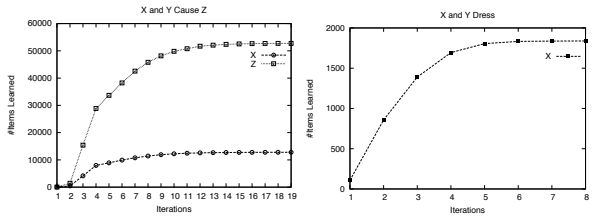

Figure 2: Items extracted in 10 iterations.

The speed of leaning is related to the connectivity behavior of the arguments of the relation. Intuitively, a densely connected graph takes shorter time (i.e., fewer iterations) to be learned, as in the *"work on"* relation, while a weakly connected network takes longer time to harvest the same amount of information, as in the *"work for"* relation.

6 Results

In this section, we evaluate the results of our knowledge harvesting algorithm. Initially, we decided to conduct an automatic evaluation comparing our results to knowledge bases that have been extracted in a similar way (i.e., through pattern application over unstructured text). However, it is not always possible to perform a complete comparison, because either researchers have not fully explored the same relations we have studied, or for those relations that overlap, the gold standard data was not available.

The online demo of TextRunner[2] (Yates et al., 2007) actually allowed us to collect the arguments for all our semantic relations. However, due to Web based query limitations, TextRunner returns only the first 1000 snippets. Since we do not have the complete and ranked output of TextRunner, comparing results in terms of recall and precision is impossible.

Turning instead to results obtained from structured sources (which one expects to have high correctness), we found that two of our relations overlap with those of the freely available ontology Yago (Suchanek et al., 2007), which was harvested from the Infoboxes tables in Wikipedia. In addition, we also had two human annotators judge as many results as we could afford, to obtain Precision. We conducted two evaluations, one for the arguments and one for the supertypes.

[2]http://www.cs.washington.edu/research/textrunner/

6.1 Human-Based Argument Evaluation

In this section, we discuss the results of the harvested arguments. For each relation, we selected the top 200 highly ranked arguments. We hired two annotators to judge their correctness. We created detailed annotation guidelines that define the labels for the arguments of the relations, as shown in Table 2. (Previously, for the same task, researchers have not conducted such an exhaustive and detailed human-based evaluation.) The annotation was conducted using the CAT system[3].

TYPE	LABEL	EXAMPLES
Correct	Person	*John, Mary*
	Role	*mother, president*
	Group	*team, Japanese*
	Physical	*yellow, shabby*
	NonPhysical	*ugly, thought*
	NonLiving	*airplane*
	Organization	*IBM, parliament*
	Location	*village, New York, in the house*
	Time	*at 5 o'clock*
	Event	*party, prom, earthquake*
	State	*sick, anrgy*
	Manner	*live in happiness*
	Medium	*work on Linux, Word*
	Fixed phrase	*go to war*
Incorrect	Error	*wrong part-of-speech tag*
	Other	*none of the above*

Table 2: *Annotation Labels.*

We allow multiple labels to be assigned to the same concept, because sometimes the concept can appear in different contexts that carry various conceptual representations. Although the labels can be easily collapsed to judge correct and incorrect terms, the fine-grained annotation shown here provides a better overview of the information learned by our algorithm.

We measured the inter-annotator agreement for all labels and relations considering that a single entry can be tagged with multiple labels. The Kappa score is around 0.80. This judgement is good enough to warrant using these human judgements to estimate the accuracy of the algorithm. We compute *Accuracy* as the number of examples tagged as $Correct$ divided by the total number of examples.

Table 4 shows the obtained results. The overall accuracy of the argument harvesting phase is 91%. The majority of the occurred errors are due to part-of-speech tagging. Table 3 shows a sample of 10 randomly selected examples from the top 200 ranked and manually annotated arguments.

Relation	*Arguments*
(X) Dress:	stylish, comfortable, expensive, shabby, gorgeous silver, clean, casual, Indian, black
(X) Person:	honest, caring, happy, intelligent, gifted friendly, responsible, mature, wise, outgoing
(X) Cause:	pressure, stress, fire, bacteria, cholesterol flood, ice, cocaine, injuries, wars
GoTo (Z):	school, bed, New York, the movies, the park, a bar the hospital, the church, the mall, the beach
LiveIn (Z):	peace, close proximity, harmony, Chicago, town New York, London, California, a house, Australia
WorkFor (Z):	a company, the local prison, a gangster, the show a boss, children, UNICEF, a living, Hispanics

Table 3: *Examples of Harvested Arguments.*

6.2 Comparison against Existing Resources

In this section, we compare the performance of our approach with the semantic knowledge base Yago[4] that contains 2 million entities[5], 95% of which were manually confirmed to be correct. In this study, we compare only the unique arguments of the *"live in"* and *"work at"* relations. We provide Precision scores using the following measures:

$$Pr_{Yago} = \frac{\#terms\ found\ in\ Yago}{\#terms\ harvested\ by\ system}$$

$$Pr_{Human} = \frac{\#terms\ judged\ correct\ by\ human}{\#terms\ harvested\ by\ system}$$

$$NotInYago = \#terms\ judged\ correct\ by\ human\ but\ not\ in\ Yago$$

Table 5 shows the obtained results.

We carefully analyzed those arguments that were found by one of the systems but were missing in the other. The recursive patterns learn information about non-famous entities like Peter and famous entities like Michael Jordan. In contrast, Yago contains entries mostly about famous entities, because this is the predominant knowledge in Wikipedia. For the *"live in"* relation, both repositories contain the same city and country names. However, the recursive pattern learned arguments like *pain*, *effort* which express a manner of living, and locations like *slums*, *box*. This information is missing from Yago. Similarly for the *"work at"* relation, both systems learned that people work at universities. In addition, the recursive pattern learned a diversity of company names absent from Yago.

While it is expected that our algorithm finds many terms not contained in Yago—specifically, the information not deemed worthy of inclusion in Wikipedia—we are interested in the relatively large number of terms contained in Yago but not found by our algorithm. To our knowledge, no

other automated harvesting algorithm has ever been compared to Yago, and our results here form a baseline that we aim to improve upon. And in the future, one can build an extensive knowledge harvesting system combining the wisdom of the crowd and Wikipedia.

6.3 Human-Based Supertype Evaluation

In this section, we discuss the results of harvesting the supertypes of the learned arguments. Figure 3 shows the top 100 ranked supertypes for the *"cause"* and *"work on"* relations. The x-axis indicates a supertype, the y-axis denotes the number of different argument pairs that lead to the discovery of the supertype.

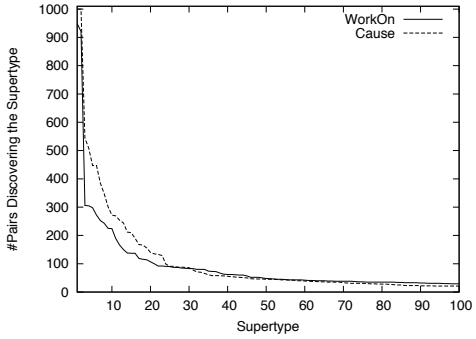

Figure 3: Ranked Supertypes.

The decline of the curve indicates that certain supertypes are preferred and shared among different argument pairs. It is interesting to note that the text on the Web prefers a small set of supertypes, and to see what they are. These most-popular harvested types tend to be the more descriptive terms. The results indicate that one does not need an elaborate supertype hierarchy to handle the selectional restrictions of semantic relations.

Since our problem definition differs from available related work, and WordNet does not contain all harvested arguments as shown in (Hovy et al., 2009), it is not possible to make a direct comparison. Instead, we conduct a manual evaluation of the most highly ranked supertypes which normally are the top 20. The overall accuracy of the supertypes for all relations is 92%. Table 6 shows the top 10 highly ranked supertypes for six of our relations.

Relation	*Arguments*
(Sup_x) **Celebrate**:	men, people, nations, angels, workers, children countries, teams, parents, teachers
(Sup_x) **Dress**:	colors, effects, color tones, activities, patterns styles, materials, size, languages, aspects

Table 6: *Examples of Harvested Supertypes.*

7 Conclusion

We propose a minimally supervised algorithm that uses only one seed example and a recursive lexico-syntactic pattern to learn in bootstrapping fashion the selectional restrictions of a large class of semantic relations. The principal contribution of the paper is to demonstrate that this kind of pattern can be applied to almost any kind of semantic relation, as long as it is expressible in a concise surface pattern, and that the recursive mechanism that allows each newly acquired term to restart harvesting automatically is a significant advance over patterns that require a handful of seeds to initiate the learning process. It also shows how one can combine free-form but undirected pattern-learning approaches like TextRunner with more-controlled but effort-intensive approaches like commonly used.

In our evaluation, we show that our algorithm is capable of extracting high quality non-trivial information from unstructured text given very restricted input (one seed). To measure the performance of our approach, we use various semantic relations expressed with three lexico-syntactic patterns. For two of the relations, we compare results with the freely available ontology Yago, and conduct a manual evaluation of the harvested terms.

We will release the annotated and the harvested data to the public to be used for comparison by other knowledge harvesting algorithms.

The success of the proposed framework opens many challenging directions. We plan to use the algorithm described in this paper to learn the selectional restrictions of numerous other relations, in order to build a rich knowledge repository

that can support a variety of applications, including textual entailment, information extraction, and question answering.

A Transition-Based Parser for 2-Planar Dependency Structures

Carlos Gómez-Rodríguez

Abstract

Finding a class of structures that is rich enough for adequate linguistic representation yet restricted enough for efficient computational processing is an important problem for dependency parsing. In this paper, we present a transition system for 2-planar dependency trees – trees that can be decomposed into at most two planar graphs – and show that it can be used to implement a classifier-based parser that runs in linear time and outperforms a state-of-the-art transition-based parser on four data sets from the CoNLL-X shared task. In addition, we present an efficient method for determining whether an arbitrary tree is 2-planar and show that 99% or more of the trees in existing treebanks are 2-planar.

1 Introduction

Dependency-based syntactic parsing has become a widely used technique in natural language processing, and many different parsing models have been proposed in recent years (Yamada and Matsumoto, 2003; Nivre et al., 2004; McDonald et al., 2005a; Titov and Henderson, 2007; Martins et al., 2009). One of the unresolved issues in this area is the proper treatment of non-projective dependency trees, which seem to be required for an adequate representation of predicate-argument structure, but which undermine the efficiency of dependency parsing (Neuhaus and Bröker, 1997; Buch-Kromann, 2006; McDonald and Satta, 2007).

Caught between the Scylla of linguistically inadequate projective trees and the Charybdis of computationally intractable non-projective trees, some researchers have sought a middle ground by exploring classes of *mildly* non-projective dependency structures that strike a better balance between expressivity and complexity (Nivre, 2006; Kuhlmann and Nivre, 2006; Kuhlmann and Möhl, 2007; Havelka, 2007). Although these proposals seem to have a very good fit with linguistic data, in the sense that they often cover 99% or more of the structures found in existing treebanks, the development of efficient parsing algorithms for these classes has met with more limited success. For example, while both Kuhlmann and Satta (2009) and Gómez-Rodríguez et al. (2009) have shown how well-nested dependency trees with bounded gap degree can be parsed in polynomial time, the best time complexity for lexicalized parsing of this class remains a prohibitive $O(n^7)$, which makes the practical usefulness questionable.

In this paper, we explore another characterization of mildly non-projective dependency trees based on the notion of multiplanarity. This was originally proposed by Yli-Jyrä (2003) but has so far played a marginal role in the dependency parsing literature, because no algorithm was known for determining whether an arbitrary tree was m-planar, and no parsing algorithm existed for any constant value of m. The contribution of this paper is twofold. First, we present a procedure for determining the minimal number m such that a dependency tree is m-planar and use it to show that the overwhelming majority of sentences in dependency treebanks have a tree that is at most 2-planar. Secondly, we present a transition-based parsing algorithm for 2-planar dependency trees, developed in two steps. We begin by showing how the stack-based algorithm of Nivre (2003) can be generalized from projective to planar structures. We then extend the system by adding a second stack and show that the resulting system captures exactly the set of 2-planar structures. Although the contributions of this paper are mainly theoretical, we also present an empirical evaluation of the 2-planar parser, showing that it outperforms the projective parser on four data sets from the CoNLL-X shared task (Buchholz and Marsi, 2006).

2 Preliminaries

2.1 Dependency Graphs

Let $w = w_1 \dots w_n$ be an input string.[1] An **interval** (with endpoints i and j) of the string w is a set of the form $[i, j] = \{w_k \mid i \leq k \leq j\}$.

Definition 1. *A **dependency graph** for w is a directed graph $G = (V_w, E)$, where $V_w = [1, n]$ and $E \subseteq V_w \times V_w$.*

We call an edge (w_i, w_j) in a dependency graph G a **dependency link**[2] from w_i to w_j. We say that w_i is the **parent** (or **head**) of w_j and, conversely, that w_j is a syntactic **child** (or **dependent**) of w_i. For convenience, we write $w_i \rightarrow w_j \in E$ if the link (w_i, w_j) exists; $w_i \leftrightarrow w_j \in E$ if there is a link from w_i to w_j or from w_j to w_i; $w_i \rightarrow^* w_j \in E$ if there is a (possibly empty) directed path from w_i to w_j; and $w_i \leftrightarrow^* w_j \in E$ if there is a (possibly empty) path between w_i and w_j in the undirected graph underlying G (omitting reference to E when clear from the context). The **projection** of a node w_i, denoted $\lfloor w_i \rfloor$, is the set of reflexive-transitive dependents of w_i: $\lfloor w_i \rfloor = \{w_j \in V \mid w_i \rightarrow^* w_j\}$.

Most dependency representations do not allow arbitrary dependency graphs but typically require graphs to be acyclic and have at most one head per node. Such a graph is called a dependency *forest*.

Definition 2. *A dependency graph G for a string $w_1 \dots w_n$ is said to be a **forest** iff it satisfies:*

1. *Acyclicity: If $w_i \rightarrow^* w_j$, then not $w_j \rightarrow w_i$.*
2. *Single-head: If $w_j \rightarrow w_i$, then not $w_k \rightarrow w_i$ (for every $k \neq j$).*

Nodes in a forest that do not have a head are called **roots**. Some frameworks require that dependency forests have a unique root (i.e., are connected). Such a forest is called a **dependency tree**.

2.2 Projectivity

For reasons of computational efficiency, many dependency parsers are restricted to work with *projective* dependency structures, that is, forests in which the projection of each node corresponds to a contiguous substring of the input:

Definition 3. *A dependency forest G for a string $w_1 \dots w_n$ is **projective** iff $\lfloor w_i \rfloor$ is an interval for every word $w_i \in [1, n]$.*

Projective dependency trees correspond to the set of structures that can be induced from lexicalised context-free derivations (Kuhlmann, 2007; Gaifman, 1965). Like context-free grammars, projective dependency trees are not sufficient to represent all the linguistic phenomena observed in natural languages, but they have the advantage of being efficiently parsable: their parsing problem can be solved in cubic time with chart parsing techniques (Eisner, 1996; Gómez-Rodríguez et al., 2008), while in the case of general non-projective dependency forests, it is only tractable under strong independence assumptions (McDonald et al., 2005b; McDonald and Satta, 2007).

2.3 Planarity

The concept of *planarity* (Sleator and Temperley, 1993) is closely related to projectivity[3] and can be informally defined as the property of a dependency forest whose links can be drawn *above* the words without crossing.[4] To define planarity more formally, we first define **crossing links** as follows: let (w_i, w_k) and (w_j, w_l) be dependency links in a dependency graph G. Without loss of generality, we assume that $min(i, k) \leq min(j, l)$. Then, the links are said to be crossing if $min(i, k) < min(j, l) < max(i, k) < max(j, l)$.

Definition 4. *A dependency graph is **planar** iff it does not contain a pair of crossing links.*

2.4 Multiplanarity

The concept of planarity on its own does not seem to be very relevant as an extension of projectivity for practical dependency parsing. According to the results by Kuhlmann and Nivre (2006), most non-projective structures in dependency treebanks are also non-planar, so being able to parse planar structures will only give us a modest improvement in coverage with respect to a projective parser. However, our interest in planarity is motivated by the fact that it can be generalised to **multiplanarity** (Yli-Jyrä, 2003):

[1] For notational convenience, we will assume throughout the paper that all symbols in an input string are distinct, i.e., $i \neq j \Leftrightarrow w_i \neq w_j$. This can be guaranteed in practice by annotating each terminal symbol with its position in the input.

[2] In practice, dependency links are usually **labeled**, but to simplify the presentation we will ignore labels throughout most of the paper. However, all the results and algorithms presented can be applied to labeled dependency graphs and will be so applied in the experimental evaluation.

[3] For dependency forests that are extended with a unique artificial root located at position 0, as is commonly done, the two notions are equivalent.

[4] Planarity in the context of dependency structures is not to be confused with the homonymous concept in graph theory, which does not restrict links to be drawn above the nodes.

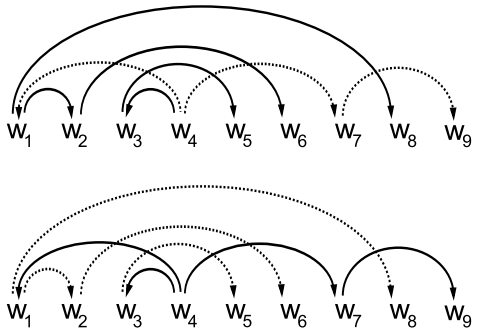

Figure 1: A 2-planar dependency structure with two different ways of distributing its links into two planes (represented by solid and dotted lines).

Definition 5. *A dependency graph $G = (V, E)$ is **m-planar** iff there exist planar dependency graphs $G_1 = (V, E_1), \ldots, G_m = (V, E_m)$ (called **planes**) such that $E = E_1 \cup \cdots \cup E_m$.*

Intuitively, we can associate planes with colours and say that a dependency graph G is m-planar if it is possible to assign one of m colours to each of its links in such a way that links with the same colour do not cross. Note that there may be multiple ways of dividing an m-planar graph into planes, as shown in the example of Figure 1.

3 Determining Multiplanarity

Several constraints on non-projective dependency structures have been proposed recently that seek a good balance between parsing efficiency and coverage of non-projective phenomena present in natural language treebanks. For example, Kuhlmann and Nivre (2006) and Havelka (2007) have shown that the vast majority of structures present in existing treebanks are well-nested and have a small gap degree (Bodirsky et al., 2005), leading to an interest in parsers for these kinds of structures (Gómez-Rodríguez et al., 2009). No similar analysis has been performed for m-planar structures, although Yli-Jyrä (2003) provides evidence that all except two structures in the Danish dependency treebank are at most 3-planar. However, his analysis is based on constraints that restrict the possible ways of assigning planes to dependency links, and he is not guaranteed to find the minimal number m for which a given structure is m-planar.

In this section, we provide a procedure for finding the minimal number m such that a dependency graph is m-planar and use it to show that the vast majority of sentences in dependency treebanks are

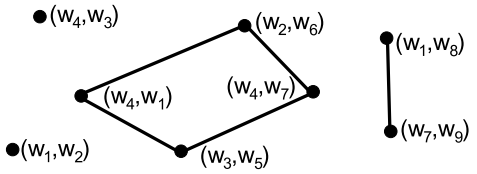

Figure 2: The crossings graph corresponding to the dependency structure of Figure 1.

at most 2-planar, with a coverage comparable to that of well-nestedness. The idea is to reduce the problem of determining whether a dependency graph $G = (V, E)$ is m-planar, for a given value of m, to a standard graph colouring problem. Consider first the following undirected graph:

$U(G) = (E, C)$ where
$C = \{\{e_i, e_j\} \mid e_i, e_j \text{ are crossing links in } G\}$

This graph, which we call the **crossings graph** of G, has one node corresponding to each link in the dependency graph G, with an undirected link between two nodes if they correspond to crossing links in G. Figure 2 shows the crossings graph of the 2-planar structure in Figure 1.

As noted in Section 2.4, a dependency graph G is m-planar if each of its links can be assigned one of m colours in such a way that links with the same colours do not cross. In terms of the crossings graph, this means that G is m-planar if each of the *nodes* of $U(G)$ can be assigned one of m colours such that no two neighbours have the same colour. This amounts to solving the well-known k-colouring problem for $U(G)$, where $k = m$.

For $k = 1$ the problem is trivial: a graph is 1-colourable only if it has no edges. For $k = 2$, the problem can be solved in time linear in the size of the graph by simple breadth-first search. Given a graph $U = (V, E)$, we pick an arbitrary node v and give it one of two colours. This forces us to give the other colour to all its neighbours, the first colour to the neighbours' neighbours, and so on. This process continues until we have processed all the nodes in the connected component of v. If this has resulted in assigning two different colours to the same node, the graph is not 2-colourable. Otherwise, we have obtained a 2-colouring of the connected component of U that contains v. If there are still unprocessed nodes, we repeat the process by arbitrarily selecting one of them, continue with the rest of the connected components, and in this way obtain a 2-colouring of the whole graph if it

Table 1: Proportion of dependency trees classified by projectivity, planarity, m-planarity and ill-nestedness in treebanks for Arabic (Hajič et al., 2004), Czech (Hajič et al., 2006), Danish (Kromann, 2003), Dutch (van der Beek et al., 2002), German (Brants et al., 2002), Portuguese (Afonso et al., 2002), Swedish (Nilsson et al., 2005) and Turkish (Oflazer et al., 2003; Atalay et al., 2003).

exists. Since this process can be completed by visiting each node and edge of the graph U once, its complexity is $O(V + E)$. The crossings graph of a dependency graph with n nodes can trivially be built in time $O(n^2)$ by checking each pair of dependency links to determine if they cross, and cannot contain more than n^2 edges, which means that we can check if the dependency graph for a sentence of length n is 2-planar in $O(n^2)$ time.

For $k > 2$, the k-colouring problem is known to be NP-complete (Karp, 1972). However, we have found this not to be a problem when measuring multiplanarity in natural language treebanks, since the effective problem size can be reduced by noting that each connected component of the crossings graph can be treated separately, and that nodes that are not part of a cycle need not be considered.[5] Given that non-projective sentences in natural language tend to have a small proportion of non-projective links (Nivre and Nilsson, 2005), the connected components of their crossings graphs are very small, and k-colourings for them can quickly be found by brute-force search.

By applying these techniques to dependency treebanks of several languages, we obtain the data shown in Table 1. As we can see, the coverage provided by the 2-planarity constraint is comparable to that of well-nestedness. In most of the treebanks, well over 99% of the sentences are 2-planar, and 3-planarity has almost total coverage. As we will see below, the class of 2-planar dependency structures not only has good coverage of linguistic phenomena in existing treebanks but is also efficiently parsable with transition-based parsing methods, making it a practically interesting subclass of non-projective dependency structures.

[5] If we have a valid colouring for all the cycles in the graph, the rest of the nodes can be safely coloured by breadth-first search as in the $k = 2$ case.

4 Parsing 1-Planar Structures

In this section, we present a deterministic linear-time parser for planar dependency structures. The parser is a variant of Nivre's arc-eager projective parser (Nivre, 2003), modified so that it can also handle graphs that are planar but not projective. As seen in Table 1, this only gives a modest improvement in coverage compared to projective parsing, so the main interest of this algorithm lies in the fact that it can be generalised to deal with 2-planar structures, as shown in the next section.

4.1 Transition Systems

In the transition-based framework of Nivre (2008), a deterministic dependency parser is defined by a non-deterministic **transition system**, specifying a set of elementary operations that can be executed during the parsing process, and an **oracle** that deterministically selects a single transition at each choice point of the parsing process.

Definition 6. *A **transition system** for dependency parsing is a quadruple $S = (C, T, c_s, C_t)$ where*

1. *C is a set of possible parser **configurations**,*
2. *T is a set of **transitions**, each of which is a partial function $t : C \rightarrow C$,*
3. *c_s is a function that maps each input sentence w to an **initial configuration** $c_s(w) \in C$,*
4. *$C_t \subseteq C$ is a set of **terminal configurations**.*

Definition 7. *An **oracle** for a transition system $S = (C, T, c_s, C_t)$ is a function $o : C \rightarrow T$.*

An input sentence w can be parsed using a transition system $S = (C, T, c_s, C_t)$ and an oracle o by starting in the initial configuration $c_s(w)$, calling the oracle function on the current configuration c, and updating the configuration by applying the transition $o(c)$ returned by the oracle. This process is repeated until a terminal configuration is

Initial configuration: $c_s(w_1 \dots w_n) = \langle [], [w_1 \dots w_n], \emptyset \rangle$

Terminal configurations: $C_f = \{\langle \Sigma, [], A \rangle \in C\}$

Transitions:

SHIFT $\langle \Sigma, w_i|B, A\rangle \Rightarrow \langle \Sigma|w_i, B, A\rangle$

REDUCE $\langle \Sigma|w_i, B, A\rangle \Rightarrow \langle \Sigma, B, A\rangle$

LEFT-ARC $\langle \Sigma|w_i, w_j|B, A\rangle \Rightarrow \langle \Sigma|w_i, w_j|B, A \cup \{(w_j, w_i)\}\rangle$
only if $\nexists k|(w_k, w_i) \in A$ (single-head) and not $w_i \leftrightarrow^* w_j \in A$ (acyclicity).

RIGHT-ARC $\langle \Sigma|w_i, w_j|B, A\rangle \Rightarrow \langle \Sigma|w_i, w_j|B, A \cup \{(w_i, w_j)\}\rangle$
only if $\nexists k|(w_k, w_j) \in A$ (single-head) and not $w_i \leftrightarrow^* w_j \in A$ (acyclicity).

Figure 3: Transition system for planar dependency parsing.

reached, and the dependency analysis of the sentence is defined by the terminal configuration.

Each sequence of configurations that the parser can traverse from an initial configuration to a terminal configuration for some input w is called a **transition sequence**. If we associate each configuration c of a transition system $S = (C, T, c_s, C_t)$ with a dependency graph $g(c)$, we can say that S is **sound** for a class of dependency graphs $\mathcal{G}$ if, for every sentence w and transition sequence $(c_s(w), c_1, \dots, c_f)$ of S, $g(c_f)$ is in $\mathcal{G}$, and that S is **complete** for $\mathcal{G}$ if, for every sentence w and dependency graph $G \in \mathcal{G}$ for w, there is a transition sequence $(c_s(w), c_1, \dots, c_f)$ such that $g(c_f) = G$. A transition system that is sound and complete for $\mathcal{G}$ is said to be **correct** for $\mathcal{G}$.

Note that, apart from a correct transition system, a practical parser needs a good oracle to achieve the desired results, since a transition system only specifies how to reach all the possible dependency graphs that could be associated to a sentence, but not how to select the correct one. Oracles for practical parsers can be obtained by training classifiers on treebank data (Nivre et al., 2004).

4.2 A Transition System for Planar Structures

A correct transition system for the class of planar dependency forests can be obtained as a variant of the arc-eager projective system by Nivre (2003). As in that system, the set of configurations of the planar transition system is the set of all triples $c = \langle \Sigma, B, A\rangle$ such that Σ and B are disjoint lists of words from V_w (for some input w), and A is a set of dependency links over V_w. The list B, called the **buffer**, is initialised to the input string and is used to hold the words that are still to be read from the input. The list Σ, called the **stack**, is initially empty and holds words that have dependency links pending to be created. The system is shown in Figure 3, where we use the notation $\Sigma|w_i$ for a stack with top w_i and tail Σ, and we invert the notation for the buffer for clarity (i.e., $w_i|B$ is a buffer with top w_i and tail B).

The system reads the input from left to right and creates links in a left-to-right order by executing its four transitions:

1. SHIFT: pops the first (leftmost) word in the buffer, and pushes it to the stack.
2. LEFT-ARC: adds a link from the first word in the buffer to the top of the stack.
3. RIGHT-ARC: adds a link from the top of the stack to the first word in the buffer.
4. REDUCE: pops the top word from the stack, implying that we have finished building links to or from it.

Note that the planar parser's transitions are more fine-grained than those of the arc-eager projective parser by Nivre (2003), which pops the stack as part of its LEFT-ARC transition and shifts a word as part of its RIGHT-ARC transition. Forcing these actions after creating dependency links rules out structures whose root is covered by a dependency link, which are planar but not projective. In order to support these structures, we therefore simplify the ARC transitions (LEFT-ARC and RIGHT-ARC) so that they only create an arc. For the same reason, we remove the constraint in Nivre's parser by which words without a head cannot be reduced. This has the side effect of making the parser able to output cyclic graphs. Since we are interested in planar dependency *forests*, which do not contain cycles, we only apply ARC transitions after checking that there is no undirected path between the nodes to be linked. This check can be done without affecting the linear-time complexity of the

parser by storing the weakly connected component of each node in $g(c)$.

The fine-grained transitions used by this parser have also been used by Sagae and Tsujii (2008) to parse DAGs. However, the latter parser differs from ours in the constraints, since it does not allow the reduction of words without a head (disallowing forests with covered roots) and does not enforce the acyclicity constraint (which is guaranteed by post-processing the graphs to break cycles).

4.3 Correctness and Complexity

For reasons of space, we can only give a sketch of the correctness proof. We wish to prove that the planar transition system is sound and complete for the set $\mathcal{F}_p$ of all planar dependency forests. To prove soundness, we have to show that, for every sentence w and transition sequence $(c_s(w), c_1, \ldots, c_f)$, the graph $g(c_f)$ associated with c_f is in $\mathcal{F}_p$. We take the graph associated with a configuration $c = (\Sigma, B, A)$ to be $g(c) = (V_w, A)$. With this, we prove the stronger claim that $g(c) \in \mathcal{F}_p$ for every configuration c that belongs to some transition sequence starting with $c_s(w)$. This amounts to showing that in every configuration c reachable from $c_s(w)$, $g(c)$ meets the following three conditions that characterise a planar dependency forest: (1) $g(c)$ does not contain nodes with more than one head; (2) $g(c)$ is acyclic; and (3) $g(c)$ contains no crossing links. (1) is trivially guaranteed by the single-head constraint; (2) follows from (1) and the acyclicity constraint; and (3) can be established by proving that there is no transition sequence that will invoke two ARC transitions on node pairs that would create crossing links. At the point when a link from w_i to w_j is created, we know that all the words strictly located between w_i and w_j are not in the stack or in the buffer, so no links can be created to or from them.

To prove completeness, we show that every planar dependency forest $G = (V, E) \in \mathcal{F}_p$ for a sentence w can be produced by applying the oracle function that maps a configuration $\langle \Sigma | w_i, w_j | B, A \rangle$ to:

1. LEFT-ARC if $w_j \rightarrow w_i \in (E \setminus A)$,
2. RIGHT-ARC if $w_i \rightarrow w_j \in (E \setminus A)$,
3. REDUCE if $\exists x_{[x<i]}[w_x \leftrightarrow w_j \in (E \setminus A)]$,
4. SHIFT otherwise.

We show completeness by setting the following invariants on transitions traversed by the application of the oracle:

1. $\forall a, b_{[a,b<j]}[w_a \leftrightarrow w_b \in E \Rightarrow w_a \leftrightarrow w_b \in A]$
2. $[w_i \leftrightarrow w_j \in A \Rightarrow$
   $\forall k_{[i<k<j]}[w_k \leftrightarrow w_j \in E \Rightarrow w_k \leftrightarrow w_j \in A]]$
3. $\forall k_{[k<j]}[w_k \notin \Sigma \Rightarrow$
   $\forall l_{[l>k]}[w_k \leftrightarrow w_l \in E \Rightarrow w_k \leftrightarrow w_l \in A]]$

We can show that each branch of the oracle function keeps these invariants true. When we reach a terminal configuration (which always happens after a finite number of transitions, since every transition generating a configuration $c = \langle \Sigma, B, A \rangle$ decreases the value of the variant function $|E| + |\Sigma| + 2|B| - |A|$), it can be deduced from the invariant that $A = E$, which proves completeness.

The worst-case complexity of a deterministic transition-based parser is given by an upper bound on transition sequence length (Nivre, 2008). For the planar system, like its projective counterpart, the length is clearly $O(n)$ (where n is the number of input words), since there can be no more than n SHIFT transitions, n REDUCE transitions, and n ARC transitions in a transition sequence.

5 Parsing 2-Planar Structures

The planar parser introduced in the previous section can be extended to parse all 2-planar dependency structures by adding a second stack to the system and making REDUCE and ARC transitions apply to only one of the stacks at a time. This means that the set of links created in the context of each individual stack will be planar, but pairs of links created in different stacks are allowed to cross. In this way, the parser will build a 2-planar dependency forest by using each of the stacks to construct one of its two planes.

The 2-planar transition system, shown in Figure 4, has configurations of the form $\langle \Sigma_0, \Sigma_1, B, A \rangle$, where we call Σ_0 the **active stack** and Σ_1 the **inactive stack**, and the following transitions:

1. SHIFT: pops the first (leftmost) word in the buffer, and pushes it to *both* stacks.
2. LEFT-ARC: adds a link from the first word in the buffer to the top of the *active* stack.
3. RIGHT-ARC: adds a link from the top of the *active* stack to the first word in the buffer.
4. REDUCE: pops the top word from the *active* stack, implying that we have added all links to or from it on the plane tied to that stack.
5. SWITCH: makes the active stack inactive and vice versa, changing the plane the parser is working with.

Initial configuration: $c_s(w_1 \dots w_n) = \langle [], [], [w_1 \dots w_n], \emptyset \rangle$

Terminal configurations: $C_f = \{\langle \Sigma_0, \Sigma_1, [], A \rangle \in C\}$

Transitions:

SHIFT $\langle \Sigma_0, \Sigma_1, w_i|B, A\rangle \Rightarrow \langle \Sigma_0|w_i, \Sigma_1|w_i, B, A\rangle$

REDUCE $\langle \Sigma_0|w_i, \Sigma_1, B, A\rangle \Rightarrow \langle \Sigma_0, \Sigma_1, B, A\rangle$

LEFT-ARC $\langle \Sigma_0|w_i, \Sigma_1, w_j|B, A\rangle \Rightarrow \langle \Sigma_0|w_i, \Sigma_1, w_j|B, A \cup \{(w_j, w_i)\}\rangle$
only if $\nexists k \mid (w_k, w_i) \in A$ (single-head) and not $w_i \leftrightarrow^* w_j \in A$ (acyclicity).

RIGHT-ARC $\langle \Sigma_0|w_i, \Sigma_1, w_j|B, A\rangle \Rightarrow \langle \Sigma_0|w_i, \Sigma_1, w_j|B, A \cup \{(w_i, w_j)\}\rangle$
only if $\nexists k|(w_k, w_j) \in A$ (single-head) and not $w_i \leftrightarrow^* w_j \in A$ (acyclicity).

SWITCH $\langle \Sigma_0, \Sigma_1, B, A\rangle \Rightarrow \langle \Sigma_1, \Sigma_0, B, A\rangle$

Figure 4: Transition system for 2-planar dependency parsing.

5.1 Correctness and Complexity

As in the planar case, we provide a brief sketch of the proof that the transition system in Figure 4 is correct for the set $\mathcal{F}_{2p}$ of 2-planar dependency forests. Soundness follows from a reasoning analogous to the planar case, but applying the proof of planarity separately to each stack. In this way, we prove that the sets of dependency links created by linking to or from the top of each of the two stacks are always planar graphs, and thus their union (which is the dependency graph stored in A) is 2-planar. This, together with the single-head and acyclicity constraints, guarantees that the dependency graphs associated with reachable configurations are always 2-planar dependency forests.

For completeness, we assume an extended form of the transition system where transitions take the form $\langle \Sigma_0, \Sigma_1, B, A, p\rangle$, where p is a flag taking values in $\{0, 1\}$ which equals 0 for initial configurations and gets flipped by each application of a SWITCH transition. Then we show that every 2-planar dependency forest $G \in \mathcal{F}_{2p}$, with planes $G_0 = (V, E_0)$ and $G_1 = (V, E_1)$, can be produced by this system by applying the oracle function that maps a configuration $\langle \Sigma_0|w_i, \Sigma_1, w_j|B, A, p\rangle$ to:

1. LEFT-ARC if $w_j \rightarrow w_i \in (E_p \setminus A)$,
2. RIGHT-ARC if $w_i \rightarrow w_j \in (E_p \setminus A)$,
3. REDUCE if $\exists x_{[x<i]}[w_x \leftrightarrow w_j \in (E_p \setminus A) \wedge \neg\exists y_{[x<y\leq i]}[w_y \leftrightarrow w_j \in (E_{\overline{p}} \setminus A)]]$,
4. SWITCH if $\exists x < j : (w_x, w_j)$ or $(w_j, w_x) \in (E_{\overline{p}} \setminus A)$,
5. SHIFT otherwise.

This can be shown by employing invariants analogous to the planar case, with the difference that the third invariant applies to each stack and its corresponding plane: if Σ_y is associated with the plane E_x,[6] we have:

3. $\forall k_{[k<j]}[w_k \notin \Sigma_y] \Rightarrow$
   $\forall l_{[l>k]}[w_k \leftrightarrow w_l \in E_x] \Rightarrow [w_k \leftrightarrow w_l \in A]$

Since the presence of the flag p in configurations does not affect the set of dependency graphs generated by the system, the completeness of the system extended with the flag p implies that of the system in Figure 4.

We can show that the complexity of the 2-planar system is $O(n)$ by the same kind of reasoning as for the 1-planar system, with the added complication that we must constrain the system to prevent two adjacent SWITCH transitions. In fact, without this restriction, the parser is not even guaranteed to terminate.

5.2 Implementation

In practical settings, oracles for transition-based parsers can be approximated by classifiers trained on treebank data (Nivre, 2008). To do this, we need an oracle that will generate transition sequences for gold-standard dependency graphs. In the case of the planar parser of Section 4.2, the oracle of 4.3 is suitable for this purpose. However, in the case of the 2-planar parser, the oracle used for the completeness proof in Section 5.1 cannot be used directly, since it requires the gold-standard trees to be divided into two planes in order to generate a transition sequence.

Of course, it is possible to use the algorithm presented in Section 3 to obtain a division of sentences into planes. However, for training purposes and to obtain a robust behaviour if non-2-planar

[6] The plane corresponding to each stack in a configuration changes with each SWITCH transition: Σ_x is associated with E_x in configurations where $p = 0$, and with $E_{\overline{x}}$ in those where $p = 1$.

Parser	Czech				Danish				German				Portuguese			
	LAS	UAS	NPP	NPR	LAS	UAS	NPP	NPR	LAS	UAS	NPP	NPR	LAS	UAS	NPP	NPR
2-planar	79.24	85.30	68.9	**60.7**	**83.81**	88.50	**66.7**	20.0	**86.50**	**88.84**	57.1	**45.8**	87.04	**90.82**	82.8	33.8
Malt P	78.18	84.12	–	–	83.31	88.30	–	–	85.36	88.06	–	–	86.60	90.20	–	–
Malt PP	**79.80**	**85.70**	**76.7**	56.1	83.67	**88.52**	41.7	**25.0**	85.76	88.66	**58.1**	40.7	**87.08**	90.66	**83.3**	**46.2**

Table 2: Parsing accuracy for 2-planar parser in comparison to MaltParser with (PP) and without (P) pseudo-projective transformations. LAS = labeled attachment score; UAS = unlabeled attachment score; NPP = precision on non-projective arcs; NPR = recall on non-projective arcs.

sentences are found, it is more convenient that the oracle can distribute dependency links into the planes incrementally, and that it produces a distribution of links that only uses SWITCH transitions when it is strictly needed to account for non-planarity. Thus we use a more complex version of the oracle which performs a search in the crossings graph to check if a dependency link can be built on the plane of the active stack, and only performs a switch when this is not possible. This has proved to work well in practice, as will be observed in the results in the next section.

6 Empirical Evaluation

In order to get a first estimate of the empirical accuracy that can be obtained with transition-based 2-planar parsing, we have evaluated the parser on four data sets from the CoNLL-X shared task (Buchholz and Marsi, 2006): Czech, Danish, German and Portuguese. As our baseline, we take the strictly projective arc-eager transition system proposed by Nivre (2003), as implemented in the freely available MaltParser system (Nivre et al., 2006a), with and without the pseudo-projective parsing technique for recovering non-projective dependencies (Nivre and Nilsson, 2005). For the two baseline systems, we use the parameter settings used by Nivre et al. (2006b) in the original shared task, where the pseudo-projective version of MaltParser was one of the two top performing systems (Buchholz and Marsi, 2006). For our 2-planar parser, we use the same kernelized SVM classifiers as MaltParser, using the LIBSVM package (Chang and Lin, 2001), with feature models that are similar to MaltParser but extended with features defined over the second stack.[7]

In Table 2, we report labeled (LAS) and unlabeled (UAS) attachment score on the four languages for all three systems. For the two systems that are capable of recovering non-projective dependencies, we also report precision (NPP) and recall (NPR) specifically on non-projective dependency arcs. The results show that the 2-planar parser outperforms the strictly projective variant of MaltParser on all metrics for all languages, and that it performs on a par with the pseudo-projective variant with respect to both overall attachment score and precision and recall on non-projective dependencies. These results look very promising in view of the fact that very little effort has been spent on optimizing the training oracle and feature model for the 2-planar parser so far.

It is worth mentioning that the 2-planar parser has two advantages over the pseudo-projective parser. The first is simplicity, given that it is based on a single transition system and makes a single pass over the input, whereas the pseudo-projective parsing technique involves preprocessing of training data and post-processing of parser output (Nivre and Nilsson, 2005). The second is the fact that it parses a well-defined class of dependency structures, with known coverage[8], whereas no formal characterization exists of the class of structures parsable by the pseudo-projective parser.

7 Conclusion

In this paper, we have presented an efficient algorithm for deciding whether a dependency graph is 2-planar and a transition-based parsing algorithm that is provably correct for 2-planar dependency forests, neither of which existed in the literature before. In addition, we have presented empirical results showing that the class of 2-planar dependency forests includes the overwhelming majority of structures found in existing treebanks and that a deterministic classifier-based implementation of the 2-planar parser gives state-of-the-art accuracy on four different languages.

[7] Complete information about experimental settings can be found at http://stp.lingfil.uu.se/ nivre/exp/.

[8] If more coverage is desired, the 2-planar parser can be generalised to m-planar structures for larger values of m by adding additional stacks. However, this comes at the cost of more complex training models, making the practical interest of increasing m beyond 2 dubious.

Viterbi Training for PCFGs: Hardness Results and Competitiveness of Uniform Initialization

Shay B. Cohen and **Noah A. Smith**
School of Computer Science
Carnegie Mellon University
Pittsburgh, PA 15213, USA
{scohen,nasmith}@cs.cmu.edu

Abstract

We consider the search for a maximum likelihood assignment of hidden derivations and grammar weights for a probabilistic context-free grammar, the problem approximately solved by "Viterbi training." We show that solving and even approximating Viterbi training for PCFGs is NP-hard. We motivate the use of uniform-at-random initialization for Viterbi EM as an optimal initializer in absence of further information about the correct model parameters, providing an approximate bound on the log-likelihood.

1 Introduction

Probabilistic context-free grammars are an essential ingredient in many natural language processing models (Charniak, 1997; Collins, 2003; Johnson et al., 2006; Cohen and Smith, 2009, *inter alia*). Various algorithms for training such models have been proposed, including unsupervised methods. Many of these are based on the expectation-maximization (EM) algorithm.

There are alternatives to EM, and one such alternative is Viterbi EM, also called "hard" EM or "sparse" EM (Neal and Hinton, 1998). Instead of using the parameters (which are maintained in the algorithm's current state) to find the true posterior over the derivations, Viterbi EM algorithm uses a posterior focused on the Viterbi parse of those parameters. Viterbi EM and variants have been used in various settings in natural language processing (Yejin and Cardie, 2007; Wang et al., 2007; Goldwater and Johnson, 2005; DeNero and Klein, 2008; Spitkovsky et al., 2010).

Viterbi EM can be understood as a coordinate ascent procedure that locally optimizes a function; we call this optimization goal "Viterbi training."

In this paper, we explore Viterbi training for probabilistic context-free grammars. We first show that under the assumption that P $\neq$ NP, solving and even approximating the Viterbi training problem is hard. This result holds even for hidden Markov models. We extend the main hardness result to the EM algorithm (giving an alternative proof to this known result), as well as the problem of *conditional* Viterbi training. We then describe a "competitiveness" result for uniform initialization of Viterbi EM: we show that initialization of the trees in an E-step which uses uniform distributions over the trees is optimal with respect to a certain approximate bound.

The rest of this paper is organized as follows. §2 gives background on PCFGs and introduces some notation. §3 explains Viterbi training, the declarative form of Viterbi EM. §4 describes a hardness result for Viterbi training. §5 extends this result to a hardness result of approximation and §6 further extends these results for other cases. §7 describes the advantages in using uniform-at-random initialization for Viterbi training. We relate these results to work on the k-means problem in §8.

2 Background and Notation

We assume familiarity with probabilistic context-free grammars (PCFGs). A PCFG $\boldsymbol{G}$ consists of:

- A finite set of nonterminal symbols $\mathcal{N}$;
- A finite set of terminal symbols Σ;
- For each $A \in \mathcal{N}$, a set of rewrite rules $R(A)$ of the form $A \rightarrow \alpha$, where $\alpha \in (\mathcal{N} \cup \Sigma)^*$, and $\mathcal{R} = \cup_{A \in \mathcal{N}} R(A)$;
- For each rule $A \rightarrow \alpha$, a probability $\theta_{A \rightarrow \alpha}$. The collection of probabilities is denoted $\boldsymbol{\theta}$, and they are constrained such that:

$$\begin{aligned} \forall (A \rightarrow \alpha) \in R(A), \quad \theta_{A \rightarrow \alpha} &\geq 0 \\ \forall A \in \mathcal{N}, \quad \sum_{\alpha : (A \rightarrow \alpha) \in R(A)} \theta_{A \rightarrow \alpha} &= 1 \end{aligned}$$

That is, $\boldsymbol{\theta}$ is grouped into $|\mathcal{N}|$ multinomial distributions.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1502–1511,
Uppsala, Sweden, 11-16 July 2010.

Under the PCFG, the joint probability of a string $x \in \Sigma^*$ and a grammatical derivation z is[1]

$$p(x, z \mid \boldsymbol{\theta}) = \prod_{(A\to\alpha)\in\mathcal{R}} (\theta_{A\to\alpha})^{f_{A\to\alpha}(z)} \quad (1)$$
$$= \exp \sum_{(A\to\alpha)\in\mathcal{R}} f_{A\to\alpha}(z) \log \theta_{A\to\alpha}$$

where $f_{A\to\alpha}(z)$ is a function that "counts" the number of times the rule $A \to \alpha$ appears in the derivation z. $f_A(z)$ will similarly denote the number of times that nonterminal A appears in z. Given a sample of derivations $\boldsymbol{z} = \langle z_1, \ldots, z_n \rangle$, let:

$$F_{A\to\alpha}(\boldsymbol{z}) = \sum_{i=1}^{n} f_{A\to\alpha}(z_i) \quad (2)$$

$$F_A(\boldsymbol{z}) = \sum_{i=1}^{n} f_A(z_i) \quad (3)$$

We use the following notation for $\boldsymbol{G}$:

- $L(\boldsymbol{G})$ is the set of all strings (sentences) x that can be generated using the grammar $\boldsymbol{G}$ (the "language of $\boldsymbol{G}$").
- $D(\boldsymbol{G})$ is the set of all possible derivations z that can be generated using the grammar $\boldsymbol{G}$.
- $D(\boldsymbol{G}, x)$ is the set of all possible derivations z that can be generated using the grammar $\boldsymbol{G}$ and have the yield x.

3 Viterbi Training

Viterbi EM, or "hard" EM, is an unsupervised learning algorithm, used in NLP in various settings (Yejin and Cardie, 2007; Wang et al., 2007; Goldwater and Johnson, 2005; DeNero and Klein, 2008; Spitkovsky et al., 2010). In the context of PCFGs, it aims to select parameters $\boldsymbol{\theta}$ and phrase-structure trees $\boldsymbol{z}$ jointly. It does so by iteratively updating a state consisting of $(\boldsymbol{\theta}, \boldsymbol{z})$. The state is initialized with some value, then the algorithm alternates between (i) a "hard" E-step, where the strings $x_1, \ldots, x_n$ are parsed according to a current, fixed $\boldsymbol{\theta}$, giving new values for $\boldsymbol{z}$, and (ii) an M-step, where the $\boldsymbol{\theta}$ are selected to maximize likelihood, with $\boldsymbol{z}$ fixed.

With PCFGs, the E-step requires running an algorithm such as (probabilistic) CKY or Earley's algorithm, while the M-step normalizes frequency counts $F_{A\to\alpha}(\boldsymbol{z})$ to obtain the maximum likelihood estimate's closed-form solution.

We can understand Viterbi EM as a coordinate ascent procedure that approximates the solution to the following declarative problem:

Problem 1. ViterbiTrain
Input: *$\boldsymbol{G}$ context-free grammar, $x_1, \ldots, x_n$ training instances from $L(\boldsymbol{G})$*
Output: *$\boldsymbol{\theta}$ and $z_1, \ldots, z_n$ such that*

$$(\boldsymbol{\theta}, z_1, \ldots, z_n) = \operatorname*{argmax}_{\boldsymbol{\theta}, \boldsymbol{z}} \prod_{i=1}^{n} p(x_i, z_i \mid \boldsymbol{\theta}) \quad (4)$$

The optimization problem in Eq. 4 is non-convex and, as we will show in §4, hard to optimize. Therefore it is necessary to resort to approximate algorithms like Viterbi EM.

Neal and Hinton (1998) use the term "sparse EM" to refer to a version of the EM algorithm where the E-step finds the modes of hidden variables (rather than marginals as in standard EM). Viterbi EM is a variant of this, where the E-step finds the mode for each x_i's derivation, $\operatorname{argmax}_{z\in D(\boldsymbol{G},x_i)} p(x_i, z \mid \boldsymbol{\theta})$.

We will refer to

$$\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{z}) = \prod_{i=1}^{n} p(x_i, z_i \mid \boldsymbol{\theta}) \quad (5)$$

as "the objective function of ViterbiTrain."

Viterbi training and Viterbi EM are closely related to **self-training**, an important concept in semi-supervised NLP (Charniak, 1997; McClosky et al., 2006a; McClosky et al., 2006b). With self-training, the model is learned with some seed annotated data, and then iterates by labeling new, unannotated data and adding it to the original annotated training set. McClosky et al. consider self-training to be "one round of Viterbi EM" with supervised initialization using labeled seed data. We refer the reader to Abney (2007) for more details.

4 Hardness of Viterbi Training

We now describe hardness results for Problem 1. We first note that the following problem is known to be NP-hard, and in fact, NP-complete (Sipser, 2006):

Problem 2. 3-SAT
Input: *A formula $\phi = \bigwedge_{i=1}^{m} (a_i \vee b_i \vee c_i)$ in conjunctive normal form, such that each clause has* 3

[1] Note that $x = \text{yield}(z)$; if the derivation is known, the string is also known. On the other hand, there may be many derivations with the same yield, perhaps even infinitely many.

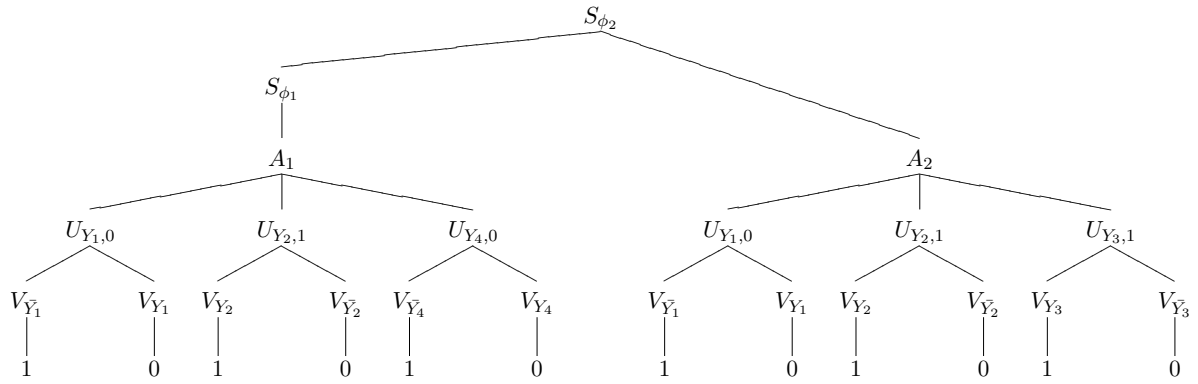

Figure 1: An example of a Viterbi parse tree which represents a satisfying assignment for $\phi = (Y_1 \vee Y_2 \vee \bar{Y_4}) \wedge (\bar{Y_1} \vee \bar{Y_2} \vee Y_3)$. In $\boldsymbol{\theta}_\phi$, all rules appearing in the parse tree have probability 1. The extracted assignment would be $Y_1 = 0, Y_2 = 1, Y_3 = 1, Y_4 = 0$. Note that there is no usage of two different rules for a single nonterminal.

literals.

Output: *1 if there is a satisfying assignment for ϕ and 0 otherwise.*

We now describe a reduction of 3-SAT to Problem 1. Given an instance of the 3-SAT problem, the reduction will, in polynomial time, create a grammar and a single string such that solving the ViterbiTrain problem for this grammar and string will yield a solution for the instance of the 3-SAT problem.

Let $\phi = \bigwedge_{i=1}^{m} (a_i \vee b_i \vee c_i)$ be an instance of the 3-SAT problem, where a_i, b_i and c_i are literals over the set of variables $\{Y_1, \ldots, Y_N\}$ (a literal refers to a variable Y_j or its negation, $\bar{Y_j}$). Let C_j be the jth clause in ϕ, such that $C_j = a_j \vee b_j \vee c_j$. We define the following context-free grammar $\boldsymbol{G}_\phi$ and string to parse s_ϕ:

1. The terminals of $\boldsymbol{G}_\phi$ are the binary digits $\Sigma = \{0, 1\}$.
2. We create N nonterminals V_{Y_r}, $r \in \{1, \ldots, N\}$ and rules $V_{Y_r} \to 0$ and $V_{Y_r} \to 1$.
3. We create N nonterminals $V_{\bar{Y}_r}$, $r \in \{1, \ldots, N\}$ and rules $V_{\bar{Y}_r} \to 0$ and $V_{\bar{Y}_r} \to 1$.
4. We create $U_{Y_r,1} \to V_{Y_r} V_{\bar{Y}_r}$ and $U_{Y_r,0} \to V_{\bar{Y}_r} V_{Y_r}$.
5. We create the rule $S_{\phi_1} \to A_1$. For each $j \in \{2, \ldots, m\}$, we create a rule $S_{\phi_j} \to S_{\phi_{j-1}} A_j$ where S_{ϕ_j} is a new nonterminal indexed by $\phi_j \triangleq \bigwedge_{i=1}^{j} C_i$ and A_j is also a new nonterminal indexed by $j \in \{1, \ldots, m\}$.
6. Let $C_j = a_j \vee b_j \vee c_j$ be clause j in ϕ. Let $Y(a_j)$ be the variable that a_j mentions. Let (y_1, y_2, y_3) be a satisfying assignment for C_j where $y_k \in \{0, 1\}$ and is the value of $Y(a_j)$, $Y(b_j)$ and $Y(c_j)$ respectively for $k \in \{1, 2, 3\}$. For each such clause-satisfying assignment, we add the rule:
$$A_j \to U_{Y(a_j),y_1} U_{Y(b_j),y_2} U_{Y(c_j),y_3} \qquad (6)$$
For each A_j, we would have at most 7 rules of that form, since one rule will be logically inconsistent with $a_j \vee b_j \vee c_j$.
7. The grammar's start symbol is S_{ϕ_n}.
8. The string to parse is $s_\phi = (10)^{3m}$, i.e. $3m$ consecutive occurrences of the string 10.

A parse of the string s_ϕ using $\boldsymbol{G}_\phi$ will be used to get an assignment by setting $Y_r = 0$ if the rule $V_{Y_r} \to 0$ or $V_{\bar{Y}_r} \to 1$ are used in the derivation of the parse tree, and 1 otherwise. Notice that at this point we do not exclude "contradictions" coming from the parse tree, such as $V_{Y_3} \to 0$ used in the tree together with $V_{Y_3} \to 1$ or $V_{\bar{Y}_3} \to 0$. The following lemma gives a condition under which the assignment is consistent (so contradictions do not occur in the parse tree):

Lemma 1. *Let ϕ be an instance of the 3-SAT problem, and let $\boldsymbol{G}_\phi$ be a probabilistic CFG based on the above grammar with weights $\boldsymbol{\theta}_\phi$. If the (multiplicative) weight of the Viterbi parse of s_ϕ is 1, then the assignment extracted from the parse tree is consistent.*

Proof. Since the probability of the Viterbi parse is 1, all rules of the form $\{V_{Y_r}, V_{\bar{Y}_r}\} \to \{0, 1\}$ which appear in the parse tree have probability 1 as well. There are two possible types of inconsistencies. We show that neither exists in the Viterbi parse:

1. For any r, an appearance of both rules of the form $V_{Y_r} \to 0$ and $V_{Y_r} \to 1$ cannot occur because all rules that appear in the Viterbi parse tree have probability 1.
2. For any r, an appearance of rules of the form $V_{Y_r} \to 1$ and $V_{\bar{Y_r}} \to 1$ cannot occur, because whenever we have an appearance of the rule $V_{Y_r} \to 0$, we have an adjacent appearance of the rule $V_{\bar{Y_r}} \to 1$ (because we parse substrings of the form 10), and then again we use the fact that all rules in the parse tree have probability 1. The case of $V_{Y_r} \to 0$ and $V_{\bar{Y_r}} \to 0$ is handled analogously.

Thus, both possible inconsistencies are ruled out, resulting in a consistent assignment. □

Figure 1 gives an example of an application of the reduction.

Lemma 2. *Define ϕ, $\boldsymbol{G}_\phi$ as before. There exists $\boldsymbol{\theta}_\phi$ such that the Viterbi parse of s_ϕ is 1 if and only if ϕ is satisfiable. Moreover, the satisfying assignment is the one extracted from the parse tree with weight 1 of s_ϕ under $\boldsymbol{\theta}_\phi$.*

Proof. ($\Longrightarrow$) Assume that there is a satisfying assignment. Each clause $C_j = a_j \vee b_j \vee c_j$ is satisfied using a tuple (y_1, y_2, y_3) which assigns value for $Y(a_j)$, $Y(b_j)$ and $Y(c_j)$. This assignment corresponds the following rule

$$A_j \to U_{Y(a_j),y_1} U_{Y(b_j),y_2} U_{Y(c_j),y_3} \qquad (7)$$

Set its probability to 1, and set all other rules of A_j to 0. In addition, for each r, if $Y_r = y$, set the probabilities of the rules $V_{Y_r} \to y$ and $V_{\bar{Y_r}} \to 1-y$ to 1 and $V_{\bar{Y_r}} \to y$ and $V_{Y_r} \to 1 - y$ to 0. The rest of the weights for $S_{\phi_j} \to S_{\phi_{j-1}} A_j$ are set to 1. This assignment of rule probabilities results in a Viterbi parse of weight 1.

($\Longleftarrow$) Assume that the Viterbi parse has probability 1. From Lemma 1, we know that we can extract a consistent assignment from the Viterbi parse. In addition, for each clause C_j we have a rule

$$A_j \to U_{Y(a_j),y_1} U_{Y(b_j),y_2} U_{Y(c_j),y_3} \qquad (8)$$

that is assigned probability 1, for some (y_1, y_2, y_3). One can verify that (y_1, y_2, y_3) are the values of the assignment for the corresponding variables in clause C_j, and that they satisfy this clause. This means that each clause is satisfied by the assignment we extracted. □

In order to show an NP-hardness result, we need to "convert" ViterbiTrain to a decision problem. The natural way to do it, following Lemmas 1 and 2, is to state the decision problem for ViterbiTrain as "given $\boldsymbol{G}$ and $x_1, \ldots, x_n$ and $\alpha \geq 0$, is the optimized value of the objective function $\mathcal{L}(\boldsymbol{\theta}, \boldsymbol{z}) \geq \alpha$?" and use $\alpha = 1$ together with Lemmas 1 and 2. (Naturally, an algorithm for solving ViterbiTrain can easily be used to solve its decision problem.)

Theorem 3. *The decision version of the* ViterbiTrain *problem is NP-hard.*

5 Hardness of Approximation

A natural path of exploration following the hardness result we showed is determining whether an *approximation* of ViterbiTrain is also hard. Perhaps there is an efficient approximation algorithm for ViterbiTrain we could use instead of coordinate ascent algorithms such as Viterbi EM. Recall that such algorithms' main guarantee is identifying a local maximum; we know nothing about how far it will be from the global maximum.

We next show that approximating the objective function of ViterbiTrain with a constant factor of ρ is hard for any $\rho \in (\frac{1}{2}, 1]$ (i.e., $1/2 + \epsilon$ approximation is hard for any $\epsilon \leq 1/2$). This means that, under the P $\neq$ NP assumption, there is no efficient algorithm that, given a grammar $\boldsymbol{G}$ and a sample of sentences $x_1, \ldots, x_n$, returns $\boldsymbol{\theta}'$ and $\boldsymbol{z}'$ such that:

$$\mathcal{L}(\boldsymbol{\theta}', \boldsymbol{z}') \quad \geq \quad \rho \cdot \max_{\boldsymbol{\theta}, \boldsymbol{z}} \prod_{i=1}^{n} p(x_i, z_i \mid \boldsymbol{\theta}) \qquad (9)$$

We will continue to use the same reduction from §4. Let s_ϕ be the string from that reduction, and let $(\boldsymbol{\theta}, z)$ be the optimal solution for ViterbiTrain given $\boldsymbol{G}_\phi$ and s_ϕ. We first note that if $p(s_\phi, z \mid \boldsymbol{\theta}) < 1$ (implying that there is no satisfying assignment), then there must be a nonterminal which appears along with two different rules in z.

This means that we have a nonterminal $B \in \mathcal{N}$ with some rule $B \to \alpha$ that appears k times, while the nonterminal appears in the parse $r \geq k + 1$ times. Given the tree z, the $\boldsymbol{\theta}$ that maximizes the objective function is the maximum likelihood estimate (MLE) for z (counting and normalizing the rules).[2] We therefore know that the ViterbiTrain objective function, $\mathcal{L}(\boldsymbol{\theta}, z)$, is at

[2] Note that we can only make $p(z \mid \boldsymbol{\theta}, x)$ greater by using $\boldsymbol{\theta}$ to be the MLE for the derivation z.

most $\left(\frac{k}{r}\right)^k$, because it includes a factor equal to $\left(\frac{f_{B\to\alpha}(z)}{f_B(z)}\right)^{f_{B\to\alpha}(z)}$, where $f_B(z)$ is the number of times nonterminal B appears in z (hence $f_B(z) = r$) and $f_{B\to\alpha}(z)$ is the number of times $B \to \alpha$ appears in z (hence $f_{B\to\alpha}(z) = k$). For any $k \geq 1, r \geq k+1$:

$$\left(\frac{k}{r}\right)^k \leq \left(\frac{k}{k+1}\right)^k \leq \frac{1}{2} \qquad (10)$$

This means that if the value of the objective function of ViterbiTrain is not 1 using the reduction from §4, then it is at most $\frac{1}{2}$. If we had an efficient approximate algorithm with approximation coefficient $\rho > \frac{1}{2}$ (Eq. 9 holds), then in order to solve 3-SAT for formula ϕ, we could run the algorithm on $\boldsymbol{G}_\phi$ and s_ϕ and check whether the assignment to $(\boldsymbol{\theta}, z)$ that the algorithm returns satisfies ϕ or not, and return our response accordingly.

If ϕ were satisfiable, then the true maximal value of $\mathfrak{L}$ would be 1, and the approximation algorithm would return $(\boldsymbol{\theta}, z)$ such that $\mathfrak{L}(\boldsymbol{\theta}, z) \geq \rho > \frac{1}{2}$. z would have to correspond to a satisfying assignment, and in fact $p(z \mid \boldsymbol{\theta}) = 1$, because in any other case, the probability of a derivation which does not represent a satisfying assignment is smaller than $\frac{1}{2}$. If ϕ were not satisfiable, then the approximation algorithm would never return a $(\boldsymbol{\theta}, z)$ that results in a satisfying assignment (because such a $(\boldsymbol{\theta}, z)$ does not exist).

The conclusion is that an efficient algorithm for approximating the objective function of ViterbiTrain (Eq. 4) within a factor of $\frac{1}{2} + \epsilon$ is unlikely to exist. If there were such an algorithm, we could use it to solve 3-SAT using the reduction from §4.

6 Extensions of the Hardness Result

An alternative problem to Problem 1, a variant of Viterbi-training, is the following (see, for example, Klein and Manning, 2001):

Problem 3. ConditionalViterbiTrain
Input: $\boldsymbol{G}$ *context-free grammar,* $x_1, \ldots, x_n$ *training instances from* $L(\boldsymbol{G})$
Output: $\boldsymbol{\theta}$ *and* $z_1, \ldots, z_n$ *such that*

$$(\boldsymbol{\theta}, z_1, \ldots, z_n) = \operatorname*{argmax}_{\boldsymbol{\theta}, \boldsymbol{z}} \prod_{i=1}^{n} p(z_i \mid \boldsymbol{\theta}, x_i) \quad (11)$$

Here, instead of maximizing the likelihood, we maximize the *conditional* likelihood. Note that there is a hidden assumption in this problem definition, that x_i can be parsed using the grammar $\boldsymbol{G}$. Otherwise, the quantity $p(z_i \mid \boldsymbol{\theta}, x_i)$ is not well-defined. We can extend ConditionalViterbiTrain to return $\perp$ in the case of not having a parse for one of the x_i—this can be efficiently checked using a run of a cubic-time parser on each of the strings x_i with the grammar $\boldsymbol{G}$.

An approximate technique for this problem is similar to Viterbi EM, only modifying the M-step to maximize the conditional, rather than joint, likelihood. This new M-step will not have a closed form and may require auxiliary optimization techniques like gradient ascent.

Our hardness result for ViterbiTrain applies to ConditionalViterbiTrain as well. The reason is that if $p(z, s_\phi \mid \boldsymbol{\theta}_\phi) = 1$ for a ϕ with a satisfying assignment, then $L(\boldsymbol{G}) = \{s_\phi\}$ and $D(\boldsymbol{G}) = \{z\}$. This implies that $p(z \mid \boldsymbol{\theta}_\phi, s_\phi) = 1$. If ϕ is unsatisfiable, then for the optimal $\boldsymbol{\theta}$ of ViterbiTrain we have z and z' such that $0 < p(z, s_\phi \mid \boldsymbol{\theta}_\phi) < 1$ and $0 < p(z', s_\phi \mid \boldsymbol{\theta}_\phi) < 1$, and therefore $p(z \mid \boldsymbol{\theta}_\phi, s_\phi) < 1$, which means the conditional objective function will not obtain the value 1. (Note that there always exist some parameters $\boldsymbol{\theta}_\phi$ that generate s_ϕ.) So, again, given an algorithm for ConditionalViterbiTrain, we can discern between a satisfiable formula and an unsatisfiable formula, using the reduction from §4 with the given algorithm, and identify whether the value of the objective function is 1 or strictly less than 1. We get the result that:

Theorem 4. *The decision problem of* ConditionalViterbiTrain *problem is NP-hard.*

where the decision problem of ConditionalViterbiTrain is defined analogously to the decision problem of ViterbiTrain.

We can similarly show that finding the global maximum of the marginalized likelihood:

$$\max_{\boldsymbol{\theta}} \frac{1}{n} \sum_{i=1}^{n} \log \sum_{z} p(x_i, z \mid \boldsymbol{\theta}) \qquad (12)$$

is NP-hard. The reasoning follows. Using the reduction from before, if ϕ is satisfiable, then Eq. 12 gets value 0. If ϕ is unsatisfiable, then we would still get value 0 only if $L(\boldsymbol{G}) = \{s_\phi\}$. If $\boldsymbol{G}_\phi$ generates a single derivation for $(10)^{3m}$, then we actually do have a satisfying assignment from

Lemma 1. Otherwise (more than a single derivation), the optimal $\boldsymbol{\theta}$ would have to give fractional probabilities to rules of the form $V_{Y_r} \rightarrow \{0, 1\}$ (or $V_{\bar{Y}_r} \rightarrow \{0, 1\}$). In that case, it is no longer true that $(10)^{3m}$ is the only generated sentence, which is a contradiction.

The quantity in Eq. 12 can be maximized approximately using algorithms like EM, so this gives a hardness result for optimizing the objective function of EM for PCFGs. Day (1983) previously showed that maximizing the marginalized likelihood for hidden Markov models is NP-hard.

We note that the grammar we use for all of our results is not recursive. Therefore, we can encode this grammar as a hidden Markov model, strengthening our result from PCFGs to HMMs.[3]

7 Uniform-at-Random Initialization

In the previous sections, we showed that solving Viterbi training is hard, and therefore requires an approximation algorithm. Viterbi EM, which is an example of such algorithm, is dependent on an initialization of either $\boldsymbol{\theta}$ to start with an E-step or $\boldsymbol{z}$ to start with an M-step. In the absence of a better-informed initializer, it is reasonable to initialize $\boldsymbol{z}$ using a uniform distribution over $D(\boldsymbol{G}, x_i)$ for each i. If $D(\boldsymbol{G}, x_i)$ is finite, it can be done efficiently by setting $\boldsymbol{\theta} = \mathbf{1}$ (ignoring the normalization constraint), running the inside algorithm, and sampling from the (unnormalized) posterior given by the chart (Johnson et al., 2007). We turn next to an analysis of this initialization technique that suggests it is well-motivated.

The sketch of our result is as follows: we first give an asymptotic upper bound for the log-likelihood of derivations and sentences. This bound, which has an information-theoretic interpretation, depends on a parameter λ, which depends on the distribution from which the derivations were chosen. We then show that this bound is minimized when we pick λ such that this distribution is (conditioned on the sentence) a uniform distribution over derivations.

Let $q(x)$ be any distribution over $L(\boldsymbol{G})$ and $\boldsymbol{\theta}$ some parameters for $\boldsymbol{G}$. Let $f(z)$ be some feature function (such as the one that counts the number of appearances of a certain rule in a derivation), and then:

$$\mathbb{E}_{q,\boldsymbol{\theta}}[f] \triangleq \sum_{x \in L(\boldsymbol{G})} q(x) \sum_{z \in D(\boldsymbol{G},x)} p(z \mid \boldsymbol{\theta}, x) f(z)$$

which gives the expected value of the feature function $f(z)$ under the distribution $q(x) \times p(z \mid \boldsymbol{\theta}, x)$. We will make the following assumption about $\boldsymbol{G}$:

Condition 1. *There exists some $\boldsymbol{\theta}_I$ such that $\forall x \in L(\boldsymbol{G}), \forall z \in D(\boldsymbol{G}, x)$, $p(z \mid \boldsymbol{\theta}_I, x) = 1/|D(\boldsymbol{G}, x)|$.*

This condition is satisfied, for example, when $\boldsymbol{G}$ is in Chomsky normal form and for all $A, A' \in \mathcal{N}$, $|R(A)| = |R(A')|$. Then, if we set $\theta_{A \rightarrow \alpha} = 1/|R(A)|$, we get that all derivations of x will have the same number of rules and hence the same probability. This condition does not hold for grammars with unary cycles because $|D(\boldsymbol{G}, x)|$ may be infinite for some derivations. Such grammars are not commonly used in NLP.

Let us assume that some "correct" parameters $\boldsymbol{\theta}^*$ exist, and that our data were drawn from a distribution parametrized by $\boldsymbol{\theta}^*$. The goal of this section is to motivate the following initialization for $\boldsymbol{\theta}$, which we call UniformInit:

1. Initialize $\boldsymbol{z}$ by sampling from the uniform distribution over $D(\boldsymbol{G}, x_i)$ for each x_i.
2. Update the grammar parameters using maximum likelihood estimation.

7.1 Bounding the Objective

To show our result, we require first the following definition due to Freund et al. (1997):

Definition 5. *A distribution p_1 is within $\lambda \geq 1$ of a distribution p_2 if for every event A, we have*

$$\frac{1}{\lambda} \leq \frac{p_1(A)}{p_2(A)} \leq \lambda \tag{13}$$

For any feature function $f(z)$ and any two sets of parameters $\boldsymbol{\theta}_2$ and $\boldsymbol{\theta}_1$ for $\boldsymbol{G}$ and for any marginal $q(x)$, if $p(z \mid \boldsymbol{\theta}_1, x)$ is within λ of $p(z \mid \boldsymbol{\theta}_2, x)$ for all x then:

$$\frac{\mathbb{E}_{q,\boldsymbol{\theta}_1}[f]}{\lambda} \leq \mathbb{E}_{q,\boldsymbol{\theta}_2}[f] \leq \lambda \mathbb{E}_{q,\boldsymbol{\theta}_1}[f] \tag{14}$$

Let $\boldsymbol{\theta}_0$ be a set of parameters such that we perform the following procedure in initializing Viterbi EM: first, we sample from the posterior distribution $p(z \mid \boldsymbol{\theta}_0, x)$, and then update the parameters with maximum likelihood estimate, in a regular M-step. Let λ be such that $p(z \mid \boldsymbol{\theta}_0, x)$ is within λ of $p(z \mid \boldsymbol{\theta}^*, x)$ (for all $x \in L(\boldsymbol{G})$). (Later we will show that UniformInit is a wise choice for making λ small. Note that UniformInit is equivalent to the procedure mentioned above with $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_I$.)

[3] We thank an anonymous reviewer for pointing this out.

Consider $\tilde{p}_n(x)$, the empirical distribution over $x_1, \ldots, x_n$. As $n \to \infty$, we have that $\tilde{p}_n(x) \to p^*(x)$, almost surely, where p^* is:

$$p^*(x) = \sum_z p^*(x, z \mid \boldsymbol{\theta}^*) \tag{15}$$

This means that as $n \to \infty$ we have $\mathbb{E}_{\tilde{p}_n, \boldsymbol{\theta}}[f] \to \mathbb{E}_{p^*, \boldsymbol{\theta}}[f]$. Now, let $\boldsymbol{z}_0 = (z_{0,1}, \ldots, z_{0,n})$ be samples from $p(z \mid \boldsymbol{\theta}_0, x_i)$ for $i \in \{1, \ldots, n\}$. Then, from simple MLE computation, we know that the value

$$\begin{aligned} &\max_{\boldsymbol{\theta}'} \prod_{i=1}^{n} p(x_i, z_{0,i} \mid \boldsymbol{\theta}') \qquad (16) \\ &= \prod_{(A \to \alpha) \in \mathcal{R}} \left(\frac{F_{A \to \alpha}(\boldsymbol{z}_0)}{F_A(\boldsymbol{z}_0)} \right)^{F_{A \to \alpha}(\boldsymbol{z}_0)} \end{aligned}$$

We also know that for $\boldsymbol{\theta}_0$, from the consistency of MLE, for large enough samples:

$$\frac{F_{A \to \alpha}(\boldsymbol{z}_0)}{F_A(\boldsymbol{z}_0)} \approx \frac{\mathbb{E}_{\tilde{p}_n, \boldsymbol{\theta}_0}[f_{A \to \alpha}]}{\mathbb{E}_{\tilde{p}_n, \boldsymbol{\theta}_0}[f_A]} \tag{17}$$

which means that we have the following as n grows (starting from the ViterbiTrain objective with initial state $\boldsymbol{z} = \boldsymbol{z}_0$):

$$\begin{aligned} &\max_{\boldsymbol{\theta}'} \prod_{i=1}^{n} p(x_i, z_{0,i} \mid \boldsymbol{\theta}') \qquad (18) \\ &\overset{\text{(Eq. 16)}}{=} \prod_{(A \to \alpha) \in \mathcal{R}} \left(\frac{F_{A \to \alpha}(\boldsymbol{z}_0)}{F_A(\boldsymbol{z}_0)} \right)^{F_{A \to \alpha}(\boldsymbol{z}_0)} \qquad (19) \\ &\overset{\text{(Eq. 17)}}{\approx} \prod_{(A \to \alpha) \in \mathcal{R}} \left(\frac{\mathbb{E}_{\tilde{p}_n, \boldsymbol{\theta}_0}[f_{A \to \alpha}]}{\mathbb{E}_{\tilde{p}_n, \boldsymbol{\theta}_0}[f_A]} \right)^{F_{A \to \alpha}(\boldsymbol{z}_0)} \qquad (20) \end{aligned}$$

We next use the fact that $\tilde{p}_n(x) \approx p^*(x)$ for large n, and apply Eq. 14, noting again our assumption that $p(z \mid \boldsymbol{\theta}_0, x)$ is within λ of $p(z \mid \boldsymbol{\theta}^*, x)$. We also let $B = \sum_i |z_i|$, where $|z_i|$ is the number of nodes in the derivation z_i. Note that $F_A(z_i) \leq B$. The above quantity (Eq. 20) is approximately bounded above by

$$\begin{aligned} &\prod_{(A \to \alpha) \in \mathcal{R}} \frac{1}{\lambda^{2B}} \left(\frac{\mathbb{E}_{p^*, \boldsymbol{\theta}^*}[f_{A \to \alpha}]}{\mathbb{E}_{p^*, \boldsymbol{\theta}^*}[f_A]} \right)^{F_{A \to \alpha}(\boldsymbol{z}_0)} \qquad (21) \\ &= \frac{1}{\lambda^{2|\mathcal{R}|B}} \prod_{(A \to \alpha) \in \mathcal{R}} (\theta^*_{A \to \alpha})^{F_{A \to \alpha}(\boldsymbol{z}_0)} \qquad (22) \end{aligned}$$

Eq. 22 follows from:

$$\theta^*_{A \to \alpha} = \frac{\mathbb{E}_{p^*, \boldsymbol{\theta}^*}[f_{A \to \alpha}]}{\mathbb{E}_{p^*, \boldsymbol{\theta}^*}[f_A]} \tag{23}$$

If we continue to develop Eq. 22 and apply Eq. 17 and Eq. 23 again, we get that:

$$\begin{aligned} &\frac{1}{\lambda^{2|\mathcal{R}|B}} \prod_{(A \to \alpha) \in \mathcal{R}} (\theta^*_{A \to \alpha})^{F_{A \to \alpha}(\boldsymbol{z}_0)} \\ &= \frac{1}{\lambda^{2|\mathcal{R}|B}} \prod_{(A \to \alpha) \in \mathcal{R}} (\theta^*_{A \to \alpha})^{F_{A \to \alpha}(\boldsymbol{z}_0) \cdot \frac{F_A(\boldsymbol{z}_0)}{F_A(\boldsymbol{z}_0)}} \\ &\approx \frac{1}{\lambda^{2|\mathcal{R}|B}} \prod_{(A \to \alpha) \in \mathcal{R}} (\theta^*_{A \to \alpha})^{\frac{\mathbb{E}_{p^*, \boldsymbol{\theta}_0}[f_{A \to \alpha}]}{\mathbb{E}_{p^*, \boldsymbol{\theta}_0}[f_A]} \cdot F_A(\boldsymbol{z}_0)} \\ &\geq \frac{1}{\lambda^{2|\mathcal{R}|B}} \prod_{(A \to \alpha) \in \mathcal{R}} (\theta^*_{A \to \alpha})^{\lambda^2 \theta^*_{A \to \alpha} F_A(\boldsymbol{z}_0)} \\ &\geq \frac{1}{\lambda^{2|\mathcal{R}|B}} \underbrace{\left(\prod_{(A \to \alpha) \in \mathcal{R}} (\theta^*_{A \to \alpha})^{n \theta^*_{A \to \alpha}} \right)}_{T(\boldsymbol{\theta}^*, n)}^{B\lambda^2/n} \qquad (24) \\ &= \left(\frac{1}{\lambda^{2|\mathcal{R}|B}} \right) T(\boldsymbol{\theta}^*, n)^{B\lambda^2/n} \qquad (25) \\ &\triangleq d(\lambda; \boldsymbol{\theta}^*, |\mathcal{R}|, B) \qquad (26) \end{aligned}$$

where Eq. 24 is the result of $F_A(\boldsymbol{z}_0) \leq B$.

For two series $\{a_n\}$ and $\{b_n\}$, let "$a_n \gtrapprox b_n$" denote that $\lim_{n \to \infty} a_n \geq \lim_{n \to \infty} b_n$. In other words, a_n is asymptotically larger than b_n. Then, if we changed the representation of the objective function of the ViterbiTrain problem to *log*-likelihood, for $\boldsymbol{\theta}'$ that maximizes Eq. 18 (with some simple algebra) we have:

$$\begin{aligned} &\frac{1}{n} \sum_{i=1}^{n} \log_2 p(x_i, z_{0,i} \mid \boldsymbol{\theta}') \qquad (27) \\ &\gtrapprox -\frac{2|\mathcal{R}|B}{n} \log_2 \lambda + \frac{B\lambda^2}{n} \left(\frac{1}{n} \log_2 T(\boldsymbol{\theta}^*, n) \right) \\ &= -\frac{2|\mathcal{R}|B}{n} \log_2 \lambda - |\mathcal{N}| \frac{B\lambda^2}{|\mathcal{N}|n} \sum_{A \in \mathcal{N}} H(\boldsymbol{\theta}^*, A) \qquad (28) \end{aligned}$$

where

$$H(\boldsymbol{\theta}^*, A) = -\sum_{(A \to \alpha) \in R(A)} \theta^*_{A \to \alpha} \log_2 \theta^*_{A \to \alpha} \tag{29}$$

is the entropy of the multinomial for nonterminal A. $H(\boldsymbol{\theta}^*, A)$ can be thought of as the minimal number of bits required to encode a choice of a rule from A, if chosen independently from the other rules. All together, the quantity $\frac{B}{|\mathcal{N}|n} \left(\sum_{A \in \mathcal{N}} H(\boldsymbol{\theta}^*, A) \right)$ is the average number of bits required to encode a tree in our sample using

$\boldsymbol{\theta}^*$, while removing dependence among all rules and assuming that each node at the tree is chosen uniformly.[4] This means that the log-likelihood, for large n, is bounded from above by a linear function of the (average) number of bits required to optimally encode n trees of total size B, while assuming independence among the rules in a tree. We note that the quantity B/n will tend toward the average size of a tree, which, under Condition 1, must be finite.

Our final approximate bound from Eq. 28 relates the choice of distribution, from which sample $\boldsymbol{z}_0$, to λ. The lower bound in Eq. 28 is a monotone-decreasing function of λ. We seek to make λ as small as possible to make the bound tight. We next show that the uniform distribution optimizes λ in that sense.

7.2 Optimizing λ

Note that the optimal choice of λ, for a single x and for candidate initializer $\boldsymbol{\theta}'$, is

$$\lambda_{\text{opt}}(x, \boldsymbol{\theta}^*; \boldsymbol{\theta}_0) \quad = \quad \sup_{z \in D(\boldsymbol{G}, x)} \frac{p(z \mid \boldsymbol{\theta}_0, x)}{p(z \mid \boldsymbol{\theta}^*, x)} \tag{30}$$

In order to avoid degenerate cases, we will add another condition on the true model, $\boldsymbol{\theta}^*$:

Condition 2. *There exists $\tau > 0$ such that, for any $x \in L(\boldsymbol{G})$ and for any $z \in D(\boldsymbol{G}, x)$, $p(z \mid \boldsymbol{\theta}^*, x) \geq \tau$.*

This is a strong condition, forcing the cardinality of $D(\boldsymbol{G})$ to be finite, but it is not unreasonable if natural language sentences are effectively bounded in length.

Without further information about $\boldsymbol{\theta}^*$ (other than that it satisfies Condition 2), we may want to consider the worst-case scenario of possible λ, hence we seek initializer $\boldsymbol{\theta}_0$ such that

$$\Lambda(x; \boldsymbol{\theta}_0) \quad \triangleq \quad \sup_{\boldsymbol{\theta}} \lambda_{\text{opt}}(x, \boldsymbol{\theta}; \boldsymbol{\theta}_0) \tag{31}$$

is minimized. If $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_I$, then we have that $p(z \mid \boldsymbol{\theta}_I, x) = |D(\boldsymbol{G}, x)|^{-1} \triangleq \mu_x$. Together with Condition 2, this implies that

$$\frac{p(z \mid \boldsymbol{\theta}_I, x)}{p(z \mid \boldsymbol{\theta}^*, x)} \quad \leq \quad \frac{\mu_x}{\tau} \tag{32}$$

and hence $\lambda_{\text{opt}}(x, \boldsymbol{\theta}^*) \leq \mu_x/\tau$ for any $\boldsymbol{\theta}^*$, hence $\Lambda(x; \boldsymbol{\theta}_I) \leq \mu_x/\tau$. However, if we choose $\boldsymbol{\theta}_0 \neq \boldsymbol{\theta}_I$, we have that $p(z' \mid \boldsymbol{\theta}_0, x) > \mu_x$ for some z', hence, for $\boldsymbol{\theta}^*$ such that it assigns probability τ on z', we have that

$$\sup_{z \in D(\boldsymbol{G}, x)} \frac{p(z \mid \boldsymbol{\theta}_0, x)}{p(z \mid \boldsymbol{\theta}^*, x)} \quad > \quad \frac{\mu_x}{\tau} \tag{33}$$

and hence $\lambda_{\text{opt}}(x, \boldsymbol{\theta}^*; \boldsymbol{\theta}') > \mu_x/\tau$, so $\Lambda(x; \boldsymbol{\theta}') > \mu_x/\tau$. So, to optimize for the worst-case scenario over true distributions with respect to λ, we are motivated to choose $\boldsymbol{\theta}_0 = \boldsymbol{\theta}_I$ as defined in Condition 1. Indeed, UniformInit uses $\boldsymbol{\theta}_I$ to initialize the state of Viterbi EM.

We note that if $\boldsymbol{\theta}_I$ was known for a specific grammar, then we could have used it as a direct initializer. However, Condition 1 only guarantees its existence, and does not give a practical way to identify it. In general, as mentioned above, $\boldsymbol{\theta} = \mathbf{1}$ can be used to obtain a weighted CFG that satisfies $p(z \mid \boldsymbol{\theta}, x) = 1/|D(\boldsymbol{G}, x)|$. Since we require a uniform posterior distribution, the number of derivations of a fixed length is finite. This means that we can converted the weighted CFG with $\boldsymbol{\theta} = \mathbf{1}$ to a PCFG with the same posterior (Smith and Johnson, 2007), and identify the appropriate $\boldsymbol{\theta}_I$.

8 Related Work

Viterbi training is closely related to the k-means clustering problem, where the objective is to find k centroids for a given set of d-dimensional points such that the sum of distances between the points and the closest centroid is minimized. The analog for Viterbi EM for the k-means problem is the k-means clustering algorithm (Lloyd, 1982), a coordinate ascent algorithm for solving the k-means problem. It works by iterating between an E-like-step, in which each point is assigned the closest centroid, and an M-like-step, in which the centroids are set to be the center of each cluster.

"k" in k-means corresponds, in a sense, to the size of our grammar. k-means has been shown to be NP-hard both when k varies and d is fixed and when d varies and k is fixed (Aloise et al., 2009; Mahajan et al., 2009). An open problem relating to our hardness result would be whether ViterbiTrain (or ConditionalViterbiTrain) is hard even if we do not permit grammars of arbitrarily large size, or at least, constrain the number of rules that do not rewrite to terminals (in our current reduction, the

[4] We note that Grenander (1967) describes a (linear) relationship between the *derivational entropy* and $H(\boldsymbol{\theta}^*, A)$. The derivational entropy is defined as $h(\boldsymbol{\theta}^*, A) = -\sum_{x,z} p(x, z \mid \boldsymbol{\theta}^*) \log p(x, z \mid \boldsymbol{\theta}^*)$, where z ranges over trees that have nonterminal A as the root. It follows immediately from Grenander's result that $\sum_A H(\boldsymbol{\theta}^*, A) \leq \sum_A h(\boldsymbol{\theta}^*, A)$.

size of the grammar grows as the size of the 3-SAT formula grows).

On a related note to §7, Arthur and Vassilvitskii (2007) described a greedy initialization algorithm for initializing the centroids of k-means, called k-means++. They show that their initialization is $O(\log k)$-competitive; i.e., it approximates the optimal clusters assignment by a factor of $O(\log k)$. In §7.1, we showed that uniform-at-random initialization is approximately $O(|\mathcal{N}|L\lambda^2/n)$-competitive (modulo an additive constant) for CNF grammars, where n is the number of sentences, L is the total length of sentences and λ is a measure for distance between the true distribution and the uniform distribution.[5]

Many combinatorial problems in NLP involving phrase-structure trees, alignments, and dependency graphs are hard (Sima'an, 1996; Goodman, 1998; Knight, 1999; Casacuberta and de la Higuera, 2000; Lyngsø and Pederson, 2002; Udupa and Maji, 2006; McDonald and Satta, 2007; DeNero and Klein, 2008, *inter alia*). Of special relevance to this paper is Abe and Warmuth (1992), who showed that the problem of finding maximum likelihood model of probabilistic automata is hard even for a single string and an automaton with two states. Understanding the complexity of NLP problems, we believe, is crucial as we seek effective practical approximations when necessary.

9 Conclusion

We described some properties of Viterbi training for probabilistic context-free grammars. We showed that Viterbi training is NP-hard and, in fact, NP-hard to approximate. We gave motivation for uniform-at-random initialization for derivations in the Viterbi EM algorithm.

Abstract

Constructing an encoding of a concept lattice using short bit vectors allows for efficient computation of join operations on the lattice. Join is the central operation any unification-based parser must support. We extend the traditional bit vector encoding, which represents join failure using the zero vector, to count any vector with less than a fixed number of one bits as failure. This allows non-joinable elements to share bits, resulting in a smaller vector size. A constraint solver is used to construct the encoding, and a variety of techniques are employed to find near-optimal solutions and handle timeouts. An evaluation is provided comparing the extended representation of failure with traditional bit vector techniques.

1 Introduction

The use of bit vectors is almost as old as HPSG parsing itself. Since they were first suggested in the programming languages literature (Aït-Kaci et al., 1989) as a method for computing the unification of two types without table lookup, bit vectors have been attractive because of three speed advantages:

- The classical bit vector encoding uses bitwise AND to calculate type unification. This is hard to beat.
- Hash tables, the most common alternative, involve computing the Dedekind-MacNeille completion (DMC) at compile time if the input type hierarchy is not a bounded-complete partial order. That is exponential time in the worst case; most bit vector methods avoid explicitly computing it.
- With large type signatures, the table that indexes unifiable pairs of types may be so large that it pushes working parsing memory into swap. This loss of *locality of reference* costs time.

Why isn't everyone using bit vectors? For the most part, the reason is their size. The classical encoding given by Aït-Kaci et al. (1989) is at least as large as the number of meet-irreducible types, which in the parlance of HPSG type signatures is the number of unary-branching types plus the number of maximally specific types. For the English Resource Grammar (ERG) (Copestake and Flickinger, 2000), these are 314 and 2474 respectively. While some systems use them nonetheless (PET (Callmeier, 2000) does, as a very notable exception), it is clear that the size of these codes is a source of concern.

Again, it has been so since the very beginning: Aït-Kaci et al. (1989) devoted several pages to a discussion of how to "modularize" type codes, which typically achieves a smaller code in exchange for a larger-time operation than bitwise AND as the implementation of type unification. However, in this and later work on the subject (e.g. (Fall, 1996)), one constant has been that we know our unification has failed when the implementation returns the zero vector. *Zero preservation* (Mellish, 1991; Mellish, 1992), i.e., detecting a type unification failure, is just as important as obtaining the right answer quickly when it succeeds.

The approach of the present paper borrows from recent statistical machine translation research, which addresses the problem of efficiently representing large-scale language models using a mathematical construction called a *Bloom filter* (Talbot and Osborne, 2007). The approach is best combined with modularization in order to further reduce the size of the codes, but its novelty lies in

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1512–1521,
Uppsala, Sweden, 11-16 July 2010.

the observation that counting the number of one bits in an integer is implemented in the basic instruction sets of many CPUs. The question then arises whether smaller codes would be obtained by relaxing zero preservation so that *any* resulting vector with at most λ bits is interpreted as failure, with $\lambda \geq 1$.

Penn (2002) generalized join-preserving encodings of partial orders to the case where more than one code can be used to represent the same object, but the focus there was on codes arising from successful unifications; there was still only one representative for failure. To our knowledge, the present paper is the first generalization of zero preservation in CL or any other application domain of partial order encodings.

We note at the outset that we are not using Bloom filters as such, but rather a derandomized encoding scheme that shares with Bloom filters the essential insight that λ can be greater than zero without adverse consequences for the required algebraic properties of the encoding. Deterministic variants of Bloom filters may in turn prove to be of some value in language modelling.

1.1 Notation and definitions

A partial order $\langle X, \sqsubseteq \rangle$ consists of a set X and a reflexive, antisymmetric, and transitive binary relation $\sqsubseteq$. We use $u \sqcup v$ to denote the unique least upper bound or *join* of $u, v \in X$, if one exists, and $u \sqcap v$ for the greatest lower bound or *meet*. If we need a second partial order, we use $\preceq$ for its order relation and $\curlyvee$ for its join operation. We are especially interested in a class of partial orders called *meet semilattices*, in which every pair of elements has a unique meet. In a meet semilattice, the join of two elements is unique when it exists at all, and there is a unique globally least element $\bot$ ("*bottom*").

A *successor* of an element $u \in X$ is an element $v \neq u \in X$ such that $u \sqsubseteq v$ and there is no $w \in X$ with $w \neq u, w \neq v$, and $u \sqsubseteq w \sqsubseteq v$, i.e., v follows u in X with no other elements in between. A *maximal* element has no successor. A *meet irreducible* element is an element $u \in X$ such that for any $v, w \in X$, if $u = v \sqcap w$ then $u = v$ or $u = w$. A meet irreducible has at most one successor.

Given two partial orders $\langle X, \sqsubseteq \rangle$ and $\langle Y, \preceq \rangle$, an *embedding* of X into Y is a pair of functions $f : X \to Y$ and $g : (Y \times Y) \to \{0, 1\}$, which may have some of the following properties for all $u, v \in X$:

$$u \sqsubseteq v \Rightarrow f(u) \preceq f(v) \quad (1)$$

$$\mathit{defined}(u \sqcup v) \Rightarrow g(f(u), f(v)) = 1 \quad (2)$$

$$\neg \mathit{defined}(u \sqcup v) \Rightarrow g(f(u), f(v)) = 0 \quad (3)$$

$$u \sqcup v = w \Leftrightarrow f(u) \curlyvee f(v) = f(w) \quad (4)$$

With property (1), the embedding is said to preserve order; with property (2), it preserves success; with property (3), it preserves failure; and with property (4), it preserves joins.

2 Bit-vector encoding

Intuitively, taking the join of two types in a type hierarchy is like taking the intersection of two sets. Types often represent sets of possible values, and the type represented by the join really does represent the intersection of the sets that formed the input. So it seems natural to embed a partial order of types $\langle X, \sqsubseteq \rangle$ into a partial order (in fact, a lattice) of sets $\langle Y, \preceq \rangle$, where Y is the power set of some set Z, and $\preceq$ is the superset relation $\supseteq$. Then join $\curlyvee$ is simply set intersection $\cap$. The embedding function g, which indicates whether a join exists, can be naturally defined by $g(f(u), f(v)) = 0$ if and only if $f(u) \cap f(v) = \emptyset$. It remains to choose the underlying set Z and embedding function f.

Aït-Kaci et al. (1989) developed what has become the standard technique of this type. They set Z to be the set of all meet irreducible elements in X; and $f(u) = \{v \in Z | v \sqsupseteq u\}$, that is, the meet irreducible elements greater than or equal to u. The resulting embedding preserves order, success, failure, and joins. If Z is chosen to be the maximal elements of X instead, then join preservation is lost but the embedding still preserves order, success, and failure. The sets can be represented efficiently by vectors of bits. We hope to minimize the size of the largest set $f(\bot)$, which determines the vector length.

It follows from the work of Markowsky (1980) that the construction of Aït-Kaci et al. is optimal among encodings that use sets with intersection for meet and empty set for failure: with Y defined as the power set of some set Z, $\sqsubseteq$ as $\supseteq$, $\sqcup$ as $\cap$, and $g(f(u), f(v)) = 0$ if and only if $f(u) \cap f(v) = \emptyset$, then the smallest Z that will preserve order, success, failure, and joins is the set of all meet irreducible elements of X. No shorter bit vectors are possible.

We construct shorter bit vectors by modifying the definition of g, so that the minimality results

no longer apply. In the following discussion we present first an intuitive and then a technical description of our approach.

2.1 Intuition from Bloom filters

Vectors generated by the above construction tend to be quite sparse, or if not sparse, at least boring. Consider a meet semilattice containing only the bottom element $\perp$ and n maximal elements all incomparable to each other. Then each bit vector would consist of either all ones, or all zeroes except for a single one. We would thus be spending n bits to represent a choice among $n + 1$ alternatives, which should fit into a logarithmic number of bits. The meet semilattices that occur in practice are more complicated than this example, but they tend to contain things like it as a substructure. With the traditional bit vector construction, each of the maximal elements consumes its own bit, even though those bits are highly correlated.

The well-known technique called Bloom filtering (Bloom, 1970) addresses a similar issue. There, it is desired to store a large array of bits subject to two considerations. First, most of the bits are zeroes. Second, we are willing to accept a small proportion of one-sided errors, where every query that should correctly return one does so, but some queries that should correctly return zero might actually return one instead.

The solution proposed by Bloom and widely used in the decades since is to map the entries in the large bit array pseudorandomly (by means of a hash function) into the entries of a small bit array. To store a one bit we find its hashed location and store it there. If we query a bit for which the answer should be zero but it happens to have the same hashed location as another query with the answer one, then we return a one and that is one of our tolerated errors.

To reduce the error rate we can elaborate the construction further: with some fixed k, we use k hash functions to map each bit in the large array to several locations in the small one. Figure 1 illustrates the technique with $k = 3$. Each bit has three hashed locations. On a query, we check all three; they must all contain ones for the query to return a one. There will be many collisions of individual hashed locations, as shown; but the chances are good that when we query a bit we did not intend to store in the filter, at least one of its hashed locations will still be empty, and so the query will

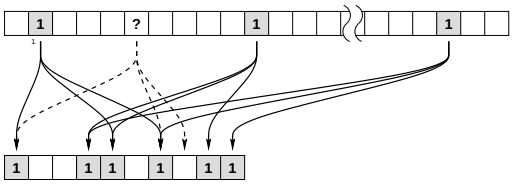

Figure 1: A Bloom filter

return zero. Bloom describes how to calculate the optimal value of k, and the necessary length of the hashed array, to achieve any desired bound on the error rate. In general, the hashed array can be much smaller than the original unhashed array (Bloom, 1970).

Classical Bloom filtering applied to the sparse vectors of the embedding would create some percentage of incorrect join results, which would then have to be handled by other techniques. Our work described here combines the idea of using k hash functions to reduce the error rate, with perfect hashes designed in a precomputation step to bring the error rate to zero.

2.2 Modified failure detection

In the traditional bit vector construction, types map to sets, join is computed by intersection of sets, and the empty set corresponds to failure (where no join exists). Following the lead of Bloom filters, we change the embedding function $g(f(u), f(v))$ to be 0 if and only if $|f(u) \cap f(v)| \leq \lambda$ for some constant λ. With $\lambda = 0$ this is the same as before. Choosing greater values of λ allows us to re-use set elements in different parts of the type hierarchy while still avoiding collisions.

Figure 2 shows an example meet semilattice. In the traditional construction, to preserve joins we must assign one bit to each of the meet-irreducible elements $\{d, e, f, g, h, i, j, k, l, m\}$, for a total of ten bits. But we can use eight bits and still preserve joins by setting $g(f(u), f(v)) = 0$ if and only if $|f(u) \cap f(v)| \leq \lambda = 1$, and f as follows.

$$
\begin{array}{cc}
f(\perp) = \{1,2,3,4,5,6,7,8\} & \\
f(a) = \{1,2,3,4,5\} & \\
f(b) = \{1,6,7,8\} & f(c) = \{1,2,3\} \\
f(d) = \{2,3,4,5\} & f(e) = \{1,6\} \\
f(f) = \{1,7\} & f(g) = \{1,8\} \\
f(h) = \{6,7\} & f(i) = \{6,8\} \\
f(j) = \{1,2\} & f(k) = \{1,3\} \\
f(l) = \{2,3\} & f(m) = \{2,3,4\}
\end{array}
\tag{5}
$$

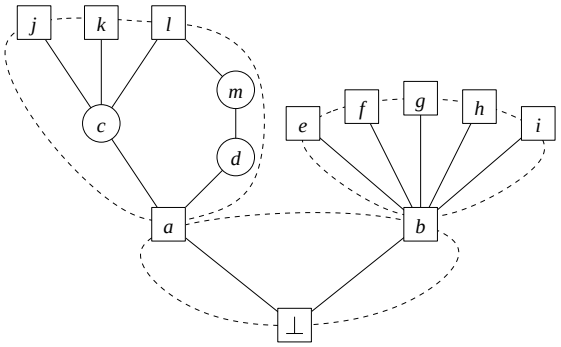

Figure 2: An example meet semilattice; $\perp$ is the most general type.

As a more general example, consider the very simple meet semilattice consisting of just a least element $\perp$ with n maximal elements incomparable to each other. For a given λ we can represent this in b bits by choosing the smallest b such that $\binom{b}{\lambda+1} \geq n$ and assigning each maximal element a distinct choice of the bits. With optimal choice of λ, b is logarithmic in n.

2.3 Modules

As Aït-Kaci et al. (1989) described, partial orders encountered in practice often resemble trees. Both their technique and ours are at a disadvantage when applied to large trees; in particular, if the bottom of the partial order has successors which are not joinable with each other, then those will be assigned large sets with little overlap, and bits in the vectors will tend to be wasted.

To avoid wasting bits, we examine the partial order X in a precomputation step to find the *modules*, which are the smallest upward-closed subsets of X such that for any $x \in X$, if x has at least two joinable successors, then x is in a module. This is similar to ALE's definition of module (Penn, 1999), but not the same. The definition of Aït-Kaci et al. (1989) also differs from ours. Under our definition, every module has a unique least element, and not every type is in a module. For instance, in Figure 2, the only module has a as its least element. In the ERG's type hierarchy, there are 11 modules, with sizes ranging from 10 to 1998 types.

To find the join of two types in the same module, we find the intersection of their encodings and check whether it is of size greater than λ. If the types belong to two distinct modules, there is no join. For the remaining cases, where at least one of the types lacks a module, we observe that the module bottoms and non-module types form a tree, and the join can be computed in that tree. If x is a type in the module whose bottom is y, and z has no module, then $x \sqcup z = y \sqcup z$ unless $y \sqcup z = y$ in which case $x \sqcup z = x$; so it only remains to compute joins within the tree. Our implementation does that by table lookup. More sophisticated approaches could be appropriate on larger trees.

3 Set programming

Ideally, we would like to have an efficient algorithm for finding the best possible encoding of any given meet semilattice. The encoding can be represented as a collection of sets of integers (representing bit indices that contain ones), and an optimal encoding is the collection of sets whose overall union is smallest subject to the constraint that the collection forms an encoding at all. This combinatorial optimization problem is a form of *set programming*; and set programming problems are widely studied. We begin by defining the form of set programming we will use.

Definition 1 *Choose set variables $S_1, S_2, \ldots, S_n$ to minimize $b = |\bigcup_{i=1}^{n} S_i|$ subject to some constraints of the forms $|S_i| \geq r_i$, $S_i \subseteq S_j$, $S_i \not\supseteq S_j$, $|S_i \cap S_j| \leq \lambda$, and $S_i \cap S_j = S_k$. The constant λ is the same for all constraints. Set elements may be arbitrary, but we generally assume they are the integers $\{1 \ldots b\}$ for convenience.*

The reduction of partial order representation to set programming is clear: we create a set variable for every type, force the maximal types' sets to contain at least $\lambda + 1$ elements, and then use subset to enforce that every type is a superset of all its successors (preserving order and success). We limit the maximum intersection of incomparable types to preserve failure. To preserve joins, if that property is desired, we add a constraint $S_i \not\supseteq S_j$ for every pair of types $x_i \not\sqsubseteq x_j$ and one of the form $S_i \cap S_j = S_k$ for every x_i, x_j, x_k such that $x_i \sqcup x_j = x_k$..

Given a constraint satisfaction problem like this one, we can ask two questions: is there a *feasible* solution, assigning values to the variables so all constraints are satisfied; and if so what is the *optimal* solution, producing the best value of the objective while remaining feasible? In our problem, there is always a feasible solution we can find by the *generalized Aït-Kaci et al. construction* (GAK), which consists of assigning λ bits

shared among all types; adding enough unshared new bits to maximal elements to satisfy cardinality constraints; adding one new bit to each non-maximal meet irreducible type; and propagating all the bits down the hierarchy to satisfy the subset constraints. Since the GAK solution is feasible, it provides a useful upper bound on the result of the set programming.

Ongoing research on set programming has produced a variety of software tools for solving these problems. However, at first blush our instances are much too large for readily-available set programming tools. Grammars like ERG contain thousands of types. We use binary constraints between every pair of types, for a total of millions of constraints—and these are variables and constraints over a domain of sets, not integers or reals. General-purpose set programming software cannot handle such instances.

3.1 Simplifying the instances

First of all, we only use minimum cardinality constraints $|S_i| \geq r_i$ for maximal types; and every $r_i \geq \lambda + 1$. Given a feasible bit assignment for a maximal type with more than r_i elements in its set S_i, we can always remove elements until it has exactly r_i elements, without violating the other constraints. As a result, instead of using constraints $|S_i| \geq r_i$ we can use constraints $|S_i| = r_i$. Doing so reduces the search space.

Subset is transitive; so if we have constraints $S_i \subseteq S_j$ and $S_j \subseteq S_k$, then $S_i \subseteq S_k$ is implied and we need not specify it as a constraint. Similarly, if we have $S_i \subseteq S_j$ and $S_i \nsubseteq S_k$, then we have $S_j \nsubseteq S_k$. Furthermore, if S_i and S_j have maximum intersection λ, then any subset of S_i also has maximum intersection λ with any subset of S_k, and we need not specify those constraints either.

Now, let a *choke-vertex* in the partial order $\langle X, \sqsubseteq \rangle$ be an element $u \in X$ such that for every $v, w \in X$ where v is a successor of w and $u \sqsubseteq v$, we have $u \sqsubseteq w$. That is, any chain of successors from elements not after u to elements after u, must pass through u. Figure 2 shows choke-vertices as squares. We call these choke-vertices by analogy with the graph theoretic concept of cut-vertices in the Hasse diagram of the partial order; but note that some vertices (like j and k) can be choke-vertices without being cut-vertices, and some vertices (like c) can be cut-vertices without being choke-vertices. Maximal and minimal elements are always choke-vertices.

Choke-vertices are important because the optimal bit assignment for elements after a choke-vertex u is almost independent of the bit assignment elsewhere in the partial order. Removing the redundant constraints means there are no constraints between elements after u and elements before, or incomparable with, u. All constraints across u must involve u directly. As a result, we can solve a smaller instance consisting of u and everything after it, to find the minimal number of bits r_u for representing u. Then we solve the rest of the problem with a constraint $|S_u| = r_u$, excluding all partial order elements after u, and then combine the two solutions with any arbitrary bijection between the set elements assigned to u in each solution. Assuming optimal solutions to both sub-problems, the result is an optimal solution to the original problem.

3.2 Splitting into components

If we cut the partial order at every choke-vertex, we reduce the huge and impractical encoding problem to a collection of smaller ones. The cutting expresses the original partial order as a tree of *components*, each of which corresponds to a set programming instance. Components are shown by the dashed lines in Figure 2. We can find an optimal encoding for the entire partial order by optimally encoding the components, starting with the leaves of that tree and working our way back to the root.

The division into components creates a collection of set programming instances with a wide range of sizes and difficulty; we examine each instance and choose appropriate techniques for each one. Table 1 summarizes the rules used to solve an instance, and shows the number of times each rule was applied in a typical run with the modules extracted from ERG, a ten-minute timeout, and each λ from 0 to 10.

In many simple cases, GAK is provably optimal. These include when $\lambda = 0$ regardless of the structure of the component; when the component consists of a bottom and zero, one, or two non-joinable successors; and when there is one element (a *top*) greater than all other elements in the component. We can easily recognize these cases and apply GAK to them.

Another important special case is when the

Condition	Succ.	Fail.	Method
$\lambda = 0$	216		GAK (optimal)
$\exists$ top	510		GAK (optimal)
2 successors	850		GAK (optimal)
3 or 4 successors	70		exponential variable
only ULs	420		b-choose-$(\lambda+1)$ special case
before UL removal	251	59	`ic_sets`
after UL removal	9	50	`ic_sets`
remaining	50		GAK

Table 1: Rules for solving an instance in the ERG

component consists of a bottom and some number k of pairwise non-joinable successors, and the successors all have required cardinality $\lambda + 1$. Then the optimal encoding comes from finding the smallest b such that $\binom{b}{\lambda+1}$ is at least k, and giving each successor a distinct combination of the b bits.

3.3 Removing unary leaves

For components that do not have one of the special forms described above, it becomes necessary to solve the set programming problem. Some of our instances are small enough to apply constraint solving software directly; but for larger instances, we have one more technique to bring them into the tractable range.

Definition 2 *A* unary leaf *(UL) is an element x in a partial order $\langle X, \sqsubseteq \rangle$ such that x is maximal and x is the successor of exactly one other element.*

ULs are special because their set programming constraints always take a particular form: if x is a UL and a successor of y, then the constraints on its set S_x are exactly that $|S_x| = \lambda + 1$, $S_x \subseteq S_y$, and S_x has intersection of size at most λ with the set for any other successor of y. Other constraints disappear by the simplifications described earlier.

Furthermore, ULs occur frequently in the partial orders we consider in practice; and by increasing the number of sets in an instance, they have a disproportionate effect on the difficulty of solving the set programming problem. We therefore implement a special solution process for instances containing ULs: we remove them all, solve the resulting instance, and then add them back one at a time while attempting to increase the overall number of elements as little as possible.

This process of removing ULs, solving, and adding them back in, may in general produce suboptimal solutions, so we use it only when the solver cannot find a solution on the full-sized problem. In practical experiments, the solver generally either produces an optimal or very nearly optimal solution within a time limit on the order of ten minutes; or fails to produce a feasible solution at all, even with a much longer limit. Testing whether it finds a solution is then a useful way to determine whether UL removal is worthwhile.

Recall that in an instance consisting of k ULs and a bottom, an optimal solution consists of finding the smallest b such that $\binom{b}{\lambda+1}$ is at least k; that is the number of bits for the bottom, and we can choose any k distinct subsets of size $\lambda + 1$ for the ULs. Augmenting an existing solution to include additional ULs involves a similar calculation.

To add a UL x as the successor of an element y without increasing the total number of bits, we must find a choice of $\lambda + 1$ of the bits already assigned to y, sharing at most λ bits with any of y's other successors. Those successors are in general sets of arbitrary size, but all that matters for assigning x is how many subsets of size $\lambda + 1$ they already cover. The UL can use any such subset not covered by an existing successor of y. Our algorithm counts the subsets already covered, and compares that with the number of choices of $\lambda+1$ bits from the bits assigned to y. If enough choices remain, we use them; otherwise, we add bits until there are enough choices.

3.4 Solving

For instances with a small number of sets and relatively large number of elements in the sets, we use an *exponential variable* solver. This encodes the set programming problem into integer programming. For each element $x \in \{1, 2, \ldots, b\}$, let $c(x) = \{i | x \in S_i\}$; that is, $c(x)$ represents the indices of all the sets in the problem that contain the element x. There are $2^n - 1$ possible values of $c(x)$, because each element must be in at least one set. We create an integer variable for each of those values. Each element is counted once, so the sum of the integer variables is b. The constraints translate into simple inequalities on sums of the variables; and the system of constraints can be solved with standard integer programming techniques. After solving the integer programming problem we can then assign elements arbitrarily

to the appropriate combinations of sets.

Where applicable, the exponential variable approach works well, because it breaks all the symmetries between set elements. It also continues to function well even when the sets are large, since nothing in the problem directly grows when we increase b. The wide domains of the variables may be advantageous for some integer programming solvers as well. However, it creates an integer programming problem of size exponential in the number of sets. As a result, it is only applicable to instances with a very few set variables.

For more general set programming instances, we feed the instance directly into a solver designed for such problems. We used the ECL^{i}PS^e logic programming system (Cisco Systems, 2008), which offers several set programming solvers as libraries, and settled on the ic_sets library. This is a straightforward set programming solver based on containment bounds. We extended the solver by adding a lightweight not-subset constraint, and customized heuristics for variable and value selection designed to guide the solver to a feasible solution as soon as possible. We choose variables near the top of the instance first, and prefer to assign values that share exactly λ bits with existing assigned values. We also do limited symmetry breaking, in that whenever we assign a bit not shared with any current assignment, the choice of bit is arbitrary so we assume it must be the lowest-index bit. That symmetry breaking speeds up the search significantly.

The present work is primarily on the benefits of nonzero λ, and so a detailed study of general set programming techniques would be inappropriate; but we made informal tests of several other set-programming solvers. We had hoped that a solver using containment-lexicographic hybrid bounds as described by Sadler and Gervet (Sadler and Gervet, 2008) would offer good performance, and chose the ECL^{i}PS^e framework partly to gain access to its ic_hybrid_sets implementation of such bounds. In practice, however, ic_hybrid_sets gave consistently worse performance than ic_sets (typically by an approximate factor of two). It appears that in intuitive terms, the lexicographic bounds rarely narrowed the domains of variables much until the variables were almost entirely labelled anyway, at which point containment bounds were almost as good; and meanwhile the increased overhead of maintaining the extra bounds slowed down the entire process to more than compensate for the improved propagation. We also evaluated the Cardinal solver included in ECL^{i}PS^e, which offers stronger propagation of cardinality information; it lacked other needed features and seemed no more efficient than ic_sets. Among these three solvers, the improvements associated with our custom variable and value heuristics greatly outweighed the baseline differences between the solvers; and the differences were in optimization time rather than quality of the returned solutions.

Solvers with available source code were preferred for ease of customization, and free solvers were preferred for economy, but a license for ILOG CPLEX (IBM, 2008) was available and we tried using it with the natural encoding of sets as vectors of binary variables. It solved small instances to optimality in time comparable to that of ECL^{i}PS^e. However, for medium to large instances, CPLEX proved impractical. An instance with n sets of up to b bits, dense with pairwise constraints like subset and maximum intersection, requires $\Theta(n^2b)$ variables when encoded into integer programming in the natural way. CPLEX stores a copy of the relaxed problem, with significant bookkeeping information per variable, for every node in the search tree. It is capable of storing most of the tree in compressed form on disk, but in our larger instances even a single node is too large; CPLEX exhausts memory while loading its input. The ECL^{i}PS^e solver also stores each set variable in a data structure that increases linearly with the number of elements, so that the size of the problem as stored by ECL^{i}PS^e is also $\Theta(n^2b)$; but the constant for ECL^{i}PS^e appears to be much smaller, and its search algorithm stores only incremental updates (with nodes per set instead of per element) on a stack as it explores the tree. As a result, the ECL^{i}PS^e solver can process much larger instances than CPLEX without exhausting memory.

Encoding into SAT would allow use of the sophisticated solvers available for that problem. Unfortunately, cardinality constraints are notoriously difficult to encode in Boolean logic. The obvious encoding of our problem into CNFSAT would require $O(n^2b\lambda)$ clauses and variables. Encodings into Boolean variables with richer constraints than CNFSAT (we tried, for instance, the SICStus Prolog clp(FD) implementation (Carlsson et al., 1997)) generally exhausted memory on much smaller instances than those handled by the set-

Module	n	b_0	λ	b_λ
`mrs_min`	10	7	0	7
`conj`	13	8	1	7
`list`	27	15	1	11
`local_min`	27	21	1	10

`synsem_min`	612	255	0	255
`sign_min`	1025	489	3	357
`mod_relation`	1998	1749	6	284
entire ERG	4305	2788	140	985

Table 2: Best encodings of the ERG and its modules: n is number of types, b_0 is vector length with $\lambda = 0$, and λ is parameter that gives the shortest vector length b_λ.

variable solvers, while offering no improvement in speed.

4 Evaluation

Table 2 shows the size of our smallest encodings to date for the entire ERG without modularization, and for each of its modules. These were found by running the optimization process of the previous section on Intel Xeon servers with a timeout of 30 minutes for each invocation of the solver (which may occur several times per module). Under those conditions, some modules take a long time to optimize—as much as two hours per tested value of λ for `sign_min`. The Xeon's hyperthreading feature makes reproducibility of timing results difficult, but we found that results almost never improved with additional time allowance beyond the first few seconds in any case, so the practical effect of the timing variations should be minimal.

These results show some significant improvements in vector length for the larger modules. However, they do not reveal the entire story. In particular, the apparent superiority of $\lambda = 0$ for the `synsem_min` module should not be taken as indicating that no higher λ could be better: rather, that module includes a very difficult set programming instance on which the solver failed and fell back to GAK. For the even larger modules, nonzero λ proved helpful despite solver failures, because of the bits saved by UL removal. UL removal is clearly a significant advantage, but only for the modules where the solver is failing anyway. One important lesson seems to be that further work on set programming solvers would be beneficial: any future more capable set programming solver could be applied to the unsolved instances and would be expected to save more bits.

Encoding	length	time	space
Lookup table	n/a	140	72496
Modular, best λ	0–357	321	203
Modular, $\lambda = 0$	0–1749	747	579
Non-mod, $\lambda = 0$	2788	4651	1530
Non-mod, $\lambda = 1$	1243	2224	706
Non-mod, $\lambda = 2$	1140	2008	656
Non-mod, $\lambda = 9$	1069	1981	622
Non-mod, $\lambda = 140$	985	3018	572

Table 3: Query performance. Vector length in bits, time in milliseconds, space in Kbytes.

Table 3 and Figure 3 show the performance of the join query with various encodings. These results are from a simple implementation in C that tests all ordered pairs of types for joinability. As well as testing the non-modular ERG encoding for different values of λ, we tested the modularized encoding with $\lambda = 0$ for all modules (to show the effect of modularization alone) and with λ chosen per-module to give the shortest vectors. For comparison, we also tested a simple lookup table. The same implementation sufficed for all these tests, by means of putting all types in one module for the non-modular bit vectors or no types in any module for the pure lookup table. The times shown are milliseconds of user CPU time to test all join tests (roughly 18.5 million of them), on a non-hyperthreading Intel Pentium 4 with a clock speed of 2.66GHz and 1G of RAM, running Linux. Space consumption shown is the total amount of dynamically-allocated memory used to store the vectors and lookup table.

The non-modular encoding with $\lambda = 0$ is the basic encoding of Aït-Kaci et al. (1989). As Table 3 shows, we achieved more than a factor of two improvement from that, in both time and vector length, just by setting $\lambda = 1$. Larger values offered further small improvements in length up to $\lambda = 140$, which gave the minimum vector length of 985. That is a shallow minimum; both $\lambda = 120$ and $\lambda = 160$ gave vector lengths of 986, and the length slowly increased with greater λ.

However, the fastest bit-count on this architec-

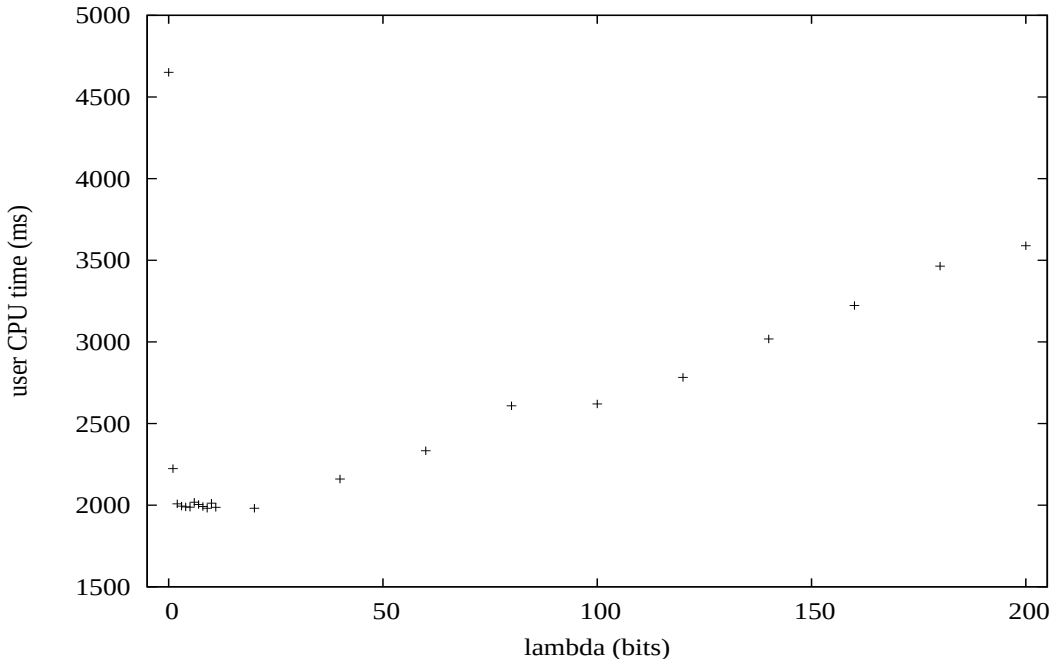

Figure 3: Query performance for the ERG without modularization.

ture, using a technique first published by Wegner (1960), requires time increasing with the number of nonzero bits it counts; and a similar effect would appear on a word-by-word basis even if we used a constant-time per-word count. As a result, there is a time cost associated with using larger λ, so that the fastest value is not necessarily the one that gives the shortest vectors. In our experiments, $\lambda = 9$ gave the fastest joins for the non-modular encoding of the ERG. As shown in Figure 3, all small nonzero λ gave very similar times.

Modularization helps a lot, both with $\lambda = 0$, and when we choose the optimal λ per module. Here, too, the use of optimal λ improves both time and space by more than a factor of two. Our best bit-vector encoding, the modularized one with per-module optimal λ, is only a little less than half the speed of the lookup table; and this test favours the lookup table by giving it a full word for every entry (no time spent shifting and masking bits) and testing the pairs in a simple two-level loop (almost purely sequential access).

5 Conclusion

We have described a generalization of conventional bit vector concept lattice encoding techniques to the case where all vectors with λ or fewer one bits represent failure; traditional encodings are the case $\lambda = 0$. Increasing λ can reduce the overall storage space and improve speed.

A good encoding requires a kind of perfect hash, the design of which maps naturally to constraint programming over sets of integers. We have described a practical framework for solving the instances of constraint programming thus created, in which we can apply existing or future constraint solvers to the subproblems for which they are best suited; and a technique for modularizing practical type hierarchies to get better value from the bit vector encodings. We have evaluated the resulting encodings on the ERG's type system, and examined the performance of the associated unification test. Modularization, and the use of nonzero λ, each independently provide significant savings in both time and vector length.

The modified failure detection concept suggests several directions for future work, including evaluation of the new encodings in the context of a large-scale HPSG parser; incorporation of further developments in constraint solvers; and the possibility of approximate encodings that would permit one-sided errors as in traditional Bloom filtering.

Abstract

One of the main obstacles to high-performance Word Sense Disambiguation (WSD) is the knowledge acquisition bottleneck. In this paper, we present a methodology to automatically extend WordNet with large amounts of semantic relations from an encyclopedic resource, namely Wikipedia. We show that, when provided with a vast amount of high-quality semantic relations, simple knowledge-lean disambiguation algorithms compete with state-of-the-art supervised WSD systems in a coarse-grained all-words setting and outperform them on gold-standard domain-specific datasets.

1 Introduction

Knowledge lies at the core of Word Sense Disambiguation (WSD), the task of computationally identifying the meanings of words in context (Navigli, 2009b). In the recent years, two main approaches have been studied that rely on a fixed sense inventory, i.e., supervised and knowledge-based methods. In order to achieve high performance, supervised approaches require large training sets where instances (target words in context) are hand-annotated with the most appropriate word senses. Producing this kind of knowledge is extremely costly: at a throughput of one sense annotation per minute (Edmonds, 2000) and tagging one thousand examples per word, dozens of person-years would be required for enabling a supervised classifier to disambiguate all the words in the English lexicon with high accuracy. In contrast, knowledge-based approaches exploit the information contained in wide-coverage lexical resources, such as WordNet (Fellbaum, 1998). However, it has been demonstrated that the amount of lexical and semantic information contained in such resources is typically insufficient for high-performance WSD (Cuadros and Rigau, 2006). Several methods have been proposed to automatically extend existing resources (cf. Section 2) and it has been shown that highly-interconnected semantic networks have a great impact on WSD (Navigli and Lapata, 2010). However, to date, the real potential of knowledge-rich WSD systems has been shown only in the presence of either a large manually-developed extension of WordNet (Navigli and Velardi, 2005) or sophisticated WSD algorithms (Agirre et al., 2009).

The contributions of this paper are two-fold. First, we relieve the knowledge acquisition bottleneck by developing a methodology to extend WordNet with millions of semantic relations. The relations are harvested from an encyclopedic resource, namely Wikipedia. Wikipedia pages are automatically associated with WordNet senses, and topical, semantic associative relations from Wikipedia are transferred to WordNet, thus producing a much richer lexical resource. Second, two simple knowledge-based algorithms that exploit our extended WordNet are applied to standard WSD datasets. The results show that the integration of vast amounts of semantic relations in knowledge-based systems yields performance competitive with state-of-the-art supervised approaches on open-text WSD. In addition, we support previous findings from Agirre et al. (2009) that in a domain-specific WSD scenario knowledge-based systems perform better than supervised ones, and we show that, given enough knowledge, simple algorithms perform better than more sophisticated ones.

2 Related Work

In the last three decades, a large body of work has been presented that concerns the development of automatic methods for the enrichment of existing resources such as WordNet. These in-

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1522–1531,
Uppsala, Sweden, 11-16 July 2010.

clude proposals to extract semantic information from dictionaries (e.g. Chodorow et al. (1985) and Rigau et al. (1998)), approaches using lexico-syntactic patterns (Hearst, 1992; Cimiano et al., 2004; Girju et al., 2006), heuristic methods based on lexical and semantic regularities (Harabagiu et al., 1999), taxonomy-based ontologization (Pennacchiotti and Pantel, 2006; Snow et al., 2006). Other approaches include the extraction of semantic preferences from sense-annotated (Agirre and Martinez, 2001) and raw corpora (McCarthy and Carroll, 2003), as well as the disambiguation of dictionary glosses based on cyclic graph patterns (Navigli, 2009a). Other works rely on the disambiguation of collocations, either obtained from specialized learner's dictionaries (Navigli and Velardi, 2005) or extracted by means of statistical techniques (Cuadros and Rigau, 2008), e.g. based on the method proposed by Agirre and de Lacalle (2004). But while most of these methods represent state-of-the-art proposals for enriching lexical and taxonomic resources, none concentrates on augmenting WordNet with associative semantic relations for many domains on a very large scale. To overcome this limitation, we exploit Wikipedia, a collaboratively generated Web encyclopedia.

The use of collaborative contributions from volunteers has been previously shown to be beneficial in the Open Mind Word Expert project (Chklovski and Mihalcea, 2002). However, its current status indicates that the project remains a mainly academic attempt. In contrast, due to its low entrance barrier and vast user base, Wikipedia provides large amounts of information at practically no cost. Previous work aimed at transforming its content into a knowledge base includes open-domain relation extraction (Wu and Weld, 2007), the acquisition of taxonomic (Ponzetto and Strube, 2007a; Suchanek et al., 2008; Wu and Weld, 2008) and other semantic relations (Nastase and Strube, 2008), as well as lexical reference rules (Shnarch et al., 2009). Applications using the knowledge contained in Wikipedia include, among others, text categorization (Gabrilovich and Markovitch, 2006), computing semantic similarity of texts (Gabrilovich and Markovitch, 2007; Ponzetto and Strube, 2007b; Milne and Witten, 2008a), coreference resolution (Ponzetto and Strube, 2007b), multi-document summarization (Nastase, 2008), and text generation (Sauper and Barzilay, 2009).

In our work we follow this line of research and show that knowledge harvested from Wikipedia can be used effectively to improve the performance of a WSD system. Our proposal builds on previous insights from Bunescu and Paşca (2006) and Mihalcea (2007) that pages in Wikipedia can be taken as word senses. Mihalcea (2007) manually maps Wikipedia pages to WordNet senses to perform lexical-sample WSD. We extend her proposal in three important ways: (1) we *fully automatize* the mapping between Wikipedia pages and WordNet senses; (2) we use the mappings to *enrich an existing resource*, i.e. WordNet, rather than annotating text with sense labels; (3) we deploy the knowledge encoded by this mapping to perform *unrestricted* WSD, rather than apply it to a lexical sample setting.

Knowledge from Wikipedia is injected into a WSD system by means of a mapping to WordNet. Previous efforts aimed at automatically linking Wikipedia to WordNet include full use of the first WordNet sense heuristic (Suchanek et al., 2008), a graph-based mapping of Wikipedia categories to WordNet synsets (Ponzetto and Navigli, 2009), a model based on vector spaces (Ruiz-Casado et al., 2005) and a supervised approach using keyword extraction (Reiter et al., 2008). These latter methods rely only on text overlap techniques and neither they take advantage of the input from Wikipedia being semi-structured, e.g. hyperlinked, nor they propose a high-performing probabilistic formulation of the mapping problem, a task to which we turn in the next section.

3 Extending WordNet

Our approach consists of two main phases: first, a mapping is automatically established between Wikipedia pages and WordNet senses; second, the relations connecting Wikipedia pages are transferred to WordNet. As a result, an extended version of WordNet is produced, that we call WordNet++. We present the two resources used in our methodology in Section 3.1. Sections 3.2 and 3.3 illustrate the two phases of our approach.

3.1 Knowledge Resources

WordNet. Being the most widely used computational lexicon of English in Natural Language Processing, WordNet is an essential resource for WSD. A concept in WordNet is represented as a synonym set, or *synset*, i.e. the set of words which share a common meaning. For instance, the con-

cept of soda drink is expressed as:

{ pop^2_n, soda^2_n, soda pop^1_n, soda water^2_n, tonic^2_n }

where each word's subscripts and superscripts indicate their parts of speech (e.g. n stands for noun) and sense number[1], respectively. For each synset, WordNet provides a textual definition, or gloss. For example, the gloss of the above synset is: "a sweet drink containing carbonated water and flavoring".

Wikipedia. Our second resource, Wikipedia, is a collaborative Web encyclopedia composed of pages[2]. A Wikipedia page (henceforth, Wikipage) presents the knowledge about a specific concept (e.g. SODA (SOFT DRINK)) or named entity (e.g. FOOD STANDARDS AGENCY). The page typically contains hypertext linked to other relevant Wikipages. For instance, SODA (SOFT DRINK) is linked to COLA, FLAVORED WATER, LEMONADE, and many others. The title of a Wikipage (e.g. SODA (SOFT DRINK)) is composed of the lemma of the concept defined (e.g. soda) plus an optional label in parentheses which specifies its meaning in case the lemma is ambiguous (e.g. SOFT DRINK VS. SODIUM CARBONATE). Finally, some Wikipages are redirections to other pages, e.g. SODA (SODIUM CARBONATE) redirects to SODIUM CARBONATE.

3.2 Mapping Wikipedia to WordNet

During the first phase of our methodology we aim to establish links between Wikipages and WordNet senses. Formally, given the entire set of pages $Senses_{\text{Wiki}}$ and WordNet senses $Senses_{\text{WN}}$, we aim to acquire a mapping:

$$\mu : Senses_{\text{Wiki}} \rightarrow Senses_{\text{WN}},$$

such that, for each Wikipage $w \in Senses_{\text{Wiki}}$:

$$\mu(w) = \begin{cases} s \in Senses_{\text{WN}}(w) & \text{if a link can be established,} \\ \epsilon & \text{otherwise,} \end{cases}$$

where $Senses_{\text{WN}}(w)$ is the set of senses of the *lemma* of w in WordNet. For example, if our mapping methodology linked SODA (SOFT DRINK) to the corresponding WordNet sense soda^2_n, we would have μ(SODA (SOFT DRINK)) = soda^2_n.

In order to establish a mapping between the two resources, we first identify different kinds of disambiguation contexts for Wikipages (Section 3.2.1) and WordNet senses (Section 3.2.2). Next, we intersect these contexts to perform the mapping (see Section 3.2.3).

3.2.1 Disambiguation Context of a Wikipage

Given a target Wikipage w which we aim to map to a WordNet sense of w, we use the following information as a disambiguation context:

- **Sense labels**: e.g. given the page SODA (SOFT DRINK), the words soft and drink are added to the disambiguation context.
- **Links**: the titles' lemmas of the pages linked from the Wikipage w (outgoing links). For instance, the links in the Wikipage SODA (SOFT DRINK) include soda, lemonade, sugar, etc.
- **Categories**: Wikipages are classified according to one or more categories, which represent meta-information used to categorize them. For instance, the Wikipage SODA (SOFT DRINK) is categorized as SOFT DRINKS. Since many categories are very specific and do not appear in WordNet (e.g., SWEDISH WRITERS or SCIENTISTS WHO COMMITTED SUICIDE), we use the lemmas of their syntactic heads as disambiguation context (i.e. writer and scientist). To this end, we use the category heads provided by Ponzetto and Navigli (2009).

Given a Wikipage w, we define its disambiguation context $Ctx(w)$ as the set of words obtained from some or all of the three sources above.

3.2.2 Disambiguation Context of a WordNet Sense

Given a WordNet sense s and its synset S, we use the following information as disambiguation context to provide evidence for a potential link in our mapping μ:

- **Synonymy**: all synonyms of s in synset S. For instance, given the synset of soda^2_n, all its synonyms are included in the context (that is, tonic, soda pop, pop, etc.).

[1] We use WordNet version 3.0. We use word senses to unambiguously denote the corresponding synsets (e.g. plane^1_n for { airplane^1_n, aeroplane^1_n, plane^1_n }).

[2] `http://download.wikipedia.org`. We use the English Wikipedia database dump from November 3, 2009, which includes 3,083,466 articles. Throughout this paper, we use Sans Serif for words, SMALL CAPS for Wikipedia pages and CAPITALS for Wikipedia categories.

- **Hypernymy/Hyponymy**: all synonyms in the synsets H such that H is either a hypernym (i.e., a generalization) or a hyponym (i.e., a specialization) of S. For example, given soda^2_n, we include the words from its hypernym { soft drink^1_n }.

- **Sisterhood**: words from the sisters of S. A sister synset S' is such that S and S' have a common direct hypernym. For example, given soda^2_n, it can be found that bitter lemon^1_n and soda^2_n are sisters. Thus the words bitter and lemon are included in the disambiguation context of s.

- **Gloss**: the set of lemmas of the content words occurring within the gloss of s. For instance, given $s = \text{soda}^2_n$, defined as "a sweet drink containing carbonated water and flavoring", we add to the disambiguation context of s the following lemmas: sweet, drink, contain, carbonated, water, flavoring.

Given a WordNet sense s, we define its disambiguation context $Ctx(s)$ as the set of words obtained from some or all of the four sources above.

3.2.3 Mapping Algorithm

In order to link each Wikipedia page to a WordNet sense, we developed a novel algorithm, whose pseudocode is shown in Algorithm 1. The following steps are performed:

- Initially (lines 1-2), our mapping μ is empty, i.e. it links each Wikipage w to ϵ.

- For each Wikipage w whose lemma is monosemous both in Wikipedia and WordNet (i.e. $|Senses_{\text{Wiki}}(w)| = |Senses_{\text{WN}}(w)| = 1$) we map w to its only WordNet sense w^1_n (lines 3-5).

- Finally, for each remaining Wikipage w for which no mapping was previously found (i.e., $\mu(w) = \epsilon$, line 7), we do the following:
  - lines 8-10: for each Wikipage d which is a redirection to w, for which a mapping was previously found (i.e. $\mu(d) \neq \epsilon$, that is, d is monosemous in both Wikipedia and WordNet) and such that it maps to a sense $\mu(d)$ in a synset S that also contains a sense of w, we map w to the corresponding sense in S.
  - lines 11-14: if a Wikipage w has not been linked yet, we assign the most likely sense to w based on the maximization of the conditional probabilities $p(s|w)$ over the senses $s \in Senses_{\text{WN}}(w)$ (no mapping is established if a tie occurs, line 13).

Algorithm 1 The mapping algorithm

Input: $Senses_{\text{Wiki}}$, $Senses_{\text{WN}}$
Output: a mapping $\mu : Senses_{\text{Wiki}} \rightarrow Senses_{\text{WN}}$

1: **for each** $w \in Senses_{\text{Wiki}}$
2: $\quad \mu(w) := \epsilon$
3: **for each** $w \in Senses_{\text{Wiki}}$
4: $\quad$ **if** $|Senses_{\text{Wiki}}(w)| = |Senses_{\text{WN}}(w)| = 1$ **then**
5: $\quad\quad \mu(w) := w^1_n$
6: **for each** $w \in Senses_{\text{Wiki}}$
7: $\quad$ **if** $\mu(w) = \epsilon$ **then**
8: $\quad\quad$ **for each** $d \in Senses_{\text{Wiki}}$ s.t. d redirects to w
9: $\quad\quad\quad$ **if** $\mu(d) \neq \epsilon$ and $\mu(d)$ is in a synset of w **then**
10: $\quad\quad\quad\quad \mu(w) :=$ sense of w in synset of $\mu(d)$; **break**
11: **for each** $w \in Senses_{\text{Wiki}}$
12: $\quad$ **if** $\mu(w) = \epsilon$ **then**
13: $\quad\quad$ **if** no tie occurs **then**
14: $\quad\quad\quad \mu(w) := \underset{s \in Senses_{\text{WN}}(w)}{\text{argmax}} \; p(s|w)$
15: **return** μ

As a result of the execution of the algorithm, the mapping μ is returned (line 15). At the heart of the mapping algorithm lies the calculation of the conditional probability $p(s|w)$ of selecting the WordNet sense s given the Wikipage w. The sense s which maximizes this probability can be obtained as follows:

$$\mu(w) = \underset{s \in Senses_{\text{WN}}(w)}{\text{argmax}} \; p(s|w) = \underset{s}{\text{argmax}} \frac{p(s,w)}{p(w)} = \underset{s}{\text{argmax}} \, p(s,w)$$

The latter formula is obtained by observing that $p(w)$ does not influence our maximization, as it is a constant independent of s. As a result, the most appropriate sense s is determined by maximizing the joint probability $p(s,w)$ of sense s and page w. We estimate $p(s,w)$ as:

$$p(s,w) = \frac{score(s,w)}{\sum_{\substack{s' \in Senses_{\text{WN}}(w), \\ w' \in Senses_{\text{Wiki}}(w)}} score(s',w')},$$

where $score(s,w) = |Ctx(s) \cap Ctx(w)| + 1$ (we add 1 as a smoothing factor). Thus, in our algorithm we determine the best sense s by computing the intersection of the disambiguation contexts of s and w, and normalizing by the scores summed over all senses of w in Wikipedia and WordNet.

3.2.4 Example

We illustrate the execution of our mapping algorithm by way of an example. Let us focus on the

Wikipage SODA (SOFT DRINK). The word soda is polysemous both in Wikipedia and WordNet, thus lines 3–5 of the algorithm do not concern this Wikipage. Lines 6–14 aim to find a mapping μ(SODA (SOFT DRINK)) to an appropriate WordNet sense of the word. First, we check whether a redirection exists to SODA (SOFT DRINK) that was previously disambiguated (lines 8–10). Next, we construct the disambiguation context for the Wikipage by including words from its label, links and categories (cf. Section 3.2.1). The context includes, among others, the following words: soft, drink, cola, sugar. We now construct the disambiguation context for the two WordNet senses of soda (cf. Section 3.2.2), namely the sodium carbonate (#1) and the drink (#2) senses. To do so, we include words from their synsets, hypernyms, hyponyms, sisters, and glosses. The context for soda_n^1 includes: salt, acetate, chlorate, benzoate. The context for soda_n^2 contains instead: soft, drink, cola, bitter, etc. The sense with the largest intersection is #2, so the following mapping is established: μ(SODA (SOFT DRINK)) = soda_n^2.

3.3 Transferring Semantic Relations

The output of the algorithm presented in the previous section is a mapping between Wikipages and WordNet senses (that is, implicitly, synsets). Our insight is to use this alignment to enable the *transfer of semantic relations from Wikipedia to WordNet*. In fact, given a Wikipage w we can collect all Wikipedia links occurring in that page. For any such link from w to w', if the two Wikipages are mapped to WordNet senses (i.e., $\mu(w) \neq \epsilon$ and $\mu(w') \neq \epsilon$), we can transfer the corresponding edge $(\mu(w), \mu(w'))$ to WordNet. Note that $\mu(w)$ and $\mu(w')$ are noun senses, as Wikipages describe nominal concepts or named entities. We refer to this extended resource as WordNet++.

For instance, consider the Wikipage SODA (SOFT DRINK). This page contains, among others, a link to the Wikipage SYRUP. Assuming μ(SODA (SODA DRINK)) = soda_n^2 and μ(SYRUP) = syrup_n^1, we can add the corresponding semantic relation (soda_n^2, syrup_n^1) to WordNet[3].

Thus, WordNet++ represents an extension of WordNet which includes semantic associative relations between synsets. These are originally found in Wikipedia and then integrated into WordNet by means of our mapping. In turn, WordNet++ represents the English-only subset of a larger multilingual resource, BabelNet (Navigli and Ponzetto, 2010), where lexicalizations of the synsets are harvested for many languages using the so-called Wikipedia inter-language links and applying a machine translation system.

[3]Note that such relations are *unlabeled*. However, for our purposes this has no impact, since our algorithms do not distinguish between *is-a* and other kinds of relations in the lexical knowledge base (cf. Section 4.2).

4 Experiments

We perform two sets of experiments: we first evaluate the intrinsic quality of our mapping (Section 4.1) and then quantify the impact of WordNet++ for coarse-grained (Section 4.2) and domain-specific WSD (Section 4.3).

4.1 Evaluation of the Mapping

Experimental setting. We first conducted an evaluation of the mapping quality. To create a gold standard for evaluation, we started from the set of all lemmas contained both in WordNet and Wikipedia: the intersection between the two resources includes 80,295 lemmas which correspond to 105,797 WordNet senses and 199,735 Wikipedia pages. The average polysemy is 1.3 and 2.5 for WordNet senses and Wikipages, respectively (2.8 and 4.7 when excluding monosemous words). We selected a random sample of 1,000 Wikipages and asked an annotator with previous experience in lexicographic annotation to provide the correct WordNet sense for each page title (an empty sense label was given if no correct mapping was possible). 505 non-empty mappings were found, i.e. Wikipedia pages with a corresponding WordNet sense. In order to quantify the quality of the annotations and the difficulty of the task, a second annotator sense tagged a subset of 200 pages from the original sample. We computed the inter-annotator agreement using the kappa coefficient (Carletta, 1996) and found out that our annotators achieved an agreement coefficient κ of 0.9, indicating almost perfect agreement.

Table 1 summarizes the performance of our disambiguation algorithm against the manually annotated dataset. Evaluation is performed in terms of standard measures of precision (the ratio of correct sense labels to the non-empty labels output by the mapping algorithm), recall (the ratio of correct sense labels to the total of non-empty labels in the gold standard) and F_1-measure ($\frac{2PR}{P+R}$). We also calculate accuracy, which accounts for

	P	R	F_1	A
Structure	**82.2**	68.1	74.5	81.1
Gloss	81.1	64.2	71.7	78.8
Structure + Gloss	81.9	**77.5**	**79.6**	**84.4**
MFS BL	24.3	47.8	32.2	24.3
Random BL	23.8	46.8	31.6	23.9

Table 1: Performance of the mapping algorithm.

empty sense labels (that is, calculated on all 1,000 test instances). As baseline we use the most frequent WordNet sense (MFS), as well as a random sense assignment. We evaluate the mapping methodology described in Section 3.2 against different disambiguation contexts for the WordNet senses (cf. Section 3.2.2), i.e. structure-based (including synonymy, hypernymy/hyponymy and sisterhood), gloss-derived evidence, and a combination of the two. As disambiguation context of a Wikipage (Section 3.2.1) we use all information available, i.e. sense labels, links and categories[4].

Results and discussion. The results show that our method improves on the baseline by a large margin and that higher performance can be achieved by using more disambiguation information. That is, using a richer disambiguation context helps to better choose the most appropriate WordNet sense for a Wikipedia page. The combination of structural and gloss information attains a slight variation in terms of precision (-0.3% and $+0.8\%$ compared to Structure and Gloss respectively), but a significantly high increase in recall ($+9.4\%$ and $+13.3\%$). This implies that the different disambiguation contexts only partially overlap and, when used separately, each produces different mappings with a similar level of precision. In the joint approach, the harmonic mean of precision and recall, i.e. F_1, is in fact 5 and 8 points higher than when separately using structural and gloss information, respectively.

As for the baselines, the most frequent sense is just 0.6% and 0.4% above the random baseline in terms of F_1 and accuracy, respectively. A χ^2 test reveals in fact no statistically significant difference at $p < 0.05$. This is related to the random distribution of senses in our dataset and the Wikipedia unbiased coverage of WordNet senses. So selecting the most frequent sense rather than any other sense for each target page represents a choice as arbitrary as picking a sense at random.

The final mapping contains 81,533 pairs of Wikipages and word senses they map to, covering 55.7% of the noun senses in WordNet.

Using our best performing mapping we are able to extend WordNet with 1,902,859 semantic edges: of these, 97.93% are deemed novel, i.e. no direct edge could previously be found between the synsets. In addition, we performed a stricter evaluation of the novelty of our relations by checking whether these can still be found indirectly by searching for a connecting path between the two synsets of interest. Here we found that 91.3%, 87.2% and 78.9% of the relations are novel to WordNet when performing a graph search of maximum depth of 2, 3 and 4, respectively.

4.2 Coarse-grained WSD

Experimental setting. We extrinsically evaluate the impact of WordNet++ on the Semeval-2007 coarse-grained all-words WSD task (Navigli et al., 2007). Performing experiments in a coarse-grained setting is a natural choice for several reasons: first, it has been argued that the fine granularity of WordNet is one of the main obstacles to accurate WSD (cf. the discussion in Navigli (2009b)); second, the meanings of Wikipedia pages are intuitively coarser than those in WordNet[5]. For instance, mapping TRAVEL to the first or the second sense in WordNet is an arbitrary choice, as the Wikipage refers to both senses. Finally, given their different nature, WordNet and Wikipedia do not fully overlap. Accordingly, we expect the transfer of semantic relations from Wikipedia to WordNet to have sometimes the side effect to penalize some fine-grained senses of a word.

We experiment with two simple knowledge-based algorithms that are set to perform coarse-grained WSD on a sentence-by-sentence basis:

- **Simplified Extended Lesk (ExtLesk):** The first algorithm is a simplified version of the Lesk

[4]We leave out the evaluation of different contexts for a Wikipage for the sake of brevity. During prototyping we found that the best results were given by using the largest context available, as reported in Table 1.

[5]Note that our polysemy rates from Section 4.1 also include Wikipages whose lemma is contained in WordNet, but which have out-of-domain meanings, i.e. encyclopedic entries referring to specialized named entities such as e.g., DISCOVERY (SPACE SHUTTLE) or FIELD ARTILLERY (MAGAZINE). We computed the polysemy rate for a random sample of 20 polysemous words by manually removing these NEs and found that Wikipedia's polysemy rate is indeed lower than that of WordNet – i.e. average polysemy of 2.1 vs. 2.8.

algorithm (Lesk, 1986), that performs WSD based on the overlap between the context surrounding the target word to be disambiguated and the definitions of its candidate senses (Kilgarriff and Rosenzweig, 2000). Given a target word w, this method assigns to w the sense whose gloss has the highest overlap (i.e. most words in common) with the context of w, namely the set of content words co-occurring with it in a pre-defined window (a sentence in our case). Due to the limited context provided by the WordNet glosses, we follow Banerjee and Pedersen (2003) and expand the gloss of each sense s to include words from the glosses of those synsets in a semantic relation with s. These include all WordNet synsets which are directly connected to s, either by means of the semantic pointers found in WordNet or through the unlabeled links found in WordNet++.

- **Degree Centrality (Degree):** The second algorithm is a graph-based approach that relies on the notion of vertex degree (Navigli and Lapata, 2010). Starting from each sense s of the target word, it performs a depth-first search (DFS) of the WordNet(++) graph and collects all the paths connecting s to senses of other words in context. As a result, a sentence graph is produced. A maximum search depth is established to limit the size of this graph. The sense of the target word with the highest vertex degree is selected. We follow Navigli and Lapata (2010) and run Degree in a weakly supervised setting where the system attempts no sense assignment if the highest degree score is below a certain (empirically estimated) threshold. The optimal threshold and maximum search depth are estimated by maximizing Degree's F_1 on a development set of 1,000 randomly chosen noun instances from the SemCor corpus (Miller et al., 1993). Experiments on the development dataset using Degree on WordNet++ revealed a performance far lower than expected. Error analysis showed that many instances were incorrectly disambiguated, due to the noise from weak semantic links, e.g. the links from SODA (SOFT DRINK) to EUROPE or AUSTRALIA. Accordingly, in order to improve the disambiguation performance, we developed a filter to rule out weak semantic relations from WordNet++. Given a WordNet++ edge $(\mu(w), \mu(w'))$ where w and w' are both Wikipages and w links to w', we first collect all words from the category labels of w and w' into two bags of words. We remove stopwords and lemmatize the remaining words. We then compute the degree of overlap between the two sets of categories as the number of words in common between the two bags of words, normalized in the $[0, 1]$ interval. We finally retain the link for the DFS if such score is above an empirically determined threshold. The optimal value for this category overlap threshold was again estimated by maximizing Degree's F_1 on the development set. The final graph used by Degree consists of WordNet, together with 152,944 relations from our semantic relation enrichment method (cf. Section 3.3).

Resource	Algorithm	Nouns only		
		P	R	F_1
WordNet	ExtLesk	83.6	57.7	68.3
	Degree	86.3	65.5	74.5
Wikipedia	ExtLesk	82.3	64.1	72.0
	Degree	**96.2**	40.1	57.4
WordNet++	ExtLesk	82.7	69.2	75.4
	Degree	87.3	72.7	**79.4**
	MFS BL	77.4	**77.4**	77.4
	Random BL	63.5	63.5	63.5

Table 2: Performance on Semeval-2007 coarse-grained all-words WSD (nouns only subset).

Results and discussion. We report our results in terms of precision, recall and F_1-measure on the Semeval-2007 coarse-grained all-words dataset (Navigli et al., 2007). We first evaluated ExtLesk and Degree using three different resources: (1) WordNet only; (2) Wikipedia only, i.e. only those relations harvested from the links found within Wikipedia pages; (3) their union, i.e. WordNet++. In Table 2 we report the results on nouns only. As common practice, we compare with random sense assignment and the most frequent sense (MFS) from SemCor as baselines. Enriching WordNet with encyclopedic relations from Wikipedia yields a consistent improvement against using WordNet (+7.1% and +4.9% F_1 for ExtLesk and Degree) or Wikipedia (+3.4% and +22.0%) alone. The best results are obtained by using Degree with WordNet++. The better performance of Wikipedia against WordNet when using ExtLesk (+3.7%) highlights the quality of the relations extracted. However, no such improvement is found with De-

Algorithm	Nouns only P/R/F_1	All words P/R/F_1
ExtLesk	81.0	79.1
Degree	**85.5**	**81.7**
SUSSX-FR	81.1	77.0
TreeMatch	N/A	73.6
NUS-PT	82.3	**82.5**
SSI	**84.1**	**83.2**
MFS BL	77.4	78.9
Random BL	63.5	62.7

Table 3: Performance on Semeval-2007 coarse-grained all-words WSD with MFS as a back-off strategy when no sense assignment is attempted.

gree, due to its lower recall. Interestingly, Degree on WordNet++ beats the MFS baseline, which is notably a difficult competitor for unsupervised and knowledge-lean systems.

We finally compare our two algorithms using WordNet++ with state-of-the-art WSD systems, namely the best unsupervised (Koeling and McCarthy, 2007, SUSSX-FR) and supervised (Chan et al., 2007, NUS-PT) systems participating in the Semeval-2007 coarse-grained all-words task. We also compare with SSI (Navigli and Velardi, 2005) – a knowledge-based system that participated out of competition – and the unsupervised proposal from Chen et al. (2009, TreeMatch). Table 3 shows the results for nouns (1,108) and all words (2,269 words): we use the MFS as a back-off strategy when no sense assignment is attempted. Degree with WordNet++ achieves the best performance in the literature[6]. On the noun-only subset of the data, its performance is comparable with SSI and significantly better than the best supervised and unsupervised systems (+3.2% and +4.4% F_1 against NUS-PT and SUSSX-FR). On the entire dataset, it outperforms SUSSX-FR and TreeMatch (+4.7% and +8.1%) and its recall is not statistically different from that of SSI and NUS-PT. This result is particularly interesting, given that WordNet++ is extended only with relations between nominals, and, in contrast to SSI, it does not rely on a costly annotation effort to engineer the set of semantic relations. Last but not least, we achieve state-of-the-art performance with a much simpler algorithm that is based on the notion of vertex degree in a graph.

[6]The differences between the results in bold in each column of the table are not statistically significant at $p < 0.05$.

Algorithm	Sports P/R/F_1	Finance P/R/F_1
k-NN †	30.3	43.4
Static PR †	20.1	39.6
Personalized PR †	35.6	46.9
ExtLesk	40.1	45.6
Degree	**42.0**	**47.8**
MFS BL	19.6	37.1
Random BL	19.5	19.6

Table 4: Performance on the Sports and Finance sections of the dataset from Koeling et al. (2005): † indicates results from Agirre et al. (2009).

4.3 Domain WSD

The main strength of Wikipedia is to provide wide coverage for many specific domains. Accordingly, on the Semeval dataset our system achieves the best performance on a domain-specific text, namely d004, a document on computer science where we achieve 82.9% F_1 (+6.8% when compared with the best supervised system, namely NUS-PT). To test whether our performance on the Semeval dataset is an artifact of the data, i.e. d004 coming from Wikipedia itself, we evaluated our system on the Sports and Finance sections of the domain corpora from Koeling et al. (2005). In Table 4 we report our results on these datasets and compare them with Personalized PageRank, the state-of-the-art system from Agirre et al. (2009)[7], as well as Static PageRank and a k-NN supervised WSD system trained on SemCor.

The results we obtain on the two domains with our best configuration (Degree using WordNet++) outperform by a large margin k-NN, thus supporting the findings from Agirre et al. (2009) that knowledge-based systems exhibit a more robust performance than their supervised alternatives when evaluated across different domains. In addition, our system achieves better results than Static and Personalized PageRank, indicating that competitive disambiguation performance can still be achieved by a less sophisticated knowledge-based WSD algorithm when provided with a rich amount of high-quality knowledge. Finally, the results show that WordNet++ enables competitive performance also in a fine-grained domain setting.

[7]We compare only with those system configurations performing token-based WSD, i.e. disambiguating each instance of a target word separately, since our aim is not to perform type-based disambiguation.

5 Conclusions

In this paper, we have presented a large-scale method for the automatic enrichment of a computational lexicon with encyclopedic relational knowledge[8]. Our experiments show that the large amount of knowledge injected into WordNet is of high quality and, more importantly, it enables simple knowledge-based WSD systems to perform as well as the highest-performing supervised ones in a coarse-grained setting and to outperform them on domain-specific text. Thus, our results go one step beyond previous findings (Cuadros and Rigau, 2006; Agirre et al., 2009; Navigli and Lapata, 2010) and prove that knowledge-rich disambiguation is a competitive alternative to supervised systems, even when relying on a simple algorithm. We note, however, that the present contribution does not show *which* knowledge-rich algorithm performs best with WordNet++. In fact, more sophisticated approaches, such as Personalized PageRank (Agirre and Soroa, 2009), could be still applied to yield even higher performance. We leave such exploration to future work. Moreover, while the mapping has been used to enrich WordNet with a large amount of semantic edges, the method can be reversed and applied to the encyclopedic resource itself, that is Wikipedia, to perform disambiguation with the corresponding sense inventory (cf. the task of wikification proposed by Mihalcea and Csomai (2007) and Milne and Witten (2008b)). In this paper, we focused on English Word Sense Disambiguation. However, since WordNet++ is part of a multilingual semantic network (Navigli and Ponzetto, 2010), we plan to explore the impact of this knowledge in a multilingual setting.

[8]The resulting resource, WordNet++, is freely available at `http://lcl.uniroma1.it/wordnetplusplus` for research purposes.

Abstract

In spite of decades of research on word sense disambiguation (WSD), all-words general purpose WSD has remained a distant goal. Many supervised WSD systems have been built, but the effort of creating the training corpus - *annotated sense marked corpora* - has always been a matter of concern. Therefore, attempts have been made to develop unsupervised and knowledge based techniques for WSD which do not need sense marked corpora. However such approaches have not proved effective, since they typically do not better Wordnet first sense baseline accuracy. Our research reported here proposes to stick to the supervised approach, but with far less demand on annotation. We show that if we have ANY sense marked corpora, be it from mixed domain or a specific domain, a small amount of annotation in ANY other domain can deliver the goods almost as if exhaustive sense marking were available in that domain. We have tested our approach across Tourism and Health domain corpora, using also the well known mixed domain SemCor corpus. Accuracy figures close to self domain training lend credence to the viability of our approach. Our contribution thus lies in finding a convenient middle ground between pure supervised and pure unsupervised WSD. Finally, our approach is not restricted to any specific set of target words, a departure from a commonly observed practice in domain specific WSD.

1 Introduction

Amongst annotation tasks, sense marking surely takes the cake, demanding as it does high level of language competence, topic comprehension and domain sensitivity. This makes supervised approaches to WSD a difficult proposition (Agirre et al., 2009b; Agirre et al., 2009a; McCarthy et al., 2007). Unsupervised and knowledge based approaches have been tried with the hope of creating WSD systems with no need for sense marked corpora (Koeling et al., 2005; McCarthy et al., 2007; Agirre et al., 2009b). However, the accuracy figures of such systems are low.

Our work here is motivated by the desire to develop *annotation-lean all-words* domain adapted techniques for supervised WSD. It is a common observation that domain specific WSD exhibits high level of accuracy even for the all-words scenario (Khapra et al., 2010) - provided training and testing are on the same domain. Also domain adaptation - in which training happens in one domain and testing in another - often is able to attain good levels of performance, albeit on a specific set of target words (Chan and Ng, 2007; Agirre and de Lacalle, 2009). To the best of our knowledge there does not exist a system that solves the combined problem of *all words domain adapted WSD*. We thus propose the following:

a. For any target domain, create a small amount of sense annotated corpus.

b. Mix it with an existing sense annotated corpus – from a mixed domain or specific domain – to train the WSD engine.

This procedure tested on four adaptation scenarios, *viz.*, (i) SemCor (Miller et al., 1993) to Tourism, (ii) SemCor to Health, (iii) Tourism to Health and (iv) Health to Tourism has consistently yielded good performance (to be explained in sections 6 and 7).

The remainder of this paper is organized as follows. In section 2 we discuss previous work in the area of domain adaptation for WSD. In section 3

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1532–1541,
Uppsala, Sweden, 11-16 July 2010.

we discuss three state of art supervised, unsupervised and knowledge based algorithms for WSD. Section 4 discusses the injection strategy for domain adaptation. In section 5 we describe the dataset used for our experiments. We then present the results in section 6 followed by discussions in section 7. Section 8 examines whether there is any need for intelligent choice of injections. Section 9 concludes the paper highlighting possible future directions.

2 Related Work

Domain specific WSD for selected target words has been attempted by Ng and Lee (1996), Agirre and de Lacalle (2009), Chan and Ng (2007), Koeling et al. (2005) and Agirre et al. (2009b). They report results on three publicly available lexical sample datasets, *viz.*, DSO corpus (Ng and Lee, 1996), MEDLINE corpus (Weeber et al., 2001) and the corpus made available by Koeling et al. (2005). Each of these datasets contains a handful of target words (41-191 words) which are sense marked in the corpus.

Our main inspiration comes from the target-word specific results reported by Chan and Ng (2007) and Agirre and de Lacalle (2009). The former showed that adding just 30% of the target data to the source data achieved the same performance as that obtained by taking the entire source and target data. Agirre and de Lacalle (2009) reported a 22% error reduction when source and target data were combined for training a classifier, as compared to the case when only the target data was used for training the classifier. However, both these works focused on *target word specific* WSD and do not address all-words domain specific WSD.

In the unsupervised setting, McCarthy et al. (2007) showed that their predominant sense acquisition method gives good results on the corpus of Koeling et al. (2005). In particular, they showed that the performance of their method is comparable to the most frequent sense obtained from a tagged corpus, thereby making a strong case for unsupervised methods for domain-specific WSD. More recently, Agirre et al. (2009b) showed that knowledge based approaches which rely only on the semantic relations captured by the Wordnet graph outperform supervised approaches when applied to specific domains. The good results obtained by McCarthy et al. (2007) and Agirre et al. (2009b) for unsupervised and knowledge based approaches respectively have cast a doubt on the viability of supervised approaches which rely on sense tagged corpora. However, these conclusions were drawn only from the performance on certain target words, leaving open the question of their utility in all words WSD.

We believe our work contributes to the WSD research in the following way: (i) it shows that there is promise in supervised approach to all-word WSD, through the instrument of domain adaptation; (ii) it places in perspective some very recently reported unsupervised and knowledge based techniques of WSD; (ii) it answers some questions arising out of the debate between supervision and unsupervision in WSD; and finally (iv) it explores a convenient middle ground between unsupervised and supervised WSD – the territory of "annotate-little and inject" paradigm.

3 WSD algorithms employed by us

In this section we describe the knowledge based, unsupervised and supervised approaches used for our experiments.

3.1 Knowledge Based Approach

Agirre et al. (2009b) showed that a graph based algorithm which uses only the relations between concepts in a Lexical Knowledge Base (LKB) can outperform supervised approaches when tested on specific domains (for a set of chosen target words). We employ their method which involves the following steps:

1. Represent Wordnet as a graph where the concepts (*i.e.*, synsets) act as nodes and the relations between concepts define edges in the graph.
2. Apply a context-dependent *Personalized PageRank* algorithm on this graph by introducing the context words as nodes into the graph and linking them with their respective synsets.
3. These nodes corresponding to the context words then inject probability mass into the synsets they are linked to, thereby influencing the final relevance of all nodes in the graph.

We used the publicly available implementation of this algorithm[1] for our experiments.

[1] http://ixa2.si.ehu.es/ukb/

3.2 Unsupervised Approach

McCarthy et al. (2007) used an untagged corpus to construct a thesaurus of related words. They then found the predominant sense (i.e., the most frequent sense) of each target word using pair-wise Wordnet based similarity measures by pairing the target word with its top-k neighbors in the thesaurus. Each target word is then disambiguated by assigning it its predominant sense – the motivation being that the predominant sense is a powerful, hard-to-beat baseline. We implemented their method using the following steps:

1. Obtain a domain-specific untagged corpus (we crawled a corpus of approximately 9M words from the web).
2. Extract grammatical relations from this text using a dependency parser[2] (Klein and Manning, 2003).
3. Use the grammatical relations thus extracted to construct features for identifying the k nearest neighbors for each word using the distributional similarity score described in (Lin, 1998).
4. Rank the senses of each target word in the test set using a weighted sum of the distributional similarity scores of the neighbors. The weights in the sum are based on Wordnet Similarity scores (Patwardhan and Pedersen, 2003).
5. Each target word in the test set is then disambiguated by simply assigning it its predominant sense obtained using the above method.

3.3 Supervised approach

Khapra et al. (2010) proposed a supervised algorithm for domain-specific WSD and showed that it beats the most frequent corpus sense and performs on par with other state of the art algorithms like PageRank. We implemented their iterative algorithm which involves the following steps:

1. Tag all monosemous words in the sentence.
2. Iteratively disambiguate the remaining words in the sentence in increasing order of their degree of polysemy.
3. At each stage rank the candidate senses of a word using the scoring function of Equation (1) which combines corpus based parameters (such as, sense distributions and corpus co-occurrence) and Wordnet based parameters (such as, semantic similarity, conceptual distance, *etc.*)

$$S^* = \arg\max_i(\theta_i V_i + \sum_{j \in J} W_{ij} * V_i * V_j) \quad (1)$$

where,

$i \in$ *Candidate Synsets*
$J =$ *Set of disambiguated words*
$\theta_i = BelongingnessToDominantConcept(S_i)$
$V_i = P(S_i|word)$
$W_{ij} = CorpusCooccurrence(S_i, S_j)$
$* 1/WNConceptualDistance(S_i, S_j)$
$* 1/WNSemanticGraphDistance(S_i, S_j)$

4. Select the candidate synset with maximizes the above score as the winner sense.

4 Injections for Supervised Adaptation

This section describes the main interest of our work i.e. *adaptation using injections*. For supervised adaptation, we use the supervised algorithm described above (Khapra et al., 2010) in the following 3 settings as proposed by Agirre et al. (2009a):

a. **Source setting:** We train the algorithm on a mixed-domain corpus (SemCor) or a domain-specific corpus (say, Tourism) and test it on a different domain (say, Health). A good performance in this setting would indicate robustness to domain-shifts.

b. **Target setting:** We train and test the algorithm using data from the same domain. This gives the skyline performance, i.e., the best performance that can be achieved if sense marked data from the target domain were available.

c. **Adaptation setting:** This setting is the main focus of interest in the paper. We augment the training data which could be from one domain or mixed domain with a small amount of data from the target domain. This combined data is then used for training. The aim here is to reach as close to the skyline performance using as little data as possible. For injecting data from the target domain we randomly select some sense marked words from the target domain and add

them to the training data. An obvious question which arises at this point is "Why were the words selected at random?" or "Can selection of words using some active learning strategy yield better results than a random selection?" We discuss this question in detail in Section 7 and show that a random set of injections performs no worse than a craftily selected set of injections.

5 DataSet Preparation

Due to the lack of any publicly available all-words domain specific sense marked corpora we set upon the task of collecting data from two domains, *viz.*, *Tourism and Health*. The data for Tourism domain was downloaded from Indian Tourism websites whereas the data for Health domain was obtained from two doctors. This data was manually sense annotated by two lexicographers adept in English. Princeton Wordnet 2.1[3] (Fellbaum, 1998) was used as the sense inventory. A total of 1,34,095 words from the Tourism domain and 42,046 words from the Health domain were manually sense marked. Some files were sense marked by both the lexicographers and the Inter Tagger Agreement (ITA) calculated from these files was 83% which is comparable to the 78% ITA reported on the SemCor corpus considering the domain-specific nature of the corpus.

We now present different statistics about the corpora. Table 1 summarizes the number of polysemous and monosemous words in each category. Note that we do not use the monosemous words while calculating precision and recall of our algorithms.

Table 2 shows the average number of instances per polysemous word in the 3 corpora. We note that the number of instances per word in the Tourism domain is comparable to that in the SemCor corpus whereas the number of instances per word in the Health corpus is smaller due to the overall smaller size of the Health corpus.

Tables 3 and 4 summarize the average degree of Wordnet polysemy and corpus polysemy of the polysemous words in the corpus. Wordnet polysemy is the number of senses of a word as listed in the Wordnet, whereas corpus polysemy is the number of senses of a word actually appearing in the corpus. As expected, the average degree of corpus polysemy (Table 4) is much less than the average degree of Wordnet polysemy (Table 3). Further, the average degree of corpus polysemy (Table 4) in the two domains is less than that in the mixed-domain SemCor corpus, which is expected due to the domain specific nature of the corpora.

Finally, Table 5 summarizes the number of unique polysemous words per category in each domain.

Category	No. of unique polysemous words		
	Health	Tourism	SemCor
Noun	2188	4229	5871
Verb	984	1591	2565
Adjective	1024	1635	2640
Adverb	217	308	463
All	4413	7763	11539

Table 5: Number of unique polysemous words per category in each domain.

[3] http://wordnetweb.princeton.edu/perl/webwn

The data is currently being enhanced by manually sense marking more words from each domain and will be soon freely available[4] for research purposes.

6 Results

We tested the 3 algorithms described in section 4 using SemCor, Tourism and Health domain corpora. We did a 2-fold cross validation for supervised adaptation and report the average performance over the two folds. Since the knowledge based and unsupervised methods do not need any training data we simply test it on the entire corpus from the two domains.

6.1 Knowledge Based approach

The results obtained by applying the Personalized PageRank (PPR) method to Tourism and Health data are summarized in Table 6. We also report the Wordnet first sense baseline (WFS).

Domain	Algorithm	P(%)	R(%)	F(%)
Tourism	PPR	53.1	53.1	53.1
	WFS	62.5	62.5	62.5
Health	PPR	51.1	51.1	51.1
	WFS	65.5	65.5	65.5

Table 6: Comparing the performance of Personalized PageRank (PPR) with Wordnet First Sense Baseline (WFS)

6.2 Unsupervised approach

The predominant sense for each word in the two domains was calculated using the method described in section 4.2. McCarthy et al. (2004) reported that the best results were obtained using $k = 50$ neighbors and the Wordnet Similarity ***jcn*** measure (Jiang and Conrath, 1997). Following them, we used $k = 50$ and observed that the best results for nouns and verbs were obtained using the ***jcn*** measure and the best results for adjectives and adverbs were obtained using the ***lesk*** measure (Banerjee and Pedersen, 2002). Accordingly, we used ***jcn*** for nouns and verbs and ***lesk*** for adjectives and adverbs. Each target word in the test set is then disambiguated by simply assigning it its predominant sense obtained using the above method. We tested this approach only on Tourism domain due to unavailability of large untagged Health corpus which is needed for constructing the thesaurus. The results are summarized in Table 7.

Domain	Algorithm	P(%)	R(%)	F(%)
Tourism	McCarthy	51.85	49.32	50.55
	WFS	62.50	62.50	62.50

Table 7: Comparing the performance of unsupervised approach with Wordnet First Sense Baseline (WFS)

6.3 Supervised adaptation

We report results in the **source setting**, **target setting** and **adaptation setting** as described earlier using the following four combinations for source and target data:

1. ***SemCor to Tourism (SC→T)*** where SemCor is used as the source domain and Tourism as the target (test) domain.
2. ***SemCor to Health (SC→H)*** where SemCor is used as the source domain and Health as the target (test) domain.
3. ***Tourism to Health (T→H)*** where Tourism is used as the source domain and Health as the target (test) domain.
4. ***Health to Tourism (H→T)*** where Health is used as the source domain and Tourism as the target (test) domain.

In each case, the target domain data was divided into two folds. One fold was set aside for testing and the other for injecting data in the ***adaptation setting***. We increased the size of the injected target examples from 1000 to 14000 words in increments of 1000. We then repeated the same experiment by reversing the role of the two folds.

Figures 1, 2, 3 and 4 show the graphs of the average F-score over the 2-folds for SC→T, SC→H, T→H and H→T respectively. The x-axis represents the amount of training data (in words) injected from the target domain and the y-axis represents the F-score. The different curves in each graph are as follows:

a. *only_random* : This curve plots the performance obtained using x randomly selected sense tagged words from the target domain and zero sense tagged words from the source domain (x was varied from 1000 to 14000 words in increments of 1000).

[4] http://www.cfilt.iitb.ac.in/wsd/annotated_corpus

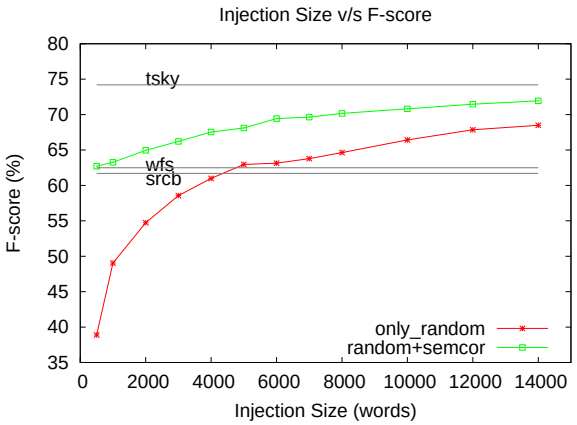

Figure 1: Supervised adaptation from SemCor to Tourism using injections

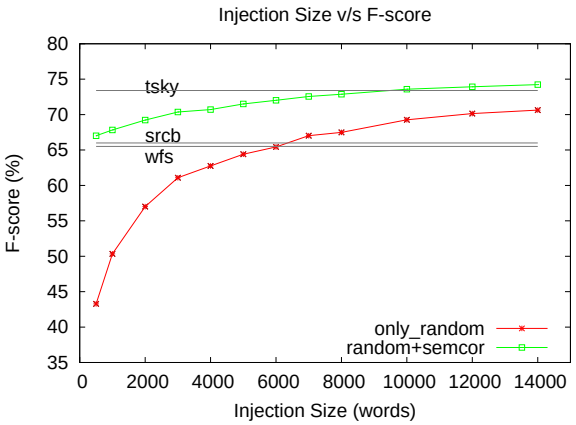

Figure 2: Supervised adaptation from SemCor to Health using injections

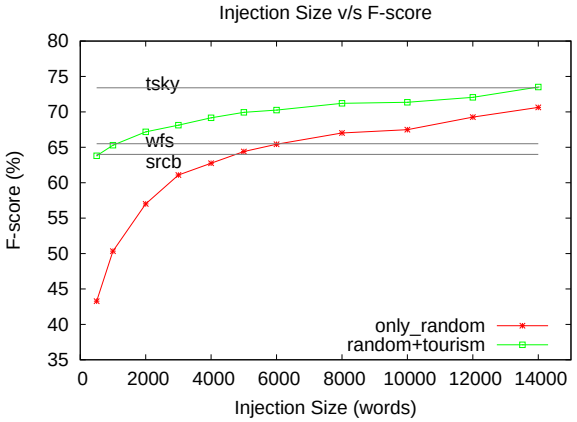

Figure 3: Supervised adaptation from Tourism to Health using injections

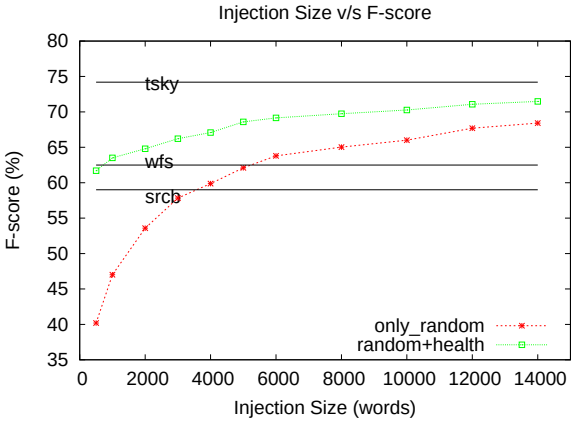

Figure 4: Supervised adaptation from Health to Tourism using injections

b. *random+source* : This curve plots the performance obtained by mixing x randomly selected sense tagged words from the target domain with the entire training data from the source domain (again x was varied from 1000 to 14000 words in increments of 1000).

c. *source_baseline* ***(srcb)*** : This represents the F-score obtained by training on the source data alone without mixing any examples from the target domain.

d. *wordnet_first_sense* ***(wfs)*** : This represents the F-score obtained by selecting the first sense from Wordnet, a typically reported baseline.

e. *target_skyline* ***(tsky)*** : This represents the average 2-fold F-score obtained by training on one entire fold of the target data itself (*Health*: 15320 polysemous words; *Tourism*: 47242 polysemous words) and testing on the other fold.

These graphs along with other results are discussed in the next section.

7 Discussions

We discuss the performance of the three approaches.

7.1 Knowledge Based and Unsupervised approaches

It is apparent from Tables 6 and 7 that knowledge based and unsupervised approaches do not perform well when compared to the Wordnet first sense (which is freely available and hence can be used for disambiguation). Further, we observe that the performance of these approaches is even less than the *source_baseline* (*i.e.*, the case when training data from a source domain is applied as it is to a target domain - without using any injections). These observations bring out the weaknesses of these approaches when used in an all-words setting and clearly indicate that they come nowhere close to replacing a supervised system.

7.2 Supervised adaptation

1. The F-score obtained by training on SemCor (mixed-domain corpus) and testing on the two target domains without using any injections (***srcb***) – F-score of 61.7% on Tourism and F-score of 65.5% on Health – is comparable to the best result reported on the SEMEVAL datasets (65.02%, where both training and testing happens on a mixed-domain corpus (Snyder and Palmer, 2004)). This is in contrast to previous studies (Escudero et al., 2000; Agirre and Martinez, 2004) which suggest that instead of adapting from a generic/mixed domain to a specific domain, it is better to completely ignore the generic examples and use hand-tagged data from the target domain itself. The main reason for the contrasting results is that the earlier work focused only on a handful of target words whereas we focus on all words appearing in the corpus. So, while the behavior of a few target words would change drastically when the domain changes, a majority of the words will exhibit the same behavior (*i.e.*, same predominant sense) even when the domain changes. We agree that the overall performance is still lower than that obtained by training on the domain-specific corpora. However, it is still better than the performance of unsupervised and knowledge based approaches which tilts the scale in favor of supervised approaches even when only mixed domain sense marked corpora is available.

2. Adding injections from the target domain improves the performance. As the amount of injection increases the performance approaches the skyline, and in the case of SC→H and T→H it even crosses the skyline performance showing that combining the source and target data can give better performance than using the target data alone. This is consistent with the domain adaptation results reported by Agirre and de Lacalle (2009) on a specific set of target words.

3. The performance of *random+source* is always better than *only_random* indicating that the data from the source domain does help to improve performance. A detailed analysis showed that the gain obtained by using the source data is attributable to reducing recall errors by increasing the coverage of seen words.

4. Adapting from one specific domain (*Tourism or Health*) to another specific domain (*Health or Tourism*) gives the same performance as that obtained by adapting from a mixed-domain (*SemCor*) to a specific domain (*Tourism, Health*). This is an interesting observation as it suggests that as long as data from one domain is available it is easy to build a WSD engine that works for other domains by injecting a small amount of data from these domains.

To verify that the results are consistent, we randomly selected 5 different sets of injections from fold-1 and tested the performance on fold-2. We then repeated the same experiment by reversing the roles of the two folds. The results were indeed consistent irrespective of the set of injections used. Due to lack of space we have not included the results for these 5 different sets of injections.

7.3 Quantifying the trade-off between performance and corpus size

To correctly quantify the benefit of adding injections from the target domain, we calculated the amount of target data (*peak_size*) that is needed to reach the skyline F-score (*peak_F*) in the absence of any data from the source domain. The *peak_size* was found to be 35000 (Tourism) and 14000 (Health) corresponding to *peak_F* values of 74.2% (Tourism) and 73.4% (Health). We then plotted a graph (Figure 5) to capture the relation between the size of injections (expressed as a percentage of the *peak_size*) and the F-score (expressed as a percentage of the *peak_F*).

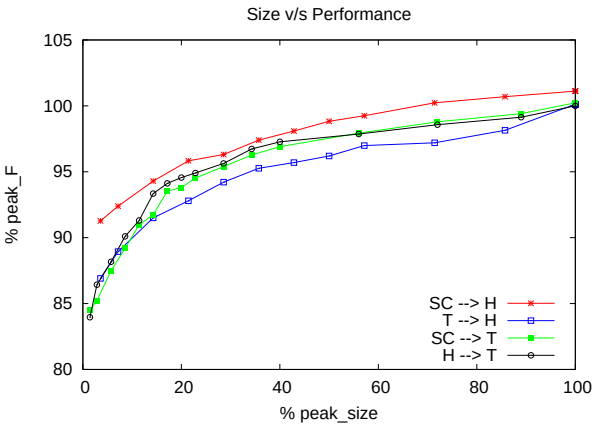

Figure 5: Trade-off between performance and corpus size

We observe that by mixing only 20-40% of the *peak_size* with the source domain we can obtain up to 95% of the performance obtained by using the

entire target data (*peak_size*). In absolute terms, the size of the injections is only 7000-9000 polysemous words which is a very small price to pay considering the performance benefits.

8 Does the choice of injections matter?

An obvious question which arises at this point is *"Why were the words selected at random?"* or *"Can selection of words using some active learning strategy yield better results than a random selection?"* An answer to this question requires a more thorough understanding of the *sense-behavior* exhibited by words across domains. In any scenario involving a shift from domain D_1 to domain D_2, we will always encounter words belonging to the following 4 categories:

a. W_{D_1} : This class includes words which are encountered only in the source domain D_1 and do not appear in the target domain D_2. Since we are interested in adapting to the target domain and since these words do not appear in the target domain, it is quite obvious that they are **not important** for the problem of domain adaptation.

b. W_{D_2} : This class includes words which are encountered only in the target domain D_2 and do not appear in the source domain D_1. Again, it is quite obvious that these words are **important** for the problem of domain adaptation. They fall in the category of unseen words and need handling from that point of view.

c. $W_{D1D2_{conformists}}$: This class includes words which are encountered in both the domains and exhibit the same predominant sense in both the domains. Correct identification of these words is **important** so that we can use the predominant sense learned from D_1 for disambiguating instances of these words appearing in D_2.

d. $W_{D1D2_{non-conformists}}$: This class includes words which are encountered in both the domains but their predominant sense in the target domain D_2 **does not conform** to the predominant sense learned from the source domain D_1. Correct identification of these words is **important** so that we can ignore the predominant senses learned from D_1 while disambiguating instances of these words appearing in D_2.

Table 8 summarizes the percentage of words that fall in each category in each of the three adaptation scenarios. The fact that nearly 50-60% of the words fall in the "conformist" category once again makes a strong case for reusing sense tagged data from one domain to another domain.

Category	SC→T	SC→H	T→H
$\mathbf{W_{D_2}}$	7.14%	5.45%	13.61%
Conformists	49.54%	60.43%	54.31%
Non-Conformists	43.30%	34.11%	32.06%

Table 8: Percentage of Words belonging to each category in the three settings.

The above characterization suggests that an *ideal* domain adaptation strategy should focus on injecting W_{D_2} and $W_{D1D2_{non-conformists}}$ as these would yield maximum benefits if injected into the training data. While it is easy to identify the W_{D_2} words, *"identifying non-conformists"* is a hard problem which itself requires some type of WSD[5]. However, just to prove that a *random* injection strategy does as good as an *ideal* strategy we assume the presence of an *oracle* which identifies the $W_{D1D2_{non-conformists}}$. We then augment the training data with 5-8 instances for W_{D_2} and $W_{D1D2_{non-conformists}}$ words thus identified. We observed that adding more than 5-8 instances per word does not improve the performance. This is due to the "one sense per domain" phenomenon – seeing only a few instances of a word is sufficient to identify the predominant sense of the word. Further, to ensure a better overall performance, the instances of the most frequent words are injected first followed by less frequent words till we exhaust the total size of the injections (1000, 2000 and so on). We observed that there was a 75-80% overlap between the words selected by random strategy and oracle strategy. This is because oracle selects the most frequent words which also have a high chance of getting selected when a random sampling is done.

Figures 6, 7, 8 and 9 compare the performance of the two strategies. We see that the random strategy does as well as the oracle strategy thereby supporting our claim that *if we have sense marked corpus from one domain then simply injecting ANY small amount of data from the target domain will*

[5]Note that the unsupervised predominant sense acquisition method of McCarthy et al. (2007) implicitly identifies conformists and non-conformists

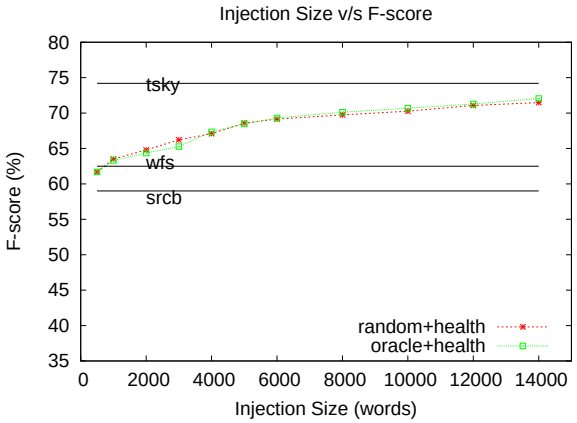

Figure 9: Comparing random strategy with oracle based ideal strategy for Health to Tourism adaptation

do the job.

9 Conclusion and Future Work

Based on our study of WSD in 4 domain adaptation scenarios, we make the following conclusions:

1. Supervised adaptation by mixing small amount of data (7000-9000 words) from the target domain with the source domain gives nearly the same performance (F-score of around 70% in all the 4 adaptation scenarios) as that obtained by training on the entire target domain data.

2. Unsupervised and knowledge based approaches which use distributional similarity and Wordnet based similarity measures do not compare well with the Wordnet first sense baseline performance and do not come anywhere close to the performance of supervised adaptation.

3. Supervised adaptation from a mixed domain to a specific domain gives the same performance as that from one specific domain (Tourism) to another specific domain (Health).

4. Supervised adaptation is not sensitive to the type of data being injected. This is an interesting finding with the following implication: as long as one has sense marked corpus - be it from a mixed or specific domain - simply injecting ANY small amount of data from the target domain suffices to beget good accuracy.

As future work, we would like to test our work on the Environment domain data which was released as part of the SEMEVAL 2010 shared task on "All-words Word Sense Disambiguation on a Specific Domain".

Abstract

Word Sense Disambiguation remains one of the most complex problems facing computational linguists to date. In this paper we present a system that combines evidence from a monolingual WSD system together with that from a multilingual WSD system to yield state of the art performance on standard All-Words data sets. The monolingual system is based on a modification of the graph based state of the art algorithm In-Degree. The multilingual system is an improvement over an All-Words unsupervised approach, SALAAM. SALAAM exploits multilingual evidence as a means of disambiguation. In this paper, we present modifications to both of the original approaches and then their combination. We finally report the highest results obtained to date on the SENSEVAL 2 standard data set using an unsupervised method, we achieve an overall F measure of 64.58 using a voting scheme.

1 Introduction

Despite advances in natural language processing (NLP), Word Sense Disambiguation (WSD) is still considered one of the most challenging problems in the field. Ever since the field's inception, WSD has been perceived as one of the central problems in NLP. WSD is viewed as an enabling technology that could potentially have far reaching impact on NLP applications in general. We are starting to see the beginnings of a positive effect of WSD in NLP applications such as Machine Translation (Carpuat and Wu, 2007; Chan et al., 2007).

Advances in WSD research in the current millennium can be attributed to several key factors: the availability of large scale computational lexical resources such as WordNets (Fellbaum, 1998; Miller, 1990), the availability of large scale corpora, the existence and dissemination of standardized data sets over the past 10 years through different testbeds such as SENSEVAL and SEMEVAL competitions,[1] devising more robust computing algorithms to handle large scale data sets, and simply advancement in hardware machinery.

In this paper, we address the problem of WSD of all content words in a sentence, All-Words data. In this framework, the task is to associate all tokens with their contextually relevant meaning definitions from some computational lexical resource. Our work hinges upon combining two high quality WSD systems that rely on essentially different sources of evidence. The two WSD systems are a monolingual system `RelCont` and a multilingual system `TransCont`. `RelCont` is an enhancement on an existing graph based algorithm, In-Degree, first described in (Navigli and Lapata, 2007). `TransCont` is an enhancement over an existing approach that leverages multilingual evidence through projection, `SALAAM`, described in detail in (Diab and Resnik, 2002). Similar to the leveraged systems, the current combined approach is unsupervised, namely it does not rely on training data from the onset. We show that by combining both sources of evidence, our approach yields the highest performance for an unsupervised system to date on standard All-Words data sets.

This paper is organized as follows: Section 2 delves into the problem of WSD in more detail; Section 3 explores some of the relevant related work; in Section 4, we describe the two WSD systems in some detail emphasizing the improvements to the basic systems in addition to a description of our combination approach; we present our experimental set up and results in Section 5; we discuss the results and our overall observations with error analysis in Section 6; Finally, we con-

clude in Section 7.

2 Word Sense Disambiguation

The definition of WSD has taken on several different practical meanings in recent years. In the latest SEMEVAL 2010 workshop, there are 18 tasks defined, several of which are on different languages, however we recognize the widening of the definition of the task of WSD. In addition to the traditional All-Words and Lexical Sample tasks, we note new tasks on word sense discrimination (no sense inventory needed, the different senses are merely distinguished), lexical substitution using synonyms of words as substitutes both monolingually and multilingually, as well as meaning definitions obtained from different languages namely using words in translation.

Our paper is about the classical All-Words (AW) task of WSD. In this task, all content bearing words in running text are disambiguated from a static lexical resource. For example a sentence such as 'I walked by the bank and saw many beautiful plants there.' will have the verbs 'walked, saw', the nouns 'bank, plants', the adjectives 'many, beautiful', and the adverb 'there', be disambiguated from a standard lexical resource. Hence, using WordNet,[2] 'walked' will be assigned the corresponding meaning definitions of: *t*o use one's feet to advance; to advance by steps, 'saw' will be assigned the meaning definition of: *t*o perceive by sight or have the power to perceive by sight, the noun 'bank' will be assigned the meaning definition of: *s*loping land especially the slope beside a body of water, and so on.

3 Related Works

Many systems over the years have been proposed for the task. A thorough review of the state of the art through the late 1990s (Ide and Veronis, 1998) and more recently in (Navigli, 2009). Several techniques have been used to tackle the problem ranging from rule based/knowledge based approaches to unsupervised and supervised machine learning techniques. To date, the best approaches that solve the AW WSD task are supervised as illustrated in the different SenseEval and SEMEVAL AW task (Palmer et al., 2001; Snyder and Palmer, 2004; Pradhan et al., 2007).

In this paper, we present an unsupervised combination approach to the AW WSD problem that relies on WN similarity measures in conjunction with evidence obtained through exploiting multilingual evidence. We will review the closely relevant related work on which this current investigation is based.[3]

4 Our Approach

Our current investigation exploits two basic unsupervised approaches that perform at state-of-the-art for the AW WSD task in an unsupervised setting. Crucially the two systems rely on different sources of evidence allowing them to complement each other to a large extent leading to better performance than for each system independently. Given a target content word and co-occurring contextual clues, the monolingual system `RelCont` attempts to assign the approporiate meaning definition to the target word. Such words by definition are semantically related words. `TransCont`, on the other hand, is the multilingual system. `TransCont` defines the notion of context in the translational space using a foreign word as a filter for defining the contextual content words for a given target word. In this multilingual setting, all the words that are mapped to (aligned with) the same orthographic form in a foreign language constitute the context. In the next subsections we describe the two approaches `RelCont` and `TransCont` in some detail, then we proceed to describe two combination methods for the two approaches: `MERGE` and `VOTE`.

4.1 Monolingual System `RelCont`

`RelCont` is based on an extension of a state-of-the-art WSD approach by (Sinha and Mihalcea, 2007), henceforth (SM07). In the basic SM07 work, the authors combine different semantic similarity measures with different graph based algorithms as an extension to work in (Mihalcea, 2005). Given a sequence of words $W = \{w_1, w_2 ... w_n\}$, each word w_i with several senses $\{s_{i1}, s_{i2} ... s_{im}\}$. A graph G = (V,E) is defined such that there exists a vertex v for each sense. Two senses of two different words may be connected by an edge e, depending on their distance. That two senses are connected suggests they should have influence on each other, accordingly a maximum

[2] http://wordnet.princeton.edu

[3] We acknowledge the existence of many research papers that tackled the AW WSD problem using unsupervised approaches, yet for lack of space we will not be able to review most of them.

allowable distance is set. They explore 4 different graph based algorithms. The highest yielding algorithm in their work is the In-Degree algorithm combining different WN similarity measures depending on POS. They used the Jiang and Conrath (JCN) (Jiang and Conrath., 1997) similarity measure within nouns, the Leacock & Chodorow (LCH) (Leacock and Chodorow, 1998) similarity measure within verbs, and the Lesk (Lesk, 1986) similarity measure within adjectives, within adverbs, and among different POS tag pairings. They evaluate their work against the SENSEVAL 2 AW test data (SV2AW). They tune the parameters of their algorithm – namely, the normalization ratio for some of these measures – on the SENSEVAL 3 data set. They report a state-of-the-art unsupervised system that yields an overall performance across all AW POS sets of 57.2%.

In our current work, we extend the SM07 work in some interesting ways. A detailed narrative of our approach is described in (Guo and Diab, 2009). Briefly, we focus on the In-Degree graph based algorithm since it is the best performer in the SM07 work. The In-Degree algorithm presents the problem as a weighted graph with senses as nodes and the similarity between senses as weights on edges. The In-Degree of a vertex refers to the number of edges incident on that vertex. In the weighted graph, the In-Degree for each vertex is calculated by summing the weights on the edges that are incident on it. After all the In-Degree values for each sense are computed, the sense with maximum value is chosen as the final sense for that word.

In this paper, we use the In-Degree algorithm while applying some modifications to the basic similarity measures exploited and the WN lexical resource tapped into. Similar to the original In-Degree algorithm, we produce a probabilistic ranked list of senses. Our modifications are described as follows:

JCN for Verb-Verb Similarity In our implementation of the In-Degree algorithm, we use the JCN similarity measure for both Noun-Noun similarity calculation similar to SM07. However, different from SM07, instead of using LCH for Verb-Verb similarity, we use the JCN metric as it yields better performance in our experimentations.

Expand Lesk Following the intuition in (Pedersen et al., 2005), henceforth (PEA05), we expand the basic Lesk similarity measure to take into account the glosses for all the relations for the synsets on the contextual words and compare them with the glosses of the target word senses, therefore going beyond the is-a relation. We exploit the observation that WN senses are too fine-grained, accordingly the neighbors would be slightly varied while sharing significant semantic meaning content. To find similar senses, we use the relations: hypernym, hyponym, similar attributes, similar verb group, pertinym, holonym, and meronyms.[4] The algorithm assumes that the words in the input are POS tagged. In PEA05, the authors retrieve all the relevant neighbors to form a bag of words for both the target sense and the surrounding senses of the context words, they specifically focus on the Lesk similarity measure. In our current work, we employ the neighbors in a disambiguation strategy using different similarity measures one pair at a time. Our algorithm takes as input a target sense and a sense pertaining to a word in the surrounding context, and returns a sense similarity score. We do not apply the WN relations expansion to the target sense. It is only applied to the contextual word.[5]

For the monolingual system, we employ the same normalization values used in SM07 for the different similarity measures. Namely for the Lesk and Expand-Lesk, we use the same cut-off value of 240, accordingly, if the Lesk or Expand-Lesk similarity value returns $0 <= 240$ it is converted to a real number in the interval [0,1], any similarity over 240 is by default mapped to 1. We will refer to the Expand-Lesk with this threshold as Lesk2. We also experimented with different thresholds for the Lesk and Expand-Lesk similarity measure using the SENSEVAL 3 data as a tuning set. We found that a cut-off threshold of 40 was also useful. We will refer to this variant of Expand-Lesk with a cut off threshold of 40 as Lesk3. For JCN, similar to SM07, the values are from 0.04 to 0.2, we mapped them to the interval [0,1]. We did not run any calibration studies beyond the what was reported in SM07.

[4] In our experiments, we varied the number of relations to employ and they all yielded relatively similar results. Hence in this paper, we report results using all the relations listed above.

[5] We experimented with expanding both the contextual sense and the target sense and we found that the unreliability of some of the relations is detrimental to the algorithm's performance. Hence we decided empirically to expand only the contextual word.

SemCor Expansion of WN A part of the `RelCont` approach relies on using the Lesk algorithm. Accordingly, the availability of glosses associated with the WN entries is extremely beneficial. Therefore, we expand the number of glosses available in WN by using the SemCor data set, thereby adding more examples to compare. The SemCor corpus is a corpus that is manually sense tagged (Miller, 1990).[6] In this expansion, depending on the version of WN, we use the sense-index file in the WN Database to convert the SemCor data to the appropriate version sense annotations. We augment the sense entries for the different POS WN databases with example usages from SemCor. The augmentation is done as a look up table external to WN proper since we did not want to dabble with the WN offsets. We set a cap of 30 additional examples per synset. We used the first 30 examples with no filtering criteria. Many of the synsets had no additional examples. WN1.7.1 comprises a total of 26875 synsets, of which 25940 synsets are augmented with SemCor examples.[7]

4.2 Multilingual System `TransCont`

`TransCont` is based on the WSD system SALAAM (Diab and Resnik, 2002), henceforth (DR02). The SALAAM system leverages word alignments from parallel corpora to perform WSD. The SALAAM algorithm exploits the word correspondence cross linguistically to tag word senses on words in running text. It relies on several underlying assumptions. The first assumption is that senses of polysemous words in one language could be lexicalized differently in other languages. For example, 'bank' in English would be translated as *banque* or *rive de fleuve* in French, depending on context. The other assumption is that if Language 1 (L1) words are translated to the same orthographic form in Language 2 (L2), then they share the some element of meaning, they are semantically similar.[8]

The SALAAM algorithm can be described as follows. Given a parallel corpus of L1-L2 that is sentence and word aligned, group all the word types in L1 that map to same word in L2 creating clusters referred to as *t*ypesets. Then perform disambiguation on the typeset clusters using WN. Once senses are identified for each word in the cluster, the senses are propagated back to the original word instances in the corpus. In the SALAAM algorithm, the disambiguation step is carried out as follows: within each of these target sets consider all possible sense tags for each word and choose sense tags informed by semantic similarity with all the other words in the whole group. The algorithm is a greedy algorithm that aims at maximizing the similarity of the chosen sense across all the words in the set. The SALAAM disambiguation algorithm used the noun groupings (NounGroupings) algorithm described in DR02. The algorithm applies disambiguation within POS tag. The authors report only results on the nouns only since NounGroupings heavily exploits the hierarchy structure of the WN noun taxonomy, which does not exist for adjectives and adverbs, and is very shallow for verbs.

Essentially SALAAM relies on variability in translation as it is important to have multiple words in a typeset to allow for disambiguation. In the original SALAAM system, the authors automatically translated several balanced corpora in order to render more variable data for the approach to show it's impact. The corpora that were translated are: the WSJ, the Brown corpus and all the SENSEVAL data. The data were translated to different languages (Arabic, French and Spanish) using state of art MT systems. They employed the automatic alignment system GIZA++ (Och and Ney, 2003) to obtain word alignments in a single direction from L1 to L2.

For `TransCont` we use the basic SALAAM approach with some crucial modifications that lead to better performance. We still rely on parallel corpora, we extract typesets based on the intersection of word alignments in both alignment directions using more advanced GIZA++ machinery. In contrast to DR02, we experiment with all four POS: Verbs (V), Nouns (N), Adjectives (A) and Adverbs (R). Moreover, we modified the underlying disambiguation method on the typesets. We still employ WN similarity, however, we do not use the NounGroupings algorithm. Our disambiguation method relies on calculating the sense pair similarity exhaustively across all the

[6] Using SemCor in this setting to augment WN does hint of using supervised data in the WSD process, however, since our approach does not rely on training data and SemCor is not used in our algorithm directly to tag data, but to augment a rich knowledge resource, we contend that this does not affect our system's designation as an unsupervised system.

[7] Some example sentences are repeated across different synsets and POS since the SemCor data is annotated as an All-Words tagged data set.

[8] We implicitly make the underlying simplifying assumption that the L2 words are less ambiguous than the L1 words.

word types in a typeset and choosing the combination that yields the highest similarity. We experimented with all the WN similarity measures in the WN similarity package.[9] We also experiment with Lesk2 and Lesk3 as well as other measures, however we do not use SemCor examples with `TransCont`. We found that the best results are yielded using the Lesk2/Lesk3 similarity measure for N, A and R POS tagsets, while the Lin and JCN measures yield the best performance for the verbs. In contrast to the DR02 approach, we modify the internal WSD process to use the `In-Degree` algorithm on the typeset, so each sense obtains a confidence, and the sense(s) with the highest confidences are returned.

4.3 Combining `RelCont` and `TransCont`

Our objective is to combine the different sources of evidence for the purposes of producing an effective overall global WSD system that is able to disambiguate all content words in running text. We combine the two systems in two different ways.

4.3.1 MERGE

In this combination scheme, the words in the typeset that result from the `TransCont` approach are added to the context of the target word in the `RelCont` approach. However the typeset words are not treated the same as the words that come from the surrounding context in the `In-Degree` algorithm as we recognize that words that are yielded in the typesets are semantically similar in terms of content rather than being co-occurring words as is the case for contextual words in RelCont. Heeding this difference, we proceed to calculate similarity for words in the typesets using different similarity measures. In the case of noun-noun similarity, in the original `RelCont` experiments we use JCN, however with the words present in the `TransCont` typesets we use one of the Lesk variants, Lesk2 or Lesk3. Our observation is that the JCN measure is relatively coarser grained, compared to Lesk measures, therefore it is sufficient in case of lexical relatedness therefore works well in case of the context words. Yet for the words yielded in the `TransCont` typesets a method that exploits the underlying rich relations in the noun hierarchy captures the semantic similarity more aptly. In the case of verbs we still maintain the JCN similarity as it most effective given the shallowness of the verb hierarchy and the inherent nature of the verbal synsets which are differentiated along syntactic rather than semantic dimensions. We employ the Lesk algorithm still with A-A and R-R similarity and when comparing across different POS tag pairings.

4.3.2 VOTE

In this combination scheme, the output of the global disambiguation system is simply an intersection of the two outputs from the two underlying systems `RelCont` and `TransCont`. Specifically, we sum up the confidence ranging from 0 to 1 of the two system `In-Degree` algorithm outputs to obtain a final confidence for each sense, choosing the sense(s) that yields the highest confidences. The fact that `TransCont` uses `In-Degree` internally allows for a seamless integration.

5 Experiments and Results

5.1 Data

The parallel data we experiment with are the same standard data sets as in (Diab and Resnik, 2002), namely, Senseval 2 English AW data sets (SV2AW) (Palmer et al., 2001), and Seneval 3 English AW (SV3AW) data set. We use the true POS tag sets in the test data as rendered in the Penn Tree Bank.[10] We present our results on WordNet 1.7.1 for ease of comparison with previous results.

5.2 Evaluation Metrics

We use the `scorer2` software to report fine-grained (P)recision and (R)ecall and (F)-measure.

5.3 Baselines

We consider here several baselines. 1. A random baseline (RAND) is the most appropriate baseline for an unsupervised approach.2. We include the most frequent sense baseline (MFBL), though we note that we consider the most frequent sense or first sense baseline to be a supervised baseline since it depends crucially on SemCor in ranking the senses within WN.[11] 3. The SM07 results as a

[9] http://wn-similarity.sourceforge.net/

[10] We exclude the data points that have a tag of "U" in the gold standard for both baselines and our system.

[11] From an application standpoint, we do not find the first sense baseline to be of interest since it introduces a strong level of uniformity – removing semantic variability – which is not desirable. Even if the first sense achieves higher results in data sets, it is an artifact of the size of the data and the very limited number of documents under investigation.

monolingual baseline. 4. The DR02 results as the multilingual baseline.

5.4 Experimental Results

5.4.1 RelCont

We present the results for 4 different experimental conditions for RelCont: JCN-V which uses JCN instead of LCH for verb-verb similarity comparison, we consider this our base condition; +ExpandL is adding the Lesk Expansion to the base condition, namely Lesk2;[12] +SemCor adds the SemCor expansion to the base condition; and finally +ExpandL_SemCor, adds the latter both conditions simultaneously. Table 1 illustrates the obtained results for the SV2AW using WordNet 1.7.1 since it is the most studied data set and for ease of comparison with previous studies. We break the results down by POS tag (N)oun, (V)erb, (A)djective, and Adve(R)b. The coverage for SV2AW is 98.17% losing some of the verb and adverb target words.

Our overall results on all the data sets clearly outperform the baseline as well as state-of-the-art performance using an unsupervised system (SM07) in overall f-measure across all the data sets. We are unable to beat the most frequent baseline (MFBL) which is obtained using the first sense. However MFBL is a supervised baseline and our approach is unsupervised. Our implementation of SM07 is slightly higher than those reported in (Sinha and Mihalcea, 2007) (57.12%) is probably due to the fact that we do not consider the items tagged as "U" and also we resolve some of the POS tag mismatches between the gold set and the test data. We note that for the SV2AW data set our coverage is not 100% due to some POS tag mismatches that could not have been resolved automatically. These POS tag problems have to do mainly with multiword expressions. In observing the performance of the overall RelCont, we note that using JCN for verbs clearly outperforms using the LCH similarity measure. Using SemCor to augment WN examples seems to have the biggest impact. Combining SemCor with ExpandL yields the best results.

Observing the results yielded per POS in Table 1, ExpandL seems to have the biggest impact on the Nouns only. This is understandable since the noun hierarchy has the most dense relations and the most consistent ones. SemCor augmentation of WN seemed to benefit all POS significantly except for nouns. In fact the performance on the nouns deteriorated from the base condition JCN-V from 68.7 to 68.3%. This maybe due to inconsistencies in the annotations of nouns in SemCor or the very fine granularity of the nouns in WN. We know that 72% of the nouns, 74% of the verbs, 68.9% of the adjectives, and 81.9% of the adverbs directly exploited the use of SemCor augmented examples. Combining SemCor and ExpandL seems to have a positive impact on the verbs and adverbs, but not on the nouns and adjectives. These trends are not held consistently across data sets. For example, we see that SemCor augmentation helps all POS tag sets over using ExpandL alone or even when combined with SemCor. We note the similar trends in performance for the SV3AW data.

Compared to state of the art systems, RelCont with an overall F-measure performance of 62.13% outperforms the best unsupervised system of 57.5% UNED-AW-U2 for SV2 (Navigli, 2009). It is worth noting that it is higher than several of the supervised systems. Moreover, RelCont yields better overall results on SV3 at 59.87 compared to the best unsupervised system IRST-DDD-U which yielded an F-measure of 58.3% (Navigli, 2009).

5.4.2 TransCont

For the TransCont results we illustrate the original SALAAM results as our baseline. Similar to the DR02 work, we actually use the same SALAAM parallel corpora comprising more than 5.5M English tokens translated using a single machine translation system GlobalLink. Therefore our parallel corpus is the French English translation condition mentioned in DR02 work as FrGl. We have 4 experimental conditions: FRGL using Lesk2 for all POS tags in the typeset disambiguation (Lesk2); FRGL using Lesk3 for all POS tags (Lesk3); using Lesk3 for N, A and R but LIN similarity measure for verbs (Lesk3_Lin); using Lesk3 for N, A and R but JCN for verbs (Lesk3_JCN).

In Table 3 we note the the Lesk3_JCN followed immediately by Lesk3_Lin yield the best performance. The trend holds for both SV2AW and SV3AW. Essentially our new implementation of the multilingual system significantly outperforms the original DR02 implementation for all experimental conditions.

[12] Using Lesk3 yields almost the same results

5.4.3 Global Combined WSD

In this section we present the results of the global combined WSD system. All the combined experimental conditions have the same percentage coverage.[13] We present the results combining using MERGE and using VOTE. We have chosen 4 baseline systems: (1) SM07; (2) the our baseline monolingual system using JCN for verb-verb comparisons (RelCont-BL), so as to distinguish the level of improvement that could be attributed to the multilingual system in the combination results; as well as (3) and (4) our best individual system results from `RelCont` (ExpandL_SemCor) referred to in the tables below as (RelCont-Final) and `TransCont` using the best experimental condition (Lesk3_JCN). Table 5 and 6 illustrates the overall performance of our combined approach.

In Table 5 we note that the combined conditions outperform the two base systems independently, using `TransCont` is always helpful for any of the 3 monolingual systems, no matter we use VOTE or MERGE. In general the trend is that VOTE outperforms MERGE, however they exhibit different behaviors with respect to what works for each POS.

In Table 6 the combined result is not always better than the corresponding monolingual system. When applying to our baseline monolingual system, the combined result is still better. However, we observed worse results for ExpandL_Semcor, RelCont-Final. There may be 2 main reasons for the loss: (1) SV3 is the tuning set in SM07, and we inherit the thresholds for similarity metrics from that study. Accordingly, an overfitting of the thresholds is probably happening in this case; (2) `TransCont` results are not good enough on the SV3AW data. Comparing the `RelCont` and `TransCont` system results, we find a drop in f-measure of -1.37% in SV2AW, in contrast to a much larger drop in performance for the SV3AW data set where the drop in performance is -6.38% when comparing `RelCont-BL` to `TransCont` and nearly -10% comparing against `RelCont-Final`.

6 Discussion

We looked closely at the data in the combined conditions attempting to get a feel for the data and understand what was captured and what was not. Some of the good examples that are captured in the combined system that are not tagged in `RelCont` is the case of *ringer* in *Like most of the other 6,000 churches in Britain with sets of bells , St. Michael once had its own " band " of ringers , who would herald every Sunday morning and evening service* .. The `RelCont` answer is *ringer* sense number 4: *(horseshoes) the successful throw of a horseshoe*

[13] We do not back off in any of our systems to a default sense, hence the coverage is not at a 100%.

or quoit so as to encircle a stake or peg. When the merged system is employed we see the correct sense being chosen as sense number 1 in the MERGE condition: defined in WN as *a person who rings church bells (as for summoning the congregation)* resulting from a corresponding translation into French as *s*onneur.

We did some basic data analysis on the items we are incapable of capturing. Several of them are cases of metonymy in examples such as "the English are known...", the sense of *English* here is clearly in reference to the people of England, however, our WSD system preferred the language sense of the word. These cases are not gotten by any of our systems. If it had access to syntactic/semantic roles we assume it could capture that this sense of the word entails volition for example. Other types of errors resulted from the lack of a way to explicitly identify multiwords.

Looking at the performance of `TransCont` we note that much of the loss is a result of the lack of variability in the translations which is a key factor in the performance of the algorithm. For example for the 157 adjective target test words in SV2AW, there was a single word alignment for 51 of the cases, losing any tagging for these words.

7 Conclusions and Future Directions

In this paper we present a framework that combines orthogonal sources of evidence to create a state-of-the-art system for the task of WSD disambiguation for AW. Our approach yields an overall global F measure of 64.58 for the standard SV2AW data set combining monolingual and multilingual evidence. The approach can be further refined by adding other types of orthogonal features such as syntactic features and semantic role label features. Adding SemCor examples to `TransCont` should have a positive impact on performance. Also adding more languages as illustrated by the DR02 work should also yield much better performance.

Abstract

Most previous work on trainable language generation has focused on two paradigms: (a) using a statistical model to rank a set of generated utterances, or (b) using statistics to inform the generation decision process. Both approaches rely on the existence of a handcrafted generator, which limits their scalability to new domains. This paper presents BAGEL, a statistical language generator which uses dynamic Bayesian networks to learn from semantically-aligned data produced by 42 untrained annotators. A human evaluation shows that BAGEL can generate natural and informative utterances from *unseen* inputs in the information presentation domain. Additionally, generation performance on sparse datasets is improved significantly by using certainty-based active learning, yielding ratings close to the human gold standard with a fraction of the data.

1 Introduction

The field of natural language generation (NLG) is one of the last areas of computational linguistics to embrace statistical methods. Over the past decade, statistical NLG has followed two lines of research. The first one, pioneered by Langkilde and Knight (1998), introduces statistics in the generation process by training a model which reranks candidate outputs of a handcrafted generator. While their HALOGEN system uses an n-gram language model trained on news articles, other systems have used hierarchical syntactic models (Bangalore and Rambow, 2000), models trained on user ratings of utterance quality (Walker et al., 2002), or alignment models trained on speaker-specific corpora (Isard et al., 2006).

A second line of research has focused on introducing statistics at the generation decision level, by training models that find the set of generation parameters maximising an objective function, e.g. producing a target linguistic style (Paiva and Evans, 2005; Mairesse and Walker, 2008), generating the most likely context-free derivations given a corpus (Belz, 2008), or maximising the expected reward using reinforcement learning (Rieser and Lemon, 2009). While such methods do not suffer from the computational cost of an overgeneration phase, they still require a handcrafted generator to define the generation decision space within which statistics can be used to find an optimal solution.

This paper presents BAGEL (Bayesian networks for generation using active learning), an NLG system that can be fully trained from aligned data. While the main requirement of the generator is to produce natural utterances within a dialogue system domain, a second objective is to minimise the overall development effort. In this regard, a major advantage of data-driven methods is the shift of the effort from model design and implementation to data annotation. In the case of NLG systems, learning to produce paraphrases can be facilitated by collecting data from a large sample of annotators. Our meaning representation should therefore (a) be intuitive enough to be understood by untrained annotators, and (b) provide useful generalisation properties for generating unseen inputs. Section 2 describes BAGEL's meaning representation, which satisfies both requirements. Section 3 then details how our meaning representation is mapped to a phrase sequence, using a dynamic Bayesian network with backoff smoothing.

Within a given domain, the same semantic concept can occur in different utterances. Section 4 details how BAGEL exploits this redundancy

This research was partly funded by the UK EPSRC under grant agreement EP/F013930/1 and funded by the EU FP7 Programme under grant agreement 216594 (CLASSiC project: www.classic-project.org).

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1552–1561,
Uppsala, Sweden, 11-16 July 2010.

to improve generation performance on sparse datasets, by guiding the data collection process using *certainty-based active learning* (Lewis and Catlett, 1994). We train BAGEL in the information presentation domain, from a corpus of utterances produced by 42 untrained annotators (see Section 5.1). An automated evaluation metric is used to compare preliminary model and training configurations in Section 5.2, while Section 5.3 shows that the resulting system produces natural and informative utterances, according to 18 human judges. Finally, our human evaluation shows that training using active learning significantly improves generation performance on sparse datasets, yielding results close to the human gold standard using a fraction of the data.

2 Phrase-based generation from semantic stacks

BAGEL uses a *stack-based* semantic representation to constrain the sequence of semantic concepts to be searched. This representation can be seen as a linearised semantic tree similar to the one previously used for natural language understanding in the Hidden Vector State model (He and Young, 2005). A stack representation provides useful generalisation properties (see Section 3.1), while the resulting stack sequences are relatively easy to align (see Section 5.1). In the context of dialogue systems, Table 1 illustrates how the input dialogue act is first mapped to a set of stacks of semantic concepts, and then aligned with a word sequence. The bottom concept in the stack will typically be a *dialogue act type*, e.g. an utterance providing information about the object under discussion (`inform`) or specifying that the request of the user cannot be met (`reject`). Other concepts include attributes of that object (e.g., `food`, `area`), values for those attributes (e.g., `Chinese`, `riverside`), as well as special symbols for negating underlying concepts (e.g., `not`) or specifying that they are irrelevant (e.g., `dontcare`).

The generator's goal is thus finding the most likely realisation given an *unordered* set of *mandatory* semantic stacks $\mathcal{S}_m$ derived from the input dialogue act. For example, $s =$`inform(area(centre))` is a mandatory stack associated with the dialogue act in Table 1 (frame 8). While mandatory stacks must all be conveyed in the output realisation, $\mathcal{S}_m$ does not contain the optional *intermediary* stacks $\mathcal{S}_i$ that can refer to (a) general attributes of the object under discussion (e.g., `inform(area)` in Table 1), or (b) to concepts that are not in the input at all, which are associated with the singleton stack `inform` (e.g., phrases expressing the dialogue act type, or clause aggregation operations). For example, the stack sequence in Table 1 contains 3 intermediary stacks for $t = 2, 5$ and 7.

BAGEL's granularity is defined by the semantic annotation in the training data, rather than external linguistic knowledge about what constitutes a unit of meaning, i.e. contiguous words belonging to the same semantic stack are modelled as an atomic observation unit or *phrase*.[1] In contrast with word-level models, a major advantage of phrase-based generation models is that they can model long-range dependencies and domain-specific idiomatic phrases with fewer parameters.

3 Dynamic Bayesian networks for NLG

Dynamic Bayesian networks have been used successfully for speech recognition, natural language understanding, dialogue management and text-to-speech synthesis (Rabiner, 1989; He and Young, 2005; Lefèvre, 2006; Thomson and Young, 2010; Tokuda et al., 2000). Such models provide a principled framework for predicting elements in a large structured space, such as required for non-trivial NLG tasks. Additionally, their probabilistic nature makes them suitable for modelling linguistic variation, i.e. there can be multiple valid paraphrases for a given input.

BAGEL models the generation task as finding the most likely sequence of realisation phrases $\mathbf{R}^* = (r_1 ... r_L)$ given an unordered set of mandatory semantic stacks $\mathcal{S}_m$, with $|\mathcal{S}_m| \leq L$. BAGEL must thus derive the optimal sequence of semantic stacks $\mathbf{S}^*$ that will appear in the utterance given $\mathcal{S}_m$, i.e. by inserting intermediary stacks if needed and by performing content ordering. Any number of intermediary stacks can be inserted between two consecutive mandatory stacks, as long as all their concepts are included in either the previous or following mandatory stack, and as long as each stack transition leads to a different stack (see example in Table 1). Let us define the set of possible stack sequences matching these constraints as $Seq(\mathcal{S}_m) \subseteq \{\mathbf{S} = (s_1 ... s_L) \text{ s.t. } s_t \in \mathcal{S}_m \cup \mathcal{S}_i\}$.

We propose a model which estimates the dis-

[1] The term *phrase* is thus defined here as any sequence of one or more words.

Charlie Chan	*is a*	*Chinese*	*restaurant*	*near*	*Cineworld*	*in the*	*centre of town*
Charlie Chan name inform	`inform`	**Chinese food inform**	**restaurant type inform**	`near inform`	**Cineworld near inform**	`area inform`	**centre area inform**
$t=1$	$t=2$	$t=3$	$t=4$	$t=5$	$t=6$	$t=7$	$t=8$

Table 1: Example semantic stacks aligned with an utterance for the dialogue act `inform(name(Charlie Chan) type(restaurant) area(centre) food(Chinese) near(Cineworld))`. Mandatory stacks are in bold.

tribution $P(\mathbf{R}|\mathcal{S}_m)$ from a training set of realisation phrases aligned with semantic stack sequences, by marginalising over all stack sequences in $Seq(\mathcal{S}_m)$:

$$\begin{aligned} P(\mathbf{R}|\mathcal{S}_m) &= \sum_{\mathbf{S}\in Seq(\mathcal{S}_m)} P(\mathbf{R},\mathbf{S}|\mathcal{S}_m) \\ &= \sum_{\mathbf{S}\in Seq(\mathcal{S}_m)} P(\mathbf{R}|\mathbf{S},\mathcal{S}_m)P(\mathbf{S}|\mathcal{S}_m) \\ &= \sum_{\mathbf{S}\in Seq(\mathcal{S}_m)} P(\mathbf{R}|\mathbf{S})P(\mathbf{S}|\mathcal{S}_m) \qquad (1) \end{aligned}$$

Inference over the model defined in (1) requires the decoding algorithm to consider all possible orderings over $Seq(\mathcal{S}_m)$ together with all possible realisations, which is intractable for non-trivial domains. We thus make the additional assumption that the most likely sequence of semantic stacks $\mathbf{S}^*$ given $\mathcal{S}_m$ is the one yielding the optimal realisation phrase sequence:

$$P(\mathbf{R}|\mathcal{S}_m) \approx P(\mathbf{R}|\mathbf{S}^*)P(\mathbf{S}^*|\mathcal{S}_m) \qquad (2)$$

$$\text{with } \mathbf{S}^* = \operatorname*{argmax}_{\mathbf{S}\in Seq(\mathcal{S}_m)} P(\mathbf{S}|\mathcal{S}_m) \qquad (3)$$

The semantic stacks are therefore decoded first using the model in Fig. 1 to solve the argmax in (3). The decoded stack sequence $\mathbf{S}^*$ is then treated as observed in the realisation phase, in which the model in Fig. 2 is used to find the realisation phrase sequence $\mathbf{R}^*$ maximising $P(\mathbf{R}|\mathbf{S}^*)$ over all phrase sequences of length $L = |\mathbf{S}^*|$ in our vocabulary:

$$\begin{aligned} \mathbf{R}^* &= \operatorname*{argmax}_{\mathbf{R}=(r_1\ldots r_L)} P(\mathbf{R}|\mathbf{S}^*)P(\mathbf{S}^*|\mathcal{S}_m) \qquad (4) \\ &= \operatorname*{argmax}_{\mathbf{R}=(r_1\ldots r_L)} P(\mathbf{R}|\mathbf{S}^*) \qquad (5) \end{aligned}$$

In order to reduce model complexity, we factorise our model by conditioning the realisation phrase at time t on the previous phrase r_{t-1}, and the previous, current, and following semantic stacks. The semantic stack s_t at time t is assumed

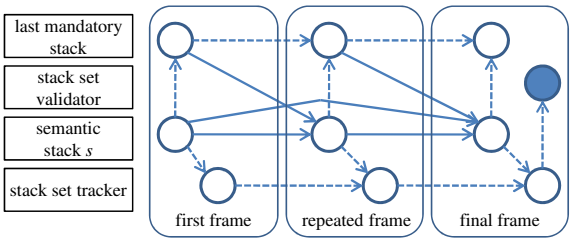

Figure 1: Graphical model for the semantic decoding phase. Plain arrows indicate smoothed probability distributions, dashed arrows indicate deterministic relations, and shaded nodes are observed. The generation of the `end` semantic stack symbol deterministically triggers the final frame.

to depend only on the previous two stacks and the last mandatory stack $s_u \in \mathcal{S}_m$ with $1 \le u < t$:

$$P(\mathbf{S}|\mathcal{S}_m) = \begin{cases} \prod_{t=1}^{T} P(s_t|s_{t-1}, s_{t-2}, s_u) \\ \quad \text{if } \mathbf{S} \in Seq(\mathcal{S}_m) \\ 0 \quad \text{otherwise} \end{cases} \qquad (6)$$

$$P(\mathbf{R}|\mathbf{S}^*) = \prod_{t=1}^{T} P(r_t|r_{t-1}, s^*_{t-1}, s^*_t, s^*_{t+1}) \qquad (7)$$

While dynamic Bayesian networks typically take sequential inputs, mapping a *set* of semantic stacks to a sequence of phrases is achieved by keeping track of the mandatory stacks that were visited in the current sequence (see stack set tracker variable in Fig. 1), and pruning any sequence that has not included all mandatory input stacks on reaching the final frame (see observed stack set validator variable in Fig. 1). Since the number of intermediary stacks is not known at decoding time, the network is unrolled for a fixed number of frames T defining the maximum number of phrases that can be generated (e.g., $T = 50$). The end of the stack sequence is then determined by a special `end` symbol, which can only be emitted within the T frames once all mandatory stacks have been visited. The probability of the resulting utterance is thus computed over all frames up to the `end` symbol, which determines the length

L of $\mathbf{S}^*$ and $\mathbf{R}^*$. While the decoding constraints enforce that $L > |\mathcal{S}_m|$, the search for $\mathbf{S}^*$ requires comparing sequences of different lengths. A consequence is that shorter sequences containing only mandatory stacks are likely to be favoured. While future work should investigate length normalisation strategies, we find that the learned transition probabilities are skewed enough to favour stack sequences including intermediary stacks.

Once the topology and the decoding constraints of the network have been defined, any inference algorithm can be used to search for $\mathbf{S}^*$ and $\mathbf{R}^*$. We use the junction tree algorithm implemented in the Graphical Model ToolKit (GMTK) for our experiments (Bilmes and Zweig, 2002), however both problems can be solved using a standard Viterbi search given the appropriate state representation. In terms of computational complexity, it is important to note that the number of stack sequences $Seq(\mathcal{S}_m)$ to search over increases exponentially with the number of input mandatory stacks. Nevertheless, we find that real-time performance can be achieved by pruning low probability sequences, without affecting the quality of the solution.

3.1 Generalisation to unseen semantic stacks

In order to generalise to semantic stacks which have not been observed during training, the realisation phrase r is made dependent on underspecified stack configurations, i.e. the tail l and the head h of the stack. For example, the last stack in Table 1 is associated with the head `centre` and the tail `inform(area)`. As a result, BAGEL assigns non-zero probabilities to realisation phrases in unseen semantic contexts, by backing off to the head and the tail of the stack. A consequence is that BAGEL's lexical realisation can generalise across contexts. For example, if `reject(area(centre))` was never observed at training time, $P(r = \text{centre of town}|s = \texttt{reject(area(centre))})$ will be estimated by backing off to $P(r = \text{centre of town}|h = \texttt{centre})$. BAGEL can thus generate 'there are no venues in the centre of town' if the phrase 'centre of town' was associated with the concept `centre` in a different context, such as `inform(area(centre))`. The final realisation model is illustrated in Fig. 2:

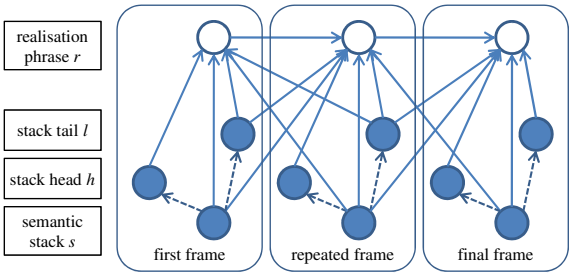

Figure 2: Graphical model for the realisation phase. Dashed arrows indicate deterministic relations, and shaded node are observed.

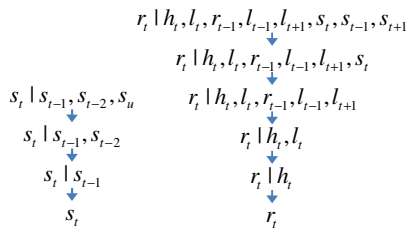

Figure 3: Backoff graphs for the semantic decoding and realisation models.

$$P(\mathbf{R}|\mathbf{S}^*) = \prod_{t=1}^{L} P(r_t|r_{t-1}, h_t, l_{t-1}, l_t, l_{t+1}, s^*_{t-1}, s^*_t, s^*_{t+1}) \quad (8)$$

Conditional probability distributions are represented as factored language models smoothed using Witten-Bell interpolated backoff smoothing (Bilmes and Kirchhoff, 2003), according to the backoff graphs in Fig. 3. Variables which are the furthest away in time are dropped first, and partial stack variables are dropped last as they are observed the most.

It is important to note that generating unseen semantic stacks requires all possible mandatory semantic stacks in the target domain to be predefined, in order for all stack unigrams to be assigned a smoothed non-zero probability.

3.2 High cardinality concept abstraction

While one should expect a trainable generator to learn multiple lexical realisations for low-cardinality semantic concepts, learning lexical realisations for high-cardinality database entries (e.g., proper names) would increase the number of model parameters prohibitively. We thus divide pre-terminal concepts in the semantic stacks into two types: (a) *enumerable* attributes whose values are associated with distinct semantic stacks in

our model (e.g., inform(pricerange(cheap))), and (b) *non-enumerable* attributes whose values are replaced by a generic symbol before training in both the utterance and the semantic stack (e.g., inform(name(X)). These symbolic values are then replaced in the surface realisation by the corresponding value in the input specification. A consequence is that our model can only learn synonymous lexical realisations for enumerable attributes.

4 Certainty-based active learning

A major issue with trainable NLG systems is the lack of availability of domain-specific data. It is therefore essential to produce NLG models that minimise the data annotation cost.

BAGEL supports the optimisation of the data collection process through active learning, in which the next semantic input to annotate is determined by the current model. The probabilistic nature of BAGEL allows the use of *certainty-based* active learning (Lewis and Catlett, 1994), by querying the k semantic inputs for which the model is the least certain about its output realisation. Given a finite semantic input space $\mathcal{I}$ representing all possible dialogue acts in our domain (i.e., the set of all sets of mandatory semantic stacks $\mathcal{S}_m$), BAGEL's active learning training process iterates over the following steps:

1. Generate an utterance for each semantic input $\mathcal{S}_m \in \mathcal{I}$ using the current model.[2]
2. Annotate the k semantic inputs $\{\mathcal{S}_m^1 ... \mathcal{S}_m^k\}$ yielding the lowest realisation probability, i.e. for $q \in (1..k)$

$$\mathcal{S}_m^q = \underset{\mathcal{S}_m \in \mathcal{I} \setminus \{\mathcal{S}_m^1 ... \mathcal{S}_m^{q-1}\}}{\operatorname{argmin}} (\max_{\mathbf{R}} P(\mathbf{R}|\mathcal{S}_m)) \quad (9)$$

   with $P(\mathbf{R}|\mathcal{S}_m)$ defined in (2).
3. Retrain the model with the additional k data points.

The number of utterances to be queried k should depend on the flexibility of the annotators and the time required for generating all possible utterances in the domain.

5 Experimental method

BAGEL's factored language models are trained using the SRILM toolkit (Stolcke, 2002), and decoding is performed using GMTK's junction tree inference algorithm (Bilmes and Zweig, 2002). Since each active learning iteration requires generating all training utterances in our domain, they are generated using a larger clique pruning threshold than the test utterances used for evaluation.

5.1 Corpus collection

We train BAGEL in the context of a dialogue system providing information about restaurants in Cambridge. The domain contains two dialogue act types: (a) inform: presenting information about a restaurant (see Table 1), and (b) reject: informing that the user's constraints cannot be met (e.g., 'There is no cheap restaurant in the centre'). Our domain contains 8 restaurant attributes: name, food, near, pricerange, postcode, phone, address, and area, out of which food, pricerange, and area are treated as enumerable.[3] Our input semantic space is approximated by the set of information presentation dialogue acts produced over 20,000 simulated dialogues between our statistical dialogue manager (Young et al., 2010) and an agenda-based user simulator (Schatzmann et al., 2007), which results in 202 unique dialogue acts after replacing non-enumerable values by a generic symbol. Each dialogue act contains an average of 4.48 mandatory semantic stacks.

As one of our objectives is to test whether BAGEL can learn from data provided by a large sample of untrained annotators, we collected a corpus of semantically-aligned utterances using Amazon's Mechanical Turk data collection service. A crucial aspect of data collection for NLG is to ensure that the annotators understand the meaning of the semantics to be conveyed. Annotators were first asked to provide an utterance matching an abstract description of the dialogue act, regardless of the order in which the constraints are presented (e.g., *Offer the venue Taj Mahal and provide the information type(restaurant), area(riverside), food(Indian), near(The Red Lion)*). The order of the constraints in the description was randomised to reduce the effect of priming. The annotators were then asked to align the attributes (e.g., *Indicate the region of the utterance related to the concept 'area'*), and the attribute values (e.g., *Indicate only the words related to the concept 'riverside'*). Two paraphrases were collected for each dialogue act in our domain, resulting in a total of 404 aligned ut-

[2] Sampling methods can be used if $\mathcal{I}$ is infinite or too large.

terances produced by 42 native speakers of English. After manually checking and normalising the dataset,[4] the layered annotations were automatically mapped to phrase-level semantic stacks by splitting the utterance into phrases at annotation boundaries. Each annotated utterance is then converted into a sequence of symbols such as in Table 2, which are used to estimate the conditional probability distributions defined in (6) and (8). The resulting vocabulary consists of 52 distinct semantic stacks and 109 distinct realisation phrases, with an average of 8.35 phrases per utterance.

5.2 BLEU score evaluation

We first evaluate BAGEL using the BLEU automated metric (Papineni et al., 2002), which measures the word n-gram overlap between the generated utterances and the 2 reference paraphrases over a test corpus (with n up to 4). While BLEU suffers from known issues such as a bias towards statistical NLG systems (Reiter and Belz, 2009), it provides useful information when comparing similar systems. We evaluate BAGEL for different training set sizes, model dependencies, and active learning parameters. Our results are averaged over a 10-fold cross-validation over distinct dialogue acts, i.e. dialogue acts used for testing are *not seen* at training time,[5] and all systems are tested on the same folds. The training and test sets respectively contain an average of 181 and 21 distinct dialogue acts, and each dialogue act is associated with two paraphrases, resulting in 362 training utterances.

[4]The normalisation process took around 4 person-hour for 404 utterances.

[5]We do not evaluate performance on dialogue acts used for training, as the training examples can trivially be used as generation templates.

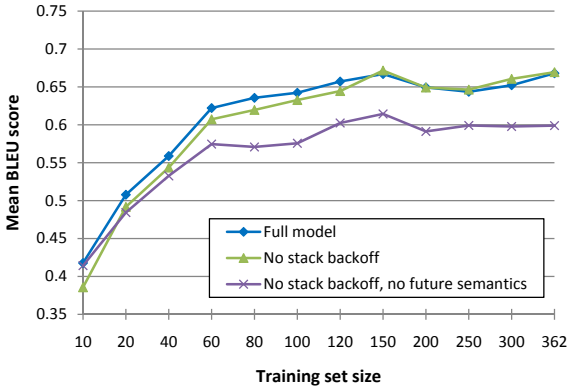

Figure 4: BLEU score averaged over a 10-fold cross-validation for different training set sizes and network topologies, using random sampling.

Results: Fig. 4 shows that adding a dependency on the future semantic stack improves performances for all training set sizes, despite the added model complexity. Backing off to partial stacks also improves performance, but only for sparse training sets.

Fig. 5 compares the full model trained using random sampling in Fig. 4 with the same model trained using certainty-based active learning, for different values of k. As our dataset only contains two paraphrases per dialogue act, the same dialogue act can only be queried twice during the active learning procedure. A consequence is that the training set used for active learning converges towards the randomly sampled set as its size increases. Results show that increasing the training set one utterance at a time using active learning ($k = 1$) significantly outperforms random sampling when using 40, 80, and 100 utterances ($p < .05$, two-tailed). Increasing the number of utterances to be queried at each iteration to $k = 10$ results in a smaller performance increase. A possi-

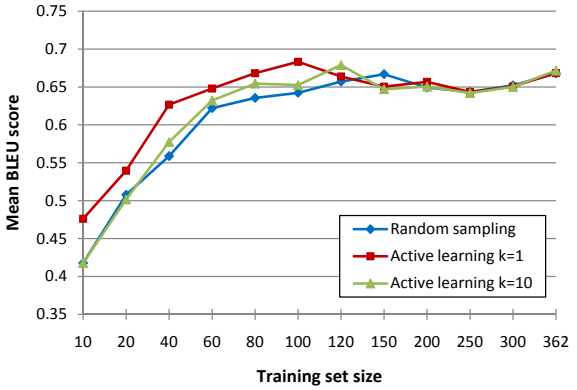

Figure 5: BLEU score averaged over a 10-fold cross-validation for different numbers of queries per iteration, using the full model with the query selection criterion (9).

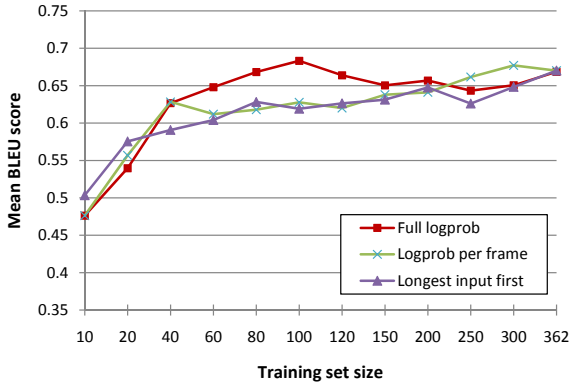

Figure 6: BLEU score averaged over a 10-fold cross-validation for different query selection criteria, using the full model with $k = 1$.

ble explanation is that the model is likely to assign low probabilities to similar inputs, thus any value above $k = 1$ might result in redundant queries within an iteration.

As the length of the semantic stack sequence is not known before decoding, the active learning selection criterion presented in (9) is biased towards longer utterances, which tend to have a lower probability. However, Fig. 6 shows that normalising the log probability by the number of semantic stacks does not improve overall learning performance. Although a possible explanation is that longer inputs tend to contain more information to learn from, Fig. 6 shows that a baseline selecting the largest remaining semantic input at each iteration performs worse than the active learning scheme for training sets above 20 utterances. The full log probability selection criterion defined in (9) is therefore used throughout the rest of the paper (with $k = 1$).

5.3 Human evaluation

While automated metrics provide useful information for comparing different systems, human feedback is needed to assess (a) the quality of BAGEL's outputs, and (b) whether training models using active learning has a significant impact on user perceptions. We evaluate BAGEL through a large-scale subjective rating experiment using Amazon's Mechanical Turk service.

For each dialogue act in our domain, participants are presented with a 'gold standard' human utterance from our dataset, which they must compare with utterances generated by models trained with and without active learning on a set of 20, 40, 100, and 362 utterances (full training set), as well as with the second human utterance in our dataset. See example utterances in Table 3. The judges are then asked to evaluate the *informativeness* and *naturalness* of each of the 8 utterances on a 5 point likert-scale. Naturalness is defined as whether the utterance could have been produced by a human, and informativeness is defined as whether it contains all the information in the gold standard utterance. Each utterance is taken from the test folds of the cross-validation experiment presented in Section 5.2, i.e. the models are trained on up to 90% of the data and the training set does not contain the dialogue act being tested.

Results: Figs. 7 and 8 compare the naturalness and informativeness scores of each system averaged over all 202 dialogue acts. A paired t-test shows that models trained on 40 utterances or less produce utterances that are rated significantly lower than human utterances for both naturalness and informativeness ($p < .05$, two-tailed). However, models trained on 100 utterances or more do not perform significantly worse than human utterances for both dimensions, with a mean difference below .10 over 202 comparisons. Given the large sample size, this result suggests that BAGEL can successfully learn our domain using a fraction of our initial dataset.

As far as the learning method is concerned, a paired t-test shows that models trained on 20 and 40 utterances using active learning significantly outperform models trained using random sampling, for both dimensions ($p < .05$). The largest increase is observed using 20 utterances, i.e. the naturalness increases by .49 and the informativeness by .37. When training on 100 utterances, the effect of active learning becomes insignificant. In-

Input	inform(name(the Fountain) near(the Arts Picture House) area(centre) pricerange(cheap))
Human	There is an inexpensive restaurant called the Fountain in the centre of town near the Arts Picture House
Rand-20	The Fountain is a restaurant near the Arts Picture House located in the city centre cheap price range

Full set	Browns is a cheap restaurant in the city centre near the Crowne Plaza and El Shaddai

Table 3: Example utterances for different input dialogue acts and system configurations. *AL-20* = active learning with 20 utterances, *Rand* = random sampling.

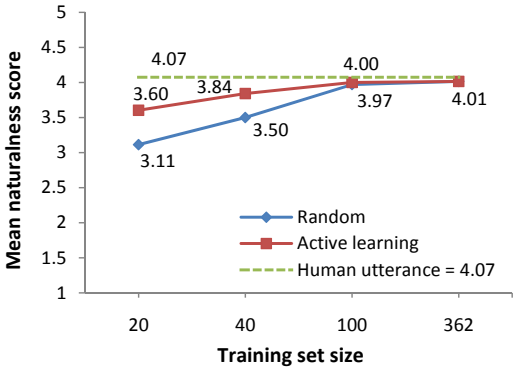

Figure 7: Naturalness mean opinion scores for different training set sizes, using random sampling and active learning. Differences for training set sizes of 20 and 40 are all significant ($p < .05$).

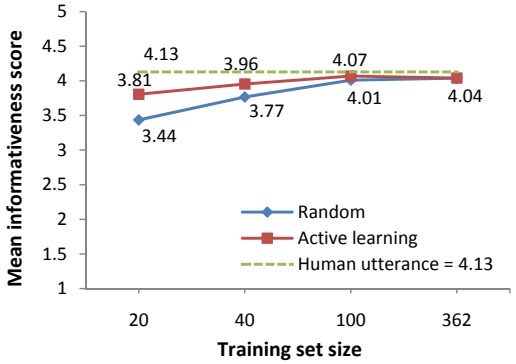

Figure 8: Informativeness mean opinion scores for different training set sizes, using random sampling and active learning. Differences for training set sizes of 20 and 40 are all significant ($p < .05$).

terestingly, while models trained on 100 utterances outperform models trained on 40 utterances using random sampling ($p < .05$), they do not significantly outperform models trained on 40 utterances using active learning ($p = .15$ for naturalness and $p = .41$ for informativeness). These results suggest that certainty-based active learning is beneficial for training a generator from a limited amount of data given the domain size.

Looking back at the results presented in Section 5.2, we find that the BLEU score correlates with a Pearson correlation coefficient of .42 with the mean naturalness score and .35 with the mean informativeness score, over all folds of all systems tested ($n = 70$, $p < .01$). This is lower than previous correlations reported by Reiter and Belz (2009) in the shipping forecast domain with non-expert judges ($r = .80$), possibly because our domain is larger and more open to subjectivity.

6 Related work

While most previous work on trainable NLG relies on a handcrafted component (see Section 1), recent research has started exploring fully data-driven NLG models.

Factored language models have recently been used for surface realisation within the OpenCCG framework (White et al., 2007; Espinosa et al., 2008). More generally, chart generators for different grammatical formalisms have been trained from syntactic treebanks (White et al., 2007; Nakanishi et al., 2005), as well as from semantically-annotated treebanks (Varges and Mellish, 2001). However, a major difference with our approach is that BAGEL uses domain-specific data to generate a surface form directly from semantic concepts, without any syntactic annotation (see Section 7 for further discussion).

This work is strongly related to Wong and Mooney's WASP^{-1} generation system (2007), which combines a language model with an inverted synchronous CFG parsing model, effectively casting the generation task as a translation problem from a meaning representation to natural language. WASP^{-1} relies on GIZA++ to align utterances with derivations of the meaning representation (Och and Ney, 2003). Although early experiments showed that GIZA++ did not perform well on our data—possibly because of the coarse granularity of our semantic representation—future work should evaluate the generalisation performance of synchronous CFGs in a dialogue system domain.

Although we do not know of any work on active learning for NLG, previous work has used active learning for semantic parsing and information extraction (Thompson et al., 1999; Tang et al., 2002), spoken language understanding (Tur et al., 2003), speech recognition (Hakkani-Tür et al., 2002), word alignment (Sassano, 2002), and more recently for statistical machine translation (Bloodgood and Callison-Burch, 2010). While certainty-based methods have been widely used, future work should investigate the performance of *committee-based* active learning for NLG, in which examples are selected based on the level of disagreement between models trained on subsets of the data (Freund et al., 1997).

7 Discussion and conclusion

This paper presents and evaluates BAGEL, a statistical language generator that can be trained entirely from data, with no handcrafting required beyond the semantic annotation. All the required subtasks—i.e. content ordering, aggregation, lexical selection and realisation—are learned from data using a unified model. To train BAGEL in a dialogue system domain, we propose a stack-based semantic representation at the phrase level, which is expressive enough to generate natural utterances from *unseen* inputs, yet simple enough for data to be collected from 42 untrained annotators with a minimal normalisation step. A human evaluation over 202 dialogue acts does not show any difference in naturalness and informativeness between BAGEL's outputs and human utterances. Additionally, we find that the data collection process can be optimised using active learning, resulting in a significant increase in performance when training data is limited, according to ratings from 18 human judges.[6] These results suggest that the proposed framework can largely reduce the development time of NLG systems.

While this paper only evaluates the most likely realisation given a dialogue act, we believe that BAGEL's probabilistic nature and generalisation capabilities are well suited to model the linguistic variation resulting from the diversity of annotators. Our first objective is thus to evaluate the quality of BAGEL's n-best outputs, and test whether sampling from the output distribution can improve naturalness and user satisfaction within a dialogue.

Our results suggest that explicitly modelling syntax is not necessary for our domain, possibly because of the lack of syntactic complexity compared with formal written language. Nevertheless, future work should investigate whether syntactic information can improve performance in more complex domains. For example, the realisation phrase can easily be conditioned on syntactic constructs governing that phrase, and the recursive nature of syntax can be modelled by keeping track of the depth of the current embedded clause. While syntactic information can be included with no human effort by using syntactic parsers, their robustness to dialogue system utterances must first be evaluated.

Finally, recent years have seen HMM-based synthesis models become competitive with unit selection methods (Tokuda et al., 2000). Our long term objective is to take advantage of those advances to jointly optimise the language generation and the speech synthesis process, by combining both components into a unified probabilistic concept-to-speech generation model.

Plot Induction and Evolutionary Search for Story Generation

Neil McIntyre and **Mirella Lapata**
School of Informatics, University of Edinburgh

n.d.mcintyre@sms.ed.ac.uk, mlap@inf.ed.ac.uk

Abstract

In this paper we develop a story generator that leverages knowledge inherent in corpora without requiring extensive manual involvement. A key feature in our approach is the reliance on a story planner which we acquire automatically by recording events, their participants, and their precedence relationships in a training corpus. Contrary to previous work our system does not follow a generate-and-rank architecture. Instead, we employ evolutionary search techniques to explore the space of possible stories which we argue are well suited to the story generation task. Experiments on generating simple children's stories show that our system outperforms previous data-driven approaches.

1 Introduction

Computer story generation has met with fascination since the early days of artificial intelligence. Indeed, over the years, several generators have been developed capable of creating stories that resemble human output. To name only a few, TALE-SPIN (Meehan, 1977) generates stories through problem solving, MINSTREL (Turner, 1992) relies on an episodic memory scheme, essentially a repository of previous hand-coded stories, to solve the problems in the current story, and MAKEBELIEVE (Liu and Singh, 2002) uses commonsense knowledge to generate short stories from an initial seed story (supplied by the user). A large body of more recent work views story generation as a form of agent-based planning (Swartjes and Theune, 2008; Pizzi et al., 2007). The agents act as characters with a list of goals. They form plans of action and try to fulfill them. Interesting stories emerge as plans interact and cause failures and possible replanning.

The broader appeal of computational story generation lies in its application potential. Examples include the entertainment industry and the development of tools that produce large numbers of plots automatically that might provide inspiration to professional screen writers (Agudo et al., 2004); rendering video games more interesting by allowing the plot to adapt dynamically to the players' actions (Barros and Musse, 2007); and assisting teachers to create or personalize stories for their students (Riedl and Young, 2004).

A major stumbling block for the widespread use of computational story generators is their reliance on expensive, manually created resources. A typical story generator will make use of a knowledge base for providing detailed domain-specific information about the characters and objects involved in the story and their relations. It will also have a story planner that specifies how these characters interact, what their goals are and how their actions result in different story plots. Finally, a sentence planner (coupled with a surface realizer) will render an abstract story specification into natural language text. Traditionally, most of this knowledge is created by hand, and the effort must be repeated for new domains, new characters and plot elements.

Fortunately, recent work in natural language processing has taken significant steps towards developing algorithms that learn some of this knowledge *automatically* from natural language corpora. Chambers and Jurafsky (2009, 2008) propose an unsupervised method for learning *narrative schemas*, chains of events whose arguments are filled with participant semantic roles defined over words. An example schema is {X arrest, X charge, X raid, X seize, X confiscate, X detain, X deport}, where X stands for the argument types {*police, agent, authority, government*}. Their approach relies on the intuition that in a coherent text events that are about the same participants are

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1562–1572,
Uppsala, Sweden, 11-16 July 2010.

likely to be part of the same story or narrative. Their model extracts narrative chains, essentially events that share argument slots and merges them into schemas. The latter could be used to construct or enrich the knowledge base of a story generator.

In McIntyre and Lapata (2009) we presented a story generator that leverages knowledge inherent in corpora without requiring extensive manual involvement. The generator operates over predicate-argument and predicate-predicate co-occurrence tuples gathered from training data. These are used to produce a large set of candidate stories which are subsequently ranked based on their interestingness and coherence. The approach is unusual in that it does not involve an explicit story planning component. Stories are created stochastically by selecting entities and the events they are most frequently attested with.

In this work we develop a story generator that is also data-driven but crucially relies on a story planner for creating meaningful stories. Inspired by Chambers and Jurafsky (2009) we acquire story plots automatically by recording events, their participants, and their precedence relationships as attested in a training corpus. Entities give rise to different potential plots which in turn generate multiple stories. Contrary to our previous work (McIntyre and Lapata, 2009), we do not follow a generate-and-rank architecture. Instead, we search the space of possible stories using Genetic Algorithms (GAs) which we argue are advantageous in the story generation setting, as they can search large fitness landscapes while greatly reducing the risk of getting stuck in local optima. By virtue of exploring the search space more broadly, we are able to generate creative stories without an explicit interest scoring module.

In the remainder of this paper we give a brief overview of the system described in McIntyre and Lapata (2009) and discuss previous applications of GAs in natural language generation (Section 2). Next, we detail our approach, specifically how plots are created and used in conjunction with genetic search (Sections 3 and 4). Finally, we present our experimental results (Sections 6 and 7) and conclude the paper with discussion of future work.

2 Related Work

Our work builds on and extends the story generator developed in McIntyre and Lapata (2009). The system creates simple children's stories in an interactive context: the user supplies the topic of the story and its desired length (number of sentences). The generator creates a story following a pipeline architecture typical of natural language generation systems (Reiter and Dale, 2000) consisting of content selection, sentence planning, and surface realization.

The content of a story is determined by consulting a data-driven knowledge base that records the entities (i.e., nouns) appearing in a corpus and the actions they perform. These are encoded as dependency relations (e.g., *subj-verb*, *verb-obj*). In order to promote between-sentence coherence the generator also make use of an *action graph* that contains action-role pairs and the likelihood of transitioning from one to another. The sentence planner aggregates together entities and their actions into a sentence using phrase structure rules. Finally, surface realization is performed by interfacing RealPro (Lavoie and Rambow, 1997) with a language model. The system searches for the best story overall as well as the best sentences that can be generated from the knowledge base. Unlikely stories are pruned using beam search. In addition, stories are reranked using two scoring functions based on coherence and interest. These are learnt from training data, i.e., stories labeled with numeric values for interest and coherence.

Evolutionary search techniques have been previously employed in natural language generation, especially in the context of document planning. Structuring a set of facts into a coherent text is effectively a search problem that may lead to combinatorial explosion for large domains. Mellish et al. (1998) (and subsequently Karamanis and Manurung 2002) advocate genetic algorithms as an alternative to exhaustively searching for the optimal ordering of descriptions of museum artefacts. Rather than requiring a global optimum to be found, the genetic algorithm selects an order (based on coherence) that is good enough for people to understand. Cheng and Mellish (2000) focus on the interaction of aggregation and text planning and use genetic algorithms to search for the best aggregated document that satisfies coherence constraints.

The application of genetic algorithms to story generation is novel to our knowledge. Our work also departs from McIntyre and Lapata (2009) in two important ways. Firstly, our generator does not rely on a knowledge base of seemingly unrelated entities and relations. Rather, we employ

a document planner to create and structure a plot for a story. The planner is built automatically from a training corpus and creates plots dynamically depending on the protagonists of the story. Secondly, our search procedure is simpler and more global; instead of searching for the best story twice (i.e., by first finding the *n*-best stories and then subsequently reranking them based on coherence and interest), our genetic algorithm explores the space of possible stories once.

3 Plot Generation

Following previous work (e.g., Shim and Kim 2002; McIntyre and Lapata 2009) we assume that the user supplies a sentence (e.g., *the princess loves the prince*) from which the system creates a story. Each entity in this sentence (e.g., *princess*, *prince*) is associated with its own *narrative schema*, a set of key events and actors co-occurring with it in the training corpus. Our narrative schemas differ slightly from Chambers and Jurafsky (2009). They acquire schematic representations of situations akin to FrameNet (Fillmore et al., 2003): schemas consists of semantically similar predicates and the entities evoked by them. In our setting, every entity has its own schema, and predicates associated with it are ordered. Plots are generated by merging the entity-specific narrative schemas which subsequently serve as the input to the genetic algorithm. In the following we describe how the narrative schemas are extracted and plots merged, and then discuss our evolutionary search procedure.

Entity-based Schema Extraction Before we can generate a plot for a story we must have an idea of the actions associated with the entities in the story, the order in which these actions are performed and also which other entities can participate. This information is stored in a directed graph which we explain below. Our algorithm processes each document at a time, it operates over dependency structures and assumes that entity mentions have been resolved. In our experiments we used Rasp (Briscoe and Carroll, 2002), a broad coverage dependency parser, and the OpenNLP[1] coreference resolution engine.[2] However, any dependency parser or coreference tool could serve our purpose. We also assume that the actions associated with a given entity are ordered and that linear order corresponds to temporal order. This is a gross simplification as it is well known that temporal relationships between events are not limited to precedence, they may overlap, occur simultaneously, or be temporally unrelated. We could have obtained a more accurate ordering using a temporal classifier (see Chambers and Jurafsky 2008), however we leave this to future work.

For each entity e in the corpus we build a directed graph $G = (V, E)$ whose nodes V denote predicate argument relationships, and edges E represent transitions from node V_i to node V_j. As an example of our schema construction process, consider a very small corpus consisting of the two documents shown in Figure 1. The schema for *princess* after processing the first document is given on the left hand side. Each node in this graph corresponds to an action attested with *princess* (we also record who performs it and where or how). Nodes are themselves dependency trees (see Figure 4a), but are linearized in the figure for the sake of brevity. Edges in the graph indicate ordering and are weighted using the mutual information metric proposed in Lin (1998) (the weights are omitted from the example).[3] The first sentence in the text gives rise to the first node in the graph, the second sentence to the second node, and so on. Note that the third sentence is not present in the graph as it is not about the *princess*.

When processing the second document, we simply expand this graph. Before inserting a new node, we check if it can be merged with an already existing one. Nodes are merged only if they have the same verb and similar arguments, with the focal entity (i.e., *princess*) appearing in the same argument slot. In our example, the nodes "prince marry princess in castle" and "prince marry princess in temple" can be merged as they contain the same verb and number of similar arguments. The nodes "princess have influence" and "princess have baby" cannot be merged as *influence* and *baby* are semantically unrelated. We compute argument similarity using WordNet (Fellbaum, 1998) and the measure proposed by Wu and Palmer (1994) which is based on path length. We merge nodes with related arguments only if their similarity exceeds a threshold (determined empirically).

[1] See `http://opennlp.sourceforge.net/`.

[2] The coreference resolution tool we employ is not error-free and on occasion will fail to resolve a pronoun. We map unresolved pronouns to the generic labels *person* or *object*.

[3] We use mutual information to identify event sequences strongly associated with the graph entity.

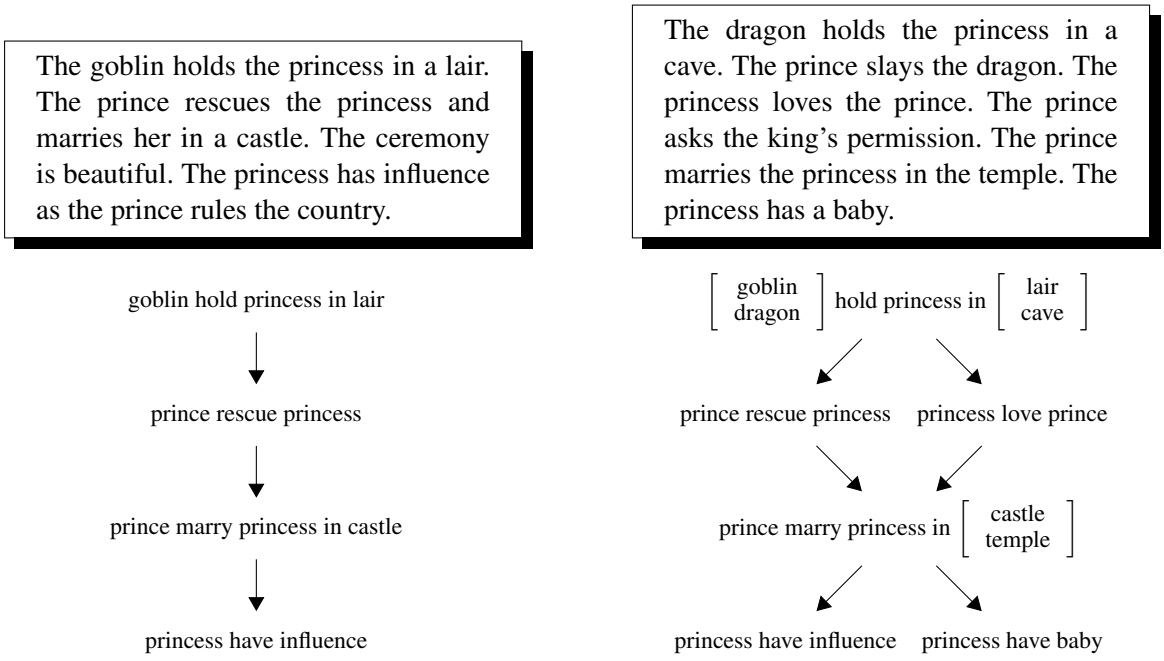

Figure 1: Example of schema construction for the entity *princess*

The schema construction algorithm terminates when graphs like the ones shown in Figure 1 (right hand side) have been created for all entities in the corpus.

Building a Story Plot Our generator takes an input sentence and uses it to instantiate several plots. We achieve this by merging the schemas associated with the entities in the sentence into a plot graph. As an example, consider again the sentence *the princess loves the prince* which requires combing the schemas representing *prince* and *princess* shown in Figures 2 and 1 (right hand side), respectively. Again, we look for nodes that can be merged based on the identity of the actions involved and the (WordNet) similarity of their arguments. However, we disallow the merging of nodes with focal entities appearing in the same argument slot (e.g., "[prince, princess] cries").

Once the plot graph is created, a depth first search starting from the node corresponding to the input sentence, finds all paths with length matching the desired story length (cycles are disallowed). Assuming we wish to generate a story consisting of three sentences, the graph in Figure 3 would create four plots. These are (princess love prince, prince marry princess in [castle, temple], princess have influence), (princess love prince, prince marry princess in [castle, temple], princess have baby), (princess love prince, prince marry princess in [castle, temple], prince rule country), and (princess love prince, prince ask king's permission prince marry princess in [castle, temple]). Each of these plots represents two different stories one with *castle* and one with *temple* in it.

Sentence Planning The sentence planner is interleaved with the story planner and influences the final structure of each sentence in the story. To avoid generating short sentences — note that nodes in the plot graph consist of a single action and would otherwise correspond to a sentence with a single clause — we combine pairs of nodes within the same graph by looking at intrasentential verb-verb co-occurrences in the training corpus. For example, the nodes (prince have problem, prince keep secret) could become the sentence *the prince has a problem keeping a secret*. We leave it up to the sentence planner to decide how the two actions should be combined.[4] The sentence planner will also insert adverbs and adjectives, using co-occurrence likelihoods acquired from the training corpus. It is essentially a phrase structure grammar compiled from the lexical resources made available by Korhonen and Briscoe (2006) and Grishman et al. (1994). The grammar rules act as templates for combining clauses and filling argument slots.

[4] We only turn an action into a subclause if its subject entity is same as that of the previous action.

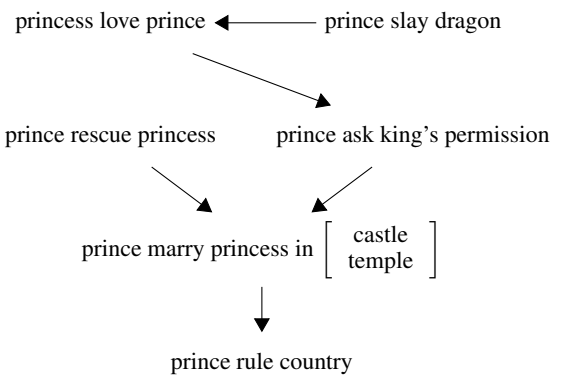

Figure 2: Narrative schema for the entity *prince*.

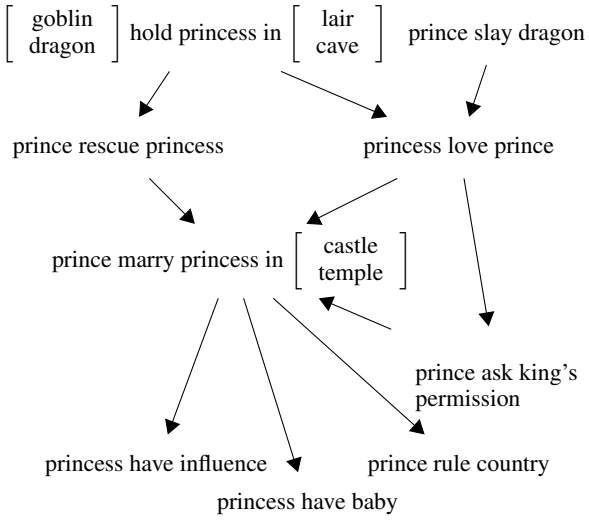

Figure 3: Plot graph for the input sentence *the princess loves the prince*.

4 Genetic Algorithms

The example shown in Figure 3 is a simplified version of a plot graph. The latter would normally contain hundreds of nodes and give rise to thousands of stories once lexical variables have been expanded. Searching the story space is a difficult optimization problem, that must satisfy several constraints: the story should be of a certain length, overall coherent, creative, display some form of event progression, and generally make sense. We argue that evolutionary search is appealing here, as it can find global optimal solutions in a more efficient way than traditional optimization methods.

In this study we employ genetic algorithms (GAs) a well-known search technique for finding approximate (or exact) solutions to optimization problems. The basic idea behind GAs is based on "natural selection" and the Darwinian principle of the survival of the fittest (Mitchell, 1998). An initial population is randomly created containing a predefined number of individuals (or solutions), each represented by a genetic string (e.g., a population of chromosomes). Each individual is evaluated according to an objective function (also called a fitness function). A number of individuals are then chosen as parents from the population according to their fitness, and undergo *crossover* (also called recombination) and *mutation* in order to develop the new population. Offspring with better fitness are then inserted into the population, replacing the inferior individuals in the previous generation.

The algorithm thus identifies the individuals with the optimizing fitness values, and those with lower fitness will naturally get discarded from the population. This cycle is repeated for a given number of generations, or stopped when the solution obtained is considered optimal. This process leads to the evolution of a population in which the individuals are more and more suited to their environment, just as natural adaptation. We describe below how we developed a genetic algorithm for our story generation problem.

Initial Population Rather than start with a random population, we seed the initial population with story plots generated from our plot graph. For an input sentence, we generate all possible plots. The latter are then randomly sampled until a population of the desired size is created. Contrary to McIntyre and Lapata (2009), we initialize the search with complete stories, rather than generate one sentence at a time. The genetic algorithm will thus avoid the pitfall of selecting early on a solution that will later prove detrimental.

Crossover Each plot is represented as an ordered graph of dependency trees (corresponding to sentences). We have decided to use crossover of a single point between two selected parents. The children will therefore contain sentences up to the crossover point of the first parent and sentences after that point of the second. Figure 4a shows two parents (prince rescue princess, prince marry princess in castle, princess have baby) and (prince rescue princess, prince love princess, princess kiss prince) and how two new plots are created by swapping their last nodes.

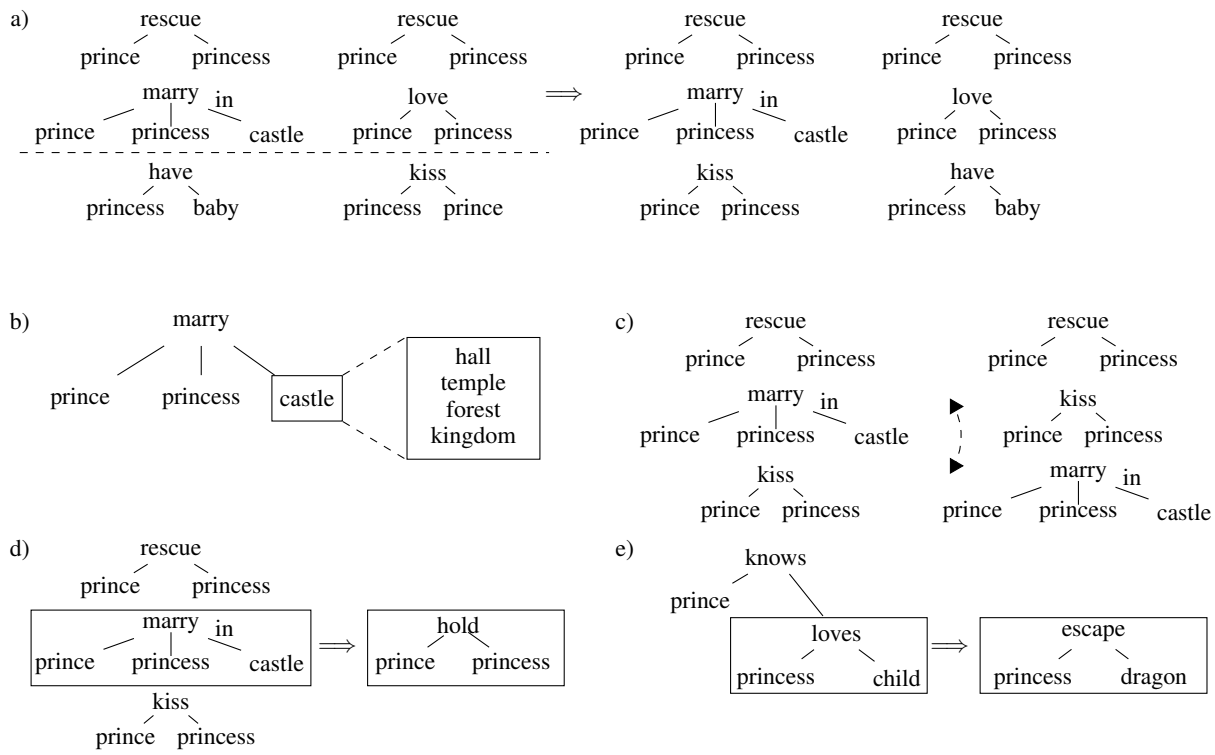

Figure 4: Example of genetic algorithm operators as they are applied to plot structures: a) crossover of two plots on a single point, indicated by the dashed line, resulting in two children which are a recombination of the parents; b) mutation of a lexical node, *church* can be replaced from a list of semantically related candidates; c) sentences can be switched under mutation to create a potentially more coherent structure; d) if the matrix verb undergoes mutation then, a random sentence is generated to replace it; e) if the verb chosen for mutation is the head of a subclause, then a random subclause replaces it.

Mutation Mutation can occur on any verb, noun, adverb, or adjective in the plot. If a noun, adverb or adjective is chosen to undergo mutation, then we simply substitute it with a new lexical item that is sufficiently similar (see Figure 4b for an example). Verbs, however, have structural importance in the stories and we cannot simply replace them without taking account of their arguments. If a matrix verb is chosen to undergo mutation, then a new random sentence is generated to replace the entire sentence (see Figure 4d). If it is a subclause, then it is replaced with a randomly generated clause, headed by a verb that has been seen in the corpus to co-occur with the matrix verb (Figure 4e). The sentence planner selects and fills template trees for generating random clauses. Mutation may also change the order of any two nodes in the graph in the hope that this will increase the story's coherence or create some element of surprise (see Figure 4c).

Selection To choose the plots for the next generation, we used fitness proportional selection (also know as roulette-wheel selection, Goldberg 1989) which chooses candidates randomly but with a bias towards those with a larger proportion of the population's combined fitness. We do not want to always select the fittest candidates as there may be valid partial solutions held within less fit members of the population. However, we did employ some elitism by allowing the top 1% of solutions to be copied straight from one generation to the next. Note that our candidates may also represent invalid solutions. For instance, through crossover it is possible to create a plot in which all or some nodes are identical. If any such candidates are identified, they are assigned a low fitness, without however being eliminated from the population as some could be used to create fitter solutions.

In a traditional GA, the fitness function deals with one optimization objective. It is possible to optimize several objectives either using a vot-

ing model or more sophisticated methods such as Pareto ranking (Goldberg, 1989). Following previous work (Mellish et al., 1998) we used a single fitness function that scored candidates based on their coherence. Our function was learned from training data using the Entity Grid document representation proposed in Barzilay and Lapata (2007). An entity grid is a two-dimensional array in which columns correspond to entities and rows to sentences. Each cell indicates whether an entity appears in a given sentence or not and whether it is a subject, object or neither. For training, this representation is converted into a feature vector of entity transition sequences and a model is learnt from examples of coherent and incoherent stories. The latter can be easily created by permuting the sentences of coherent stories (assuming that the original story is more coherent than its permutations).

In addition to coherence, in McIntyre and Lapata (2009) we used a scoring function based on interest which we approximated with lexical and syntactic features such as the number of noun/verb tokens/types, the number of subjects/objects, the number of letters, word familiarity, imagery, and so on. An interest-based scoring function made sense in our previous setup as a means of selecting unusual stories. However, in the context of genetic search such a function seems redundant as interesting stories emerge naturally through the operations of crossover and mutation.

5 Surface Realization

Once the final generation of the population has been reached, the fittest story is selected for surface realization. The realizer takes each sentence in the story and reformulates it into input compatible with the RealPro (Lavoie and Rambow, 1997) text generation engine. Realpro creates several variants of the same story differing in the choice of determiners, number (singular or plural), and prepositions. A language model is then used to select the most probable realization (Knight and Hatzivassiloglou, 1995). Ideally, the realizer should also select an appropriate tense for the sentence. However, we make the simplifying assumption that all sentences are in the present tense.

6 Experimental Setup

In this section we present our experimental set-up for assessing the performance of our story generator. We give details on our training corpus, system, parameters (such as the population size for the GA search), the baselines used for comparison, and explain how our system output was evaluated.

Corpus The generator was trained on the same corpus used in McIntyre and Lapata (2009), 437 stories from the Andrew Lang fairy tales collection.[5] The average story length is 125.18 sentences. The corpus contains 15,789 word tokens. Following McIntyre and Lapata, we discarded tokens that did not appear in the Children's Printed Word Database[6], a database of printed word frequencies as read by children aged between five and nine. From this corpus we extracted narrative schemas for 667 entities in total. We disregarded any graph that contained less than 10 nodes as too small. The graphs had on average 61.04 nodes, with an average clustering rate[7] of 0.027 which indicates that they are substantially connected.

Parameter Setting Considerable latitude is available when selecting parameters for the GA. These involve the population size, crossover, and mutation rates. To evaluate which setting was best, we asked two human evaluators to rate (on a 1–5 scale) stories produced with a population size ranging from 1,000 to 10,000, crossover rate of 0.1 to 0.6 and mutation rate of 0.001 to 0.1. For each run of the system a limit was set to 5,000 generations. The human ratings revealed that the best stories were produced for a population size of 10,000, a crossover rate of 0.1% and a mutation rate of 0.1%. Compared to previous work (e.g., Karamanis and Manurung 2002) our crossover rate may seem low and the mutation rate high. However, it makes intuitively sense, as high crossover may lead to incoherence by disrupting canonical action sequences found in the plots. On the other hand, a higher mutation will raise the likelihood of a lexical item being swapped for another and may improve overall coherence and interest. The fitness function was trained on 200 documents from the fairy tales collection using Joachims's (2002) SVM^{light} package and entity transition sequences of length 2. The realizer was interfaced with a trigram language model trained on the British National Corpus with the SRI toolkit.

[6] `http://www.essex.ac.uk/psychology/cpwd/`

[7] Clustering rate (or transitivity) is the number of triangles in the graph — sets of three vertices each of which is connected to each of the others.

Evaluation We compared the stories generated by the GA against those produced by the rank-based system described in McIntyre and Lapata (2009) and a system that creates stories from the plot graph, without any stochastic search. Since plot graphs are weighted, we can simply select the graph with the highest weight. After expanding all lexical variables, the chosen plot graph will give rise to different stories (e.g., *castle* or *temple* in the example above). We select the story ranked highest according to our coherence function. In addition, we included a baseline which randomly selects sentences from the training corpus provided they contain either of the story protagonists (i.e., entities in the input sentence). Sentence length was limited to 12 words or less as this was on average the length of the sentences generated by our GA system.

Each system created stories for 12 input sentences, resulting in 48 (4×12) stories for evaluation. The sentences used commonly occurring entities in the fairy tales corpus (e.g., *The child watches the bird*, *The emperor rules the kingdom.*, *The wizard casts the spell.*). The stories were split into three sets containing four stories from each system but with only one story from each input sentence. All stories had the same length, namely five sentences. Human judges were presented with one of the three sets and asked to rate the stories on a scale of 1 to 5 for fluency (was the sentence grammatical?), coherence (does the story make sense overall?) and interest (how interesting is the story?). The stories were presented in random order and participants were told that all of them were generated by a computer program. They were instructed to rate more favorably interesting stories, stories that were comprehensible and overall grammatical. The study was conducted over the Internet using WebExp (Keller et al., 2009) and was completed by 56 volunteers, all self reported native English speakers.

7 Results

Our results are summarized in Table 1 which lists the average human ratings for the four systems. We performed an Analysis of Variance (ANOVA) to examine the effect of system type on the story generation task. Statistical tests were carried out on the mean of the ratings shown in Table 1 for fluency, coherence, and interest.

In terms of interest, the GA-based system is significantly better than the Rank-based, Plot-based and Random ones (using a Post-hoc Tukey test, $\alpha < 0.05$). With regard to fluency, the Rank-based system is significantly worse than the rest ($\alpha < 0.01$). Interestingly, the sentences generated by the GA and Plot-based systems are as fluent as those created by humans. Recall that the Random system, simply selects sentences from the training corpus. Finally, the GA system is significantly more coherent than the Rank-based and Random systems ($\alpha < 0.05$), but not the Plot-based one. This is not surprising, the GA and Plot-based systems rely on similar plots to create a coherent story. The performance of the Random system is also inferior as it does not have any explicit coherence enforcing mechanism. The Rank-based system is perceived overall worse. As this system is also the least fluent, we conjecture that participants are influenced in their coherence judgments by the grammaticality of the stories.

System	Fluency	Coherence	Interest
GA-based	3.09	2.48	2.36
Plot-based	3.03	2.36	2.14^{*}
Rank-based	1.96^{**}	1.65^{*}	1.85^{*}
Random	3.10	2.23^{*}	2.20^{*}

Table 1: Human evaluation results: mean story ratings for four story generators; $^{*}: p < 0.05$, $^{**}: p < 0.01$, significantly different from GA-based system.

Overall our results indicate that an explicit story planner improves the quality of the generated stories, especially when coupled with a search mechanism that advantageously explores the search space. It is worth noting that the Plot-based system is relatively simple, however the explicit use of a story plot, seems to make up for the lack of sophisticated search and more elaborate linguistic information. Example stories generated by the four systems are shown in Table 2 for the input sentences *The emperor rules the kingdom* and *The child watches the bird*.

Possible extensions and improvements to the current work are many and varied. Firstly, we could improve the quality of our plot graphs by taking temporal knowledge into account and making use of knowledge bases such as WordNet and ConceptNet (Liu and Davenport, 2004), a freely available commonsense knowledge base. Secondly, our fitness function optimizes one ob-

PlotGA	The emperor rules the kingdom. The kingdom holds on to the emperor. The emperor rides out of the kingdom. The kingdom speaks out against the emperor. The emperor lies.	The child watches the bird. The bird weeps for the child. The child begs the bird to listen.The bird dresses up the child. The child grows up.
Plot	The emperor rules the kingdom. The emperor takes over. The emperor goes on to feel for the kingdom. Possibly the emperor sleeps. The emperor steals.	The child watches the bird. The bird comes to eat away at the child. The child does thoroughly. The bird sees the child. The child sits down.
Rank	The emperor rules the kingdom. The kingdom lives from the reign to the emperor. The emperor feels that the brothers tempt a beauty into the game. The kingdom saves the life from crumbling the earth into the bird. The kingdom forces the whip into wiping the tears on the towel.	The child watches the bird. The bird lives from the reign to the child. The child thanks the victory for blessing the thought. The child loves to hate the sun with the thought. The child hopes to delay the duty from the happiness.
Random	Exclaimed the emperor when Petru had put his question. In the meantime, mind you take good care of our kingdom. At first the emperor felt rather distressed. The dinner of an emperor! Thus they arrived at the court of the emperor.	They cried, “what a beautiful child!” “No, that I cannot do, my child” he said at last. “What is the matter, dear child?” “You wicked child,” cried the Witch. Well, I will watch till the bird comes.

Table 2: Stories generated by a system that uses plots and genetic search (PlotGA), a system that uses only plots (Plot), McIntyre and Lapata (2009)’s rank-based system (Rank) and a system that randomly pastes together sentences from the training corpus (Random).

jective, namely coherence. In the future we plan to explore multiple objectives, such as whether the story is verbose, readable (using existing readability metrics), has two many or two few protagonists, and so on.

Thirdly, our stories would benefit from some explicit modeling of discourse structure. Although the plot graph captures the progression of the actions in a story, we would also like to know where in the story these actions are likely to occur—some tend to appear in the beginning and others in the end. Such information would allow us to structure the stories better and render them more natural sounding. For example, an improvement would be the inclusion of proper endings, as the stories are currently cut off at an arbitrary point when the desired maximum length is reached.

Finally, the fluency of the stories would benefit from generating referring expressions, multiple tense forms, indirect speech, aggregation and generally more elaborate syntactic structure.

Abstract

We present a natural language generation approach which models, exploits, and manipulates the non-linguistic context in situated communication, using techniques from AI planning. We show how to generate instructions which deliberately guide the hearer to a location that is convenient for the generation of simple referring expressions, and how to generate referring expressions with context-dependent adjectives. We implement and evaluate our approach in the framework of the Challenge on Generating Instructions in Virtual Environments, finding that it performs well even under the constraints of real-time generation.

1 Introduction

The problem of situated natural language generation (NLG)—i.e., of generating natural language in the context of a physical (or virtual) environment—has received increasing attention in the past few years. On the one hand, this is because it is the foundation of various emerging applications, including human-robot interaction and mobile navigation systems, and is the focus of a current evaluation effort, the Challenges on Generating Instructions in Virtual Environments (GIVE; (Koller et al., 2010b)). On the other hand, situated generation comes with interesting theoretical challenges: Compared to the generation of pure text, the interpretation of expressions in situated communication is sensitive to the non-linguistic context, and this context can change as easily as the user can move around in the environment.

One interesting aspect of situated communication from an NLG perspective is that this non-linguistic context can be manipulated by the speaker. Consider the following segment of discourse between an instruction giver (IG) and an instruction follower (IF), which is adapted from the SCARE corpus (Stoia et al., 2008):

(1) IG: *Walk forward and then turn right.*
IF: (walks and turns)
IG: *OK. Now hit the button in the middle.*

In this example, the IG plans to refer to an object (here, a button); and in order to do so, gives a navigation instruction to guide the IF to a convenient location at which she can then use a simple referring expression (RE). That is, there is an interaction between navigation instructions (intended to manipulate the non-linguistic context in a certain way) and referring expressions (which exploit the non-linguistic context). Although such subdialogues are common in SCARE, we are not aware of any previous research that can generate them in a computationally feasible manner.

This paper presents an approach to generation which is able to model the effect of an utterance on the non-linguistic context, and to intentionally generate utterances such as the above as part of a process of referring to objects. Our approach builds upon the CRISP generation system (Koller and Stone, 2007), which translates generation problems into planning problems and solves these with an AI planner. We extend the CRISP planning operators with the perlocutionary effects that uttering a particular word has on the physical environment if it is understood correctly; more specifically, on the position and orientation of the hearer. This allows the planner to predict the non-linguistic context in which a later part of the utterance will be interpreted, and therefore to search for contexts that allow the use of simple REs. As a result, the work of referring to an object gets distributed over multiple utterances of low cognitive load rather than a single complex noun phrase.

A second contribution of our paper is the generation of REs involving context-dependent adjectives: A button can be described as "the left blue

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1573–1582,
Uppsala, Sweden, 11-16 July 2010.

button" even if there is a red button to its left. We model adjectives whose interpretation depends on the nominal phrases they modify, as well as on the non-linguistic context, by keeping track of the distractors that remain after uttering a series of modifiers. Thus, unlike most other RE generation approaches, we are not restricted to building an RE by simply intersecting lexically specified sets representing the extensions of different attributes, but can correctly generate expressions whose meaning depends on the context in a number of ways. In this way we are able to refer to objects earlier and more flexibly.

We implement and evaluate our approach in the context of a GIVE NLG system, by using the GIVE-1 software infrastructure and a GIVE-1 evaluation world. This shows that our system generates an instruction-giving discourse as in (1) in about a second. It outperforms a mostly non-situated baseline significantly, and compares well against a second baseline based on one of the top-performing systems of the GIVE-1 Challenge. Next to the practical usefulness this evaluation establishes, we argue that our approach to jointly modeling the grammatical and physical effects of a communicative action can also inform new models of the pragmatics of speech acts.

Plan of the paper. We discuss related work in Section 2, and review the CRISP system, on which our work is based, in Section 3. We then show in Section 4 how we extend CRISP to generate navigation-and-reference discourses as in (1), and add context-dependent adjectives in Section 5. We evaluate our system in Section 6; Section 7 concludes and points to future work.

2 Related work

The research reported here can be seen in the wider context of approaches to generating referring expressions. Since the foundational work of Dale and Reiter (1995), there has been a considerable amount of literature on this topic. Our work departs from the mainstream in two ways. First, it exploits the situated communicative setting to deliberately modify the context in which an RE is generated. Second, unlike most other RE generation systems, we allow the contribution of a modifier to an RE to depend both on the context and on the rest of the RE.

We are aware of only one earlier study on generation of REs with focus on interleaving navigation and referring (Stoia et al., 2006). In this machine learning approach, Stoia et al. train classifiers that signal when the context conditions (e.g. visibility of target and distractors) are appropriate for the generation of an RE. This method can be then used as part of a content selection component of an NLG system. Such a component, however, can only inform a system on whether to choose navigation over RE generation at a given point of the discourse, and is not able to help it decide what kind of navigational instructions to generate so that subsequent REs become simple.

To our knowledge, the only previous research on generating REs with context-dependent modifiers is van Deemter's (2006) algorithm for generating vague adjectives. Unlike van Deemter, we integrate the RE generation process tightly with the syntactic realization, which allows us to generate REs with more than one context-dependent modifier and model the effect of their linear order on the meaning of the phrase. In modeling the context, we focus on the non-linguistic context and the influence of each of the RE's words; this is in contrast to previous research on context-sensitive generation of REs, which mainly focused on the discourse context (Krahmer and Theune, 2002). Our interpretation of context-dependent modifiers picks up ideas by Kamp and Partee (1995) and implements them in a practical system, while our method of ordering modifiers is linguistically informed by the class-based paradigm (e.g., Mitchell (2009)).

On the other hand, our work also stands in a tradition of NLG research that is based on AI planning. Early approaches (Perrault and Allen, 1980; Appelt, 1985) provided compelling intuitions for this connection, but were not computationally viable. The research we report here can be seen as combining Appelt's idea of using planning for sentence-level NLG with a computationally benign variant of Perrault et al.'s approach of modeling the intended perlocutionary effects of a speech act as the effects of a planning operator. Our work is linked to a growing body of very recent work that applies modern planning research to various problems in NLG (Steedman and Petrick, 2007; Brenner and Kruijff-Korbayová, 2008; Benotti, 2009). It is directly based on Koller and Stone's (2007) reimplementation of the SPUD generator (Stone et al., 2003) with planning. As far as we know, ours is the first system in the SPUD tradi-

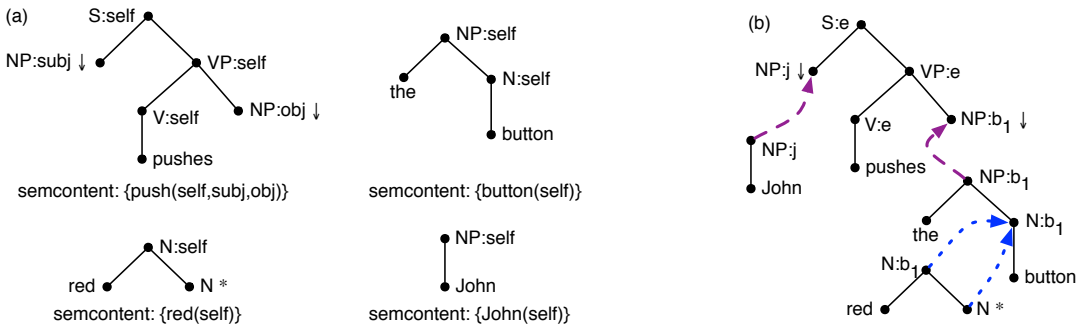

Figure 1: (a) An example grammar; (b) a derivation of "John pushes the red button" using (a).

tion that explicitly models the context change effects of an utterance.

While nothing in our work directly hinges on this, we implemented our approach in the context of an NLG system for the GIVE Challenge (Koller et al., 2010b), that is, as an instruction giving system for virtual worlds. This makes our system comparable with other approaches to instruction giving implemented in the GIVE framework.

3 Sentence generation as planning

Our work is based on the CRISP system (Koller and Stone, 2007), which encodes sentence generation with tree-adjoining grammars (TAG; (Joshi and Schabes, 1997)) as an AI planning problem and solves that using efficient planners. It then decodes the resulting plan into a TAG derivation, from which it can read off a sentence. In this section, we briefly recall how this works. For space reasons, we will present primarily examples instead of definitions.

3.1 TAG sentence generation

The CRISP generation problem (like that of SPUD (Stone et al., 2003)) assumes a lexicon of entries consisting of a TAG elementary tree annotated with semantic and pragmatic information. An example is shown in Fig. 1a. In addition to the elementary tree, each lexicon entry specifies its *semantic content* and possibly a *semantic requirement*, which can express certain presuppositions triggered by this entry. The nodes in the tree may be labeled with argument names such as *semantic roles*, which specify the participants in the relation expressed by the lexicon entry; in the example, every entry uses the semantic role self representing the event or individual itself, and the entry for "pushes" furthermore uses subj and obj for the subject and object argument, respectively. We combine here for simplicity the entries for "the" and "button" into "the button".

For generation, we assume as input a knowledge base and a communicative goal in addition to the grammar. The goal is to compute a derivation that expresses the communicative goal in a sentence that is grammatically correct and complete; whose meaning is justified by the knowledge base; and in which all REs can be resolved to unique individuals in the world by the hearer. Let's say, for example, that we have a knowledge base $\{\mathsf{push}(e, \mathsf{j}, b_1), \mathsf{John}(\mathsf{j}), \mathsf{button}(b_1), \mathsf{button}(b_2), \mathsf{red}(b_1)\}$. Then we can combine instances of the trees for "John", "pushes", and "the button" into a grammatically complete derivation. However, because both b_1 and b_2 satisfy the semantic content of "the button", we must adjoin "red" into the derivation to make the RE refer uniquely to b_1. The complete derivation is shown in Fig. 1b; we can read off the output sentence "John pushes the red button" from the leaves of the derived tree we build in this way.

3.2 TAG generation as planning

In the CRISP system, Koller and Stone (2007) show how this generation problem can be solved by converting it into a planning problem (Nau et al., 2004). The basic idea is to encode the partial derivation in the planning state, and to encode the action of adding each elementary tree in the planning operators. The encoding of our example as a planning problem is shown in Fig. 2.

In the example, we start with an initial state which contains the entire knowledge base, plus atoms $\mathsf{subst}(\mathrm{S}, \mathsf{root})$ and $\mathsf{ref}(\mathsf{root}, e)$ expressing that we want to generate a sentence about the event e. We can then apply the (instantiated) action $\textbf{pushes}(\mathsf{root}, \mathsf{n}_1, \mathsf{n}_2, \mathsf{n}_3, e, \mathsf{j}, b_1)$, which models the act of substituting the elementary tree for "pushes"

pushes$(u, u_1, u_2, u_n, x, x_1, x_2)$:
Precond: $\mathsf{subst}(\mathrm{S}, u), \mathsf{ref}(u, x), \mathsf{push}(x, x_1, x_2), \mathsf{current}(u_1), \mathsf{next}(u_1, u_2), \mathsf{next}(u_2, u_n)$
Effect: $\neg\mathsf{subst}(\mathrm{S}, u), \mathsf{subst}(\mathrm{NP}, u_1), \mathsf{subst}(\mathrm{NP}, u_2), \mathsf{ref}(u_1, x_1), \mathsf{ref}(u_2, x_2), \forall y.\mathsf{distractor}(u_1, y), \forall y.\mathsf{distractor}(u_2, y)$

John(u, x):
Precond: $\mathsf{subst}(\mathrm{NP}, u), \mathsf{ref}(u, x), \mathsf{John}(x)$
Effect: $\neg\mathsf{subst}(\mathrm{NP}, u), \forall y.\neg\mathsf{John}(y) \rightarrow \neg\mathsf{distractor}(u, y)$

the-button(u, x):
Precond: $\mathsf{subst}(\mathrm{NP}, u), \mathsf{ref}(u, x), \mathsf{button}(x)$
Effect: $\neg\mathsf{subst}(\mathrm{NP}, u), \mathsf{canadjoin}(\mathrm{N}, u), \forall y.\neg\mathsf{button}(y) \rightarrow \neg\mathsf{distractor}(u, y)$

red(u, x):
Precond: $\mathsf{canadjoin}(\mathrm{N}, u), \mathsf{ref}(u, x), \mathsf{red}(x)$
Effect: $\forall y.\neg\mathsf{red}(y) \rightarrow \neg\mathsf{distractor}(u, y)$

Figure 2: CRISP planning operators for the elementary trees in Fig. 1.

into the substitution node root: It can only be applied because root is an unfilled substitution node (precondition $\mathsf{subst}(\mathrm{S}, \mathsf{root})$), and its effect is to remove $\mathsf{subst}(\mathrm{S}, \mathsf{root})$ from the planning state while adding two new atoms $\mathsf{subst}(\mathrm{NP}, \mathsf{n}_1)$ and $\mathsf{subst}(\mathrm{NP}, \mathsf{n}_2)$ for the substitution nodes of the "pushes" tree. The planning state maintains information about which individual each node refers to in the ref atoms. The current and next atoms are needed to select unused names for newly introduced syntax nodes.[1] Finally, the action introduces a number of distractor atoms including $\mathsf{distractor}(\mathsf{n}_2, e)$ and $\mathsf{distractor}(\mathsf{n}_2, b_2)$, expressing that the RE at n_2 can still be misunderstood by the hearer as e or b_2.

In this new state, all subst and distractor atoms for n_1 can be eliminated with the action **John**$(\mathsf{n}_1, \mathsf{j})$. We can also apply the action **the-button**(n_2, b_1) to eliminate $\mathsf{subst}(\mathrm{NP}, \mathsf{n}_2)$ and $\mathsf{distractor}(\mathsf{n}_2, e)$, since e is not a button. However $\mathsf{distractor}(\mathsf{n}_2, b_2)$ remains. Now because the action **the-button** also introduced the atom $\mathsf{canadjoin}(\mathrm{N}, \mathsf{n}_2)$, we can remove the final distractor atom by applying **red**(n_2, b_1). This brings us into a goal state, and we are done. Goal states in CRISP planning problems are characterized by axioms such as $\forall A \forall u.\neg\mathsf{subst}(A, u)$ (encoding grammatical completeness) and $\forall u \forall x.\neg\mathsf{distractor}(u, x)$ (requiring unique reference).

[1] This is a different solution to the name-selection problem than in Koller and Stone (2007). It is simpler and improves computational efficiency.

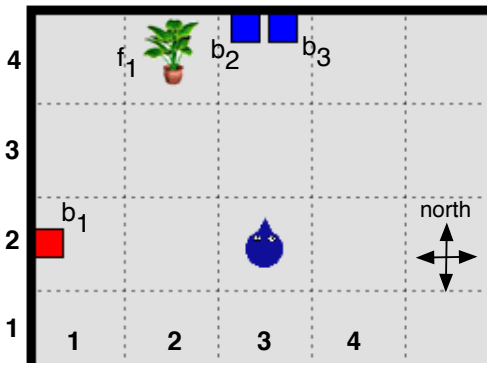

Figure 3: An example map for instruction giving.

3.3 Decoding the plan

An AI planner such as FF (Hoffmann and Nebel, 2001) can compute a plan for a planning problem that consists of the planning operators in Fig. 2 and a specification of the initial state and the goal. We can then decode this plan into the TAG derivation shown in Fig. 1b. The basic idea of this decoding step is that an action with a precondition $\mathsf{subst}(A, u)$ fills the substitution node u, while an action with a precondition $\mathsf{canadjoin}(A, u)$ adjoins into a node of category A in the elementary tree that was substituted into u. CRISP allows multiple trees to adjoin into the same node. In this case, the decoder executes the adjunctions in the order in which they occur in the plan.

4 Context manipulation

We are now ready to describe our NLG approach, SCRISP ("Situated CRISP"), which extends CRISP to take the non-linguistic context of the generated utterance into account, and deliberately manipulate it to simplify RE generation.

As a simplified version of our introductory instruction giving example (1), consider the map in Fig. 3. The instruction follower (IF), who is located on the map at position $\mathsf{pos}_{3,2}$ facing north, sees the scene from the first-person perspective as in Fig. 7. Now an instruction giver (IG) could instruct the IF to press the button b_1 in this scene by saying "push the button on the wall to your left". Interpreting this instruction is difficult for the IF because it requires her to either memorize the RE until she has turned to see the button, or to perform a mental rotation task to visualize b_1 internally. Alternatively, the IG can first instruct the IF to "turn left"; once the IF has done this, the IG can then simply say "now push the button in front

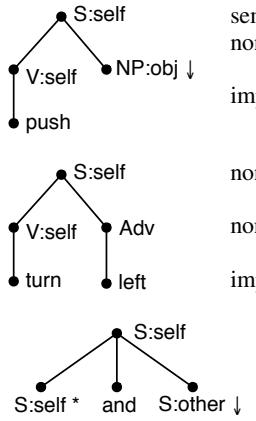

Figure 4: An example SCRISP lexicon.

turnleft(u, x, o_1, o_2):
Precond: subst(S, u), ref(u, x), player–ori(o_1), next–ori–left(o_1, o_2), ...
Effect: ¬subst(S, u), ¬player–ori(o_1), player–ori(o_2), to–do(turnleft), ...

push$(u, u_1, u_n, x, x_1, p, o)$:
Precond: subst(S, u), ref(u, x), player–pos(p), player–ori(o), visible(p, o, x_1), ...
Effect: ¬subst(S, u), subst(NP, u_1), ref(u_1, x_1), $\forall y.(y \neq x_1 \wedge \text{visible}(p, o, y) \rightarrow \text{distractor}(u_1, y))$, to–do(push($x_1$)), canadjoin(S, u), ...

and(u, u_1, u_n, e_1, e_2):
Precond: canadjoin(S, u), ref(u, e_1), ...
Effect: subst(S, u_1), ref(u_1, e_2), ...

Figure 5: SCRISP planning operators for the lexicon in Fig. 4.

of you". This lowers the cognitive load on the IF, and presumably improves the rate of correctly interpreted REs.

SCRISP is capable of deliberately generating such context-changing navigation instructions. The key idea of our approach is to extend the CRISP planning operators with preconditions and effects that describe the (simulated) physical environment: A "turn left" action, for example, modifies the IF's orientation in space and changes the set of visible objects; a "push" operator can then pick up this changed set and restrict the distractors of the forthcoming RE it introduces (i.e. "the button") to only objects that are visible in the changed context. We also extend CRISP to generate imperative rather than declarative sentences.

4.1 Situated CRISP

We define a lexicon for SCRISP to be a CRISP lexicon in which every lexicon entry may also describe *non-linguistic conditions*, *non-linguistic effects* and *imperative effects*. Each of these is a set of atoms over constants, semantic roles, and possibly some free variables. Non-linguistic conditions specify what must be true in the world so a particular instance of a lexicon entry can be uttered felicitously; non-linguistic effects specify what changes uttering the word brings about in the world; and imperative effects contribute to the IF's "to-do list" (Portner, 2007) by adding the properties they denote.

A small lexicon for our example is shown in Fig. 4. This lexicon specifies that saying "push X" puts pushing X on the IF's to-do list, and carries the presupposition that X must be visible from the location where "push X" is uttered; this reflects our simplifying assumption that the IG can only refer to objects that are currently visible. Similarly, "turn left" puts turning left on the IF's agenda. In addition, the lexicon entry for "turn left" specifies that, under the assumption that the IF understands and follows the instruction, they will turn 90 degrees to the left after hearing it. The planning operators are written in a way that assumes that the intended (perlocutionary) effects of an utterance actually come true. This assumption is crucial in connecting the non-linguistic effects of one SCRISP action to the non-linguistic preconditions of another, and generalizes to a scalable model of planning perlocutionary acts. We discuss this in more detail in Koller et al. (2010a).

We then translate a SCRISP generation problem into a planning problem. In addition to what CRISP does, we translate all non-linguistic conditions into preconditions and all non-linguistic effects into effects of the planning operator, adding any free variables to the operator's parameters. An imperative effect P is translated into an effect to–do(P). The operators for the example lexicon of Fig. 4 are shown in Fig. 5. Finally, we add information about the situated environment to the initial state, and specify the planning goal by adding to–do(P) atoms for each atom P that is to be placed on the IF's agenda.

4.2 An example

Now let's look at how this generates the appropriate instructions for our example scene of Fig. 3. We encode the state of the world as depicted in the map in an initial state which contains, among others, the atoms player–pos($\text{pos}_{3,2}$), player–ori(north), next–ori–left(north, west),

visible($\mathsf{pos}_{3,2}$, west, b_1), etc.[2] We want the IF to press b_1, so we add to–do(push(b_1)) to the goal.

We can start by applying the action **turnleft**(root, e, north, west) to the initial state. Next to the ordinary grammatical effects from CRISP, this action makes player–ori(west) true. The new state does not contain any subst atoms, but we can continue the sentence by adjoining "and", i.e. by applying the action **and**(root, n_1, n_2, e, e_1). This produces a new atom subst(S, e_1), which satisfies one precondition of **push**(n_1, n_2, n_3, e_1, b_1, $\mathsf{pos}_{3,2}$, west). Because **turnleft** changed the player orientation, the visible precondition of **push** is now satisfied too (unlike in the initial state, in which b_1 was not visible). Applying the action **push** now introduces the need to substitute a noun phrase for the object, which we can eliminate with an application of **the-button**(n_2, b_1) as in Subsection 3.2.

Since there are no other visible buttons from $\mathsf{pos}_{3,2}$ facing west, there are no remaining distractor atoms at this point, and a goal state has been reached. Together, this four-step plan decodes into the sentence "turn left and push the button". The final state contains the atoms to–do(push(b_1)) and to–do(turnleft), indicating that an IF that understands and accepts this instruction also accepts these two commitments into their to-do list.

5 Generating context-dependent adjectives

Now consider if we wanted to instruct the IF to press b_2 in Fig. 3 instead of b_1, say with the instruction "push the left button". This is still challenging, because (like most other approaches to RE generation) CRISP interprets adjectives by simply intersecting all their extensions. In the case of "left", the most reasonable way to do this would be to interpret it as "leftmost among all visible objects"; but this is f_1 in the example, and so there is no distinguishing RE for b_2.

In truth, spatial adjectives like "left" and "upper" depend on the context in two different ways. On the one hand, they are interpreted with respect to the current spatio-visual context, in that what is on the left depends on the current position and orientation of the hearer. On the other hand, they also depend on the meaning of the phrase they modify: "the left button" is not necessarily both a button and further to the left than all other objects, it is only the leftmost object among the buttons.

We will now show how to extend SCRISP so it can generate REs that use such context-dependent adjectives.

left(u, x):
  Precond: $\forall y.\neg$(distractor(u, y) $\wedge$ left–of(y, x)),
    canadjoin(N, u), ref(u, x)
  Effect: $\forall y.$(left–of(x, y) $\rightarrow \neg$distractor(u, y)),
    premod–index(u, 2), ...

red(u, x):
  Precond: red(x), canadjoin(N, u), ref(u, x),
    $\neg$premod–index(u, 2)
  Effect: $\forall y.(\neg$red(y) $\rightarrow \neg$distractor(u, y)),
    premod–index(u, 1), ...

Figure 6: SCRISP operators for context-dependent and context-independent adjectives.

5.1 Context-dependence of adjectives in SCRISP

As a planning-based approach to NLG, SCRISP is not limited to simply intersecting sets of potential referents that only depend on the attributes that contribute to an RE: Distractors are removed by applying operators which may have context-sensitive conditions depending on the referent and the distractors that are still left.

Our encoding of context-dependent adjectives as planning operators is shown in Fig. 6. We only show the operators here for lack of space; they can of course be computed automatically from lexicon entries. In addition to the ordinary CRISP preconditions, the **left** operator has a precondition requiring that no current distractor for the RE u is to the left of x, capturing a presupposition of the adjective. Its effect is that everything that is to the right of x is no longer a distractor for u. Notice that we allow that there may still be distractors after **left** has been applied (above or below x); we only require unique reference in the goal state. (Ignore the premod–index part of the effect for now; we will get to that in a moment.)

Let's say that we are computing a plan for referring to b_2 in the example map of Fig. 3, starting with **push**(root, n_1, n_2, e, b_2, $\mathsf{pos}_{3,1}$, north) and **the-button**(n_1, b_2). The state after these two actions is not a goal state, because it still contains the atom distractor(n_1, b_3) (the plant f_1 was removed as a distractor by the action **the-button**).

[2] In a more complex situation, it may be infeasible to exhaustively model visibility in this way. This could be fixed by connecting the planner to an external spatial reasoner (Dornhege et al., 2009).

Now assume that we have modeled the spatial relations between all objects in the initial state in left–of and above atoms; in particular, we have left–of(b_2, b_3). Then the action instance **left**(n_1, b_2) is applicable in this state, as there is no other object that is still a distractor in this state and that is to the left of b_2. Applying **left** removes distractor(n_1, b_3) from the state. Thus we have reached a goal state; the complete plan decodes to the sentence "push the left button".

This system is sensitive to the order in which operators for context-dependent adjectives are applied. To generate the RE "the upper left button", for instance, we first apply the **left** action and then the **upper** action, and therefore **upper** only needs to remove distractors in the leftmost position. On the other hand, the RE "the left upper button" corresponds to first applying **upper** and then **left**. These action sequences succeed in removing all distractors for different context states, which is consistent with the difference in meaning between the two REs.

Furthermore, notice that the adjective operators themselves do not interact directly with the encoding of the context in atoms like visible and player–pos, just like the noun operators in Section 4 didn't. The REs to which the adjectives and nouns contribute are introduced by verb operators; it is these verb operators that inspect the current context and initialize the distractor set for the new RE appropriately. This makes the correctness of the generated sentence independent of the order in which noun and adjective operators occur in the plan. We only need to ensure that the verbs are ordered correctly, and the workload of modeling interactions with the non-linguistic context is limited to a single place in the encoding.

5.2 Adjective word order

One final challenge that arises in our system is to generate the adjectives in the correct order, which on top of semantically valid must be linguistically acceptable. In particular, it is known that some types of adjectives are limited with respect to the word order in which they can occur in a noun phrase. For instance, "large foreign financial firms" sounds perfectly acceptable, but "? foreign large financial firms" sounds odd (Shaw and Hatzivassiloglou, 1999). In our setting, some adjective orders are forbidden because only one order produces a correct and distinguishing description of the target referent (cf. "upper left" vs. "left upper" example above). However, there are also other constraints at work: "? the red left button" is rather odd even when it is a semantically correct description, whereas "the left red button" is fine.

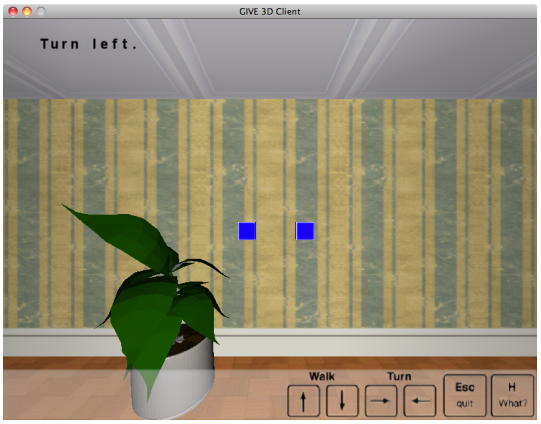

Figure 7: The IF's view of the scene in Fig. 3, as rendered by the GIVE client.

To ensure that SCRISP chooses to generate these adjectives correctly, we follow a class-based approach to the premodifier ordering problem (Mitchell, 2009). In our lexicon we assign adjectives denoting spatial relations ("left") to one class and adjectives denoting color ("red") to another; then we require that spatial adjectives must always precede color adjectives. We enforce this by keeping track of the current *premodifier index* of the RE in atoms of the form premod–index. Any newly generated RE node starts off with a premodifier index of zero; adjoining an adjective of a certain class then raises this number to the index for that class. As the operators in Fig. 6 illustrate, color adjectives such as "red" have index one and can only be used while the index is not higher; once an adjective from a higher class (such as "left", of a class with index two) is used, the premod–index precondition of the "red" operator will fail. For this reason, we can generate a plan for "the left red button", but not for "? the red left button", as desired.

6 Evaluation

To establish the quality of the generated instructions, we implemented SCRISP as part of a generation system in the GIVE-1 framework, and evaluated it against two baselines. GIVE-1 was the First Challenge on Generating Instructions in Virtual Environments, which was completed in 2009

SCRISP	*1. Turn right and move one step.* *2. Push* ***the right red button****.*
Baseline A	*1. Press* ***the right red button on the wall to your right****.*
Baseline B	*1. Turn right.* *2. Walk forward 3 steps.* *3. Turn right.* *4. Walk forward 1 step.* *5. Turn left.* *6. Good! Now press* ***the left button****.*

Table 1: Example system instructions generated in the same scene. REs for the target are typeset in boldface.

(Koller et al., 2010b). In this challenge, systems must generate real-time instructions that help users perform a task in a treasure-hunt virtual environment such as the one shown in Fig. 7.

We conducted our evaluation in World 2 from GIVE-1, which was deliberately designed to be challenging for RE generation. The world consists of one room filled with several objects and buttons, most of which cannot be distinguished by simple descriptions. Moreover, some of those may activate an alarm and cause the player to lose the game. The player's moves and turns are discrete and the NLG system has complete and accurate real-time information about the state of the world. Instructions that each of the three systems under comparison generated in an example scene of the evaluation world are presented in Table 1.

The evaluation took place online via the Amazon Mechanical Turk, where we collected 25 games for each system. We focus on four measures of evaluation: success rates for solving the task and resolving the generated REs, average task completion time (in seconds) for successful games, and average distance (in steps) between the IF and the referent at the time when the RE was generated. As in the challenge, the task is considered as solved if the player has correctly been led through manipulating all target objects required to discover and collect the treasure; in World 2, the minimum number of such targets is eight. An RE is successfully resolved if it results in the manipulation of the referent, whereas manipulation of an alarm-triggering distractor ends the game unsuccessfully.

6.1 The SCRISP system

Our system receives as input a plan for what the IF should do to solve the task, and successively takes object-manipulating actions as the communicative goals for SCRISP. Then, for each of the communicative goals, it generates instructions using SCRISP, segments them into navigation and action parts, and presents these to the user as separate instructions sequentially (see Table 1).

For each instruction, SCRISP thus draws from a knowledge base of about 1500 facts and a grammar of about 30 lexicon entries. We use the FF planner (Hoffmann and Nebel, 2001; Koller and Hoffmann, 2010) to solve the planning problems. The maximum planning time for any instruction is 1.03 seconds on a 3.06 GHz Intel Core 2 Duo CPU. So although our planning-based system tackles a very difficult search problem, FF is very good at solving it—fast enough to generate instructions in real time.

	success		**RE**	
	rate	**time**	**success**	**distance**
SCRISP	69%	306	71%	2.49
Baseline A	16%**	230	49%**	1.97*
Baseline B	84%	288	81%*	2.00*

Table 2: Evaluation results. Differences to SCRISP are significant at $*p < .05$, $**p < .005$ (Pearson's chi-square test for system success rates; unpaired two-sample t-test for the rest).

6.2 Comparison with Baseline A

Baseline A is a very basic system designed to simulate the performance of a classical RE generation module which does not attempt to manipulate the visual context. We hand-coded a correct distinguishing RE for each target button in the world; the only way in which Baseline A reacts to changes of the context is to describe on which wall the button is with respect to the user's current orientation (e.g. "Press the right red button *on the wall to your right*").

As Table 2 shows, our system guided 69% of users to complete the task successfully, compared to only 16% for Baseline A (difference is statistically significant at $p < .005$; Pearson's chi-square test). This is primarily because only 49% of the REs generated by Baseline A were successful. This comparison illustrates the importance of REs that minimize the cognitive load on the IF to avoid misunderstandings.

6.3 Comparison with Baseline B

Baseline B is a corrected and improved version of the "Austin" system (Chen and Karpov, 2009),

one of the best-performing systems of the GIVE-1 Challenge. Baseline B, like the original "Austin" system, issues navigation instructions by precomputing the shortest path from the IF's current location to the target, and generates REs using the description logic based algorithm of Areces et al. (2008). Unlike the original system, which inflexibly navigates the user all the way to the target, Baseline B starts off with navigation, and opportunistically instructs the IF to push a button once it has become visible and can be described by a distinguishing RE. We fixed bugs in the original implementation of the RE generation module, so that Baseline B generates only unambiguous REs. The module nonetheless naively treats all adjectives as intersective and is not sensitive to the context of their comparison set. Specifically, a button cannot be referred to as "the *right* red button" if it is not the rightmost of all visible objects—which explains the long chain of navigational instructions the system produced in Table 1.

We did not find any significant differences in the success rates or task completion times between this system and SCRISP, but the former achieved a higher RE success rate (see Table 2). However, a closer analysis shows that SCRISP was able to generate REs from significantly further away. This means that SCRISP's RE generator solves a harder problem, as it typically has to deal with more visible distractors. Furthermore, because of the increased distance, the system's execution monitoring strategies (e.g. for detection and repair of misunderstandings) become increasingly important, and this was not a focus of this work. In summary, then, we take the results to mean that SCRISP performs quite capably in comparison to a top-ranked GIVE-1 system.

7 Conclusion

In this paper, we have shown how situated instructions can be generated using AI planning. We exploited the planner's ability to model the perlocutionary effects of communicative actions for efficient generation. We showed how this made it possible to generate instructions that manipulate the non-linguistic context in convenient ways, and to generate correct REs with context-dependent adjectives.

We believe that this illustrates the power of a planning-based approach to NLG to flexibly model very different phenomena. An interesting topic for future work, for instance, is to expand our notion of context by taking visual and discourse salience into account when generating REs. In addition, we plan to experiment with assigning costs to planning operators in a metric planning problem (Hoffmann, 2002) in order to model the cognitive cost of an RE (Krahmer et al., 2003) and compute minimal-cost instruction sequences.

On a more theoretical level, the SCRISP actions model the physical effects of a correctly understood and grounded instruction directly as effects of the planning operator. This is computationally much less complex than classical speech act planning (Perrault and Allen, 1980), in which the intended physical effect comes at the end of a long chain of inferences. But our approach is also very optimistic in estimating the perlocutionary effects of an instruction, and must be complemented by an appropriate model of execution monitoring. What this means for a novel scalable approach to the pragmatics of speech acts (Koller et al., 2010a) is, we believe, an interesting avenue for future research.

Acknowledgments. We are grateful to Jörg Hoffmann for improving the efficiency of FF in the SCRISP domain at a crucial time, and to Margaret Mitchell, Matthew Stone and Kees van Deemter for helping us expand our view of the context-dependent adjective generation problem. We also thank Ines Rehbein and Josef Ruppenhofer for testing early implementations of our system, and Andrew Gargett as well as the reviewers for their helpful comments.

Beyond NomBank: A Study of Implicit Arguments for Nominal Predicates

Matthew Gerber and **Joyce Y. Chai**
Department of Computer Science
Michigan State University
East Lansing, Michigan, USA
{gerberm2,jchai}@cse.msu.edu

Abstract

Despite its substantial coverage, NomBank does not account for all within-sentence arguments and ignores extra-sentential arguments altogether. These arguments, which we call *implicit*, are important to semantic processing, and their recovery could potentially benefit many NLP applications. We present a study of implicit arguments for a select group of frequent nominal predicates. We show that implicit arguments are pervasive for these predicates, adding 65% to the coverage of NomBank. We demonstrate the feasibility of recovering implicit arguments with a supervised classification model. Our results and analyses provide a baseline for future work on this emerging task.

1 Introduction

Verbal and nominal semantic role labeling (SRL) have been studied independently of each other (Carreras and Màrquez, 2005; Gerber et al., 2009) as well as jointly (Surdeanu et al., 2008; Hajič et al., 2009). These studies have demonstrated the maturity of SRL within an evaluation setting that restricts the argument search space to the sentence containing the predicate of interest. However, as shown by the following example from the Penn TreeBank (Marcus et al., 1993), this restriction excludes extra-sentential arguments:

(1) [arg_0 The two companies] [$pred$ **produce**] [arg_1 market pulp, containerboard and white paper]. The goods could be manufactured closer to customers, saving [$pred$ **shipping**] costs.

The first sentence in Example 1 includes the PropBank (Kingsbury et al., 2002) analysis of the verbal predicate *produce*, where arg_0 is the agentive producer and arg_1 is the produced entity. The second sentence contains an instance of the nominal predicate *shipping* that is not associated with arguments in NomBank (Meyers, 2007).

From the sentences in Example 1, the reader can infer that *The two companies* refers to the agents (arg_0) of the *shipping* predicate. The reader can also infer that *market pulp, containerboard and white paper* refers to the shipped entities (arg_1 of *shipping*).[1] These extra-sentential arguments have not been annotated for the *shipping* predicate and cannot be identified by a system that restricts the argument search space to the sentence containing the predicate. NomBank also ignores many within-sentence arguments. This is shown in the second sentence of Example 1, where *The goods* can be interpreted as the arg_1 of *shipping*. These examples demonstrate the presence of arguments that are not included in NomBank and cannot easily be identified by systems trained on the resource. We refer to these arguments as *implicit*.

This paper presents our study of implicit arguments for nominal predicates. We began our study by annotating implicit arguments for a select group of predicates. For these predicates, we found that implicit arguments add 65% to the existing role coverage of NomBank.[2] This increase has implications for tasks (e.g., question answering, information extraction, and summarization) that benefit from semantic analysis. Using our annotations, we constructed a feature-based model for automatic implicit argument identification that unifies standard verbal and nominal SRL. Our results indicate a 59% relative (15-point absolute) gain in F_1 over an informed baseline. Our analyses highlight strengths and weaknesses of the approach, providing insights for future work on this emerging task.

[1] In PropBank and NomBank, the interpretation of each role (e.g., arg_0) is specific to a predicate sense.

[2] Role coverage indicates the percentage of roles filled.

Proceedings of the 48th Annual Meeting of the Association for Computational Linguistics, pages 1583–1592,
Uppsala, Sweden, 11-16 July 2010.

In the following section, we review related research, which is historically sparse but recently gaining traction. We present our annotation effort in Section 3, and follow with our implicit argument identification model in Section 4. In Section 5, we describe the evaluation setting and present our experimental results. We analyze these results in Section 6 and conclude in Section 7.

2 Related work

Palmer et al. (1986) made one of the earliest attempts to automatically recover extra-sentential arguments. Their approach used a fine-grained domain model to assess the compatibility of candidate arguments and the slots needing to be filled.

A phenomenon similar to the implicit argument has been studied in the context of Japanese anaphora resolution, where a missing case-marked constituent is viewed as a zero-anaphoric expression whose antecedent is treated as the implicit argument of the predicate of interest. This behavior has been annotated manually by Iida et al. (2007), and researchers have applied standard SRL techniques to this corpus, resulting in systems that are able to identify missing case-marked expressions in the surrounding discourse (Imamura et al., 2009). Sasano et al. (2004) conducted similar work with Japanese indirect anaphora. The authors used automatically derived nominal case frames to identify antecedents. However, as noted by Iida et al., grammatical cases do not stand in a one-to-one relationship with semantic roles in Japanese (the same is true for English).

Fillmore and Baker (2001) provided a detailed case study of implicit arguments (termed *null instantiations* in that work), but did not provide concrete methods to account for them automatically. Previously, we demonstrated the importance of filtering out nominal predicates that take no local arguments (Gerber et al., 2009); however, this work did not address the identification of implicit arguments. Burchardt et al. (2005) suggested approaches to implicit argument identification based on observed coreference patterns; however, the authors did not implement and evaluate such methods. We draw insights from all three of these studies. We show that the identification of implicit arguments for nominal predicates leads to fuller semantic interpretations when compared to traditional SRL methods. Furthermore, motivated by Burchardt et al., our model uses a quantitative analysis of naturally occurring coreference patterns to aid implicit argument identification.

Most recently, Ruppenhofer et al. (2009) conducted SemEval Task 10, "Linking Events and Their Participants in Discourse", which evaluated implicit argument identification systems over a common test set. The task organizers annotated implicit arguments across entire passages, resulting in data that cover many distinct predicates, each associated with a small number of annotated instances. In contrast, our study focused on a select group of nominal predicates, each associated with a large number of annotated instances.

3 Data annotation and analysis

3.1 Data annotation

Implicit arguments have not been annotated within the Penn TreeBank, which is the textual and syntactic basis for NomBank. Thus, to facilitate our study, we annotated implicit arguments for instances of nominal predicates within the standard training, development, and testing sections of the TreeBank. We limited our attention to nominal predicates with unambiguous role sets (i.e., senses) that are derived from verbal role sets. We then ranked this set of predicates using two pieces of information: (1) the average difference between the number of roles expressed in nominal form (in NomBank) versus verbal form (in PropBank) and (2) the frequency of the nominal form in the corpus. We assumed that the former gives an indication as to how many implicit roles an instance of the nominal predicate might have. The product of (1) and (2) thus indicates the potential prevalence of implicit arguments for a predicate. To focus our study, we ranked the predicates in NomBank according to this product and selected the top ten, shown in Table 1.

We annotated implicit arguments document-by-document, selecting all singular and plural nouns derived from the predicates in Table 1. For each missing argument position of each predicate instance, we inspected the local discourse for a suitable implicit argument. We limited our attention to the current sentence as well as all preceding sentences in the document, annotating all mentions of an implicit argument within this window.

In the remainder of this paper, we will use $iarg_n$ to refer to an implicit argument position n. We will use arg_n to refer to an argument provided by PropBank or NomBank. We will use p to mark

		Pre-annotation			Post-annotation	
			Role average			
Predicate	#	Role coverage (%)	Noun	Verb	Role coverage (%)	Noun role average
price	217	42.4	1.7	1.7	55.3	2.2
sale	185	24.3	1.2	2.0	42.0	2.1
investor	160	35.0	1.1	2.0	54.6	1.6
fund	109	8.7	0.4	2.0	21.6	0.9
loss	104	33.2	1.3	2.0	46.9	1.9
plan	102	30.9	1.2	1.8	49.3	2.0
investment	102	15.7	0.5	2.0	33.3	1.0
cost	101	26.2	1.1	2.3	47.5	1.9
bid	88	26.9	0.8	2.2	72.0	2.2
loan	85	22.4	1.1	2.5	41.2	2.1
Overall	1,253	28.0	1.1	2.0	46.2	1.8

Table 1: Predicates targeted for annotation. The second column gives the number of predicate instances annotated. *Pre-annotation* numbers only include NomBank annotations, whereas *Post-annotation* numbers include NomBank and implicit argument annotations. *Role coverage* indicates the percentage of roles filled. *Role average* indicates how many roles, on average, are filled for an instance of a predicate's noun form or verb form within the TreeBank. Verbal role averages were computed using PropBank.

predicate instances. Below, we give an example annotation for an instance of the *investment* predicate:

(2) [$iarg_0$ Participants] will be able to transfer [$iarg_1$ money] to [$iarg_2$ other investment funds]. The [p **investment**] choices are limited to [$iarg_2$ a stock fund and a money-market fund].

NomBank does not associate this instance of *investment* with any arguments; however, we were able to identify the investor ($iarg_0$), the thing invested ($iarg_1$), and two mentions of the thing invested in ($iarg_2$).

Our data set was also independently annotated by an undergraduate linguistics student. For each missing argument position, the student was asked to identify the closest acceptable implicit argument within the current and preceding sentences. The argument position was left unfilled if no acceptable constituent could be found. For a missing argument position, the student's annotation agreed with our own if both identified the same constituent or both left the position unfilled. Analysis indicated an agreement of 67% using Cohen's kappa coefficient (Cohen, 1960).

3.2 Annotation analysis

Role coverage for a predicate instance is equal to the number of filled roles divided by the number of roles in the predicate's lexicon entry. Role coverage for the marked predicate in Example 2 is 0/3 for NomBank-only arguments and 3/3 when the annotated implicit arguments are also considered. Returning to Table 1, the third column gives role coverage percentages for NomBank-only arguments. The sixth column gives role coverage percentages when both NomBank arguments and the annotated implicit arguments are considered. Overall, the addition of implicit arguments created a 65% relative (18-point absolute) gain in role coverage across the 1,253 predicate instances that we annotated.

The predicates in Table 1 are typically associated with fewer arguments on average than their corresponding verbal predicates. When considering NomBank-only arguments, this difference (compare columns four and five) varies from zero (for *price*) to a factor of five (for *fund*). When implicit arguments are included in the comparison, these differences are reduced and many nominal predicates express approximately the same number of arguments on average as their verbal counterparts (compare the fifth and seventh columns).

In addition to role coverage and average count, we examined the location of implicit arguments. Figure 1 shows that approximately 56% of the implicit arguments in our data can be resolved within the sentence containing the predicate. The remaining implicit arguments require up to forty-six sen-

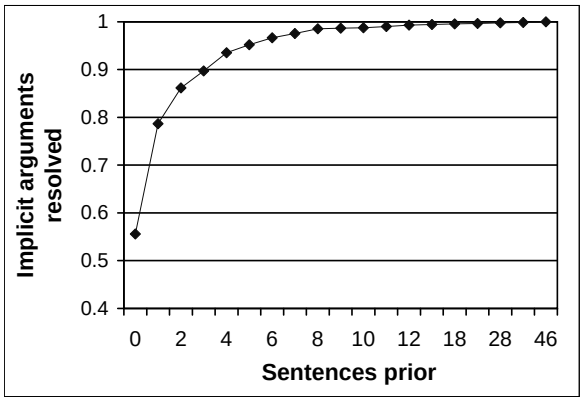

Figure 1: Location of implicit arguments. For missing argument positions with an implicit filler, the y-axis indicates the likelihood of the filler being found at least once in the previous x sentences.

tences for resolution; however, a vast majority of these can be resolved within the previous few sentences. Section 6 discusses implications of this skewed distribution.

4 Implicit argument identification

4.1 Model formulation

In our study, we assumed that each sentence in a document had been analyzed for PropBank and NomBank predicate-argument structure. NomBank includes a lexicon listing the possible argument positions for a predicate, allowing us to identify missing argument positions with a simple lookup. Given a nominal predicate instance p with a missing argument position $iarg_n$, the task is to search the surrounding discourse for a constituent c that fills $iarg_n$. Our model conducts this search over all constituents annotated by either PropBank or NomBank with non-adjunct labels.

A candidate constituent c will often form a coreference chain with other constituents in the discourse. Consider the following abridged sentences, which are adjacent in their Penn TreeBank document:

(3) [Mexico] desperately needs investment.

(4) Conservative Japanese investors are put off by [Mexico's] investment regulations.

(5) Japan is the fourth largest investor in [c Mexico], with 5% of the total [p **investments**].

NomBank does not associate the labeled instance of *investment* with any arguments, but it is clear from the surrounding discourse that constituent c (referring to Mexico) is the thing being invested in (the $iarg_2$). When determining whether c is the $iarg_2$ of *investment*, one can draw evidence from other mentions in c's coreference chain. Example 3 states that Mexico needs investment. Example 4 states that Mexico regulates investment. These propositions, which can be derived via traditional SRL analyses, should increase our confidence that c is the $iarg_2$ of *investment* in Example 5.

Thus, the unit of classification for a candidate constituent c is the three-tuple $\langle p, iarg_n, c' \rangle$, where c' is a coreference chain comprising c and its coreferent constituents.[3] We defined a binary classification function $Pr(+|\langle p, iarg_n, c' \rangle)$ that predicts the probability that the entity referred to by c fills the missing argument position $iarg_n$ of predicate instance p. In the remainder of this paper, we will refer to c as the *primary filler*, differentiating it from other mentions in the coreference chain c'. In the following section, we present the feature set used to represent each three-tuple within the classification function.

4.2 Model features

Starting with a wide range of features, we performed floating forward feature selection (Pudil et al., 1994) over held-out development data comprising implicit argument annotations from section 24 of the Penn TreeBank. As part of the feature selection process, we conducted a grid search for the best per-class cost within LibLinear's logistic regression solver (Fan et al., 2008). This was done to reduce the negative effects of data imbalance, which is severe even when selecting candidates from the current and previous few sentences. Table 2 shows the selected features, which are quite different from those used in our previous work to identify traditional semantic arguments (Gerber et al., 2009).[4] Below, we give further explanations for some of the features.

Feature 1 models the semantic role relationship between each mention in c' and the missing argument position $iarg_n$. To reduce data sparsity, this feature generalizes predicates and argument positions to their VerbNet (Kipper, 2005) classes and

[3] We used OpenNLP for coreference identification: http://opennlp.sourceforge.net

[4] We have omitted many of the lowest-ranked features. Descriptions of these features can be obtained by contacting the authors.

#	Feature value description
1*	For every f, the VerbNet class/role of p_f/arg_f concatenated with the class/role of p/$iarg_n$.
2*	Average pointwise mutual information between $\langle p, iarg_n \rangle$ and any $\langle p_f, arg_f \rangle$.
3	Percentage of all f that are definite noun phrases.
4	Minimum absolute sentence distance from any f to p.
5*	Minimum pointwise mutual information between $\langle p, iarg_n \rangle$ and any $\langle p_f, arg_f \rangle$.
6	Frequency of the nominal form of p within the document that contains it.
7	Nominal form of p concatenated with $iarg_n$.
8	Nominal form of p concatenated with the sorted integer argument indexes from all arg_n of p.
9	Number of mentions in c'.
10*	Head word of p's right sibling node.
11	For every f, the synset (Fellbaum, 1998) for the head of f concatenated with p and $iarg_n$.
12	Part of speech of the head of p's parent node.
13	Average absolute sentence distance from any f to p.
14*	Discourse relation whose two discourse units cover c (the primary filler) and p.
15	Number of left siblings of p.
16	Whether p is the head of its parent node.
17	Number of right siblings of p.

Table 2: Features for determining whether c fills $iarg_n$ of predicate p. For each mention f (denoting a $f$iller) in the coreference chain c', we define p_f and arg_f to be the predicate and argument position of f. Features are sorted in descending order of feature selection gain. Unless otherwise noted, all predicates were normalized to their verbal form and all argument positions (e.g., arg_n and $iarg_n$) were interpreted as labels instead of word content. Features marked with an asterisk are explained in Section 4.2.

semantic roles using SemLink.[5] For explanation purposes, consider again Example 1, where we are trying to fill the $iarg_0$ of *shipping*. Let c' contain a single mention, *The two companies*, which is the arg_0 of *produce*. As described in Table 2, feature 1 is instantiated with a value of *create.agent-send.agent*, where *create* and *send* are the VerbNet classes that contain *produce* and *ship*, respectively. In the conversion to LibLinear's instance representation, this instantiation is converted into a single binary feature *create.agent-send.agent* whose value is one. Features 1 and 11 are instantiated once for each mention in c', allowing the model to consider information from multiple mentions of the same entity.

Features 2 and 5 are inspired by the work of Chambers and Jurafsky (2008), who investigated unsupervised learning of narrative event sequences using pointwise mutual information (PMI) between syntactic positions. We used a similar PMI score, but defined it with respect to semantic arguments instead of syntactic dependencies. Thus, the values for features 2 and 5 are computed as follows (the notation is explained in the caption for Table 2):

$$pmi(\langle p, iarg_n \rangle, \langle p_f, arg_f \rangle) = log \frac{P_{coref}(\langle p, iarg_n \rangle, \langle p_f, arg_f \rangle)}{P_{coref}(\langle p, iarg_n \rangle, *) P_{coref}(\langle p_f, arg_f \rangle, *)} \quad (6)$$

To compute Equation 6, we first labeled a subset of the Gigaword corpus (Graff, 2003) using the verbal SRL system of Punyakanok et al. (2008) and the nominal SRL system of Gerber et al. (2009). We then identified coreferent pairs of arguments using OpenNLP. Suppose the resulting data has N coreferential pairs of argument positions. Also suppose that M of these pairs comprise $\langle p, arg_n \rangle$ and $\langle p_f, arg_f \rangle$. The numerator in Equation 6 is defined as $\frac{M}{N}$. Each term in the denominator is obtained similarly, except that M is computed as the total number of coreference pairs comprising an argument position (e.g., $\langle p, arg_n \rangle$) and *any* other argument position. Like Chambers and Jurafsky, we also used the discounting method suggested by Pantel and Ravichandran (2004) for low-frequency observations. The PMI score is somewhat noisy due to imperfect output, but it provides information that is useful for classification.

[5] http://verbs.colorado.edu/semlink

Feature 10 does not depend on c' and is specific to each predicate. Consider the following example:

(7) Statistics Canada reported that its [arg_1 industrial-product] [p **price**] index dropped 2% in September.

The "[p price] index" collocation is rarely associated with an arg_0 in NomBank or with an $iarg_0$ in our annotations (both argument positions denote the seller). Feature 10 accounts for this type of behavior by encoding the syntactic head of p's right sibling. The value of feature 10 for Example 7 is *price:index*. Contrast this with the following:

(8) [$iarg_0$ The company] is trying to prevent further [p **price**] drops.

The value of feature 10 for Example 8 is *price:drop*. This feature captures an important distinction between the two uses of *price*: the former rarely takes an $iarg_0$, whereas the latter often does. Features 12 and 15-17 account for predicate-specific behaviors in a similar manner.

Feature 14 identifies the discourse relation (if any) that holds between the candidate constituent c and the filled predicate p. Consider the following example:

(9) [$iarg_0$ SFE Technologies] reported a net loss of $889,000 on sales of $23.4 million.

(10) That compared with an operating [p **loss**] of [arg_1 $1.9 million] on sales of $27.4 million in the year-earlier period.

In this case, a *comparison* discourse relation (signaled by the underlined text) holds between the first and sentence sentence. The coherence provided by this relation encourages an inference that identifies the marked $iarg_0$ (the loser). Throughout our study, we used gold-standard discourse relations provided by the Penn Discourse TreeBank (Prasad et al., 2008).

5 Evaluation

We trained the feature-based logistic regression model over 816 annotated predicate instances associated with 650 implicitly filled argument positions (not all predicate instances had implicit arguments). During training, a candidate three-tuple $\langle p, iarg_n, c' \rangle$ was given a positive label if the candidate implicit argument c (the primary filler) was annotated as filling the missing argument position. To factor out errors from standard SRL analyses, the model used gold-standard argument labels provided by PropBank and NomBank. As shown in Figure 1 (Section 3.2), implicit arguments tend to be located in close proximity to the predicate. We found that using all candidate constituents c within the current and previous two sentences worked best on our development data.

We compared our supervised model with the simple baseline heuristic defined below:[6]

> Fill $iarg_n$ for predicate instance p with the nearest constituent in the two-sentence candidate window that fills arg_n for a different instance of p, where all nominal predicates are normalized to their verbal forms.

The normalization allows an existing arg_0 for the verb *invested* to fill an $iarg_0$ for the noun *investment*. We also evaluated an oracle model that made gold-standard predictions for candidates within the two-sentence prediction window.

We evaluated these models using the methodology proposed by Ruppenhofer et al. (2009). For each missing argument position of a predicate instance, the models were required to either (1) identify a single constituent that fills the missing argument position or (2) make no prediction and leave the missing argument position unfilled. We scored predictions using the Dice coefficient, which is defined as follows:

$$\frac{2 * |Predicted \bigcap True|}{|Predicted| + |True|} \quad (11)$$

$Predicted$ is the set of tokens subsumed by the constituent predicted by the model as filling a missing argument position. $True$ is the set of tokens from a single annotated constituent that fills the missing argument position. The model's prediction receives a score equal to the maximum Dice overlap across any one of the annotated fillers. Precision is equal to the summed prediction scores divided by the number of argument positions filled by the model. Recall is equal to the summed prediction scores divided by the number of argument positions filled in our annotated data. Predictions not covering the head of a true filler were assigned a score of zero.

[6] This heuristic outperformed a more complicated heuristic that relied on the PMI score described in section 4.2.

			Baseline			Discriminative				Oracle	
	#	Imp. #	P	R	F_1	P	R	F_1	p	R	F_1
sale	64	60	50.0	28.3	36.2	47.2	41.7	**44.2**	0.118	80.0	88.9
price	121	53	24.0	11.3	15.4	36.0	32.6	**34.2**	0.008	88.7	94.0
investor	78	35	33.3	5.7	9.8	36.8	40.0	**38.4**	< 0.001	91.4	95.5
bid	19	26	100.0	19.2	**32.3**	23.8	19.2	21.3	0.280	57.7	73.2
plan	25	20	83.3	25.0	38.5	78.6	55.0	**64.7**	0.060	82.7	89.4
cost	25	17	66.7	23.5	34.8	61.1	64.7	**62.9**	0.024	94.1	97.0
loss	30	12	71.4	41.7	52.6	83.3	83.3	**83.3**	0.020	100.0	100.0
loan	11	9	50.0	11.1	18.2	42.9	33.3	**37.5**	0.277	88.9	94.1
investment	21	8	0.0	0.0	0.0	40.0	25.0	**30.8**	0.182	87.5	93.3
fund	43	6	0.0	0.0	0.0	14.3	16.7	**15.4**	0.576	50.0	66.7
Overall	437	246	48.4	18.3	26.5	44.5	40.4	**42.3**	< 0.001	83.1	90.7

Table 3: Evaluation results. The second column gives the number of predicate instances evaluated. The third column gives the number of ground-truth implicitly filled argument positions for the predicate instances (not all instances had implicit arguments). P, R, and F_1 indicate precision, recall, and F-measure ($\beta = 1$), respectively. p-values denote the bootstrapped significance of the difference in F_1 between the baseline and discriminative models. Oracle precision (not shown) is 100% for all predicates.

Our evaluation data comprised 437 predicate instances associated with 246 implicitly filled argument positions. Table 3 presents the results. Predicates with the highest number of implicit arguments - *sale* and *price* - showed F_1 increases of 8 points and 18.8 points, respectively. Overall, the discriminative model increased F_1 performance 15.8 points (59.6%) over the baseline.

We measured human performance on this task by running our undergraduate assistant's annotations against the evaluation data. Our assistant achieved an overall F_1 score of 58.4% using the same candidate window as the baseline and discriminative models. The difference in F_1 between the discriminative and human results had an exact p-value of less than 0.001. All significance testing was performed using a two-tailed bootstrap method similar to the one described by Efron and Tibshirani (1993).

6 Discussion

6.1 Feature ablation

We conducted an ablation study to measure the contribution of specific feature sets. Table 4 presents the ablation configurations and results. For each configuration, we retrained and retested the discriminative model using the features described. As shown, we observed significant losses when excluding features that relate the semantic roles of mentions in c' to the semantic role of the missing argument position (first configuration). The second configuration tested the effect of using *only* the SRL-based features. This also resulted in significant performance losses, suggesting that the other features contribute useful information. Lastly, we tested the effect of removing discourse relations (feature 14), which are likely to be difficult to extract reliably in a practical setting. As shown, this feature did not have a statistically significant effect on performance and could be excluded in future applications of the model.

	Percent change (p-value)		
Configuration	P	R	F_1
Remove 1,2,5	-35.3 (< 0.01)	-36.1 (< 0.01)	-35.7 (< 0.01)
Use 1,2,5 only	-26.3 (< 0.01)	-11.9 (0.05)	-19.2 (< 0.01)
Remove 14	0.2 (0.95)	1.0 (0.66)	0.7 (0.73)

Table 4: Feature ablation results. The first column lists the feature configurations. All changes are percentages relative to the full-featured discriminative model. p-values for the changes are indicated in parentheses.

6.2 Unclassified true implicit arguments

Of all the errors made by the system, approximately 19% were caused by the system's failure to

generate a candidate constituent c that was a correct implicit argument. Without such a candidate, the system stood no chance of identifying a correct implicit argument. Two factors contributed to this type of error, the first being our assumption that implicit arguments are also core (i.e., arg_n) arguments to traditional SRL structures. Approximately 8% of the overall error was due to a failure of this assumption. In many cases, the true implicit argument filled a non-core (i.e., adjunct) role within PropBank or NomBank.

More frequently, however, true implicit arguments were missed because the candidate window was too narrow. This accounts for 12% of the overall error. Oracle recall (second-to-last column in Table 3) indicates the nominals that suffered most from windowing errors. For example, the *sale* predicate was associated with the highest number of true implicit arguments, but only 80% of those could be resolved within the two-sentence candidate window. Empirically, we found that extending the candidate window uniformly for all predicates did not increase performance on the development data. The oracle results suggest that predicate-specific window settings might offer some advantage.

6.3 The *investment* and *fund* predicates

In Section 4.2, we discussed the *price* predicate, which frequently occurs in the "[p price] index" collocation. We observed that this collocation is rarely associated with either an overt arg_0 or an implicit $iarg_0$. Similar observations can be made for the *investment* and *fund* predicates. Although these two predicates are frequent, they are rarely associated with implicit arguments: *investment* takes only eight implicit arguments across its 21 instances, and *fund* takes only six implicit arguments across its 43 instances. This behavior is due in large part to collocations such as "[p investment] banker", "stock [p fund]", and "mutual [p fund]", which use predicate senses that are not eventive. Such collocations also violate our assumption that differences between the PropBank and NomBank argument structure for a predicate are indicative of implicit arguments (see Section 3.1 for this assumption).

Despite their lack of implicit arguments, it is important to account for predicates such as *investment* and *fund* because incorrect prediction of implicit arguments for them can lower precision. This is precisely what happened for the *fund* predicate, where the model incorrectly identified many implicit arguments for "stock [p fund]" and "mutual [p fund]". The left context of *fund* should help the model avoid this type of error; however, our feature selection process did not identify any overall gains from including this information.

6.4 Improvements versus the baseline

The baseline heuristic covers the simple case where identical predicates share arguments in the same position. Thus, it is interesting to examine cases where the baseline heuristic failed but the discriminative model succeeded. Consider the following sentence:

(12) Mr. Rogers recommends that [p **investors**] sell [$iarg_2$ takeover-related stock].

Neither NomBank nor the baseline heuristic associate the marked predicate in Example 12 with any arguments; however, the feature-based model was able to correctly identify the marked $iarg_2$ as the entity being invested in. This inference captured a tendency of investors to sell the things they have invested in.

We conclude our discussion with an example of an extra-sentential implicit argument:

(13) [$iarg_0$ Olivetti] has denied that it violated the rules, asserting that the shipments were properly licensed. However, the legality of these [p **sales**] is still an open question.

As shown in Example 13, the system was able to correctly identify *Olivetti* as the agent in the selling event of the second sentence. This inference involved two key steps. First, the system identified coreferent mentions of *Olivetti* that participated in exporting and supplying events (not shown). Second, the system identified a tendency for exporters and suppliers to also be sellers. Using this knowledge, the system extracted information that could not be extracted by the baseline heuristic or a traditional SRL system.

7 Conclusions and future work

Current SRL approaches limit the search for arguments to the sentence containing the predicate of interest. Many systems take this assumption a step further and restrict the search to the predicate's local syntactic environment; however, predicates and the sentences that contain them rarely

exist in isolation. As shown throughout this paper, they are usually embedded in a coherent and semantically rich discourse that must be taken into account. We have presented a preliminary study of implicit arguments for nominal predicates that focused specifically on this problem.

Our contribution is three-fold. First, we have created gold-standard implicit argument annotations for a small set of pervasive nominal predicates.[7] Our analysis shows that these annotations add 65% to the role coverage of NomBank. Second, we have demonstrated the feasibility of recovering implicit arguments for many of the predicates, thus establishing a baseline for future work on this emerging task. Third, our study suggests a few ways in which this research can be moved forward. As shown in Section 6, many errors were caused by the absence of true implicit arguments within the set of candidate constituents. More intelligent windowing strategies in addition to alternate candidate sources might offer some improvement. Although we consistently observed development gains from using automatic coreference resolution, this process creates errors that need to be studied more closely. It will also be important to study implicit argument patterns of non-verbal predicates such as the partitive *percent*. These predicates are among the most frequent in the TreeBank and are likely to require approaches that differ from the ones we pursued.

Finally, any extension of this work is likely to encounter a significant knowledge acquisition bottleneck. Implicit argument annotation is difficult because it requires both argument and coreference identification (the data produced by Ruppenhofer et al. (2009) is similar). Thus, it might be productive to focus future work on (1) the extraction of relevant knowledge from existing resources (e.g., our use of coreference patterns from Gigaword) or (2) semi-supervised learning of implicit argument models from a combination of labeled and unlabeled data.

Acknowledgments

We would like to thank the anonymous reviewers for their helpful questions and comments. We would also like to thank Malcolm Doering for his annotation effort. This work was supported in part by NSF grants IIS-0347548 and IIS-0840538.
